## ABSTRACT

This study tests the efficacy of diatoms and soft algae (non-diatoms) as indicators of environmental conditions in streams located throughout the Lahontan Basin, USA. Potential diatom assemblages indicative of land-use practices that augment the degree of sedimentation, nutrient concentrations, and secondary salinization were identified.

Diatom and soft algal communities were analyzed in 65 stream habitats in the Lahontan Basin during 1996 through 1999 and 2001. In addition to elevation, twenty-five abiotic parameters were measured at each site and tested as determinants of diatom and soft algal distributions. Stream sites ranged from 5340 to 9340 feet asl and had a wide range of gradients, discharge, substrate, canopy cover, and water quality conditions.

Two hundred and twenty-five diatom taxa and over 30 soft algal taxa were identified in the stream habitats, with indications that algal assemblages were closely correlated with stream abiotic determinants. Diatoms were better indicators of stream conditions than soft algal communities, although species of the filamentous green alga, *Stigeoclonium* were abundant in habitats considered to have low ecosystem integrity. Also, density of cyanobacteria showed a strong positive relationship with %fines + sand and a negative association with hard substrates in stream channels. Diatom density showed the reverse associations with substrates.

Several metrics were used to test the efficacy of diatom assemblages and individual species as determinants of stream conditions in the Lahontan Basin. A multidimensional ordination showed elevation, canopy, specific conductance, pH, total Kjeldahl nitrogen, total phosphorus, and substrate conditions to be significantly correlated with diatom community structure. Diatom communities ordinated stream habitats into systems with coarse substrates, high canopy cover, and low and nutrient conditions from streams with fine substrates, low canopy cover, and elevated nutrient conditions. The latter systems were considered to have low ecosystem integrity.

An ANOSIM analysis of *a priori* grouping designations based on general stream conditions showed that diatom communities in habitats with abiotic conditions that correlated with high ecosystem integrity had significantly different diatom community compositions than those with low ecosystem integrity. Based on multidimensional ordination analyses, the diatom assemblages in the Lahontan Basin with high ecosystem integrity included *Achnanthidium minutissima*, *Eunotia bilunaris*, *Fragilaria arcus*, *Fragilaria tenera*, *Tabellaria flocculosa*, and *Tetracyclus rupestris*. In contrast, diatom assemblages with low ecosystem integrity included *Cyclotella meneghiniana*, *Melosira varians*, *Nitzschia frustulum*, *Nitzschia frustulum*, *Nitzschia palea*, and *Nitzschia sigmoidea*. The diatom taxa of *Amphipleura pellucida*, *Amphora coffeaeformis*, *Melosira varians*, *Nitzschia frustulum*, and *Nitzschia palea* were indicators of increased salinity.

Principal component analysis also showed a strong relationship between diatom species and selected abiotic determinants with strong loadings for canopy cover, conductance, nutrient concentrations, and substrate conditions. Similar relationships were found between diatom species and abiotic determinants as those outlined for the ordination analysis.

Motile diatom taxa of *Navicula*, *Nitzschia*, and *Surirella* were most abundant in assemblages with fine substrata and a degree high of embeddedness. Species such as *Cocconeis placentula* var. *euglypta*, *Cyclotella meneghiniana*, *Fragilaria ulna*, *Gyrosigma accuminatum*, *Nitzschia frustulum*, *Nitzschia palea*, *Nitzschia dissipata*, and *Rhopalodia gibba* were considered to be most tolerant of disturbed sites with substrata composed of a high percentage of fines and sand and a high degree of embeddedness.

An extensive literature search concurred with findings on associations between diatom assemblages in the Lahontan Basin and abiotic determinants that augment high sedimentation, nutrient concentrations, and salinity in stream channels.

## INTRODUCTION

Benthic algae are critical components in most stream food webs (Stevenson 1996, Wehr and Sheath 2003). These organisms help stabilize substrata and provide food and habitat for many other organisms, especially invertebrates. Because benthic algal assemblages are attached to substrata, they serve as “micro environmental-loggers” for physical, chemical, and biological disturbances that occur in stream reaches during the time in which the assemblages develop.

Diatoms are especially good indicators of the environmental integrity of lotic ecosystems because they are common in most streams and provide the primary food source for many invertebrates and some juvenile fishes that reside in these systems (Dixit *et al.* 1992, Lowe and Pan 1996, Stevenson and Pan 1999). In addition, diatoms are useful monitors of change because: 1) they are readily dispersed and can invade a variety of habitats; 2) they are relatively easy to sample and create minimal impact to resident biota during collections; 3) their response time (generation time) lies between bacteria (hourly) and macroinvertebrates (triannual), and 4) diatoms are sensitive to subtle changes in environmental conditions and/or disturbances that may not visibly affect other communities, or may only affect other communities at lower levels of disturbance (Bahls 1993, Stevenson and Pan 1999, Stevenson and Bahls 1999).

In addition, the identification of diatoms is based on morphological features of their rigid walls (frustules) made of silicon dioxide (glass). This provides an opportunity to prepare permanent reference slides of diatom assemblages under different environmental regimes for use in assessing water conditions. Many investigators have used various diatom metrics to determine environmental conditions in streams including discharge and

hydraulic fluctuations (Duncan and Blinn 1989, Biggs and Hicky 1994, Benenati *et al.* 1998), light (Duncan and Blinn 1989, Hardwick *et al.* 1992), temperature (Squires *et al.* 1979, Tuchman and Blinn 1979, Blinn *et al.* 1989), salinity (Blinn and Bailey 2001), nutrients (Patrick 1977, Bahls *et al.* 1992, van Dam *et al.* 1994, Hill *et al.* 2000, Blinn and Bailey 2001), and herbivory (Colletti *et al.* 1987, Steinman *et al.* 1987).

Soft algae (non-diatoms) have also been used as indicators of biological integrity (Palmer 1962, Fjerdingstadt 1965, Palmer 1979, Hill *et al.* 2000), but may have less efficacy than diatoms in this respect due to their highly variable morphology. In contrast to diatoms, the complete identification of many species of soft algae requires reproductive structures and material may need to be cultured in the laboratory for full identification (Stevenson and Pan 1999). Also, soft algal material must be chemically preserved and therefore requires more space than diatom reference slides and needs continual maintenance.

The objectives of this study were to: 1) determine the utility of diatoms and soft algae as predictors of environmental conditions and ecosystem integrity for streams in the Lahontan Basin, and 2) identify those species which best serve as indicators of these environmental determinants and develop monitoring indices with diatoms and soft algae to assess the environmental health of streams throughout the basin.

## METHODS

Abiotic determinants (elevation, discharge, dissolved oxygen, water temperature, specific conductance, alkalinity, pH, % canopy cover, % slope, and substrate composition were taken from a larger data set collected for macroinvertebrates (SEE Herbst and Suk 1999). Chemical analyses for nutrients and major ions followed procedures outlined by Clesceri *et al.* (1998).

Algal samples were collected on submerged substrates from 65 stream sites throughout the Lahontan Basin during 1996 through 1999 and 2001 (SEE Table 1). Replicate collections ( $n = 3$ ) were made at each stream site. Each collection (25 ml) was split equally for diatom and soft algal analyses. Samples for diatoms were digested following the procedures of Van der Werff (1955) and permanent Hyrax® slide mounts were prepared for each collection; i.e., one slide per sample. A minimum of 300 diatom valves was counted from each slide preparation. Density and relative abundance values for each diatom species were averaged from the set of three collections at each site in the final analyses. Percent of live diatoms (presence of intact chloroplast) were determined from each sample collected for soft algal analyses during 2001. Diatom nomenclature followed that of Fourtanier and Kociolek (1999). A diversity index ( $H'$ ) was calculated for diatom assemblages for each site (Shannon and Weaver 1949).

Soft algal analyses were performed on each collection ( $n = 3$ ) with either a Sedgwick Rafter chamber or Palmer counting cell depending on cell densities. Protocols for cell density estimates followed that of Stevenson and Bahls (1999). Percent cover of aquatic macrophytes was also estimated at each stream site.

Relative abundance of motile diatoms in each stream habitat was used in a siltation index. Total relative abundance of *Navicula*, *Nitzschia*, and *Surirella* (NNS) species was estimated for each stream habitat as proposed by Stevenson and Bahls (1999). Species in these genera have some of the most advanced and efficient motility systems in diatoms (Lowe 2003), and are able to migrate to the surface if covered by silt. Therefore, these taxa may represent a good indicator of siltation disturbance (i.e., embeddedness, % fines + sand) in lotic environments. A paired Student *t* test was used to determine significant differences between % of fines and sand for the NNS index.

The following index for % fines + sand (FSI) was also used to examine the distribution of diatom taxa along substrate gradients:

$$FSI_x = \frac{\sum_{i=1}^{Nx} [\log_{10} (RA_i \cdot 100)] (\% \text{ fines \& sand})}{Nx},$$

where  $RA_i$  = relative abundance (percent) of species  $x$  at a given site, and  $N$  = number of sites in which species  $x$  occurred. Similar indices were calculated for % embeddedness (EMBI), water temperature (TEMPI), total Kjeldahl nitrogen (TKNI), total phosphorus (TPI), and specific conductance (CONDI). These univariate indices provide a relative numeric scale to evaluate the response of various diatom taxa to potential disturbance factors in the Lahontan Basin. Blinn and Bailey (2001) have used similar metrics for determining the response of diatoms to salinity and nutrients in streams in Victoria, Australia.

