The description of potential pollution sources culminates in a narrative assessment of the risk potential that sources of pollution pose to stormwater quality. This assessment should clearly point to activities, materials, and physical features of the facility that have a reasonable potential to contribute significant amounts of pollutants to stormwater. Any such activities, materials, or features must be addressed by the measures and controls subsequently described in the plan. In conducting the assessment, the facility operator must consider loading and unloading operations, outdoor storage activities, outdoor manufacturing or processing activities, significant dust or particulate generating processes, and onsite waste disposal practices. The assessment must list any significant pollution sources at the site and identify the pollutant parameter or parameters (i.e., biochemical oxygen demand, suspended solids, etc.) associated with each source.

Measures and Controls

Following completion of the source identification and assessment phase, the permittee must evaluate, select, and describe the pollution prevention measures, BMPs, and other controls that the facility will implement. BMPs include processes, procedures, schedules of activities, prohibitions on practices, and other management practices that prevent or reduce the discharge of pollutants in stormwater runoff.

The plan requirements emphasize the implementation of pollution prevention measures that reduce possible pollutant discharges at the source. Source reduction measures include, among others, preventive maintenance, chemical substitution, spill prevention, good housekeeping, training, proper materials management, material segregation or covering, water diversion, and dust control. The remaining classes of BMPs, which involve recycling or treatment of stormwater, allow the reuse of stormwater or attempt to lower pollutant concentrations before discharge.

The pollution prevention plan must include a schedule specifying the time or times during which each control or practice will be implemented. In addition, the plan should discuss ways in which the controls and practices relate to one another and, when taken as a whole, produce an integrated and consistent approach for preventing or controlling potential stormwater contamination problems. The portion of tne plan that describes the measures and controls must address the following minimum components:

- *Good housekeeping:* Good housekeeping involves using common sense to identify ways to maintain a clean and orderly facility and keep contaminants out of separate storm sewers. It includes establishing protocols to reduce the possibility of mishandling chemicals or equipment, and training employees in good housekeeping techniques.
- *Preventive maintenance:* Permittees must develop a preventive maintenance program that involves regular inspection and maintenance of stormwater management devices and other equipment and systems. The program description should identify the devices, equipment, and systems that will be inspected; provide a schedule for inspections and tests; and address appropriate adjustment, cleaning, repair, or replacement of devices, equipment, and systems. For stormwater management devices such as catch basins and oil/water separators, the preventive maintenance program should provide for periodic removal of debris to ensure that the devices are operating efficiently.
- *Spill prevention and response procedures:* Based on an assessment of possible spill scenarios, permittees must specify appropriate material handling procedures, storage requirements, containment or diversion equipment, and spill cleanup procedures that will minimize the potential for spills and in the event of a spill enable proper and timely response. Areas and activities that typically pose a high risk for spills include loading and unloading areas, storage areas, process activities, and waste disposal activities. These activities and areas, and their accompanying drainage points, must be described in the plan. For a spill prevention and response program to be effective, employees should clearly understand the proper procedures and requirements and have the equipment necessary to respond to spills.
- *Inspections:* Qualified facility personnel must be identified to inspect designated equipment and areas of the facility at appropriate intervals specified in the plan. A set of tracking or followup procedures must be used to ensure that appropriate actions are taken in response to the inspections.
- *Employee training:* The pollution prevention plan must describe a program for informing personnel at all levels of responsibility of the components and goals of the stormwater pollution prevention plan. Where appropriate, contractor personnel also must be trained in relevant aspects of stormwater pollution prevention.
- *Recordkeeping and internal reporting procedures:* The pollution prevention plan must describe procedures for developing and retaining records on the status and effectiveness of plan implementation. At a minimum, records must address spills, monitoring, and inspection and maintenance activities. The plan also must describe a system that enables timely reporting of stormwater management-related information to appropriate plant personnel.
- *Sediment and erosion control:* The pollution prevention plan must identify areas that, due to topography, activities, soils, cover materials, or other factors, have a high potential for significant soil erosion. The plan must identify measures that will be implemented to limit erosion in these areas.
- *Management of runoff:* The plan must contain a narrative evaluation of the appropriateness of traditional stormwater management practices (i.e., practices other than those that control pollutant sources) that divert, infiltrate, reuse, or otherwise manage stormwater runoff to reduce the discharge of pollutants. Appropriate measures may include, among others, vegetative swales, collection and reuse of stormwater, inlet controls, snow management, infiltration devices, and wet detention/retention basins.

Based on the results of the evaluation, the plan must identify practices that the permittee determines to be reasonable and appropriate for the facility. The plan also should describe the particular pollutant source area or activity to be controlled by each stormwater management practice. Reasonable and appropriate practices must be implemented and maintained according to the provisions prescribed in the plan.

In selecting stormwater management measures, it is important to consider the potential effects of each method on other water resources, such as ground water. Although stormwater pollution prevention plans primarily focus on stormwater management, facilities must also consider potential ground-water pollution problems and take appropriate steps to avoid adversely affecting ground-water quality. For example, if the water table is unusually high in an area, an infiltration pond may contaminate a ground-water source unless special preventive measures are taken. Under EPA's July 1991 Ground Water Protection Strategy, states are encouraged to develop comprehensive state ground-water protection programs (CSGWPP). Efforts to control stormwater should be compatible with state ground-water objectives as reflected in CSGWPPs.

Comprehensive Site Compliance Evaluation

The stormwater pollution prevention plan must describe the scope and content of comprehensive site inspections that qualified personnel will conduct to 1) confirm the accuracy of the description of potential pollution sources contained in the plan, 2) determine the effectiveness of the plan, and 3) assess compliance with the terms and conditions of the permit. The plan must indicate the frequency of such evaluations, which in certain cases must be at least once a year.

Material handling and storage areas and other potential sources of pollution must be visually inspected for evidence of actual or potential pollutant discharges to the drainage system. Inspectors also must observe erosion controls and structural stormwater management devices to ensure that each is operating correctly. Equipment needed to implement the pollution prevention plan, such as that used during spill response activities, must be inspected to confirm that it is in proper working order. The results of each site inspection must be documented in a report signed by an authorized company official.

Based on the results of each inspection, the description of potential pollution sources and the measures and controls in the plan must be revised as appropriate within 2 weeks after each inspection.

Special Requirements for Selected Facilities

EPA's general permits also establish special requirements for selected classes of facilities. These include:

- *Sampling requirements:* Targeted classes of facilities are required to monitor their stormwater discharges for specified parameters. Facilities that are a member of a targeted class but that can certify that they do not have materials or equipment exposed to precipitation are not required to monitor. This is intended to provide facilities with an incentive to eliminate exposure to precipitation.
- *EPCRA facilities:* Certain facilities that are subject to reporting requirements under Section 313 of the Emergency Planning and Community Right-to-Know Act (EPCRA) because they manufacture or use large amounts of toxic chemicals are subject to special requirements under the NPDES general permits. These special requirements include provisions that are similar to spill prevention, countermeasure, and control (SPCC) plan requirements, and include provisions for secondary containment or equivalent controls for liquid storage areas. In addition, a professional engineer (PE) must inspect the site, review the plan, and certify that the stormwater pollution prevention plan has been prepared in accordance with good engineering practices.
- *Salt piles:* Salt piles must be enclosed or covered to prevent exposure to precipitation.
- *Coal pile runoff:* The permit establishes numeric effluent limitations for coal pile runoff.

Municipal Role in Implementation

The NPDES stormwater program establishes a permit approach that envisions complementary, cooperative efforts by the permit-issuing agency and municipal operators of large and medium municipal separate storm sewer systems to develop programs that result in controls on pollutants in stormwater discharges associated with industrial activity that discharge through municipal systems.

Under the complementary permit approach, stormwater discharges associated with industrial activity that discharge through large and medium municipal separate storm sewer systems are required to obtain permit coverage. Permits for these discharges will establish requirements (such as pollution prevention requirements or monitoring) for industrial operators. Any records, reports, or information obtained by the NPDES permit-issuing authority as part of the permit implementation process, including site-specific stormwater pollution prevention programs that are developed pursuant to the draft general permit, are available to municipalities. This will assist municipalities in reviewing the adequacy of such requirements and developing priorities among industrial stormwater sources. In addition, these permits provide a basis for enforcement actions directly against the owner or operator of stormwater discharges associated with industrial activity.

A second permit, issued to the operator of the large or medium municipal separate storm sewer, establishes the responsibilities of the municipal operators in controlling pollutants from stormwater associated with industrial activity that discharges through their systems. Municipal programs to reduce pollutants in industrial site runoff specifically will address municipal responsibilities in controlling pollutants from industrial facilities. In addition, programs to identify and control nonstormwater discharges to municipal separate storm sewer systems will in many cases focus on industrial areas because these areas often have a significant potential for illicit connections, spills, and improper dumping.

Municipal operators of these systems can assist NPDES permit issuing authorities:

- By identifying priority stormwater discharges associated with industrial activity to their systems.
- In inspecting facilities and reviewing and evaluating stormwater pollution prevention plans that industrial facilities are required to develop under the draft general permit.
- In compliance efforts regarding stormwater discharges associated with industrial activity to their municipal systems.

A pilot program conducted by municipalities in the Santa Clara Valley illustrates how a municipality can work with an NPDES authority to control pollutants in stormwater discharges associated with industrial activities. (A more complete description of the pilot program and its findings is provided in the Santa Clara Valley Nonpoint Source Pollution Control Program [3]). One of the major goals of the program was to reduce discharges to storm drains of dry- and wet-weather heavy metals that result from activities such as processing, storage, and maintenance activities conducted at industrial sites. Components of the program included the following:

- Municipalities developed industrial inspection and illegal dumping/illicit connection programs to ensure that activities focus on priority industries.
- Monitoring requirements were established in the California NPDES general permit for industries. Municipalities evaluated monitoring data collected by priority industries.
- The California NPDES general permit allowed for exemption for industries from monitoring where the municipality provides certification that the industry pollution prevention plan is adequate.
- Municipalities developed industry specific guidance.[2]
- Municipalities implemented a "Clean Bay Business" award program.
- Market-based incentives were considered, such as trading reductions from car pooling and telecommunication programs for pretreatment requirements.

Key findings of the pilot programs identified the following components needed for a successful program:

- Hands-on field training conducted by an experienced industrial inspector.
- Classroom training on industrial stormwater requirements and on methods of communicating with facility managers.
- Classroom training on other related industrial regulatory programs (e.g., HAZMAT, pretreatment).
- A reference manual on the regulations and local legal authority.
- Adequate legal authority to allow site access and take progressive enforcement actions.
- Prioritizing facilities based on existing information before conducting inspections.
- Advance communications, in the form of a letter, to industries before conducting the inspections.
- A plan for followup actions, including enforcement, where necessary.

The Role of Education and Training in the Development of the Delaware Sediment and Stormwater Management Program

Frank M. Piorko and H. Earl Shaver
Delaware Department of Natural Resources and Environmental Control, Dover, Delaware

On May 31, 1990, the General Assembly of the State of Delaware enacted new legislation on stormwater management and placed it within the revised framework of the state's sediment control law to emphasize the integral relationship between the two programs. Governor Castle signed the legislation into law at a public ceremony on June 15, 1990. The effective date of the regulations was January 23, 1991. Program implementation was initiated on July 1, 1991.

The role of education and training in the development and implementation of Delaware's sediment and stormwater program was recognized at the legislative onset. The educational effort continued through the evolution, development, and promulgation of the regulations and remains an essential component of program strategy. The sediment and stormwater regulations are specific as to the training requirements and opportunities for education that are to be provided for contractors, construction review/inspection personnel, and plan design professionals.

This paper discusses the education and training accomplishments to date, their value to successful program inauguration, and specific training objectives being developed to meet the requirements of the new law and regulations in Delaware.

Background

The State of Delaware has had an erosion and sediment control program since 1978. That program was only marginally successful due to budget and personnel limitations. Environmentally oriented initiatives in other states and within the federal government have since provided an impetus for the Department of Natural Resources and Environmental Control (DNREC) to attempt program improvements with respect to sediment control and stormwater management.

In 1989, DNREC representatives conducted onsite reviews of the existing sediment control program to document program effectiveness. It was readily apparent that too few resources were devoted to a program that lacked legislative and regulatory authority. The site problems were recorded through slide documentation so that a public education program could be developed that clearly showed the need for program improvements.

At the same time, DNREC, in association with local conservation districts, was considering the need for a statewide stormwater management program that considered water quantity and water quality requirements. Fortunately (or unfortunately, depending on the perspective), during the summer of 1989, Delaware had several severe flooding events that reinforced the concept that the state needed a stormwater management program that would prevent existing problems from getting worse.

Delaware does not have a strong environmental lobby group to advocate the passage of new environmental programs, so DNREC has developed a consensus-style approach to get legislation and subsequent regulations accepted by the legislative bodies and the regulated community.

Legislative Process

As the legislation was developed, DNREC sponsored two workshops at which the concept behind the proposed legislation was discussed in a public forum accompanied by slide presentations. The slide presentation focused on problem identification, the proposed state program to address the problems, and the degree to which, in the opinion of DNREC, the sediment and stormwater program was going to evolve. Individual meetings were held with contractors' associations, engineering consultants, land developers, and the general public.

In addition to those workshops and meetings, presentations were made to legislative committees in an informal setting so that individual committee members would have a basic understanding of the need for legislation.

The proposed legislation passed through a state senate committee and the full senate in only 2 days, with not one negative vote. The passage of the legislation through two committees in the state house of representatives and the full house took approximately 1½ months and again received no negative votes. The educational process prior to submission of the legislation and during the legislative process was so successful that not one affected group submitted comments that were in opposition to the legislation. The legislation passed through three committees and two houses unanimously. The legislation was signed into law by Governor Castle in a public ceremony on June 15, 1990.

Regulatory Process

The legislation has several components that specifically address education and training, but one component critical to the process of regulation adoption was the requirement in the law that the regulations were to be developed with the assistance of a regulatory advisory committee. Recognizing the need for program consensus, DNREC placed the regulatory advisory committee requirement within the legislation so that the affected entities would participate in the regulatory process.

The regulatory advisory committee was composed of representatives of 20 organizations representing such groups as contractors, developers, consulting engineers, utility companies, local governments, and conservation districts. DNREC prepared drafts of the regulations prior to meetings. Each section, subsection, paragraph, sentence, and word that was proposed for the regulations was subject to the scrutiny of the regulatory review committee. Each member of the committee did not have to approve all aspects of the regulations, but rather the committee needed to substantially concur. Eight full committee meetings were held, and through the meeting process committee members could understand the rationale behind the various regulatory requirements. As a result, the committee members substantially concurred on all aspects of the regulations. In fact, committee members tended to become advocates of the regulations when they were published for public input.

In addition to the regulatory review committee process, meetings were also held with any interested individual or entity. Once the regulations were in a rough state of completion, three public workshops were held around the state to solicit input from a broader range of interests than just those represented by the regulatory review committee. The input received during this public review process was limited, but the informal public process prepared people for what was intended in the regulations so that any significant opposition to any of the requirements could be addressed before the formal regulation adoption process.

On the basis of the input received from the workshops, DNREC initiated formal regulation adoption procedures with no major changes to the body of the regulations. Announcements were placed in newspapers regarding DNREC's intentions, and a formal public hearing was held on January 16, 1991. Due to the consensus-building process, in which the regulated community participated in developing the regulations, not one adverse comment was received during the public hearing process. The entire public hearing took less than 15 minutes, as there were no questions or comments due to public awareness of the regulations' contents.

The entire process of legislative and regulatory development and approval clearly demonstrates that a consensus-building approach to environmental requirements may be an effective means of obtaining the programmatic infrastructure needed to implement an effective program. In large part due to the strong involvement of the regulated community, there is a significant effort in the law and regulations regarding education and training of contractors, inspectors, consultants, and the general public. It is the position of the authors that environmental programs can only be effective if the regulated community is involved in program development and evolution, recognizes the program need, and understands and accepts their obligations under the regulatory requirements. The individual educational and training obligations under the law and regulations are discussed as they affect the overall sediment and stormwater program.

Delaware Sediment and Stormwater Contractor Certification Program

During the development of the Delaware Sediment and Stormwater Regulations, a provision was made to provide for mandatory training and certification of individuals performing sediment and stormwater related construction. Section 13 of the regulations states that "After July 1, 1991, any applicant seeking sediment and stormwater plan approval shall certify to the appropriate plan approval agency that all responsible personnel involved in the construction project will have a certificate of attendance at a Departmental sponsored or approved training course for the control of sediment and stormwater, before initiation of land-disturbing activity."

"Responsible personnel" means any foreman or superintendent who is in charge of onsite clearing and land-disturbing activities for sediment and stormwater control associated with a construction project.

"Land-disturbing activity" means a land change or construction activity for residential, commercial, silvicultural, industrial, and institutional land uses that may result in soil erosion from water or wind or movement of sediments or pollutants into state waters or onto lands in the state, or which may result in accelerated stormwater runoff including, but not limited to, clearing, grading, excavating, transporting, and filling of land.

Contractor Certification Program Development

The development of the Contractor Certification Program was part of a general sediment and stormwater educational package funded by a Section 205 (G) grant under the Clean Water Act from the U.S. Environmental Protection Agency. Other tasks included a review of similar programs throughout the mid-Atlantic region, contracting for aerial photography of sites under construction, preparation of a portable soils exhibit, and identifying future training and educational needs. The grant tasks were carried out jointly through a memorandum of understanding between DNREC's Division of Water Resources and the New Castle Conservation District. A steering committee was formed in April 1990 and met seven times over the course of the following 9 months. The purpose of the committee was to provide input for the development and implementation of the grant tasks.

It was determined that the certification program was to use a slide presentation format since excellent documentation was already available and additional field slides were easily obtained. In addition to the field slides of sediment and stormwater construction practices, text and technical slides needed preparation. A local company was contracted to produce this material.

The certification program was developed with a 3½- to 4-hour time frame in mind. This would allow for morning or afternoon sessions, even occasional evenings, as necessary. Maryland has enjoyed success for many years in their sediment control training program using a similar format and time frame.

A 55-page narrative describing the slide presentation was developed and made available to the audience upon request. This was done to encourage attention to the slide presentation rather than preoccupation with taking notes. Finally, it was decided that participants should receive a durable plastic laminate card with the state logo and the individual's name and certification number imprinted on it. This would give the participants a tangible item to associate with the completion of the program.

Contractor Certification Program Implementation

By the end of January 1991, the program was ready to be presented. Certain restrictions were placed upon class size in order to communicate most effectively. Optimal class size was 30 to 40 members. Limiting the class size meant that the program would have to be presented many times; therefore, by July 1, 1991, not all of the contractors needing to complete the certification program would have the opportunity to do so. The Sediment and Stormwater Regulations provide for interim certification if individuals notify DNREC of their intent to register for the next available course.

The certification program was designed for presentation in two ways. First, the conservation districts, counties, and other agencies given the responsibility of certain program elements would set up the programs in their own jurisdictions, giving them a chance to meet with the regulated community and explain local program requirements. Second, DNREC would present the program to any regulated company, business or organization if they could provide a suitable location and a minimum of 15 individuals to be trained. DNREC also provided training for DNREC staff and several hundred Delaware Department of Transportation inspectors, technical staff, and engineers.

Throughout the first 6 months of presentations, we were surprised and pleased not only with the response from the contractors but also from the engineers, consultants, and developers who wanted to attend the certification program. All told, from February 1991 until July 1991, DNREC presented the program on 37 occasions, certifying over 1,100 individuals from 300 companies and organizations.

As stated earlier, this was possible only with the assistance from the three state conservation districts, county governments, the Department of Transportation, and organizations such as the Associated Builders and Contractors and the Delaware Contractors Association. As of January 1, 1993, almost 2,000 individuals have completed this training.

Initially, a program quiz was developed not so much to grade the participants but to obtain feedback on the retention of the material being provided. A program evaluation was later substituted for the quiz so that we could determine if any changes or improvements should be made to the training program. A representative sample of 100 evaluations was compiled, the results of which appear in Figure 1. Most notable is that 96 percent of respondents would recommend this training (Question 7), and 86 percent wished to continue in this training (Question 8).

By continuing the Contractor Certification Program, not only are the requirements of the Delaware Sediment and Stormwater Regulations being met, but the knowledge gained by the participants in this program is being transferred to the field through proper construction practices.

Delaware Certified Construction Reviewer Course

The Delaware Sediment and Stormwater Regulations also provide for special site inspection or review requirements under certain site conditions. Section 12 of the

VOL 12

9044

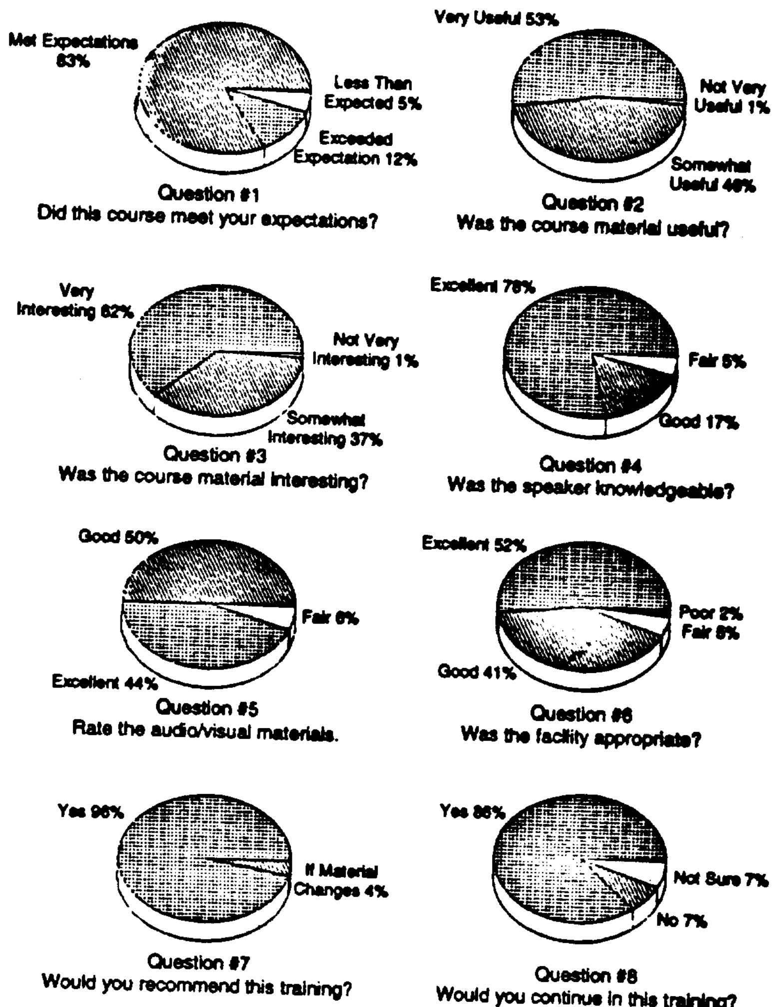

Figure 1. Sediment and stormwater contractor certification program course evaluation.

regulations identifies these site conditions that allow DNREC or the appropriate plan approval agency to require that a certified construction reviewer be present on site. Examples of site conditions that would warrant this requirement would be a site in excess of 50 acres of disturbed area or any site experiencing significant sediment and stormwater problems. The owner or developer of the site in these cases would be responsible for providing a certified construction reviewer for any or all parts of the construction phase as deemed necessary by the plan approval agency. The main responsibility of these individuals is to ensure the adequacy of construction pursuant to the approved sediment and stormwater management plan.

As with the Contractor Certification Program, DNREC has the responsibility to provide training to certify these construction reviewers. A formal Sediment and Stormwater Management Certified Construction Reviewer Course was developed in cooperation with Delaware Technical and Community College. Course material was developed to instruct participants in basic hydrology and hydraulics, soils, vegetative establishment, construction practices, plan preparation and implementation, inspection, enforcement, and maintenance. To instruct this course, over 20 professionals in the area of sediment and stormwater management were recruited, representing government agencies, private industry, and the consulting and engineering community.

The course format was developed to be presented in eight 3½-hour weekly sessions. An examination was developed and arrangements made with Delaware Technical and Community College for Continuing Education Credits to be issued.

We anticipated a lot of interest in this course offering, so registration was limited to one individual per company or organization. In addition to the private community, an attempt was made to include at least one individual that works for each agency responsible for delegation of sediment and stormwater program elements. In all, 85 seats were quickly filled for this course. The second time this course was offered, the class sessions were reduced to four all-day sessions. This seemed to suit the class participants' schedule better.

One important measure of success is the evaluation question that asked class participants to indicate whether the course did not meet, met, or exceeded expectations. The breakdown is as follows:

- 41 responses, or 74 percent of the class, stated that the course met their expectations.
- 12 responses, or 22 percent of the class, stated that the course exceeded their expectations.
- 2 responses, or 3.5 percent of the class, stated that the course did not meet their expectations.

The success of this program is directly attributable to the preparation of the speakers, the attentiveness of the class, and the hard work of the Delaware Sediment and Stormwater Program staff.

Stormwater Management Technical Sessions

The engineering and design community in Delaware has also indicated the need for DNREC to present more design-oriented training in sediment and stormwater management. To date, there have been several workshops in U.S. Department of Agriculture Soil Conservation Service TR-55 and TR-20 hydrologic analyses sponsored by local conservation districts and enlisting the assistance of the Soil Conservation Service. DNREC recognizes the need to expand this basic training and make available more design-oriented training for the consultant community.

Coinciding with the development and release of the *Delaware Stormwater Management Design Manual* in the summer of 1993, training classes were scheduled to present this material in modules, as the manual was developed. This training will help ensure that stormwater management practices are designed to meet established minimum criteria.

Summary

The education and training component of the Delaware Sediment and Stormwater Management Program is one of several areas of program development that will continue to respond to the needs of the regulated community. One obvious benefit in a small state like Delaware is that the efforts of a regulatory agency in providing education and training to the regulated community are recognized and appreciated. As previously discussed, the Sediment and Stormwater Management Program depends highly on interagency cooperation and communication with the businesses and industry involved. By maintaining education and training objectives as a high priority, DNREC will increase chances for program success.

Development and Implementation of an Urban Nonpoint Pollution Educational and Informational Program

Richard Badics
Washtenaw County Environmental Services Department,
Ann Arbor, Michigan

Abstract

Sampling, Abatement, Follow-up, Education, and Response (SAFER) was formed by the Washtenaw County's Environmental Interest Group on January 1, 1992. SAFER includes the county departments of Environmental Coordination, Environmental Services, Drain Commissioner, Planning, and Cooperative Extension, as well as the Soil Conservation District, Huron River Watershed Council, Ecology Center of Ann Arbor, and the Southeast Regional Groundwater Education Center. The purpose of SAFER is to "provide for coordination of water protection programs through inter- and intra-county agencies and group cooperation."

Education is a key element of SAFER. Four groups are targeted for education by SAFER: government, business and industry, community groups, and schools. SAFER members develop their own specific educational programs and materials. Through SAFER, these are coordinated to provide uniform and accurate information to targeted segments of the community. This avoids costly duplication of services.

To effectively deliver an educational program, the target audience must first be determined, then an analysis of existing educational programs must be made to build on past successes. Through this process, an approach is determined that is most likely to be successful. Prior to beginning the educational program, the establishment of an evaluation process is critical.

Overview of Washtenaw County's SAFER Group

Sampling, Abatement, Follow-up, Education, and Response (SAFER) was formed by Washtenaw County's Environmental Issues Group on January 1, 1992. The Environmental Issues Group consists of departments within Washtenaw County government that indirectly or directly manage the environment of Washtenaw County. This provides the county with a coordinated approach to addressing environmental issues. The Environmental Issues Group is chaired by the Environmental Coordination Office. Other member groups within the Environmental Interest Group are the Sheriff's Department, Environmental Services, Emergency Management, Planning, Public Works, Drain Commissioner, and Cooperative Extension, as well as the county's Health Officer. This group meets monthly to discuss the status of county programming, pending state and federal legislation, "hot" environmental topics or issues, and strategic planning.

SAFER was formed as a work group of the Environmental Issues Group "to provide for coordinative water protection programs through inter- and intracounty agencies and group cooperation." SAFER consists of groups internal and external to Washtenaw County government that are involved in dealing with the county's ground and surface water. SAFER includes the county departments of Environmental Coordination, Environmental Services, Drain Commissioner, Planning, Cooperative Extension, Soil Conservation District, Huron River Watershed Council, and Ecology Center of Ann Arbor, as well as the Southeast Regional Groundwater Education Center (SER-GEM). During its first year of operation in 1992, the group focused on categorizing and compiling all current water quality programs and their products. The 1992 SAFER Directory compiled over 100 products addressing water quality issues within the county.

Education is a key element of SAFER. Four target groups for educational programs in SAFER are government, business and industry, community groups, and schools. The SAFER Educational Subcommittee in 1993 is compiling all educational programs and materials on water quality related issues, similar to the 1992 SAFER Directory. Through SAFER, educational materials are coordinated to provide current and accurate

VOL 12

9047

information to the community while avoiding costly duplication of services.

Urban Nonpoint Pollution Education

The development and implementation of a nonpoint pollution educational and informational program is critical to a successful urban project. Public awareness of urban nonpoint pollution is relatively low, and the media tends to focus on health or environmental risks that are easy to define, such as AIDS or hazardous waste issues. Due to its nature, nonpoint pollution is harder to pinpoint. Urban nonpoint pollution prevention requires a long-term commitment to changing attitudes.

Urban nonpoint pollution can be directly attributed to people. We all contribute to it. People are accustomed to focusing on easier issues, where the blame can be attributed to activities outside their control. An example is auto safety. People are very concerned about vehicle safety when a manufacturing error is the cause, such as exploding gas tanks. These same people, however, are not as focused on actions that they control, such as wearing seat belts.

An environmental example is oil spills. A study by the Michigan Department of Natural Resources (MDNR) in 1989 found that more oil is illegally released into the environment in Michigan annually than was released in the Valdez tanker incident. Getting people to buy into the idea that they are a major part of the problem is a critical step in gathering their support and cooperation.

Target Audience

Before an education information program can be developed, the target audience must be identified. A general educational approach will not change the habits of a wide range of target groups. Each targeted group must be analyzed independently to understand its particular needs and to develop specific actions it can take. Next, the various media options must be explored.

A multimedia approach enhances the opportunities of reaching larger segments within the target audience. For example, handing out flyers at a garden show will not reach several socioeconomic classes; a spot on a local radio station may be more appropriate. Some common public outreach materials are fact sheets, pamphlets, radio, television, newspapers, magazines, displays, models, posters, group presentations, and one-on-one or community events.

Using existing resources in your educational program is important. An educational program workshop for composting in the community could also be a forum for supplying information to the public on preventing urban nonpoint pollution through the proper application of fertilizers and use of environmentally friendly alternatives to pesticides. By networking with existing programs in the community, nonprofit programs will not compete for and confuse the audience.

Educational Gaps

After analyzing current educational resources within the community, identify audiences and approaches not currently used. All targeted groups need to receive your message. Target groups in the community must "buy into" their contribution to nonpoint pollution and their ability to prevent or minimize it. Urban educational programs must be innovative, well conceived, multimedia, and coordinated with other educational programs in the community.

A large number of ongoing urban nonpoint education programs exist in communities throughout the country. These programs have been developed for various types of audiences. Prior to implementing a program "from scratch," review all ongoing programs. These can be found in EPA "News Notes," as well as through professional groups, conferences, and environmental publications. Regional EPA offices are also a valuable resource for finding suitable ongoing programs. Using existing programs saves time and money.

Program Evaluation

An integral part of all educational programs is evaluation. Valuable time and resources can be wasted if information supplied to an audience is not effective. When developing the evaluation mechanism for the educational process, make sure the educational program focus enhances the overall water quality objectives. One way to evaluate the educational process is to apply Bennett's Hierarchy of Evidence for Program Evaluation. Bennett uses seven steps of evaluation. In an inverted scale, these steps are:

1. Inputs of program resources that are used to make the program work.
2. Activities which can include internal events, such as planning, or external events involving an audience.
3. Involvement of the target audience in activities, focusing on hands-on type activities.
4. The target audience's view of the program.
5. KASA change, or the change in knowledge, attitudes, skills, or aspirations of the audience.
6. Changes in behavior that result from the educational program.
7. End results that reflect the program's goals and objectives.

Many techniques can be used to measure the seven Bennett attributes. The basic who, what, where, and when questions are useful when establishing the specific evaluation technique.

Many books and guides can help in developing program evaluation. Studying these before finalizing an evaluation process is highly recommended. If there are time constraints or expertise is not available for evaluation, this component can be done by an outside party. The key is to establish the evaluation mechanism before implementing the educational program.

Huron River Pollution Abatement Program

Overview

The Huron River Pollution Abatement Project (HRPAP), which encompassed the urbanized area of Washtenaw County, was formed and implemented in 1986 by the county's Drain Commissioner's Office in conjunction with the Environmental Services Department. Public education was a major objective of the project. The educational program used by the HRPAP was designed after reviewing earlier area pilot water quality programs and their targeted community groups. The HRPAP focused on business, industry, community, and school groups.

Business/Industry

The HRPAP conducted surveys and dye tests of facilities located in the urbanized areas of Washtenaw County. Staff interviewed facility owners and managers on their particular businesses and gained critical information about their operations. When a common need was found—for example, an owner unable to dispose of a certain type of waste—the project staff worked with the owner to resolve the problem. For example, many facility operators with oil separators were not familiar with separators and were unable to find a licensed waste hauler to service them. The HRPAP developed a maintenance guideline for the operators, contacted all local waste haulers, and developed a list of haulers that would service oil separators. This information was then distributed to all facilities with oil separators.

Community and Civic Group Education

Over 200 educational presentations were made to the community during the HRPAP's 6 years. The HRPAP used various media to educate the community. One of the most effective was the local press. Articles concerning the HRPAP were published on an ongoing basis. Press releases noted significant events and common problems found within the community.

A second approach to outreach was through community events. Examples are the Ann Arbor City Art Fair and the Ypsilanti City Heritage Festival. These events attract hundreds of thousands of people. Display booths and pamphlets were developed for participating in these events. This became a forum for discussing water quality related issues one-on-one with the public.

School Education

The HRPAP made its first school educational presentation to a third-grade class in 1988. Word of mouth led to over 25 presentations per year in six local school districts. HRPAP student interns with an educational background formulated lesson plans for different grade levels on nonpoint pollution and related topics, such as the water cycle and household hazardous waste.

In classrooms, educational programs concentrated on hands-on activities. Two water quality models were built. One electronic model, entitled "Pathways to Pollution," lights up various pollution pathways when the appropriate button is pushed. A second model is a transparent representation of a town showing the sanitary and storm sewer systems. The students place a dye into catch basins, floor drains, and toilets to observe the route the water takes directly to the stream or the wastewater treatment plant. This model has examples of both proper and improper connections.

Conclusions

The majority of urban nonpoint pollution can be directly attributed to the activities of people. Most people are not aware of the impacts their routine activities at home and at work have on water quality. Education is a key component to improving urban water quality problems. Key target audiences in the community need to be identified, existing educational resources studied, educational program gaps identified, and an evaluation process included to measure a program's effectiveness.

The key to an educational program is to focus on practical activities that the target group can do to eliminate water pollution. A long-term, sustained educational effort leads to an increased awareness and respect for the interdependence of all elements in the ecosystem and for how individual activities affect them. This ultimately leads to a sense of mutual responsibility and a long-term commitment to continued environmentally sound actions.

Training for Use of New York's Guidelines for Urban Erosion and Sediment Control

Donald W. Lake, Jr.
U.S. Department of Agriculture,
Soil Conservation Service, Syracuse, New York

Introduction

New York State still does not have a statewide erosion and sediment control law. Unlike many of its neighboring states, New York continues to leave the initiation of such control to local units of government. Historically, counties, towns, and villages have enacted ordinances once a significant environmental accident has occurred. Jurisdiction occurs at the local level, with planning boards having approval authority to issue permits to develop. Because each board is dealing with its local area, the regulations and processes for gaining approval vary from locale to locale.

Technical standards for controlling erosion and sediment were developed by the Soil Conservation Service in March 1988 and issued as *New York Guidelines for Urban Erosion and Sediment Control*. This document provides design details and specifications for both temporary and permanent management practices, as well as resource-planning concepts. Known as the "Blue Book," the document provides consistency in the technical approach to erosion and sediment control plans for construction sites. It has been adopted by the New York State Department of Environmental Conservation and the U.S. Army Corps of Engineers, Buffalo District, as criteria for erosion and sediment control plans. The New York State Department of Transportation has incorporated many of its details into its highway design manual.

In April 1992, the New York State Department of Environmental Conservation (NYS-DEC), Division of Water, published *Reducing the Impacts of Stormwater Runoff From New Development*. This document establishes performance standards for stormwater management control in New York for projects requiring NYS-DEC review. Standards were set for both water quantity and water quality. Water quantity is addressed by requiring no greater discharges from the site after development than present before development for the 2-, 10-, and 100-year frequency storm events. Water quality is addressed by retaining the "first flush," which is defined as the greater of one-half inch of runoff or runoff resulting from a 1-year, 24-hour storm, from the land area for which the infiltration rate has been changed.

These two documents finally provide guidance for erosion and sediment control and stormwater management for local units of governments as well as regulatory agency staffs. Their use and application depends on what the site's size and resource constraints are and whether a local ordinance is in place. The local approval process, in communities with such a regulation, generally requires a formal review of the plan with its erosion and sediment control and stormwater management component by either the town or village engineer and a local soil and water conservation district staff person or health department official. Unfortunately, many of these individuals are unable to identify problems or lack the knowledge of design details to control sediment from the site.

Once a developer begins operations in the field, the building inspector, code enforcement officer, or health department official is responsible for inspecting the site for compliance to the approved plan as well as to ensure that the contractor maintains the installed practices. These field inspectors require training in the concepts of erosion and sediment control installation and maintenance.

Clean Water Act Mandates

On October 1, 1992, stormwater regulations went into effect under the Clean Water Act that require individuals, agencies, and municipalities to apply for a National Pollutant Discharge Elimination System (NPDES) permit for stormwater discharges from a variety of activities. New York State is a NPDES-delegated state, and the

Department of Environmental Conservation is administering this program through their State Pollutant Discharge Elimination System (SPDES) permit. One of the 11 categories covered in the regulations is construction activity. Under this activity, any site where 5 or more acres are disturbed must have an erosion and sediment control plan and a stormwater management plan. The 5-acre size limit has been challenged as arbitrary, and the size limit could be changed to 1 acre of disturbed area. A developer needs to file a Notice of Intent at least 48 hours before beginning operations to have "coverage." This notice is filed with the U.S. Environmental Protection Agency in Newington, Virginia. Under the regulations, copies of the erosion and sediment control plan and stormwater management plan are to be kept on site. Copies of each are also sent to the municipality that has jurisdiction. NYS-DEC does not want the notices or plans sent to its offices; they will nòt be reviewing or approving these plans. Who will? What will be the local impacts?

As a result of this mandate, many New York counties, towns, and villages will be receiving many erosion and sediment control and stormwater management plans. The majority of these units of government are still unaware of the requirements of the national program and of what their role is or should be. There is a great need for administrators, planners, and legislators to become aware of the program and the process. Technical staff need to learn the principles of planning, design, construction, and inspection for erosion and sediment control and stormwater management systems.

Positive aspects of the NYS-DEC approach to the program include the opportunity for local policy development, provisions for local ordinances, and the formation of interagency partnerships. Because NYS-DEC recognizes that authority should rest at the local level, communities have control over the quality of the natural resources in their backyards. Of course this may require additional staff or cooperation with other agencies to assist with implementation.

Training Programs

Early efforts in erosion and sediment control began with awareness seminars at the local level. The seminars usually lasted 2 hours an evening for local officials involved in the site review and approval process. Recognizing problems, learning the planning steps, and becoming familiar with practices and guidelines were the limit of these seminars.

The complexity of requirements and the technical needs have increased dramatically due to recent mandates. The Soil Conservation Service, in cooperation with NYS-DEC and Syracuse University, has developed a tiered educational program in erosion and sediment control and stormwater management.

A 1-day seminar has been developed for planning board members, environmental management council members, legislators, and town boards, and has included legal advisors, consulting engineers, and other agency personnel responsible for environmental analysis. This agenda is included as Figure 1. This seminar stresses site planning through a slide presentation that demonstrates problems without control and shows practices necessary to maintain resources on the site. Stormwater management performance standards are reviewed in accordance with NYS-DEC criteria. This seminar is reinforced with two specific site examples. Attendees are asked to work in small design teams to design an erosion and sediment control plan for the first site. These same design teams are asked to critique the second site, which already has an erosion and sediment control plan. Thus, attendees go from designers to reviewers in applying their knowledge of these principles.

A 2-day workshop has been developed for the technical staffs of resource agencies, consulting engineers, local governments, and others with technical review or design responsibility (see Figure 2). This session begins with a quick overview of the principles of erosion and sediment control, then continues with a class exercise to design an erosion and sediment control plan for a development site while working in design teams of approximately four individuals. The afternoon of the first day is spent at a field site gathering specific resource information and data to design a detailed erosion and sediment control plan for the site. The design teams also compute and compare peak discharges for the site for predevelopment and postdevelopment conditions using Soil Conservation Service Technical Release 55, Urban Hydrology for Small Watersheds (TR-55). The session concludes with group presentations.

A 3-day short course with Syracuse University has been developed to address the specific technical needs of consulting engineers working with stormwater and erosion control systems. This tuition-based course provides for more indepth design of erosion and sediment control practices using a field site. Sizing stormwater detention basins is also required. In addition to the increased technical emphasis, additional speakers from state and local agencies provide a component on rules and regulations. Syracuse University awards two continuing education units for this course, which 57 people have completed to date. The agenda is included as Figure 3.

Urban Erosion Control and Stormwater Design (CIE 600) stands as a fully accredited 3-hour graduate level course in the Civil and Environmental Engineering Department at Syracuse University. It was taught for the first time in the 1992 fall semester and will be taught again this September. It was developed as a hands-on course that requires detailed designs for two projects, using field trips and six additional site review projects.

EROSION AND SEDIMENT CONTROL SEMINAR
AGENDA

8:30 AM	Registration
9:00 AM	Introduction and Course Overview
9:15 AM	Developing an Erosion and Sediment Control Plan — Planning Considerations — Factors That Influence Erosion — Elements for a Sound Plan — Vegetative and Structural Components — Standards and Specifications
11:00 AM	Site Example — Develop Conceptual Erosion and Sediment Control Plans
12:00 PM	LUNCH (ON YOUR OWN)
1:00 PM	Site Review — Critique an Erosion and Sediment Plan for a Specific Site
3:30 PM	Wrap Up/Summary
4:30 PM	Adjournment

EROSION AND SEDIMENT CONTROL

SHORT COURSE AGENDA
April 28-30, 1992

First Day

9:00 AM	Registration and Coffee	Dr. Stephan Nix
	Introduction and Course Overview	
10:00 AM	Legislation, Ordinances, and Regulatory Review Process	Mr. Robin Warrender Mr. William Morton Mr. Russell Nemecek
11:00 AM	Developing Your Stormwater Management Plan and Practices	Mr. William Morton
12:00 PM	Lunch	
1:00 PM	Urban Hydrology and Flow Routing	Mr. Donald W. Lake, Jr.
2:15 PM	Break	
2:30 PM	Urban Hydrology and Flow Routing (continued)	
4:30 PM	Adjourn	

Second Day

8:00 AM	Developing Your Erosion Control Plan	Mr. Donald W. Lake, Jr.
9:30 AM	Break	
9:45 AM	Erosion and Sediment Control Practice Standards	Mr. Donald W. Lake, Jr.
11:30 AM	Lunch (En Route to Field Site)	
12:00 PM	Field Tour/Site Problems	Mr. Donald W. Lake, Jr.
3:00 PM	Group Design Session	
5:00 PM	Adjourn	

Third Day

8:00 AM	Group Presentations and Critiques	
10:00 AM	Break	
10:15 AM	Group Presentations (continued)	
11:45 AM	Wrap Up—Adjourn Short Course	Dr. Stephan Nix
1:00 PM	Certified Professional Erosion Specialist Exam Part II (Optional)	Mr. Donald W. Lake, Jr.

Figure 3. Erosion and Sediment Control short course agenda.

In addition, the class participates in a town planning board meeting. Syllabus topics (see Figure 4) include manual and computer analyses of stormwater discharges and lectures by a plant materials specialist, a code enforcement officer, and governmental representatives dealing with rules and regulations. Twelve students enrolled in the first class, which was extremely well received by both students and the people who provided the example sites.

Summary

Over 2,600 people have received training through 76 different seminars, workshops, short courses, and the graduate course since the training effort began in the fall of 1988. These tiered training sessions have evolved one after another based on needs at the local level. Leaders in the NYS-DEC recognized that benefits are local so training efforts should be local. This has led to interagency cooperative agreements between the U.S. Department of Agriculture, Soil Conservation Service, and NYS-DEC to bring training directly to the communities.

There is no sign of these training requests letting up. An average of 10 requests for the seminar sessions are made at the local level during the year. In addition, the proposed cooperative agreement for Fiscal Year 1994 between the Soil Conservation Service and NYS-DEC calls for five 1-day seminars, four 2-day workshops, four 2-day TR-55 hydrology workshops, and two short courses. The Syracuse University graduate course will be taught again this fall. Future projects also include workshops for New York State code enforcement officers, development of a field notebook for job superintendents, and field application courses for equipment operators. After all, equipment operators have the last word in installation.

We have come a long way, but we can see that challenges are still ahead of us to educate public planners, legislators, consultants, technical staff, and contractors in the use of sound erosion and sediment control and stormwater management practices to protect and enhance water quality and the environment.

Field Office Technical Guide: *Urban Standards and Specifications*

Gary N. Parker
U.S. Department of Agriculture, Soil Conservation Service
Champaign, Illinois

VOL 12

9058

Abstract

The *Field Office Technical Guide* is the primary technical reference for the Soil Conservation Service (SCS). It presently contains general resource references and soil and site information, and describes conservation management systems, practice standards and specifications, and conservation effects. Although SCS maintains offices and provides assistance in all Illinois counties, the technical guide does not contain any information specific to natural resource use and management in urban areas. Therefore, in June 1992 the SCS in Illinois entered into an agreement with the Illinois Environmental Protection Agency to develop technical information describing best management practices (BMPs) for controlling urban nonpoint source water pollution.

Currently in development, this information will include 40 BMP standards and accompanying construction specifications, material specifications, and standard drawings. It will also include estimates of pollutant removal effectiveness and stormwater pollutant export, as well as planning and design criteria. When complete, this material will become part of the *Field Office Technical Guide*. The Illinois Environmental Protection Agency will also use the information in a separate, stand-alone technical manual. This material will be useful to planners, engineers, architects, and construction contractors, as well as to local government staff.

Background

The Soil Conservation Service (SCS), an agency of the U.S. Department of Agriculture, is the major federal agency providing natural resource management assistance on nonfederal land. Its primary responsibility is to provide leadership and expertise in managing natural resources in nonurban areas. Currently, SCS maintains a network of field offices in nearly every county in the country, providing local citizens with direct access to a wide range of technical specialists. These specialists include engineers, soil scientists, biologists, agronomists, and natural resource planners.

The technical material and expertise that has been developed to support SCS activities largely pertains to agricultural or rural settings. For example, the seed mixtures that most SCS specifications call for are those appropriate for agricultural areas and not necessarily for parks, recreation sites, or lawns. In addition, design criteria for waterways and diversions assume an agricultural land use context.

Despite this rural, nonurban emphasis within the agency, SCS maintains a field staff in urban and urbanizing areas. In Illinois, this urban staff serves over one-half the state's population. This urban presence has enabled SCS to develop some urban expertise. For instance, SCS TR-55 hydrology modeling techniques are widely used to estimate runoff from urban areas. Moreover, the PL-566 watershed projects constructed in the Chicago suburbs have given the agency some expertise in urban construction site issues. The SCS, however, has not provided any systematic technical support to its field staff on natural resource management issues in an urban setting. It has instead relied on the ability of its staff to adapt the provided information from a rural to an urban environment.

To become more effective in addressing key natural resource issues in urbanizing areas, the SCS in Illinois has initiated several activities:

- It is actively participating in a coalition of state and federal agencies to prepare a strategy for coordinating agency activities in northeastern Illinois.
- It is reviewing and clarifying its policy relative to providing assistance in nonagricultural areas.

- It is expanding the technical information its staff uses when providing assistance to decision-makers in urban areas.

The third initiative listed is the subject of this paper. In June 1992, SCS entered into an agreement with the Illinois Environmental Protection Agency to prepare a set of standards and specifications describing BMPs for controlling urban nonpoint source water pollution. In addition, the SCS will provide estimates on the range of pollutant removal effectiveness and criteria for planning runoff management. The agency will incorporate all this material into its *Field Office Technical Guide*.

Field Office Technical Guide

The *Field Office Technical Guide* is the primary technical reference for the SCS. It contains technical information about conservation of soil, water, air, plant, and animal resources. The guide is designed for use by technically trained people who are assisting landowners and users, land managers, government officials, and other decision-makers to plan, apply, and maintain appropriate conservation practices. The technical guide also is a major reference for those addressing top-priority resource goals identified by the National Program for Soil and Water Conservation. These goals are to reduce the damage caused by excessive erosion and to protect water from nonpoint source pollutants. The technical guide identifies sediment, nutrients, animal waste, pesticides, and salinity as nonpoint source pollutants.

