FLOODS, SEDIMENTATION, AND ALLUVIAL SOIL FORMATION AS DYNAMIC PROCESSES MAINTAINING SUPERLATIVE REDWOOD GROVES

1981

Paul J. Zinke[1]

> *There is an answer to the question as to why the redwood trees have shown such pertinacity of life in that particular environment, where their existence has been so successfully maintained, where other trees in other environments have shown no such life persistence. It is because that particular environment has proved to be peculiarly adapted to the well being of the sequoia, and conversely, the sequoia especially fits this particular environment. The reason for the great longevity of this forest species is that in that region there has been a perfect balance between the redwood tree and all or nearly all surrounding conditions.* (Thomas Edison, 1926)

ABSTRACT

New sediment accretion to soil profiles was found to be related to tree ring growth acceleration in old redwood trees growing on alluvial soils subject to flooding. It is inferred that the vigor of growth of these trees is rejuvenated periodically by sedimentation of new soil material that is consistent in texture with past deposits. However, it was observed that drastic changes in quality of sediment, either due to change in texture, or in organic matter content, resulted in death to trees on these alluvial flats.

INTRODUCTION

The preservation of superlative redwood groves should be based upon an understanding of their relation to the dynamic processes of flooding and sediment deposition which has created and sustained them. Changes in these processes and the resulting change in conditions in these forests may be counter to preservation efforts.

The superlative groves of redwood (*Sequoia sempervirens* D. Don Endl.) on alluvial flats in north coastal California are both initiated and rejuvenated by relatively infrequent flood events. Management and preservation of these groves must involve a watershed management program that maintains a favorable magnitude and frequency of flooding and sediment transport. Long-term changes

Rehabilitation in Redwood Nat'l Park and other Pacific coastal areas

in the frequency of overbank flooding or in the quality of sediment may have unfavorable consequences for the vigor and longevity of the trees. This paper is concerned with the interrelationships between superlative redwood groves on alluvial soils and long-term watershed processes.

What are the conditions in which these tall trees have originated and survived? Can we use historical evidence as a basis for describing them, and what historical evidence is there? Have present conditions changed and in what manner? To what extent is restoration needed and feasible if deleteriou change has occurred? How do we know what conditions at present may be deleterious, and how do we know if our actions are bringing them about? How do we achieve the proper balance between the requirements of these trees and environmental processes which affect the areas we presume to manage?

Finding answers to these questions requires a perspective in time that goes beyond the scope of daily decision-making based on economic and political criteria. It means assuming a perspective with a breadth in time comparable to the age of the trees. Frequently when we live and work in close association with the redwoods, it is difficult to maintain this perspective.

REVIEW OF PAST WORK

An awareness of the need for active management of the superlative groves is not new. In the early 1960's, Howard Libby of the Arcata Redwood Company established the "Tall Tree Committee" to advise the company on problems of sustaining the Libby Tree and the grove surrounding it (now known as the Tall Tree Grove of Redwood National Park). At that time, the top of the tree was dying back, and the bank of Redwood Creek was eroding. A series of steps was taken upon advice of the committee to solve the problems, including a revetment of a large redwood log against the bank, and moving the creek to the opposite side of the channel. This was done by excavating stream bed materials from one side of the channel and piling them alongside the eroding bank. During a period prior to this, Hammond Lumber Compan had maintained the stream on the opposite side of the channel from the grove This was done by the excavation of gravel and rock from the stream bed for surfacing roads. Since this operation stopped bed load had accumulated again and the stream shifted against the Tall Trees Grove bank. Thus the need for active management based on an understanding of natural processes continues.

The dynamic relationship between trees and soil of the superlative groves can be understood only in a whole watershed context. The soil of an alluvia flat was built up over centuries by flooding, which deposits the silt loam upon which the tall redwood trees grow. E. Fritz (1934) documented the history of deposition at Richardson Grove by examining the root system of a fallen redwood. He found that seven floods at varying intervals had deposited 11 feet of sediment. The root system of the tree responded to these continuous new layers of soil by developing successive layers of roots, each developing in what was the surface of the new sediment. Stone and Vasey (1968) found that redwood roots could rapidly grow upwards to occupy this new sediment. However, recreational use may impede this. Meinecke (1929) found that heavy foot or vehicle traffic results in soil compaction, which hinders the ability of roots to invade a new soil profile. Gravel introduced for road construction has the same effect.