Principal components analysis was used to determine relationships between

dependent (diatom taxa) and independent abiotic determinants with SYSTAT software (Version 5.1, Wilkinson 1989). Correlations between various paired combinations of diatom taxa and determinant variables were also calculated using Pearson's product-moment correlation coefficient with SYSTAT software. Significant differences between paired measurements were obtained from Bonferroni adjusted alpha values ( $p < 0.05$ ) as well as under less conservative matrix of probabilities ( $p < 0.05$ ).

In addition, non-metric multi-dimensional scaling ordination techniques were employed to investigate relationships between stream sites based on diatom community composition and to relate community composition to abiotic determinants. Ordinations were based on Bray-Curtis dissimilarity distances using relative frequencies of species occurrence for diatom communities (Minchin 1999). Twenty-six abiotic determinants were fitted into the ordination space as vectors to show relationships of diatom community composition along physicochemical gradients. The environmental determinants tested were: elevation, % canopy cover, % slope, discharge, dissolved oxygen, alkalinity, specific conductance, pH, water temperature, turbidity, embeddedness, SiO<sub>2</sub>, total Kjeldahl, NO<sub>3</sub>/NO<sub>2</sub>, soluble reactive phosphorus, dissolved phosphorus, total phosphorus, SO<sub>4</sub>, Ca, Mg, and substrate composition (% fines, % sand, % fines + sand, % gravel, % cobble, % boulder). The fit of abiotic vectors to diatom community composition and soft algal measurements were tested against 1000 random iterations of fit (Kantvilas and Minchin 1989). Significance levels for vector correlations were adjusted to experiment wide alpha levels of  $p < 0.05$  using Dunn-Sidak sequential tests (Ury 1979). During field collections, sites were judged as either degraded or un-degraded depending on a holistic visual assessment of substrate conditions, canopy-

cover, salinity, and nutrient conditions, i.e., general health of the system. We tested the similarity of community composition between degraded and un-degraded sites using Analysis of Similarity (ANOSIM) routine (Clark 1993), which tests *a priori* grouping designations against 1000 random group designations in ordination space. Analyses were made using DECODA software (Minchin 1999).

## RESULTS

*Abiotic determinants:* Values for the abiotic determinants used in the analyses of diatoms and soft algae are provided in Table 1. These data represent a subset of a larger data set collected for macroinvertebrates (SEE Herbst and Suk 1999).

Stream habitats ranged from 5340 to 9340 feet asl with Marble Creek the lowest site examined and Virginia Creek the highest in elevation (Table 1). Marble, Hot Springs, Trout (Bennett Flat), Deep, Heavenly, Saxon, Cold, Hidden Valley, north fork of Squaw, Nye, Rock, Hilton, Robinson, Burcham, McGee, Swauger, Parker, Deadman creek sites and Upper Truckee River (Forest) had canopy cover values >50%. Middle Squaw, East Walker, Perazzo, Dexter, Upper Owens, Poore, Kirman, Mammoth, O'Harell, Little Walker, and Bodie creek sites had <5% canopy cover.

Water temperatures at the time of collection ranged from a high of 22.8°C at lower Squaw Creek (9VI01) to a low of 7.3°C at Upper Truckee River (forest site). pH was generally circumneutral except for the Upper Truckee forest site and Marble, Convict SNARL, O'Harrel, Kirman, lower Cottonwood (99), McGee, and Swauger creek sites each with pH values ≥8. The most dilute stream habitats included Upper Truckee River and Taylor, Independence, Hidden Valley, Lacey Canyon, Rush, Deadman, Dunderberg, Glass, Hilton, Little Walker, O'Harrel, Rock, Swauger, Parker, Virginia, and West Walker, and the north and south forks of Squaw creek sites with specific conductance values ≤60 µS/cm (Table 1). Clearwater, Kirman, Lower Hot, Nye, and Upper Owens creeks had conductance values >200 µS/cm; Nye Creek (451 µS/cm) had the highest conductance.

The average total Kjeldahl nitrogen (TKN) and total phosphorus (TP) concentrations in the 27 streams examined during 2001 were 0.098 and 0.0192 mg/L, respectively (Table 1). Trout Creek at Bennett Flat, Alder Creek, and Trout Creek below Fallen Leaf had TKN concentrations >2 mg/L, and Trout Creek below Bennett Flat, Deep Creek, Convict SNARL, and Trout Creek below Fallen Leaf had TP concentrations >0.04 mg/L (Table 1). Streams with  $\leq$ 0.1 mg/L TKN included East Martis, Hot Springs, Bear Creek, Squaw Creek middle, Squaw Creek lower, Taylor, Independence, Perazzo, Heavenly, Saxon, Cold, Hidden Valley Creek, Lacey, Rush, Convict SNARL, Robinson, Parker, and the north and south forks of Squaw creek sites. All of these stream sites had TP concentrations <0.016 (SE  $\pm$ 0.005).

Bonferonni adjustments showed that temperature had a significant negative relationship with dissolved oxygen ( $r = -0.45$ ), and elevation had a significant negative association with TKN ( $r = -0.42$ ), % gravel ( $r = -0.42$ ), and % cobble ( $r = -0.40$ ; Table 2). As expected, % fines + sand showed a strong significant positive relationship to embeddedness ( $r = 0.73$ ) and a significant negative relationship to cobble ( $r = -0.42$ ). Both gravel and cobble showed a significant negative relationship to elevation ( $r = -0.40$ ) and embeddedness showed a significant positive relationship to water temperature ( $r = 0.40$ ). Specific conductance and alkalinity showed a highly significant positive relationship ( $r = 0.90$ ). Also, both alkalinity and conductance showed a significant positive relationship to TKN and TP ( $r = 0.52$ ). There were no significant correlations between silica and diatom cell density or any diatom species.

Under a less conservative matrix of probability, fines + sand also showed a significant negative relationship to gravel and boulder. Also, less conservative probabilities showed

elevation to have a negative association with alkalinity ( $r = -0.29$ ) and conductance ( $r = -0.27$ ). Patterns of negative relationships emerged between elevation and the abiotic determinants of dissolved oxygen and % slope (Table 2). No clear relationships were apparent between elevation and the determinants of water temperature, pH, discharge, canopy cover, or nutrients (Table 2).

*Diatom distribution and ecology:* Two hundred and twenty-five diatom taxa were identified from 65 stream habitats throughout the Lahontan Basin (Table 3). The identifications for some taxa are not complete and need further examination (SEE Appendix Tables 1a-1m). The mean frequencies for all diatom taxa for each stream site are provided in Appendix Tables 1a-1m. The average number of diatom taxa for the stream sites was 43 (SE  $\pm 1$ ). Clearwater had the highest number of taxa (67) and the north fork of Squaw Creek had the fewest taxa (22; Table 4).

Estimated densities of diatoms averaged 535,824 (SE  $\pm 117,230$ ) valves/cm<sup>2</sup> for all 65 stream sites. East Martis, Alder, and Trout Creek at Bennett Flat had the highest diatom densities ( $\geq 2.4$  million valves/cm<sup>2</sup>) and the forest site on the Upper Truckee River (18,610 valves/cm<sup>2</sup>) had the lowest diatom density (Table 4).

Diatom H' ranged from a low of 1.5 in the north fork of Squaw Creek to 4.6 in the Little Truckee River (Table 4). There were significant positive correlations between diatom H' and % gravel ( $r = 0.53$ ) and % cobble ( $r = 0.60$ ), while number of diatom taxa showed significant negative correlations to % fines + sand ( $r = -0.41$ ), gravel ( $r = -0.48$ ), and cobble ( $r = -0.53$ ). Percent live diatoms showed significant positive associations with dissolved oxygen ( $r = 0.65$ ) and canopy ( $r = 0.58$ ), but negative correlations with

water temperature ( $r = -0.41$ ) and gravel ( $r = -0.43$ ; Table 2). Under a less conservative matrix of probability, pH showed a significant positive relationship to live diatoms ( $r = 0.53$ ).

The overall relative frequencies and mean % embeddedness, % F + S, and elevation are presented in Table 5 for numerically important taxa. These 66 taxa represent 85% of the mean frequency of diatom taxa collected in the stream habitats. *Achnanthidium minutissima*, *Planothidium lanceolata*, and *Cocconeis placentula* var. *euglypta* had the highest mean frequencies in the Lahontan Basin at 13.1%, 8.3% and 7.5%, respectively.

Taxa that were present in at least 75% of the stream habitats included, *A. minutissima*, *C. placentula* var. *euglypta*, *Cymbella affinis*, *Fragilaria capucina*, *Fragilaria capucina* var. *vaucheriae*, *Fragilaria ulna*, *Gomphonema parvulum*, *Navicula cryptocephala*, *Navicula veneta*, *Nitzschia dissipata*, *Nitzschia frustulum*, *Nitzschia palea*, *P. lanceolata*, *Reimeria sinuata*, and *Rhoicosphenia abbreviata*. *Achnanthidium minutissima*, *F. capucina* var *vaucheriae*, and *F. ulna* were found in all stream sites sampled.