The *Field Office Technical Guide* contains five sections:

- The "General Resource References" section lists references, cost data, maps, climate data, cultural resources information, threatened and endangered species, and pertinent state/local laws, ordinances, and regulations.
- The "Soil and Site Information" section describes the soil survey of the local area. It contains soil descriptions and interpretations that can be used to make decisions about land use and management. This section identifies soil characteristics that limit or affect land use and management, and rates soils according to limitations, capability, or potential.
- The section on "Conservation Management Systems" provides information for developing resource management systems to prevent or treat problems associated with soil, water, air, and related plant and animal resources. This section includes quality criteria that describe the level of resource protection that decision-makers should try to achieve to meet resource quality goals.
- The "Practice Standards and Specifications" section alphabetically lists conservation practices used by the field office, followed by practice standards and specifications. It may also include references and documentation requirements for the individual practices. Practice standards establish the minimum level of acceptable quality for planning, designing, installing, operating, and maintaining conservation practices. Practice specifications describe the technical details and workmanship required to install the practice, as well as the quality and extent of materials used in the practice.
- The last section, "Conservation Effects," contains information describing the economic and environmental effects of implementing particular practices and systems. The purpose of this section is to provide decision-makers with a way to evaluate the extent to which various alternatives can meet their goals.

As stated previously, this guide is the primary technical reference for SCS staff, particularly those at the field level. The guide is also useful to Soil and Water Conservation District staff, and to consultants and staff of state, county, and municipal governments. To expand its usefulness, however, the SCS urban field staff in Illinois have recommended that the guide include information that is directly relevant to natural resource management in an urban environment and is user friendly to urban clients. The material now being developed will attempt to meet that need.

New Material for the *Field Office Technical Guide*

The new material will supplement and expand the existing material in the guide's fourth section, *Practice Standards and Specifications*. The SCS will modify or develop 40 BMPs that deal specifically with urban natural resource management.

Each BMP standard will follow a uniform format:

- "Definition": describes what the practice is.
- "Purpose": explains what the intended effect of the practice is, that is, why this practice is used.
- "Conditions Where the Practice Applies": describes the types of sites where the practice would be appropriate; this section also describes limiting factors such as slope percent, maximum drainage areas, and maximum flow velocities.
- "Criteria": describes, in general terms, material and construction requirements and usually provides references to specific material and/or construction specifications.
- "Considerations": offers general information regarding factors to consider when deciding on the appropriateness of a particular practice; in some cases, this section is a brief, narrative, nontechnical summary of the "Conditions" section.

- "Plan and Specification Requirements": describes the nature and extent of the information the contractor needs to build the practice; it lists the requirements of the plans and specifications needed to install a practice.
- "Operation and Maintenance Requirements": describes the needed operation and maintenance actions and suggests the frequency with which they should be performed.

The revised fourth section of the technical guide will also include all the material specifications and constructions referenced in the practice standards, as well as a series of standard drawings for the practices. The standards and specifications will be available on computer disk. The standard drawings, which will be developed using a CAD system, also will be available on disk. This will allow engineers and consultants to access the material in preparing construction plans and specifications.

In addition to the SCS incorporating the new material into the Illinois *Field Office Technical Guide*, the Illinois Environmental Protection Agency plans to issue a stand-alone technical manual of those standards for use by consultants, state agencies, and local governments. The project is scheduled for completion in December 1994.

Stormwater Outreach at the Federal Level: Challenges and Successes

Kimberly O. Hankins
Office of Wastewater Enforcement and Compliance,
Office of Water, U.S. Environmental Protection Agency, Washington, DC

Background

Stormwater regulations brought a distinctly different community into the realm of U.S. Environmental Protection Agency (EPA) regulation. Many members of this community have never before been regulated by an environmental program. The regulated community now includes all major cities and unincorporated areas with populations of 100,000 or more, as well as a very large, diverse group of industries. The most important factor influencing success with the stormwater regulations is education. By educating all parties concerned with the program, the community can begin to practice all that EPA is learning about how to provide a cleaner, safer environment.

The principal elements of an outreach program are communication and education, with a focus on influencing how people and organizations act. Given this, the National Pollutant Discharge Elimination System (NPDES) stormwater outreach program at the national level should, among other things:

- Disseminate information and educate people about the effects of receiving water pollution from diffuse sources, such as the loss of recreational activities.
- Promote positive environmental results, including the reduction of pollutant loadings into receiving waters.

Theoretically, accomplishing these goals should elicit a successful outreach program at any level. In fact, success is much more elusive. Of course, many outreach programs implement this theory very effectively. At the federal level, however, EPA has 16 different customers reflecting 10 EPA regions, 50 states, thousands of municipalities, and hundreds of thousands of facilities, trade associations, and professional groups. Moreover, when factoring in to this multitude Congress, EPA's own management, and scarce resources, a successful outreach program becomes a tremendously complex and costly endeavor.

At the federal level, it is crucial to provide as much information as possible to as many people as possible. Therein lies the biggest challenge in outreach at the federal level. This paper presents some of the challenges in developing an outreach strategy for the stormwater program at the federal level. It also describes some of the projects EPA's Office of Water has under way, some of which have worked very well and some of which have not. In addition, the paper discusses what the future holds for the stormwater outreach program.

Challenges of Developing a Stormwater Outreach Strategy

For its first year or so, the strategy of the stormwater outreach program consisted of a hotline, which addressed most needs, and speaking engagements, which filled in the gaps.

Almost immediately after the NPDES stormwater program was born, several years ago, the stormwater hotline was established. Since its inception, the hotline has received over 90,000 calls. The hotline staff answers questions, distributes documents, and handles registration for EPA workshops and seminars.

The other important element of the early stages of the stormwater program was speaking engagements and workshops. These continue to be one of the best ways to get "the word out" correctly. Regulated communities need to know exactly how the stormwater program affects them. For example, the program held 12 workshops between 1990 and 1991 to explain the November 10, 1990, regulations.

As the stormwater program matured, it became apparent that the community needed a more substantial outreach strategy. The hotline staff quickly found it difficult to refer all policy interpretation calls to EPA stormwater staff. At that time, the staff at Headquarters was very small and the regions were overburdened.

Consequently, the Headquarters stormwater staff expanded, and one of its first tasks was to develop an outreach plan. The first step was to identify the plan's customers, which turned out to be just about everyone. Primary customers are the regions and states. Of course, there are 11 categories of regulated industries and over 200 municipalities in Phase I alone. The list of customers continues to grow when the general public, elected officials, professional associations, trade groups, and consultants all are factored in. These groups require a different level of understanding of stormwater regulations. This presented a major challenge because the staff needed to examine each document and ensure that it satisfied the needs of more than one group of customers.

This early outreach strategy assumed knowledge of what the customers wanted. The assumption, however, was wrong. There was one crucial step in strategy development that the stormwater staff neglected to complete: ask the customers. Because of their enormous number, however, asking them all was impossible. Some customers, of course, in addition to the regulated community, are the states and regions, who are trying desperately to run their own stormwater programs. These customers were finally asked about the outreach plan at the 1992 Stormwater Coordinator's Conference in Atlanta, Georgia. The stormwater staff reviewed what they had been doing to date, and customers offered helpful suggestions on what to do next. Customers also participated in a session specifically targeted at designing the stormwater workshops held in April 1993 in Annapolis, Maryland, so as to ensure customer input.

During this meeting, it became apparent that many states and regions were duplicating work unnecessarily, that is, developing something that another state had already developed. This was very frustrating for all those involved. Some kind of clearinghouse or electronic communications system was desperately needed. Research, however, had already shown that it could cost from $750,000 to $1 million to set up such a system. This cost prevented Headquarters from accomplishing this effort on its own. Therefore, it asked the states to help by directing their 104(b)(3) grant funds to this effort. This seemed the only way to accomplish the goal quickly and effectively. Although this sounded like it would work, it has not. There is quite a bit of reluctance to use that money for this task. Therefore, stormwater personnel have begun to look for other avenues.

The challenges multiply when budget constraints are considered. One of the biggest problems involves printing a developed document. The printing budget at Headquarters has taken some very serious cuts. Despite attempts to solve this problem, difficulties continue. For instance, Headquarters has tried to distribute items electronically, but this can cause more problems than it solves. Budget cutbacks have seriously hampered plans to develop more public education materials than are currently available.

Of course, nearly everyone has been hit very hard by budget problems. Some states and counties have offered very creative ideas about getting the "most bang for your buck!" This issue has shed new light on the problem of getting out as much information as possible.

These are just some of the challenges stormwater staff have faced in putting together an outreach strategy. The next section describes some current outreach projects.

Current and Developing Outreach Activities

Research

A primary task has been to research existing outreach activities. Much information on these activities exists, and both researchers and audiences find this an ongoing educational process. Research efforts include:

- Research on outreach activities
  Audience: Headquarters management, regions
- Research on videos
  Audience: Headquarters management
- Research on clearinghouses
  Audience: Headquarters management, regions

Current research on existing outreach activities examines their successes and failures. Hopefully, this effort will help target materials and practices that can be expanded to a national level. While outreach videos have had difficulty with funding, the staff is researching what is out there, again, in case it finds something that works well and can be expanded to a national level. Finally, research on clearinghouses began before stormwater staff heard from the regions and states. The staff tried to learn of available clearinghouses to examine the possibility of their use or adaptation.

Outreach Strategy

The strategy is expected to be presented in a dynamic document. Its audience is Headquarters management and the regions. Hopefully, the document will provide an adaptable framework for designing and completing outreach projects within an assigned time frame.

Fact Sheet Development

Because the stormwater program involves so many issues and firestorms staff often produce fact sheets to clear up confusion. Past fact sheets have focused on:

- The Transportation Act's effect on the stormwater program.
- The Ninth Circuit Court decision that affected municipalities.
- The Municipal Part II guidance document.
- Phase II progress and results of public meetings.

Question and Answer Document

The audience for this document is the regions and industries via trade associations. The first volume was developed based on questions from the hotline. The staff compiled over 50 commonly asked questions and answers into one document, which has been distributed through the hotline.

The second volume covers more complex interpretations of the regulations, including questions on sampling, group applications, and the Ninth Circuit Court decisions. Again, distribution will probably proceed through the hotline.

Stormwater Workshops

In fiscal year (FY) 1991, the stormwater staff at Headquarters conducted 12 workshops on the basics of the stormwater program. The workshop audience consisted of regions, states, and the regulated community. The objective was to inform as many people as possible about the requirements of the November 16, 1990, rule. Attendance was in the thousands. The effort was successful.

In FY 1992, the stormwater staff presented workshops and spoke to over 4,000 people. These workshops focused on the requirements of the general permit and the development of pollution prevention plans. In addition, workshops for municipalities covered the requirements of the Part 2 municipal application. All these workshops were well received and also considered successful.

The FY 1993 workshops presented by Headquarters focused on developing pollution prevention plans. The staff developed a workshop series with the first day targeted to reach state and EPA regional representatives. This day is a train-the-trainer session to teach the audience how to lead a workshop on pollution prevention for industry. The second day is designed for the industrial regulated community and focuses on industrial and construction pollution prevention plan development. This day should include case studies and interactive exercises.

These workshops mark the first effort by the stormwater program to conduct workshops of this kind. The hope was to meet the objectives identified by the regions and states at the 1992 Stormwater Coordinator's Conference in Atlanta. Due to budget problems, Headquarters was limited to the number of workshops it could conduct in each region. The goal was, however, for state and regional staff to be able to present the workshops on their own. Each state was to receive a set of slides and speaking materials for its own use.

Municipal Support Division/Permits Division Pamphlet on Stormwater

The audience for this publication is Headquarters, the regions, and the general public. This project has experienced difficulties getting started due to contractual problems. It is, however, now moving ahead toward completion. The pamphlet is predominantly aimed at members of the general public who have little or no knowledge of the stormwater program.

Updated Stormwater Overview

This document addresses general information needs. Its audience consists of Headquarters, the regions, and the general public. The Overview reviews who the stormwater program covers, what their application options are, and what the deadlines are associated with those applications. As the program grows and changes, the Overview is updated. Distribution is currently through the stormwater hotline.

Raindrop Report (Status of the Stormwater Program)

This document is targeted to Headquarters, the regions, and the general public. It supplies a brief update on current activities in the stormwater program and features relevant information from recent *Federal Registers*. In addition, it describes outreach activities and provides specifics on applications submitted and general permits.

Articles for Newsletters

Stormwater staff are developing articles by request for publication in various journals and newsletters. They are trying to establish a regular submittal effort to some publications, such as the *Nonpoint Source News Notes*, which is published by the Headquarters nonpoint source program to supplement the bulletin board.

General Permit Effectiveness Study

The purpose of this effort is to determine the effectiveness of the general permit approach in implementing Phase I. The evaluation assesses, among other things, the rate of compliance, the level of awareness, and the quality of pollution prevention plans being developed. This effort also is identifying obstacles that prohibit the general permit from being as effective as possible.

Monthly Conference Calls

As of March 1993, Headquarters had completed 15 regularly scheduled conference calls with stormwater regional coordinators. These meetings have proven very successful, and they should continue.

Stormwater Awards

These awards recognize municipalities and industries that demonstrate a commitment to protecting and improving the quality of the nation's waters through outstanding implementation of innovative and cost-effective stormwater control programs and projects. In 1991, the winner for a stormwater control program or project by a municipality was Murray City, Utah. In 1992, the city of Orlando, Florida, won, and Prince George's County, Maryland, took second place. Nominations are sought from the 10 EPA regions.

National Stormwater Coordinator's Conference

This annual event is indispensable for planning and feedback from the states and regions. The meeting is designed for regional and state stormwater coordinators, as well as for Headquarters staff.

Continuous Speaking Engagements

Stormwater staff receive requests to speak to groups twice a week on average. While they are not always able to fill some requests because of a limited travel budget, the staff respond to as many as possible. In FY 1992, staff participated in about two dozen talks or seminars, not including the workshops.

Phase II Outreach Meetings

The Phase II Outreach Meetings are a series of meetings designed to include individuals that may be affected by the Phase II regulations in the development of those regulations. As of this writing, four meetings have been held (two in Washington, one in Dallas, and one in Chicago) to involve as many people as possible.

Information and Education Catalog

Another important project is the management and periodic update of the Information and Education Catalog, which was distributed at the National Urban Runoff Management Conference. The author and Tom Davenport manage this project. Everyone concerned should have a copy of this excellent document. Management plans to expand the manual to include stormwater information. In addition to putting out several calls for information, the conference registration packet included a form to fill out if individuals wanted this catalog to include a particular document. Management believes this document will help in the tremendous demand for technology transfer in the stormwater and nonpoint source programs. This, of course, is a top priority that customers have requested.

Electronic Sources

Linking to other clearinghouses and bulletin boards should improve communications. The nonpoint source program at Headquarters has been extremely helpful by placing information and announcements on its electronic bulletin board and in the *Nonpoint Source News Notes* publication. This has proven to be a good way to meet customer needs.

Further Considerations

Education is becoming one of the most important aspects of the stormwater program as people learn about the regulation and how it affects their day-to-day lives. Industries as part of their pollution prevention plans are developing training and education programs for their own employees. Cities are training their employees in sampling techniques and safety procedures as well as developing excellent public education programs. Tremendous efforts involving stormwater education are being undertaken. Stormwater Headquarters needs to know about the successful programs to help the lesser programs learn.

As this program moves forward, each success in educating those affected by the stormwater program, including the general public, leads to greater accomplishments. As these successes continue to build, more people will understand the intent and effects of protecting and cleaning up the waters of our nation. It is a cycle in which we all play a major role.

Training for Construction Site Erosion Control and Stormwater Facility Inspection

Richard Horner
University of Washington, Seattle, Washington

Abstract

Probably the leading reason that stormwater management programs fail in effectively protecting water resources is the lack of followup to ensure that permit conditions are met, approved designs are properly installed, and temporary and permanent management practices and facilities are maintained. Avoiding this downfall requires obtaining the legal authority for and then instituting a coordinated program extending from the first submission of permit applications through construction and all phases of site operation. This program should have components covering the construction phase as well as permanent practices and facilities. While somewhat different elements are appropriate for the two components, they share the common precepts of sound underlying planning; competent plan review; and effective inspection, maintenance, and enforcement. The University of Washington's Center for Urban Water Resources Management and Office of Engineering Continuing Education have developed and are offering courses to train personnel responsible for various aspects of the suggested program. This paper emphasizes the training for site inspectors. For construction-site inspectors, it covers the role of the erosion and sediment control (ESC) plan, the applicability of many ESC practices, key points to check when inspecting them, and how to deal with various circumstances that can arise during inspections. For permanent drainage system inspectors, the paper covers both the initial construction and continuing operation of facilities and offers guidance on key inspection points and such issues as safety, tracking maintenance, and waste handling.

Introduction

Effective stormwater management requires successful execution of steps at all phases of a project. These phases and the accompanying management steps include analysis of potential problems in the planning stage, quality design of programs and practices to protect aquatic resources as the project takes shape, competent review of plans at the permit application point, proper implementation of approved plans during construction, and correct operation and practices at facilities after their installation. All phases of the process need improvement through a better basis in knowledge and greater skills in application. Probably the weakest areas and the leading causes of program failures and environmental damage are implementation during construction and long-term operations.

Redressing this weakness will require widespread development of comprehensive and aggressive programs of inspection during the construction of developments and their stormwater management systems, followed by ongoing inspection of operating systems to ensure sufficient maintenance for continuing adequate performance. The diffusion of development and tradition of local land-use control prevalent in most of the United States will necessitate local acquisition of the legal authority, where it does not now exist, to institute these programs. As is already occurring in some places, it is likely that larger units of government will become involved in setting standards for these programs. The U.S. Environmental Protection Agency's National Pollutant Discharge Elimination System (NPDES) program is presently extending authority over programs in the largest cities and counties and at sites of construction larger than 5 acres and involving industrial activity. Still, the details and the responsibility for conducting the programs will very likely rest with local governments.

The concern of this discussion is the development and execution of local programs to upgrade significantly the quality of followup to increase the probability that approved stormwater management plans are effective. The scope of the programs envisioned would extend from the point of permit issuance through construction and all the years of site operation to follow project completion. The programs might be considered to have distinct components, covering, for example, erosion and sediment control (ESC) inspection at construction sites, inspection of the construction of storm runoff quantity and quality control facilities, and the periodic inspection and maintenance of operating facilities. However they are structured, these programs should embrace some common principles. They should be the logical extension of and ultimate implementation vehicle for the foregoing phases of planning, design, and plan review. Further, they should be conceived and conducted as essential elements of a successful program, deserving of the needed funding, staffing, support by administrators and public officials, training of personnel, and enforcement authority.

This discussion covers aspects of program development and especially emphasizes training for site inspectors. For these purposes it divides the overall program into two components. One covers construction site ESC programs. The second covers permanent drainage practices and facilities, both their inspection at construction and followup inspection and maintenance. In both cases, the paper recommends program structures and discusses some key program elements. It then offers specific examples of inspection checks to perform in the field. The goal of the paper is to give the reader a basis for beginning program design and undertaking the key element of training the staff who will be charged with its performance.

The discussion was derived from two courses developed and offered by the University of Washington's Center for Urban Water Resources Management and Office of Engineering Continuing Education. The course coverage is organized in the same manner as this presentation, and course manuals are available for ESC inspector training (1) and permanent drainage system inspector training (2). Important contributions to the material presented in these courses and in this discussion have been made by local governments and state agencies in the Puget Sound area of Washington state that have been working actively to improve stormwater management through good followup.

Construction Site ESC Inspection Programs

Program Development

Program Elements

The following elements are recommended for a comprehensive construction site ESC program:

- ESC planning
- A plan review process
- Contractor education
- An inspection and enforcement process

The subsections to follow cover two of these program elements in detail, ESC planning and inspection and enforcement. The latter discussion is then extended in the following section to examples of inspection guidelines for common practices.

ESC Planning

ESC planning is an absolute prerequisite for an effective program. A careful site analysis should produce a stand-alone plan (i.e., a plan devoted exclusively to this aspect of the project) developed with the same thoroughness and care as any other plan in the overall construction set. It is intended for use by the plan reviewer, the construction superintendent and other contractor personnel, and the construction site inspector. This subsection outlines the ESC planning process from beginning to end and concludes with an example of a complete plan.

In approaching an ESC plan, the planner must:

- Understand the erosion process, so that it can be controlled.
- Know the site and the construction plan, so that both potential problems and solutions will be apparent.
- Understand the various ways that erosion can be prevented or that eroded sediments can be caught.

The erosion process is first reviewed for the lessons it can offer ESC planning. Erosion has been understood for thousands of years, as is attested by the extensive evidence of terraced farming—some continuing today—in steep terrain in ancient cultures. Figure 1 illustrates the types of erosion and its nature. Soils can be loosened and set in motion initially by the impact of falling raindrops. Erosion progresses, although gradually, as runoff flows in a sheet over a bare surface and exerts shear stress, which is a function of velocity, on soil particles. The rate of erosion increases when flow concentrates and increases in velocity. Channels formed by these flows are known as rills. When rills join and form highly concentrated, rapidly flowing channels, the rate increases still further, a stage termed gully erosion. Erosion can progress still further to mass wasting when a whole area loses stability.

Several factors involving site soils, vegetation, and topography influence the erosion process. Soil erodability is greater in the case of silts and fine sands than clays or soils with a substantial gravel content. Relatively high organic content also offers cohesiveness that resists erosion. Clays tend to produce a larger volume of runoff, however, because of their relatively poor permeability, which exerts more erosive stress on soil. Vegetative cover offers a number of important advantages, including reducing raindrop impact, slowing runoff velocity, helping to absorb water, and holding soil in place. In regard to topography, both slope gradient and length tend to increase velocity and the resulting frictional

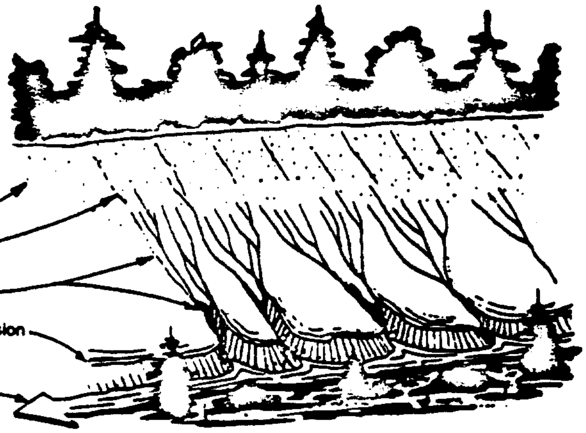

Figure 1. Soil erosion processes (3).

shear stress. Erosion hazards relative to slope gradient and length are listed in Table 1.

Acquiring the familiarity with the site and proposed construction necessary to proceed with the ESC plan involves data collection and analysis. Site data should be collected in regard to:

- Soils
- Vegetation
- Topography
- Ground-water table
- Neighboring water bodies
- Adjacent properties
- Drainage routes and patterns (define subbasins)
- Potential areas of serious erosion problems
- Existing development, utilities, and dump sites

The following construction plan information should be cataloged at the outset of planning:

- Grading (location, amount)
- Topographic changes
- Clearing and grading limits
- Drainage changes

Table 1. Soil Erodability Relative to Slope Gradient and Length

Erosion Hazard	Slope Gradient	Maximum Length
Low	0-7%	300 ft
Moderate	7-15%	150 ft
High	>15%	75 ft

- Materials to be used and locations of use and storage
- Access points

ESC planning should proceed with reference to certain basic principles, as follows:

- First consider all means of preventing erosion; only consider trapping sediments from unavoidable erosion. Prevention has the potential to be more effective in resource protection than later treatment and less costly.
- Phase construction and post clearing limits to maintain as much natural vegetation as possible and for as long as possible.
- Plan construction to fit the site; use terrain advantageously and avoid critical areas.
- Cluster buildings and other developed features, and minimize their impact on impervious area.
- Plan for control of erosion subbasin by subbasin.
- Minimize extent and duration of vegetation removal (especially during wet season) and soil disturbance.
- Stabilize and protect disturbed areas as soon as possible.
- Use natural drainage features, existing vegetation, and materials found on the site.
- Minimize slope length and gradient to control runoff velocities.
- Divert offsite runoff away from disturbed areas.
- Retain any released sediment within the construction area and reduce tracking off site.
- Have a thorough maintenance and followup program.
- Take measures to control potential pollution from construction materials (e.g., paving materials, petroleum

products, other vehicle fluids, fertilizers, pesticides, grinding and sanding debris, wastes).

An ESC plan consists of a narrative and site plans. Points that should be covered by the narrative include 1) a project description, 2) a description of existing and modified site conditions, 3) descriptions of ESC best management practices (BMPs), 4) descriptions of BMPs for pollutants other than sediments, 5) plans for permanent stabilization, 6) calculations, and 7) provisions for inspection and maintenance. Site plans are maps and engineering plans illustrating and specifying the project's location, existing and modified site conditions, and BMPs. The set of site plans should include 1) a data collection worksheet (principally showing topography, soils, and vegetation), 2) a data analysis worksheet (mainly indicating drainage subbasins and primary drainage courses), 3) a site plan development worksheet (showing existing and finished contours, roadways, and permanent stormwater facilities), 4) the ESC plan (showing BMP locations), and 5) diagrams of representative BMPs, as appropriate. The ESC plan (item 4 in the set) is the key element for implementing the plan. BMPs are usually specified on this plan using a system of symbols, which are defined in a legend.

Inspection and Enforcement

The most important general needs of an inspection and enforcement program are a staff dedicated to the function, specific staff training, and administrative support. These needs are best provided for by a dedicated revenue source, such as a stormwater utility assessment. The staff should not have unrelated and distracting duties such as inspection of other facets of construction. Initial training should offer needed background in, for instance, legal and regulatory requirements, water quality, hydrology, soils, and vegetation. Subsequent training should provide detailed coverage of BMP requirements, such as discussed in the following section. Strong support from administrators is essential for a staff undertaking a relatively new function that might be unpopular in terms of economic interests.

Beyond these basic needs are some specific issues to clarify during program development for incorporation as formal program elements. Recommendations on the issues presented in this paper are drawn from experience in the Puget Sound region, especially in King County and the cities of Bellevue and Redmond. One of these issues is the response to a situation in which measures in an approved ESC plan proved inadequate. Strong permit review should normally limit these instances, but unforeseen circumstances can still arise. Inflexible adherence to an ESC plan can be self-defeating when measures prove to be inadequate for whatever reason; thus, the jurisdiction should retain the authority to require additional measures if needed. This option should be noted in a statement on each ESC plan.

A second issue is how field change orders will be handled. The policy should call for careful but expeditious consideration of requests for plan changes, generally after consultation with plan review personnel. Finally at issue is the granting of variances from code requirements. Conditions on granting variances should be strict and specific, such as:

- The expected result should be at least comparable to the outcome expected to be achieved with the approved method.
- Sufficient background information and justification should be presented for adequate assessment of the alternative.
- The ability should be retained with the variance to meet objectives of safety, function, appearance, environmental protection, and maintainability based on sound engineering judgment.
- The variance should be in the public interest.

Enforcement authority must be obtained and the system of enforcement defined and made clear to the regulated parties. A system successfully used by the city of Bellevue has a sequence of three steps, as follows:

- A verbal warning, with a deadline for correction.
- A correction notice (with specifications of corrections), a deadline, and a warning about the consequences of noncompliance.
- A stop-work order, with a warning about the consequences of noncompliance.

ESC Practices and Their Inspection

Categories of Practices

The numerous ESC practices in use can be categorized in various ways. The most basic division is between erosion control practices, which prevent or minimize erosion, and sediment control practices, which attempt to capture soil released through erosion. Within each of these broad groupings are several categories that represent general strategies for achieving either erosion control or sediment control. In addition to sediments, construction sites can generate many other pollutants, such as petroleum products, solvents, paints, sanding dusts, pesticides, and fertilizers. It is most efficient to manage those materials along with sediments and to inspect the management practices for them simultaneously with ESC inspection. Therefore, these practices represent another basic division.

Following is the breakdown of ESC practices used by Reinelt (1), with the number of individual practices in each category. The 29 practices represented are by no means the only ones, but they are the most widely recognized and used. Twenty-two of the 29 (all but the sediment trapping techniques) are preventive and are thus generally the most cost-effective options; however, the straw bale and filter fabric fences and sedimentation ponds among the trapping techniques are most commonly used practices.

1. Erosion control
    1.1. Natural vegetative cover—two practices
    1.2. Temporary cover—three practices
    1.3. Permanent vegetation establishment—two practices
    1.4. Stabilized construction entrance and roads—three practices
    1.5. Runoff control—eight practices
2. Sediment trapping techniques—seven practices
3. Management of other construction site pollutants—four practices

The following passages provide inspection checklists for example practices, generally the most common, in each category and subcategory. The checklists are divided into checks to be made when the practice is implemented and checks to be made on each followup visit to determine the need for maintenance or replacement of the ESC materials. Many of the points are illustrated in diagrams that accompany the checklists.

While much of an inspector's work is performed in the field, it is often advisable or even absolutely necessary to do some background work in the office before going out to inspect an installation. This work mainly consists of consulting the ESC plan to determine the specifications. The plan should be retained on the construction site should the inspector or construction personnel need to refer to it.

1. Erosion control

1.1. Natural vegetative cover

1.1.1. Phasing construction

Phasing construction is a practice in which clearing operations are performed in stages to take advantage of cover that exists on site before construction.

Installation checks:

1. Are areas that will not be cleared set off with plainly visible clearing-limit fencing?
2. Is plainly visible flagging placed at the drip line of trees to be protected (see Figure 2)?
3. Are fills and cuts near protected trees treated as shown in Figure 2?
4. Is final vegetation established as soon as portions of the site can be made ready?

Maintenance checks:

1. Do fencing and flagging need repair or replacement for personnel to see it clearly?
2. Do exposed or injured roots of protected trees need covering or dressing?

1.2. Temporary cover

Temporary cover practices recognize that portions of most construction sites remain unworked for months, during which time very large amounts of erosion can occur unless these areas are stabilized. Stabilization can be achieved with temporary seeding or various kinds of slope coverings, or both. Slope coverings include both mulches and commercial mats and blankets. It is often necessary to apply temporary cover to different areas several times during construction.

Mulches, mats, and blankets can serve several purposes in erosion control: covering the slope temporarily to prevent erosion by raindrop impact and the friction of runoff, holding water to encourage grass growth, protecting grass seedlings from heat, and enriching the soil. Straw, hay, wood fiber, wood chips, and other natural organic materials can serve as mulches. Inspection guidelines for straw and wood fiber are given below as examples. Mats and blankets are manufactured from both natural and synthetic materials. Guidelines are given for several varieties.

1.2.1. Temporary seeding

Installation checks:

1. Is the soil stabilized within the period specified by regulation? (This period varies from place to place, depending on climate patterns. In the Puget Sound area of Washington, which receives most of its rainfall in the winter, the specified periods are within 2

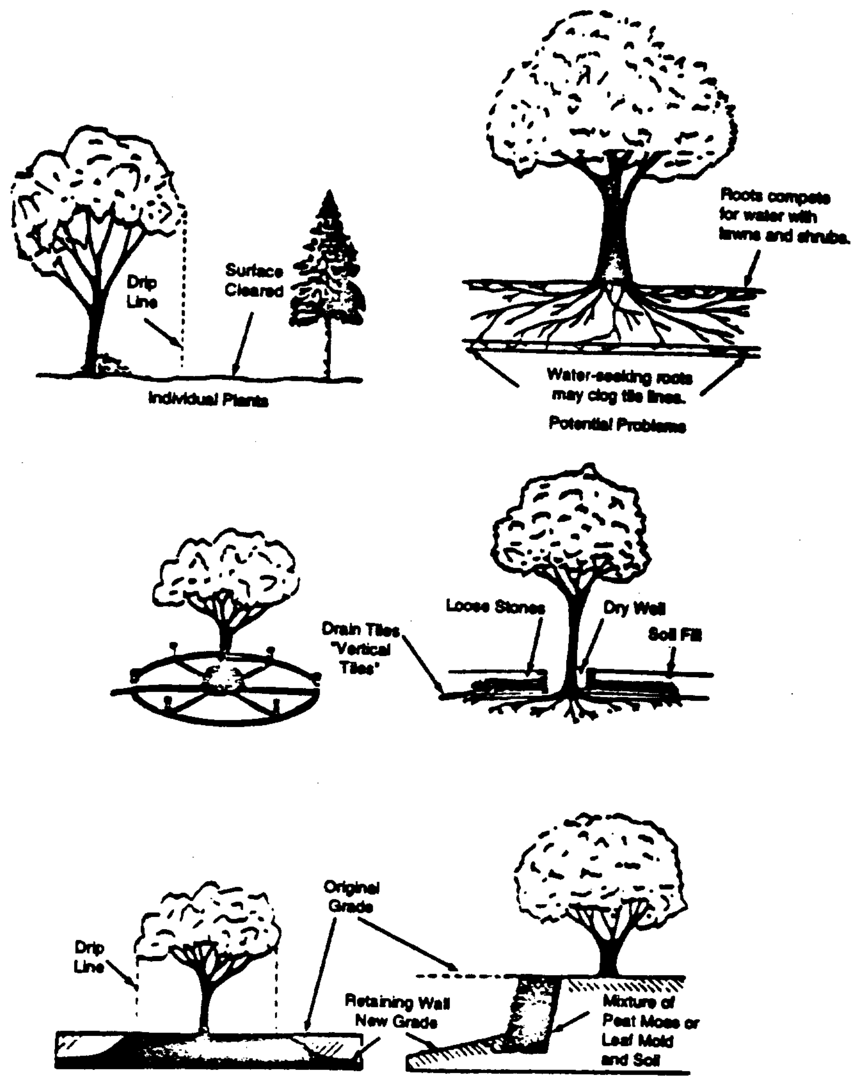

Figure 2. Guidelines for preserving natural vegetation (3).

days during the months October to April and within 7 days during the months May to September.)

2. If used without slope covering practices, is temporary seeding limited to slopes of less than 10 percent and 100 ft in length? If the slope exceeds either limit, is a mulch or mat slope covering used?

3. Has the seedbed been prepared with at least 2 to 4 in. of tilled topsoil?

4. Is fertilizer use limited as much as possible; if used, is it applied in amounts no greater than the needs of the grass for the prevailing soil conditions?

5. Is mulch applied for protection if seeding occurs when temperatures can be high or runoff is likely to occur before the grass is well established?
6. Is irrigation provided if planted when rainfall might be insufficient for good establishment?

Maintenance checks:

1. Is it necessary to irrigate and/or reseed?
2. Is maintenance fertilizer needed?

1.2.2. Straw mulch

Straw mulch can be used without seeding or, for better erosion control, with seeding.

Installation checks:

1. Is the straw spread generally a minimum of 2 in. deep (corresponds to 2 to 3 tons per acre) and greater on very steep slopes, adjacent to sensitive areas, and where concentrated flow passes over the slope?
2. Is the mulch anchored as needed by crimping, disking, rolling, or punching into soil or by moistening, tackifying, or netting?

Maintenance checks:

1. Is replacement needed as a result of blowing away or decomposition over time?
2. Is there any fire hazard requiring moistening?

1.2.3. Wood fiber mulch

Wood fiber mulch should only be used with seeding and generally should be used with a soil bonding agent.

Installation checks:

1. Is the mulch used with seeding and a soil bonding agent? Were the bonding agent distributor's application guidelines followed?
2. Has the wood fiber been applied to cover the soil completely, allowing no bare soil to show through (corresponds to about 1 ton per acre and is adequate for most circumstances)? Are there any special circumstances, such as seeding during hot weather, when the amount should be increased by about 50 percent?

Maintenance checks:

1. Is replacement needed as a result of loss over time?

1.2.4. Excelsior

Excelsior is a product made of fine wood shavings that assume a more-or-less helical form. As a consequence of this form, excelsior does not lie in close contact with the soil and allows runoff to drain beneath it and cause erosion. Therefore, it should be used only with seeding, where it is very useful in holding moisture and providing protection from direct sun in hot periods. Suppliers generally market several grades for sheet and channelized flow and different velocities.

Installation checks:

1. Is the excelsior used only with seeding?
2. Was an appropriate material selected according to manufacturer's recommendations and then placed and stapled as recommended by the manufacturer?
3. On slopes, was it placed 3 ft over the crest or in an anchor ditch?
4. In ditches, was it placed in the direction of water flow with any seams offset 6 in. from the ditch centerline?

Maintenance checks:

1. Is replacement needed as a result of damage or loss over time?

1.2.5. Mats and blankets

Examples of materials produced in a mat or blanket form for erosion control are jute, woven straw, and synthetics. Mats can be used without seeding, or with seeding for better erosion control. As with excelsior, suppliers generally market several grades for sheet and channelized flow and different velocities.

Installation checks:

1. Was an appropriate material selected according to manufacturer's recommendations and then placed and stapled as recommended by the manufacturer?
2. Was it placed in the direction of water flow, in full contact with the soil but not tightly stretched?

Maintenance checks:

1. Is replacement needed as a result of damage or loss over time?

1.3. Permanent vegetation establishment

Permanent vegetation should be established as soon as possible after all construction is completed in each segment of the site. Grass can be established by seeding or sodding. Seeding is generally preferred because of the lower cost and greater flexibility in selecting grass species. Sod is often available only in limited varieties, which may not be the most suitable for erosion control and other purposes unless grown to order. In some cases, overseeding with preferred species is recommended in the spring, when grass must be established with sod in the winter. Species should be selected based on local climatological and soil conditions, with reference to regional guidance documents, and, when necessary, in consultation with regional experts.

1.3.1. Permanent seeding

Installation checks:

1. Has the seedbed been prepared by loosening with a plow if subsoils are highly compacted, spreading 2 to 6 in. of topsoil, and lightly rolling?
2. Is fertilizer use limited as much as possible; if used, is it applied in amounts no greater than the needs of the grass for the prevailing soil conditions?
3. Is mulch applied for protection if seeding occurs when temperatures can be high or runoff is likely to occur before the grass is well established?
4. Is irrigation provided if planted when rainfall might be insufficient for good establishment?

Maintenance checks:

1. Is it nencessary to water, reseed, or add fertilizer?

1.3.2. Sodding

Installation checks:

1. Is the sod placed from the lowest area and perpendicular to water flow?
2. Are sod strips wedged tightly together and joints staggered at least 12 in.?
3. Is the sod stapled if on a steep slope?

Maintenance checks:

1. Is overseeding needed, either to repair damage or to install a preferred grass species?

1.4. Stabilized construction entrance and roads

The entrance is the most important access route to stabilize, since it is the last point at which tracking sediment off site can be stopped. If equipment travels extensively on unstabilized roads on the site, a tire and vehicle undercarriage wash near the entrance will be needed. Perform washing on crushed rock. Wash water will require treatment in a sediment pond or trap.

1.4.1. Stabilized construction entrance (see Figure 3)

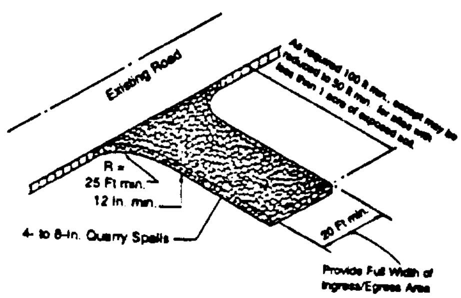

Figure 3. Stabilized construction entrance (from Washington Department of Ecology, 1992).

VOL 12

9072

Installation checks:

1. Is the entrance constructed with quarry spalls 4 to 8 in. in size and at least 12 in. thick?
2. Is the stabilized entrance sized correctly for the site?
3. If the entrance sits on a slope, is a filter fabric fence in place downgradient?

Maintenance checks:

1. Is the entrance clogged with sediments, requiring top dressing the pad with clean 2-in. rock?
2. Is it necessary to clean up any sediments carried from the site onto the street?

1.5. Runoff control

Runoff control represents various practices designed to keep water from coming in contact with bare soil or controlling its velocity if it does. Included are drains for surface and subsurface water, dikes and swales placed across slopes to interrupt runoff, and roughness created on the surface to reduce velocity. Example guidelines presented below are for a pipe slope drain and surface roughening.

1.5.1. Pipe slope drain (see Figure 4)

A temporary pipe slope drain is an effective technique for preventing erosion on a slope caused by runoff from a higher elevation. Upslope runoff needs to be collected and directed into the drain effectively and then discharged in a controlled way to prevent erosion at the bottom of the slope.

Installation checks:

1. Are no more than 10 acres drained into a single pipe slope drain?
2. Was a minimum 6-in. metal toe plate placed at the entrance to prevent undercutting?
3. Is runoff directed into the pipe with interceptor dikes at least 1 ft higher at all points than the top of the pipe?
4. Is there a slope toward the pipe on a grade of at least 3 percent at the inlet?
5. If the pipe is 12 in. in diameter or larger, was a flared entrance section installed and connected securely to the drain with water-tight connecting bands?

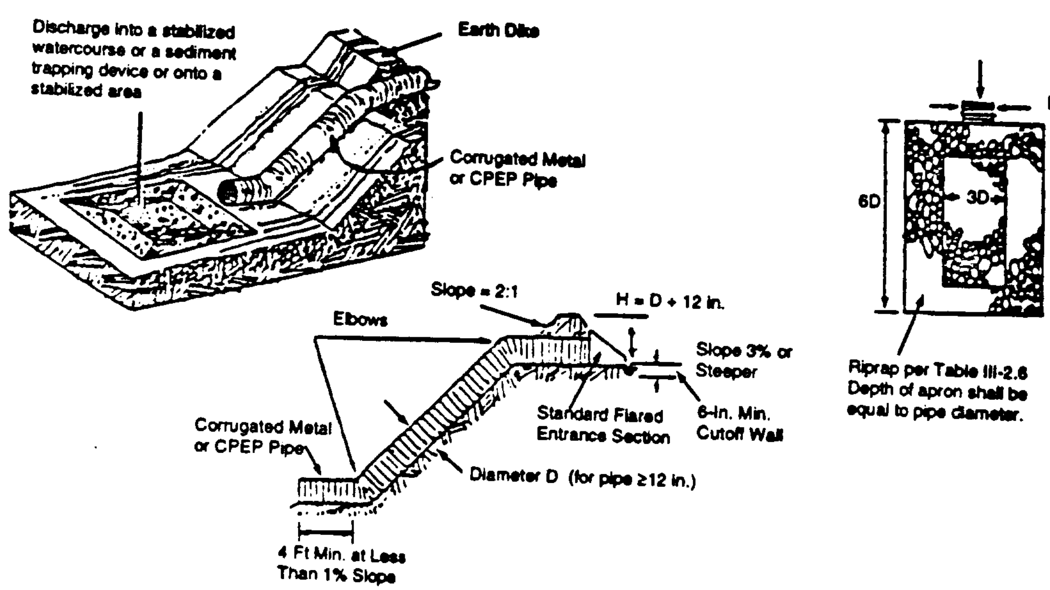

Figure 4. Pipe slope drain details (3).

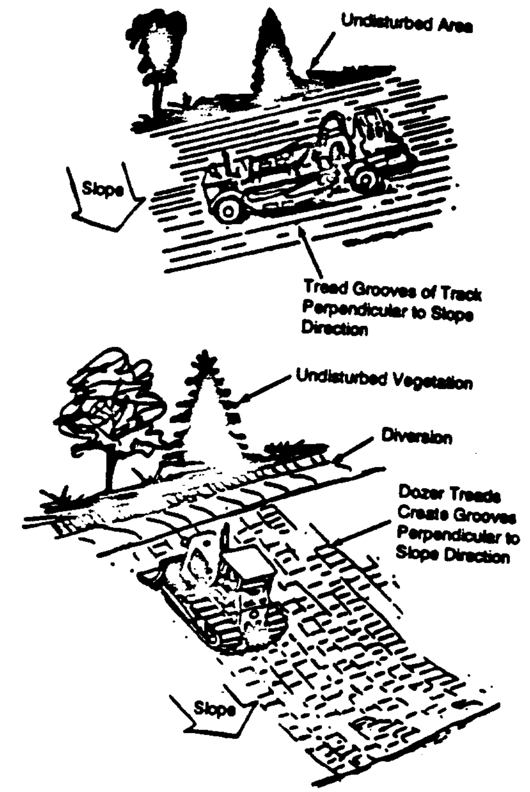

Figure 5. Examples of surface roughening using heavy equipment (3).

6. Was the soil thoroughly compacted at the entrance and underneath the pipe?

7. Were gasketed, water-tight fittings placed between pipe sections, were the sections securely fastened, and was the drain anchored to the soil?

8. Was the area below the outlet stabilized with a riprap apron?

9. If the drainage can carry sediment, is it treated in a sediment pond or trap?

Maintenance checks:

1. Is undercutting or bypassing occurring at the inlet, requiring reinforcing of the headwall with compacted earth or sandbags?

2. Is erosion occurring at the outlet, necessitating rebuilding the apron?

1.5.2. Surface roughening (see Figure 5)

A roughened surface is an easy and inexpensive way to reduce runoff velocity, encourage the growth of vegetation, increase runoff infiltration, and trap some sediment. It is not effective enough to use alone but can reduce the load on sediment trapping installations downstream. Roughening is best used on slopes steeper than 3 horizontal to 1 vertical that do not require mowing. There are several methods of roughening a surface, all of which involve forming horizontal depressions with equipment. Methods include tracking perpendicular to the slope direction, driving treaded equipment along the slope direction to get grooves perpendicular to the slope, or tilling (preferred because it avoids compaction). On steeper slopes (steeper than 2 horizontal to 1 vertical) a stair-step pattern should be formed.

Installation checks:

1. Have all exposed slopes steeper than 3 horizontal to 1 vertical been roughened, with 40- to 50-in. stair-step patterns formed on slopes steeper than 2 horizontal to 1 vertical?

2. Was the soil scarified if it was heavily compacted by the roughening?

3. Was the area seeded as quickly as possible?

Maintenance checks:

1. Have rills appeared that should be regraded and reseeded?

2. Sediment trapping techniques

Trapping sediments once they are released requires slowing the transport velocity sufficiently for soil particles to settle (i.e., reducing the velocity below the settling velocity of the particles). Soil particles range over several orders of magnitude in size, from the small clays to the large sands. Settling velocity is approximately related to the square of the particle diameter; thus, halving the diameter approximately quadruples the time needed for settlement. Therefore, as particles decrease in size, they become

VOL 12

9074

increasingly difficult to remove from a runoff stream. This fact is largely why preventive techniques are more cost effective than sediment trapping practices and are strongly preferred.

The two basic types of sediment trapping techniques in use are sediment barriers and settling ponds. Sediment barriers include the commonly used filter fabric and straw bale fences as well as brush fences and barriers constructed of gravel. Both types trap sediments in the same way, by ponding water. Although that mechanism is more obvious in the case of ponds than of barriers, practices of the latter type actually provide only a minimum of filtering capability and primarily slow the flow of water long enough for some particles to settle. Thus, they can only trap relatively large particles, generally the larger silts and sands. The trapping ability of settling ponds depends on their size. While they can theoretically be made large enough to trap any size particle, practical sizes generally limit efficient removal to the medium silts and larger.

2.1. Sediment barriers

Several principles apply to the various types of sediment barriers. Maximizing a sediment barrier's ponding volume maximizes the amount of sediment trapped. Therefore, the barriers should be placed away from the immediate toe of slopes in order to increase the area for ponding. It is very important that sediment barriers be aligned on the contour, not up and down slopes. This alignment places them at a right angle to flow paths and also increases ponding volume. Slopes draining to sediment barriers generally should not be more than 100 ft long. Sediment barriers must be trenched in and staked to hold up under the pressure of the wall of water they will dam. Finally, sediment barriers do not provide effective sediment removal from concentrated flows. While straw bales are sometimes used in ditches, rock check dams are really a better alternative for decreasing velocity in channels.

2.1.1. Filter fabric fence (see Figure 6)

Installation checks:

1. Are filter fabric fences used only in the following applications:

   Maximum of 1 acre served by a single fence?

   Maximum 1:1 slope gradient and 100-ft slope length?

   Sheet flow situation (never in concentrated flow)?

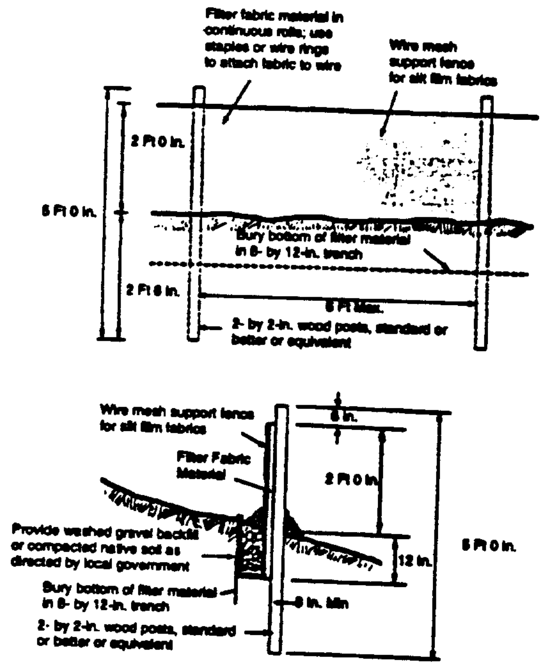

Figure 6. Filter fabric fence detail (3).