The deleterious effect of flood-deposited gravels was verified later by Stone and Vasey in their studies. Helley and La Marche (1968) noted the relation between a change in sediment quality and the death of redwood trees along Blue Creek, a tributary of the Klamath River. In Rockefeller Grove at Bull Creek, the dynamic processes include not only flood, sedimentation, and bank cutting, but also fire (Zinke, 1977). These processes have led to the development of the largest biomass accumulation ever measured: 3461 metric tons per hectare, with a volume of 10,817 m^3 per hectare (Fujimori, 1977). In summary, there are dynamic events occurring in relation to redwood trees, some beneficial such as floods and related sediment, some detrimental such as floods with gravel and bedload deposition or excess compaction of soil.

I began soils studies relating to these problems shortly after the 1955 flood along the Eel River and its tributaties such as Bull Creek in order to understand some of these processes. This period of time has encompassed several flood depositions, as 1955, 1964, and 1974 in these groves, and has enabled the development of a chronology of the sedimentation for slightly more than a thousand years.

ALLUVIAL SOILS OF THE REDWOOD GROVES

The soil under a superlative redwood forest such as that at Bull Creek Flat is evidence of a dynamic process of periodic flooding and sediment deposition. The response of the trees varies. Sometimes growth accelerates and sometimes death occurs, either by felling the tree due to bank cutting, or swamping the base of the tree with sediment having undesirable characteristics.

The flood of 1955 cut a steep bank into the soils of Rockefeller Grove in lower Bull Creek Flat. I had a large pit excavated into this bank to expose the various sediment layers, as shown in Figures One and Two. A sketch of this pitface is shown in Figure Three. Soils were sampled at uniform intervals from this face. Samples were taken to allow measures of the soil bulk density (over dry weight per unit field volume), and various physical and chemical properties.

The most obvious feature of the soil was its layering in distinct beds of sediment deposition as seen in the figures. During excavation in the summer of 1958, the recent deposit of the flood of 1955 was apparent on top of the pit. This bed of recent flood sediment overlay at least fourteen other

identifiable sediment deposits. The soil was built of a column of sediment deposits 8.23 m deep, resting upon a stony layer that was obviously a stream deposit. The dynamic nature of the area was demonstrated by the flood of 1964 which tore another three meters out of this bank, felling a large tree. I subsequently measured this tree for foliage, bark, wood and root biomass and sampled it for chemical analyses (Zinke, Strangenberger, and Colwell, 1979). The flood of 1964 left a sediment deposit over the floor of the grove, and another flood and sediment deposit occurred in 1974. These have been monitored, and their properties determined. Thus, when one deals with an alluvial flat even with trees more than a thousand years old, the area is subject to continuous events of new flood and sediment accretion, bank cutting, and tree falling. Each site will have its own history, as well as extreme events shared in common with other sites, and this should be determined where such knowledge is critical to management perspective.

CHRONOLOGY OF SEDIMENT DEPOSITION

The chronology of the deposition layers is of immediate interest, since if this can be determined, it is possible to characterize the rate of the various dynamic processes occurring on the site, and the probability of occurrence of flood events that bring about sediment deposition.

Carbon 14 dating on deposited charcoal was carried out on the lowest of the sediment layers in order to obtain an age for the entire sediment profile (Dr. Hans Suess, School of Sciences and Engineering, U.C. San Diego, La Jolla). Charcoal samples from the bottom of the soil profile indicated an age of 1000 years ± 100 years.

Ages of nearby trees were of a similar order of magnitude; about one thousand years, with variation due to discontinuous rings, established by ring counts on a tree fallen in the 1955 flood. This indicated an age of 960 years at the cross section at 10 feet up the tree bole. The age of the lowest layer of this Bull Creek alluvium was judged to be 1000 years, substantiated by both the radio-carbon dating, and the tree ring analyses. The first soil layer was therefore initiated by a flood deposited sediment in 955 A.D.

I found that tree ring growth on the trees had a periodic variation in width that coincided with sediment deposition. An example is seen in Figure 4, showing periodic ~~annual~~ radial growth based upon tree ring width measurements. These data indicate a series of intermittent accelerations in growth rate. Known dated floods of 1934, 1916, and 1861 correlate with the three most recent growth accelerations as indicated by wider tree ring widths after these dates. Not all floods, however, result in sediment deposition, as some floods remove surface materials (Fritz 1956). Flood frequency may actually be higher than the frequency of growth accelerating sedimentation.