The percentage of fines + sand (F + S) associated with stream substrates showed a significant positive relationship to the motile diatom index of NNS ( $t = 9.1$ ;  $p < 0.001$ ). Stream habitats with  $<10\%$  F + S had mean NNS values of 0.15 ( $n = 21$ ; SE  $\pm 0.03$ ), whereas those with  $\geq 50\%$  F + S had mean NNS values of 0.27 ( $n = 13$ ; SE 0.02, Table 6). Sites with both low NNS and F + S values included Parker, Bear, Independence, Taylor, Virginia, Green, Convict SNARL, McGee, Perazzo, Lacey, and Deep creeks (Table 6). In contrast, sites with high substrate indices included Clearwater, Burcham, Kirman,

Heavenly Valley, East Walker, Dexter, Bodie, O'Harrel, Adobe, and Lower Cottonwood creeks.

The association of numerically dominant taxa to several important abiotic determinants are presented in Table 7. A high value for each index indicates a strong positive association between the abiotic determinant and diatom species. For example, species with high values for temperature (TEMPI) are commonly associated with higher water temperatures in the Lahontan Basin. Therefore, species with low TEMPI values such as *Achnanthes exigua* (Acex), *Aulacoseira ambigua* (Auam), *Fragilaria arcus* (Frar), *Frustulia rhombooides* (Frrh), *Gomphonema truncatum* (Gotr), *Tabellaria flocculosa* (Tafl), and *Tetracyclus rupestris* (Teru) are commonly associated with colder water habitats and those with high TEMPI values such as *C. placentula* var *euglypta* (Copleu), *F. capucina* (Frca), *F. capucina* var. *vaucheriae* (Frcav), *F. ulna* (Frul), *N. dissipata* (Nidi), *N. frustulum* (Nifr), *N. palea* (Nipa), and *P. lanceolata* (Plla) are associated with warmer water habitats.

The fines + sand (FSI) and embeddedness (EMBI) indices identified relationships between diatom taxa and stream substrate conditions in the Lahontan Basin. Low values for each index indicated an association with low degrees of fines + sand and embeddedness. For example, *Cyclotella stelligera* (Cyst), *Diatoma mesodon* (Dime), *Eunotia bilunaris* (Eubi), *F. arcus*, *Fragilaria tenera* (Frte), *G. truncatum*, *T. rupestris*, and *T. flocculosa* had low substrate indices (Table 7). In contrast, *Amphipleura pellilucida* (Ampel), *C. placentula* var. *euglypta*, *Cyclotella meneghiniana* (Cyme), *F. capucina*, *F. capucina* var. *vaucheriae*, *F. ulna*, *Gomphonema clevei* (Gocl), *Hantzschia amphioxys* (Haam), *N. dissipata*, *N. frustulum*, *N. palea*, and *Staurosira construens* (Stco)

were associated with stream habitats with a high percentage of fines + sand and a high degree of embeddedness.

Cluster analysis of EMBI values illustrated the relative relationships of numerically important diatom species to substrate conditions in the Lahontan Basin (Fig. 1). Diatom species in Group I were commonly associated with stream habitats with low embeddedness, while species in Group II included species more commonly associated with embeddedness. *Tetracyclus rupestris*, *D. mesodon*, *T. flocculosa*, *F. arcus*, and *E. bilunaris* were clustered within a subgroup in Group I with the lowest association with embeddedness, while *C. placentula* var. *euglypta*, *N. frustulum*, *N. dissipata*, *F. ulna*, and *G. clevei* were clustered in subgroups of Group II with the highest association with embeddedness. Other numerically important diatom species are distributed along the axis based on their association to embeddedness (Fig. 1).

Diatom species showed different responses to total Kjeldahl nitrogen (TKNI) and total phosphorus (TPI) indices. Cluster analyses of TKNI values showed that *T. rupestris*, *T. flocculosa*, *A. ambigua*, and *Epithemia sorex* (Epso) were most commonly associated with low total Kjeldahl nitrogen concentrations (Fig. 2), while *T. rupestris*, *T. flocculosa*, *F. tenera*, *Pinnularia divergens* (Pidi), *Pinnularia gibba* (Pigi), and *F. arcus* were most commonly associated with low total phosphorus concentrations (Fig. 3). *Cocconeis placentula* var. *euglypta*, *G. clevei*, *N. dissipata*, *N. palea*, *Rhoicosphenia abbreviata* (Rhab), *F. ulna*, and *P. lanceolata* (Plla) were commonly associated with habitats with high total Kjeldahl nitrogen concentrations, while *C. placentula* var. *euglypta*, *G. clevei*, *R. abbreviata*, *Gomphoneis herculeana* (Gohe), *Cyclotella*

*meneghiniana* (Cyme), *N. dissipata*, and *P. lanceolata* were commonly associated with high total phosphorus concentrations.

Cluster analysis of specific conductance index (SPI) values showed distinct diatom communities associated with salinity in three groups (Fig. 4). *Tetracyclus rupestris*, *T. flocculosa*, *F. arcus*, *A. ambigua*, *F. tenera*, *D. mesodon*, and *E. bilunaris* were clustered within Group I and most commonly associated with stream habitats with low salinities and *C. placentula* var. *euglypta*, *N. palea*, *C. meneghiniana*, *N. dissipata*, *E. sorex*, *N. frustulum*, and *R. abbreviata* were clustered in Group III or most commonly associated with stream habitats with higher salinities. Diatom species in Group II were commonly associated with habitats with moderate salinities (Fig. 4).

Principal component analysis showed strong relationships between diatom taxa and selected abiotic determinants with strong loadings for elevation, canopy cover, temperature, specific conductance, total Kjeldahl nitrogen (TKN), total phosphorus (TP), and embeddedness. *Aulacoseira ambigua*, *E. bilunaris*, *D. mesodon*, and *T. rupestris* showed strong positive loadings for elevation, slope, canopy cover, dissolved oxygen, and negative loadings for temperature, specific conductance, TKN, TP, and embeddedness (Fig. 5). *Fragilaria arcus*, *F. tenera*, *P. divergens*, *P. gibba*, and *T. floculosa* also showed strong negative loadings for embeddedness, specific conductance, total Kjeldahl nitrogen, and total phosphorus.

*Melosira varians* (Meva), *G. herculeana*, *N. dissipata*, and *R. abbreviata* showed strong positive loadings for TP and embeddedness, while *A. pellucida*, *C. meneghiniana*, *Meridion circulare* (Meci), *N. frustulum*, and *N. palea* showed strong positive loadings for specific conductance and TKN (Fig. 5).

Nine taxa showed significant relationships to abiotic determinants when adjusted to Bonferroni values. Both *Didymosphenia geminata* ( $r = 0.80$ ) and *E. sorex* ( $r = 0.50$ ) showed significant positive correlations to discharge, and *G. clevei* ( $r = 0.62$ ) showed a positive association to gravel. *Tetracyclus rupestris* showed a negative correlation to dissolved oxygen ( $r = -0.47$ ) and a positive correlation to elevation ( $r = 0.60$ ). Both *Surirella angustata* ( $r = 0.68$ ) and *R. abbreviata* ( $r = 0.73$ ) showed positive correlations to TKN, and *R. sinuata* showed a positive correlation to TP ( $r = 0.77$ ). *Achnanthes exigua* showed a positive correlation to specific conductance ( $r = 0.49$ ) and *N. palea* showed a positive correlation to  $Mg^{++}$  ( $r = 0.69$ ).

Under a less conservative matrix of probability, several patterns were apparent. *Didymosphenia geminata* ( $r = 0.46$ ), *Hantzschia amphioxys* ( $r = 0.30$ ), *Nitzschia gracilis* ( $r = 0.40$ ), and *R. abbreviata* ( $r = 0.44$ ) showed significant positive associations with embeddedness; *R. gibba* ( $r = 0.36$ ) showed a positive correlation to specific conductance; *C. meneghiniana* ( $r = 0.55$ ), *N. dissipata* ( $r = 0.41$ ), and *N. palea* ( $r = 0.35$ ) showed positive correlations with TKN; and *Fragilaria crotonensis* ( $r = 0.62$ ), *Nitzschia amphibia* ( $r = 0.51$ ), and *R. abbreviata* ( $r = 0.44$ ) showed positive correlations with TP.

Also, when adjusted to Bonferroni values, *A. ambigua* showed significant positive relationships to *E. bilunaris* ( $r = 0.42$ ) and *T. flocculosa* ( $r = 0.40$ ), and *D. mesosdon* showed a positive relationship to *E. bilunaris* ( $r = 0.52$ ). In addition, *C. meneghiniana* showed positive correlations with *N. palea* ( $r = 0.52$ ) and *N. sigmoidea* ( $r = 0.72$ ); *M. varians* a positive correlation with *N. sigmoidea* ( $r = 0.72$ ); *T. rupestris* showed a positive correlation ( $r = 0.45$ ) to *F. capucina* var. *vaucheriae*; and *N. sigmoidea* showed positive correlations to *N. frustulum* ( $r = 0.71$ ), and *N. palea* ( $r = 0.88$ ).

Under a less conservative matrix of probability, *F. arcus* was positively correlated with *T. rupestris* ( $r = 0.30$ ), and *N. dissipata* showed positive correlations with *M. varians* ( $r = 0.41$ ), *N. frustulum* ( $r = 0.27$ ), *N. palea* ( $r = 0.32$ ), *N. sigmoidea* ( $r = 0.44$ ), and *R. abbreviata* ( $r = 0.27$ ).