2. Is the fence aligned to slope contours as well as possible?

3. Is the fence installed so that its height above the soil is no more than 3 ft?

4. Are posts 2 x 4 in. wood or 1.33 lb/ft steel, or the equivalent?

5. Are posts buried 2.5 ft deep whenever possible and spaced no more than 6 ft apart?

6. Is fabric attached on the upslope side with staples (at least 1 in.), tie wires, or hog rings?

7. Is the end of the fabric buried in a trench sized as shown in Figure 6 and backfilled on both the upslope and downslope sides (as shown)?

8. Is splicing avoided if possible? If impossible, is splicing done only at posts and overlapped at least 6 in.?

9. Nonwoven and woven monofilament materials have the best properties for silt fencing. If a woven slit-film fabric is used, is wire mesh reinforcing (14-gauge rein-

forcing wire mesh with openings no larger than 6 in.) placed on the upslope side and fastened the same as the fabric?

Maintenance checks:

1. Is it necessary to restake, reattach, or replace the fence to maintain all of the above conditions?

2. Is sediment removal needed (before it reaches 1/3 the height of the fence)?

2.1.2. Straw bale fence (see Figure 7)

Straw bale fences tend to swell when they get wet and require frequent maintenance. They are not highly recommended but could be more effective if used according to the following guidelines.

Installation checks:

1. Are straw bale fences used only in the following applications:

   Maximum of 1/4 acre served per 100 ft of fence length?

   Maximum 2:1 slope gradient and 100-ft slope length?

2. Is the fence aligned to slope contours as well as possible?

3. Are the bales bound with wire, preferably, or string placed around the sides of the bale, parallel to the ground?

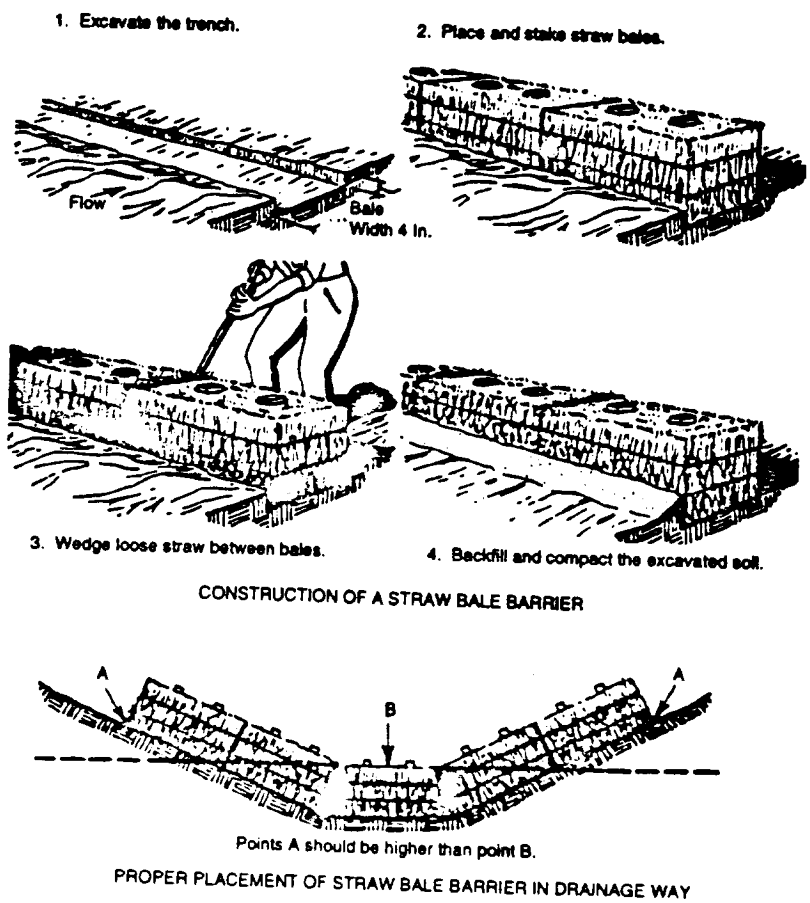

Figure 7. Proper installation of straw bale fences (3).

4. Are the bales installed in a 4-in. trench, as shown in Figure 7, and backfilled with 4 in. of soil on the upslope side?

5. Are the bales forced together as tightly as possible and anchored with at least two stakes or pieces of rebar per bale driven toward the previous bale and flush with the top of the bale?

6. Are gaps wedged with straw, and is straw spread on the upslope side?

7. Are straw bale fences used in channels with concentrated flow only when velocities are low and placed as shown in Figure 7 (perpendicular to flow and extending at least one bale length above the mid-channel bale)?

Maintenance checks:

1. Is it necessary to replace the fence to maintain all of the above conditions?

2. Is sediment removal needed (before it reaches 1/2 the height of the fence)?

2.2. Settling ponds

Settling ponds have several advantages. They can function through all construction phases and have relatively low maintenance requirements. They can also be located to intercept runoff both before and after the onsite drainage system is developed.

The three types of settling ponds in use differ only in their outlet structure. The term sediment basin is used to describe a settling pond with a pipe outlet that generally serves a drainage area of 3 to 10 acres. A sediment trap is a settling pond with a stable spillway outlet and a smaller service area. The third type is a permanent water quantity control pond put in temporary service during construction; such a pond is designed to drain completely between storms in permanent service. This operating mode is not appropriate for ESC application, however, because the residence time is too short for good particle trapping and settled material becomes resuspended during draining. Therefore, a temporary riser outlet needs to be installed for use during construction.

A key point in the design and construction of a settling pond is to avoid short-circuiting by the water. Short-circuiting can cut the actual residence time far below the theoretical value and harm performance. Ways of avoiding it are to divide the pond into two or more cells, locate the inlet and outlet far apart, and install baffling to increase the flow path.

2.2.1. Sediment basin (see Figure 8)

Installation checks:

1. Is the bottom graded to be as level as possible?

2. Is the pond no deeper than 7 ft with 1 ft of freeboard?

3. Are side slopes no steeper than 3 horizontal to 1 vertical?

4. Does the pond have an emergency spillway that is 1 ft deep, with a width two to three times the number of acres served by the pond, and lined with 2 to 4 in. of rocks?

5. Does the pond discharge through a riser pipe having at least two 1-in. diameter orifices at the top of the sediment storage zone?

6. Are inlet and outlet areas protected from erosion with riprap?

7. Is baffling installed if the length-to-width ratio is less than 6 or if the entrance velocity is high?

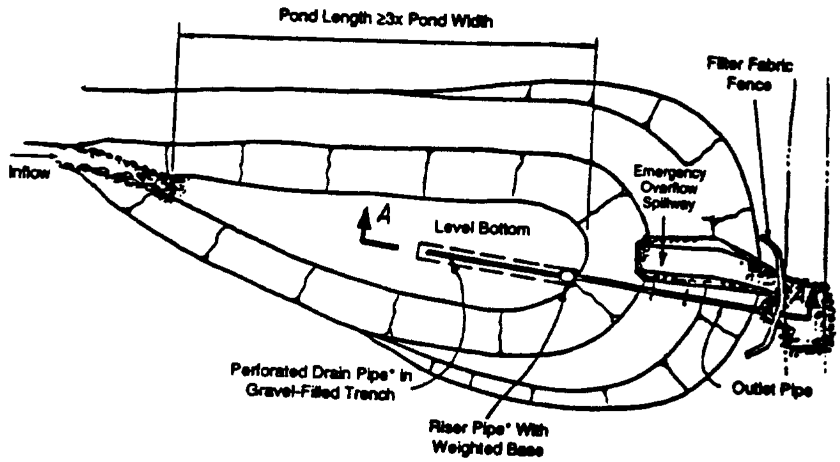
8. A good feature to prevent short-circuiting of flow is a two-celled pond, preferably with cells divided by sandbags or a rock berm and connected by a riser pipe similar to that used for the outlet. A less preferred arrangement is dividing the pond with a filter fabric fence. Is this feature installed if specified in the design?

9. Is the pond fenced if it presents any safety hazard to children?

Maintenance checks:

1. Is sediment removal needed (before 1.5 ft accumulates)?

2. Are any outlet orifices clogged and in need of cleaning?



*Sediment dewatering may be accomplished with perforated pipe in trench as shown or with a perforated riser pipe covered with filter fabric and a gravel "cone." A control structure may also be required; see Conditions Where Practice Applies.

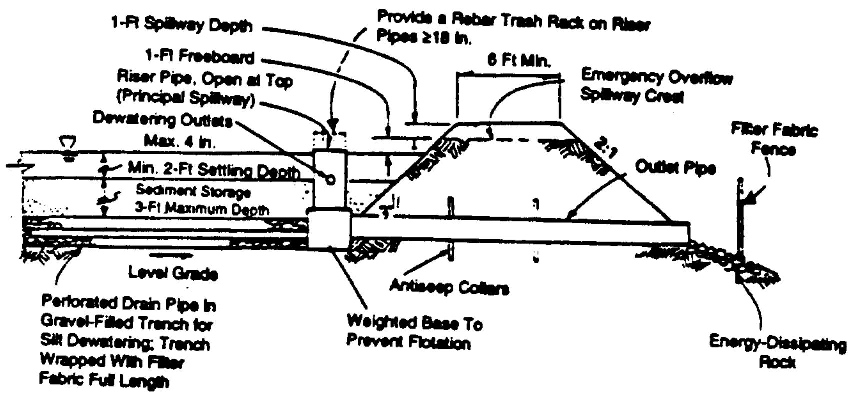


Figure 8. Typical sediment basin (3).

3. Are any embankments damaged and in need of compaction or rebuilding?
4. Has riprap or spillway lining material been lost and need to be replaced?
5. Are there signs of excessive drainage to the pond, requiring rerouting or pond enlargement?
6. Are there signs of excessive sediment loading to the pond, requiring stabilization of the drainage area?

3. Management of other construction site pollutants

Construction sites can create pollution problems over and above erosion and sediments through paving operations, handling and storage of various materials, spills, and waste handling. Inspectors should also be aware of the potential for runoff contamination from these sources and inspect the site according to the following guidelines.

3.1. Handling cement and concrete

Inspection checks:

1. Do concrete trucks have a designated washout area with a sediment trap?

VOL 12

9078

2. Is exposed-aggregate driveway wash water drained toward a collection point at the side or into a sediment trap, where it cannot get into a street drainage system?

3.2. Material storage and handling

Inspection checks:

1. Are weather-resistant enclosures used for the storage and handling of materials, such as paints, coatings, wood preservatives, pesticides, fuels, lubricants, and solvents, and for potentially polluting wastes?
2. Are there designated and clearly communicated procedures for handling materials and wastes and washing containers?
3. Is a chemical inventory maintained, including Material Safety Data Sheets?
4. Are containers and enclosures inspected periodically for leakage, indicating the need for maintenance?

3.3. Spill containment

Inspection checks:

1. Has a spill control plan been developed, and have supplies been obtained to implement it? Does the plan include:

   Who to notify if a spill occurs?

   Specific instructions for different products?

   Who is in charge?

   Spill containment procedures?

   Easy to find and use spill cleanup kits?

   How a spill will be prevented from getting into a drainage system (e.g., valving, diversion, absorption)?

   A disposal plan?

   A worker education program?

3.4. Waste management

Inspection checks:

1. Have waste reduction practices been instituted (e.g., reusing solvents, substituting for toxic products, minimizing quantities of materials used)?
2. Have recycling practices been instituted (e.g., waste separation for recycling, purchasing recycled materials)?
3. Are hazardous and nonhazardous wastes separated and each disposed of properly and promptly?
4. Has an employee education program on waste management been established?

Inspection Programs for Permanent Drainage Practices and Facilities

Program Development

Program Elements

The following elements are recommended for a comprehensive inspection program for permanent drainage practices and facilities:

- Stormwater management planning
- Plan review process
- Construction inspection and enforcement process
- Followup inspection and long-term maintenance process

The stormwater management planning step ensures that each site considered for a permit receives comprehensive analysis. The extensive considerations in this portion of the recommended program are beyond the scope of this discussion. The third element refers to inspection of the stormwater management facilities themselves when they are built to determine whether installation has been consistent with the approved plans. The final element seeks to ensure that facilities continue to operate properly. The next subsection covers programmatic aspects of the followup inspection and long-term maintenance process. The discussion is then extended in the following section to examples of inspection guidelines for common practices and facilities.

Followup Inspection and Long-Term Maintenance Process

Recommended features for a followup inspection and maintenance program are:

- An ordinance designating public authority and public and private responsibilities.
- A tracking system.
- An inspection schedule.
- A maintenance schedule.
- A safety program.
- A citizen response program.
- A detailing of proper waste disposal practices.
- A maintenance contractor education program.

The discussion below elaborates on several of these features, drawing principally on experience in King County, Bellevue, Olympia, and elsewhere in the Puget Sound region of Washington. The examples in the section that follows this discussion present guidance on establishing schedules for common facilities and the specific checks to be made during inspection visits.

Public Versus Private Responsibilities. Whereas inspection is usually a public function, the question of responsibility often arises with respect to the upkeep of privately owned facilities. One model involves establishing a multiyear bonding period, during which the developer has all responsibility. Often after this period and a demonstration of effective operation, the government agency responsible for stormwater management then takes over operation and maintenance. A second model calls for leaving maintenance as a private function (performed by a commercial property owner or homeowners' association), with inspection by the public agency. In this approach, the government assumes the responsibility and assesses costs if the private party does not meet its responsibility. Effective application of this strategy requires that private maintenance contractors competently perform the needed work. The frequent lack of qualified contractors requires government agencies to consider training and certifying them.

Tracking System. King County, Washington, offers a useful model for a tracking system to organize long-term inspections and maintenance. The King County approach uses a computerized information system. Each inspector is assigned an inventory of facilities to inspect and specify maintenance and is given a laptop computer to use in the field. The information system contains an identification number for each facility, its type (e.g., wet pond, infiltration basin), location, any special needs, and data on previous experiences. At the conclusion of each visit, the inspector enters a maintenance needs assessment in the computer database. The computer then generates a maintenance work order.

Safety. Safety is a major consideration because of potentially harmful air quality in below-ground spaces, corroded supports, traffic, falling objects, sharp edges, poisonous plants and insects, and lifting. The safety portion of an inspection and maintenance program should include:

- Testing instruments for harmful atmospheres (explosive, containing hydrogen sulfide, lacking in oxygen); a tester should be capable of checking all potential conditions of concern, and all enclosed spaces should be tested before an inspector enters.
- Ventilating equipment.
- Checking for structural soundness before entering a manhole.
- Traffic warning devices.
- Ladders, safety harnesses, and hard hats.
- Removing poisonous plants and threatening insect nests.
- Adequate personnel.
- Safety training.

Waste Handling. Major maintenance on large facilities should be scheduled when the least runoff is expected. It is often a good idea to use ESC-type installations such as filter fabric fences, sandbags, grassed drainage areas, and revegetation to prevent escape of sediments during maintenance.

Although the vactor truck is the maintenance workhorse, a problem concerns mixing waste that may be relatively clean with very dirty waste. A solution, but an expensive one, is to have "clean" and "dirty" trucks. Another issue concerns disposal of both solids and separated "decant" water picked up by vactor trucks. The best solution for decant water is to discharge it to a special decant station that has sediment and oil separation equipment, before the water is discharged to a sanitary sewer. Few facilities currently operate this way, and most vactor waste is discharged directly to a sanitary sewer. This practice can result in pollutants entering surface waters because of inadequate treatment at the municipal wastewater plant. It can also deliver toxic materials that can upset biological processes at the treatment plant. Guidelines are needed but generally do not exist for disposing of solids. The best programs now send them to a lined municipal landfill, unless they fail a "looks bad and smells bad" test, in which case they are treated as hazardous waste.

Permanent Drainage Practices and Facilities and Their Inspection

Categories of Practices and Facilities

Following is the breakdown of practices used by Reinelt (2), with the number of individual practices in each category:

1. Stormwater devices—three practices
2. Detention facilities—eight practices
3. Infiltration facilities—five practices
4. Biofilters—three practices

The 19 practices represented include some variations on common devices, depending on their intended function, as specified by the Stormwater Management Manual for the Puget Sound Basin (3). For example, detention facilities include "wet ponds," which have a quantity control function, and "water quality wet ponds," which are treatment devices.

The following passages provide inspection checklists for example practices and facilities, generally the most common, in each category. The practices and facilities themselves are described only very briefly in this section. For detailed descriptions, consult a stormwater management manual or textbook. The checklists are divided into checks to make when the practice or facility is first installed and checks to be made on each followup visit to determine the need for maintenance. Many of the points are illustrated in diagrams that accompany the checklists. Also presented for a number of practices are tables of maintenance standards. These tables have been developed over time in the Puget Sound area, and several jurisdictions have contributed to them.

While much of an inspector's work is performed in the field, it is often advisable or even absolutely necessary to do some background work in the office before going out to inspect an installation. This work mainly consists of consulting the design plans to determine the specifications.

Too infrequent inspection and maintenance is one of the main reasons for poor performance by stormwater facilities. The frequency of followup inspections should be determined based on the type of device and the circumstances where it is installed. An inspection and maintenance plan should be developed before an installation goes into service. As a general rule, surface facilities should undergo a drive-by inspection at least monthly and after any rain totaling 0.5 in. or more in 24 hr.

1. Stormwater devices

This group includes devices used for collection and conveyance of stormwater, as well as special-purpose facilities. Within the category are catch basins, pipes and culverts, and oil/water separators. Inspection guidelines are given for oil/water separators as a complete example. Tables of maintenance standards are included for the other types of facilities.

1.1. Oil-Water separators

Figure 9 illustrates the three basic types of oil-water separators. The spill control unit's purpose is to catch small spills; it is not capable of separating dispersed oil. The American Petroleum Institute (API) separator is a baffled tank that can separate "free" (unemulsified) oil but requires a relatively large volume for effectiveness. The coalescing plate (CP) separator can separate free oil in a much smaller volume because of the large surface area provided for oil collection by the corrugated plate pack. The following guidelines generally apply to all types, except as noted.

Installation checks

1. Is the type appropriate for the service?
2. Is the unit sized and installed as specified in the plans?
3. Are adequate removable covers provided for observation and maintenance?
4. Is runoff excluded from roofs and other areas unlikely to contain oil?
5. Is any pump in use placed downstream to prevent mechanical emulsification?
6. Is detergent use avoided upstream to prevent chemical emulsification?
7. For API and CP separators, is a forebay provided sized at 20 ft^2 of surface area per 10,000 ft^2 of drainage area?
8. For API and CP separators, is an afterbay provided for placement of absorbents?
9. For the CP separator, are the plates no more than 3/4 in. apart and at 45 to 60 degrees from horizontal?

Maintenance checks:

1. Is weekly inspection performed by the owner?
2. Are oil and any solids removed frequently enough (at least just before the main runoff period and then after the first major runoff event)?
3. Are absorbents replaced as needed, but at least at the beginning and end of the main runoff season?
4. Is the effluent shutoff valve operational for closure during cleaning?
5. Are waste oil and solids disposed of as specified by regulations?
6. Is any standing water that is removed discharged to the sanitary sewer and then replaced with clean water?

1.2. Pipes and culverts

Refer to Table 2 for a summary of maintenance standards for conveyance facilities.

1.3. Catch basins

Catch basins are routinely placed between the drain inlets in streets and parking lots and the conveyances that transport water away to settle large solids. Refer to Table 3 for a summary of maintenance standards.

2. Detention facilities

Detention facilities include ponds that are designed and operated either to drain within hours after a

Table 2. Maintenance Standards for Pipes and Culverts

Defect	Conditions When Maintenance Needed	Maintenance Results
Sediment and debris	Accumulated sediment that exceeds 20% of the diameter of the pipe.	Pipe cleaned of all sediment and debris.
Vegetation	Vegetation that reduces free movement of water through pipes.	All vegetation removed so water flows freely through pipes.
Damage	Protective coating is damaged; rust is causing more than 50% of deterioration to any part of pipe.	Pipe repaired or replaced.
	Any dent that decreases the end area of pipe by more than 20%.	Pipe repaired or replaced.
Debris barriers	Trash or debris that is plugging more than 20% of the openings in the barrier.	Barrier clear to receive capacity flow.
Damaged/ Missing bars	Bars are bent out of shape more than 3 in.	Bars in place with no bend >3/4 in.
	Bars are missing or entire barrier is missing.	Bars in place according to design.
	Bars are loose and rust is causing 50% deterioration to any part of barrier.	Repair or replace barrier to design standards.

storm (dry ponds), to drain within a day or two (extended-detention dry ponds), or to retain a permanent or semipermanent pool (wet ponds). These ponds can have water quantity control objectives, or water quality control objectives, or both, although dry ponds offer few water quality benefits. Detention facilities also include below-ground concrete vaults and storage pipes, the latter sometimes referred to as tanks. These devices serve primarily quantity control purposes, although if they have relatively long water residence times they can collect some solids. Other facilities sometimes included in this category are parking lot and rooftop storage. Constructed wetlands can be placed in either this group or with biofilters. Inspection guidelines are given for wet ponds as a complete example. A table of maintenance standards is included for vaults and tanks as well.

2.1. Wet ponds

Figure 10 illustrates a typical wet pond. A wet pond has a "dead storage" permanent or semipermanent pool and a "live storage" zone that fills during runoff events and then drains fairly quickly. Its design basis differs depending on its purpose (quantity control or quality control, or both), but the checks made when it is installed and later while it is operating are

Table 3. Maintenance Standards for Catch Basins

Defect	Conditions When Maintenance Needed	Maintenance Results
Trash and debris (including sediment)	Trash or debris of more than 1/2 ft^3 located in front of the catch basin opening or is blocking capacity of basin by >10%.	No trash or debris located immediately in front of catch basin opening.
	Trash or debris in the basin that exceeds 1/3 to 1/2 the depth from the bottom of the basin to the invert of the lowest pipe into or out of the basin.	No trash or debris in catch basin.
	Trash or debris in any inlet or outlet pipe blocking more than 1/3 of the height.	Inlet and outlet pipes free of trash or debris.
	Dead animals or debris that could generate odors that would cause complaints or dangerous gases.	No dead animals or vegetation present.
	Deposits of garbage exceeding 1 ft^3 in volume.	No garbage in catch basin.
Structural damage to frame or top slab	Corner of frame extends more than 3/4 in. past curb face into the street (if applicable).	Frame is even with curb.
	Top slab has holes larger than 2 $in.^2$ or cracks wider than 1/4 in. (intent is to make sure all material runs in to basin).	Top slab is free of holes and cracks.
	Frame not sitting flush on top slab (i.e., separation of >3/4 in. of the frame from top of slab).	Frame is sitting flush on top of slab.
Cracks in basin walls or bottom	Cracks wider than 1/2 in. and longer than 3 ft, any evidence of soil particles entering catch basin through cracks, or structure is unsound.	Basin replaced or repaired to design standards.
	Cracks wider than 1/2 in. and longer than 1 ft at the joint of any inlet/outlet pipe or any evidence of soil particles entering catch basin through crack.	No cracks more than 1/4 in. wide at joint of inlet/outlet pipe.
Settlement/ Misalignment	Basin has settled more than 1 in. or has rotated more than 2 in. out of alignment.	Basin replaced or repaired to design standard.
Fire hazard	Presence of chemicals such as natural gas, oil, and gasoline.	No flammable chemicals present.
Vegetation	Vegetation growing across and blocking >10% of basin.	No vegetation blocking opening to basin.
	Vegetation (or roots) growing in inlet/outlet pipe joints that is >6 in. tall and <6 in. apart.	No vegetation or root growth present.
Pollution	Nonflammable chemicals of >1/2 ft^3 per 3 ft of basin length.	No pollution present other than surface film.

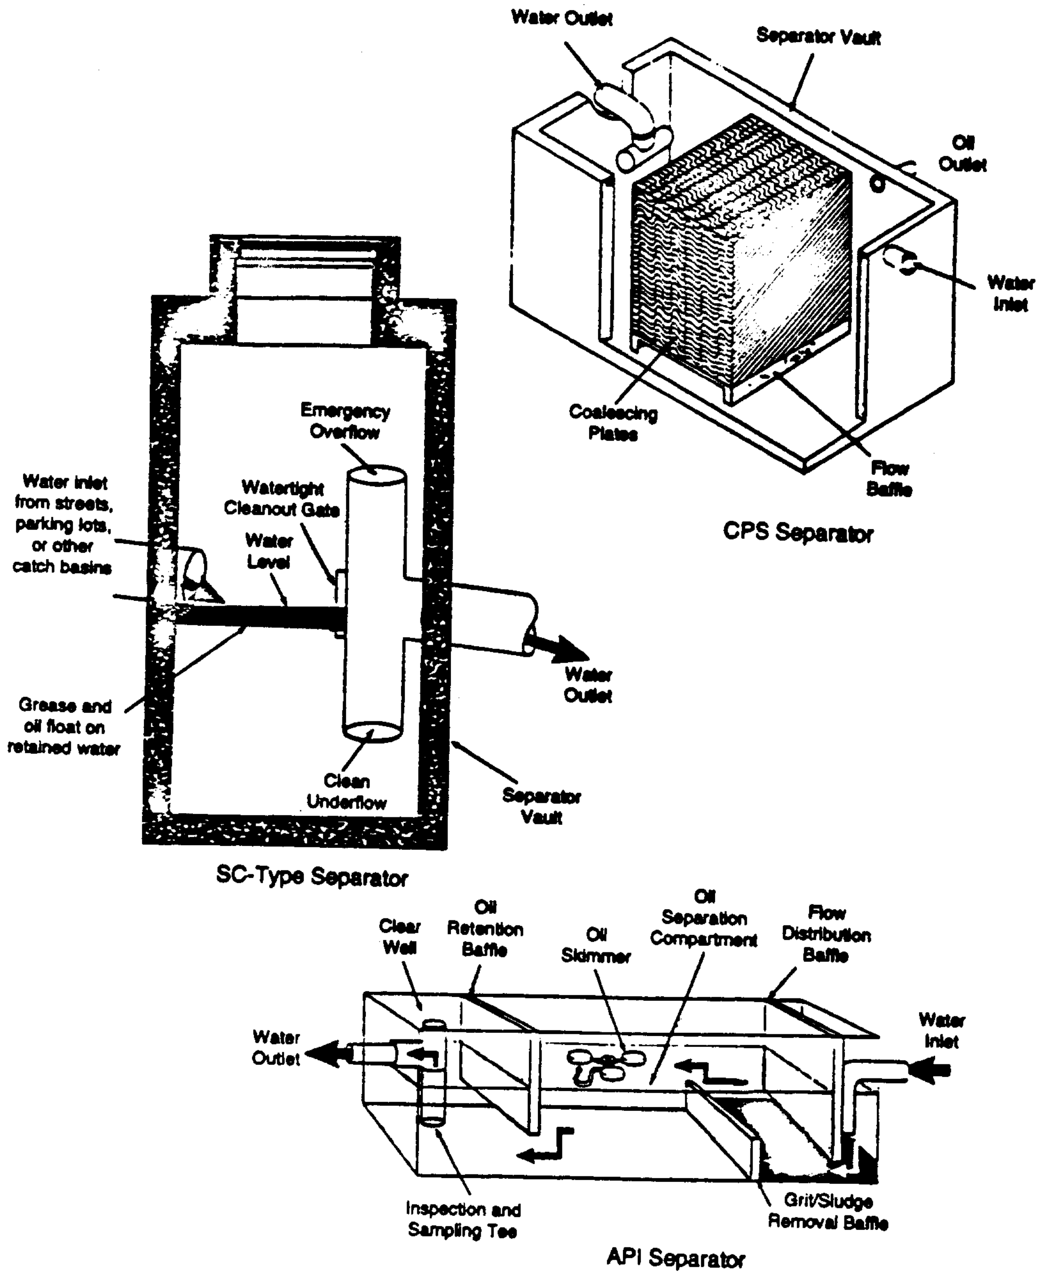

Figure 9. Types of oil/water separators (3).

R0042389

VOL 12

90083

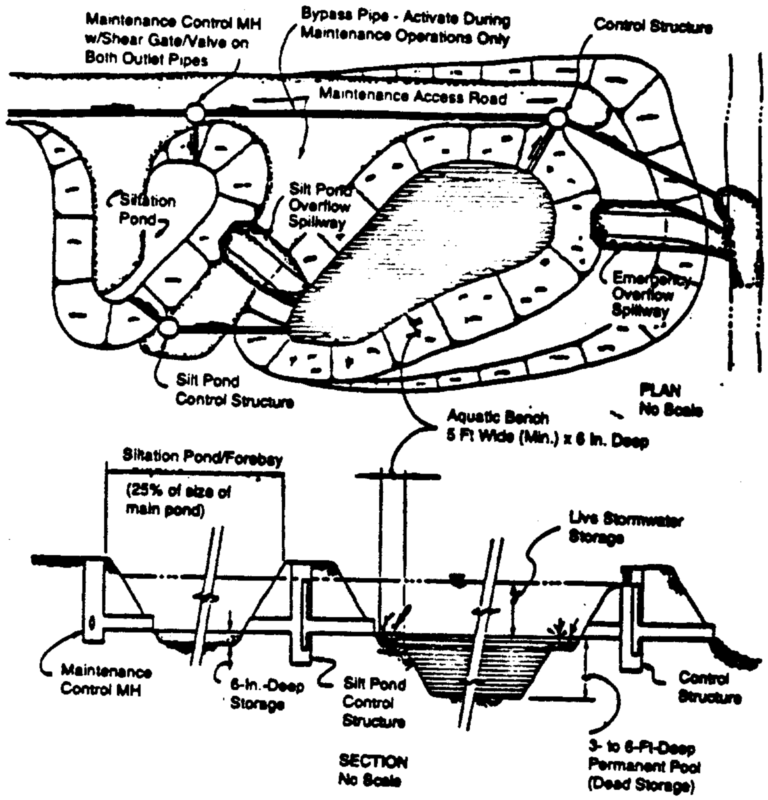

Figure 10. Typical wet pond (3).

generally the same, with the few exceptions noted.

Installation checks:

1. Does construction comply with local requirements for earthwork, concrete, other masonry, reinforcing steel, pipe, water gates, metalwork, and woodwork?
2. Are all dimensions as specified in the approved plan?
3. Are interior side slopes no steeper than 3 horizontal to 1 vertical and exterior side slopes no steeper than 2:1?
4. Is the bottom level?
5. Are the spillways (between cells, if any, and the emergency outlet spillway) sized and reinforced as specified in the approved plan?
6. Is a drain provided that can drain the dead storage zone within 4 hr if necessary?
7. Are inlet and outlet areas stabilized as necessary to avoid erosion?
8. Are safety concerns addressed, for example, with such features as a shallow bench completely around the edge of the pond, barrier plantings to discourage approach by children, and/or fencing (should not be necessary if sloped as recommended and other safety features are provided)?
9. For a water quality pond, is the effective length-to-width ratio at least 3:1 minimum, 5:1 preferably; are the inlet and outlet separated to the greatest width possible?

Maintenance checks:

1. Has a maintenance plan and schedule been developed?
2. Refer to Table 4 for specific checks and maintenance standards (these standards apply to other types of ponds as well).

VOL 12

9084

Table 4. Maintenance Standards for Detention Facilities

Defect	Conditions When Maintenance Needed	Maintenance Results
Trash and debris	Any trash or debris that exceeds 1 ft^3/ 1,000 ft^2. There should be no evidence of dumping.	Trash and debris cleared from site.
Poisonous vegetation	Presence of any poisonous vegetation that constitutes a hazard to maintenance personnel or to the public (e.g., poison oak, stinging nettles, devil's club).	No evidence of poisonous vegetation. Coordinate with health department.
Pollution	One gallon or more of oil, gas, or contaminants, or any amount that could 1) cause damage to plant, animal, or aquatic life, 2) constitute a fire hazard, 3) be flushed downstream during storms, or 4) contaminate ground water.	No contaminents present other than surface film. Coordinate with local health department.
Unmowed grass/ ground cover	In residential areas, mowing is needed when the cover exceeds 18 in. in height. Otherwise match facility cover with adjacent ground cover and terrain as long as there is no decrease in facility function.	Grass/ground cover should be mowed to 2 in. Maintain dense cover on slopes and in bottom of dry ponds.
Rodent holes	Any evidence of rodent holes if facility is acting as a dam or berm, or any evidence of water piping through dam or berm via rodent holes.	Rodents destroyed and dam or berm repaired. Coordinate with local health department.
Insects	When insects such as wasps or hornets interfere with maintenance activities.	Insects destroyed or removed from site. Coordinate with people who remove wasps for antivenom protection.
Tree growth	Tree growth does not allow maintenance access or interfere with maintenance activity. If trees are not interfering with access, leave trees alone.	Trees do not hinder maintenance activities.
Erosion of pond side slopes	Eroded damage >2 in. deep where cause of damage is still present or where there is potential for continued erosion.	Slopes stabilized with appropriate erosion control BMPs (e.g., seeding, mats, riprap).
Sediment accumulation in forebay/pond	Accumulated sediment 10% of the design forebay/pond depth, or every 3 yr.	Sediment cleaned out to design depth. Reseed if necessary for erosion control.
Dike settling	Any part of dike that has settled >4 in.	Dike is rebuilt to design elevation.
Rocks missing from overflow spillway	Only one layer of rock above native soil in an area of 5 ft^2 or greater, or any exposed soil.	Rock replaced to design standard.
Inadequate spillway size	Emergency overflow or spillway not large enough to handle flows from large storm events.	Increase capacity of spillway to current design standards.
Missing, broken, or damaged fencing	Any defect in fencing that permits easy entrance to the pond.	Fencing repaired to prevent entrance.
	Damaged fencing including posts out of plumb by >6 in., top rails bent >6 in., missing or loose tension wire, missing or sagging barbed wire, missing or bent extension arms.	Repair fencing and barbed wire to design standards
	Fencing parts that have a rusting or scaling condition that is affecting structural adequacy.	Structurally adequate posts or parts with protective coating.
	Opening in fencing that allows passage of an 8-in. diameter ball.	No opening in fence.
Erosion under fencing	Erosion >4 in. deep and 12 to 18 in. wide, permitting an opening under fence.	No opening under fence >4 in.
Missing or damaged gates	Missing or damaged gate, locking device, or hinges.	Gates, locking devices, and hinges repaired.
	Gate is out of plumb >6 in. and out of design alignment >1 ft.	Gate is aligned and vertical.
	Missing stretcher bar, bands, or ties.	Stretcher bar, bands, and ties in place.
Blocked or damaged access roads	Debris that could damage vehicle tires.	Roadway free of debris.
	Obstructions that reduce clearance above road surface to <14 ft (e.g., tree branches, wires).	Roadway clear overhead to 14 ft.
	Any obstructions restricting access to a 10- to 12-ft width for a distance of >12 ft, or any point restricting access to a width of <10 ft.	Obstructions moved to allow at least a 12-ft access route.
	Any road settlement, potholes, mushy spots, or ruts that prevent or hinder maintenance access.	Road surface repaired and smooth.
	Weeds or brush on or near road surface that hinder access, or are >6 in. tall and <6 in. apart within a 400 ft^2 area.	Weeds and brush on or near road surface cut to 2 in.
	Erosion within 1 ft of the roadway >8 in. wide and 6 in. deep.	Shoulder and road free of erosion.

2.2. Vaults and tanks

Refer to Table 5 for a summary of maintenance standards for closed detention systems.

3. Infiltration facilities

Infiltration facilities discharge most of the entering water to the ground. They include surface basins and trenches, below-ground perforated pipes, roof drain systems, and porous pavements. Inspection guidelines are given for infiltration basins as a complete example. A table of maintenance standards is included for infiltration trenches as well.

3.1. Infiltration basins (see Figure 11 for a typical basin)

Installation checks:

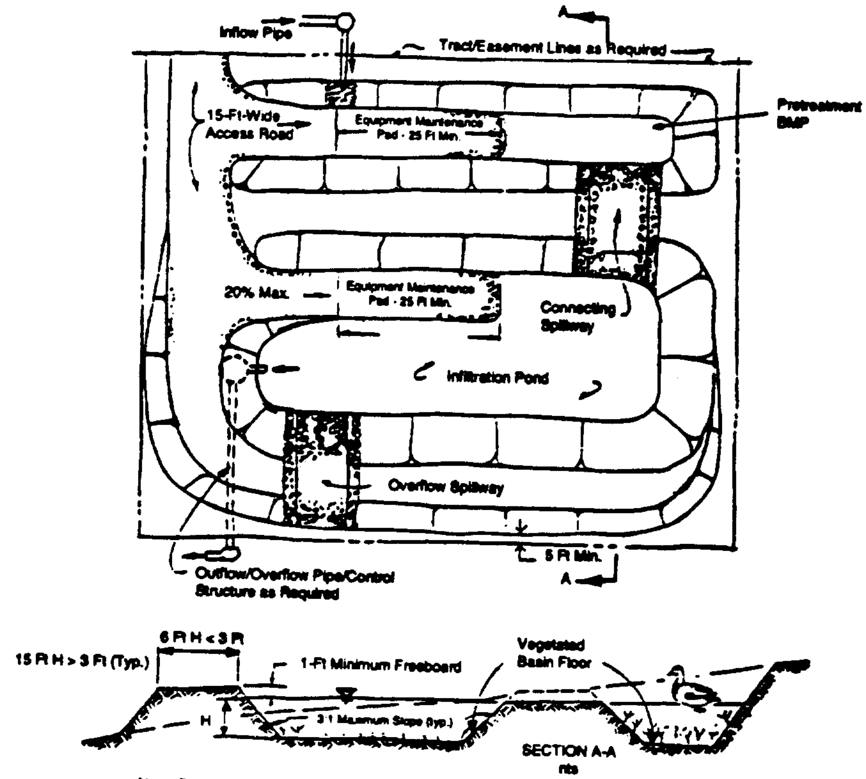
1. Does construction comply with local requirements for earthwork, concrete, other masonry, reinforcing steel, pipe, water gates, metalwork, and woodwork?
2. Are all dimensions as specified in the approved plan?
3. Does the timing of basin construction avoid the entrance of any runoff containing sediment from elsewhere on the site?
4. Is the basin preceded by a pretreatment device (e.g., presettling basin or biofilter) to prevent failure caused by siltation?
5. Is the basin at least 50 ft from any slope greater than 15 percent and at least 100 ft upslope and 20 ft downslope of any building?
6. Is the outlet orifice design consistent with the infiltration capacity on which the facility is based (e.g., to avoid the collection of more water than can infiltrate in 48 hr)?
7. Are the spillways (between cells, if any, and the emergency outlet spillway) sized and reinforced as specified in the approved plan?
8. Are all disturbed areas stabilized to prevent erosion?
9. After final grading, has the bed been deeply tilled to provide a well-aerated, highly porous surface texture?

Maintenance checks:

1. Has a maintenance plan and schedule been developed?
2. Refer to Table 6 for specific checks and maintenance standards.

Table 5. Maintenance Standards for Closed Detention Systems

Defect	Conditions When Maintenance Needed	Maintenance Results
Plugged air vents	Half of the end area of a vent is blocked at any point with debris and sediment.	Vents free of debris and sediment.
Debris and sediment in storage area.	Accumulated sediment depth is >10% of the diameter of the storage area for 1/2 the length of storage vault or any point exceeds 15% of the diameter. Example: 72-in. storage tank would require cleaning when sediment reaches a depth of 7 in. for more than 1/2 the tank length.	All sediment and debris removed from storage area.
Cracks in joints between tank/pipe sections	Any crack allowing material to be transported into the facility.	All joints between tanks or pipe sections are sealed.
Problems with manhole cover	Cover is missing or only partially in place. Any open manhole requires maintenance.	Manhole is closed and secured.
	Locking mechanism cannot be opened by one maintenance person with proper tools. Bolts into frame have <1/2 in. of thread (may not apply to self-locking lids).	Mechanism is repaired or replaced so it functions properly.
	Cover difficult to remove by one maintenance person applying 80 lb of lift.	Cover can be removed and reinstalled by one maintenance person.
Ladder rungs of manhole unsafe	Local government safety officer or maintenance person judges that ladder is unsafe due to missing rungs, misalignment, rust, or cracks.	Ladder meets design standards and allows for maintenance access.
Catch basins	See Table 3.	See Table 3.



Note: Detail is schematic representation only. Actual configuration will vary depending on specific site constraints and applicable design criteria.

Figure 11. Typical infiltration basin (3).

3. In addition, is tilling necessary to restore infiltration capacity (regular annual tilling is recommended)?

3.2. Infiltration trenches

Refer to Table 7 for a summary of maintenance standards for infiltration trenches.

4. Biofilters

The term "biofilter" applies to vegetated land treatment systems. Biofilters can be in the form of vegetated swales, in which water flows at some measurable depth or in a thin sheet across broad surface areas, sometimes called "filter strips." Constructed wetlands are also sometimes put in this category. The guidelines given below generally pertain to swales and filter strips, although some exceptions are noted. Inspection of constructed wetlands should be conducted with reference to both these guidelines and those given above for wet ponds.

4.1. Biofiltration swales and filter strips

Installation checks:

1. Are the dimensions and plantings as specified in the approved plan?
2. Is the vegetation cover dense and uniform?
3. If the biofilter is a swale, is it parabolic or trapezoidal in shape, with side slopes no steeper than 3 horizontal to 1 vertical?
4. Is the biofilter placed relative to buildings and trees in such a way that no portion will

VOL 12

9087

Table 6. Maintenance Standards for Infiltration Basins

Defect	Condition When Maintenance Needed	Maintenance Results
Sediment buildup in system	Soil texture test indicates facility is not functioning as designed.	Sediment is removed and/or facility is cleaned so that system works according to design. A forebay or presettling basin is installed to reduce sediment transport to facility.
Poor facility drainage (more than 48 hr)	Soil texture test indicates facility is not functioning as designed.	Additional volume added through excavation to provide needed storage. Soil aerated and rototilled to improve drainage.
Sediment trapping area	Sediment and debris fill >10% of sediment mapping facility or sump.	Sediment trapping facility or sump cleaned of accumulated sediment.
No sediment trapping facility	Stormwater enters infiltration area without pretreatment.	Trapping facility (presettling basin, detention pond, biofilter) is added before infiltration facility.

Table 7. Maintenance Standards for Infiltration Trenches

Defect	Condition When Maintenance Needed	Maintenance Results
Sediment and debris buildup in trench	By visual inspection, little or no water flows through the trench during large storms.	Debris blocking infiltration trench is removed. Gravel in infiltration trench is replaced or cleaned.
Observation well	Observation well buried, covered, or inaccessible.	The observation well/cap is accessible to the inspector for opening and inspection.
Water percolates up from trench	Trench water or water with dye percolating to surface.	Gravel and filter fabric in infiltration trench is replaced or cleaned. Trench functions according to design standards.
Filter fabric exposed	Filter fabric is exposed or damaged.	Filter fabric is replaced or repaired and covered with proper backfill material.

be shaded throughout the day and possibly experience poor plant growth?

5. If the longitudinal slope is less than 2 percent or if the water table can reach the root zone of vegetation, is water-resistant vegetation planted to survive a standing water condition or is an underdrain system installed to assist drainage (note: underdrains may not be practical with a large filter strip)?

6. If the longitudinal slope is in the range of 4 to 6 percent, are check dams provided approximately every 50 to 100 ft to reduce velocity (note: check dams may not be practical on a larger filter strip)?

7. If the slope on which a swale is installed exceeds 6 percent, does it traverse the slope in such a way that no reach slopes more than 4 percent, or 6 percent with check dams?

8. Is the lateral slope entirely uniform to avoid any tendency for the flow to channelize?

9. Is flow introduced in such a way that entrance velocity is dissipated quickly, flow is distributed uniformly, and erosion is avoided (e.g., by using a riprap pad or some means of level spreading)?

10. Was construction-phase runoff excluded or was the biofilter reestablished after construction, and are upslope areas stabilized to avoid erosion into the biofilter?

11. Is a bypass in place for flows larger than the flow rate for which the biofilter is designed to provide runoff treatment, or is the facility sufficiently large to pass at least the 100-yr, 24-hr storm without eroding (a bypass is preferred to maintain the treatment function and prevent resuspension of settled material)?

Maintenance checks:

1. Has a maintenance plan and schedule been developed?

2. Refer to Table 8 for specific checks and maintenance standards.

Table 8. Maintenance Standards for Biofilters

Defect	Conditions When Maintenance Needed	Maintenance Results
Trash and debris	Dumping of yard wastes. Accumulation of nondegradable materials.	Remove degradable wastes and compost. Recycle other waste when possible.
Sediment buildup	Accumulation >20% of design depth.	Cleaned or flushed to match design. Vegetation restored as necessary.
Poor vegetation cover	Vegetation sparse and/or weedy. Overgrown with woody vegetation.	Aerate soil and plant. Remove woody growth and replace.
Erosion damage to slopes	Erosion >2 in. deep where cause still present or potential exists for continued erosion.	Find cause and eliminate. Stabilize with appropriate erosion controls (e.g., seeding, mat, mulch).
Conversion to use incompatible with water quality control	Filled, planted appropriately, or blocked.	Discuss with nearby property owners and specify corrections to be made.
Poor drainage	Water stands in swale.	Determine cause. If water table is high, consider rebuilding with liner or underdrain. If slope <1%, use underdrain.

Note to Readers

Economic Valuation of Natural Resources: A Handbook for Coastal Resource Policymakers is the outcome of COP-sponsored environmental valuation workshops. As the text to support the teaching in these workshops developed and as the need to transfer this information to a wider audience of coastal managers than workshop attendees became apparent, it was decided to present the Handbook as a stand-alone document. The Handbook is a unique blend of writing by highly regarded experts in the field specifically tailored for the management community and input by managers who have attended the COP workshops. Each workshop participant is asked to provide comments on the curriculum, teaching effectiveness, and materials. Over the past three years, these comments have helped us to improve all aspects of the training.

The NOAA Coastal Ocean Program (COP) provides a focal point through which the agency, together with other organizations with responsibilities for the coastal environment and its resources, can make significant strides toward finding solutions to critical problems. By working together toward these solutions, we can ensure the sustainability of these coastal resources and allow for compatible economic development that will enhance the well-being of the Nation now and in future generations. The goals of the program parallel those of the NOAA Strategic Plan.

A specific objective of COP is to provide the highest quality scientific information to coastal managers in time for critical decision making and in a format useful for these decisions. To help achieve this, COP inaugurated a program of developing documents that would synthesize information on issues that were of high priority to coastal managers. A three-step process was used to develop such documents: 1) to compile a list of critical topics in the coastal ocean through a survey of coastal resource managers and to prioritize and select those suitable for the document series through the use of a panel of multidisciplinary technical experts; 2) to solicit proposals to do research on these topics and select principal investigators through a rigorous peer-review process; and 3) to develop peer-reviewed documents based on the winning proposals. Seven topics were selected in the initial round, but the series is expanding because of the suitability of findings from other COP-funded research to appear in this synthesis format. The documents already published are listed on the inside back cover.

As with all of its products, COP is very interested in ascertaining the utility of the Decision Analysis Series particularly in regard to its application to the management decision process. Therefore, we encourage you to write, fax, call, or E-mail us with your comments. Please be assured that we will appreciate these comments, either positive or negative, and that they will help us direct our future efforts. Our address and telephone and fax numbers are on the inside front cover. My Internet address is DSCAVIA@HQ.NOAA.GOV.

ACKNOWLEDGMENTS

This handbook has grown out of a series of workshops sponsored by the NOAA Coastal Ocean Program (COP). The workshops were developed to meet an expressed priority need on the part of coastal resource managers for more information in the area of environmental valuation. The workshop concept was developed by Rodney Weiher and Katherine Wellman, both at the time in the Economics Group in the NOAA Office of the Chief Scientist, who were asked by COP to formulate a program to meet managerial needs. Nancy Bockstael and Douglas Lipton of the University of Maryland's Department of Agricultural and Resource Economics were brought into the team. Together this team, with coordination from Isobel Sheifer of COP, helped to lay the foundation and framework of the workshops and the handbook that grew out of them.

The handbook contains the written substance of the material being taught at the workshops. The first part of each workshop is devoted to the teaching of a core curriculum by Wellman and Lipton, who have been participating in these workshops beginning with a pilot in Durham, New Hampshire, in summer 1992. The second part of the workshop involves the innovative use of case studies through which workshop attendees get an opportunity to try out these newly studied techniques in actual case situations under the tutelage of a case leader. In addition to individuals already mentioned, case studies have been facilitated by Lewis Queirolo of the NOAA National Marine Fisheries Service, Rebecca Baldwin of the U.S. Forest Service, and Elliot Rosenberg of the Environmental Protection Agency.

Among those making the greatest contribution to the development of this handbook have been the participants in the workshops. By filling out evaluation forms at the end of each session and by their private conversations with teachers and other workshop personnel, participants have helped us improve what we teach, how we teach it, and the sequence of teaching exercises. Participation levels in case study sessions and the kind of discussions that take place have indicated to us which cases were the best tools to promote the learning experience we hoped to achieve.