In order to determine the frequency of growth accelerating sediment deposition, I plotted the cumulative radial growth against time for two trees (Figure 5). One tree was located at 159 feet elevation above sea level in

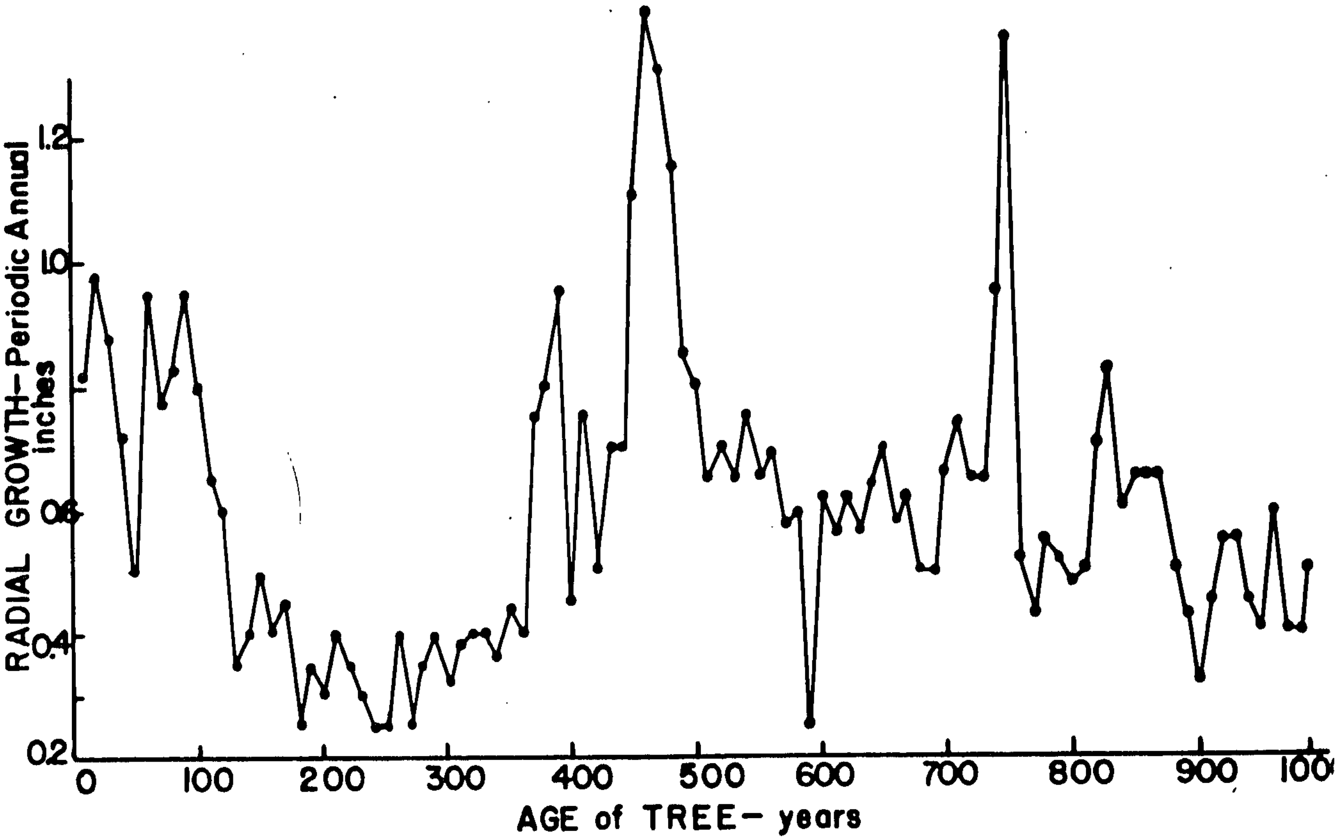

Figure 4: Radial width of tree rings measured on cross section of tree which fell near the deep soil excavation.