Bonferroni adjusted tests showed a significant positive relationship between diatom density and TKN ( $r = 0.56$ ), but not with diatom density and TP ( $r = 0.07$ ). There were also significant positive correlations between diatom density and aquatic macrophytes ( $r = 0.50$ ) and density of the filamentous green alga, *Stigeoclonium* ( $r = 0.41$ ), but not with *Cladophora* ( $r = 0.23$ ) or cyanobacteria density ( $r = -0.02$ ).

A non-metric multi-dimensional ordination of 65 stream habitats based on the relative abundance of 51 numerically important diatom taxa was completed in three dimensions with a minimum stress of 0.144. Additional dimensions did not significantly reduce stress or enhance interpretation. Differences in communities were best explained by vectors of elevation (MAX 0.523,  $p = 0.001$ ), canopy (MAX 0.511,  $p = 0.001$ ), pH (MAX 0.553,  $p = 0.001$ ), conductance (MAX 0.482,  $p = 0.001$ ), dissolved oxygen (MAX 0.410,  $p = 0.012$ ), total phosphorus (MAX 0.615,  $p = 0.001$ ), total Kjeldahl nitrogen (MAX 0.535,  $p = 0.037$ ), and substrate conditions (% fine + sand, MAX 0.412,  $p = 0.028$ ; % gravel MAX 0.682,  $p = 0.001$ ; cobble MAX 0.638,  $p = 0.001$ ). Those abiotic vectors with the longest lines best explain relationships between diatom community structure. Also, habitats aligned along abiotic vectors show strong correlations to that specific determinant with the strongest correlations near the terminal point on the vector.

Stream diatom communities in habitats located on the upper left side of Fig. 6 such as Swauger, Little Walker, McGee, Convict (96), Green, Deep, Virginia, and Taylor

creeks showed positive correlations to habitats with hard substrates and reduced nutrient concentrations (total Kjeldahl nitrogen and total phosphorus). Over 85% of the stream habitats in the upper left side of the ordination are associated with diatom communities in hard substrates and reduced nutrients. These conditions generally suggest high quality habitats with high ecosystem integrity and biological diversity (Platts *et al.* 1983, Raven *et al.* 1998, Barbour *et al.* 1999).

In contrast, stream diatom communities in habitats located on the right side of Fig. 6 such as Bodie (96), Clearwater (97), E. Martis, Hot Springs, Juniper, Little Truckee, North Prosser, Nye, Rush, Trout (BF), Trout (BFL), Sagehen, Saxon and Slinkard creeks showed strong positive correlations to fines + sand and/or total Kjeldahl nitrogen. Nearly 70% of the stream habitats on the right side of the ordination are associated with diatom communities in fine substrates, low canopy, and elevated nutrients, especially total Kjeldahl nitrogen. These conditions generally suggest low quality habitats with low ecosystem integrity and biological diversity (Platts *et al.* 1983, Raven *et al.* 1998, Barbour *et al.* 1999).

In general, mean diatom cell density showed a positive association with hard substrates, whereas mean cyanobacteria cell density showed a strong positive association with fine substrates (Fig. 6). Stream diatom communities in habitats along and/or near the conductance vector in Figure 6 suggest a positive relationship to specific conductance. These include the stream habitats of Lower Hot, Kirman, and Poore.

An ANOSIM analysis of *a priori* grouping designations based on general stream conditions (substrate and canopy) showed that diatom communities in habitats with abiotic conditions correlated with high ecosystem integrity and biological diversity as

described above (generally on the left side of Fig. 6), and low ecosystem integrity and biological diversity (generally on the right side of Fig. 6) had significantly different diatom community compositions (ANOSIM  $R = 0.156$ ;  $p = 0.0001$ ).

Species averages fitted into ordination space indicated that many diatom species were associated with the measured environmental determinants (Fig. 7). Habitats aligned along abiotic vectors show strong correlations to that specific determinant with the strongest correlations near the terminal point on the vector. Diatom taxa clustered on the upper left side of the plot, including *Achnanthidium minutissima* (Acmi), *Fragilaria arcus* (Frar), *Fragilaria tenera* (Frte), *Pinnularia divergens* (Pidi), *Tabellaria flocculosa* (Tafl), and *Tetracyclus rupestris* (Teru) formed assemblages in habitats with coarse substrates and low total Kjeldahl nitrogen concentrations.

In contrast, species on the right side of the plot such as *Cocconeis placentula* var. *euglypta* (Copleu), *Cyclotella meneghiniana* (Cyme), *Melosira varians* (Meva), *Nitzschia frustulum* (Nifr), *Nitzschia palea* (Nipa), and *Rhoicosphenia abbreviata* (Rhab), formed assemblages in habitats with a high percentage of fines + sand and total Kjeldahl nitrogen concentrations. *Cocconeis placentula* var. *euglypta* and *R. abbreviata* showed especially strong positive correlation with total Kjeldahl nitrogen (Fig. 7).

*Soft algal distribution and ecology:* The average density of soft algae per site was 357,778 ( $SE \pm 92,923$ ) cells/cm<sup>2</sup> or about 40% of the total algal composition (diatom and soft algae) in the stream sites examined (Table 4). Average total cell density of combined diatom and soft algae per site was 893,037 ( $SE \pm 147,230$ ) cells cm<sup>2</sup>. Sites at lower Cottonwood, East Walker, Marble, Nye, Bodie, Lower Hot, Kirman, Upper Owens, and

Perazzo creeks had soft algal densities of  $>1,000,000$  cells  $\text{cm}^2$ . Sites at Little Walker, Dunderburg, Burcham, Trout (Bennett Flat), Saxon, Hidden Valley, and Parker creeks had low densities of soft algae ( $<10,000$  cells/ $\text{cm}^2$ ).

About 68% of the soft algal densities were cyanobacteria (*Phormidium*, *Nostoc*, *Calothrix*, and *Chroococcus*). The average number of cyanobacterian species per site was 2.6 (SE  $\pm 0.2$ ). Cyanobacteria were recorded at all sites with highest densities at lower Cottonwood, E. Walker, Marble, Nye, Bodie, Lower Hot, and Upper Owens stream sites. Mean density of cyanobacteria per site was 241,642 (SE  $\pm 65,603$ ) cells  $\text{cm}^2$ .

The average number of green algal species per site was 2 (SE  $\pm 0.2$ ). Branched, filamentous species of *Cladophora* and *Stigeoclonium* were the most common green algal species with mean densities of 61,126 (SE  $\pm 1,436$ ) and 38,785 (SE  $\pm 18,446$ ) cells  $\text{cm}^2$ , respectively. Highest densities of *Cladophora* and *Stigeoclonium* were found at Adobe, Clearwater, Bodie, Kirman, E. Walker, Hot Springs, Robinson, E. Martis, and Little Truckee. No filamentous green algae were collected at Deadman, Deep, Dog, Dunderberg, McGee, Little Walker, Marble, Parker, Saxon, Independence, south fork of Squaw, Alder, and Swauger creek sites. Mean density of green algae per site was 111,138 (SE  $\pm 7800$ ) cells  $\text{cm}^2$ .

Bonferroni adjusted values showed a significant positive association between soft algal density and conductance ( $r = 0.55$ ), alkalinity ( $r = 0.52$ ), % fines + sand ( $r = 0.56$ ), and % embeddedness ( $r = 0.56$ ; Table 2). Cyanobacteria density showed a similar significant relationship to these four abiotic determinants (Table 2). There was also a significant positive correlation between densities of *Stigeoclonium* and diatoms ( $r = 0.41$ ), but not between *Cladophora* and diatom density. Also, *Stigeoclonium* density

showed a significant positive correlation to the diatom species *N. palea* ( $r = 0.50$ ). Under a less conservative matrix of probability, % slope showed a positive association with soft algal density ( $r = 0.31$ ) and cyanobacteria ( $r = 0.27$ ).

## DISCUSSION

Diatom assemblages and individual species provided reliable indicators of stream conditions on sedimentation, nutrients, and salinity throughout the Lahontan Basin. A multi-dimensional ordination showed that elevation, canopy, pH, specific conductance, dissolved oxygen, total phosphorus, total Kjeldahl nitrogen, and substrate conditions were the most significant environmental determinants influencing diatom community structure in the Lahontan Basin. Principal components analysis showed similar patterns for these same abiotic determinants. Indices for motile diatoms, % embeddedness, and % fines + sand also validated the findings for substrate conditions. The interactions between these abiotic factors produced highly varied diatom assemblages across different stream habitats, but with distinctive and similar diatom communities in habitats with similar abiotic conditions.

An ANOSIM analysis of *a priori* grouping designations based on general stream conditions showed that diatom communities in habitats with abiotic conditions correlated with high ecosystem integrity had significantly different diatom community compositions than those with low ecosystem integrity. Diatom communities ordinated stream habitats into streams with coarse substrata, high canopy cover, and low nutrient concentrations from systems with fine substrata, low canopy cover, and high nutrients, especially total Kjeldahl nitrogen. The diatom species of *Achnanthidium minutissima*, *Fragilaria arcus*, *Fragilaria tenera*, *Pinnularia divergens*, *Tabellaria flocculosa*, and *Tetracyclus rupestris* formed assemblages in habitats with coarse stable substrata, high canopy cover, and low nutrient concentrations. These taxa are considered to represent stream habitats with relatively high ecological integrity in the Lahontan Basin. In an

extensive, long-term survey of diatom communities in streams throughout Montana, USA, Bahls (1993) found that most of the above taxa were highly sensitive to pollution disturbance, including siltation and nutrient enrichment.