As the handbook has developed and become refined, we feel it is important to transfer this kind of information to the widest possible audience of coastal managers, regardless of their workshop attendance. To that end, we have undertaken a revision of materials to make the document a stand-alone learning tool and have included cases from many regions of the country to make the scope of this part of the learning truly national. However, it should be noted that a case study for one region can be used by managers anywhere as a guide to understanding environmental valuation. The problems recounted in these cases have general applicability.

Merrill Leffler and Sandy Harpe have been responsible for editing and design of the text.

Economic Valuation of Natural Resources is not a textbook but a guide for policy makers and managers regarding how to assess and understand the economic value of the coastal resources for which they are stewards. We hope it will receive wide distribution and use.

PREFACE

Professionals who are responsible for coastal environmental and natural resource planning and management have a need to become conversant with new concepts designed to provide quantitative measures of the environmental benefits of natural resources. These amenities range from beaches to wetlands to clean water and other assets that normally are not bought and sold in every-day markets.

At all levels of government — from federal agencies to townships and counties — decision-makers are being asked to account for the costs and benefits of proposed actions. To non-specialists, the tools of professional economists are often poorly understood and sometimes inappropriate for the problem at hand. This handbook is intended to bridge this gap.

The most widely used organizing tool for dealing with natural and environmental resource choices is benefit-cost analysis — it offers a convenient way to carefully identify and array, quantitatively if possible, the major costs, benefits, and consequences of a proposed policy or regulation. The major strength of benefit-cost analysis is not necessarily the predicted outcome, which depends upon assumptions and techniques, but the process itself, which forces an approach to decision-making that is based largely on rigorous and quantitative reasoning.

However, a major shortfall of benefit-cost analysis has been the difficulty of quantifying both benefits and costs of actions that impact environmental assets not normally, nor even regularly, bought and sold in markets. Failure to account for these assets, to omit them from the benefit-cost equation, could seriously bias decisionmaking, often to the detriment of the environment. Economists and other social scientists have put a great deal of effort into addressing this shortcoming by developing techniques to quantify these non-market benefits.

The major focus of this handbook is on introducing and illustrating concepts of environmental valuation, among them Travel Cost models and Contingent Valuation. These concepts, combined with advances in natural sciences that allow us to better understand how changes in the natural environment influence human behavior, aim to address some of the more serious shortcomings in the application of economic analysis to natural resource and environmental management and policy analysis.

Because the handbook is intended for non-economists, it addresses basic concepts of economic value such as willingness-to-pay and other tools often used in decision making such as cost-effectiveness analysis, economic impact analysis, and sustainable development. A number of regionally oriented case studies are included to illustrate the practical application of these concepts and techniques.

The National Oceanic and Atmospheric Administration's Coastal Ocean Program and its Economics Group participated in the development of the handbook and a series of regional workshops for state and local coastal planners and managers in an effort to relate advances in the physical sciences to modern environmental, economic, management, and policy problems.

History and Legislative Mandates for Environmental Valuation

In the earliest versions of benefit-cost analysis of federal projects, there was no provision for accounting for economic gains or losses due to environmental benefit or harm. Even when aware of the physical harm a project or policy would have on the environment, decisionmakers were unable to quantify these using the available economic tools of the time. Economic theory has progressed to address the problems of environmental valuation, as have federal environmental laws and regulations.

HISTORY

Environmental valuation has its origin in the River and Harbor Act of 1902. This Act required a board of engineers to report on the desirability of the Army Corps of Engineers' river and harbor projects by accounting for both the costs and benefits to commerce.

In the 1930s, the idea of broader social justification for projects emerged as a theme. For example, the Flood Control Act of 1936 authorized federal participation in flood-control schemes if the benefits of such actions exceeded the estimated costs. The practice of such analyses then spread to other agencies concerned with water development projects. The purpose was both to justify public works projects and to help decide who should pay for these projects.

By the end of World War II, federal agencies had broadened their approach to account for secondary, or indirect, benefits and costs as well as intangibles. Intangibles reflected what are now considered environmental assets. This was really the beginning of benefit-cost analysis (as will be discussed in greater detail in Chapter 3). In the 1950s, a federal interagency committee produced the Green

Book, an attempt to codify and agree on general principles of project justification. This document was notable for bringing in the language of welfare economics.[1]

In the late 1960s, the environmental movement began. Pollution control was of particular concern and the economics community was ready and willing to play a role. Unfortunately, the economic view had little impact on the initial surge of legislation for pollution control. Two of the cornerstones of federal environmental policy on pollution control — the Clean Air Act of 1970 and the Clean Water Act of 1972 — explicitly prohibited weighing benefits and costs in the setting of environmental standards. Instead, standards were based solely on public health criteria.

While the National Environmental Policy Act of 1969 (as amended through 1982) required the use of benefit-cost analysis in environmental impact statements, environmental valuation did not really come into its own until the 1980s, when Executive Order 12291 (the Regulatory Impact Analysis requirement) was issued.[2] Additional environmental legislation, particularly the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA), gave natural resource trustees the right to claim damages for injuries to natural resources that result from the release of oil and other hazardous materials into publicly owned rivers, lakes, estuaries, oceans, or other aquatic or terrestrial habitats. The natural resource damage assessment process explicitly calls for the estimate of interim lost values of injured natural resources and resource services.

During the 1980s, interest in environmental valuation continued to expand, and this attention has continued into the 1990s. This increased attention stems from the implementation of the Oil Pollution Act of 1990 and its subsequent natural resource damage assessment regulations. The Act put pressure both inside and outside of government to improve the decision-making criteria affecting public funds and resources. In addition, relatively recent legislative mandates, through amendments to existing legislation, have strengthened the requirement of net economic benefit analysis as part of management and regulatory programs.

[2] Early in the Reagan Administration the President issued Executive Order 12291. This Order requires cabinet-level departments to prepare benefits-cost analyses justifying major rules. These analyses are scrutinized by the Office of Information and Regulatory Affairs within the Office of Management and Budget. Executive Order 12291 has subsequently been superseded by Executive Order 12866.

9103

LEGISLATIVE MANDATES

The following section provides a summary of legislation which indicates the extent of the applications of environmental valuation in the coastal and marine resource management and policy arena.

▸ **WETLANDS PERMITTING.** Among the many pieces of legislation related to wetlands, the most important is probably Section 404 of the Clean Water Act which is a component of the permit process necessary for wetlands conversion for development. When making a permitting decision, the Army Corps of Engineers is expected to balance the public and private benefits of the project against the costs, and to take into account environmental values. No guidelines are provided on how the Army Corp of Engineers should measure costs and benefits. Nor is there any requirement that an actual study be conducted. However, agencies making recommendations to the Corps can (and occasionally do) make their arguments in terms of costs and benefits.

▸ **NONPOINT SOURCE POLLUTION CONTROL.** Section 319 of the Clean Water Act establishes a national program to control nonpoint sources of water pollution. In addition, Section 6217b of Coastal Zone Act Reauthorization Amendments of 1990 requires that all states with coastal management programs must develop and submit to EPA and NOAA for approval a Coastal Nonpoint Pollution Control Program. Under Section 6217g, EPA is required to publish guidance for specifying economically feasible management measures. All management measures in *Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters* are to be economically achievable and cost-effective. This language does little to aid the coastal manager or planner in actually evaluating which management measures create the greatest welfare to society. In order to determine the depth and breadth of nonpoint source pollution control, the value of the resources (water quality, shellfish beds, recreation) must be determined. Once the value of the resources is established, the costs of such regulations can be weighed against the benefits (i.e., enhanced resource and resource service quality).

▸ **ENVIRONMENTAL REGULATION.** The National Environmental Policy Act (NEPA) requires federal government agencies to conduct an assessment of environmental impacts of proposed legislation and "other major federal actions significantly affecting the quality of the human environment." Over the years this authority has been extended to include any actions funded in part or regulated by the federal government, even though they are carried out by private parties. The result of the assessment is an Environmental Impact Statement (EIS). Under NEPA, benefit-cost analysis is discussed but not required. When a benefit-cost analysis is prepared, a discussion of the relationship between the analysis and any analyses of unquantifiable environmental impacts, values and amenities must be included.

► FISHERIES MANAGEMENT. The Magnuson Fishery Conservation and Management Act of 1976 and its amendments require the preparation of fishery management plans under federal jurisdiction by the Fisheries Management Councils for review by the Secretary of Commerce/National Oceanic and Atmospheric Administration (NOAA). Benefit-cost analysis is required under the regulatory impact review component of the plan. Typical analyses might include determining the value of a recreational fishing day or the value of a sector of the commercial fishing industry to society. The National Marine Fisheries Service (for Commerce and NOAA) has issued guidance from time to time on economic analysis, but the adequacy of these analyses has yet to be challenged in court.

► LITIGATION OF OIL AND HAZARDOUS WASTE SPILLS. The Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA) mandates the preparation of regulations by which natural resource damages from spills of oil or hazardous substances should be assessed to compensate society for losses before the resources are fully restored. The Oil Pollution Act of 1990 (OPA) also mandates the preparation of regulations by which natural resource damages, specifically from oil spills, will be calculated. Under CERCLA and OPA, in the event of a spill of oil or other hazardous substances, the public must be compensated for natural resource injuries in order to make them as well off as they would have been without the spill. In developing a damage claim, the resource trustees must determine the value of lost resources and service flows pending restoration. In this case, values may include the value of injured marine mammals or seabirds or the value society attaches to just knowing that a natural wilderness area exists. CERCLA and OPA natural resource damage assessment has attempted to incorporate state-of-the-art environmental valuation techniques. Methods for measuring damages are discussed by name in the regulations, in-

VOL 12

A Sampling of Legislative Mandates

- Wetlands Permitting: Section 404 of Clean Water Act
- Litigation of Oil and Hazardous Waste Spills: The Comprehensive Environment Response, Compensation and Liability Act of 1980
- Oil Pollution Act of 1990
- Coastal Resource Management: Coastal Zone Management Act of 1972 (as amended)
- Marine Sanctuary Designation: Marine Protection, Research and Sanctuaries Act of 1972 (as amended)

cluding travel costs, hedonic valuation, and contingent valuation. Also discussed is the range of types of values, including market-related, nonmarket use values, and nonuse values.

▶ OTHERS. The Coastal Zone Management Act of 1972 (as amended) identifies coastal resource uses subject to management that may require benefit-cost analysis including the siting of major facilities related to energy; fisheries developments, recreation, ports and transportation; and the location of new commercial and industrial developments. In addition, the Act encourages the preparation of Special Area Management Plans (SAMP) for reasonable coastal-dependent economic growth. Net economic benefit analysis, in this case, is prepared by state Coastal Zone Management (CZM) programs and submitted to NOAA, which issues SAMP funds.

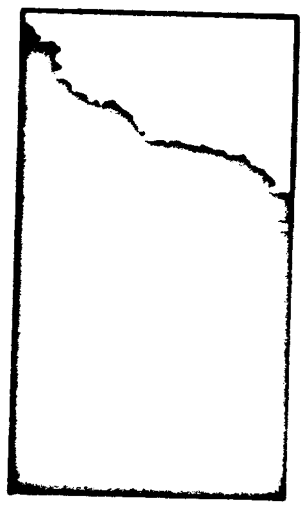
The Marine Protection, Research and Sanctuaries Act of 1972 (as amended) requires that public and socio-economic benefits derived from sanctuary designation be assessed as part of the approval process for a proposed site. In addition, an environmental impact statement, fisheries management guidance, and ocean pollution regulations are required.

The National Estuary Program (NEP) was established under Sections 317 and 320 of the Water Quality Act of 1987 (amendments to the Clean Water Act). Under the NEP, the Administrator of EPA is authorized to convene management conferences that represent a partnership across federal, state, and local levels, designed to reach consensus on priority problems of the estuary, the causes of those problems, and the actions that must be taken to correct those problems. The management conference also provides a mechanism for obtaining commitments to take action. These commitments, reflected in the Comprehensive Conservation and Management Plan (CCMP), are the result of the NEP process. Development of the CCMP is critically dependent on the determination of values of estuarine functions and services. Environmental valuation could be an integral part of the scientific characterization process, linking science with policy-relevant issues. Such values could play a major role in the socio-political acceptability of action plan alternatives laid out as a part of the CCMP development and implementation process. Recent guidelines on the role of environmental valuation in NEP planning have been issued by the EPA Ocean Coastal Protection Division.

2

Concepts in Environmental Valuation

The term *value* in economics has a precise definition — it is the price individuals are willing to pay in order to obtain a good or service. The basic economic concepts of supply and demand are employed to estimate willingness-to-pay (called producer surplus and consumer surplus, respectively). This idea of value and its measure remain consistent whether a market good or a state of the environment is at stake.



The term *value*, in the context of coastal issues, can have different meanings to those with different interests. To an ecologist, the value of a salt marsh might mean the significance or importance of the marsh to the reproductive capacity of certain species of fish. To a coastal engineer, the value of a salt marsh may be associated with its contribution to shoreline stabilization. In general, these values are mathematical and functional: mathematical, meaning magnitude, and functional, meaning the physical or biological relationships of one entity to another. These values exist whether or not humans prefer them or are even aware of them.

ECONOMIC VALUE

A fundamental distinction between the way economics and other disciplines such as ecology use the term value is the economic emphasis on human preferences. Thus, the functionality of economic value is between one entity and a set of human preferences. If a coastal area is degraded so it supports a lower abundance of organisms, an ecologist would characterize this degraded area as less valuable for those organisms than a non-degraded area. In economic terms, however, a polluted area only has less value than an otherwise equivalent non-polluted area if some individual members of society prefer non-polluted to polluted areas. If no one cares that there are fewer organisms in the polluted area, then there is no difference in economic value. Typically, some members of society will display a preference for an environment that is less degraded.

Economic value is a measure of what the maximum amount an individual is willing to forego in other goods and services in order to obtain some good, service, or state of the world. This measure of welfare is formally expressed in a concept called *willingness-to-pay* (WTP). Thus, the lost value from the degraded environment is the maximum amount individuals are willing to pay to have a state where that same area is free of pollution.

A common difficulty in understanding economic valuation is distinguishing between what something is valued at by individuals and what its economic value really is. Thus, one can find commercial fish landings in the United States in 1993 *valued* at $3.5 billion and assume that is the value of our commercial fishery. But what is the willingness-to-pay of commercial fishers to be able to land this catch? If all the fisheries were closed tomorrow, would we have to pay $3.5 billion a year in compensation to leave them as well off as if the fishery were open? The answer would be yes only if fishing was a completely costless activity, which we know it isn't. The harvesters have to pay for fuel, gear, and, of course, their time which would have been available for alternative income earning endeavors. The fishery, therefore, is worth somewhat less to the harvesters. Figuring how much it is worth is the subject of Chapter 5, Measuring the Value of Non-Market Goods and Services.

In assessing the value of some policy or management plan, the economist is interested in estimating how much an individual's (or society's) well-being would change: how much it will decrease if a natural resource were lost or increase if a natural resource or resource service were better managed or its quality improved. In other words, when economists try to estimate the economic value of a coastal resource or resource service, they attempt to answer one of two questions:

- How much are people willing to trade (give up) of other goods and services to have some natural resource or resource service?
- How much better off would people be if a policy or management plan action were implemented and the amount or quality of a resource or resource service were improved?

Characteristics of Economic Value

- **Products or services have value only if human beings value them, directly or indirectly.**
- **Value is measured in terms of trade-offs, and is therefore relative.**
- **Typically, money is used as a unit of account.**
- **To determine values for society as a whole, values are aggregated from individual values.**

SCARCE RESOURCES, LARGE DEMANDS

The economic definition of value is rooted in a simple idea: all resoures are scarce, but the demands for those resources are large relative to their availability. There is never enough labor or land or water to do all the things that all individuals might wish. Because resources are scarce, it is necessary to make choices about how society will use what is available. We make choices about the amount of money to devote to schools, roads, libraries, and natural resource protection programs individually and collectively. These choices are often based on complex tradeoffs; thus, value is revealed in decisions about how individuals and society collectively choose to allocate these resources. People may recoil at the notion of placing a value on the natural environment, but there are other uses or alterations of that environment that might be proposed. Society always has to compromise, giving up something to get something else.

The most direct and visible monetary symbol for a good is its market price. The relationship between a good's market price and its value in terms of willingness-to-pay (WTP) can be confusing. We might think, for example, that because an individual buys a certain good at a market price of $8, then $8 is what the individual is willing to pay for this good, and thus $8 is the value to the individual. Such reasoning, however, is not necessarily true. If an individual spends $8 to obtain a good, we know only that the good is worth at least this much to the individual; he or she may also have been willing to spend more, for instance a maximum of $10, to obtain the good. In this case, the $8 market price is only a lower bound estimate of the total value of the good to the individual, that is, the individual's total WTP for the good.

You might conclude from this example that total market expenditures for a good (i.e., price times quantity sold) would constitute a lower bound estimate of its consumer value. The problem with this conclusion is that the appropriate economic measure of welfare or value is *net benefit*, not total value. The net benefits society derives from a good is represented by net WTP, or the amount society would be willing to pay to produce and/or use a good *beyond that which it actually does pay*.

The same principle of economic value holds for *non-market goods*, goods that do not have observable market prices. For example, consider the case of a recreational fisher who would be willing to spend up to $30 a day to use a particular fishing site, but only has to spend $20 a day in travel and associated costs. The net benefit or economic value to the fisher of a fishing day at the site is not the $20 expenditure, but the $10 difference between what that fisher would be willing to spend and what he or she actually has to spend. If a development project eliminated all fishing opportunity at the site, the fisher would lose the satisfaction of fishing there, as represented by $10 a day in net benefits. The $20 a day he or she would have spent to visit the site would not be lost but would be available to spend elsewhere.

Because market expenditures are not measures of net benefits, we cannot use expenditures on the purchase of related goods as a direct measure of the *social value* of the good. Several steps must be taken to provide the information on social value.

Because a market provides a forum for society to express relative preferences in monetary terms, market transactions can be used to infer preferences, and thus economic values. Also, non-market goods can sometimes be valued based on information on preferences provided by market transactions for related products. For example, we

VOL 12

Economic Value Based on Net Willingness to Pay (WTP)

Consider the case in which only one unit of a certain market good, oysters, is produced at a cost of $1 per dozen and sold at a price of $8. If the purchaser had been willing to pay $10, the net benefit of a dozen oysters to this consumer would be $2 ($10 less $8) — this amount is called consumer surplus. At $8 a dozen, the producer earns $7 from the sale (the selling price minus the production price), so the net benefit of the good to the producer is $7 (called producer surplus). The total economic value of a dozen oysters is thus $9 ($2 net benefit to the consumer plus $7 net benefit to the producer). If for some reason the producer was denied the opportunity to produce and sell oysters (say because of a moratorium on fishing) — and the consumer was denied the opportunity to buy and consume oysters — the total loss to these individuals would be $9.

can estimate the value of a recreational site by travel expenditures (i.e., gas, lodging, meals).

9/1/1

CONSUMER AND PRODUCER SURPLUS

In measuring the general satisfaction that society as a whole derives from a good or service, economists often use the concepts of *consumer surplus* and *producer surplus* to approximate the net willingness-to-pay (WTP). When a good is exchanged in a perfectly competitive market, its market price measures the consumer demand (marginal WTP) for the last unit of the good purchased. Market price is determined by the equilibrium of demand and supply, i.e., the price and quantity that correspond to the level at which the consumer's WTP for the next unit produced is equal to the cost of producing it. For all other units of the good purchased, however, the consumer marginal WTP for each unit exceeds market price.

Before discussing consumer and producer surplus, it will be useful to first review supply and demand curves. Supply curves describe the relationship between the quantities of a producer's good or service and the price the producer receives. This relationship is shown

R0042417

in Figure 2.1. The price for fish and shellfish or whale watching trips, for example, might be represented by the ex-vessel price or fee, respectively. The greater the quantity of whale watching trips or fish produced, the higher the incremental costs (e.g., fuel, ice and crew wages). The producer will produce a higher quantity only for a higher price. Thus, supply curves are upward sloping. Industry supply curves are the aggregation of the quantities of individual firm supply curves.

Demand curves describe the price-quantity relationship for a particular good or service for a consumer (Figure 2.2). They describe what a consumer is willing to pay for various quantities of the good or service, such as whale watching trips or fresh fish. As the number of whale watching trips or fish offered to a consumer increases, satiation sets in and the consumer's WTP for the marginal unit is less. Thus, the demand curve slopes downward to the right. Consumer demand curves are summations of the quantities of individual demand curves.

The excess of what consumers are willing to pay over what they actually do pay for the total quantity of a good purchased is called *consumer surplus* (Figure 2.3); it represents the good's value to consumers in terms of net WTP, and is represented by the area under the good's demand curve, bounded by price (Figure 2.2). Moreover, a good's market-clearing price — the price that satisfies suppply and demand simultaneously, represented by the intersection of the supply and demand curves — also corresponds to the marginal cost of producing the last unit of output. For all other units of the good produced, however, the producer marginal production cost for each unit is less than market price.

The excess of what producers earn over their production costs for the total quantity of a good sold is called *producer surplus* or economic rent. This value represents the production value or net benefit of the good to producers, and it is represented by the area over the good's supply curve, bounded by price (Figure 2.3). While not an exact measure of social welfare, the sum of consumer surplus and producer surplus provides a useful approximation of the net benefit of a good or service.

The concept and measurement of economic value, generally upheld in courts of law, has been evolving. There are clearly issues that have not yet been resolved in this conceptual framework. For example, there is controversy about whether it is appropriate to use a minimal amount one is willing to accept when estimating welfare losses due to environmental damage. Yet, these concepts are useful. They bring us closer than we have ever been before to incorporating some ple, to weigh social benefits associated with a commercial development project against environmental benefits that would be lost should the project be implemented. Such a *social accounting* analysis tallies all real costs associated with an activity, including the cost of lost or damaged environmental assets and quality of life. Desirable characteristics of this social accounting scheme are these: it is internally consistent (i.e., the underlying theory does not change with circumstance), usually intuitively appealing, and acceptable in major courts of law.

The measurement of gains or losses is a *net value* (i.e., the value of a site's services over and above the next best alternative). As we will see, the estimates of benefits are not restricted to losses in commercial enterprises, such as losses to commercial fisheries. Benefit measures attempt to account for the subjective preferences of society regarding the use and existence of coastal or marine resources. For example, in siting a proposed development project, the location should be where the net benefits (commercial gains from the development) minus the costs of production and environmental damages it causes, are maximized. If benefits are negative, then the development would represent an inefficient use of society's resources. For example, a shopping mall built on wetlands provides less net benefits than the same project, just as convenient to shoppers, built on common uplands.

As a general rule, the fewer substitutes available for a good or service, the greater the loss. Thus, a site that provides excellent recreational experiences might be adjacent to another site that provides equally good recreational experiences. The loss to the recreationist from losing one site would be smaller than if there were no close substitute. However, if elimination of one site causes congestion at another site and lowers the quality of the recreational experience for everyone, then those losses must also be taken into account.

Gains from development will be higher where substitutes are fewer and more costly. Take again the simple case of a shopping mall: gains from a new shopping mall would be the extra profits the retail stores could make plus the gains to consumers from having shorter distances to travel to shop. However, if another mall exists nearby, consumers will gain little from the additional mall and the retail stores in the first mall may lose almost as much in profit as those made by stores in the new mall. The net value to shoppers, real estate, and stores owners is the figure that should be compared to the losses from building the mall.

THE SOCIAL ACCOUNTING SCHEME: A CASE STUDY

Orian Corporation v. State of Washington Department of Ecology illustrates how environmental economists employ social accounting techniques as a first step in doing an economic valuation The case provides an example of the role environmental valuation could play in decisions related to development of environmentally sensitive areas and, potentially, to the determination of compensation in the event of a regulatory taking.

In the 1960s, the Orian Corporation proposed to dredge and fill lands that they owned in the Padilla Bay tidelands of Skagit County in northwestern Washington State to create a Venetian-style community. According to Charles Lean, former Assistant Attorney General and counsel for the State of Washington in *Orian*, the planned community would have been the most populous town in Skagit County.

Padilla Bay is home to the largest contiguous expanse of eelgrass in the state, serves as a salmon and dungeness crab nursery, and is critical habitat to thousands of ducks and geese, as well as endangered bald eagles and peregrine falcons. Recognizing the importance of these natural resources, Skagit County's 1976 Shoreline Master Program (administered by the Washington State Department of Ecology), required by the State's Shoreline Management Act, designated Padilla Bay tidelands "aquatic," which prohibited all uses except nonintensive recreation and aquaculture. The use restrictions in Skagit County's Shoreline Master Program essentially barred Orian's plans to dredge and fill the bay for an overwater housing development.

Orian Corporation argued the shoreline regulations constituted a "regulatory taking" and sued for the right to develop the property. The courts had to determine whether state interference with Orian's use of the property was sufficiently restrictive to deny Orian any reasonable use of the land without offering fair market value. The Washington Supreme Court held that the shoreline regulations did not cause an unconstitutional taking on two grounds.

First, the court held that "the public trust doctrine would have prohibited the intended development anyway, despite the Shoreline Management Act. Therefore, since there was no right to place fills or

of the natural resource values that we all know exist into the trade-off decisions that are made by government agencies and by courts.

ENVIRONMENTAL VALUATION

Environmental valuation is a series of techniques that economists use to assess the economic value of market and non-market goods, namely natural resources and resource services. It applies the *welfare economics* concepts of producer and consumer surplus to issues involving natural resources and the state of the environment. Welfare economics tries to answer the question "Is society better off?" Environmental valuation is the application of welfare economics when the differences in circumstances relate to the uses or states of natural resources or the quality of the environment.

When economists refer to evaluating societal benefits, it is necessary to recognize two "states of the world": *with* and *without*. *Without* is the base state if an activity, circumstance and policy does not change. *With* is the state when the change occurs. A distinction is made between *with* and *without* and *before* and *after*. *Before* and *after* does not control for changes in the state of the world that do not result from the action or policy in question. Economists try, for exam-build houses in the first place, there was no taking. The state does not have to pay for taking a property right which never existed." Second, the Supreme Court declared that the shoreline regulations did not violate the Constitution because "whenever the state imposes land use restrictions in order to safeguard the public interest in health, the environment, and the fiscal integrity of the area," it is a legitimate use of police power and is "insulated" from takings claims.

The court, however, also recognized that regulations intended to protect the Padilla Bay National Estuarine Research Reserve may have prevented reasonably profitable use of Orian's tidelands. Because the regulations were not intended to protect public health and safety but instead served to enhance the value of the publicly owned Reserve, they could have caused a temporary taking. The Court sent the case back to a lower court to resolve factual issues, where a jury held that the Padilla Bay Reserve caused a temporary taking and Orian was due compensation.

The final settlement included the cost of the acreage plus interest accrued since the creation of the Padilla Reserve in 1980, in addition to attorney fees. In exchange for $3.6 million, Orian released all claims against the Department of Ecology and transferred all rights in Padilla Bay tideflats to the state. Thus in June 1993, the Padilla Bay National Estuarine Research Reserve in Skagit County quadrupled in size with the acquisition of 8,004 acres from the Orian Corporation and its Padilla Bay associates.

Now, suppose Washington wished to assess the potential benefits and costs of allowing the Orian Corporation to proceed with this

Stakeholders in Padilla Bay Development

▸ Recreational Fishers	▸ Wildlife Viewers
▸ Fish Consumers	▸ Consumers of Housing
▸ Wildlife Viewers	
▸ Nonusers	

development project rather than incur legal costs and takings compensations. If this situation were analyzed from the environmental economist's perspective, the first step would be to ask: "Who are the players that would be affected by the decision?" That is, "Who are the gainers and losers of limiting Orian's ability to use the tidelands as they wished?" Here is a summary of how some of the stakeholders could be affected. First, the losers.

► COMMERCIAL FISHERS. Development activities on or near the shoreline could destroy salmon and dungeness crab habitat, ultimately resulting in reductions in the stocks of these species and subsequent loss of profit to local harvesters. In this market case, it is the lost profits (lost revenues minus costs) that matter — what harvesters would be willing to pay to avoid the development.

If development occurs unchecked, harvesters may move to other grounds (necessarily less desirable, or they would have already been fishing there) and so they may continue to make some profits (but probably less than they would have made). The appropriate loss to measure takes this move into account. It is a measure of how much worse off fishermen are after they make all the adjustments they can. Additionally, if their adjustments affect others (e.g., deplete other's fishing grounds), then those losses must be counted.

Economics has empirical methods for approximating all of these losses. Commercial harvesters may also have other non-commercial values associated with this environment. Harvesters may value the aesthetic setting, the wildlife they see while fishing, etc. These values are typically measured along with other people's values of this sort.

► RECREATIONAL FISHERS. The same ecological disruptions that harm the commercial fishers may also harm the recreational salmon and crab fishers. As a result of development by the Orian Corporation, the recreational fishers may have fewer grounds to fish and their catch rates may decline.

Substitution is again an issue. Recreational fishermen will have other alternative fishing sites and target species, possibly less desirable. We must measure the net effect of the development on these alternatives as well. Note that if the result makes remaining grounds more congested, this loss must be taken into account.

Unfortunately, there is no market that captures how much worse off recreational fishermen are as a result of the development. The measure we seek is the maximum amount of money recreational fishers would be willing to pay to avoid these damages. How we get this measure will be discussed in Chapter 5, Measuring the Value of Non-Market Goods and Services.

▸ **Fish Consumers.** If Orian's development were to affect the fishery for salmon and crab so that significantly fewer salmon and crab were available in the market, fish prices would rise and the consumers of fish would be negatively impacted.

Here, substitution possibilities are very important. The crab and salmon consumers will substitute other products but will, by definition, be worse off (or they would have made these choices to begin with). In addition, if their substitution causes prices of other species of fish to rise, this rise should also be taken into account.

▸ **Wildlife Viewers.** If the Orian overwater housing development on Padilla Bay were to destroy the critical habitat of migrating shorebirds, bald eagles or peregrine falcons, the available area to view these birds may be reduced, as may the number of birds themselves, thus creating an overall reduction in birdviewing opportunities. There is no market to capture these losses directly and we will need to resort to non-market techniques.

▸ **Nonusers: Naturalists and Others Who Care about the Environment but Don't Use the Tideflats of Padilla Bay.** Padilla tideflats are a relatively rare ecosystem and provide critical habitat to endangered bald eagles and peregrine falcons. There may be individuals who do not visit this area but to whom the existence of these important natural resources is valuable. These people may be willing to pay some dollar amount to prevent the destruction of this habitat. Thus, in the event that the Orian development was allowed to occur and the unique resources of Padilla Bay were impacted or injured, these individuals would experience a loss of value.

If development did occur, the following stakeholders might be gainers:

▸ **Orian Corporation.** Orian Corporation would probably be able to increase its profits from the development over and above what they would have made in the next best alternative (i.e. developing housing somewhere else). Most, if not all, of the gains from development will be measurable in markets.

VOL 12

9/1/9

R0042425

▶ WILDLIFE VIEWERS. The Orian development could enhance access to the tidelands and thus improve bird-viewing opportunities. If these prospects were to occur, the benefits to wildlife viewer might increase. Again there is no market to capture these losses directly and we will need to resort to non-market techniques to measure them.

▶ CONSUMERS OF HOUSING. If the Orian development was to have sufficient impact on the Skagit County housing market, the price of housing might drop with the increased availability of housing provided by Orian. Thus, the consumer would gain by the amount of the reduction in housing prices. Again, these gains could be measured using market prices.

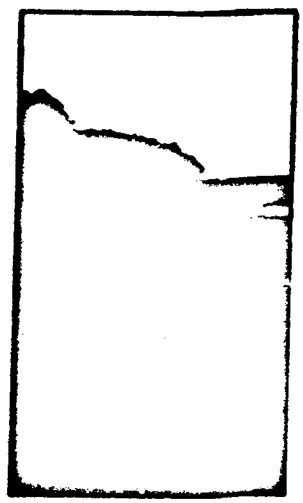
Economic Tools for Use in Coastal Management Decisionmaking

Several types of economic information are useful for coastal decisionmaking. Environmental value is important in some of these: benefit-cost analyis, natural resource damage assessments and sustainable development assessment. Other kinds of information such as economic impact analysis are often confused with value measures, but provide different information to the decision process.



Economic Tool Kit

- Economic Impact Analysis
- Cost-Effectiveness Analysis
- Benefit-Cost Analysis
- Natural Resource Damage Assessment
- Sustainable Development

Coastal management and policy decision making requires information that ranges widely from land-use impacts on natural resources to economic implications of changes to terrestrial and aquatic ecosystems. While the availability of accurate information does not mean that such decision making will necessarily be good, it is clear that the lack of accurate information will almost always contribute to uninformed decisions.

While the focus of this handbook is on environmental valuation, namely, determining the dollar value of natural and environmental resources and resource services, it is important for coastal managers and planners to recognize a variety of alternative economic approaches to generating and presenting economic information. Each approach calls for different skills and research procedures, and each is intended to answer a different question.

Which of these economic approaches planners choose depends on what they want to know. This chapter provides a brief review of the most important economic approaches that can be applied to coastal zone planning and management.

ECONOMIC IMPACT ANALYSIS

Economic impact analysis is a methodology for determining how some change in regulation, policy, or new technological breakthrough, or other action affects regional income and other economic activities including revenues, expenditures, and employment. Economic impact analyses can be focused at any level, for example:

- Local environmental groups may want to assess the impact of a wetlands law on the rate of population growth and tax base in their community
- Regional groups might need to understand the impacts of a national regulation on their particular economic circumstances
- International agencies might be interested in how efforts to control CO_2 emissions might impact the relative growth rates of rich and poor countries

To begin with, we must first distinguish economic activity from economic value. Companies supporting the worth of a proposed development plan, for example, will often cite figures on sales volume or increases in jobs. They may claim that the new development will boost sales of other companies. These numbers are measures of economic activity; they are not measures of social value, or what things are worth to people (see Chapter 2, Concepts in Environmental Valuation). Techniques for measuring the economic or market activity that such development generates is sometimes called economic impact analysis.

If a new establishment moves into a region, economic impact analysis would measure the impact or effects of this new establishment on other businesses. Assume the establishment hires local workers, buys products from local suppliers, and purchases transportation facilities or other services. The individuals and firms that the new establishment buys from may then increase their purchases from other suppliers. Economic activity, then, measures the additional income that is generated by the new spending.

Economic impact analysis does not account for social benefit or value. It does not account for what is being given up, nor what alternatives are foregone (i.e., opportunity costs). For example, an impact analysis of recreational fishing does not contain an analysis of what people would do with their time and money if, as the result of a fishery closure or moratorium, they couldn't go fishing. Would they go bowling instead of fishing? If so, would they generate more or less economic activity in the alternative activity? In addition, impact analysis does not take into account anything that is not traded on the market.

Economic Impact Vs. Social Value

Natural disasters offer examples of why economic activity is not a measure of social value. Most people would have considered society better off had Alaska's Exxon Valdez oil spill not occurred. Likewise, society would have been better off had Hurricane Andrew not hit south Florida. However, each of these disasters generated increased amounts of economic activity. A good deal of money changed hands in the form of increased demand for services, oil spill cleanup employment, construction, sales of plate glass and household supplies. While no one would claim that society benefited as a whole (clearly some individuals and businesses did), the economic impact of these events was positive.

While these expenditures represent revenue to a local community, they also represent costs to the recreationists. Furthermore, expenditures do not measure the loss of value to the angler that would result should fishing no longer be available in an area, or the gain in value to the angler that results from establishing a new fishing opportunity. From a broader perspective, increased fishing activity in one area may generate more expenditures within that area but may also mean an offset of activity and, therefore, expenditures in another area. As a result, the net gain in economic activity between areas may be zero, or even negative.

VOL 12

9/23

COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness analysis is a methodology that can be applied whenever it is unnecessary or impractical to consider the dollar value of the benefits provided by alternatives under consideration (e.g., each alternative has the same benefits expressed in monetary terms or each alternative has the same effects but dollar values have not been assigned). A project is cost-effective if it is determined to have the lowest cost of competing alternatives in present value terms for a given amount of benefits.

Suppose a community determined that its current water supply was contaminated with some chemical, and that it had to switch to an alternative supply. Assume there are several possibilities: the community could drill new wells into an uncontaminated aquifer, it could build a connector to the water supply system of a neighboring town, or it could build its own surface reservoir. A cost-effectiveness analysis would estimate the costs of these different alternatives with the aim of showing how they compared in terms of, say, the costs per million gallons of delivered water into the town system.

A cost-effectiveness modeling approach avoids the issue of evaluating benefits by setting desired objectives beforehand and searching for the lowest-cost ways of achieving these. Such an approach can facilitate the comparison among alternative policy or management plans. Cost-effectiveness analysis can help you eliminate those actions that cost more than equally, or less, effective alternatives or those actions that cost the same as more effective options. Such an approach also allows decision makers to build a "frontier" of cost-effective actions that highlights the higher marginal costs associated with different alternatives.

It may make good sense to do a cost-effectiveness analysis even before there is a strong public commitment to the objective you are costing out. In many cases, it may not be obvious how much people value a given objective. Once a cost-effectiveness analysis is done, they may be able to tell, at least in relative terms, whether any of the different alternatives would be desirable. They may be able to say something like: "We don't know exactly how much the benefits are in monetary terms, but we feel that they are more than the costs of several of the alternatives that have been costed out, so we will go ahead with at least one of them."

VOL 12

9/24

BENEFIT-COST ANALYSIS

Benefit-cost analysis is a methodology that compares the present value[3] of all social benefits with the present value of opportunity costs in using resources. It can give valuable insights into the economic efficiency of management and regulatory actions. If the net value (benefits minus costs) of a project or action is greater than zero, then the that project is considered to be economically efficient. The more the benefits exceed the costs, the better off society is in economic terms as a result of the activity.

It is important to note at the outset that the basic benefit-cost framework has limitations, among them, determining the discount rate of future costs and benefits, discounting and future generations, distributional issues, uncertainty and risk, and irreversibility; these factors will be discussed further in Chapter 7, Theory and Application: Reconciling Differences.

Despite these limitations, benefit-cost analysis is the major tool for conducting economic evaluation of public programs in natural resource management, such as flood control, irrigation, hydropower, harbor improvements, and alternative energy supply projects. It is a four-step process that includes the following elements.

▸ **SPECIFY THE PROGRAM.** Benefit-cost analysis is a tool of public analysis, though there are actually many publics. Thus, the first step is to decide on the perspective from which the study is to be done. If you are doing a benefit-cost study for a national agency, the "public" normally would be all the people living in the particular country. But if you are employed by a city or regional planning agency to do a benefit-cost analysis of a local environmental program, you would undoubtedly focus on benefits and costs accruing to people living in those areas. The first step also includes a complete specification of the main elements of the project or program: location, timing, groups involved, connections with other programs, etc.

▸ **DESCRIBE QUANTITATIVELY THE INPUTS AND OUTPUTS OF THE PROGRAM.** For some projects, determining the input and output flows is reasonably easy. in planning a wastewater treatment facility, the engineering staff will be able to provide a full physical specification of the plant, together with the inputs required to build it and keep it running. For other types of programs, such determinations can be much harder. A restriction on development in a particular region, for example, can be expected to deflect development

Benefit-Cost Analysis is a Four-Step Process

- Specifiy the project or program and alternatives.
- Describe quantitatively the inputs and outputs of the program.
- Estimate the social costs and benefits of inputs and outputs.
- Compare benefits and costs.

VOL 12

9125

[3] Field, B.C. 1994. Environmental Economics. McGraw-Hill, Inc., New York.

R0042431

Benefit-cost analysis involves measuring, adding up, and comparing all the benefits and all the costs of a particular public project or program.

elsewhere into surrounding areas. In this step, we first have to recognize the great importance of the time it can take to complete large undertakings: environmentally related projects or programs may require years. Therefore, the job of specifying inputs and outputs involves predictions of future events, sometimes many years after a project begins. Consequently, having a good understanding of factors such as future growth patterns and future rates of technological change and possible changes in consumers' preferences is important.

► ESTIMATE SOCIAL COSTS. Assigning economic values to input and output flows is to measure costs and benefits. The methods for such measurements are the subject of Chapter 4, Measuring the Value of Goods and Services Traded in Markets and Chapter 5, Measuring the Value of Non-Market Goods and Services.

► COMPARE BENEFITS AND COSTS. In this final step, total estimated costs are compared with total estimated benefits. Table 3.1 illustrates the estimated benefits and costs associated with a regulatory program to control various airborne and waterborne pollutants coming from a group of marinas.

Table 3.1. Results of a Benefit-Cost Analysis of a Proposed Emission Reduction Program for a Group of Marinas

	Totals over life of the program ($ millions)
Costs	
Private compliance	
Capital equipment	580
Operating	560
Public monitoring and enforcement	96
Total	$1,236
Benefits	
Increased benefits to recreators from improved water quality	1,896
Increased property value from reduced air emissions	382
Nonuse value increase related to ecological integrity	749
Total	$3,027
Net benefits	$1,791

Guidelines for Benefit-Cost Analysis that Incorporate Environmental Valuation

While legislation requires net economic benefit analysis, and there are clear applications for environmental valuation, the guidelines for actually doing such an analysis are limited. The two most widely referred to guidelines are the following:

- WATER RESOURCES COUNCIL. *The Economic and Environmental Principles and Guidelines for Water and Related Land Resources Implementation Studies*, 1983, is the latest in a series of guidelines published by the Water Resources Council under the Water Resource Planning Act. It provides the required guidelines to be used for estimating the benefits and costs of constructing a public works project. The early versions of these guidelines first codified the use of applied welfare economics in evaluating public projects. The guidelines establish the elements that need to be taken into account when assessing the benefits and costs of a project, and incorporate the concepts of consumer and producer surplus measures in markets, as well as their counterpart in non-market settings. Unfortunately, the methodological prescriptions are somewhat out of date.

- ENVIRONMENTAL PROTECTION AGENCY. The Environmental Protection Agency's *Guidelines for Performing Regulatory Impact Analysis*, 1991, provides the latest set of guidelines for performing benefit-cost analysis on proposed environmental regulations, as mandated by Executive Order 12291. These guidelines are, for the most part, quite good and are continually being revised to reflect methodological advances. The focus is on measuring and valuing both health and environmental effects. Techniques for valuing the benefits of environmental improvements include travel cost, hedonics, and contingent valuation. The guidelines show an awareness of distributional considerations, both across the current population and between generations.

These emissions reduce the water quality in the bay on which they are located and contribute to air pollution in the vicinity of the marinas. The dollar values are totals of various cost and benefit categories over the life of the regulatory program. Compliance costs in the industry consist of $580 million of capital equipment costs and $560 million of operating costs. Public-sector monitoring and enforcement required to achieve an acceptable level of compliance total $96 million. There are three major benefit categories: recreationists (fishers and boaters) benefit from improved water quality at an estimated value of $1,896 million; property values of local homeowners are expected to increase to $382 million because of improved air quality and visibility resulting from reduced airborne emissions;

VOL 12

9/27

R0042433

nonuse values associated with the general improvement in the ecological integrity of the bay are estimated at $749 million.

We can compare total benefits and costs in several ways. One way is to subtract the total costs from total benefits to get "net benefits." In Table 3.1, the net benefits are $1,791 million ($3,027 minus $1,236). Another criterion is the benefit-cost ratio, found by taking the ratio of benefits and costs. This shows the benefits the project will produce for each dollar of costs; the benefit-cost ratio is 2.5 ($3,027 divided by $1,236)

NATURAL RESOURCE DAMAGE ASSESSMENT

Natural resource damage assessment is a methodology for determining the liability for injury to natural assets that results from release of oil or hazardous substances. Three federal statutes — the Clean Water Act, CERCLA, and the Oil Pollution Act — all impose liability assessments for injury to natural assets that result from oil spills or hazardous wasters and other substances. Under these acts regulations for comprehensive natural resource damage assessments have been developed by the Department of the Interior and NOAA. The process includes three steps: (1) injury determination; (2) quantification of service effects; and (3) damage determination. Environmental valuation plays a role in the latter step. Natural resource damages are the sum of:

- Restoration costs
- Compensable value (diminution in value of foregone natural resource services prior to restoration)
- Damage assessment costs

► RESTORATION COSTS (which also include costs of rehabilitation, replacement, and/or acquisition of equivalent resources) include both direct and indirect costs. Direct costs are costs charged directly to the conduct of the selected alternative, such as staff time, materials, equipment, and the like. Indirect costs are costs of activities or items that support the selected alternative but cannot be directly accounted for, such as overhead.

► COMPENSABLE VALUE is the amount of money required to compensate the public for natural resource services losses between the time of the release and the time when these services are fully restored to their baseline condition. Compensable value excludes any losses associated with secondary economic impacts resulting from the release, such as losses incurred by businesses patronized by users of the injured resources (e.g., bait and tackle shops).

▸ DAMAGE ASSESSMENT COSTS are the costs of peforming the studies to determine the other costs mentioned above.

SUSTAINABLE DEVELOPMENT ASSESSMENT

Sustainable development — development that meets the economic needs of the present without compromising the ability of future generations to meet their economic needs — links two basic ideas: ecological sustainability, which implies that biological elements (including humans) and processes that keep ecosystems productive and resilient, should be maintained; and economic development, which seeks to maintain economic growth or expansion, should be undertaken.

Ecological sustainability and economic development must be linked when implementing policies that would lead to sustainable development. The ability to implement such policies requires multidisciplinary approaches which blend the perspectives, the goals, and objectives of disciplines such as ecology, social science, and economics.

Determining the value of natural resources and environmental assets in the sustainable development framework is useful in a number of ways, including:

- National and regional income accounting
- Strategic benefit-cost analysis
- Project level benefit-cost analysis

▸ NATIONAL AND REGIONAL INCOME ACCOUNTING. Environmental values may be used to modify national income accounts so that they reflect improvements and declines in environmental resources. The objective is to obtain a better index of economic well-being and avoid net loss transfers of wealth between the market and non-market sectors. Standard gross domestic product (GDP) accounts reflect only a portion of a nation's economic productivity (the portion traded in ordinary markets). Using standard accounts, a

VOL 12

9129

R0042435

county or region could destroy its resource base but show an increase in wealth. For sustainable development to be operational in economic policy, environmental accounts and standard economic accounts must be integrated.

▸ STRATEGIC BENEFIT-COST ANALYSIS. The objective of strategic benefit-cost analysis is to set priorities and make trade-offs across a range of alternative policies. Such analysis is motivated by the economic consequences of environmental investments. For instance, strategic analysis may assess the benefits of investments in salmon habitat restoration relative to nonpoint source pollution controls. Alternatively, such an analysis may respond to questions such as, "How much should we clean up? What level of investment should we make in nonpoint source pollution control or salmon habitat restoration?" Beneficial policies are selected and put together to construct an overall policy package or agenda.

▸ PROJECT-LEVEL BENEFIT-COST ANALYSIS. Examines the benefits and costs of specific policy actions and controls and extends conventional benefit-cost procedures to the non-market sector. This extension is increasingly common in development decisions. For example, a study might estimate a household's willingness to pay to hook up a centralized sewer system in order to reduce nonpoint source pollution. In controlling nonpoint source pollution, project-level analysis examines the benefits and costs of specific actions. It addresses the means and methods of control once the general direction of policy is set.

4

MEASURING THE VALUE OF GOODS AND SERVICES TRADED IN MARKETS

If goods or services are traded in the market, there are well established and accepted empirical techniques for measuring welfare changes. For measuring producer surplus, it is not necessary to estimate the supply curve. For measuring consumer surplus, it is essential to estimate the demand curves. These conventional techniques of measuring changes in value serve as a springboard for understanding non-market techniques of economic valuation.

To estimate use values, economists employ market resource valuation methodologies. For those resources for which markets exist, economists typically rely on directly observable behavior in the form of market transactions to reveal preferences or the value that individuals place on goods and services and their willingness to pay to avoid loss of such goods and services. The standard method for measuring the use value of resources traded in the marketplace is the estimation of producer and consumer surplus using market price and quantity data.

MEASURING PRODUCER SURPLUS WITHOUT ESTIMATING SUPPLY

Sometimes the measurement of changes in producer surplus does not require complicated econometric modeling to estimate the supply curve (see Chapter 2, Concepts in Environmental Valuation). Careful measurement of all the opportunity costs of production in alternative situations can be used to estimate the change in producer surplus. Consider the hypothetical case in which habitat degradation results in a reduction of striped bass available to the commercial fishery in Chesapeake Bay, a reduction in catch from 8,000 to 5,000 pounds a day. The ex-vessel price, below, refers to the price paid directly to the harvesters for whole fish.