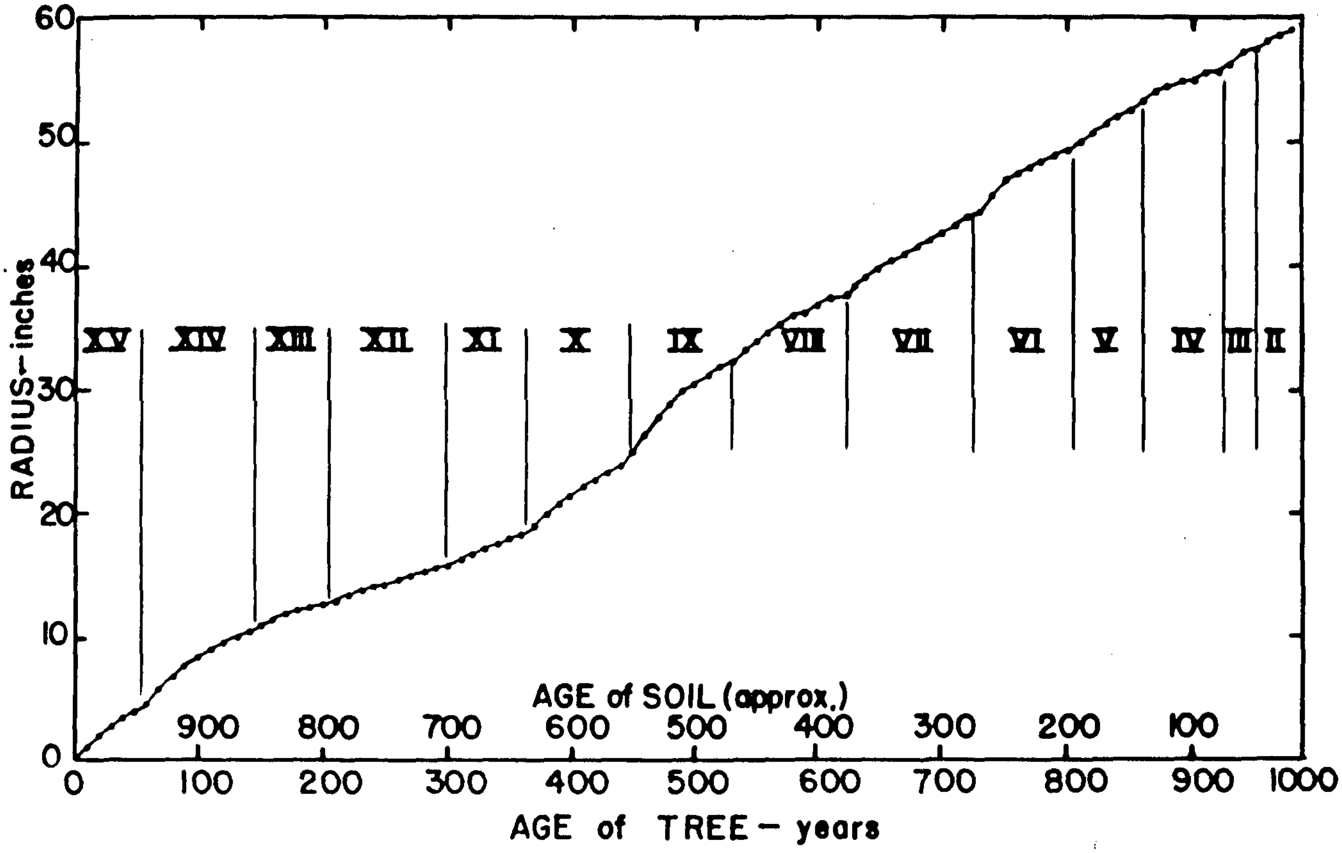

Figure 5: Cumulative radial growth and tree age from the tree which fell near the deep soil excavation in the flood of 1955.

the Rockefeller Forest at Bull Creek; the other was located at 170 feet elevation, but downstream in the Haas Grove on the main stem of the Eel River. Fourteen growth accelerations are shown, occurring at time intervals varying from 25 to 150 years. Table 1 shows the probability distributions for the intervals between periods of growth acceleration. As expected, the higher elevation tree at Haas Grove had a longer mean period between depositional events. Maximum stage of the 1955 flood was 178 feet above sea level at the confluence of the South Fork Eel and the Main Fork Eel; both sites are near the confluence and were inundated by that flood.

It is apparent that flooding and sediment deposition are periodic events, the only unique aspect being the length of the expected period between events on each alluvial flat. This will depend partly upon the natural regime of the particular watershed, and partly upon the elevation of the alluvial flat above the present streambed. In the case of the Rockefeller Grove flat on Bull Creek, the interval apparently did not change as the level of the flat rose through sedimentation because flooding heights are controlled by backwater due to the much larger flow of the main Eel level one mile downstream. This backwater type damming has been described on the Rio Grande by Kochel and Baker (1982). In the case of the Tall Tree flat on Redwood Creek, however, the main control is the elevation in the adjacent stream channel of Redwood Creek itself, as determined by bedload depositions in the creek.

There is a certain amount of error in the measurement of redwood tree age due to discontinuous rings (Fritz and Averell, 1924). This error may be 10% in a one thousand year old tree (E. Fritz, personal communication, 1961). This is about the magnitude of the error in radiocarbon dating for the same period. The error, although important in exact dating of a flood year, is not so critical in evaluating return intervals of events.

In addition to the frequency of occurrence of sedimentation events, it is important to evaluate the properties of the sediment, particularly with regard to the health of the trees. This vigor is already a problem with the Tall Tree as indicated by its top dieback.

