APPENDIX C WATER QUALITY MONITORING REPORT (2014-15 and 2015-16)

Appendix C

Malibu Creek and Dominguez Channel Watersheds – Earth-Bottom Channels Water Quality Monitoring Report 2014-15 and 2015-16 Maintenance Activities

Pursuant to Condition 49 of the Waste Discharge Requirements Order No. R4-2010-0021 (WDR), the Los Angeles County Flood Control District (LACFCD) conducted water quality monitoring during the 2015 clearance season within the Malibu Creek Watershed at all earth-bottom channels cleared during that season. As set forth in the Study Workplan approved by the Regional Board, the results of the monitoring events are set forth in the table below, which reflects the reaches analyzed; sampling dates; sampling parameters; results from upstream, within the project work area, and downstream monitoring stations; and observations and comments.

In the 2014-15 maintenance clearing, water quality monitoring and sampling were conducted at the following SBC Reaches:

Reach 26 – Project 74

Reach 34 – Medea Creek (PD T1005)

Reach 35 – Medea Creek (Under Route 101)

Reach 37 – Medea Creek (d/s of Agoura Road)

Reach 38 – Lindero Creek

In the 2014-15 maintenance clearing, water quality monitoring and sampling were conducted at the following SBC Reaches:

Reach 26 – Project 74

Reach 38 – Lindero Creek

General Observations and Comments

In evaluating the results of the monitoring events, the LACFCD has the following general observations and comments:

➤ BMPs used included fiber rolls placed perpendicular to and across the creek downstream from active clearing activities. Steps were also taken to minimize contact with water flowing within the reaches and to reduce unnecessary sediment disturbance. BMPs were generally effective in addressing the impacts of maintenance activities in the earth-bottom channel reaches. Additionally, upon noticing elevated turbidity levels, monitoring personnel notified Flood

Maintenance Division (FMD) field personnel who acted to modify BMPs and rectify the identified exceedances. However, BMPs were not always sufficient to achieve attainment of the water quality limits set forth in the WDR.

Sampling was conducted once within seven days prior to work (preconstruction sampling), daily during the first week of maintenance activities, weekly following the first week of maintenance activities (if applicable), and once within seven days after project completion (post-construction sampling).

Specific Reach Observations and Comments

Reach 26 (2014-15): Preconstruction sampling was conducted within seven days prior to the start of maintenance activities. Turbidity ranged from 5.22 NTU upstream of the work site to 8.68 NTU for the preconstruction upstream and midpoint samples, respectively. A downstream sample was not collected during preconstruction sampling and four of the five construction days as no water was not present downstream of the work site. No downstream turbidity or TSS exceedances occurred during the five days of maintenance activities. After construction, the work area was returned to its premaintenance condition and BMPs were removed. Post-construction sampling results were generally consistent with preconstruction baseline sampling levels; midpoint turbidity levels were higher than upstream turbidity levels and TSS thresholds were exceeded at both the upstream and midpoint sampling locations. No exceedances were recorded at the downstream location; therefore, water quality was not being adversely impacted downstream, and no actions were taken.

Reach 26 (2015-16): Pre-construction downstream turbidity (27.7 NTU) exceeded the upstream turbidity threshold (3.64 NTU) prior to any vegetation clearing activities taking place. Due to this initial exceedance, it was advised to the FMD staff to implement some construction BMPs to reduce turbidity measurements throughout the reach. A construction boom was placed at the upstream location, another boom at the midpoint location, and two sets of sand bags and a fiber roll at the downstream location. With all these BMPs in place, there was still a turbidity exceedance on September 30, 2015 at the downstream sampling location (48.8 NTU) compared to the upstream turbidity (21.6 NTU). On October 1, 2015, there was another turbidity exceedance of 42.6 NTU at the downstream compared to 13.9 NTU at the upstream. On October 2, 2015, a final turbidity exceedance of 48.7 NTU at the downstream compared to 13.3 NTU at the upstream occurred. Two additional fiber rolls were implemented at the downstream sampling location.

After all BMPs were in place, there were no additional downstream turbidity exceedances. It is likely that the high turbidity measurements are due to natural conditions of the creek. As shown by the pre-construction baseline result, natural turbidity levels at the downstream were higher than turbidity levels at the upstream. Parts of the reach were polluted with garbage and debris, with lots of floating plants, leaves, and film. The water was very murky and mostly stagnant throughout. The turbidity measurements throughout the reach were irregularly high on various sampling days, so it was difficult to attribute the high turbidity to one cause. It is likely, however, that the high turbidity measurements were not attributable to the construction activities taking place in the reach.

The downstream TSS value of 29 mg/L taken during the pre-construction sampling event was used as the baseline threshold value for TSS threshold exceedances. There occurred one TSS exceedance at the downstream location on October 21, 2015 where the downstream TSS was 150 mg/L. This TSS measurement was taken after two fiber rolls and two sets of sand bags had been implemented a couple weeks before due to turbidity exceedances. The multiple construction BMPs in place at the downstream significantly hindered the flow of water, causing most of the water to puddle up before the fiber rolls and collect lots of sediment, and only allowing a small flow of water to trickle through into a thin stream. Water after the downstream BMPs had high amounts of floating film and algae in the thin stream. Since the sampling stream was so small, most of this film and algae was inadvertently collected in the sample and is likely the cause of the TSS exceedance as no construction activities were taking place at the time of sampling.