In contrast, diatom species such as *Coccconeis placentula* var. *euglypta*, *Cyclotella meneghiniana*, *Melosira varians*, *Nitzschia frustulum*, *Nitzschia palea*, and *Rhoicosphenia abbreviata* formed assemblages in habitats with unstable fine substrates, low canopy cover, and high nutrient concentrations, especially for total Kjeldahl nitrogen. Many of these species are frequently associated with lower elevation streams with a high degree of embeddedness, abundant aquatic macrophytes and/or filamentous green algae, and somewhat elevated conductivity and nutrients (Lowe 1974, Patrick and Reimer 1976, Bahls et al. 1984). Bahls (1993) indicated that most of the above taxa were either moderately or highly pollution tolerant. Ordinations on diatoms in the Lahontan Basin also showed that *Gomphoneis herculeana*, *Nitzschia sigmoidea*, and *Surirella angustata* to be tolerant to pollution, but Bahls reported these taxa to be highly sensitive to pollution or systems with low ecological integrity.

The distribution of the ordinated stream habitats in Figure 6 based on diatom community structure showed some inconsistencies. Although over 85% of the stream habitats in the upper left portion of the ordination plot were made up of systems with high ecosystem integrity, several habitats with low ecosystem integrity, including O'Harrel and Heavenly creeks, were positioned in this area. This likely indicated subtle interactions between several abiotic determinants each having an influence on the structure of diatom communities. Perhaps in O'Harrel and Heavenly creeks,

conductance and dissolved oxygen in addition to coarse substrates, were important determinants for diatom community structure.

Likewise, nearly 70% of the stream habitats on the right side of the ordination plot tended to be somewhat degraded with low ecosystem integrity. However, stream habitats of Independence, Robinson, Bear, Upper Owens, and Hidden Valley tended to have abiotic conditions with high ecosystem integrity. Again, the diatom assemblages for these stream habitats may have been influenced by several abiotic determinants and hence provided a less clear pattern. For example, elevation, in addition to high total Kjeldahl nitrogen concentrations and fine substrates, may have influenced the structure of diatom communities. Kefford (1998) and Blinn and Bailey (2001) discussed similar relationships between salinization and nutrients for invertebrates and diatom communities, respectively, for streams of Victoria, Australia.

Individual diatom taxa showed subtle differences for specific environmental conditions. For example, both ordinations and principal components analysis showed *A. pellucida*, *C. meneghiniana*, *N. frustulum*, *N. palea*, and *N. sigmoidea* as good indicators for elevated concentrations of total Kjeldahl nitrogen, while *A. pediculus*, *C. placentula* var. *euglypta*, *Planothidium lanceolata*, *Reimeria sinuata*, and *R. abbreviata* are good indicators of elevated total phosphorus.

Utilization of these indicator taxa may have utility in recognizing differences in land-use practices. For example, streams with high relative abundances of the first diatom assemblage may indicate extensive use of crop fertilization and delivery of nitrogen to stream channels, whereas high relative abundances of the second assemblage may infer runoff from livestock feedlots. Blinn and Bailey (2001) also reported that *C. placentula*

var. *euglypta*, *C. meneghiniana*, *N. frustulum*, and *N. palea* are good indicators of nutrient enrichment. Other workers have also found these taxa to be good indicators of nutrient enrichment (Christie and Smol 1993, Hall and Smol 1995, Reavie et al. 1995).

Also, individual diatom taxa showed subtle associations to elevated specific conductance even though levels were relatively low and over a relatively narrow range (16-451 $\mu$ S). For example, the taxa *Amphipleura pellicuda*, *Caloneis silicula*, *Ctenophora pulchella*, *Hantzschia amphioxys*, *Nitzschia frustulum*, *Nitzschia palea*, and *Rhopalodia gibberula* showed a close association with streams such as Clearwater, Kirman, and Nye with higher conductivity levels. Other studies have shown a similar relationships between these diatom species and higher conductance (Fritz 1990, Blinn 1993, Wilson *et al.* 1994, Cumming and Smol 1993, Herbst and Blinn 1998, Blinn and Bailey 2001). These diatom taxa may provide early warning signals of increased salinization in semi-arid regions of the Lahontan Basin due to irrigation activities (Williams 1987 & 1999, Blinn and Bailey 2001).

Table 8 summarizes potential diatom taxa that may have utility in providing early warning signals for changes in the ecological integrity of streams in the Lahontan Basin. The summary table is based on results of community ordinations and principal component analyses for diatom communities in the Lahontan Basin as well as from literature on relationships between diatom distributions and abiotic determinants (Bahls *et al.* 1992, Christie and Smol 1993, van Dam *et al.* 1994, Reavie *et al.* 1995, Hill *et al.* 2000, Blinn and Bailey 2001). The occurrence of increased relative abundances of any one or all of these diatom taxa within a group may indicate changes in stream conditions.

The relatively high levels of filamentous green algae, especially *Stigeoclonium* spp. in Dexter, lower Cottonwood, Clearwater, Burcham, and Bodie creeks, suggest these streams receive higher nutrients from surrounding watersheds. These filamentous green algae have been reported to show close correlations to nutrient enrichments of phosphorus and nitrogen (Palmer 1969, Bahls 1984, Christie and Smol 1993, Wilson *et al.* 1994, Hall and Smol 1995, Reavie *et al.* 1995, Blinn and Bailey 2001). Collections during 2000 support this pattern since Little Truckee, E. Martis, and Hot Springs also had high densities of *Cladophora* and *Stigeoclonium* that coincided with their elevated total Kjeldahl nitrogen and total phosphorus concentrations (Table I). The lack of filamentous green algae in Deadman, Deep, Dog, Dunderberg, McGee, Little Walker, Marble, and Swauger suggest relatively low nutrient levels in these systems (Palmer 1969). All of these streams, except Dog and Marble had specific conductance values <100 µS/cm that also suggests lower nutrients.

The lack of any clear patterns between streams with high and low ecological integrity for both number of taxa and H' diversity suggest that nutrient enrichment and/or salinity levels have not reached high enough concentrations in the sampled streams to influence these indices. A number of studies have shown that diatom species and diversity are diminished under elevated organic enrichment (Nather Khan 1990, Whitton *et al.* 1991) and salinity (Fritz 1990, Blinn 1993, Blinn and Bailey 2001). The lack of change in the region demonstrates the resilience of this group of organisms to subtly (dramatically) shift assemblages under modified (disturbed) conditions, yet maintain their functional role to produce oxygen and food for the system. It further provides support as to why diatom species and assemblages are good indicators of environmental change.

## **ACKNOWLEDGEMENTS**

Thanks are extended to Allen Haden, Northern Arizona University, for assistance with the DECODA ordination technique and comments on an earlier draft. We also thank Thomas Suk (California Regional Water Quality Control Board, Lahontan Region) for his assistance in the coordination of this project. This project was supported in part by funds from the California State Water Resources Control Board (Agreement 704658.01.CT766; SWRCB contract #01-119-160-0) and Northern Arizona University.

## **TABLES & FIGURES**

TABLE 1. Selected abiotic determinants for 65 stream sites in the Lahontan Basin, USA during 1996-1999 and 2001. Stream sites are arranged along an elevational gradient. Collection dates are provided in parentheses. DO = dissolved oxygen, Temp = water temperature, Cond = specific conductance, F + S = % fines and sand, Embed = % embeddedness, TKN = total Kjeldahl nitrogen, TP = total phosphorus, and na = not available.

Stream	Elevation (ft)	Discharge m <sup>3</sup> /s	DO (mg/L)	Temp (°C)	Cond μS/cm	Alkalinity (mg/L)	pH	Canopy (%)	Slope (%)	F + S (%)	Embed (%)	TKN (mg/L)	TP (mg/L)

TABLE 5. Mean relative frequencies (% $\pm$ SE) in sampled habitats, maximum frequency in habitat (Max), percent of stream habitats in which taxa occurred, x % embeddedness (Embed  $\pm$ SE), x % fines + sand (F + S  $\pm$ SE), and x elevation ( $\pm$ SE) for numerically important diatom taxa collected in 65 stream habitats in the Lahontan Basin, USA. These taxa make up over 85% of the diatom assemblages in the stream habitats. Acronyms for species are provided in parentheses.

TABLE 7. Indices for abiotic determinants for numerically important diatom taxa collected in 65 stream habitats in the Lahontan Basin, USA during 1996-1999 and 2001. Diatom taxa are in alphabetical order. Abbreviations for diatom taxa are provided in Table 5. FSI = % fines + sand index; EMBI = % embeddedness index; TPI = water temperature index; TKNI = total Kjeldahl nitrogen index; TPI = total phosphorus index, and CONDI = specific conductance index. TKNI and TPI indices are based on only 27 streams as indicated in Table 1. Values in red represent taxa in the highest 20% of each index, and values in blue represent taxa in the lowest 20%. na = data not available.