Prior to the reduction in stock size the state of the fishery was estimated as follows:

Catch rate per day (pounds) = 8,000
Ex-vessel price = \$0.70/pound
Variable costs per pound = \$0.40
Total days fished in season = 16
Total revenue = 16 x 8,000 x 0.70 = \$89,600
Total variable cost[5] = 16 x \$0.40 x 8,000 = \$51,200

Producer surplus = Total revenue minus total variable cost
= \$89,600 – \$51,200 = \$38,400

To simplify the analysis, we assume that the harvesters will not change their fishing behavior, at least in the short run, due to the

[5] Variable costs or costs which vary with output. Fixed costs are not included because, by definition, they do not change in the two scenarios. Thus, even if we bothered measuring them, they would be netted out when comparing the two scenarios.

decrease in stock size. However, reduced stock size can affect harvesters by lowering their catch rate and increasing their variable costs of production. After the reduction in stock size, the state of the fishery is:

Catch rate per day = 5,000
Ex-vessel price = $0.70 (note: for simplicity we assume no price change)
Variable costs per pound = $0.50 (uses more fuel searching for fish)
Total days fished in season = 16
Total revenue = 16 x 5,000 x $0.70 = $56,000
Total variable cost = 16 x $0.50 x 5000 = $40,000

Producer surplus = $56,000 – $40,000 = $16,000

The estimated change in producer surplus is $38,400 – $16,000 = $22,400

Advantages of This Technique. We have a number that can be compared against the producer surplus created by the activity that resulted in the habitat degradation. For the average fisher, the degradation of striped bass habitat has created a welfare loss of $22,400 per year. If there are 100 fishers, the estimated welfare loss would be $2,240,000. In practice the calculation would be more complicated. What will be the predicted response of harvesters due to the reduction in stock size? Will some harvesters drop out of fishing or go after a different species? If so, what is their producer surplus in these alternative activities?

Disadvantage of This Technique. Such an analysis may be problematic because of difficulties in accurately predicting the changes in cost and earnings due to environmental change and in fisher behavior. Also, the prices and cost of inputs and outputs (true opportunity costs) may diverge from accounting costs. This is particularly a problem with fisheries because of the common property nature of the resource. The intricacies of that problem are beyond our study of environmental valuation.

Data Needs. The data required for such an analysis include detailed costs and earnings for a representative fisher. Such information could be obtained from an industry survey.

VOL 12

9133

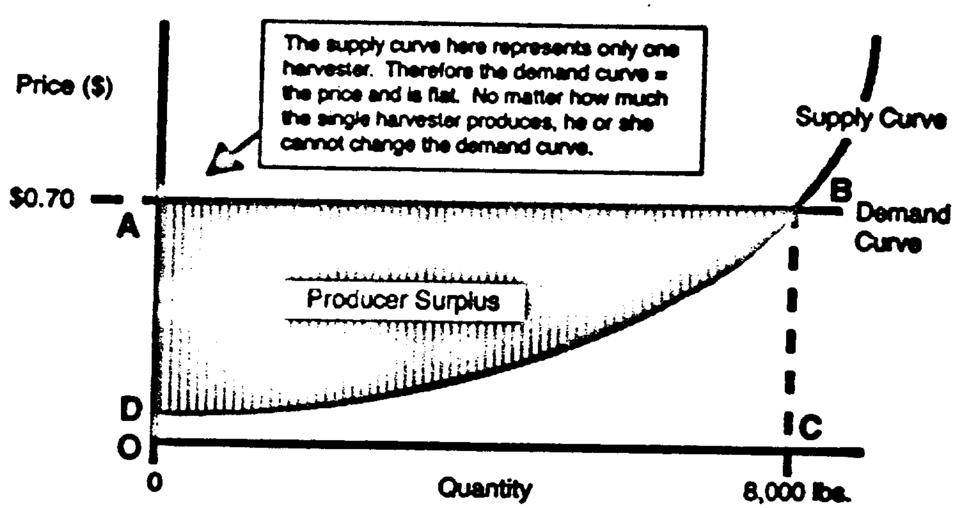
R0042439

MEASURING PRODUCER SURPLUS BY ESTIMATING SUPPLY

Econometric (statistics of economics), techniques can be used to estimate the industry supply curve — these techniques are an alternative to the previous methods for directly calculating changes in producer surplus. The method is directly linked to the previous approach for measuring producer surplus because the industry supply curve is another way of representing the variable costs of production that that method employs. The area under the industry supply curve (to any given quantity) is equal to the industry's total variable cost to produce that quantity.

From Figure 4.1 we can geometrically determine the producer suprlus: draw a rectangle connecting the price of striped bass (Y-axis) and the quantity caught (X-axis) through its point on the supply curve (OABC). The area of this rectangle is simply price times quantity or total revenue, the same as in the previous example. If we subtract from this rectangular area, the area under the supply curve (area of ODBC, equal to total industry variable costs when producing

Figure 4.1. Chesapeake Bay Striped Bass: Measuring Producer Surplus



VOL 12

9134

R0042440

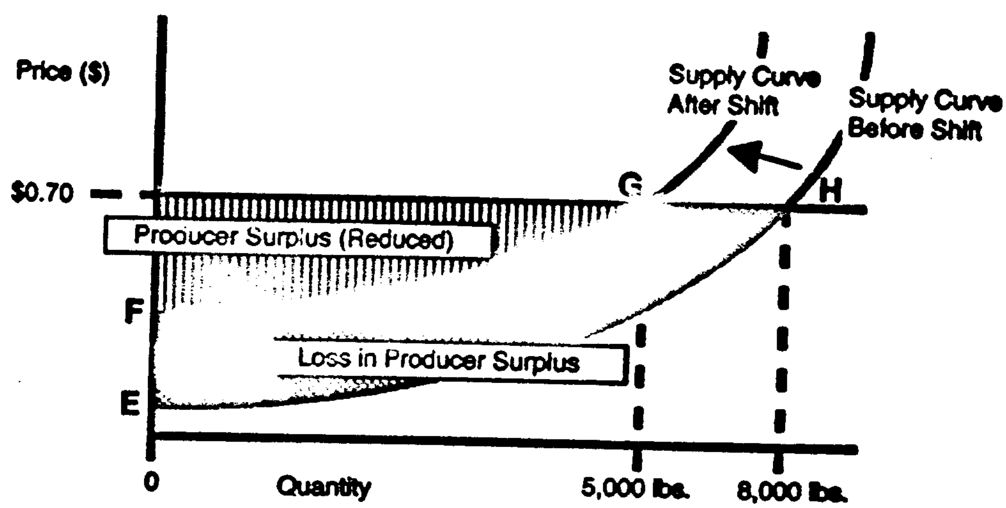
that quantity), the remaining area (ABD) is equal to the producer surplus from the previous method.

The same exercise can be done to describe the situation after the decrease in the size of Chesapeake Bay striped bass populations. The reduction in stock size causes a shift left in the industry supply curve because supply is dependent on the size of the stock. The difference between the areas of the producer surplus triangles with and without the environmental impact is the change in producer surplus (Figure 4.2) or welfare loss (area EFGH).

Disadvantage of This Technique. The major problems associated with this technique include the need to account for all the factors that affect the supply curve over time (e.g., technical change in fishing and regulations) to isolate the effect of the environmental welfare loss.

Data Needs. The data required for this analysis include time series data on input and output prices, landings, and stock abundance.

Figure 4.2. Chesapeake Bay Striped Bass: Measuring Change in Producer Surplus



VOL 12

9135

R0042441

EMPIRICAL TECHNIQUES FOR MEASURING CONSUMER SURPLUS

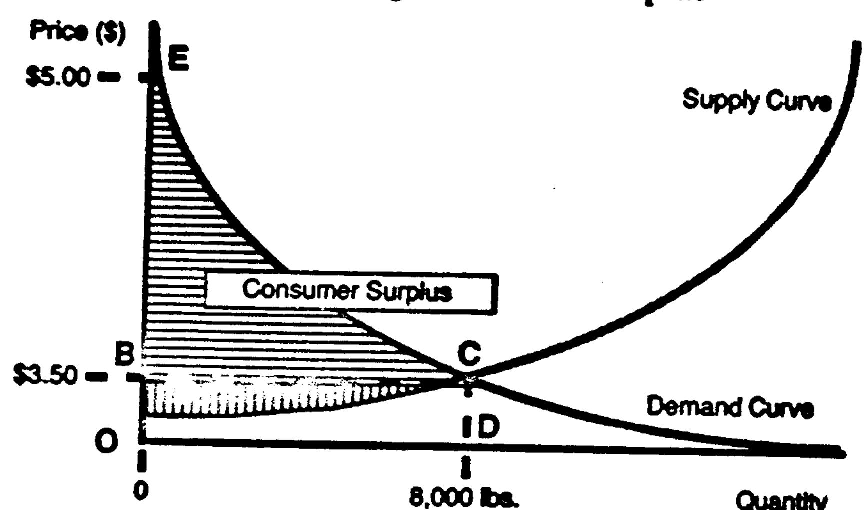
As in the case of producer surplus, econometrics can also be used to estimate consumer demand and thus changes in consumer surplus. The area under the demand curve is equal to the consumer's total willingness-to-pay. Suppose that initially fish consumers must pay $3.50 per pound at the retail fish market. At that price 8,000 pounds of fish are purchased. A simple calculation tells us:

consumer expenditures = $3.50 x 8,000 = $28,000

From Figure 4.3 we can draw a rectangle (area OBCD) connecting the price of striped bass (Y-axis) and the quantity demanded (X-axis) through its point on the demand curve. The area of this rectangle is simply price times quantity or total expenditure, the same as calculated above.

Some consumers may be willing to pay more than $3.50 per pound for their fish, but everyone pays the same price in the store. The area under the demand curve captures the information about the total amount consumers would be willing to pay for the various quantities offered. By subtracting what they actually pay, we obtain an es-

Figure 4.3. Chesapeake Bay Striped Bass: Measuring Consumer Surplus



R0042442

VOL 12

9136

timate of their net welfare from the consumption of striped bass. In our example, the total area under the demand curve (area OECD) out to 8,000 pounds is the consumer total willingness-to-pay ($34,000). Subtracting what the consumers must pay ($28,000) from their total willingness-to-pay, the consumer surplus is equal to $6,000 ($34,000 – $28,000) — this is the area BEC.

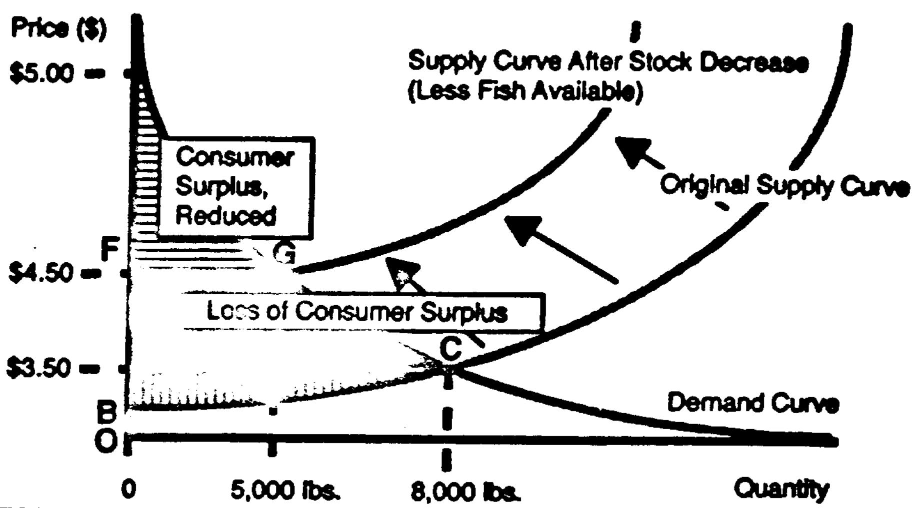
This same exercise can be done to describe the situation after the decrease in the size of Chesapeake Bay striped bass populations. As outlined previously, the reduction in stock size will cause a shift left in the industry supply curve, causing the price of striped bass to rise (Figure 4.4). The difference between the areas of the consumer surplus triangles with and without the environmental impact is the change in consumer surplus (area BFGC).

Suppose now that with the decrease in stock size and subsequent reduction (8,000 to 5,000 pounds) of striped bass being harvested consumers see an increase in the retail price from $3.50 to $4.50 per pound. A simple accounting shows:

consumer expenditures = $4.50 x 5,000 = $22,500

In this new situation, the total area under the demand curve out to 5,000 pounds is the consumer total willingness to pay ($23,750). Subtracting what the consumer must pay ($22,500) from their total

Figure 4.4. Chesapeake Bay Striped Bass: Measuring Consumer Surplus



VOL 12

9/3/7

R0042443

willingness to pay, the new consumer surplus is equal to $1,250. The estimated change in consumer surplus is then:

$6,000 – $1,250 = $4,750

or a loss of $4,750 to society.

Disadvantage of This Technique. The major difficulty with this approach is that effects from changes in supply must be separated from the effects on demand; and shifts in demand, if any, must be accounted for over time.

Data Needs. The data required for this analysis are time series information on market price for the product and quantity consumed, along with measures of other factors that affect demand.

SUMMARY

For environmental goods or services traded in markets, standard economic techniques of measuring supply and demand and determining changes in producer and consumer surplus can be applied using market price and quantity data. There is no difference in the techniques suggested here and measuring the economic value of any non-environmental good or service. In the next chapter, we demonstrate techniques economists have developed to deal with the situation when goods and services and other benefits do not result from market transactions.

5

Measuring the Value of Non-Market Goods and Services

Without the observable price and quantity data that are available when goods or services are traded in the market, economists have devised innovative techniques for measuring changes in value for natural resources and the environment. Three of the techniques, travel cost, random utility and hedonics use information to indirectly determine what a market might reveal in value if it did exist. The contingent value technique attempts to measure the change in value directly.

VOL 12

9139

R0042445

Some goods and services like recreational fishing and wildlife viewing are not traded in a well functioning, traditional market. That is, they are not supplied by private firms and consumers do not pay market prices. Nonetheless, indviduals benefit from their use and, therefore, the loss of such environmentally related goods signifies welfare losses to these individuals. Conceptually, the same measure of benefit applies to market and non-market goods, that is, the maximum amount an individual would pay to avoid losing, or gaining, access to the good. Since these are non-market benefits, typically, there is no producer, or the consumer is both the producer and consumer. Thus, measures of non-market benefits are concerned with estimates of consumer demand and consumer surplus. There are a variety of methods that have been developed to measure this value concept in the absence of markets.

Non-Market Valuation Techniques

In the absence of ownership and efficient pricing, we need special techniques to place consumer preferences for natural resources and environmental goods and services on common ground with the demands for more conventional commodities. Three types of procedures have been employed to measure these demands.

- **Travel cost and random utility models, which are based on expenditures and travel behavior for recreational opportunities**
- **Hedonic methods of decomposing prices of market goods to extract embedded values for related environmental attributes**
- **Experimental methods for eliciting preferences, either by using hypothetical settings, called contingent valuation, or by constructing a market where none existed**

Travel cost models, random utility models, and hedonic methods are indirect measures based on observable behavior. Experimental methods, or contingent valuation, are based on direct surveys of individuals.

INDIRECT MEASUREMENT TECHNIQUES

Indirect techniques rely on observable behavior to deduce how much something is worth to an individual even though it is not traded in markets. These methods produce value estimates that are conceptually identical to market values, but they must be measured more creatively since market data are not available. Indirect techniques include travel cost models, random utility models, and the hedonic pricing method.

▸ Travel Cost Model

Overview. The travel cost method is, in general, employed to estimate recreational values. This technique assumes that visitors to a particular site incur economic costs, in the form of outlays of time and travel expenses, to visit the site. In effect, these economic expenditures reflect the "price" (albeit implicit) of the goods and services provided by the site, and are an indirectly observable indication of the minimum amount that a visitor is willing to pay to use the site (with all its associated attributes).

By observing the characteristics of individuals visiting the site — for example, the specific attributes of their trip to and from the site as well as the total number of visits — economists are able to estimate the "derived demand" for the site. That is, for any given or implicit price, the derived demand relationship will determine the number of visits consumers will "purchase" at that site.

The travel method technique has a number of applications — it can be used, for example, to measure the effects on a consumer's willingness-to-pay because of changes in access costs to a recreational area, or the elimination of a site, or changes in environmental quality.

Issues that Require Attention in Travel Cost Modeling

- **Costs, because time costs are often critical in recreational consumption**
- **Characterizing the quality dimensions of the site and taking proper account of substitute sites and their characteristics**
- **Estimating both the individual's decision as to whether to use the site and his or her decision as to how much to use it**

Advantages of This Technique. The travel cost technique is relatively uncontroversial because it mimics empirical techniques used elsewhere in economics. Economists generally tend to prefer techniques of this sort because they are based on actual behavior rather than verbal responses to hypothetical scenarios. In the travel cost model, individuals are actually observed spending money and time, and their economic values are deduced from their behavior. In appropriate circumstances, this model can often be applied without enormous expense.

Disadvantages of This Technique. The greatest disadvantage of travel cost and other indirect techniques is that they can not be employed unless there is some easily observable behavior that can be used to reveal values. Thus, in the case of measurement of nonuse values these methods are inappropriate. In the case of nonuse values, there is no observable interaction between the individual and the resource in question

Travel cost models are also technically and statistically complicated. Understanding the conceptual measure requires understanding the connection between consumer surplus (measures of changes behind demand curves) and the "maximum willingness to pay" concept. In addition, data must be employed to statistically estimate increasingly sophisticated econometric models that take into account such factors as sample selection problems and non-linear consumer surplus estimates. Finally, the resulting estimates sometimes have been found to be rather sensitive to arbitrary choices of the functional form of the estimating equation and the treatment of time. Though much technical work has been dedicated to improving these methods, they will continue to be subject to the problems that plague all empirical economic estimation.

Data Needs. While the early travel cost models used information on the proportions of visitors from increasingly distant zones of origin from which their travel occurred (called "zonal models"), current methodology requires data on individual travelers. Typically this information is collected through surveys. On-site surveys can provide heavy sampling of users, but these need to be augmented with surveys of the general population in order to learn what proportion of the population uses the resource. A survey of the general population also provides data on the characteristics of the resource users as well as information that helps the economist estimate the participation decision.

Unfortunately, a travel cost study is best at assessing the current situation. To analyze the gains or losses from changes in the recreational resource, economists need to conduct travel cost studies under varying circumstances or they need a way of extrapolating the effects of change. Ideally, an important recreational resource could be subject to periodic travel cost studies, so that the effect of differing conditions of the resource could better be estimated. This is especially true if one is measuring the damages from a disaster such as the effects of an oil spill on recreational boating. Economists would find invaluable a travel cost study that had been completed before the disaster.

Estimating the Value of Recreational Bird-watching: Travel Cost Model

Suppose a development project calls for filling a wetlands area, an area that is a major bird-watching site for the region. In this case the valuation question might be: What would be a money measure of the lost value of observing birds in this area due to the development? The answer could be used as input to a benefit-cost analysis of the proposed development.

The first step in such an analysis is to survey participants on bird-watching trips about trip expenses. The second step would examine the relationship between the number of participants and trip expenses such as in the table.

Table 5.1. Travel Cost Data.

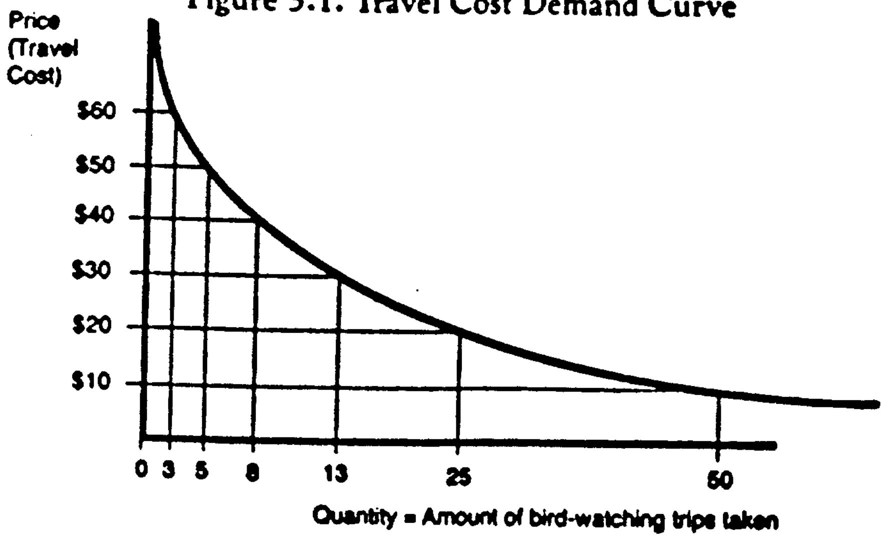
Trip Expense Range	Number of Trips
< $10	50
$10-$19	25
$20-$29	13
$30-$39	8
$40-$49	5
$50-$59	3

In the absence of such ideal studies, researchers would find any information on the level of use of the resource beneficial (e.g., historical information on number of users, their location of residence, and frequency of use). Moreover, any information that would help shape the sampling method would be valuable (e.g., when the resource is most heavily used and by whom).

As with all environmental valuation, the researcher's most difficult job is connecting the environmental event with the effect on the user. Any insights here are invaluable. In the development case, the analysis would need to be accomplished as a hypothetical case. To use results from a travel cost model, researchers need to know how recreationists would be affected by the development activity and how that effect would translate into changes in behavior.

From this and other data collected about the individual participants, we can estimate a travel cost demand curve with the travel cost as the price and the number of trips as the quantity shown in Figure 5.1. This demand curve will also be a function of other information collected from the individuals that help to explain their bird-watching behavior (e.g., income, ethnicity, education, etc.). We must also make adjustments econometrically

Figure 5.1. Travel Cost Demand Curve



for the non-participants, the people who might go bird-watching in the area under different circumstances (e.g., if they had lower travel costs).

The travel cost demand curve applies to a representative individual from a particular geographic region or socio-economic class. It is not the aggregate demand curve. To get an aggregate value measure, individual consumer surplus must be augmented by a population expansion factor which this individual represents.

This curve represents the recreational demand for bird-watching prior to the development. If bird-watching is completely eliminated at this site, then the total consumer surplus is lost. However, the more likely consequence is that the quality of the bird-watching trip will be lowered. We will need to predict how the demand curve will shift, and then measure the consumer surplus with and without the shift.

▸ Random Utility Models

Overview. Though conceptually similar to travel cost models, random utility models do not focus on the number of trips recreationists make to a given site in a season; rather, they focus on the choices of recreationists among alternative recreational sites. This type of model is particularly appropriate when substitutes are available to the individual so that the economist is measuring the value of the quality characteristics of one or more site alternatives.

VOL 12

9144

Advantages of This Technique. The same advantages that apply to travel cost models are applicable with random utility models. Many economists consider this method as the state-of-the-art in recreational demand modeling. Relative to the travel cost model, this approach deals well with substitute sites and environmental quality considerations.

Disadvantages of This Technique. The approach has all the disadvantages of the travel cost method, though it is much more data intensive.

Data Needs. Because a researcher needs to know what alternative sites are considered by recreationists, as well as recreational behavior with respect to all these alternative sites, the data requirements are greater. In addition, accurate measurements of the characteristics of alternative sites are important.

Estimating the Value of Recreational Bird-Watching: Random Utility Model

The superiority of the random utility model approach over the standard travel cost method will be evident. In a hypothetical example (Table 5.2), suppose Site I is the birdwatching area proposed for development. However, there are two other relevant sites in that area, each having its own characteristics with regard to the experience the bird-watcher will have. These experiences are represented in the example by a species diversity index and a

Table 5.2. Multiple Sites with Quality Differences.

Site Attributes	Site I Proposed Fill Site	Site II	Site III
Species Diversity Index	5.2	4.8	3.6
Bird-Spotting Index	8.7	5.9	6.3

VOL 12 9145

bird-spotting index. The greater the diversity of species and the more likely the individual will see unusual birds, the greater the value of the recreational experience. Because of locational differences and the value of time, each individual will incur different costs to go to each site. Table 5.3 summarizes the pattern of visits to the different sites by three different individuals. The data in these two tables are the type typically used to determine the value of access to the site, or changes in quality at a site. These data provide us with observable information about how individuals make tradeoffs between the quality of the site and the cost of accessing it. In the travel cost model, we only have one site, so it is difficult to determine how individuals respond to quality changes unless the quality of that site has changed over time.

Note that the random utility model requires data about participation at the study site as well as relevant alternative sites. Site characteristics are also implicitly considered in the decision model. In the example, we looked at a species diversity index and an index of number of bird spottings per hour as the relevant characteristics that vary across sites.

Table 5.3. Trip Expenditures and Number of Trips Taken (Example of data from three individuals in our sample).

	Individual	Site I	Site II	Site III
1	Travel Costs	$10	$20	$30
	Number of Trips	4	2	0
2	Travel Costs	$15	$8	$40
	Number of Trips	0	5	1
3	Travel Costs	$20	$20	$20
	Number of Trips	5	2	3

VOL 12

9147

▸ Hedonic Pricing Methods

Overview. The hedonic pricing method is another technique to determine environmental value. In its earliest applications, these techniques were intended to capture the willingness-to-pay measures associated with variations in property values that result from the presence or absence of specific environmental attributes, for instance, air pollution, noise, or water views. By comparing the market value of two properties which differ only with respect to a specific environmental attribute, economists may assess the implicit price of that amenity (or its cost when undesirable) by observing the behavior of buyers and sellers.

A variation on the approach of comparing the effects of an environmental attribute would involve comparing the price of a single piece of property over successive sales. By correcting for other factors that might influence the value of the subject property, economists are able to isolate the implicit price of some amenity or bundle of amenities which have changed over time. The price of a house may be affected by factors such as the number of bedrooms, the square footage, the existence of a pool, the proximity to local schools, shopping, highways. The price may also be affected by the proximity to, or quality of, environmental amenities. Air quality has been found to be a determinant of housing prices in Los Angeles; whether or not a property abuts a woodland may also matter. Hedonic methods can also be used to estimate the effect of certain disamenities on the price of a house, for instance, the impact on the price of a residential property adjacent to an area affected by a spill or some proposed unfavorable development.

The process for estimating an hedonic price function that relates housing prices to the quantities of various characteristics is reasonably straightforward. However, it is much more difficult to derive value measures from these estimated functions. Only under very restrictive assumptions can values be obtained directly from these estimated functions. In most cases, a two-stage procedure that depends on information from multiple markets is necessary.

Advantages of This Technique. The hedonic techniques, like travel cost and random utility models, depend on observable data resulting from the actual behavior of individuals. Market data on property sales and characteristics are available through real estate services and municipal sources and can be readily linked with other secondary data sources.

R0042453

Disadvantages of This Technique. Most environmental incidents will have only small, if any, effects on housing prices. Even where effects do exist, it may be difficult to estimate them using econometric methods because many factors, many of which are correlated, influence housing prices. For example, a house located near a factory with emissions that reduce air quality may be in a poorer section of town where schools are not as good and there are few other amenities like parks. Even when implicit prices for environmental amenities can be estimated, it is usually very difficult to obtain measures of value from these models. The connection between the implicit prices and value measures is technically very complex and sometimes empirically unobtainable.

Data Needs. Data needs include prices and characteristics of houses sold in the housing market of interest. In particular, a measure or index of the environmental amenity of interest is needed.

DIRECT TECHNIQUES

▸ *Contingent Valuation Method (CVM)*

Overview. The most obvious way to measure nonmarket values is through directly questioning individuals on their willingness-to-pay for a good or service. Called the contingent valuation method, it is a survey or questionnaire-based approach to the valuation of non-market goods and services. The dollar values obtained for the good or service are said to be contingent upon the nature of the constructed (hypothetical or simulated) market and the good or service described in the survey scenario.

The contingent valuation technique has great flexibility, allowing valuation of a wider variety of non-market goods and services than is possible with any of the indirect techniques. It is, in fact, the only method currently available for estimating nonuse values. In natural resources, contingent valuation studies generally derive values through the elicitation of respondents' willingness-to-pay to prevent injuries to natural resources or to restore injured natural resources. Since the first published contingent valuation study on valuing outdoor recreation appeared in 1963, more than 1,400 related documented papers, reports, and books have been published.

In contingent valuation methods, randomly selected samples or stratified samples of individuals selected from the general population

VOL 12

9148

are given information about a particular problem. They are then presented with a hypothetical occurrence such as a disaster and a policy action that ensures against a disaster; they are then asked how much they would be willing to pay — for instance, in extra utility taxes, income taxes, or access fees — either to avoid a negative occurrence or bring about a positive one. The actual format may take the form of a direct question ("how much?") or it may be a bidding procedure (a

9149

R0042455

ranking of alternatives) or a referenda (yes/no) vote. Economists generally prefer the referenda method of eliciting values since it is one most people are familiar with. The resulting data are then analyzed statistically and extrapolated to the population that the sample represents.

Contingent valuation studies are conducted as face-to-face interviews, telephone interviews, or mail surveys. The face-to-face is the most expensive survey administration format but is generally considered the best, especially if visual material needs to be presented. Non-response bias is always a concern in all sampling frames. In other words, people who do not respond have, on average, different values than people who do respond.

Pros and Cons of Contingent Valuation

Pros

1. Based in economic utility theory and can produce reliable estimates.
2. Most biases can be eliminated by careful survey design and implementation.
3. Currently the only method available to measure important nonuse values associated with natural resources.
4. Has been used successfully in a variety of situations.
5. Is being constantly improved to make the methodology more reliable.

Cons

1. Estimates of nonuse values are difficult to validate externally.
2. Stated intentions of willingness to pay may exceed true feelings.
3. Results may appear inconsistent with tenets of rational choice
4. Respondents may be unfamiliar with the good or service being valued and not have an adequate basis for articulating their true value
5. Respondents may express a value for the satisfaction ("warm glow") of giving rather than the value of the goods or service in question
6. Respondents may fail to take questions seriously because the financial implications of their responses are not binding.

VOL 12

9/5/1

Advantages of This Technique. In principle, contingent valuation methods can be used to estimate the economic value of anything, even if there is no observable behavior available to deduce values through other means. It is the only method that has any hope of measuring "existence values," i.e., the value that individuals place on simply knowing the natural resource exists in an improved state. This is because since existence values are not connected with use and all other methods depend on observing actual behavior associated with the resource.

Though the technique requires competent survey analysts to achieve defensible estimates, it is not difficult to understand. The responses must be statistically analyzed, but require no more than the understanding of a mean or median value.

Disadvantages of This Technique. When conducted to the exacting standards of the profession, contingent valuation methods can be very expensive because of the extensive pre-testing and survey work. In addition, while this technique appears easy, its application is fraught with problems, for example, the possibility of strategic bias by respondents or structural problems in questionnaire design. Moreover, question framing, mode of administration, payment formats, and interviewer interactions can all affect results.

Many questions have been raised about the reliability of the contingent valuation method for the calculation of nonuse values particularly in regard to natural resource damage assessment under OPA. Because this subject is complex and contentious and has ramifications not applicable to the use of CVM in applications other than damage assessment, it is not discussed here.

Data Needs. The quality of a contingent valuation questionnaire depends upon the amount of information that is known beforehand about the way people think about the resource in question. Information on who uses the resource and who knows about it are critical. When the contingent valuation method is applied to use values, the economist undertaking the survey will want to sample populations most likely to use the resource. The key point is that while all the information necessary for assessing an individual's value of the resource is collected in the survey, the economist needs help in identifying a representative sample and information to allow extrapolation to the population.

Illustration of Contingent Valuation Methodology

Suppose development along the coast of New Jersey would result in impacts to coastal waters that will lower the quality of recreational activities. It is estimated that such development might lower recreational fish catches by (100, 50, 25%), increase beach closings, and lessen the quality of the recreational boating experience. A number of environmental groups have proposed a program that will mitigate impacts of the development on recreation. It is to be funded by a tax on individuals such as yourself and would be ($5-1,500) per year. Given that the development will occur, and specifically relating to fishery catch, are you willing to fund the mitigation program at this cost to you? (A "yes" answer requires respondent to specify the amount of his/her willingness-to-pay for mitigation to prevent various levels of catch reduction.)

a. yes
b. no

Table 5.4. Willingness-to-Pay for Mitigation.

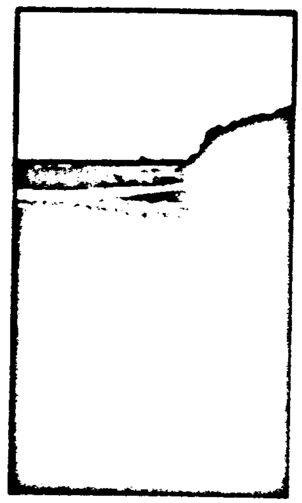
Individual's cost for mitigation	Percent Responding Yes to Reduction in Catch		
	100% Reduction	50% Reduction	25% Reduction
$5-25	100%	100%	95%
$25-50	88%	78%	65%
$50-75	51%	45%	40%
$75-100	22%	15%	12%
$100-200	8%	6%	4%
$200-300	7%	7%	6%
$300-400	5%	2%	1%
$400-500	2%	1%	1%
$500-750	1%	1%	1%
$ 750-1000	0%	0%	0%
>$1000-1500	0%	0%	0%

This data can be used to econometrically determine the mean willingness-to-pay for the mitigation program (mean=$160). The aggregate measure would be determined by multiplying the mean willingness-to-pay by the appropriate sample size. In this case, we might only be interested in fishers, beach goers, or boaters (n=10,000): Willingness-to-pay = $160 x 10,000 = $1,600,000 per year.

6

BENEFIT TRANSFER

Application of environmental valuation techniques may be expensive, particularly for local decision-making where research budgets are limited. Benefit transfer offers a lower cost alternative to performing a full-scale study for any particular issue.



VOL 12

9153

R0042459

Benefit transfer is an application of a data set developed for addressing one particular environmental or natural resource valuation question to another context. Given the expense and time associated with estimating values of non-market natural resources and services, benefit transfer can be a reasonable method for determining such values. Benefit transfer applications can be divided into three classes:

- Estimates based upon expert opinion (e.g., the transfer of average net willingness-to- pay or proxy values)
- Estimates based on observed behavior (e.g., transfer of the entire demand equation)
- Estimates based upon preference elicitation mechanisms, i.e., the contingent valuation method

Benefits transfer are considered to be valid under well-defined conditions. Factors to consider in conducting a benefit-transfer decision include some of the following considerations:

GENERAL ASSUMPTIONS

- For what purpose were the original value estimates generated?
- What user group(s) were considered in generating the initial estimate (e.g., duck hunters versus all citizens in an area)?
- Did the existing study address a specific or unique problem that may have influenced the magnitude of the estimates obtained (e.g., during a period of heightened concern for the resource in question)?
- Have general attitudes, perceptions, or levels of knowledge changed in the period since the existing study was performed in a way that would influence the value of the benefit estimate? Are these values likely to be consistent over time?
- If the value being considered is for a generic resource category (e.g., common songbirds), are the species considered in the original study relevant to the case at hand?

VOL 12

9154

- Were adjustments to the data made in the existing study? For example, were outliers deleted? Were any adjustments made for perceived biases?

- Does the existing study consider the same or a similar geographic area? Are the demographic and socio-economic characteristics of the two areas similar?

METHODOLOGY

- If the source being used presents a composite of existing values based on an earlier literature review, what methods were used to derive these composite values and what was the nature of the underlying studies?

- Were baseline conditions (e.g., ambient water quality) in the existing study similar to baseline conditions in the case at hand?

- Were variables omitted from the original study that are believed to be relevant to the case at hand? To what extent does such omission prohibit the transfer?

- If current best research practices were not used to generate the value estimate(s), can the estimate(s) be adjusted to reflect changes in the state-of-the-art?

ECONOMIC METHODS/EVALUATION

- Was the study used to generate the value estimate published in a peer reviewed journal, or did it receive other forms of peer review?

- How is the original study viewed in the professional community? How was the study viewed by its sponsor?

RESOURCE

- How does the resource that was affected compare to that considered in the referenced study (e.g., is the species of concern

VOL 12

9155

R0042461

more common in the policy study area than in the initial study area)?

- What was the nature of substitutes in the initial study area, and how does this compare to the policy study area (e.g., are alternative recreational opportunities more or less available in the policy study area)?

- Was the original analysis conducted to value all organisms of a given species, a sub-population, individual members of the species, or some other grouping?

Decision-makers should consider all available estimates, each based on the factors described above. Once a final set of values has been chosen, consideration should be given to their general magnitudes. If the existing value estimates differ significantly, or if values generated using alternative models differ significantly from one another, consideration should be given to whether they differ in a predictable and consistent manner. In some cases it may be possible to combine these estimates formally through meta analysis.[5] In all cases, more defensible benefit estimates will result from comparative analysis.

In many cases the defensibility of the transferred economic benefit estimate will depend on the quality of the underlying research. However, no globally accepted, standard criteria are available to judge the quality of existing studies. The professional and academic community can provide guidance with regard to the current minimum conditions for quality assurance of the benefit transfer.

The Economic Analysis and Research Branch of the U.S. Environmental Protection Agency, Office of Policy Planning and Evaluation has prepared *The Environmental Economics Database*, a collection of references for national resources and environmental amenity valuation studies collected over several years. Computer disks of the database are available.

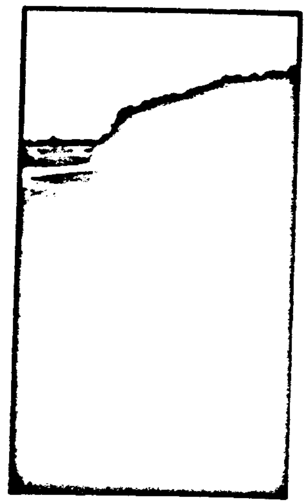
Theory and Application: Reconciling Differences

In the practical application of environmental valuation, issues such as choosing a discount rate, dealing with intergenerational transers and equity, and decision-making under risk and uncertainty can become important to the outcome and interpretation of the analysis. This chapter provides a brief introduction to these topics. Arguments about the appropriate discount rate can unduly obscure the underlying message that there is an economic value to natural resources and the environment.



Valuation of natural resources and environmental amenities can meet with difficulty under certain conditions. For example, if the use of a particular resource is impossible to reverse, the economic and social impacts over a long period of time must be considered. Such a consideraton in turn raises the question of discounting or, more generally, the efficiency and equity of resource use in the long run. Moreover, where information about the costs and benefits of alternative uses is particularly poor, perhaps because of the long period to which it must apply and the non-market character of some of the uses, decisions should take this uncertainty into account.

This section briefly examines these issues from a conceptual view. Unfortunately, theory does not spell out the precise quantitative adjustments that would be required in applying these issues to estimate benefits and costs in empirical work. The major point is this: the traditional benefit analysis of resource use and allocation as a basis for public decision-making is only one part of the decision process which must be accompanied by subjective notions of risk-taking and equity. A benefit-cost analysis in isolation should not be the sole basis for decision-making.

DISCOUNT RATES

When gains or losses from either a program or action accrue to individuals over time, discounting methods are typically used. Discounting is a procedure that deducts future values of a particular good — the aim is to determine the present value of the stream of benefits or costs in relation to the benefit or costs at different times in the future, i.e., benefits or costs occurring in different magnitudes at different dates in the future.

The basic principle of discounting is that a dollar received or paid next year is worth less than a dollar received or paid this year. For example, a dollar received this year may be deposited in a savings account earning, for example, 5 percent interest. On the one hand, at 5 percent interest, the dollar will be worth $1.05 the next year. Looked at from the discounting perspective, one dollar received or paid next year is only worth approximately $0.95 today. The *discount rate* in this situation is 5 percent, the interest on savings accounts. Other market interest rates, such as interest on bonds or corporate portfolios, may be used as discount rates as well. Such rates are based on the *private opportunity cost principle* or *private time preference*.

Discounting may reflect other social or psychological considerations. For example, many people exhibit "impatience." Understandably, they may value recreational experience more highly now than if they were promised the same experience ten years from now. The reasons are many — the immediate desire for pleasure and the relief from stress are only two. The result of preferring present consumption or change in the state of the world is positive discount rates. Alternatively, a concern for future generations might lead to the opinion that values in the future are worth as much as values today, implying a zero discount rate.

In general, the application of discounting in a social value context incorporates the more complex concept of *social time preference* and is often very difficult to determine. The problem of measurement parallels that of market and non-market goods. The private rate of time preference is revealed in markets, but the social rate is not. With respect to natural resources, the fundamental issue is one of defining a discount rate which reflects society's collective preferences regarding resource utilization or retention. The discount rate in the natural resource or environmental arena can be thought of as a measure of the opportunity cost of not having immediate access to a resource.

Suppose a decision must be made on whether or not to implement an oyster reef program in Chesapeake Bay. Assume a one-time startup cost of $100,000 (Table 7.1). The benefits associated with the program are projected for three years in increased returns to the local oyster industry: $15,000 in 1994, $80,000 in 1995, and $25,000 in 1996. Discounting will be crucial in determining whether the reef program is an efficient use of society's resources.

Table 7.1. Discounted Net Present Value (NPV) of Oyster Reef Program.

Year	1993	1994	1995	1996	NPV
Benefits of Reef Program	$0	$15,000	$80,000	$25,000	-
Reef Development Cost	-	$0	$0	$0	-
0% Discount Rate	-	-	-	-	$20,000
3% Discount Rate	-	-	-	-	$14,041
5% Discount Rate	-	-	-	-	$9,775
7% Discount Rate	-	-	-	-	$5,269
10% Discount Rate	-	-	-	-	-$1,950

Without discounting (or a zero discount rate), the net present value of the reef program is $20,000 and the program may be consid-

VOL 12

9159

R0042465

ered economically efficient. With a 5 percent discount rate, the net present value is $9,775. However, with a 10 percent discount rate the program results in a net loss of $1,950, suggesting an inefficient use of resources. Which discount rate is "correct"? The answer depends.

Difficulties arise in choosing the "correct" rate of discount. From the example, it is clear that the larger the discount rate, the more weight that is put on the present relative to the future. Large discount rates give less weight to environmental benefits or damages that don't accrue immediately but only in the long term. Real rates of between 0 and 8 percent appear regularly in the economics literature. Some have even argued for negative discount rates to reflect the implicit interest of future generations in resource management decisions.

Despite the extensive literature, a consensus does not yet exist on an appropriate procedure for discounting costs and benefits of public programs and regulations. It is clear, however, that the characteristics of natural resources (e.g., slow-growing, renewable, and typically held in public trust) necessarily imply that they should be treated differently than other private capital assets.

IMPACTS ACROSS GENERATIONS

We referred earlier to distributional implications of different outcomes. What happens when the distributional implications span generations? How do we compare situations when one generation gains and another loses? Discounting at some market-based rate of interest is commonly used to express future costs and benefits in terms of present monetary value, assuming that a value received now is worth more than the same value provided at some future date. Obviously, standard discounting procedures will weight the effect on the current generation far more heavily. Thus, some critics feel that discounting results in greater resource exploitation or use of natural capital now, at the expense of future generations. Is there an ethical basis for this discrimination against future generations?

Some economists have proposed that decisions affecting the future should be made with decision-makers placed behind a "veil of ignorance" about which generation they belong to. This impartiality criterion suggests equal use of irreplaceable resources across generations, implying a zero discount rate. But with a zero discount rate, if enough generations are involved, use of non-renewable resources (such as oil) approaches zero for any given generation. Likewise, irreversible development (such as building a dam in a unique natural area) is essentially precluded. Furthermore, a zero discount rate may foreclose future options by undervaluing investments that produce wealth and new technology that would be of great value to future generations.

Clearly, some compromise is needed between a zero discount rate, which would preclude many resource uses and perhaps prevent valuable technological advances, and a typical market rate that reflects only the atomistic time preferences of the current generation. This compromise has been called a *social rate of discount*; its argument is that the government in this role should consider the wishes (the values) of both current and future generations. Because the welfare of future generations depends on current consumption patterns, the government should assure protection of future welfare by policies that force sufficient resource conservation. In essence, the government would proclaim what it deemed to be an appropriate discount rate.

Another argument takes a more democratic approach, recognizing that the government is run by and for the current generation; thus, any saving for the future must rely on the values of the current generation. The basis of this argument is that most citizens have a set of held values that include a concern for the larger group (including the future) as well as concern for self. If people do value the welfare of the future, then what is needed is a way for that value to be expressed and measured — a way that avoids the singular context of the marketplace.

UNCERTAINTY AND RISK

In practice, environmental valuation must contend with a great deal of uncertainty. One source of uncertainty is in the problem of predicting the consequences of today's environmental policies and actions. Will the reduction in nutrients that enter coastal waters lead to increased fish populations? Will controls on development lead to cleaner estuaries? Another source of uncertainty results from the increasing use of models, both biological and economic, to predict outcomes. Modeling is inherently a source of error, as is the measurement error of data used to calibrate the models.

There is a branch of economics that deals with decision-making under uncertainty that should be an integral part of any environmental valuation exercise. Uncertainty surrounding environmental mea-

VOL 12 9161

Models are like maps that try to chart a complex territory in which the landscape cannot be completely known — they depend on variabilities in human nature and ecosystems themselves.

surements can be introduced explicitly into background analyses by three methods:

- Direct enumeration, which requires us to list all possible outcomes
- Probability calculus, which employs formulae for the computation of such statistics as the means and variance of a probability distribution
- Stochastic simulation, which is also known as Monte Carlo simulation or model sampling

While it is clear that the decision-maker should be given as much information as possible about the probability distribution of potential outcomes of environmental actions, there are no hard and fast rules as to the "correct" way to incorporate this information.

Risk is closely related to the notion of uncertainty, focusing on the outcome that is affected by uncertainty. Every project or policy decision has risk associated with it. There is always some probability that costs and benefits will not be exactly what are expected. For example, the major risk factors inherent in coastal wetlands projects are attributable to imperfect scientific knowledge of biophysical relationships, such as uncertainty about salinity effects on cordgrass growth, and probabilistic natural phenomena, such as varying meteorological and hydrological events.

A typical method of accounting for risk is to adjust discount rates upward for projects or decisions with more risk. An alternative is to establish risk rankings of projects or decisions, along with other measures of anticipated benefits. Decision-makers may select actions with lower net benefits, if they are more certain of the outcome. This is an example of risk aversion which enters into the decision process.

IRREVERSIBILITY

For many environmental risks, the possible negative impacts are irreversible in the sense that they cannot be undone by subsequent actions, for instance, the possible ecological effects of global warming and species extinction.

The possibility of irreversible effects makes current policy decisions particularly important, since recovery from poor decisions is not possible. In other words, we must live with the consequences of current policy choices without the possibility of future rectification. In general, the benefits of risk reduction are likely to be greater, if the possible negative effects of a risky activity are irreversible, than they would be if those effects could be offset, or reversed, by subsequent actions. For example, the introduction of a non-indigenous species such as the Pacific oyster to an estuary or bay in the Mid-Atlantic is riskier when the consequences are irreversible than when they are not.

The major implications of the existence of intertemporal conflict and uncertainty with respect to the use of the natural environment is that it will be most efficient to proceed very cautiously with any irreversible action.

CASE STUDIES

VOL 12

9164

ABOUT THE CASE STUDIES

The case studies in this section represent a unique learning tool for applying the economic valuation techniques presented in the text of this handbook to real-world situations. Although some of the cases have been modified and have been placed in a hypothetical context, they closely mimic actual scenarios. In reading and responding to the exercises that follow each case study, the users of this handbook can apply what they have already learned or return to the text to refresh their understanding of the techniques to be used. Typically, at the workshops where facilitated training has been given, a participant will take part in two case-study sessions on the second day of the training. These case-study sessions are conducted by a workshop leader or by other individuals with particular subject matter expertise.

In putting together this handbook, the authors have been guided by the need to make it truly national in scope. We have included cases dealing with questions that might arise in all regions of the Nation. While the cases deal with a specific state or regional context, they can be applied throughout U.S. coastal areas. In fact, we have learned that workshop participants sometimes learn more easily from materials with which they do not have familiarity. We hope you will use all of these case studies to expand your understanding of the economic value of natural resources. The authors are grateful to the following people for assisting in the development of these materials:

Case Study 1: Oyster Restoration in Chesapeake Bay

9/66

Oyster Restoration in Chesapeake Bay

Background

Since the mid-1800s the Chesapeake Bay has been a major producer of oysters to an extended market reaching as far away as California and England. During the 56-year period after 1834 when the business of packing oysters for shipment to the interior was established in Baltimore, Maryland, the average annual harvest from the Bay was 7 million bushels per year, or 392 million bushels for the period. This massive yield from both the Maryland and Virginia portions of the Bay was almost entirely the result of natural production, that is, there was little farming of oysters.

Sometime after the turn of the century, Maryland's oyster harvests dropped below that of Virginia. This change in comparative productivity may have resulted from several factors: development of widespread private leasing of Bay bottom grounds in Virginia while in Maryland public grounds remained the primary source of harvesting; growth of power dredging in Virginia, which was highly restricted in Maryland; overfishing of public beds in Maryland; and increasing destruction of oyster reefs and their consequent smothering by siltation. In the early 1900s, Virginia became the largest producer of oysters in the Chesapeake Region and on the entire Atlantic seaboard.[1]

Situation

The near-decimation of oysters in the Chesapeake Bay by protozoan diseases has stirred interest in importing a disease-resistant species of oyster for restoration of the fishery. Historical differences between the Maryland and Virginia oyster industries, however, complicate the problem of restoration. Competing interests between the commercial fisheries of both states as well as considerations of the role oysters play in the Bay's ecological health must be taken into account.