Reach 34: Downstream TSS levels exceeded maximum receiving level thresholds (> 10 mg/L) during preconstruction, both days of construction and post-construction sampling. On all of these days, downstream TSS levels were higher than midpoint and upstream levels, suggesting the source of the exceedance was attributed to maintenance activities occurring at the construction site (midpoint sample location). However, during pre-construction, downstream TSS levels were 770 mg/L, which is 77 times higher than the acceptable maximum limit and indicates a baseline TSS level exceedance. Further, the TSS level during post-construction was 730 mg/L, which is 40 mg/L less than the downstream measurement recorded during pre-construction. This suggests a return back to baseline TSS exceedance conditions. During the November 10, 2014 follow-up site visit, downstream TSS levels had dropped to 13 mg/L, which although still exceeds maximum receiving levels, is 50 times less than preconstruction TSS levels. TSS exceedances were recorded upon receipt of the analytical results from the lab and reported to FMD staff in the sampling results memo prepared for this reach.

Midpoint and downstream turbidity exceeded upstream turbidity during preconstruction sampling and was recorded as a baseline condition. During the first day of construction, a turbidity exceedance occurred and was reported to FMD field personnel. It was conveyed that the exceedance was consistent with the preconstruction exceedance for the downstream location; therefore, it would be safe to assume that this is a natural variability that occurs in that reach of the creek. The downstream turbidity level (7.45 NTU) was also lower than the midpoint (9.05 NTU), indicating the fiber roll downstream was effectively reducing turbidity. This downstream turbidity level (7.45 NTU) was also lower than the downstream turbidity level measured during pre-construction activities (9.22 NTU). No turbidity exceedance occurred on the second day of construction. Turbidity thresholds were also exceeded during post-construction sampling; both midpoint and downstream activities (25.2 NTU; 21.9 NTU) were higher than upstream turbidity levels (6.01 NTU) and preconstruction levels. On the November 10, 2014 post-construction follow-up site visit, no downstream turbidity exceedances occurred.

Reach 35: Both days of construction resulted in downstream TSS exceedances; upstream TSS levels were below threshold levels. However, these TSS measurements were 14 mg/L and 19 mg/L, which are relatively close in comparison with the maximum allowable receiving levels (10 mg/L or greater is considered an exceedance). Further, upstream TSS levels during preconstruction measurements showed a level of 14 mg/L at the upstream sampling point, suggesting natural TSS level variation in the stream. TSS exceedances were reported to FMD staff in writing upon receipt of the analytical results from the lab. No turbidity threshold exceedances occurred at Reach 35.

Reach 37: During preconstruction sampling, although baseline TSS levels exceeded the maximum receiving level of 10 mg/L or higher for the upstream and midpoint locations, the baseline downstream TSS levels did not exceed the maximum receiving level. During the first two days of construction, downstream TSS levels were 45 mg/L and 18 mg/L, respectively. Comparing this to midpoint levels those same days (660 mg/L and 110 mg/L, respectively) indicates that BMPs were effectively reducing TSS levels downstream, however, these downstream TSS levels still exceeded the upstream reference sample which was <10 mg/L. During post-construction, the downstream exceedance was 10 mg/L, which is barely above the TSS threshold. TSS exceedances were reported to FMD staff in writing upon receipt of the analytical results from the lab. Turbidity thresholds were exceeded during both construction days and postconstruction. It is important to note that during the first day of construction, the midpoint turbidity level was measured at 74.4 NTU and the downstream turbidity level was measured at 19.5 NTU, indicating that downstream BMPs were effectively reducing turbidity by approximately 74 percent. The turbidity exceedance was reported to FMD field staff. On the second day of construction, midpoint and downstream turbidity levels

improved significantly, and downstream turbidity exceeded upstream levels but only by an increase of less than 2 NTU, which is considered relatively minor. The case is the same for post-construction (0.94 NTU compared to 2.47 NTU).

Reach 38 (2014-15): No downstream TSS exceedances occurred during construction; therefore, BMPs were effectively reducing TSS levels downstream. A turbidity threshold exceedance (20 percent increase of upstream measurement) occurred downstream during construction (2.76 NTU). However, the upstream turbidity measurement was very low (1.34 NTU); therefore, this exceedance was of a relatively low magnitude and not likely detrimental to channel health. Measures to reduce turbidity in response to the exceedance included installation of two fiber rolls placed perpendicular to and across the stream. Downstream turbidity levels during post-construction sampling were comparable to upstream and preconstruction levels.

Reach 38 (2015-16): Baseline TSS measurements were taken within seven days before construction began in the reach. All baseline TSS values were below 10 mg/L throughout the stream. No downstream TSS exceedances occurred during or after construction; therefore, construction fiber rolls were effectively reducing TSS levels before reaching the downstream. Turbidity measurements remained relatively low at the downstream sampling location. A turbidity threshold exceedance occurred on the preconstruction sampling event where the downstream turbidity (2.26 NTU) was greater than a 20% increase of the upstream turbidity (1.46 NTU). This turbidity exceedance only minimally exceeded the allowable threshold and was likely due to natural variability since construction had not begun at the time of sampling. The exceedance was noted and was used as a baseline reference for future turbidity measurements. In addition, the FMD staff was notified of the turbidity exceedance and two fiber rolls were implemented in the stream to reduce any flowing solids. As a result, no further turbidity exceedances occurred at the downstream during any of the other sampling events.

This data indicates that downstream BMPs were effectively reducing turbidity and TSS. No action was necessary.