TABLE 8. Summary of diatom assemblages associated with several environmental conditions in the Lahontan Basin, USA. The table is based on results of community ordinations and principal component analyses on diatom distributions in the Lahontan Basin (this study) as well as from literature on relationships between diatom distributions and abiotic determinants (Bahls *et al.* 1992, Christie and Smol 1993, van Dam *et al.* 1994, Reavie *et al.* 1995, Hill *et al.* 2000, Blinn and Bailey 2001).

**HIGH ECOLOGICAL INTEGRITY:**

(stable, coarse substrates; high canopy cover; low salinity and nutrient concentrations)

*Achnanthidium minutissima, Diatoma mesodon, Eunotia bilunaris, Fragilaria arcus, Fragilaria tenera, Tabellaria flocculosa, Tetracyclus rupestris*

**HIGH SALINIZATION PROCESSES:**

(clear cutting, heavy irrigation)

*Amphipleura pellicuda, Amphora coffeaeformis, Caloneis silicula, Ctenophora pulchella, Hantzschia amphioxys, Melosira varians, Nitzschia frustulum, Nitzschia palea, Rhopalodia gibberula*

**HIGH NITROGEN CONCENTRATIONS:**

(livestock feed lots, crop fertilization)

*Amphipleura pellucida, Cyclotella meneghiniana, Nitzschia frustulum, Nitzschia palea, Nitzschia sigmoidea*

**HIGH PHOSPHORUS CONCENTRATIONS:**

(crop fertilization)

*Amphora pediculus, Cocconeis placentula var. euglypta, Planothidium lanceolata, Reimeria sinuata, Rhoicosphenia abbreviata*

Figure 1. Cluster analysis of selected diatom species along a substrate embeddedness gradient for streams in the Lahontan Basin, USA. Abbreviations for diatom species are provided in Table 5.

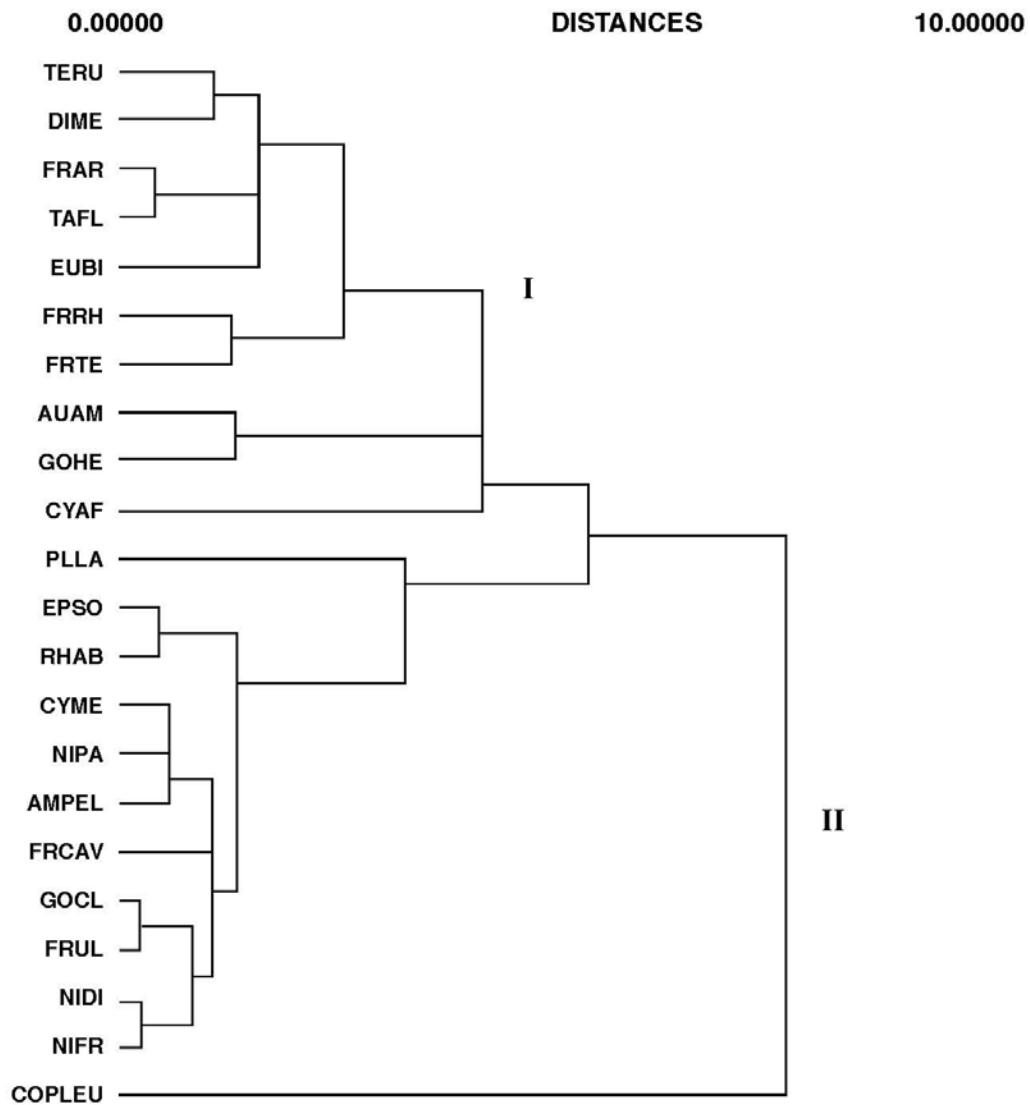

Figure 2. Cluster analysis of selected diatom species along a total Kjeldahl nitrogen gradient for streams in the Lahontan Basin, USA. Abbreviations for diatom species are provided in Table 5.

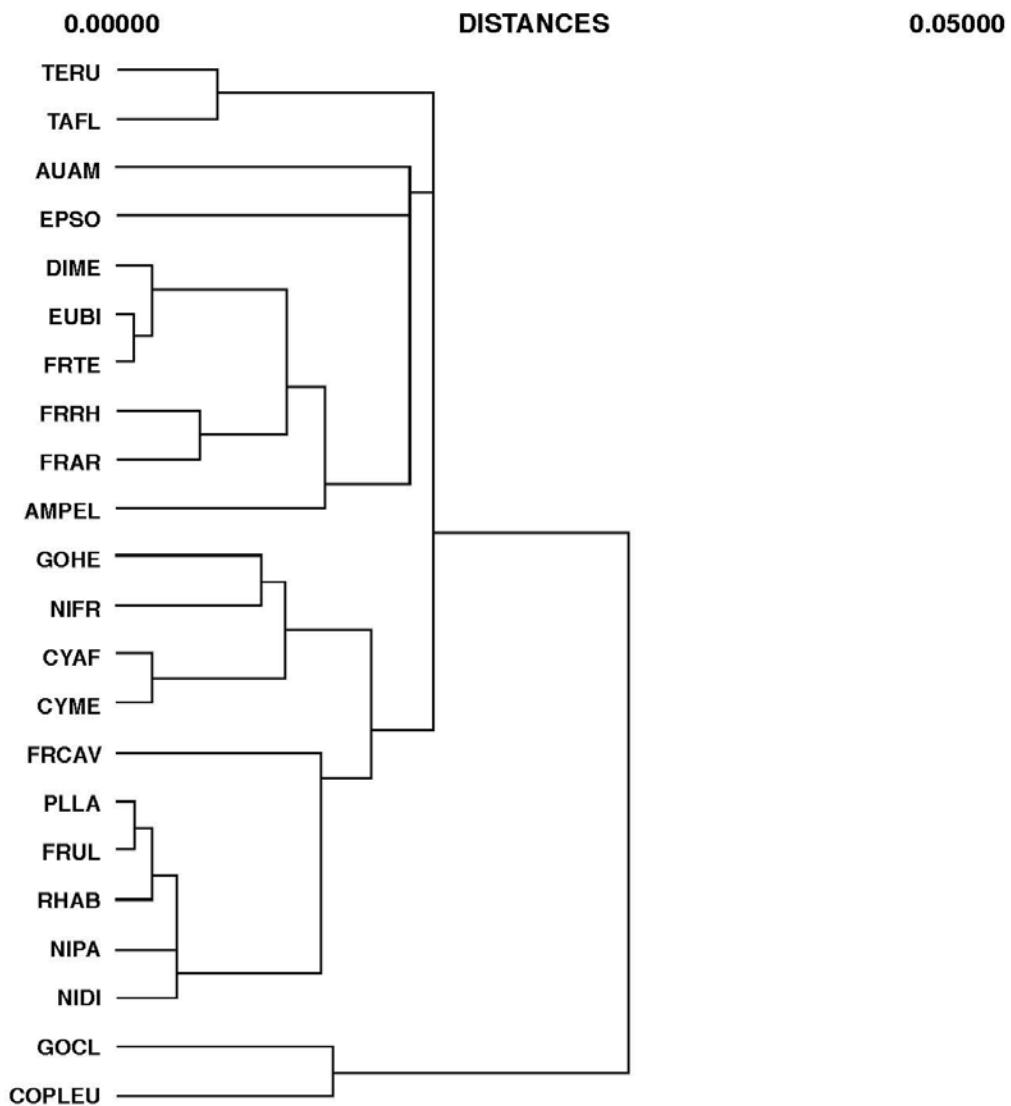

Figure 3. Cluster analysis of selected diatom species along a total phosphorus gradient for streams in the Lahontan Basin, USA. Abbreviations for diatom species are provided in Table 5.