[1] Hargis, W.J. and D.S. Haven. 1988. The Imperilled Oyster Industry of Virginia. Special Report No. 290 in Applied Marine Science and Ocean Engineering. Virginia Sea Grant Marine Advisory Services.

In 1954, Chesapeake harvests rose dramatically in response to a 15 percent increase in ex-vessel price, which was itself the result of a decrease in mid-Atlantic harvests. However, this boom did not last for long. In 1959, the protozoan pathogen *Haplosporidium nelsoni* (MSX) invaded the Chesapeake Bay and, soon after, *Perkinsus marinus* (Dermo) — both have been responsible for catastrophically killing most of the oysters in high-salinity regions of the Bay. In Virginia, leaseholders, or private growers, hold a majority of their leased bottoms in the high salinity areas affected by MSX and Dermo — public grounds are in the lower-salinity waters. Unlike Maryland watermen, who have depended for their harvests primarily on publicly open grounds, Virginia's private industry has been virtually decimated.

In spite of the MSX invasion in the Bay, oyster production in Maryland in the 1960s increased for a short period. A major reason for that increase was the discovery of pre-historic fossil shell sources and the development of a dredge to extract the shell for use as a substrate to "catch" natural oyster seed. Subsequent employment of these resources by the State of Maryland was commonly referred to as the "repletion program."[2]

Prior to the repletion program, state legislation had required processors to make 10 percent of their shucked shell available for purchase by the state in order to ensure the availability of substrate for future oyster production. The legislation also provided funds for state shell-planting activities. The discovery of additional shell sources provided a cheap alternative to freshly shucked shell and yielded significant production increases. Maryland's oyster production doubled from around 1.5 million bushels to some 3 million annually. The increase in importance of the repletion program relative to natural oyster set helped transform the oyster fishery from traditional natural resource gathering into a "put-and-take" state fishery.[3] Watermen were temporarily relieved of the constraints of nature alone and no longer solely dependent on the "recycling" of processed oyster shell.

The use of relatively inexpensive dredged shell also changed the philosophy of oyster management in Maryland from maintenance of a collapsing industry to revitalization, through repletion, of a potentially valuable one. The state switched from its regulatory role of oyster manager to a champion of production growth. Although production began to wane in the late 1960s and has continued to do so, until about 1981 Maryland oyster production remained over 2 million bushels. During this time there was concern that the market could not absorb, at an acceptable price, more than about 2.5 million bushels. In this new scenario, the market, not nature, became the constraining element.

Since the 1980s oyster production has been suffering from the reappearance of MSX and, especially, Dermo. Maryland's harvest has declined from over 2.5 million bushels during the 1980-

---

[2] The nature of oyster reproduction is such that young larvae require a hard substrate on which to attach; oyster shell provides such a material. However, if the harvested shell is not replaced in the Bay by a suitable substrate, there is a strong likelihood that the future availability of oysters will be reduced.

[3] Lipton, D.W., E.F. Lavan, and I.E. Strand. 1992. Economics of Molluscan Introductions and Transfers: The Chesapeake Bay Dilemma. Journal of Shellfish Research 11(2):511-519.

1982 season to under 250 thousand bushels in the early 1990s. As a result of the decline in supply, ex-vessel prices have risen.[4] In spite of the increased ex-vessel prices, the effect of the loss of production on the income of the Chesapeake watermen has been significant. Unlike past battles with MSX and Dermo disease, this most recent outbreak has not been relieved by the repletion program. Lipton, Laval and Strand explain that the sporadic nature of the protozoan infections have made it difficult to develop a comprehensive strategy for oyster repletion.

Proposal to Revitalize Oyster Production

In contrast to the steep decline of oyster landings in Chesapeake Bay, oyster production on the west coast of the United States grew between 1982 and 1988 by 600 thousand pounds. The source of this production increase is hatchery production of the introduced species *Crassostrea gigas* (originally from Japan). Because of evidence that C. *gigas* is more resistant to MSX and Dermo, there has been strong interest in introducing this species into the Chesapeake Bay to test its hardiness. Virginia growers, in particular, are interested in introducing such a non-native species of oyster into their waters in an effort to revive their leased grounds and their processing industry. Maryland watermen, who harvest public grounds, have generally opposed introductions even though public grounds are not nearly as productive as they once were. In the meantime, harvesters in both Maryland and Virginia have turned to alternative resources — in Maryland, to softshell clams; in Virginia, to hardshell clams; in both states, to more intensive fishing effort for blue crabs, beginning earlier in the season and lasting later. Other watermen have left commercial fishing entirely.

The decision on whether or not to introduce C. *gigas* or some other non-native oyster into the Chesapeake Bay is not as straightforward as it may appear. Several factors must be considered including the costs and benefits of such an action. The net benefits to the different groups affected by the introduction must be estimated. These benefits may be economic or ecological in nature. Other significant considerations in the decision process are the uncertainties involved.

Benefits of an Introduction

Among the expected benefits from the introduction of C. *gigas*. are those to commercial harvesters and consumers. From the Virginia industry's perspective, the argument in favor of introducing a non-native species is based on the expected economic benefits, for instance, increases in income levels and employment, as well as in increases in producer surplus or economic rent.

The measurement of producer surplus is assessed as the revenue net of costs. In this case, culturing, processing, and harvesting costs are taken into account as well as the opportunity cost of a

[4] Harvest prices are strongly influenced by the supply of the oyster yields. When both Maryland and Virginia harvests were low prior to 1960, real prices, the actual prices adjusted for the general level of inflation, were high. The tremendous increase in Maryland's production in 1966 caused real prices to drop by as much as 40%.

producer's labor — what he or she could earn in the next best employment opportunity.

As Lipton, Lavan and Strand point out, if the introduction of C. *gigas* is for the purpose of restoring a public fishery, the net benefit to producers will also depend on how the resource is managed. If an open access management regime is maintained, then net benefits to producers will be less than if a bottom leasing program or limited entry program on public grounds is instituted. Simply replacing one species with another does not necessarily eliminate the human-induced factors that caused the decline of the native species.

Consumers of oysters may also benefit from the introduction of C. *gigas* or some other non-native molluscan into the Chesapeake Bay implying further increases in social welfare. Increases in consumer surplus may occur with expected increases in the quantity of oysters available and decreases in price. Consumer welfare measures are assessed based on the demand for the introduced oyster. It is questionable, however, to what extent consumers are aware of or care about the oyster species they consume. It is entirely possible that the introduction of C. *gigas* into the Chesapeake will have negative net benefits: one reason is the negative publicity surrounding the health and safety aspects of eating molluscan shellfish. Consumer demand for the product may be highly inelastic so that a slight increase in the available quantity will be accompanied by a large decline in price.

In addition to market-oriented benefits from oyster introduction, there are potentially significant ecological functions and services that oysters may enhance, ultimately leading to long-term benefits to society. Historically, the oyster was the dominant benthic organism in the Chesapeake Bay: according to many ecologists, as reef-forming organisms, oysters played a major role in ecosystem dynamics.[5] Restoration of the oyster is seen therefore as highly desirable from an environmental perspective. The oyster's filter feeding functions could serve to filter the Bay's large amounts of algae, which could perhaps help reverse eutrophication of the Chesapeake ecosystem. Related improvements in water quality might ultimately provide ecosystem benefits in terms of improved fisheries, aesthetics and recreation and could lead to avoided costs of sewage treatment or depuration facilities.

Costs of a Species Introduction

The costs of introducing C. *gigas* or any other non-native mollusc into the Chesapeake Bay include direct costs such as the actual costs of performing the introduction, monitoring, and maintenance. In addition, there are costs associated with the introduction in the form of research dollars. That is, before an introduction is implemented, research must be conducted to determine the impact and probability of success of such an action.

Another critical cost is the risk of environmental injury resulting from species introductions. The history of molluscan introductions demonstrates that they can ferry in unintended or nuisance species that could potentially outcompete or displace a desirable native species. There are numer-

[5] Newell, R.I.E. 1988. Ecological changes in Chesapeake Bay: Are they the result of overharvesting the American Oyster, *Crassostrea virginica*? In Understanding the Estuary: Advances in Chesapeake Bay Research Consortium. Newell estimated that prior to major harvesting (pre-1870) of oyster beds, oysters filtered the entire water column in 3.3 days, while in 1988, the turnover time would have been 325 days. He further estimated that the pre-1870 populations may have been capable of removing 23-41 percent of the 1982 phytoplankton carbon production, but by 1988, they could remove only 0.4 percent.

ous examples in terrestrial and aquatic environments.[6] In addition, the introduction of a non-native species such as C. *gigas* could have unforeseen, detrimental ecological impacts.

The magnitude of the risks involved in introducing a non-native species into the Chesapeake Bay is as yet undetermined. However, it is clear that an introduction poses fewer risks for Virginia's oyster fishing industry than for Maryland's. Unlike Maryland's oyster fishery, which though much diminished is still viable, Virginia's oyster industry is failing. Thus, Virginia's industry does not risk the devastation of native species with the unintended, negative ecological consequences of an introduction. An introduction in Maryland's waters, on the other hand, puts the native *Crassostrea virginica* potentially at risk.

Dealing with Risk and Uncertainty

Compounding the debate over C. *gigas* introduction into the Chesapeake Bay is the natural ecological connection between the industries of the two states. It is likely that introductions in Virginia waters will eventually affect Maryland waters. The decimated state of Virginia's fishing industry compels its oyster producers and managers to pursue the introduction or transfer of a molluscan species in an effort to save the industry. The less urgent circumstances surrounding Maryland's industry impels its producers and managers to act more cautiously. These contrasting agendas inhibit consensus among the two states as to the appropriate course of action. The use of economics in the decision process could enhance the possibility of a resolution; towards this end, the uncertainties of an introduction can be considered within the benefit-cost framework.

Two principle methods of doing a benefit-cost analysis are through *expected net benefits* and *game-theoretic* approaches. In the expected net benefits approach, the distributions about the costs and benefits are used and the value of net benefits are calculated. Conceptually, the procedure is straightforward. However, the distributions about net benefits are not easy to ascertain, particularly when considering future events. As a result, a higher discount rate is often used with more risky selections.[7]

Game theory[8] can also be applied to the uncertainty involved in the decision on whether or not to allow an introduction. The game theory method is based on the two choices presented — to allow or not to allow an introduction. The approach offers the option of taking either a conservative or a more risky position with regard to possible damages from unintended negative consequences or environmental costs. The conservative position utilizes the minimax principle in which the strategy that minimizes the maximum possible losses is chosen.[9] The more risky position

VOL 12

9/7/0

makes use of probability distributions of net benefits and compares the expected value of the introduction and no-introduction scenarios, choosing the action with the greater expected value. Clearly for each strategy, measures of the consequences of introductions and damages must be made. This procedure must determine how the stream of net benefits should be discounted over time and the characteristics of the uncertainty of these measurements.

Exercise

The debate over the introduction of *C. gigas* or some other non-native oyster into Chesapeake Bay waters is highly political and full of uncertainties. Watermen are unwilling to abandon an industry that has been a fundamental element of the region's economy and culture for over a century. Virginia watermen, in particular, see molluscan introductions as a means to revitalize the failing industry. However, the uncertainty of the effects of an introduction clouds the issue. Another complication is the fact that the decision will have effects that cross jurisdictional boundaries.

The decision whether or not to allow an introduction is not isolated to the specific, individual oyster beds within the two states of Maryland and Virginia. The Chesapeake Bay ecosystem is not confined, of course, by political boundaries. Any decision that is made must take a multi-jurisdictional approach that transcends artificial divisions.

Suppose that you are a member of a Chesapeake Bay economic development council. You are tasked with developing recommendations on a Bay wide oyster development plan. Consider the role of environmental valuation in your analysis. Using the following questions as a guide, outline the study you would request of a local economist.

1. What values associated with oyster resources and services should be analyzed?

2. What techniques would you recommend in order to determine the values of these resources and services?

3. What are the limitations to the existing methodologies in this case?

4. What additional information do you need in order to determine the expected net economic benefits of a *C. gigas* introduction plan?

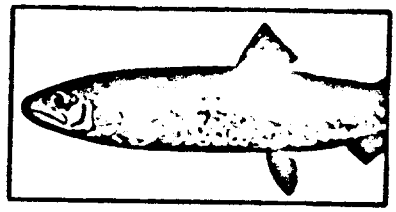
5. What discount rate would you recommend in a benefit-cost analysis of a *C. gigas* introduction plan?

6. Suppose that new technological developments offer alternative methods of oyster enhancement (e.g., bio-technological or bio-engineering of a native species immune to MSX or Dermo). What role can environmental valuation play in assessing these alternatives?

SALMON HABITAT RESTORATION IN ALASKA

Background

Alaska's salmon fisheries account for sizeable contributions to the state's economy. In 1990, commerical harvests, which were 94 percent of the 733.1 million pounds landed in the United States, were valued at $546.7 million. This amount does not account for the added value of its recreational and subsistence fishing. The health of the salmon fishery, then, is vitally important to economic health. The salmon fishery is influenced by many factors, environmental and human — from highly variable ocean conditions to the timing of harvesting, the levels of that harvesting, the impact of land-use practices on freshwater and estuarine habitats, which can be critical for spawning.



Situation

Harvesting of Alaskan forests can impact salmon habitats and lead directly to reduced spawning of smolts. A hypothethical example is presented in which a proposed regulation calls for a riparian buffer zone along critical stream habitat.

Pacific anadromous salmonids include five species of salmon that are comprised of a large number of stocks originating from specific watersheds. Salmon juveniles or smolts spawned in streams migrate to the ocean and then generally return to their natal streams to spawn. Because forestry practices can directly influence the quality and quantity of freshwater habitat, primarily through harvesting of timber and associated road building activities, their management is particulalry important for the health of salmon returning to their home streams.

Even with salmon health generally high, with record harvest levels, and with a large proportion of the land base relatively undisturbed, specific stocks could still be in decline if forest practices remove too much of the riparian vegetation or degrade channels. Under certain conditions, a given run of salmon could be considered for listing as endangered under the Endangered Species Act, which includes provisions for listing "distinct population segments."

Hypothetical Alaskan Watershed

The following example provides a set of assumptions about the economics of logging and salmon harvests — the exercise then poses a number of questions that consider issues of value. To begin with, suppose that harvesting within the Tough Choices watershed would generate 6,700 million board feet of timber with a pond log value of $401 per million board feet — pond log value reflects not just the price of the standing timber but also the costs incurred in bringing the timber to the mill, for instance, logging, road construction, and transport. Assume that by building the access roads across the watershed and by removing the trees, this timber sale will fragment the riparian habitat into patches and cause a reduction in the full capacity of the spawning ground for the coho stock that inhabits the creek. This stock of salmon would show an expected decline relative to the amount of habitat lost.

The impact of tree clearance would also affect the food web, for example, local bear and eagle populations that depend on salmon stocks could be adversely affected. Such impacts could have ripple effects, for instance, declines in recreational viewing which might be impacted because of tree harvesting and road-building. We will suppose that the only functions attributed to these trees is either commercial harvest or as an input into stream integrity and fish production, or negative effects. The value of the salmon consists of its commercial and recreational value (in current and future fisheries), as well as its subsistence and cultural value to the residents of the State of Alaska.

As part of this hypothetical example, we assume that biologists have developed an expected relationships between land clearance and the capacity of the spawning ground associated with the stream. If all the commercial timber proposed is harvested, then the spawning capacity will be reduced by 90 percent of its original capacity. If only 20 percent of the trees are harvested, a 10 percent reduction in fish capacity is expected. For every 10 percent increase in timber harvest from that level on, there will be a corresponding drop of 10 percent in fish spawning capacity. In addition, consider the following information:

Spawning capacity: 9000
Smolts per spawner: 106
Ocean survival to maturity: 43%
Commercial harvest rate: 47%
Freshwater recreational harvest: 16%
remainder available to spawn for future cycles

Ex-vessel Price: $1.42/lb
Average weight of salmon harvested: 12 lbs
Anglers' WTP: $15.92 per additional fish caught

Exercise

Given the background and information provided above and keeping in mind the various perspectives regarding "value," analyze a proposed regulation calling for a 300-foot riparian buffer zone along critical salmon streams.

Questions to consider include:

1. Are there any additional value associated with the timber and salmon resources not mentioned?

2. What measurement techniques would you employ to determine relevant values?

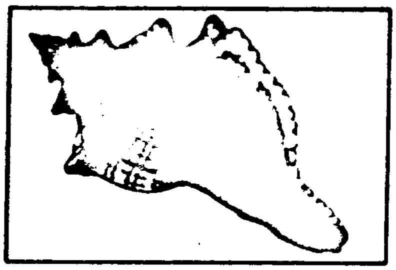
3. What additional data (aside from that provided) might you need to carry out empirical analysis?

4. What discount rate would be appropriate in the determination of net present value?

5. Society involves many individuals, and projects such as this often affect the welfare of individuals differently. The implicit assumption in constructing the estimates of costs and benefits in this example is that the welfare of all individuals is weighted equally. What if you were to eliminate this assumption and address the issues of equity and fairness? How might your decision change if you take future generations explicitly into consideration? How might you go about doing this?

6. Consider the issue of irreversibility. How might the potential for species extinction change your decision process and recommendation? How might you integrate the potential risk of irreversible outcomes into your analysis?

Florida Keys National Marine Sanctuary



Situation

With the Florida Keys ecosystem threatened by point and non-point source pollution, alternative management strategies outlined in the Florida Keys National Marine Sanctuary Plan have focused on the cost-effectiveness of different issues or activities for achieving sustainable use of the Florida Keys National Marine Sanctuary: boating, fishing, recreation, land use, water quality, zoning, and education. This case study focuses on different strategies of zoning.

Background

The marine ecosystem of the Florida Keys is the only complete tropical marine ecosystem in the continental United States. It includes extensive aquatic habitats such as coral reefs and seagrass beds. Ninety percent of the region's commercially important species use these habitats for shelter, food, or nurseries during at least one stage of their life history. Several species of threatened and endangered sea turtles are found in the Keys, including hawksbill, loggerhead, leatherback, green, and Kemp's ridley. In addition, dolphins and endangered manatees frequent the area, as well as countless species of sea and shore birds. Another aspect of the area's marine environment is the submerged cultural and historic resources, for example, submerged Paleo-Indian sites, nationally registered lighthouses, and wrecked ships going back several hundred years.

The Keys ecosystem is threatened by impacts from a number of different sources, indirect and direct. Indirect impacts contributing to the decline of the reefs and seagrass beds include polluted runoff from over-developed islands; heavy metals and other toxins which contaminate the reefs; excess nutrients from human sewage, fertilizers, detergents, and animal wastes which create algal blooms; pesticides; offshore oil and mineral mining; and saltwater/freshwater imbalances. Direct impacts include vessel groundings, diver damage to coral, and boating traffic (anchor and prop dredging) which destroys seagrass beds, and destructive fishing methods.

To protect the Keys marine ecosystem, Congress enacted the Florida Keys National Marine Sanctuary and Protection Act of 1990.[1] The legislation to provide comprehensive protection to the Keys' marine environment was prompted by recognition in the late 1980s of human impacts that threatened sanctuary resources. The sanctuary area extends approximately 220 miles southwest from the southern tip of the Florida peninsula and encompasses a 2,600-square nautical mile area of submerged lands and water surrounding Monroe County, Florida.

Protected areas and marine sanctuaries are not new to the Florida Keys area. The Key Largo and Looe Key Marine Sanctuaries were established in 1975 and 1981, respectively, and according to the Act, they will be incorporated into the new Florida Keys Sanctuary when the management plan is adopted. Numerous State and Federal parks and reserves are also located within the boundaries of the Sanctuary.

The existing regulations of current jurisdictional responsibilities allow sport and commercial fishing with hook and line; taking of spiny lobsters and stone crabs in accordance with the fishery management plan; and swimming, snorkeling, scuba diving, photography, and recreational boating. Regulations prohibit removing or damaging natural features, non-permitted marine life, or archaeological and historical resources; dredging, filling, excavating, and building; anchoring in a manner that damages coral; discharging harmful substances into the water; spear fishing or using wire fish traps; and handling or standing on coral formations. Specific regulations already in place as a result of the Florida National Marine Sanctuary Protection Act prohibit all oil drilling and exploration within the Sanctuary and the operation of tank ships or other vessels greater than 50 meters in Areas To Be Avoided, which were designated in response to the region's many historical groundings.

In addition to creating one of the largest national marine sanctuaries, the Act also requires the National Oceanic and Atmospheric Administration (NOAA), which administers the National Marine Sanctuaries program, to prepare an environmental impact statement and a comprehensive management plan for the Sanctuary with implementing regulations to govern the overall management of the Sanctuary and to protect Sanctuary resources and qualities.

The Local Economy

The Florida Keys economy is dependent on a healthy ecosystem. In 1991, Florida Keys' and Monroe County's gross earnings were $853 million. The activities that contributed most to those earnings were recreation and tourism, commercial fishing, and retirement communities. These activities combined make up more than 80 percent of the local economy. Over three million tourists visit the Keys annually, participating principally in water related sports such as fishing, diving, boating, and other ecotourism activities. In fact, 61 percent of the recreation and tourist activities are water-related — the Keys have been hailed as the most important dive destination in the world. In addition, multi-million dollar fisheries for spiny lobster, stone crab, grouper, and snapper have supported local and regional economies for generations. Commercial fishing is the fourth-

[1] The information presented in this case study was obtained from existing sources, primarily from NOAA's Florida Keys National Marine Sanctuary, Draft Management Plan/Environmental Impact Statement. While the Draft Management Plan/EIS examines several issues, this case study gives particular emphasis specifically to zoning issues and de-emphasizes other issues that were addressed in the Draft Management Plan/EIS.

largest industry in the Florida Keys region and represents 9 percent of Monroe County's private-sector employment. Case Table 3.1 provides more information about the value of specific services provided by the ecosystem and economic impacts.

Case Table 3.1. Overview of Economic Situation.

Economic Value of Florida Keys		Economic Impacts	
Service	**Value**	**Activity**	**Impact**
Annual non-market user value of water-related activities	$660 million	Gross earning provided by tourism industry	35% ($309 million)
Asset vlue of the Keys for water related activities (1990 dollars)	$22 billion	Gross earnings provided by retail trade	18.7% ($160 million)
1990 ex-vessel value of commercial fishing in sanctuary	$46 million	Population with jobs that either directly or indirectly support outdoor recreation	51%
1986 ex-vessel value of Monroe County's seafood landings	$27.4 million	Monies provided by commercial fishing	$17 million
Value of seafood landings at the harvesting, wholesale, retail and restaurant levels	$14.8 million		

NOAA's Proposed Alternative Management Plans

In fulfillment of the mandate to prepare an environmental impact statement and a comprehensive management plan for the Sanctuary, NOAA developed and assessed five alternative management plans. These plans represent different levels of regulatory control over Sanctuary resources and restriction of uses, with Alternative I being the most restrictive (total restriction of uses, except for research) and Alternative V the least restrictive (no action). The purpose of NOAA's proposed Alternative Management Plans is to ensure the sustainable use of the Key's marine environment by achieving a balance between comprehensive resource protection and multiple, compatible uses of those resources.

VOL 12

9/77

R0042483

Each of the five alternative plans are comprised of a series of management strategies that focus on the pertinent issues or activities considered to have potential resource impacts, positive or negative. These issues or activities include:

1. Boating
2. Commercial and Recreational Fishing
3. Recreation
4. Land Use
5. Water Quality
6. Zoning
7. Education

For each issue, the potential impact themes of habitats, species, use and users, and water quality were examined.

Economic Impact Assessment

The purpose of the of the Florida Keys National Marine Sanctuary and Protection Act is to provide for multiple uses of the Sanctuary as well as to ensure that its natural resources are protected for the future.[2] However, due to the implementation of management strategies, such as zoning, the Act may also result in the displacement of some Sanctuary users and consumers. Because the numerous users, consumers, and administrators of the Sanctuary have diverse and sometimes contradictory interests, a thorough examination and comparison of the Management Plans under consideration is essential. NEPA requires the assessment of environmental impacts in an Environmental Impact Statement. An analysis of the economic impacts, costs, and benefits of the proposed plans is an important part of this assessment, especially in light of the Keys' economic dependence on revenue generated from marine-related activities, and the value of the services provided by the ecosystem.

An economic impact assessment was conducted as part of the Draft Management Plan/Environmental Impact Statement. However, a net economic benefit analysis, examining the socio-economic implications of proposed actions by comparing economic costs and benefits, was not conducted. The economic impact assessment summarizes the potential impacts of proposed management strategies on various user groups and the local economy, for example, sales, employment, income. The socioeconomic impacts associated with the management strategies were assessed by issue, as outlined above and discussed in qualitative terms. The key strategies within each issue were assessed in terms of impact on user groups and expected socioeconomic costs and benefits.

Cost information for the analysis was based on negative impacts such as expected losses in user values, income, or employment. The cost information used in this assessment was provided by federal, state, and local officials with responsibilities in the Keys. Low- and high-range estimates were given for both capital and annual operating costs and costs for each proposed manage-

VOL 12

9/7/9

ment strategy. Information on the effects of proposed actions on human activities was also derived as part of the process to develop a Sanctuary resource protection zoning scheme.

Resource Protection Zones — Zoning Categories

This section describes the findings of the assessment of social and economic implications for zoning strategies proposed in the Alternative Management Plans. Zoning, as noted in the previous section, is one of the issues that has potential resource impacts.

The development of a management plan, then, provides the opportunity to establish different regulations for separate areas within the Sanctuary. Thus, one of NOAA's tasks under the Act is to consider temporal and geographic zoning to ensure protection of Sanctuary resources.

Zoning schemes were developed to ensure the protection of Sanctuary resources. The intent was to reduce both damage to those resources and threats to environmental quality, while allowing uses that are compatible with resource protection. The zones are intended to protect habitats and species by limiting consumptive and/or conflicting user activities, thus enabling resources to evolve in a natural state with minimal human influence.[3] Zoning will permit customary activities to continue in some areas, while other areas will be designated for preservation, research, or restoration. The resource protection zoning scheme proposes five types of resource protection zones (these are then described briefly):

1. Wildlife Management Zones
2. Sanctuary Preservation Areas (SPAS)
3. Existing Management Zones
4. Special-Use Zones
5. Replenishment Reserves

WILDLIFE MANAGEMENT ZONES. This strategy would affect user groups participating in wildlife observation or seeking access to these areas. Users participating in wildlife observation would see a small socio-economic benefit due to greater assurances of continued wildlife and habitat protection. However, most of these zones are already within national wildlife refuges and are under restrictions established by the U.S. Fish and Wildlife Service. As a result, the strategy is likely to have minimal socio-economic impacts on Sanctuary users.

REPLENISHMENT RESERVES. These reserves will encompass large diverse habitats and are intended to provide genetic protection for marine life. The goal is to increase the productivity in adjacent marine areas and enhance biodiversity. Sanctuary regulations will strictly limit resource use and consumption in these habitats. Some users, such as commercial lobster fishers, sport fishers, and tropical fish collectors will be displaced. However, compatible recreational activities will be permitted. Although these zones would prohibit commercial and recreational fishing, they are expected to have an overall benefit by protecting spawning and recruitment stocks from overfish-

---

[3] National Oceanic and Atmospheric Administration. (December 1994). Florida Keys National Marine Sanctuary, Draft Management Plan/Environmental Impact Statement. V2, pp. 194.

ing, promoting genetic diversity within the fishery, producing "spill-over" benefits to other non-protected areas through the migration of organisms across boundaries, and providing important baseline data for use in managing fisheries in other areas. The zones become slightly larger and/or more numerous moving from Alternative IV to Alternative II.

SANCTUARY PRESERVATION AREAS (SPAS). These zones will focus on the protection of shallow, heavily used reefs where user conflicts occur and where concentrated visitor activity leads to resource degradation. As with Replenishment Reserves, the groups that will benefit are those that value an abundance and diversity of marine wildlife, including commercial and recreational fishers and participants in water-related recreation activities. However, tropical fish collectors, lobster fishermen, recreational fishers and spear fishers displaced from these areas will be negatively impacted.

EXISTING MANAGEMENT AREAS. Because these areas are already established by federal, state, or local authorities with competent jurisdiction in the Sanctuary, this strategy will have minimal socio-economic impact.

SPECIAL-USE ZONES. This strategy will have negligible socio-economic impacts on users because only a small number of areas will be established. Academic and scientific communities will be the primary beneficiaries of this zone type.

The socio-economic information generated by this analysis was used along with the environmental impact assessment data in the selection of a Preferred Management Alternative.[4]

Exercise

While an economic impact assessment does provide some useful information in the evaluation of management alternatives, it does not provide more comprehensive information about the overall result of a given project or policy change. All of the proposed management strategies assessed in the NOAA plan affect some aspect of Sanctuary resources, either directly or indirectly.

Sanctuary resources (both natural and historic) can be considered assets that produce a flow of goods and services with both market and non-market values to users and non-users. The concept of non-market value is significant to the Keys and its economy. The area's natural resources are considered public resources, not common property or privately owned. Tradeoffs between the effects of strategy implementation on economic values and economic impact are also pertinent to the Keys. Restrictions may increase the costs of consumptive use; however, protecting a resource may not only increase its quality and value but also have a long-term economic benefit to both consumptive and non-consumptive users.

---

[4] Alternative III was chosen as the Preferred Management Plan. Volume I of the Florida Keys National Marine Sanctuary, Draft Management Plan/Environmental Impact Statement provides a description of the strategies recommended in the Management Plan. According to the selection committee, the positive environmental impacts and associated beneficial economic impacts of the Preferred Alternative (Alternative III) outweigh any potential negative impacts. Of the five alternatives, the one selected most closely meets the resource protection goals, while facilitating current Sanctuary users and user activities.

VOL 12

9/80

Some of the proposed Sanctuary Preservation Areas will displace current commercial and recreational fishers as well as tropical fish collection to non-zoned areas. This displacement may result in increased costs to fishers and consumers as well as decreased sales, employment, income, and tax revenues for the local economy dependent on this activity. However, the protection provided to these areas may have economic value to non-consumptive users. Furthermore, if resource degradation can be halted or reversed, there may be long-term benefits for consumptive users. While the existing economic assessment attempted to take these types of tradeoffs into account for each management strategy, it would be more informative to carefully consider how such an analysis is in fact operationalized. Such a consideration is one to examine in this exercise.

Reread this case study noting the economic values and costs that could be compared in a benefit-cost analysis.

1. What techniques would you recommend be used to measure the value of services identified above?

2. What types of resource values are missing?

3. What data would you need to conduct these studies?

4. Give particular attention to the effects on displaced fishers versus fishers who are not displaced, as well as to the various other tradeoffs that are made.

5. How does this information differ from the impact assessment on Resource Protection Zones provided by NOAA?

Coastal Barrier Island Preservation in North Carolina

Situation

A barrier island with a small year-round population and a large number of seasonal home owners has the potential of greater development. The island is also home to a unique forest community as well as other rare fauna. State plans to purchase large tracts of the island for preservation must consider the economic impact of shutting down further development that such preservation would entail and the alternative of purchasing a similar tract for preservation on another island.

Background

Old Baldy Island is a coastal barrier island in North Carolina.[1] It is situated at the mouth of the Cape Buffalo River, approximately three miles off the coast of Northport and about 30 miles south of Wilmatown, the fourth largest city in the state. Old Baldy Island is the largest and southernmost of a series of small islands connected by extensive salt marshes that form an area known as Smith Island. It comprises approximately 13,000 acres including upland, tidal marshes and creeks, shallow bays, and marshland. The island is 3-1/2 miles long and 1-1/2 miles wide and features a moderate climate often referred to as subtropical. The Old Baldy Island Lighthouse, built in 1817, serves as the Island's landmark — it is North Carolina's oldest lighthouse.

Located on the island is the Old Baldy Planned Unit Development, primarily a second home development; it is somewhat of an island retreat in that its access is limited to a privately operated ferry system which provides access to the mainland. While there are a limited number of year-round residents (approximately 60 at present), some 1,200 families have homes there. The neighborhood is less than 50 percent developed.

THE MARITIME FOREST. Old Baldy Island is home to a maritime evergreen forest. It is a globally imperiled forest community located on old stabilized dunes and flats protected from saltwater flooding and the most

[1] While this case study is based on a real situation, place names and some facts have been modified for the purposes of the example.

VOL 12

9/83

extreme salt spray. Encompassing approximately 355 acres, it is the largest in the state and still has undeveloped, natural transition zones from ocean to sound. The topography is that of a dune ridge and swale system: the ridges are broad and they slope gently into even broader swales, which can be wet or dry, depending on local drainage patterns. The natural communities associated with the Phase I site include salt marsh, interdunal ponds, pine lowlands, palmetto lowlands, and non-forested freshwater wetlands.

While the State has been working closely with local officials to minimize impacts from development on the maritime forest, even low-intensity development on Old Baldy Island will tend to fragment the high-quality maritime forest communities. The proposed actions would preclude even lower density development.

A special Maritime Forest Advisory Committee, set up by the North Carolina Coastal Resources Commission in 1990, recommended that the few remaining high quality tracts of maritime forest be acquired and managed for conservation purposes. The committee ranked the undeveloped maritime forest on Old Baldy Island among the top two or three maritime forests in North Carolina in terms of natural area values such as ecological integrity, uniqueness, diversity, rare species, size, and historical significance. Nags Head Woods and Buxton Woods are the two other areas of significant natural value and these two areas have already been acquired for conservation purposes.

VEGETATION. The Island is home to several species of plants that are unique. One of these is a plant commonly known as the Old Baldy Blue Curl, a small indigenous plant in the mint family. A significant feature of the forest is the many extremely old trees; they include palmettos, pines, cedars, oaks, and dogwoods. The undergrowth throughout the forest is quite dense with many vine species. The most common of the understory shrub layer are Red Bay, Wild Olive, *Prunus caroliniana*, and French Mulberry. The Island also harbors two moss species, Beach Moss and Cuban scheliessmund that are recognized as "critically imperiled species." Other plants that fall within the "critically imperiled species" designation are the Tough Bumelia and the Piedmont Flatsedge. Finally, the dunes and cape at Old Baldy are host to a newly identified species, Dune Blue Curl, which is a candidate for state and federal protection.

WILDLIFE. Old Baldy Island is North Carolina's most popular nesting area for the endangered loggerhead sea turtle, which lays its eggs along the island's 14-mile oceanfront. The Old Baldy Conservancy has a successful sea turtle conservation program which claims a 95 percent hatch rate. Other fauna of the island complex include alligators, raccoons, large numbers of tern and gulls, over-wintering brown pelicans, and migrating peregrine falcons. The freshwater ponds and marshes are used heavily by water birds, as are the extensive marshes, tidal creeks, bays, and mudflats. Nearby Battery Island is North Carolina's largest breeding rookery for egrets, herons, and ibises.

Proposal for Preservation

To preserve maritime forest, the state of North Carolina is considering purchasing land currently scheduled for development. In Phase I of the proposed preservation plan, the State will acquire approximately 125 acres of the remaining core maritime forest. In Phase II, the State will work to acquire as much of the remaining undeveloped maritime forest and associated wetlands as possible. It is anticipated that Phase II will include the purchase of additional areas along the undeveloped estuarine shoreline. North Carolina is also considering acquisition of an ocean front section that would protect a portion of the island from ocean to sound.

The Old Baldy Phase I Purchase Tract is an irregular shaped area of 96.80 acres. The Purchase Tract can be generally characterized as a gently rolling and heavily wooded maritime forest. The plan would include a Maritime Forest Protection Overlay District, protective salt spray shear zone vegetation, forest wetlands, and relic dunes and dune ridges. In addition, there would be a prohibition against the removal of trees and shrubbery (except as necessary), the filling of wetlands and ponds, and on-street parking. In addition, all construction would need to be contained to prevent runoff. To protect against the potential of introducing harmful exotic plants, only permissible plants would be allowed. The maximum lot coverage for structures, including all impervious surfaces, would not be allowed to exceed: (1) 25 percent of a building lot less than 9,000 square feet; (2) 50 percent of a lot less than 9,000 square feet in residential lots; (3) 60 percent of a commercial service or multi-family lot.

Economic Considerations

Implementing the proposed Old Baldy Island Phase I purchase would reduce the community's ad valorem tax base by approximately $10 million, the purchase price of the land. Based on the current rate of development and the type of development that has occurred, approximately 50 housing units with property values of approximately $7.5 million would be added per year, if there are no restrictions. Because of the seasonal nature of most of these residences, each of the additional residential units, if developed, would be anticipated to result in $250 per month in direct expenditures in the local community during the winter season (October-February) and $1,000 per month during the summer season. It has been estimated that the addition of more than 200 new residential units would result in the need for increased local public servants including one additional police officer, one fireman, and several municipal maintenance staff persons.

Exercise

The Old Baldy purchase is only one active maritime forest preservation option available to the State of North Carolina. Another is to purchase a similarly sized tract of maritime forest land on Little Barrier Island, also in North Carolina. The purchased land would become a nature preserve protected from development. The Old Baldy Little Barrier Islands are very similar — the main differences are smaller loggerhead sea turtle nesting areas and the absence of palmetto palm trees and beach moss on Little Barrier Island. Little Barrier Island also lacks the historical significance of Old Baldy Island, home of the Old Baldy Island Lighthouse and Captain Charlie's Station cottages built in 1903.

Little Barrier Island has extremely limited development, with no existing plans for additional construction activity. For this reason, purchasing the land is estimated to cost $2 million. Since the land on Old Baldy Island is scheduled for development, its purchase price is expected to be roughly $10 million, the appraised value of the land. Given this information consider the following questions:

1. Suppose your agency is trying to decide between purchasing the land described above on Old Baldy Island and the similarly sized tract of maritime forest land on Little Barrier Island in North Carolina. Which tract of land would you recommend trying to purchase?
   a. What additional information would you want?
   b. Does the schedule for development affect your decision?
   c. What operations other than purchase might be available (zoning, legislation, takings)?

2. Which economic approach in this handbook would you typically use in evaluating the Old Baldy Island maritime preservation proposal?

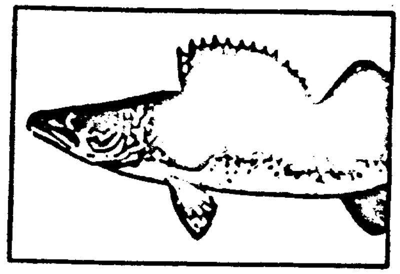
3. How would the various economic approaches be of use to others in the decision process?
   a. Developers
   b. Local agencies making decisions regarding supporting public investment decisions
   c. Interest groups
   d. Public at large
   e. Federal regulators/decision-makers

4. The residential development on Old Baldy is "upscale," but is protected by covenants and zoning restrictions. Transportation around the island is restricted to electric golf carts. Plants may not be introduced unless they are on a list of permissible shrubbery. Restrictions also exist limiting all impervious structures. You have responsibility for the enforcement of zoning laws related to the environment. Two homeowners have approached you with a proposal. One, for aesthetic reasons, prefers not to pave his driveway. The other wishes to purchase her neighbor's "right to pave" in order to build a tennis court on her property. Proponents of this proposal applaud the flexibility that allowing "tradable paving rights" affords. Property values could rise if residents are permitted to build tennis courts and other amenities on their land. They also note that less pavement would exist than if the two homeowners had paved driveways. Those opposed to the change argue that existing residents originally did not have a choice between paving a driveway, building a tennis court, and selling their rights. Further, they argue, the right to pave is an intrinsic part of the property and cannot be transferred. Finally, they fear that this is an attempt to abolish paving limitations altogether.
   a. Should residents be allowed to sell paving rights?
   b. How would you deal with the right of a future homeowner to pave his driveway if the previous owner has already sold the rights?
   c. Should your agency attempt to regulate the price for which paving rights will sell? If so, what will you consider in setting that price?
   d. What problems might arise from setting such a price?

Artificial Reef Program in Lake Erie, Ohio

Background

Artificial reefs are synthetically constructed underwater structures — they may be rock, sunken ships, auto bodies, rubber tires, and wood. Designed for structureless bottom areas in either fresh or salt water environments, they provide habitat for fish, habitat that includes food, shelter, protection, and spawning areas. Drawn by the new habitat, fish concentrate in these areas. Often artificial reefs are strategically placed at various depths and are built to particular heights to attract a specific species of fish.



Situation

Artificial reefs can be used for enhancing fisheries and economic activity by providing the structure for new fish habitats. Reefs placed in different locations in Lake Erie are demonstrating that improved fisheries habitats lead to increased recreational fishing.

Artificial reef construction may be a community effort, with technical assistance provided by state and federal agencies. Recreational fishing reefs are placed near access areas such as launch ramps and marinas and in locations where they will not interfere with navigation and commercial fishing activities.[1] Artificial reefs have been constructed all along the U.S. coast in salt water and in many inland lakes and reservoirs. Artificial reef programs have been implemented in many coastal states, e.g., Georgia, Florida, California, Texas, Alabama, Virginia, New Jersey, South Carolina, and Delaware.

Studies indicate that when artificial reefs are constructed with proper materials, placed in good locations, and developed with a specific purpose and plan, they can enhance sustainable fisheries. Research in South Carolina, for example, attributes increases in time spent fishing and catch rates to the presence of artificial reefs. In many areas, new aquatic communities created by the artificial reefs draw increased numbers of recreational and commercial fishers and scuba divers — one result is travel and tourism dollars brought in by visiting anglers and their families, thus leading to positive economic impacts to local communities.

VOL 12 9/86

Artificial Reef Program

Ohio's Lake Erie is the warmest, shallowest, and most productive of the Great Lakes; its western basin is known as the "walleye capital of the world" and produces more walleye per hectare than any other lake in the world. Historically, the western basin walleye fishery has made up the major component of Ohio's primarily recreational sport fishery.[2] As a result, Ohio's north coast has developed into a major recreational economy. The historical predominance of the walleye fishery within the western basin of Lake Erie is also the result of easy access to areas where the fish congregate.

Unlike the western basin, the central basin is deeper and larger — it also lacks the productive bottom structures that provide habitat for fish. These features, combined with the fact that schools of walleye are often located further from shore, make the walleye more difficult to locate in the central basin. Access for boat anglers is another difficulty: the rocky bluff and high bank terrain of the central basin impedes the construction of marinas and launch ramps, which are readily available to boat anglers in the western basin. As Kelch and Reutter point out, while there are many excellent fishing areas in the central basin, not all are within safe running distance for smaller boats. Fishery managers have recognized that construction of artificial reefs strategically located in areas easily accessible to boat anglers could attract greater numbers of anglers in the central basin. Furthermore, if the artificial reefs yield the expected results — attracting fish and thus increasing angler participation and catch rates — the fishery's role in helping develop a recreational economy in the Central Basin communities could be enhanced.

Ohio began an artificial reef project in 1986. While artificial reefs have been planned for the entire shoreline of Ohio, the central basin presently is the key area of development for reasons outlined above. The U.S. Army Corps of Engineers has granted permits for five sites. To date, two reef structures have been constructed — the Lorain County reef and the Cuyahoga County reef. The purpose of the reef project is to create a demonstration project to evaluate the productivity and feasibility of reef construction in other areas of Lake Erie and the other Great Lakes. Evaluation of the demonstration project's effects on recreational activity and the expected effects of similar reef structure in other coastal areas are priority needs for sustainable coastal development policy of the central basin.

The Lorain County reef consists of two reef structures, one about 370 meters long and the second about 183 meters long. The Cuyahoga County reef, also known as the Cleveland site, is made up of one reef structure 213 meters long in 8.5 meters of water and a series of unconnected sandstone "rubble piles" in deeper water. The reefs were constructed from scrap rock and concrete and are located within close proximity to ports of shelter, an advantage for smaller vessels.

The Ohio artificial reef project plans to construct additional reefs in Lake and Ashtabula Counties, but the construction is awaiting scientific evaluation of the completed structures. The only evidence available regarding the ecological and economic benefits of the artificial reefs has been anecdotal information from various anglers who report successful fishing within proximity to

[2] Lake Erie's total 1993 fish harvest yielded 12.9 million pounds of fish, only 4.3 million pounds of which were caught by commercial fish producers. The bulk of the harvest (8.6 million pounds) were caught by recreational sport and charter boat anglers.

the reefs and some underwater videos taken in 1989 and 1990. No formal scientific data demonstrating the success of the structures has been gathered. According to Dave Kelch, District Specialist with The Ohio State University's Sea Grant Program and the project's director, research is needed for both the scientific community's acceptance of the artificial reefs and for interested shoreline communities.

VOL 12

Costs and Benefits of the Artificial Reef Program

COSTS. Ohio's Artificial Reef project has been financed by the local communities, fishing public, local government, local business and industry, and fishing tackle companies. Donations exceeded $100,000, the majority of which has been used to pay marine contractors for materials placement (more than 7,000 tons of material were used to build the reefs at the Lorain site and a total of about 6,800 tons were used to construct the reefs at the Cleveland site). Much of the project supervision, fund raising and donation procurement, and materials site inspection was conducted by volunteers from the North Central Sea Grant Advisory Committee. Overall project supervision and monitoring was the responsibility of the Sea Grant District Specialist, which resulted in no monetary outlay for these services.

According to Kelch and Reutter, only $10,000 of state and federal dollars were made available. Because of the donation of material, dollars, services, and labor, exact costs for the construction of artificial reefs are difficult to assess. Estimates are that the cost of placement varied from $6 to $14 a ton (based on 1984 to 1989 costs) depending on the contractor. Small, non-union contractors fees averaged $7.50 a ton, while unionized contractor fees were as much as $14.8.

9/1/88

BENEFITS. One rationale for the Ohio Artificial Reef project is to improve the integrity of the central basin area. In the past, eastern Ohio waters have been plagued by heavy pollution. At one time the situation was so bad that the surface of the Cuyahoga River ignited. Since then, environmental enhancement measures have significantly improved water quality. Residents of the central Lake Erie region wanted assurance that the central basin could provide water-related recreational pleasures similar to those available in the western basin. The construction of artificial reefs has been perceived as an effective strategy to improve the area's character.

Additional gains to local small boat anglers are also expected: anglers should experience increases in recreational fishing value as a result of the new, productive, quality fishing sites within close proximity to sheltered ports. In addition, communities as a whole should benefit from some increases in tourist-related activities resulting from improved sportfishing opportunities.

Preliminary Analysis and Evaluation of the Artificial Reef Program

R0042494

While scientific analysis of the effects of artificial reefs on fish production has not been conducted, data on angler hours and catch rates indicate that walleye harvests have increased substantially over the last two decades (Case Table 5.1).

Two research efforts began in 1992 to evaluate the success of the artificial reefs. The aim of

Case Table 5.1. Walleye sport boat harvest in Ohio, 1975-1993.*

Year	Walleye (thousands)
1975	86
1976	638
1977	2,171
1978	1,596
1979	3,288
1980	2,165
1981	2,932
1982	3,013
1983	1,846
1984	4,038
1985	3,730
1986	4,400
1987	4,438
1988	4,890
1989	4,192
1990	2,283
1991	1,578
1992	2,082
1993	2,669

*Fish Ohio. Division of Wildlife. 1993. Ohio's Lake Erie — 1993 Sport and Commercial Harvests.

one was to determine the fish concentration ability of the reefs; towards this end, an underwater video assessment was conducted at the Lorain artificial reef site. This effort involved monthly dives at both the reef site and a non-reef control site to identify and enumerate fish as well as to determine habitat differences. Analysis reveals that the 1992 and 1993 total seasonal numbers of fish were significantly higher at the reef site than at the control site. Thus, the reefs appear to be effective as a fish concentration device.[3]

The second research effort to evaluate the effectiveness of the reefs sites was designed to identify changes in social and economic values resulting from the artificial reef project. In 1992, survey data were collected from a random sample of individuals at various launch sites and marinas regarding their recreational use and expenses on Lorain County waters. Initial analysis reveals that 87 percent of the 466 respondents (55 percent response rate) knew about the reef and 64 percent of these individuals used the reef during 1992.

The typical respondent made 20 trips to Lorain County waters during 1992 and 7.1 of those trips involved fishing out at the artificial reef for at least part of the trip. Of those respondents who traveled less than 40 miles to Lorain County, more than two-thirds used the artificial reef. Of those who traveled 40 or more miles to Lorain County, less than one-half used the artificial site. These figures indicate that the artificial reef use is dominated by local sport anglers, as intended.[4]

Exercise

This case study suggests that there are significant potential economic benefits beyond positive economic impacts from the construction of artificial reefs. Fishery managers of the Lake Erie region have expressed satisfaction with the artificial program thus far. It has been highly visible and generated much enthusiasm within the local sport-fishing community. Many believe that the reef has also helped improve the integrity of Lake Erie's central basin. Given the information pro-

[3] The Cleveland site is currently being investigated utilizing the video technique.

[4] Glenn, S.J., D.O.Kelch, and L.J. Hushak. 1994. Economic Evaluation of the Lorain County Artificial Reef in 1992: An Overview. Ohio Sea GrantProgram. Technical Summary OHSU-TS-022.

vided above, outline the economic analysis that you would recommend be included in an environmental impact statement of other similar reef programs. Use the following questions as a guide:

1. What type of economic analysis would be appropriate in determining whether to proceed with an artificial reef project?

2. Some believe environmental valuation, which would assess the benefits of artificial reef projects to society, should be standard protocol in all planned artificial reef projects within the Great Lakes. Do you agree?