PHYSICAL PROPERTIES OF SEDIMENTS AND DERIVED SOILS

I have measured various physical properties of the sediments and resulting soils in the alluvial groves along the Eel, and the Van Duzen Rivers. These properties were bulk density, or dry weight per unit field volume, the texture as percent sand, silt, clay, and the total depths of deposition. Sediment deposited in the 1974 flood along the Eel River was measured for volume weight and averaged 1.27 in Founder's Grove, and 1.21 in Rockefeller Grove. The sites were not significantly different, based upon 8 samples in each location. Apparently the value of 1.2-1.3 has been fairly consiste for the last thousand years as seems to be indicated for the bulk densities for the deep Bull Creek Flat profile plotted in Figure 6. For this profile the bulk densities tend to be higher than for most forest soils, ranging

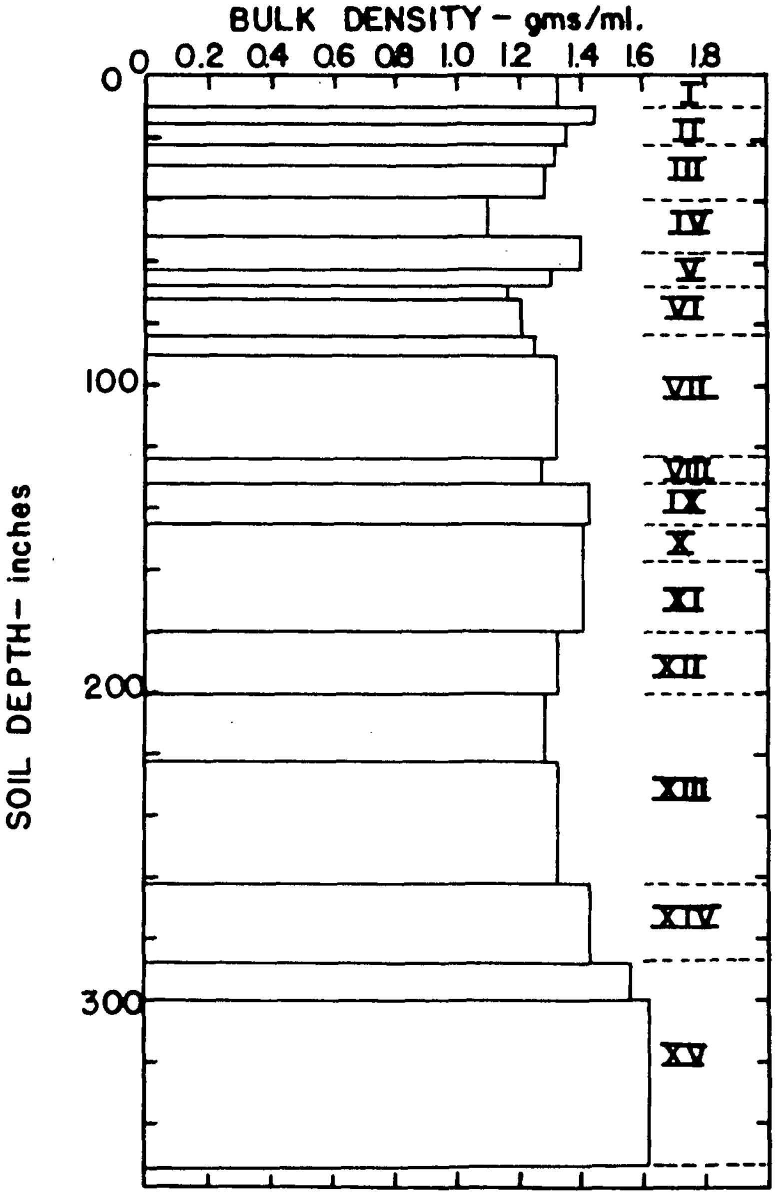

Figure 6: The bulk density (oven dry weight per unit volume) of the soil samples obtained from the deep soil excavation in Rockefeller grove. Original sediment initial density after first season settling ranged from 1.2-1.3.

Table 1: Cumulative probability of size of interval in years between tree ring growth accelerations assumed due to flood deposited sediment at two locations along the Eel River: Rockefeller Grove at 155' above sea level, and Haas Grove at 170' above sea level.[1]

Cumulative Prob. % of Intervals	Rockefeller Grove years	Haas Grove years
≥10	27.3	48
20	31.3	57.3
30	36.5	66.4
40	43.3	76
50	51.9	86.4
60	63.4	98.2
70	79.3	112.5
80	103.3	131.2
90	148.0	160.8
n	14	27
mode	24.8	59.1
arith. mean	73.9	97.1

from the 1.2 of the freshly deposited sediment to 1.6 in the lowest layers under compaction of the weight of the total sediment column. However, on surfaces which were exposed for longer periods, a surface soil below 1.2 in bulk density develops.