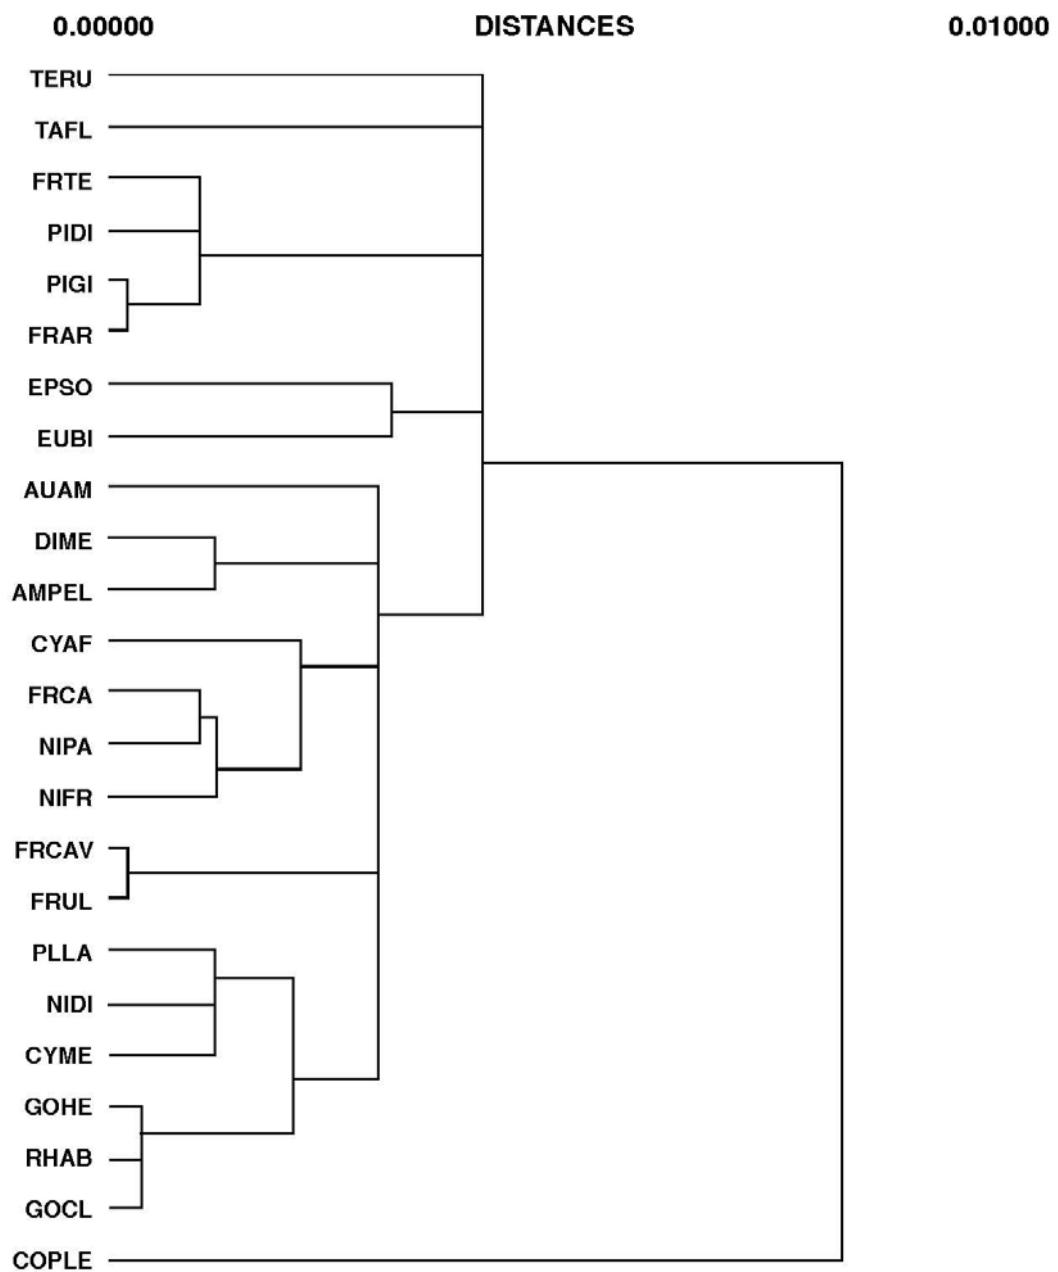

Figure 4. Cluster analysis of selected diatom species along a specific conductance gradient for streams in the Lahontan Basin, USA. Abbreviations for diatom species are provided in Table 5.

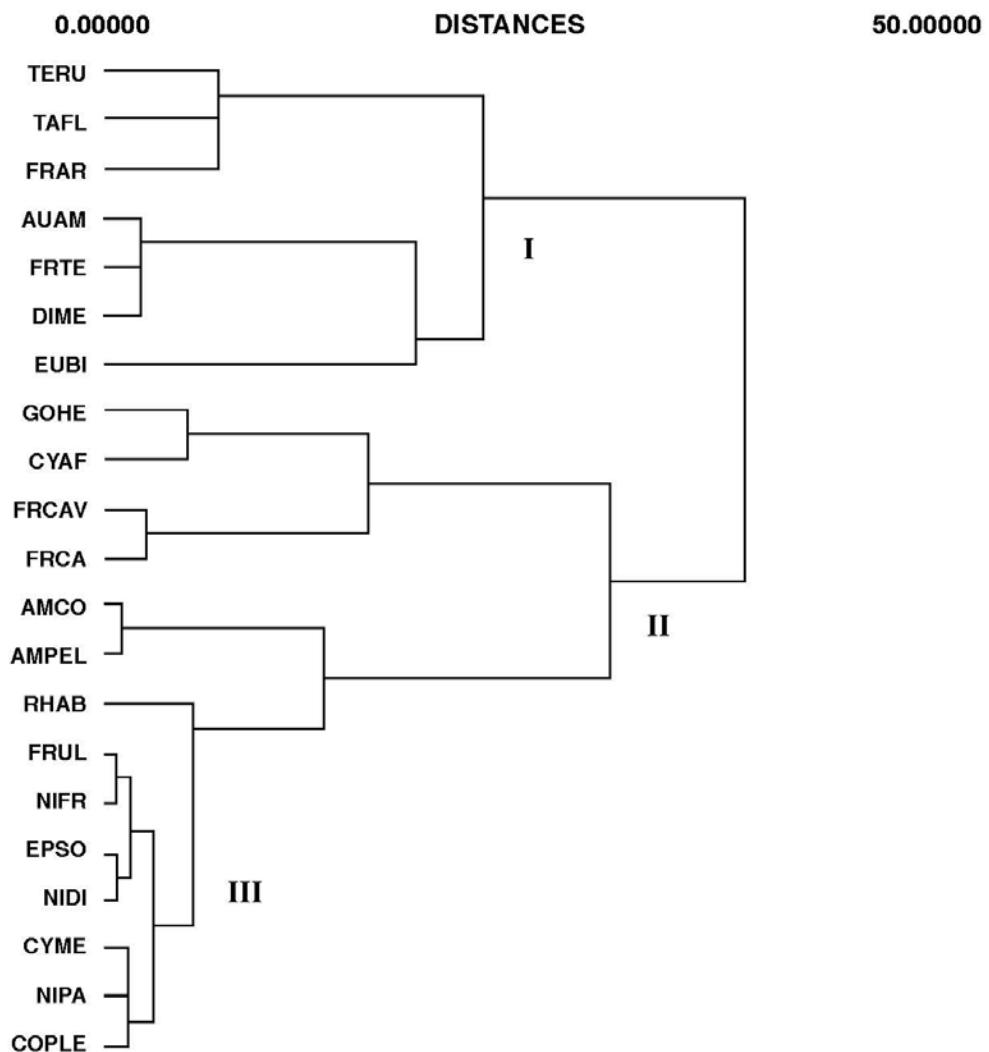

Figure 5. Plot of principal component analysis for selected environmental determinants with high loadings and diatom species in streams in the Lahontan Basin, USA. Abbreviations for diatom species are provided in Table 5.