3. Assuming adequate cost information exists, what sorts of value information would you need to assess in order to conduct a benefit-cost analysis of an artificial reef project?

4. What methodologies or techniques would you recommend for each of the value categories identified above?

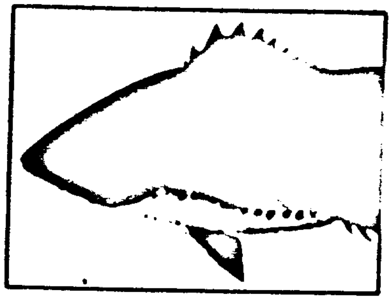
5. Fish and fishers move. How would you account for this movement in your analysis of changes in commercial or recreational fishing values?

6. Which of the various economic approaches described in this handbook would be used by different stakeholders in the policy decision process?

    - Developers
    - Local agencies making decisions regarding public investments
    - Interest groups
    - Public at large
    - Federal regulators/decision makers

7. How would economic information be developed and presented by each group?

Red Snapper Fishery Management in the Gulf of Mexico



Situation

Declines in red snapper stocks in the Gulf of Mexico have impacted commercial and recreational fishers. Among the potential management plan options is the use of Individual Transferrable Quotas (ITQ). While ITQs have been employed within the commercial fishery sector, questions arise as to their applicability within the recreational sector.

Background

In 1984 the Gulf of Mexico Fishery Management Council implemented the Reef Fish Fishery Management Plan — its goal was to manage the reef fish fishery with the Gulf for attaining the greatest overall benefit to the nation. In 1988, a National Marine Fishery Service (NMFS) stock assessment indicated that red snapper was significantly overfished and that reductions in fishing mortality rates of as much as 60 to 70 percent were necessary to rebuild red snapper stocks to a recommended 20 percent spawning stock potential ratio. The 1988 assessment also identified shrimp trawl bycatch as a significant source of juvenile red snapper mortality.

In response, the Fishery Management Council amended the 1984 Fishery Management Plan. The 1990 Amendment 1 provided for a commercial quota of 3.1 million pounds of red snapper. In 1991, the Total Allowable Catch (TAC) was set at 4.0 million pounds with a commercial quota allocation of 2.04 million pounds and a recreational daily bag limit of seven fish (1.96 million pounds). The 1991 Regulatory Amendment also contained an intent by the Council to establish a 50 percent reduction of the offshore shrimp trawler fleet snapper bycatch in 1994.

Despite the intent of the 1991 Regulatory Amendments, the effort capacity for the commercial red-snapper fishery continues to be excessively high, given current quota levels, as evidenced by the 2.04 million pound quota (1992) being filled in just 53 days. Under Amendment 6 of the Reef Fish Fishery Management Plan, a quota increase to 3.06 million pounds provided some benefits but did not prevent a derby fishery from developing. Under the same quota, the 1994 season lasted for 77 days.

VOL 12

9/92

In reaction to the current conditions in the red snapper fishery the Gulf of Mexico Fishery Management Council is now considering a proposed Amendment to the existing Reef Fish Fishery Management Plan[1]. Alternatives in this amendment include a proposal to establish a comprehensive effort management program for the red snapper fishery. The alternatives under consideration include:

1. No action (a system with additional effort controls beyond those currently allowed in the Fishery Management Plan's framework procedure for setting total allowable catch)

2. License limitation

3. Individual Transferable Quotas

Individual Transferable Quota Management System

The Council has identified an Individual Transferable Quotas scheme as the preferred alternative. An ITQ program would involve issuing either a certain poundage or percentage of the total annual commercial allocation of red snapper to each qualifying owner or operator, based on his or her historical landings in the fishery. This poundage or percentage would be that person's initial share. Shares would be the property of the shareholder, probably subject to annual administrative fees for issuing coupons and for transfers of shares. Shares or quota coupons would be transferrable. Under an ITQ system, a "bycatch" allowance for red snapper would not be needed—anyone who wanted to sell *any* red snapper would be required to have quota coupons in the amount of red snapper landed for sale.

The expectations are that an ITQ program will result in increased revenues to the fishing industry as well as decreased total costs of harvesting. In addition, ITQs will afford fishermen greater flexibility by adjusting their share holdings and determining when they will go fishing. Fishermen who choose to exit the fishery may receive economic benefit if they sell their share of harvest privilege.

Under limited access alternatives, fishers would receive specific privileges to participate in the red snapper fishery based on an initial allocation scheme. Fishers who desire to subsequently enter or increase their participation in the fishery could do so only in conjunction with another fisher who decreases his or her participation or leaves the fishery. Thus, allocation of the commercial quota among users would be self-adjusting and ideally would be independent of measures to achieve or maintain the biological goals of the Fishery Management Plan. Unlike limited access, open access systems have no limits on the number of fishers in the fishery or the amount of fish

---

[1] GMFMC. 1994. Draft Amendment 8 and Environmental Assessment (Effort Management Amendment) to the Reef Fishery Management Plan of the Reef Fish Resources of the Gulf of Mexico

any fisher can harvest in a season. Allocation among commercial fishers and total annual harvest are treated as a single combined issue and are controlled by limits on short-term effort or vessel trip limits to spread out the harvest.

Costs of an ITQ System

Costs under ITQ management will be higher than under the other proposed alternative systems largely due to the need for increased enforcement and the extensive records and tracking system for coupons (or similar accounting devices) and ITQ shares. If law enforcement can be increased only to the level necessary to enforce current regulations or license limitation systems, then the additional cost is estimated at $450,000 (Case Table 6.1). However, for "full" compliance, defined to be a compliance level of about 90 to 95 percent, the cost will be $1,540,000. Therefore, depending on the level of compliance desired or necessary to realize a substantial portion of the benefits which are possible under an ITQ program, the enforcement costs will be covered by the range just described.

The public burden costs will be $67,000 initially and $64,000 annually thereafter. The National Marine Fisheries Service's (NMFS) costs to design and maintain the ITQ system are estimated to be $230,000 for the first year and then $145,000 annually. The estimate of total costs for the ITQ program, which includes the Council and NMFS administrative costs will range from $1.17 to $2.26 (Case Table 6.2) million the first year and from $659,000 to $1.75 million annually, depending on the level of law enforcement. Case Tables 6.1 and 6.2 summarize the differences in cost between maintaining the status quo or imposing license limitations on the fishery.

Benefits

Changes in revenue to the commercial red snapper fishery are predicted based on historical prices and expectations of how different management systems will affect overall prices. In brief, the status quo is expected to result in an overall price decline of $.15 to $.40 per pound. The license limitation program is not expected to have much effect on current prices. The ITQ system can be expected to generate a price increase ranging from $.85 to $1.35 per pound based on the level of law enforcement. No information is available on the changes in benefits to recreational fishermen.

Exercise

The Gulf reef fishery is a multispecies fishery with two major user groups, namely, the recreational and commercial sectors. In 1991, the recreational sector caught about 52 million pounds of fish in the Gulf, of which no less than 13 million pounds may be considered reef fish species under the management unit of the fishery plan. For this same year, about 1.6 million individuals (coastal and non-coastal) participated in marine recreational fishing in the Gulf region, and about

Case Table 6.1. Costs associated with different management regimes for red snapper.

	Status Quo	License Limitation	ITQ
Council/NMFS administrative costs	$339,884	$339,884	$339,884
Initial public burden cost to apply for permits	2,000	3,000	3,000
Annual public burden costs to maintain management system	28,000	32,000	64,000
Initial NMFS costs to design and implement management system	0	20,000	85,000
Annual NMFS costs to maintain management system	30,000	42,000	145,000
NMFS law enforcement costs to achieve acceptable compliance[1]	450,000	450,000	450,000 to 1,540,000
Coast guard enforcement	N.A.[2]	N.A.	N.A.
Start-up plus first year	849,884	906,884	1,171,884 to 2,261,884
Continuing annual cost	508,000	524,000	659,000 to 1,749,000

[1] Current level of expenditure is estimated at $400,000. Additional $450,000 is required for any of the major alternatives.
[2] To be estimated.

VOL 12

9/1995

15.5 million fishing trips were made by the recreational fishers. There are no current estimates on the economic value of the recreational reef fishery in the Gulf.

In 1991, the commercial sector landed approximately 21.1 million pounds of reef fish with an ex-vessel value of $34.6 million[2]. In 1992, the commercial reef fish sector was composed of about 2,214 reef fish permitted vessels. Because of the moratorium on issuance of additional commercial permits implemented in May 1992, the number of permitted vessels could not significantly be more than the 1992 number. This moratorium is intended to remain in effect through 1995 unless earlier supplanted with a comprehensive limited access management system or extended by the Secretary of Commerce upon recommendation of the Gulf Council.

A major question facing the Gulf of Mexico Fishery Management Council is this: If an ITQ program for red snapper is developed, how will the initial quota be allocated between commercial and recreational fishers? All of the existing ITQ systems are designed to manage fisheries that are dominated by commercial fishing. There is no reason, however, why ITQs could not be used in recreational or combined commercial/recreational (or mixed) fisheries such as the red snapper fishery. As in commercial fisheries, problems of unlimited entry and inefficient allocation to low valued users can be overcome through the transfer of catch rights in the recreational fishery.

Theoretically, recreational fishers who have a high value for the resource could buy catch rights from other recreational fishers or from commercial fishers. Similarly commercial fishers could increase their individual share of total allowable catch by buying catch rights from recreational fishers. These sales of catch rights could be for part or all of a year or for the duration of the ITQ system. Although each group has a different motive for participating in the fishery, transfers of shares between different user groups would direct the share of rights to the most valued use. As a result, all harvest shares could be owned by either commercial or recreational fishers if they are willing to buy the harvest rights. If fishery managers decide that they want to preserve some portion of the total catch for a particular group of users then some of the catch shares can be exempt from trading.

The Council has three options. It can create ITQs for: (1) the commercial fishery only with recreational harvest regulated through bag limits and season closures; (2) a single class of ITQ shares for both commercial and recreational sectors with no restrictions on transfers between commercial and recreational fishers; or (3) two separate classes of ITQ shares — one for the commercial sector and one for the recreational sector. Separate subgroups within a recreational share class for certain groups of recreational fishers such as headboats, party boats, or other identified recreational groups could be established.

The rationale for these subgroups would be to protect certain recreational groups such as headboats or to protect stocks in specific areas. Alternatively, the initial allocation of ITQ shares could be used to address specific distributional concerns about recreational share ownership and allow full transferability to determine the most desirable pattern of share ownership.

Suppose that you are on the Gulf of Mexico Fishery Management Council. You are tasked with establishing a preferred option regarding initial allocation of ITQ shares within the current red snapper fishery. Consider the role of environmental valuation in your analysis of options. Us-

Wetland Restoration in Louisiana

Situation

Coastal wetlands in Louisiana play an essential role in the vitality of commercial and sport fishing and recreational hunting. But these wetlands are being devastated by a host of continuing human activities that range from population growth to artificial levees for flood control to the mining of offshore oil fields. Wetland restoration is critical and poses difficult choices that must take into account short and long-term costs.

Background

The Louisiana coastal zone is one of the Nation's foremost geological, biological, and cultural resources. Containing 40 percent of the country's coastal wetlands, it includes 2.5 million acres of marshes (fresh, brackish, and saline) and 637,400 acres of forested wetlands. The Louisiana coastal zone, created by the Mississippi River, is the most active deltaic land mass in North America, draining 40 percent of the 48 contiguous states and substantial areas in the Canadian provinces.[1]

Between 50 to 75 percent of Louisiana's residents live within 50 miles of the coast. These inhabitants benefit from the numerous resources and resource services that wetlands provide. They are the source of livelihood to a substantial number of people including fishers and foresters. Even those who do not depend economically on marshes benefit from the hurricane and flood protection they provide through absorption of storm surges and mitigation of flood damage. The coastal zone also serves valuable water quality treatment functions.

[1] Coastal wetland formation: The land forms within the coastal zones (with the exception of salt domes) were formed as a result of the dynamic interactions between river deposition, waves and currents, and subsidence. Over the past several thousand years, the Mississippi River has periodically changed course. This "delta switching" causes some areas of land to build while others deteriorate. When the river shifts into a new channel, land is built rapidly. The river builds a delta out into shallow shelf areas until its course becomes long, sinuous and inefficient, at which time it changes course to follow a shorter, more efficient route to the Gulf. It is this change which switches the location of the delta. The periodic switching has resulted in a series of delta lobes in various stages of abandonment and deterioration. These lobes, deprived of riverine sediment, slowly break up and erode. However, because a new delta was always building, a natural balance between sinking and accretion existed. At any one location there could be land gain or land loss. In fact, for the past 5,000 years, there has been a net coastal land gain in the Mississippi deltaic plain of between one and two square miles a year. However, the natural cycle of deltaic development — the continuous building and eroding of river basins — is no longer operative today due to human intervention (Coastal Resources Program-Louisiana Department of Transportation and Development. 1978. The Value of Wetlands in the Barataria Basin).

While the natural beauty and abundant wildlife of the wetlands attract tourists from all over the country, the region possesses a unique cultural diversity that includes Native Americans, European immigrants, and Cajun ancestry.

Commercial importance of the Louisiana coastal wetlands includes major economic activities related to commercial fishing, recreational hunting, and sport fishing. Fishing is Louisiana's oldest industry and its prominence is directly attributable to the area's extensive marsh and estuarine system.[2] The region supports the largest coastal finfish and shellfish fisheries in the country, producing two billion pounds of fish and shellfish annually. The Louisiana Wildlife and Fisheries Commission issued over 63,000 commercial fishing licenses in 1985, including almost 16,000 commercial shrimp licenses. The recreational hunting and fishing activity of the region are also substantial. The Louisiana coastal zone leads the Nation in trapping of fur-bearing animals and operates a highly regulated harvest of alligator skins.[3]

Coastal Wetland Decline — Causes and Conflict

For decades artificial levees, managed by the U.S. Army Corps of Engineers with Congressional, State, and public support, have confined the Mississippi River to its present channel, preventing a change of course and the associated development of new delta regions. The purpose of the levees is to contain overflows for navigation and flood control. However, the ecological balance and productive capacity of the adjacent wetlands are adversely affected by the lack of additional fresh water and nutrient-rich material. The river control structures confine the sediments to the river channel and transport it to deep Gulf of Mexico waters so that most of these sediments are discharged over the edge of the continental shelf, forever lost to the sediment-starved coastal zone. In addition, the Mississippi's tributary dams and other activities have significantly reduced the sediment load carried by the river.

In addition to flood control activities, another major cause of coastal erosion is construction of navigation, oil recovery, and access canals. Canals adversely impact the wetlands by interfering with sheetwater flow, allowing destruction by wave action, reducing nutrient exchange, decreasing interface, and increasing salinities. Spoil banks, created by the deposition of material dredged from the canals also result in wetland deterioration. Approximately 8 percent of the marshes in coastal Louisiana have been converted to canals and associated spoil banks.[4] Other activities, such as land reclamation projects for agricultural, urban, and industrial purposes, have also destroyed many acres of viable wetland. The pollution from toxic chemicals and oilfield brines contributes to wetland degradation as well.

Wetland loss due to flooding as a result of subsidence-related sea level rise is another problem. Sea level rise occurs as land forms shrink, resulting in a relative rise in water level. Scientific evidence exists which suggests that sea level rise may accelerate significantly due to atmos-

[4] Coalition to Restore Coastal Louisiana. 1987. Coastal Louisiana: Here Today and Gone Tomorrow? A Citizens' Program for Saving the Mississippi River Delta Region to Protect Its Heritage, Economy, and Environment. Draft for public review, p. 10.

pheric warming resulting from the greenhouse effect.[5] These rises would led to increased flooding and additional loss of coastal wetlands.[6]

The cumulative impact of human activities and natural processes on the coastal zone has been devastating. At the turn of the century, coastal Louisiana contained 4.07 million acres of wetlands. By 1978, 22 percent of the wetlands had been lost. Conservative estimates indicate that another 3 million acres have been lost since then. Current loss rates are estimated to be about 0.75 percent per year. It is projected that if losses are not reduced, another 167 million acres of Louisiana coastal wetlands will disappear or be converted by the year 2000. These predictions indicate that the Gulf shoreline will advance inland as much as 33 miles in some areas. About 1,200 businesses, residences, camps, schools, storage tanks, electric power substations, water control structures, and pumping stations would require protection or relocation. Furthermore, the U.S. Army Corps of Engineers estimates that without action to reverse projected wetland losses commercial fish and shellfish harvests will decline by 30 percent by the year 2040.[7]

The threatened disappearance of Louisiana coastal wetlands have potentially staggering economic, cultural, and environmental consequences. The loss of habitat for coastal fish, shellfish, and wildlife species would be colossal. The loss for social and cultural functions which depend on proper ecological functioning of the coastal zone would also be devastating. Furthermore, the present Louisiana coast would become uninhabitable as flooding moves further inland.

Coastal Wetland Restoration Management Plan

The prospective losses of wetland functions and services have motivated implementation of a wetland restoration policy. That policy is based on the belief that technological ingenuity and management can separate wetland destruction from some of the causes of that destruction, navigation, flood control, oil and gas production, and urban development. The short-term costs of employing advanced techniques and restoration strategies will undeniably be substantial; the long-term costs, however, of not employing environmental engineering technologies and not implementing management and restoration strategies may be far greater. A restoration program might concentrate on three tasks:

1. Enhancement of sediment and fresh water input into the coastal zone and capture of resuspended sediments

2. Repair or restoration of disturbed wetlands and barrier island transacted by exiting canals

3. Phase-out and halt to construction or expansion of canals.

---

[5] Some scientists predict that sea level rise by 2075 may range from 38 to over 200 centimeters depending on the global level of combustion of fossil fuels and emissions of other greenhouse gases.

[6] Coalition to Restore Coastal Louisiana, op. cit., p. 10.

[7] U.S. Department of the Interior, op. cit., p. 154.

Benefits and Costs of Wetland Restoration Strategies

A wetland restoration policy for the Louisiana wetlands coastal zone must manage all of its uses, both short term and long term. One key factor in developing a plan — recognition of the conflicts over multiple uses and societal tradeoffs — is determining the economic value of the wetlands. Economic values provide a basis for realistic appraisal of the wide-ranging social impacts generated by various proposed restoration developments. Thus, the overall benefits and costs of maintaining and restoring Louisiana's coastal wetland resources must be assessed.

A benefit-cost analysis can be conducted by assigning a dollar value to a unit-acre of wetland. However, the economic value of the services provided by wetlands is difficult to appraise due to the lack of a market mechanism for directly pricing those functions. For example, the benefits derived from the wetland's provision of food for commercial fish species and fur-bearing animals have often been ignored. Other values typically disregarded because of the difficulty in assigning economic value are recreational opportunities provided by the wetlands, such as hunting, crabbing, bird watching, swimming, and camping.[8]

Furthermore, the economic value of the protective services provided by wetlands, for instance, storm and flooding protection and the absorption of urban and agricultural waste products, are also difficult to assess, as are the option value and existence value. The option value is the amount which non-users place on a unique resource to know that it is there and could be used, while the existence value is the amount which non-users place on the knowledge that the wetlands exist, even if they never intend to use them directly.

Despite the data and methodological limitations, analysts have developed several different methods by which to value wetlands, including (1) economic impact analysis (EIA); (2) willingness-to-pay (WTP); and (3) energy analysis (EA). These methodologies attempt to place economic value on wetland-related activities and services. In general, some of the major services provided by wetlands can be classified into the following categories: commercial fishing, recreational fishing, commercial trapping, and recreation (subdivided into economic impact expenditures for recreation and the estimated value of user benefits related to recreational activity), and storm protection.

Gross Economic Contribution Analysis. The gross economic contribution analysis for wetland valuation focuses on the question of gross impact on the economy. In other words, values for major activities associated with wetlands are estimated on the basis of gross benefits to the economy. A per-acre value for each of the wetlands-dependent activities is determined, and the respective values are summed to derive the total estimated monetary worth of a wetland acre in its natural state. Case Table 7.1 presents the estimated gross economic contribution of a wetland acre in Louisiana's Terrebonne Parish.[9]

---

[8] Coastal Resources Program-Louisiana Department of Transportation and Development, op. cit., p. 85.

[9] For consistency within the case study, the name of this coastal area has been changed. See the source, Coastal Resources Program-Louisiana Department of Transportation and Development, op. cit., for additional information.

Case Table 7.1. Estimated Gross Economic Contribution of a Wetland Acre in the Terrebonne Wetlands.

Activity Director	Annual Return Per Acre	Present Value Per Acre
	Fishing and Hunting	
Commercial fishing	$286.36	$5,540.42
Non-commercial fishing	3.19	46.40
Commercial trapping (Pelts and meats)	11.69	170.05
	Recreation	
Economic impact of recreation expenditures	60.08	873.89
Economic value of user benefits from recreation	104.33	2,428.17
Total	$465.65	$9,058.93

WILLINGNESS-TO-PAY (WTP). The willingness-to-pay approach to wetlands valuation is based on the concept of consumer surplus — this is a measure of the amount a consumer would be willing to pay to continue receiving the good or service, over and above what the consumer is already paying. Thus, in the case of the Louisiana wetlands, WTP estimates the value of the wetlands based on an evaluation of society's willingness-to-pay to avoid the loss of an acre of wetlands or wetland area. Theoretically, this estimate represents the maximum society would pay rather than do without. WTP assumes that the resources employed to produce the good are not part of the value of the resource but are transferable to other uses. The difficulty with the technique is in obtaining true estimates from all the potential beneficiaries for all the direct and indirect goods and services provided by the wetlands. Costanza and Farber used WTP to assess the value of the Terrebonne Parish wetlands in Louisiana.[10] Case Table 7.2 summarizes their estimates of the WTP valuation wetland service categories. Column 2 shows the annual values on a per-acre basis. The authors note that it may not be appropriate to place the storm protection values on a per-acre basis.

[10] Costanza, R. and S. Farber. 1985. The Economic Value of Wetlands in Terrebonne Parish, Louisiana. Final Report to the Terrebonne Parish Policy Jury.

Case Table 7.2. Summary of WTP valuation of Terrebonne Wetlands, using 1983 dollars*.

Valuation Category	Annual per Acre Value of Wetlands	Per Acre Present Value at Various Discount Rates	Per Acre Present Value at Various Discount Rates
(1)	(2)	(3)	(4)
		8%	3%
Commercial Fishery	$25.37	$317.00	$846.00
Trapping	12.04	151.00	401.00
Recreation	3.07	46.00	181.00
Storm Protection	128.30	1,915.00	7,549.00
Total	$168.30	$2,429.00	$8,977.00
Option and Existence	NA	NA	NA

*The present values for recreation and storm protection assume population growth rates of 1.3%

Source: R. Costanza and S. Farber. 1995. *The Economic Value of Wetlands in Terrebonne Parish Louisiana*. A Final Report to the Terrebonne Policy Jury.

ENERGY ANALYSIS (EA). In contrast to WTP, energy analysis looks at the supply side of wetland values, as opposed to the demand side. The method uses the total amount of energy captured by natural ecosystems in primary production as an estimate of their potential to produce economically useful products such as fish and wildlife. The energy captured in photosynthesis is the basis for the food chain that ultimately supports all the production in wetlands, or in any natural system. Therefore, a suitable analysis of the inputs to these systems might provide a convenient index of their ultimate value to society. However, there is no guarantee that all of the products of wetlands are useful to society, and some values to society (e.g., aesthetics and recreational value) are omitted in EA estimates. Case Table 7.3 presents a summary of EA based value estimates for Louisiana wetlands as assessed by Costanza and Farber. These values range from $6,400 to $10,602/acre using an 8 percent discount rate to $17,000 to $28,600/acre using a 3 percent discount rate. Their "best estimate" for the value of an acre of wetlands is a range: $2,429 to $6,400 per acre using an 8 percent discount rate, and $8,977 to $17,000 per acre using a 3 percent discount rate.

Exercise

The activities that have had the most damaging effects on the coastal region are primarily related to the major economic uses of the Mississippi River and coastal zone for navigation, flood

Case Table 7.3. Gross primary production and energy analysis-based economic value estimates for relevant Louisiana wetland and marine habitats.

Habitat type	Total Energy Captured Measured by GPP[a] kcal/m²/yr)	Annual Equivalent Dollar Value[b] ($/ac/yr)	Net Marsh-Aquatic Change in Annual Value ($/ac/yr)	Present Value ($/ac) assuming rate[d] 8%	Present Value ($/ac) assuming rate[d] 3%
Salt marsh	48,000	624			
Salt aquatic	6,600	86	538	6,700	18,000
Brackish marsh	70,300	914			
Brackish aquatic	5,130	67	847	10,602	28,200
Fresh marsh	40,500	630			
Fresh aquatic	9,300	121	509	6,400	17,000
Coastal plankton	3,600	47 (Average)	631	7,900	21,000
Spoil banks[c]	13,000	169

control, oil and gas production, and urban development. For years the manner in which these enterprises were carried out have resulted in wetland sediment starvation and delta destruction. In essence, the Louisiana coastal zone is engaged in an economic-ecologic conflict. The region's abundant variety of resources have allowed a wide diversity of economic activity. The utilization of these resources has led to both economic development as well as ecological degradation. Coastal wetland degradation will continue unless a coastal wetlands policy which restores deltaic functions is adopted.

Suppose that you have been asked to be a member of a task force to develop a wetland restoration policy for Terrebonne Parish. Given the information provided in this case study, consider the following questions:

1. What are some of the advantages and limitations of the "valuation" approaches outlined above?

2. What role can environmental valuation play in regional wetland restoration policy?

3. How would environmental valuation at the regional level differ from the use of economics at the site level?

4. The capitalized value of an annual stream of wetland benefits is highly dependent on the discount rate, which reflects the value which people today put on retention or production of a resource for future use, and the predicted value of coastal wetlands for fish and wildlife, recreation, water quality management, storm buffer protection and other functions in future years. One can expect that the value of the coastal Louisiana wetlands would increase if their resources were to become scarce through lack of proper management. What discount would you suggest be used in this analysis?

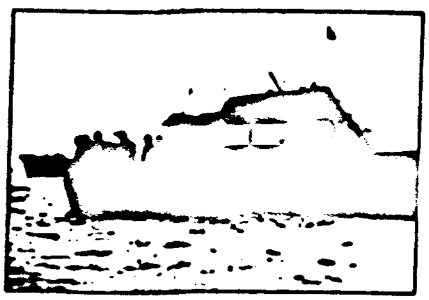
5. It has been suggested that, to date, existing legal mechanisms for regulating activities in the Louisiana coastal zone have not been sufficiently restrictive of access and navigation construction projects. A wetland restoration policy must develop more stringent regulatory programs in this regard by imposing mitigation requirements which will fully compensate for direct and indirect land loss where dredging of canals is permitted. Construction of access and navigation canals should be drastically restricted by mandating use of alternative means of access for oil and gas equipment. With regard to urban development, it has been suggested federal subsidies should be suspended (e.g., funds for low-income housing, mortgage insurance, and National Flood Insurance for urban development projects) in environmentally significant wetlands. These expenditures currently offer significant incentives for development that impacts important wetlands. They also set the stage for future federal outlays for damages caused by storms to developments located in naturally flood-prone areas. Strictly on economic grounds, would it make sense (in terms of sound public policy) to withhold incentives for developing areas subject to high flooding risks?

6. Which of the various economic approaches would be used by different stakeholders in the policy decision process? How would economic information be developed and presented by each group?

- Developers
- Local agencies making decisions regarding public investments
- Interest groups
- Public at large
- Federal regulators/decision makers

7. How can the various economic approaches aid in developing consensus among stakeholders?

NONPOINT SOURCE POLLUTION CONTROL IN CALIFORNIA



Situation

Recreational facilities such as marinas and activities such as boating can be sources of dangerous contamination in nearshore waters. Toxic compounds from antifouling paints, batteries, detergents, and sewage are a threat to water quality, living resources, and human health. Management safeguards and other control measures to prevent pollutant runoff could, in the long run, cost less than environmental clean-up costs.

Background

In the Coastal Zone Management Act (CZMA) of 1972, as amended, Congress declared it to be national policy that state coastal management programs must provide for public access to the coasts for recreational purposes. Clearly, boating and adjunct activities and facilities are an important means of public access. The availability of public access facilities and services such as marinas has helped boating to become a major industry in California. More than 650,000 pleasure boats are registered with the state and during 1986, recreational boaters engaged in an estimated 56 million boating-days.

Boater spending supports a wide range of businesses, among them, boat and equipment manufacturing, retailing, and various types of boating services. A 1986 inventory of 5,035 boating businesses throughout California revealed that these businesses had total gross receipts of $2.6 billion, employed 40,000 people, and paid $476 million in payroll. Businesses that support recreational boaters paid over $191 million in state and local taxes during that year. The direct spending by boaters on goods and services stimulates the entire California economy. Including all the other businesses that support the boating industries in California, the total economic activity traceable to boating in 1986 was more than $6.7 billion.[1] Clearly, marinas and other public access facilities and services are integral to California's economy.

However, when these facilities are poorly planned or managed, they can pose a threat to the health of aquatic systems; they can also introduce other environmental hazards. Because marinas are located at the water's edge, there is often no buffering of the release of pollutants to waterways. Adverse environmental impacts may result from the following sources of pollution associated with marinas and recreational boating:

- Pollutants illegally discharged from boats and fueling stations
- Pollutants transported in stormwater runoff from marina parking lots, roofs, and other surrounding impervious surfaces
- Physical alteration or destruction of wetlands and of shellfish and other bottom communities during the construction of marinas, ramps, and related facilities
- Pollutants generated from boat maintenance activities on land and in the water[2]

Recreational boating and marinas are increasingly popular uses of the California coastal zone. In areas such as San Diego Bay, the growth of recreational boating, along with the growth of coastal development in general, has led to a growing awareness of the need to protect waterways. Normal marina operations such as waste disposal, boat fueling, and boat maintenance and cleaning generate contaminant runoff. Moreover, storage areas for the materials required for these activities are also a source of pollutants. Of special concern are substances such as paint sandings and chippings, waste oil and grease, batteries, fuel, detergents, and sewage that can be toxic to aquatic biota, or degrade water quality and pose a threat to human health.

Historically, point source wastes from shipyards, boatyards and other repair facilities, and marinas were dumped or washed directly into the San Diego Bay. Environmental legislation over the past 20 years has put an end to these practices. However, large sinks of sand blast material and other paint-containing waste are still present in the Bay's sediments. The effects of these sinks on water quality is not known.[3]

Non-point source pollution continues to be a paramount concern as current boat maintenance activities, such as the use of antifouling paints on boat hulls, generate contaminants that can harm the marine environment. These paints that contain chemical pesticides are applied to the hulls of boats to deter the attachment and growth of aquatic organisms — the buildup of such

[2] U.S. Environmental Protection Agency. 1993. Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters. EPA Document 840-B-92-002, pp.5.2-5.3.

[3] Conway, J.B. and L.P. Locke. 1994. A Final Report on Marine Fouling and Underwater Hull Cleaning in San Diego Bay. Prepared for the California Regional Water Quality Control Board, San Diego Region.

organisms can promote hull corrosion and increase drag.

Biocides from antifouling paints generally enter the marine environment in different ways: (1) through the normal leaching process of paints as they age, and (2) through paint chips abraded from vessels' hulls in the water during underwater hull cleaning. The concern is that the copper-based biocide chemicals released from antifouling paint applied to boat hulls may be deleterious to the marinas' aquatic environment. Because of the poor tidal flushing characteristics of San Diego Bay, copper concentrations can become elevated to levels harmful to aquatic organisms.

Numerous studies have shown that the concentrations of antifouling biocides are highest near marinas and small yacht basins. A recent study assessing the average concentrations of total and dissolved copper in San Diego and Mission Bays found that while ambient copper concentrations appeared to be non-toxic, several marinas did have average dissolved copper concentrations that were above the U.S. EPA's Ambient Water Quality Criteria for saltwater aquatic life.[4]

Another study attempted to measure the deleterious effects (within the water column) of in-water maintenance of boats at recreational marinas. The study revealed that although copper releases can be significant in the immediate vicinity of a boat hull during cleaning, the water rapidly returns to pre-cleaning concentrations. However, the findings were inconclusive as to the extent and degree of dispersal of the contaminant plume and the total load to the Bay from a hull cleaning operation. Other studies have found evidence of elevated levels of copper in the tissues of organisms living in the San Diego Bay. These studies suggest that boat owners should be educated about biofouling processes and antifouling paints so that they can make sound, informed, and environmentally sensitive decisions.

Nonpoint Source Control Solutions

It is important that marina operators such as those in San Diego Bay recognize that there are alternatives to obtaining permits to pollute. They can take steps to control or minimise the entry of polluting substances into marina waters. For the most part, this control can be accomplished with simple preventive measures such as locating service equipment where the risk of spillage is reduced, providing adequate and well-marked disposal facilities, and educating the boating public about the importance of pollution prevention. Benefits of effective pollution prevention to the marina operator may be realized in terms of lower direct pollution control costs. The costs of pollution prevention could well be lower than environmental clean-up costs.

Section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA) requires coastal states (including Great Lakes states) with approved coastal zone management programs to address nonpoint pollution impacting or threatening coastal waters. States must submit Coastal Nonpoint Pollution Control Programs for approval to both the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA). Requirements for state programs are described in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance* and are summarized in a separate fact sheet. Some of the

---

management measures outlined in the guidance include practices related to the best possible siting for marinas, best available design and construction, and appropriate operation and maintenance (e.g., solid waste management, liquid waste management, and petroleum control management). Other management efforts might include staff and boater education programs on all areas of non-point source control and best management practices; petroleum station management; improved sewage pumpout systems; and installation of fuel spill controls.

California is currently revising its Nonpoint Source (NPS) Pollution Management Plan pursuant to the 1990 CZARA. For each management measure, a Technical Advisory Committee accepted or modified EPA's management measure as it should be applied to California; for each management measure, the report also addresses applicability, methods of implementation, specific implementors, enforcement mechanisms, triggers of enforcement actions, and the actions that are necessary to begin implementation.

Costs of Compliance

The California Regional Water Quality Control Board, San Diego Region, could choose to implement some of the operations and maintenance management measures outlined in the 1994 *Marina and Recreational Boating Technical Committee Report* in an attempt to improve the quality of San Diego Bay. Implementation of these measures, unlike compliance with cleanup and abatement orders by boatyards, is not expected to impose significant costs on marina operators in the area. The cost of providing recreational boating services will likely increase with implementation of management measures affecting the San Diego Bay marinas.

Nonpoint source control requirements have the potential to delay new facility construction and/or business failures of existing marinas. Some of these costs are expected to be passed along to recreational boaters. In addition to costs passed on to boaters by marinas, boaters may incur costs associated with more expensive non-toxic paints (silicone) and hull cleaners who are licensed, insured, approved under best management practices; higher cost boat maintenance (experienced labor, more frequent cleanings, required draping); and higher cost oil-change services which recycle.

Case Table 8.1[5], though not directly related to the implementation of boat-cleaning management practices, presents some high estimates of the potential costs to San Diego Bay marinas of selected operation and maintenance practices. While operations and maintenance management measures include waste disposal, education and boat-operation practices, this analysis is restricted to solid-waste disposal practices and liquid-waste disposal practices. The specific costs are associated with purchasing a commercial vacuum to collect debris at hull-maintenance sites, providing covered dumpsters for solid-waste collection, and purchasing liquid waste containers for storing and recycling oil, antifreeze, gasoline, diesel fuel, and kerosene.[6]

---

[5] U.S. Environmental Protection Agency. 1992. Economic Analysis of Coastal Nonpoint Source Pollution Controls: Marinas. Original estimates have been adjusted for the purposes of this hypothetical case study.

[6] These cost estimates are based on large-scale repair facilities. Boat maintenance at San Diego area marinas is actually small-scale, general upkeep done on individual boats

Case Table 8.1. Costs of Selected Operation and Maintenance Management Practices: High Estimates.

	Liquid Waste Management		Commercial Vacuum		Covered Dumpster	
Marina Number	Capital ($)	Operating ($/yr)	Capital ($)	Operating ($/yr)	Capital ($)	Operating ($/yr)
1	90	112	1,063	19	0	1,620
2	360	174	1,063	93	0	1,620
3	4,080	407	1,063	372	0	7,056
4	4,170	485	1,063	465	0	7,056
5	15,980	1,652	4,252	1,860	0	21,168
6	15,980	1,652	4,252	1,860	0	21,168

Key Assumptions:
1. Assume one vacuum is needed for every 250 slips of capacity.
2. Assume one filter must be replaced annually for every 50 slips of capacity. Each filter costs $93.
3. Assume model marina owners pay for dumpster rental and collection.

Benefits of Marina Operations and Management Measures

Numerous benefits are associated with the implementation of nonpoint source marina operations and maintenance management measures. For example, increases in water quality will provide improvements in the integrity of the San Diego Bay environment leading to increased recreational boating and fishing values, aesthetics and nonuse values, and reduced costs for dredging when sediments are less contaminated. The steps in determining the benefits of such control measures include:

1. Determination of the benefit categories which match potential management measures

VOL 12

9210

R0042516

2. Estimation of the benefits of each management measure in terms of how each measure will affect natural resource parameters. For example, if non-toxic hull cleansing is required, an attempt must be made to determine the linkage between reduction of pollutants such as copper and the improvement of water quality.

3. Determination of how changes in ecological parameters affect human health, recreational enjoyment, and aesthetic appreciation through impacts on market and nonmarket services provided by the Bay. For example, how does an increase in water quality affect the quantity or quality of recreational boating and other uses of San Diego Bay surface water?

4. Translation of these public health, recreational, aesthetic and ecological effects into estimates of monetary values.

In addition, there may be benefits from some best management practices such as the use of underwater hull cleaning. These benefits include increased vessel maneuverability and fuel efficiency as well as the potential for increased paint life with a corresponding decrease in total antifouling chemical discharge.

Exercise

Given the information provided above, develop an economic argument in favor of or against the implementation of boat-cleaning management measures in San Diego Bay marinas.

1. Do you see a role for environmental valuation in the development of your argument? Would it be most appropriately used in a case-by-case (marina-by-marina) implementation decision basis or as an overall policy decision?

2. What natural resources and resource services do you think should be analyzed?

3. What techniques would you recommend in order to determine the values of these resources and services?

4. What are the limitations to the existing methodologies in this case?

5. Boat-cleaning management measures are only one set of management measures and practices recommended in the EPA nonpoint source pollution control guidance. Using the economic techniques described in the seminar, how would you decide whether focusing on operations and maintenance management actions is appropriate?

6. Would other economic approaches outlined in the seminar be of use to others in the decision process?

- Developers
- Local agencies making decisions regarding supporting public investment decisions
- Interest groups
- Public at large
- Federal regulators/decision-makers

How would this information be developed and presented by each group?

How can these tools aid in the developing consensus among the various stakeholders?

7. There are numerous benefits that can be attached to the implementation of nonpoint-source management measures for marina operations and maintenance. These benefits may not be directly incurred by individual marina operators (though some cost savings may be expected), but are more likely to be felt by the public at large. Should those benefits be weighted similarly in your decision process or should one group or another be weighted more heavily? Should the marina operators be compensated for the capital costs that they will incur to implement the management measures?

8. To describe and measure the benefits of these measures, it is necessary to identify linkages between the measures, the resources of the Bay, and the activities and user groups that derive economic value from the Bay. These relationships are complex and a single measure may affect several different resource services at once. Conceptually, what would those linkages look like? What kind of data would you need to collect to analyze those linkages?

GLOSSARY

benefit-cost analysis — a technique to compare the relative economic efficiency of different states of the world usually brought about by undertaking projects or policies. A comparison is made between gross benefits of a project or policy and the opportunity costs of the action. Benefits and costs are measured as changes in consumer and producer surpluses accruing to individuals in society.

consumer surplus — a money measure of an individual or group's welfare from consumption of a good or service or the existence of a particular state of the world. This surplus is the difference between the maximum the individual is willing to pay for consumption of the good and the amount that has to be paid.

contingent valuation — a methodology to determine money measures of change in welfare by describing a hypothetical situation to respondents and eliciting how much they would be willing to pay either to obtain or to avoid a situation.

demand — in economics, the usual inverse relationship between quantity consumed (or otherwise used or even preserved) and a person's maximum willingness-to-pay for incremental increases in quantity. Market prices often (but not always) reveal the increments of willingness-to-pay. Other factors influencing willingness-to-pay include income, prices of substitutes, and, in recreational fishing, catch rate. Unlike planning where demand refers to the size of the quantity variable, economic demand is a behavioral relationship.

discounting — is a procedure to use when comparing value streams (benefits or costs) occurring in different magnitudes at different dates in the future. The procedure "discounts" future values in order to obtain the present value of the stream.

environmental valuation — procedures for valuing changes in environmental goods and services, whether or not they are traded in markets, by measuring the changes in the producer and consumer surpluses associated with these environmental goods.

existence value — see nonuse value

R0042519

gross domestic product (GDP) — aggregate annual output of the economy before deducting the value of the assets of the economy that have been used up or depreciated in the production process during the year. Gross domestic product provides a summary measure of the Nation's overall economic performance.

hedonic method — a methodology for estimating the relationship between the price of a good (e.g. housing) and the characteristics of the good (e.g. number of bedrooms, air quality, proximity to amenities, etc.). Can sometimes be used to value changes in environmental characteristics.

input-output model — a methodology that models the linkages between input supplies, outputs, and households in a regional economy that can be used to predict the impact of changes on economic activity (e.g., industry revenues and household incomes) within the region.

market benefits — benefits from goods or services bought and sold in normal commerce so that there is a revealed price that reflects consumers willingness-to-pay for the quantity offered and suppliers marginal production costs.

non-market benefits — benefits that accrue to individuals for goods, services, experiences or states of nature that are not normally traded in commerce.

nonuse value (see also use value) — value of knowing that something exists in a particular state even though there is no sensory contact with the resource.

opportunity cost — the highest value a productive resource such as labor, capital, land or a natural resource could return if placed in its best alternative use.

producer surplus — total revenue minus the opportunity cost of production, including the opportunity costs of the entrepreneurs skills, labor, capital, and ownership of natural resources.

random utility model (RUM) — an extension of the travel cost method which explicitly considers individuals participation decisions and the selection among alternative recreation sites.

supply — schedule of the quantities of goods and services that a business is willing to sell at various prices. Other factors that affect supply include input prices.

travel cost method — a methodology which relies on travel-related costs as a surrogate for price in a non-market situation in order to estimate demand and money measures of willingness-to-pay.

use value — value derived from either the consumption of a good, the utilization of a service, or that otherwise involves some sensory contact with the resource. For example, whale-watching is not consumptive but involves visual contact with the whales.

value — what one is willing to give up in order to obtain a good, service, experience, or state of nature. Economists try to measure this in dollars.

welfare economics — a field of inquiry within the broad scope of economics that is concerned with money measures of individual and social well-being, particularly in changes in well-being due to implementation of public policies.

HAZARDOUS AND TOXIC WASTES ASSOCIATED WITH URBAN STORMWATER RUNOFF

Robert E. Pitt, P.E., Ph.D., Department of Civil Engineering, University of Alabama at Birmingham
Richard Field, P.E., Chief, Storm and Combined Sewer Pollution Control Program, U.S. EPA, Edison, New Jersey

ABSTRACT

This paper summarizes some of the information obtained during a research project sponsored and directed by the EPA's Storm and Combined Sewer Research Program and conducted under a subcontract from Foster-Wheeler/Enviresponse. The research project examined a variety of organic and metallic toxicants in stormwater and combined sewer overflow (SCSO) source flows (Pitt and Barron 1990). The study was designed to use rain events and sample locations to illustrate the variables associated with toxicant concentrations in urban runoff. An attempt was made to specifically address the following questions:

1. What are the typical toxicant contaminant levels in stormwater?
2. What are the origins of these toxicants in stormwater?
3. What rain or land use factors affect toxicant concentrations in stormwater?

INTRODUCTION

Stormwater runoff has been identified as a major contributor to the degradation of many urban streams and rivers (Field and Turkeltaub 1981; Pitt and Bozeman 1982; Pitt and Bissonnette 1984). Organic and metallic toxicants are expected to be responsible for much of these detrimental effects, and have been found in urban runoff discharges during many previous studies (EPA 1983; Hoffman, et al. 1984; Fam, et al. 1987; Pereira, et al. 1988).

Table 1 summarizes the estimated discharges of commonly detected organic and metallic toxicants from all U.S. cities having populations greater than 100,000 population (which total about 15,000 square miles, Dept. of Commerce 1980). These cities will be required to participate in the EPA's stormwater permit program (Federal Register, December 7, 1988). These values are for discharges that are directly entering the nation's surface receiving waters. This information is based on the Nationwide Urban Runoff Program (NURP) results of about 100 stormwater outfall samples (EPA 1983). This NURP data is mostly for residential areas, with some commercial area influences. More recent information indicates that industrial stormwater discharges can have many times the concentrations of the toxicants as the areas represented in the NURP data (Pitt and McLean 1986). In addition, base flows occurring in storm drains during dry weather that may be contaminated by non-stormwater discharges (such as industrial waste cross-connections), can also significantly increase these estimated loadings (Pitt, et al. 1990). Therefore, the large discharges noted in Table 1 can be expected to be even much larger, when all urban areas, land uses, and flow regimes are considered. Most importantly, these are actual discharges as monitored at outfalls, and not estimated discharges associated with chemical storage or disposal operations.

METHODOLOGY

This research included the collection and analysis of several hundred urban runoff samples from a variety of source areas and under different rain conditions. A number of combined sewer overflow and detention pond samples were also included in the evaluation portion of these first phase activities. This effort was significantly greater than has been attempted previously for toxic pollutants in stormwater and will enable several critical questions to be addressed, as stated previously in the objectives.

Samples were analyzed for many organic pollutants using gas chromatographs with a mass selective detector (GC/MSD) and with an electron capture detector (GC/ECD) and metals using a graphite furnace equipped atomic adsorption spectrophotometer (GFAA). All samples were also analyzed for particle distributions from about 1 to 100 microns. All samples were also analyzed using a toxicity screening technique. All SCSO samples were also filtered to determine the liquid/solid partition coefficients of the pollutants and the relative toxicities of the filterable and nonfilterable portions of the samples. The following paragraphs briefly summarize the sampling and analyses features of this first phase research effort.

Sampling Effort

About 300 subsamples were analyzed for organic and metallic toxicants, toxicity screening, and particle size distributions. All of these samples were partitioned into filterable and non-filterable components for complete analyses.

The relative importance of different source areas (such as roofs, streets, parking areas, etc.) in contributing toxicants were examined from field studies conducted as part of this research. Samples were collected from the most significant potential source areas in residential, commercial, and industrial land uses. The areas that received the most sampling attention were parking and storage areas in industrial and commercial areas. These areas have been noted in previous studies to have the largest potential of discharging toxicants (Pitt and McLean 1986).

Sheetflow samples were collected during five Birmingham Alabama rains. Replicate samples from many of the same source areas, but during different rains, enabled differences due to rain conditions versus site locations to be statistically evaluated.

Source Area Runoff Grab Samples

The sheetflow samples were collected using manual grab procedures. Hand operated pumps created a vacuum in the sample bottle which then drew the sample directly into the container through Teflon tubes. About one liter of sample was collected, split into two containers: one 500-mL glass with Teflon lined lid was used for the organic and toxicity analyses, and another 500-mL polyethylene bottle was used for the metal and other analyses.

Most of the source area sheetflow samples were obtained from the Birmingham, Alabama area during the first phase of this project. However, cooperative researchers in Seattle, Washington also submitted a limited number of additional stormwater samples for comparison.

CSO Grab Samples

Twenty combined sewer overflow (CSO) outfall grab samples were collected in the New York City area for complete analyses. These outfall samples were used to make a preliminary evaluation of the relative toxicities of CSOs and urban stormwater runoff. These samples were collected during four different rains in New York.

Organic Pollutant Analyses

The samples were analyzed using a Hewlett Packard 5890 gas chromatograph with a 5970B mass selective detector (GC/MSD), and a Perkin-Elmer Sigma 300 gas chromatograph with an electron capture detector (GC/ECD). The following lists the organic toxicants that were analyzed in these samples:

Pesticides (detection limit: 0.3 ug/L):

BHC, heptachlor, aldrin, heptachlor epoxide, endosulfan, DDE, DDD, DDT, endrin, and chlordane.

Phthalate Esters (detection limit: 0.5 ug/L):

Bis(2-ethyhexyl) phthalate, butyl benzyl phthalate, di-n-butyl phthalate, diethyl phthalate, dimethyl phthalate, and di-n-octyl phthalate.

Polynuclear Aromatic Hydrocarbons (detection limit: 0.5 ug/L):

Acenaphthene, acenaphthylene, anthracene, benzo (a) anthracene, benzo (a) pyrene, benzo (b) fluoranthene, benzo (ghi) perylene, benzo (k) fluoranthene, chrysene, dibenzo (a,h) anthracene, fluoranthene, fluorene, indeno (1,2,3-cd) pyrene, naphthalene, phenanthrene, and pyrene.

In addition, selected nitroaromatics, haloethers, and other chlorinated hydrocarbons were also analyzed.