The coarse or gravel fractions were measured in all the samples, and for the sediment additions representing overbank flood stages and sedimentation there were few materials greater than 2 mm. in diameter. This was true for the entire depth of the sediment column.

A total of 1212 grams of sediment per square cm. of area was deposited during 1000 years on the Rockefeller Grove soil profile. Figure 7 shows the cumulative sediment amount during the centuries involved. Despite widely varying deposition intervals, the slope of this relation is fairly ıg

s

constant. Sixty percent of this deposition material was in the silt size fraction, or 728 grams. Fifteen percent of this material, 186 grams per cm^2 was clay less than 2 microns. The remaining 25 percent was sand (usually fine sand fractions). Sediment samples collected after the 1964 flood had slightly less clay content, averaging 13 percent for ten samples, and more silt with 71 percent, and less sand with 17 percent. However, there is a large variation within each deposition layer, with larger proportions of silt and clay in the topmost layers. This particle size distribution of the sediment resulted in no deleterious effects to the trees at the site, and was consistent for a long period of time. There is also textural variation across a redwood flat, with larger proportions of sand near the stream, and less inside the flat. Those concerned with preserving a grove for a long period of time on such a flat will need to anticipate a normal rate of sedimentation of a typical particle size distribution over the long period of time.

Each alluvial flat will have its own rate of accumulation based upon depth and duration of overflow flood waters. Of course, intervals between events will be variable. Certainly watershed disturbances such as fires, and natural landslides have occurred during the 1000 years of this record, and it is against this background that one needs to assess the possible effect of man-made disturbance of these hydrologic regimes. Figure 7 indicates that there may be periods of increased sedimentation, possibly due to local events augmenting sediment or to floods that are extreme in stage and duration. The trees are apparently unharmed as long as they are able to o-cupy the new sediment deposits with new roots, and are not physically felled by bank failure due to stream erosion, or sliding during the flood draw-down period.

CHEMICAL PROPERTIES OF SOILS DERIVED FROM SEDIMENT

Carbon, nitrogen, and various other chemical properties of the soil related to fertility were determined on the alluvial soils along the Eel River and Bull Creek. These elements generally show an increase in amount at the top of each new buried layer, decreasing to the top of the next layer. Successive surfaces of buried layers decrease in total content of these elements. This can be seen for carbon and nitrogen in Figures 8 and 9. It is apparent that both carbon and nitrogen are conserved in the buried layers, with an increase at each buried surface. These darker surfaces of the buried soils make it possible to identify the buried layers in the field excavation. Florence (1965) found that the new sediment, although low in fertility, had properties in terms of microbial processes that accelerated the availability of mineralized nitrogen and enhanced seedling survival. The various exchangeable cations follow a similar trend as seen in Figure 10, except that there is an obvious zone of depletion of these, and substitution by hydrogen in the most active current root zone above 2.54 meters depth. The consistent 60% calcium saturation below this depth is also of interest.

The return of redwood leaf litter to the soil surface with its content of the various elements most likely enriches the present sediment surface as long as it is exposed during the interflood interval. The extent to which this litter return enriches the particular soil depends upon the length of this interval, again a function of flooding probability, and height of the flat above the stream channel.

DEVELOPMENT OF THE FOREST ON SEDIMENT DEPOSITS

Redwood trees produce prodigious amounts of seed. During the redwood ecology studies in Humboldt Redwoods State Park, I collected seed along with leaf litter for several years. Seed counts were made of this material at locations along the South Fork of the Eel River, with seed amounts ranging from 2 to 27.9 million per acre per year. However, viability of the seed is less than 20%, and one rarely finds surviving seedlings from all this seed production each year in the groves. In contrast, following a flood year with sediment deposition, an invasion of young surviving seedlings, green as a lawn, develops on the new sediment deposit under the trees and as a margin to the grove. Figure 11 shows several age classes of such seedlings. In the foreground are the seedlings of the 1955 flood, in the middle the 1916 flood seedlings, and behind, the 1861 seedlings. Figure 12 is a photograph of Founders Grove. The seedling wave from the 1861 flood can be seen as a wall along the front of the grove itself composed of seedlings from floods of 100 years ago. Inside the grove are a few isolated giant trees, including the Giant Tree of Founders Grove, survivors of even earlier historic floods. Thus, the age class distribution within the superlative redwood grove gives us a clue to the periodicity of sediment-producing floods on that particular site, important information for the manager.