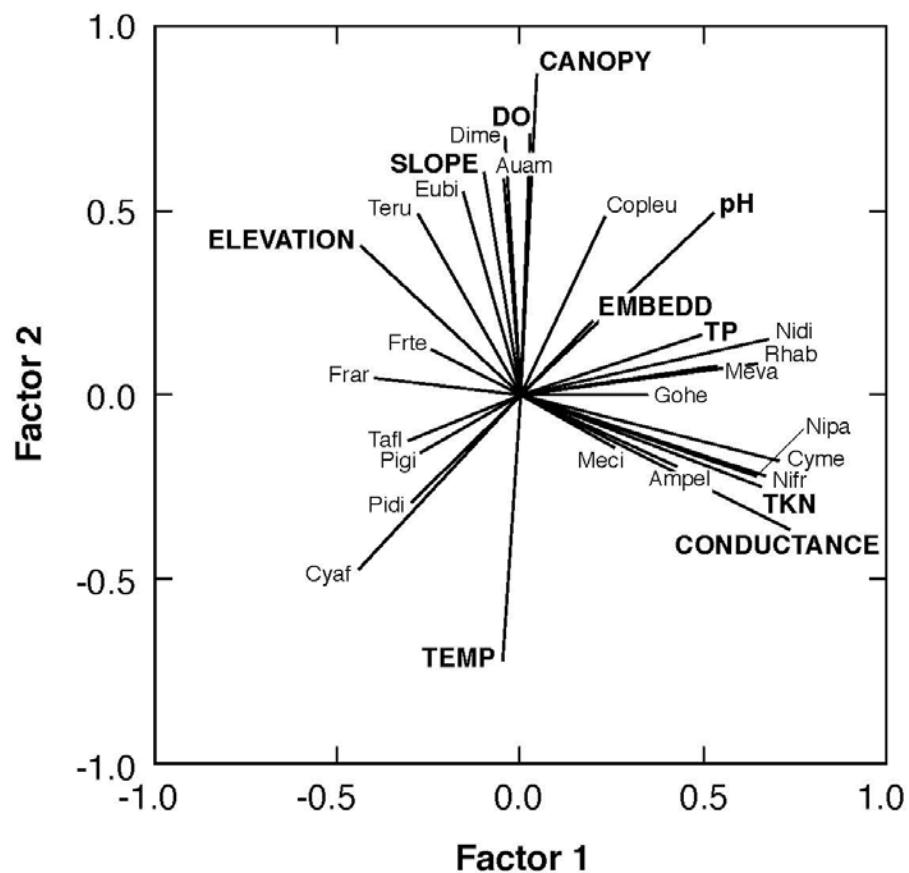

Figure 6. Multi-dimensional global nonmetric ordination of 65 stream habitats from diatom community data collected in the Lahontan Basin, USA during 2001. Ordination has a minimum stress of 0.178. Environmental determinants are shown as vectors of highest correlation to diatom community structure.

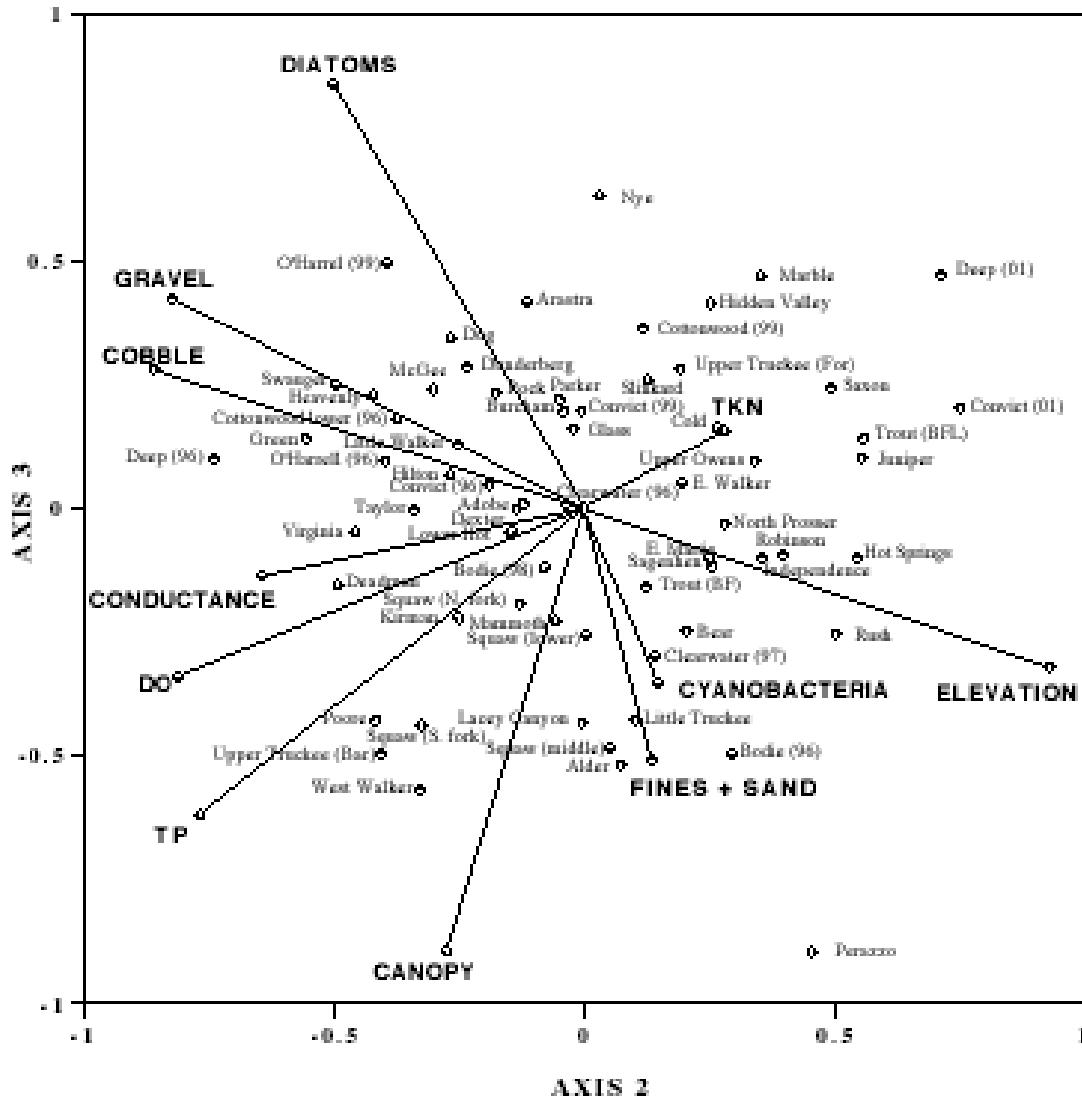

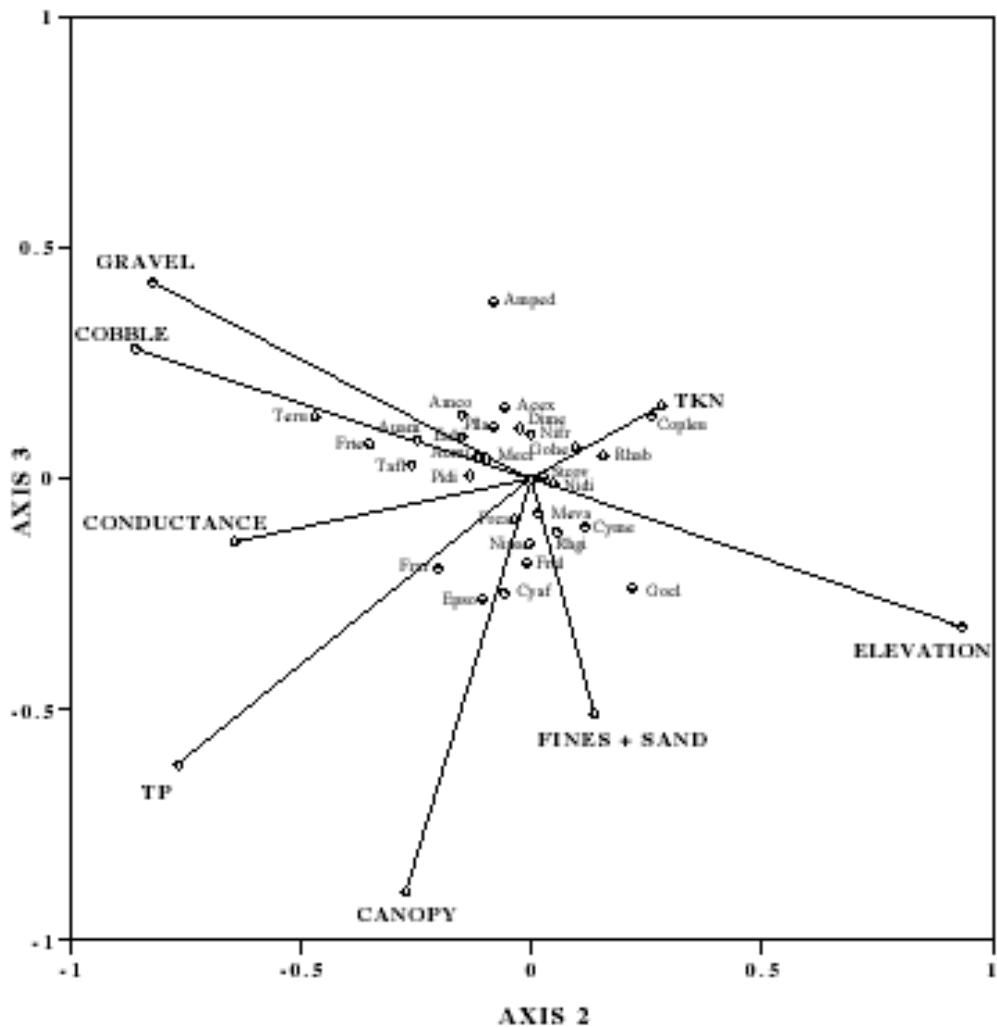

Figure 7. Multi-dimensional global nonmetric ordination of diatom community data collected from 65 stream habitats in the Lahontan Basin, USA during 2001. Ordination has a minimum stress of 0.178. Environmental determinants are shown as vectors of highest correlation to diatom community structure. Abbreviations for diatom species are provided in Table 5.

## **APPENDIXES**

APPENDIX TABLE 1a. Relative % ( $\pm$ SE) frequency of diatoms and collection dates for selected streams in the Lahontan Basin, USA. Species acronyms are in parentheses.