However, there may be detrimental effects of some flooding and deposition in redwood groves on alluvial flats. After the 1955 flood on upper Bull Creek Flat, we noticed that some of the large old trees of the grove had tops which were dying back. At the base of these trees we found deposits of sediment that were very coarse and gravelly, and choked with organic detritus. This material formed an abrupt interface with the previous silt loam deposits. Water perched at this interface during the wet season, and a blue anaerobic layer developed in the leaf litter which was buried there. The trees weakened by this abrupt change in quality of sediment were finally killed by redwood bark beetles (*Phleosinus sequoiae* Hopk.). Wherever the floods of 1955 and 1964 resulted in death to redwood trees along the Eel River, and Bull Creek, we found a deposit of coarse texture. E. Fritz (1956) reported that such a change in stream flow regime may be brought about by the sudden release of flood water and detritus due to the breaching of a log jam upstream.

A considerable loss of trees may also occur from actual failure of the stream banks where the stream cuts into such banks, and where quick drawdown following flooding causes saturated soil to slide along with trees into the stream. When these trees fall while the flow is still high, the tree bole is usually oriented downstream and parallel to the bank. Eventually such fallen trees protect the bank against further cutting by the stream. However, this natural tree groin formation formation is usually removed by the park manager, or if not, by poachers. This occurred at Cheatham grove on the Van Duzen River. This use of natural tree groins as a means of bank protection has been documented for large river systems by Framjl (1947).

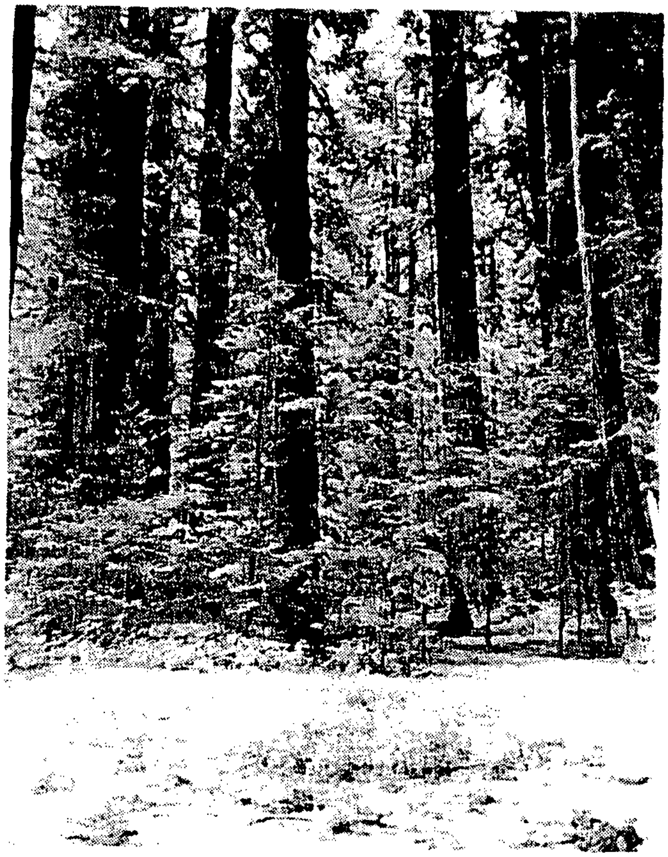

Figure 11:Seedlings of various age classes identifying sediment deposits in Stephens Grove. Foreground seedlings from 1955, intermediate height from 1916, and taller saplings from 1861.

Figure 12:Seedlings from the 1861 flood sediment now forming a wall on the outside of the Founders grove at the confluence of the main Eel and the south Fork.

RELATION BETWEEN WATERSHED CONDITIONS AND THE SUPERLATIVE REDWOOD GROVES

The close relation between the vigor of the trees, the dynamic processes of flooding and sedimentation, and a thousand-year consistent quality of sediment free from coarse fragments, or excessive bank cutting by the flooding stream, is apparent. In the case of Redwood Creek as well as in the case of the superlative groves on alluvial flats along rivers to the south, the maintenance of these groves involves avoiding undue changes in these processes. The flood events will certainly continue to occur. But the quality of the sediments reaching the alluvial flats may change. If coarse bedload material is deposited on such a flat, then the result may be a serious decline in tree vigor.

The watershed management objectives needed to maintain the balance in sediment quality favorable to the trees involve two major areas of concern: the first, the control of the channel immediately adjacent to the grove; and second, the goal of maintaining watershed conditions that minimize adverse changes in the flood and sediment regime of the stream.

The immediate goal of channel management needed to protect the Tall Trees Grove requires an assessment of the problem of potential bedload deposition in the grove related to local aggradation. Designing the means of protecting the grove against such an event can be formulated, possibly using groins, revetments, or guiding of the stream to the opposite side of the channel. A similar problem occurred at Cheatham Grove along the Van Duzen River, where excessive bank cutting was gradually destroying the grove. The problem was treated by a series of gravel fill groins extending into the channel, which diverted the river to the far shore. Sale of the fallen trees from this Nature Conservancy Reserve paid for the necessary work. Along Bull Creek, the State Park Department utilized channel clearing, and gabbions and rock revetments along the channel bank.

Upstream watershed management objectives will require an assessment of sediment and bedload sources, and the development of cooperative ways of dealing with a wide variety of owners and land use conditions. I made an initial determination of sediment sources on Redwood Creek for a study of buffer zones to the Park (Stone, Grah, and Zinke, 1969). The entire watershed was surveyed with regard to soil types and their slopes in the course of the California Cooperative Soil Vegetation Survey, making it possible to determine where critical areas of high erosion potential are located. The sediment entering the stream channel is largely a result of bank cutting and land slides. Sediment sources can be related to soil types as mapped along the banks of the creek and its tributaries. The length of stream bank occupied by each soil type was determined for forty-two and one-half-miles of banks of Redwood Creek above the Emerald Mile.

These data (shown in Table 2) indicate that twenty-eight and three-quarter-miles of bank will be actively feeding material into the channel from compound slides. These are areas of the blue-grey colored Atwell and Yorkville soil series. It is these materials which give the waters of Redwood Creek their characteristic grey color. These soil materials contribute not only

Table 2. Soil types along 42.5 miles of Redwood Creek from the Redwood National Park boundary to the Snow Camp area of the Six Rivers National Forest.

SOIL TYPE	EROSION SOURCE POTENTIAL	MILES* OF BANK	PERCENT OF DISTANCE
Atwell (823) or Atwell complex with Masterson or Hugo	Very high potential with numerous compound landslides	28.0	33.0
Yorkville (752)	Very high with compound landslides	0.75	0.9
High Terrace (400)	Moderate with debris slides and bank cutting	12.0	14.1
Masterson (821)	Moderate to low, block slides if dip of schist is downslope toward creek	43.75	39.7
Hugo (812)	Low-moderate. Debris sliding if steep slope or vegetation removed	8.5	10.0
Recent alluvial soil low terrace (200)	Low, unless bank cutting occurs	2.0	2.3

*One mile of creek considered to have two miles of bank for this study.

to suspended sediment load but also to bedload, depending upon the proportion of coarse materials they contain. Stream cutting of the banks of the hgih terraces along the creek will be another source of bedload. These high terrace soils are historical beds of the creek and deltas of tributaries left stranded above the current grade of the creek as in Redwood Valley. There are 12 miles of such high terrace soils in the Redwood Valley area in the Beaver Creek and Minor Creek areas. Fifty-two and a quarter miles of moderately stable to stable banks occur along the areas where the Masterson and the Hugo soils line the creek. However, about half of these have slopes greater than 50% and thus are potential sources of increased sediment if surface erosion or mass movement is accelerated by land use activities. A minor distance of 2 miles of stream bank are occupied by recent alluvial deposits which have a low potential as sources of sediment and bedload. Given this array of sediment sources, the priorities of action needed to achieve stability of historic watershed processes can be attainted.

Most likely the Tall Trees Grove has a long history of flooding and sedimentation, as with other similar groves on alluvial flats, and it is necessary to see that this continues with minimum adverse change. This will be difficult, because the past half-century has been one of major changes on the watershed related to human use. As can be seen from the table, more than one third of the bank length is occupied by soils having a high erosion potential. These would be critical areas to monitor if it is thought that a problem requiring renovation exists. This evaluation does not involve tributary streams, for which a similar assessment should be made.

CONCLUSIONS

1. Each alluvial flat supporting superlative redwood groves is unique in its history of dynamic events of flooding, sedimentation, and response of the trees to these events.

2. The effects of sediment deposition may be detrimental or beneficial, depending upon the quality of the sediment deposited relative to the ability of the tree roots to invade this new material.

3. Fine sediment of a silt loam quality is generally beneficial, while coarse gravelly bedload deposits are detrimental.

4. Accelerated tree growth usually occurs following deposition of sizable amounts of beneficial sediment, and the increases in tree ring width can be used to date such flood-sediment deposition events.

5. An example of such a chronology is presented for Rockefeller Grove on Bull Creek Flat.

6. Redwood seedling survival is enhanced by new sediment deposition, resulting in age classes of trees in the groves dating such deposits.

7. The history of a particular grove such as the Tall Trees Grove can be interpreted by means of the sediment profile of the soil, by the tree ring history of periods of growth acceleration due to sediment, and by the age classes of trees present in the grove.

8. All of these indicate a history of dynamic flooding, sedimentation, and rejuvenation of tree growth on the alluvial soils of the superlative groves.

9. Management of these groves with the objective of their preservation must allow for such events and their maintenance.