Metallic Pollutant Analyses

The samples were analyzed using a Perkin-Elmer graphite furnace atomic absorption spectrophotometer (GFAA). Standard EPA approved methods were used in these analyses. Aluminum, cadmium, chromium, copper, lead, nickel, and zinc were analyzed in all samples. The detection limits were about 1 ug/L, except for cadmium which had a detection limit of about 0.1 ug/L.

Low detection limits were necessary for these metal analyses. In prior studies, the total forms of most of the metals were well within the detection limits of standard flame atomic absorption spectrophotometer (AAS) procedures, but the filterable portions were commonly not detected (Pitt and McLean 1986; EPA 1983). The partitioning of the heavy metals between the solid and liquid phases is an important factor in determining the treatability of these pollutants and was therefore an important goal of this research. This information is needed to assess the fates of the metals in receiving waters and in treatment processes.

Toxicity Screening Tests

A number of previous studies have found high concentrations of toxic pollutants in SCSOs. Some urban stormwater runoff studies attempted to use conventional 96-hr fish bioassay toxicity tests (such as Pitt 1979), but very few fish died during the tests. However, in situ taxonomic studies of urban runoff receiving waters found significant evidence of toxic effects from the long-term exposure to these pollutants (such as

VOL 12

9224

reported by Pitt and Bozeman 1982, for the same stream as the negative fish bioassay tests). More recent bioassay tests have used more sensitive organisms and have detected significant SCSO toxicities (Spiegal et al. 1984 in Syracuse, NY; Mount et al. 1985 in Birmingham, AL; Mount et al. 1986 in Waterbury, CN, and Norberg-King et al. 1988 in San Francisco Bay).

The objective of this task was to obtain toxicity measurements from a large number of SCSO and source area samples, along with toxicity measurements corresponding to different SCSO sample partitions. It was necessary to use a rapid screening method to examine the relative toxicities for the different samples because of the time and financial limitations of this first phase of the research program. A series of special tests were made to compare toxicities of selected sheetflow and CSO samples to both the screening method and conventional bioassay methods.

The toxicity testing procedure that was used (Microtox from Microbics, Inc.) uses luminescent bacteria to indicate relative toxicities of samples. This procedure was used to screen all of the samples collected during this project. The partitioned samples (filterable and non-filtrable for each sample) were all tested for relative toxicity. These data enabled toxicity comparisons between different source areas, in addition to toxicity reduction potential for different treatment processes, to be made. These tests were not used to determine the absolute toxicities of the samples, but only to examine the toxicity differences between the different source areas and sample partitions. In addition, about twenty samples were also analyzed concurrently using a variety of conventional bioassay techniques, for comparison with the Microtox procedure.

<u>Particle Size Analyses</u>

Many SCSO treatment processes are very sensitive to the particle size distributions and settling velocities of the solids (Dalrymple et al. 1975). Wet detention ponds, catchbasins, grass filters, street cleaning, microscreening, filtration, swirl concentrators are some of the treatment methods that require a knowledge of particle size and/or settling characteristics. Additionally, the fate of many toxic pollutants in receiving waters is also very sensitive to these particle physical characteristics. Without knowing the specific particle size distributions and settling velocities, the necessary design information for these controls therefore remains unknown.

Unfortunately, there are wide variations in the particle distributions for different source areas (Pitt and McLean 1986), which makes the design of runoff controls having consistent performance difficult. The objective of this subtask was to obtain a statistically significant number of individual particle size distributions from many SCSO source areas.

A laser particle counter (SPC-510 from Spectrex Corp.) was used to analyze particle size distributions for all of the SCSO and receiving water samples. This instrument produces particle size distribution plots for particle sizes ranging from 0.5 microns to more than 100 microns. Settling column tests are currently being conducted to determine the specific gravities of SCSO samples which will enable settling velocities to be calculated.

<u>Treatability Tests</u>

This project also included tests to examine the treatability of source area and outfall samples. Filtration tests, in conjunction with literature information, enabled an examination to be made of the benefits of typical treatment processes to reduce toxicity and potential toxic pollutant components of SCSOs. This subtask stressed the fate mechanisms (partitioning) that can be later related to specific control processes. As an example, knowing the filterable fraction of the aggregate toxicity of a sample will allow estimates to be made concerning the maximum treatability of the waste by particle separation processes (such as catchbasins, grass filter strips, and wet detention ponds). The detailed particle size distributions obtained in this research will enable the relative benefits of various sediment barrier practices (such as filtration and screening) to be estimated. Many detailed bench-scale unit processes will be performed during the current phase of this study, and future work will include pilot- and full-scale tests of various treatment practices.

DATA OBSERVATIONS

Toxicity Observations

The Microtox procedure allowed toxicity screening tests to be conducted on each sample's total and filtered components. This screening procedure enabled about 300 samples to be evaluated. The Microtox procedure was not used to determine the absolute toxicity of the samples, or to show that urban stormwater runoff components were in fact toxic. The objectives of these analyses were to identify the most toxic source areas and to identify the approximate toxic reductions possible by complete separation of the unfiltered pollutants from the mixtures.

Actual urban stormwater runoff problems that have been monitored are quite varied, but are probably mostly associated with long-term pollutant exposures, especially through heavily polluted sediments. Receiving water concentrations during runoff events and typical laboratory bioassay tests have not shown many significant short-term receiving water problems (Field and Pitt 1990).

Each sample was tested as unfiltered and filtered. A Millipore 0.45-micron filter was used, under a gentle vacuum, to prepare the filtered samples. The toxicity, as determined by the Microtox procedure, was expressed as three values, I_{10} (the percentage light decrease after about 10 minutes of exposure), I_{35} (the percentage light decrease after about 35 minutes of exposure), and the EC_{50}. The EC_{50} is the sample dilution corresponding to a 50 percent light decrease after a 35 minute exposure. Therefore, only samples that have I_{35} values greater than 50 were further tested to determine the EC_{50} values. Higher values of I_{10} and I_{35}, and lower fractions of EC_{50}, correspond to greater toxicities.

Microbics suggests that light decrease values greater than 60 percent correspond to "highly" toxic samples, light decrease values between 20 and 60 percent correspond to "moderately" toxic samples, and light decrease values less than 20 percent correspond to "not" toxic samples. Table 2 shows the percentages of samples in each category that corresponded to each of these groupings. Also shown on Table 2 are the numbers of samples analyzed in each source area category.

The category having the largest percentage of highly toxic samples was the combined sewer overflows. The urban creeks and detention pond effluents had the largest percentage of samples that can be considered least toxic. The source areas that had the greatest toxic responses were the parking and storage areas.

Tests were conducted on unfiltered and filtered portions of each sample to indicate the toxic reduction potential associated with complete separation of the particulate pollutant components. When the toxic responses of all of the samples were compared, it was found that no significant differences in the toxic responses occurred for the unfiltered versus filtered samples. In many cases, the filtered samples actually indicated greater toxicities than their unfiltered counterparts. This was probably because of normal experimental errors (found to be about 15 percent through controlled testing).

The chemical analyses found that significant portions of the monitored toxicants were associated with the suspended solids (nonfilterable residue). Upon sample filtering, the concentrations of the toxicants were generally greatly reduced. However, as noted above, the Microtox toxicities of the samples were apparently little affected by filtration. Either other nonmonitored toxicants were responsible for the indicated toxicities and were mostly associated with filterable forms, or the toxicants associated with the suspended solids had little effect on the test organisms. The chemical analyses did find significant portions of the toxicants associated with suspended solids that may form highly toxic sediments in receiving waters. These sediments may adversely affect receiving water beneficial uses long after a runoff event.

In summary, the Microtox analyses indicated short-term toxicities associated with filtered pollutants that would not be removed through sedimentation processes. In contrast, the chemical analyses found significant toxicant concentrations associated with sediment forming materials that would affect long-term toxic responses and these could be partially removed through sedimentation and other particle separation processes.

<u>Suspended Solids Analyses</u>

Suspended solids (particulate residue), turbidity, pH, and particle size distributions were obtained for the unfiltered portions of the samples. The runoff from the paved areas all had relatively low suspended solids concentrations (generally less than 100 mg/L), while some of the sheetflows from unpaved areas had concentrations as high as 750 mg/L. The turbidity values varied in a similar manner; they were all quite low, except for the unpaved areas. Except for roof runoff and storage area runoff, the pH values were within a typical range of about 7 to 8.5. They were as low as 4.4 for roof runoff and as high as 11.6 for storage area runoff. The samples representing complex mixtures of source areas (urban creeks, detention ponds, and CSOs), all had pH values closest to 7.

For any one sample, the particle size distributions were generally narrow; the 10 to 90 percent ranges were represented by particle sizes as close as 20 microns apart. The smallest particle sizes were found for roof runoff. In contrast, landscaped areas and loading docks had some of the largest particle sizes found.

<u>Organic Toxicant Concentration Observations</u>

A major portion of the effort of this research project was spent in conducting the organic toxicant analyses. Table 3 summarizes the organics that were observed in at least ten percent of the unfiltered samples analyzed. Most of the organic compounds detected were PAHs. Two ethers were also frequently detected. This list is similar to the frequency of detection list prepared by the EPA (1983) as part of the Nationwide Urban Runoff Program.

Table 4 contains all of the observed base neutral data, while Table 5 contains all of the observed pesticide data. Roof runoff, urban creeks, and the CSOs had the greatest number of observed maximum organic toxicant values. As noted previously, the CSO category had the largest percentage of highly toxic samples. The roofs contained high concentrations of several pesticides, fluroanthenes and a pyrene. A CSO sample had an extremely high bis (2-ethly hexyl) phthalate concentration of 56 mg/L. Vehicle service areas and parking areas also had several of the observed maximums.

<u>Heavy Metal Concentration Observations</u>

Table 6 summarizes the heavy metal observations. In contrast to the organic analyses, the detection frequencies for all of the metals were very high. Roof runoff had the highest concentrations of zinc, probably associated with galvanized metal. Parking areas had the highest nickel concentrations, vehicle service areas had the highest cadmium and lead concentrations, while streets had high aluminum concentrations. Surprisingly, landscaped areas had the highest chromium and urban creeks had the highest copper concentrations.

Many observations of filterable metals were also made and are also summarized on Table 6. Except for storage areas, most of the zinc was associated with the filterable sample partitions. In contrast, very little of the nickel was found in the filterable sample partitions. Most of other metals were also found associated with the suspended solids fraction. Therefore, suspended solids separation processes would be very effective in removing heavy metals from these source areas, with the exception of zinc. Similarly, if the metals were not removed before discharge, they would likely contribute to polluted sediments in the receiving waters.

CONCLUSIONS

The following paragraphs summarize the major project conclusions, as they related to the project objectives.

Objective 1: Characterization of Toxic Components in SCSOs

Overall, about 300 sample components were analyzed to determine toxicant concentrations in sheetflows and other SCSOs as part of the first phase of this project.

Most pH values were in a narrow range of 7 to 8.5 and the suspended solids concentrations were generally less than 100 mg/L. The particle size ranges were usually narrow for any one sample, but the distribution ranges developed using all samples from a single source area were substantially greater.

Only a small fraction of the toxic organic pollutants analyzed were frequently detected. Thirteen organics were detected in more than ten percent of all samples analyzed. The greatest detection frequencies were for 1,3-dichlorobenzene and fluoranthene, which had detection frequencies of 23 percent. The organics most frequently found in these samples were similar to organics most frequently detected in prior studies conducted elsewhere and were mostly the PAHs, especially fluoranthenes and pyrenes.

Roof runoff, urban creeks, and CSO samples had the greatest frequencies of detection for the organic compounds analyzed. Vehicle service areas and parking areas had several of the observed maximum organic compound concentrations observed. Very little evidence was obtained to differentiate the solid/liquid partitioning of organics for different source areas.

The detection limits of the analyses were greater than anticipated and the frequency of detection was therefore less than if the detection limits were improved. The use of larger sample volumes would have reduced the detection limits, which would result in substantially greater detection frequencies. Most of the organics were associated with unfilterable sample portions. In contrast to the organics, the heavy metals were detected in almost all samples analyzed, including the filtered samples.

Roof runoff had the highest concentrations of zinc observed, probably due to galvanized roof drainage components. Parking areas had the highest nickel concentrations, while vehicle service areas had the highest concentrations of cadmium and lead. Urban creek samples had the highest copper concentrations, probably due to illicit discharges.

Objective 2: Relative Toxicities of Sheetflows and SCSOs

The toxicity and chemical tests were not conducted to demonstrate the toxicity of urban runoff. Many actual receiving water studies (summarized in the project report

Pitt and Barron 1990; and by Field and Pitt 1990) identified the various problems that have been associated with urban stormwater discharges. These long-term receiving water studies have demonstrated that actual urban stormwater problems are quite varied, and are probably mostly associated with long-term exposures to toxicants, especially in the sediments, and to habitat destruction associated with high flows and debris. Receiving water concentrations during runoff events and typical laboratory bioassay tests have not indicated many significant short-term problems associated with urban stormwater runoff.

The Microtox screening tests found that CSOs had the greatest percentage of samples considered the most toxic, followed by samples obtained from parking and storage areas. Runoff from paved areas all had relatively low suspended solids concentrations and turbidities, especially compared to samples obtained from unpaved areas.

About 15 percent of all of the unfiltered samples analyzed were considered highly toxic using the Microtox screening procedure. The remaining samples were approximately evenly split between being moderately toxic and not being toxic.

Preliminary data evaluations indicated that variations in observed Microtox toxicities and organic toxicant concentrations may be greater for different rains than for the different source areas sampled. As an example, high concentrations of PAHs were mostly associated with long-antecedent dry-periods.

Objective 3: Partitioning of Toxic Components and Treatability of Toxicants in SCSOs

There were no significant differences in the measured Microtox toxicities associated with the unfiltered samples and the filtered portions of the samples. However, most of the organics and metals were associated with the suspended solids of the runoff samples. An exception was for zinc, which was found mostly in the filtered sample portions. This implies that most of the Microtox measured toxicity was associated with filterable forms of the pollutants.

This preliminary result suggests that simple sedimentation, even though removing much of the mass of toxic pollutants from the water, may have minimal benefits in reducing immediate toxicant effects. Uncontrolled sedimentation, such as in lakes or reservoirs, or large rivers, may result in long-term contaminated sediment problems. However, controlled sedimentation in SCSO control devices allow effective residue management, including appropriate disposal of the potentially heavily contaminated sediments, which would minimize downstream receiving water sediment problems.

The literature review of the potential transport and fate mechanisms of these pollutants found that many processes will affect these pollutants. Sedimentation in the receiving water is the most common fate mechanism because many of the pollutants investigated are mostly associated with particulate matter. Exceptions included zinc and 1,3-dichlorobenzene which were mostly associated with the filterable sample portions. Particulate removal can occur in many SCSO control processes, including catchbasins, swirl concentrators, screens, drainage systems, and detention ponds. These control processes allow removal of the accumulated polluted sediment for final disposal in an appropriate manner. Uncontrolled sedimentation will occur in receiving waters, such as lakes, reservoirs, or large rivers. In these cases, the wide dispersal of the contaminated sediment is difficult to remove and can cause significant detrimental effects. Biological or chemical degradation of the toxicants in the sediments may occur, but is quite slow for many of the pollutants in the expected anaerobic environments. Degradation of the soluble pollutants in the water column may occur, especially when near the surface in aerated waters. Volatilization (evaporation) is also a mechanism that may affect many of the detected organic toxicants. Increased turbulence and oxygen supplies would encourage these processes that may significantly reduce pollutant concentrations.

Sorption of pollutants onto solids and metal precipitation increases the sedimentation potential of the pollutants and also encourages more efficient bonding of the pollutants in soils, preventing their leaching to surrounding waters.

FOREWORD

This document contains guidance specifying management measures for sources of nonpoint pollution in coastal waters. Nonpoint pollution is the pollution of our nation's waters caused by rainfall or snowmelt moving over and through the ground. As the runoff moves, it picks up and carries away natural pollutants and pollutants resulting from human activity, finally depositing them into lakes, rivers, wetlands, coastal waters, and ground waters. In addition, hydrologic modification is a form of nonpoint source pollution that often adversely affects the biological and physical integrity of surface waters.

In the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA), Congress recognized that nonpoint pollution is a key factor in the continuing degradation of many coastal waters and established a new program to address this pollution. Congress further recognized that the solution to nonpoint pollution lies in State and local action. Thus, in enacting the CZARA, Congress called upon States to develop and implement State Coastal Nonpoint Pollution Control Programs.

Congress assigned to the U.S. Environmental Protection Agency (EPA) the responsibility to develop this technical guidance to guide the States' development of Coastal Nonpoint Pollution Control Programs, which must be in conformity with the technical guidance. EPA developed this guidance by carefully surveying the technical literature, working with Federal and State agencies, and engaging in extensive dialogue with the public to identify the best economically achievable measures that are available to protect coastal waters from nonpoint pollution.

This "management measures" guidance addresses five source categories of nonpoint pollution: agriculture, silviculture, urban, marinas, and hydromodification. A suite of management measures is provided for each source category. In addition, we have included a chapter that provides management measures that provide other tools available to address many source categories of nonpoint pollution; these tools include the protection, restoration, and construction of wetlands, riparian areas, and vegetated treatment systems.

In addition to this "management measures" guidance, EPA and the National Oceanic and Atmospheric Administration (NOAA) have jointly published final guidance for the approval of State programs that implement management measures. That guidance explains more fully how the management measures guidance will be implemented in State programs.

We at EPA strongly believe that, working together, the States, EPA, NOAA, other Federal agencies, and local communities can achieve the goal of the Clean Water Act to make our waters fishable and swimmable. We hope that the enclosed guidance will help us all achieve our common goal.

Robert H. Wayland III, Director
Office of Wetlands, Oceans, and
Watersheds

CHAPTER 1: Introduction

I. BACKGROUND

This guidance specifying management measures for sources of nonpoint pollution in coastal waters is required under section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA). It provides guidance to States and Territories on the types of management measures that should be included in State and Territorial Coastal Nonpoint Pollution Control Programs. This chapter explains in detail the requirements of section 6217 and the approach used by the U.S. Environmental Protection Agency (EPA) to develop the management measures.

A. Nonpoint Source Pollution

1. What Is Nonpoint Source Pollution?

Nonpoint source pollution generally results from land runoff, precipitation, atmospheric deposition, drainage, seepage, or hydrologic modification. Technically, the term "nonpoint source" is defined to mean any source of water pollution that does not meet the legal definition of "point source" in section 502(14) of the Clean Water Act. That definition states:

> The term "point source" means any discernible, confined and discrete conveyance, including but not limited to any pipe, ditch, channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, or vessel or other floating craft, from which pollutants are or may be discharged. This term does not include agricultural storm water discharges and return flows from irrigated agriculture.

Although diffuse runoff is generally treated as nonpoint source pollution, runoff that enters and is discharged from conveyances such as those described above is treated as a point source discharge and hence is subject to the permit requirements of the Clean Water Act. In contrast, nonpoint sources are not subject to Federal permit requirements. The distinction between nonpoint sources and diffuse point sources is sometimes unclear. Therefore, at several points in this document, EPA provides detailed discussions to help the reader discern whether a particular source is a point source or a nonpoint source. Refer to Chapter 2, Section II.B.1 (discussing applicability of management measures to confined animal facility management); Chapter 4, Section I.E (discussing overlaps between this program and the storm water permit program for point sources); and Chapter 5, Section I.G (discussing overlaps between this program and several other programs, including the point source permit program).

Nonpoint pollution is the pollution of our nation's waters caused by rainfall or snowmelt moving over and through the ground. As the runoff moves, it picks up and carries away natural pollutants and pollutants resulting from human activity, finally depositing them into lakes, rivers, wetlands, coastal waters, and ground waters. In addition, hydrologic modification is a form of nonpoint source pollution that often adversely affects the biological and physical integrity of surface waters. A more detailed discussion of the range of nonpoint sources and their effects on water quality and riparian habitats is provided in subsequent chapters of this guidance.

2. National Efforts to Control Nonpoint Pollution

a. *Nonpoint Source Program*

During the first 15 years of the national program to abate and control water pollution, EPA and the States have focused most of their water pollution control activities on traditional "point sources," such as discharges through pipes from sewage treatment plants and industrial facilities. These point sources have been regulated by EPA and the States through the National Pollutant Discharge Elimination System (NPDES) permit program established by section 402 of the Clean Water Act. Discharges of dredged and fill materials into wetlands have also been regulated by the U.S. Army Corps of Engineers and EPA under section 404 of the Clean Water Act.

As a result of the above activities, the Nation has greatly reduced pollutant loads from point source discharges and has made considerable progress in restoring and maintaining water quality. However, the gains in controlling point sources have not solved all of the Nation's water quality problems. Recent studies and surveys by EPA and by State water quality agencies indicate that the majority of the remaining water quality impairments in our nation's rivers, streams, lakes, estuaries, coastal waters, and wetlands result from nonpoint source pollution and other nontraditional sources, such as urban storm water discharges and combined sewer overflows.

In 1987, in view of the progress achieved in controlling point sources and the growing national awareness of the increasingly dominant influence of nonpoint source pollution on water quality, Congress amended the Clean Water Act to focus greater national efforts on nonpoint sources. In the Water Quality Act of 1987, Congress amended section 101, "Declaration of Goals and Policy," to add the following fundamental principle:

> It is the national policy that programs for the control of nonpoint sources of pollution be developed and implemented in an expeditious manner so as to enable the goals of this Act to be met through the control of both point and nonpoint sources of pollution.

More importantly, Congress enacted section 319 of the Clean Water Act, which established a national program to control nonpoint sources of water pollution. Under section 319, States address nonpoint pollution by assessing nonpoint source pollution problems and causes within the State, adopting management programs to control the nonpoint source pollution, and implementing the management programs. Section 319 authorizes EPA to issue grants to States to assist them in implementing those management programs or portions of management programs which have been approved by EPA.

b. National Estuary Program

EPA also administers the National Estuary Program under section 320 of the Clean Water Act. This program focuses on point and nonpoint pollution in geographically targeted, high-priority estuarine waters. In this program, EPA assists State, regional, and local governments in developing comprehensive conservation and management plans that recommend priority corrective actions to restore estuarine water quality, fish populations, and other designated uses of the waters.

c. Pesticides Program

Another program administered by EPA that controls some forms of nonpoint pollution is the pesticides program under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). Among other provisions, this program authorizes EPA to control pesticides that may threaten ground water and surface water. FIFRA provides for the registration of pesticides and enforceable label requirements, which may include maximum rates of application, restrictions on use practices, and classification of pesticides as "restricted use" pesticides (which restricts use to certified applicators trained to handle toxic chemicals). The requirements of FIFRA, and their relationship to this guidance, are discussed more fully in Chapter 2, Section II.D, of this guidance.

B. Coastal Zone Management

The Coastal Zone Management Act of 1972 (CZMA) established a program for States and Territories to voluntarily develop comprehensive programs to protect and manage coastal resources (including the Great Lakes). To receive Federal approval and implementation funding, States and Territories had to demonstrate that they had programs, including enforceable policies, that were sufficiently comprehensive and specific both to regulate land uses, water uses, and coastal development and to resolve conflicts between competing uses. In addition, they had to have the authorities to implement the enforceable policies.

There are 29 federally approved State and Territorial programs. Despite institutional differences, each program must protect and manage important coastal resources, including wetlands, estuaries, beaches, dunes, barrier islands, coral reefs, and fish and wildlife and their habitats. Resource management and protection are accomplished in a number of ways through State laws, regulations, permits, and local plans and zoning ordinances.

While water quality protection is integral to the management of many of these coastal resources, it was not specifically cited as a purpose or policy of the original statute. The Coastal Zone Act Reauthorization Amendments of 1990, described below, specifically charged State coastal programs, as well as State nonpoint source programs, with addressing nonpoint source pollution affecting coastal water quality.

C. Coastal Zone Act Reauthorization Amendments of 1990

1. Background and Purpose of the Amendments

On November 5, 1990, Congress enacted the Coastal Zone Act Reauthorization Amendments of 1990. These Amendments were intended to address several concerns, a major one of which is the impact of nonpoint source pollution on coastal waters. In section 6202(a) of the Amendments, Congress made a set of findings, which are quoted below in pertinent part.

"1. Our oceans, coastal waters, and estuaries constitute a unique resource. The condition of the water quality in and around the coastal areas is significantly declining. Growing human pressures on the coastal ecosystem will continue to degrade this resource until adequate actions and policies are implemented.

"2. Almost one-half of our total population now lives in coastal areas. By 2010, the coastal population will have grown from 80,000,000 in 1960 to 127,000,000 people, an increase of approximately 60 percent, and population density in coastal counties will be among the highest in the Nation.

"3. Marine resources contribute to the Nation's economic stability. Commercial and recreational fishery activities support an industry with an estimated value of $12,000,000,000 a year.

"4. Wetlands play a vital role in sustaining the coastal economy and environment. Wetlands support and nourish fishery and marine resources. They also protect the Nation's shores from storm and wave damage. Coastal wetlands contribute an estimated $5,000,000,000 to the production of fish and shellfish in the United States coastal waters. Yet, 50 percent of the Nation's coastal wetlands have been destroyed, and more are likely to decline in the near future.

"5. Nonpoint source pollution is increasingly recognized as a significant factor in coastal water degradation. In urban areas, storm water and combined sewer overflow are linked to major coastal problems, and in rural areas, runoff from agricultural activities may add to coastal pollution.

"6. Coastal planning and development control measures are essential to protect coastal water quality, which is subject to continued ongoing stresses. Currently, not enough is being done to manage and protect coastal resources.

. . . .

"8. There is a clear link between coastal water quality and land use activities along the shore. State management programs under the Coastal Zone Management Act of 1972 (16 U.S.C. 1451 et seq.) are among the best tools for protecting coastal resources and must play a larger role, particularly in improving coastal zone water quality."

Based upon these findings, Congress declared that:

> "It is the purpose of Congress in this subtitle [the Coastal Zone Act Reauthorization Amendments of 1990] to enhance the effectiveness of the Coastal Zone Management Act of 1972 by increasing our understanding of the coastal environment and expanding the ability of State coastal zone management programs to address coastal environmental problems." (Section 6202(b))

2. State Coastal Nonpoint Pollution Control Programs

To address more specifically the impacts of nonpoint source pollution on coastal water quality, Congress enacted section 6217, "Protecting Coastal Waters," which was codified as 16 U.S.C. §1455b. This section provides that each State with an approved coastal zone management program must develop and submit to EPA and the National Oceanic and Atmospheric Administration (NOAA) for approval a Coastal Nonpoint Pollution Control Program. The purpose of the program "shall be to develop and implement management measures for nonpoint source pollution to restore and protect coastal waters, working in close conjunction with other State and local authorities."

Coastal Nonpoint Pollution Control Programs are not intended to supplant existing coastal zone management programs and nonpoint source management programs. Rather, they are to serve as an update and expansion of existing nonpoint source management programs and are to be coordinated closely with the existing coastal zone management programs. The legislative history indicates that the central purpose of section 6217 is to strengthen the links between Federal and State coastal zone management and water quality programs and to enhance State and local efforts to manage land use activities that degrade coastal waters and coastal habitats. The legislative history further indicates that State coastal zone and water quality agencies are to have coequal roles, analogous to the sharing of responsibility between NOAA and EPA at the Federal level.

Section 6217(b) states that each State program must "provide for the implementation, at a minimum, of management measures in conformity with the guidance published under subsection (g) to protect coastal waters generally," and also to:

(1) Identify land uses which, individually or cumulatively, may cause or contribute significantly to a degradation of (a) coastal waters where there is a failure to attain or maintain applicable water quality standards or protect designated uses, or (b) coastal waters that are threatened by reasonably foreseeable increases in pollution loadings from new or expanding sources;

(2) Identify critical coastal areas adjacent to coastal waters identified under the preceding paragraph;

(3) Implement additional management measures applicable to land uses and areas identified under paragraphs (1) and (2) above that are necessary to achieve and maintain applicable water quality standards and protect designated uses;

(4) Provide technical assistance to local governments and the public to implement the additional management measures;

(5) Provide opportunities for public participation in all aspects of the program;

(6) Establish mechanisms to improve coordination among State and local agencies and officials responsible for land use programs and permitting, water quality permitting and enforcement, habitat protection, and public health and safety; and

(7) Propose to modify State coastal zone boundaries as necessary to implement NOAA's recommendations under section 6217(e), which are based on NOAA's findings that inland boundaries must be modified to more effectively manage land and water uses to protect coastal waters.

Congress required that, within 30 months of EPA's publication of final guidance, States must develop and obtain EPA and NOAA approval of their Coastal Nonpoint Pollution Control Programs. Failure to submit an approvable program (i.e., one that meets the requirements of section 6217(b)) will result in a reduction of Federal grant dollars under the nonpoint source and coastal zone management programs. The reductions will begin in Fiscal Year 1996 (FY 1996) as a 10 percent cut, increasing to 15 percent in FY 1997, 20 percent in FY 1998, and 30 percent in FY 1999 and thereafter.

3. Management Measures Guidance

Section 6217(g) of the Coastal Zone Act Reauthorization Amendments of 1990 requires EPA to publish (and periodically revise thereafter), in consultation with NOAA, the U.S. Fish and Wildlife Service, and other Federal agencies, "guidance for specifying management measures for sources of nonpoint pollution in coastal waters." "Management measures" are defined in section 6217(g)(5) as:

> economically achievable measures for the control of the addition of pollutants from existing and new categories and classes of nonpoint sources of pollution, which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

The management measures guidance is to include at a minimum six elements set forth in section 6217(g)(2):

> "(A) a description of a range of methods, measures, or practices, including structural and nonstructural controls and operation and maintenance procedures, that constitute each measure;
>
> "(B) a description of the categories and subcategories of activities and locations for which each measure may be suitable;
>
> "(C) an identification of the individual pollutants or categories or classes of pollutants that may be controlled by the measures and the water quality effects of the measures;
>
> "(D) quantitative estimates of the pollution reduction effects and costs of the measures;
>
> "(E) a description of the factors which should be taken into account in adapting the measures to specific sites or locations; and
>
> "(F) any necessary monitoring techniques to accompany the measures to assess over time the success of the measures in reducing pollution loads and improving water quality."

State Coastal Nonpoint Pollution Control programs must provide for the implementation of management measures that are in conformity with this management measures guidance.

The legislative history (floor statement of Rep. Gerry Studds, House sponsor of section 6217, as part of debate on Omnibus Reconciliation Bill, October 26, 1990) confirms that, as indicated by the statutory language, the "management measures" approach is technology-based rather than water-quality-based. That is, the management measures are to be based on technical and economic achievability, rather than on cause-and-effect linkages between particular land use activities and particular water quality problems. As the legislative history makes clear, implementation of these technology-based management measures will allow States to concentrate their resources initially on developing and implementing measures that experts agree will reduce pollution significantly. As explained more fully in a separate document, *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, States will follow up the implementation of management measures with additional management measures to address any remaining coastal water quality problems.

The legislative history indicates that the range of management measures anticipated by Congress is broad and may include, among other measures, use of buffer strips, setbacks, techniques for identifying and protecting critical coastal areas and habitats, soil erosion and sedimentation controls, and siting and design criteria for water-related uses such as marinas. However, Congress has cautioned that the management measures should not unduly intrude upon the more intimate land use authorities properly exercised at the local level.

The legislative history also indicates that the management measures guidance, while patterned to a degree after the point source effluent guidelines' technology-based approach (see 40 CFR Parts 400-471 for examples of this approach), is not expected to have the same level of specificity as effluent guidelines. Congress has recognized that the effectiveness of a particular management measure at a particular site is subject to a variety of factors too complex to address in a single set of simple, mechanical prescriptions developed at the Federal level. Thus, the legislative history indicates that EPA's guidance should offer State officials a number of options and permit them considerable flexibility in selecting management measures that are appropriate for their State. Thus, the management measures in this document are written to allow such flexibility in implementation.

An additional major distinction drawn in the legislative history between effluent guidelines for point sources and this management measures guidance is that the management measures will not be directly or automatically applied to categories of nonpoint sources as a matter of Federal law. Instead, it is the State coastal nonpoint program, backed by the authority of State law, that must provide for the implementation of management measures in conformity with the management measures guidance. Under section 306(d)(16) of the CZMA, coastal zone programs must provide for enforceable policies and mechanisms to implement the applicable requirements of the State Coastal Nonpoint Pollution Control Program, including the management measures developed by the State "in conformity" with this guidance.

D. Program Implementation Guidance

In addition to this "management measures" guidance, EPA and NOAA have also jointly published *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*. That document provides guidance to States in interpreting and applying the various provisions of section 6217 of CZARA. It addresses issues such as the following: the basis and process for EPA/NOAA approval of State Coastal Nonpoint Pollution Control Programs; how EPA and NOAA expect State programs to implement management measures "in conformity" with this management measures guidance; how States may target sources in implementing their programs; changes in State coastal boundaries to implement their programs; and other aspects of State implementation of their programs.

II. DEVELOPMENT OF THE MANAGEMENT MEASURES GUIDANCE

A. Process Used to Develop This Guidance

Congress established a 6-month deadline (May 5, 1991) for publication of the proposed management measures guidance and an 18-month deadline (May 5, 1992) for publication of the final guidance.

EPA published the proposed guidance on June 14, 1991, and, in the interest of promoting the broadest possible consideration of the proposal by a wide variety of interested Federal and State agencies, affected industries, and citizens groups, provided a 6-month comment period. EPA received 477 public comments on the proposed guidance. In addition, EPA maintained an open process of consultation and discussion with many of the commenters and other experts. EPA's response to those comments, both written and oral, is reflected in the final guidance and is summarized in a separate document available from EPA entitled *Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters: Response to Public Comments.*

In developing the final guidance, EPA continued to draw upon a diversity of knowledgeable sources of technical nonpoint source expertise by using a work group approach. Since the guidance addresses all nationally significant categories of nonpoint sources that impact or could impact coastal waters, EPA drew upon expertise covering the very wide range of subject areas addressed in this guidance.
Because experts in the field of nonpoint source pollution tend to specialize in particular source categories, EPA decided to form work groups on a category basis. Thus, in consultation with NOAA, the U.S. Fish and Wildlife Service, and other Federal and State agencies, EPA established five work groups to develop this guidance:

(1) Urban, Construction, Highways, Airports/Bridges, and Septic Systems;
(2) Agriculture;
(3) Forestry;
(4) Marinas and Recreational Boating; and
(5) Hydromodification and Wetlands.

Each of these work groups held many 1- or 2-day meetings to discuss the technical issues related to the guidance. These meetings, which included State and Federal non-EPA participation, were very helpful to EPA in formulating the final guidance. EPA, however, made all decisions on the final contents of the guidance.

B. Scope and Contents of This Guidance

1. Categories of Nonpoint Sources Addressed

Many categories and subcategories of nonpoint sources could affect coastal waters and thus could potentially be addressed in this management measures guidance. Including all such sources in this guidance would have required more time than the tight statutory deadline allowed. For this reason, Congressman Studds stated in his floor statement, "The Conferees expect that EPA, in developing its guidance, will concentrate on the large nonpoint sources that are widely recognized as major contributors of water pollution."

This guidance thus focuses on five major categories of nonpoint sources that impair or threaten coastal waters nationally: (1) agricultural runoff; (2) urban runoff (including developing and developed areas); (3) silvicultural (forestry) runoff; (4) marinas and recreational boating; and (5) channelization and channel modification, dams, and streambank and shoreline erosion. EPA has also included management measures for wetlands, riparian areas, and vegetated treatment systems that apply generally to various categories of sources of nonpoint pollution.

2. Relationship Between This Management Measures Guidance for Coastal Nonpoint Sources and NPDES Permit Requirements for Point Sources

a. Urban Runoff

Historically, there have always been ambiguities in and overlaps between programs designed to control urban runoff nonpoint sources and those designed to control urban storm water point sources. For example, runoff may often originate from a nonpoint source but ultimately may be channelized and discharged through a point source. Potential confusion between these two programs has been heightened by Congressional enactment of two important pieces of legislation: section 402(p) of the Clean Water Act, which establishes permit requirements for certain municipal and industrial storm water discharges, and section 6217 of CZARA, which requires EPA to promulgate and States to provide for the implementation of management measures to control nonpoint pollution in coastal waters. The discussion below is intended to clarify the relationship between these two programs and describe the scope of the coastal nonpoint program and its applicability to urban runoff in coastal areas.

b. The Storm Water Permit Program

The storm water permit program is a two-phase program enacted by Congress in 1987 under section 402(p) of the Clean Water Act. Under Phase I, National Pollutant Discharge Elimination System (NPDES) permits are required to be issued for municipal separate storm sewers serving large or medium-sized populations (greater than 250,000 or 100,000 people, respectively) and for storm water discharges associated with industrial activity. Permits are also to be issued, on a case-by-case basis, if EPA or a State determines that a storm water discharge contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States. EPA published a rule implementing Phase I on November 16, 1990.

Under Phase II, EPA is to prepare two reports to Congress that assess the remaining storm water discharges; determine, to the maximum extent practicable, the nature and extent of pollutants in such discharges; and establish procedures and methods to control storm water discharges to the extent necessary to mitigate impacts on water quality. Then, EPA is to issue regulations that designate storm water discharges, in addition to those addressed in Phase I, to be regulated to protect water quality, and EPA is to establish a comprehensive program to regulate those designated sources. The program is required to establish (1) priorities, (2) requirements for State storm water management programs, and (3) expeditious deadlines.

These regulations were to have been issued by EPA not later than October 1, 1992. Because of EPA's emphasis on Phase I, however, the Agency has not yet been able to complete the studies and issue appropriate regulations as required under section 402(p).

c. Coastal Nonpoint Pollution Control Programs

As discussed above, Congress enacted section 6217 of CZARA in late 1990 to require that States develop Coastal Nonpoint Pollution Control Programs that are in conformity with this management measures guidance published by EPA.

d. Scope and Coverage of This Guidance with Respect to Storm Water

EPA is excluding from coverage under this section 6217(g) guidance all storm water discharges that are covered by Phase I of the NPDES storm water permit program. Thus EPA is excluding any discharge from a municipal separate storm sewer system serving a population of 100,000 or more; any discharge of storm water associated with industrial activity; any discharge that has already been permitted; and any discharge for which EPA or the State makes a determination that the storm water discharge contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States. All of these activities are clearly addressed by the storm water permit program and therefore are excluded from the coastal nonpoint pollution control program.

EPA is adopting a different approach with respect to other (non-Phase I) storm water discharges. At present, EPA has not yet promulgated regulations that would designate additional storm water discharges, beyond those regulated in Phase I, that will be required to be regulated in Phase II. It is thus not possible to determine at this point which additional storm water discharges will be regulated by the NPDES program and which will not. Furthermore, because of the great number of such discharges, it is likely that it would take many years to permit all of these discharges, even if EPA allows for relatively expeditious State permitting approaches such as the use of general permits.

Therefore, to give effect to the Congressional intent that coastal waters receive special and expeditious attention from EPA, NOAA, and the States, storm water runoff that potentially may be ultimately covered by Phase II of the storm water permit program is subject to this management measures guidance and will be addressed by the States' Coastal Nonpoint Pollution Control Programs. Any storm water runoff that ultimately is regulated under an NPDES permit will no longer be subject to this guidance once the permit is issued.

In addition, it should be noted that some other activities are not presently covered by NPDES permit application requirements and thus would be subject to a State's Coastal Nonpoint Pollution Control Program. Most importantly, construction activities on sites that result in the disturbance of less than 5 acres, which are not currently covered by Phase I storm water application requirements[1], are covered by the Coastal Nonpoint Pollution Control Program. Similarly, runoff from wholesale, retail, service, or commercial activities, including gas stations, which are not covered by Phase I of the NPDES storm water program, would be subject instead to a State's Coastal Nonpoint Pollution Control Program. Further, onsite disposal systems, which are generally not covered by the storm water permit program, would be subject to a State's Coastal Nonpoint Pollution Control Program.

Finally, EPA emphasizes that while different legal authorities may apply to different situations, the goals of the NPDES and CZARA programs are complementary. Many of the techniques and practices used to control urban runoff are equally applicable to both programs. Yet, the programs do not work identically. In the interest of consistency and comprehensiveness, States have the option to implement management measures in conformity with this guidance throughout the State's 6217 management area, as long as NPDES storm water requirements continue to be met by Phase I sources in that area. States are encouraged to develop consistent approaches to addressing urban runoff throughout their 6217 management areas.

e. Marinas

Another specific overlap between the storm water program and the coastal nonpoint source programs under CZARA occurs in the case of marinas (addressed in Chapter 5 of this guidance). In this guidance, EPA has attempted to avoid addressing marina activities that are clearly regulated point source discharges. Any storm water runoff at a marina that is ultimately regulated under an NPDES permit will no longer be subject to this guidance once the permit is issued. The introduction to Chapter 5 contains a detailed discussion of the scope of the NPDES program with respect to marinas and of the corresponding coverage of marinas by the CZARA program.

f. Other Point Sources

Overlapping areas between the point source and nonpoint source programs also occur with respect to concentrated animal feeding operations. Operations that meet particular size or other criteria are defined and regulated as point sources under the section 402 permit program, while other confined animal feeding operations are not currently regulated as point sources. Other overlaps may occur with respect to aspects of mining operations, oil and gas extraction, land disposal, and other activities.

[1] On May 27, 1992, the United States Court of Appeals for the Ninth Circuit invalidated EPA's exemption of construction sites smaller than 5 acres from the storm water permit program in *Natural Resources Defense Council v. EPA*, 965 F.2d 759 (9th Cir. 1992). EPA is conducting further rulemaking proceedings on this issue and will not require permit applications for construction activities under 5 acres until further rulemaking has been completed.

VOL 12

9277

EPA intends that the Coastal Nonpoint Pollution Control Programs to be developed by the States, and the management measures they contain, apply only to sources that are not required under EPA's current regulations to obtain an NPDES permit. For any discharge ultimately covered by Phase II of the storm water permitting program, the management measures will continue to apply until an NPDES permit is issued for that discharge. In this guidance, EPA has attempted to avoid addressing activities that are regulated point source discharges.

3. Contents of This Guidance

a. General

Each category of sources (agriculture, forestry, etc.) is addressed in a separate chapter of this guidance. Each chapter is divided into sections, each of which contains (1) the management measure; (2) an applicability statement that describes, when appropriate, specific activities and locations for which the measure is suitable; (3) a description of the management measure's purpose; (4) the basis for the management measure's selection; (5) information on management practices that are suitable, either alone or in combination with other practices, to achieve the management measure; (6) information on the effectiveness of the management measure and/or of practices to achieve the measure; and (7) information on costs of the measure and/or practices to achieve the measure.

b. What "Management Measures" Are

Each section of this guidance begins with a succinct statement, set off in bold typeface in a box, that specifies a "management measure." As explained earlier, "management measures" are defined in CZARA as economically achievable measures to control the addition of pollutants to our coastal waters, which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

These management measures will be incorporated by States into their coastal nonpoint programs, which under CZARA are to provide for the implementation of management measures that are "in conformity" with this guidance. Under CZARA, States are subject to a number of requirements as they develop and implement their Coastal Nonpoint Pollution Control Programs in conformity with this guidance and will have some flexibility in doing so. The application of these management measures by States to activities causing nonpoint pollution is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by EPA and NOAA.

c. What "Management Practices" Are

In addition to specifying management measures, this guidance also lists and describes management practices for illustrative purposes only. While State programs are required to specify management measures in conformity with this guidance, State programs need not specify or require the implementation of the particular management practices described in this document. As a practical matter, however, EPA anticipates that the management measures typically will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices listed in this document have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measures. EPA has also used some of these practices, or appropriate combinations of these practices, as a basis for estimating the effectiveness, costs, and economic impacts of achieving the management measures. (Economic impacts of the management measures are addressed in a separate document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters*.)

EPA recognizes that there is often site-specific, regional, and national variability in the selection of appropriate practices, as well as in the design constraints and pollution control effectiveness of practices. The list of practices for each management measure is not all-inclusive and does not preclude States or local agencies from using other technically sound practices. In all cases, however, the practice or set of practices chosen by a State needs to achieve the management measure.

EPA recognizes as well that many sources may already achieve the management measures, or that only one or two practices may need to be added to achieve the measures. Existing NPS progress should be recognized and appropriate credit given to those who have already made progress toward accomplishing our common goal to control NPS pollution. There is no need to spend additional resources for a practice that is already in existence and operational. Existing practices, plans, and systems should be viewed as building blocks for these management measures and may need no additional improvement.

III. TECHNICAL APPROACH TAKEN IN DEVELOPING THIS GUIDANCE

A. The Nonpoint Source Pollution Process

Nonpoint source pollutants are transported to surface water by a variety of means, including runoff, snowmelt, and ground-water infiltration. Ground water and surface water are both considered part of the same hydrologic cycle when designing management measures. Ground-water contributions of pollutant loadings to surface waters in coastal areas are often very significant. Hydrologic modification is another form of nonpoint source pollution that often adversely affects the biological and physical integrity of surface waters.

1. Source Control

Source control is the first opportunity in any nonpoint source control effort. Source control methods vary for different types of nonpoint source problems. Examples of source control include:

(1) Reducing or eliminating the introduction of pollutants to a land area. Examples include reduced nutrient and pesticide application.

(2) Preventing pollutants from leaving the site during land-disturbing activities. Examples include using conservation tillage, planning forest road construction to minimize erosion, siting marinas adjacent to deep waters to eliminate or minimize the need for dredging, and managing grazing to protect against overgrazing and the resulting increased soil erosion.

(3) Preventing interaction between precipitation and introduced pollutants. Examples include installing gutters and diversions to keep clean rainfall away from barnyards, diverting rainfall runoff from areas of land disturbance at construction sites, and timing chemical applications or logging activities based on weather forecasts or seasonal weather patterns.

(4) Protecting riparian habitat and other sensitive areas. Examples include protection and preservation of riparian zones, shorelines, wetlands, and highly erosive slopes.

(5) Protecting natural hydrology. Examples include the maintenance of pervious surfaces in developing areas (conditioned based on ground-water considerations), riparian zone protection, and water management.

2. Delivery Reduction

Pollution prevention often involves delivery reduction in addition to appropriate source control measures. Delivery reduction practices intercept pollutants leaving the source prior to their delivery to the receiving water by capturing the runoff or infiltrate, followed either by treating and releasing the effluent or by permanently keeping the effluent from reaching a surface water or ground-water resource. Management measures in this guidance incorporate delivery reduction practices as appropriate to achieve the greatest degree of pollutant reduction economically achievable, as required by the statute.

By their nature, delivery reduction practices often bring with them side effects that must be accounted for. For example, management practices that intercept pollutants leaving the source may reduce runoff, but also may increase infiltration to ground water. For instance, infiltration basins trap runoff and allow for its percolation. These devices, although highly successful at controlling suspended solids, may not, because of their infiltration properties, be suitable for use in areas with high ground-water tables and nitrate or pesticide residue problems. Thus, the reader should select management practices with some care for the total water quality impact of the practices.

The performance of delivery reduction practices is to a large extent dependent on suitable designs, operational conditions, and proper maintenance. For example, filter strips may be effective for controlling particulate and soluble pollutants where sedimentation is not excessive, but may be overwhelmed by high sediment input. Thus, in many cases, filter strips are used as pretreatment or supplemental treatment for other practices within a management system, rather than as an entire solution to a sedimentation problem.

These examples illustrate that the combination of source control and delivery reduction practices, as well as the application of those practices as components of management measures, is dependent on site-specific conditions. Technical factors that may affect the suitability of management measures include, but are not limited to, land use, climate, size of drainage area, soil permeability, slopes, depth to water table, space requirements, type and condition of the water resource to be protected, depth to bedrock, and pollutants to be addressed. In this management measures guidance, many of these factors are discussed as they affect the suitability of particular measures.

B. Management Measures as Systems

Technical experts who design and implement effective nonpoint source control measures do so from a management systems approach as opposed to an approach that focuses on individual practices. That is, the pollutant control achievable from any given management system is viewed as the sum of the parts, taking into account the range of effectiveness associated with each single practice, the costs of each practice, and the resulting overall cost and effectiveness. Some individual practices may not be very effective alone but, in combination with others, may provide a key function in highly effective systems. This management measures guidance attempts to adopt an approach that encourages such system-building by stating the measures in general terms, followed by discussion of specific management practices, which combined encourage the use of appropriate situation-specific sets of practices that will achieve the management measure.

C. Economic Achievability of the Proposed Management Measures

EPA has determined that all of the management measures in this guidance are economically achievable, including, where limited data were available, cost-effective. Congress defined "management measures" to mean "*economically achievable* measures ... which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives."

CHAPTER 2: Management Measures for Agriculture Sources

I. INTRODUCTION

A. What "Management Measures" Are

This chapter specifies management measures to protect coastal waters from agricultural sources of nonpoint pollution. "Management measures" are defined in section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA) as economically achievable measures to control the addition of pollutants to our coastal waters, which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

These management measures will be incorporated by States into their coastal nonpoint programs, which under CZARA are to provide for the implementation of management measures that are "in conformity" with this guidance. Under CZARA, States are subject to a number of requirements as they develop and implement their Coastal Nonpoint Pollution Control Programs in conformity with this guidance and will have some flexibility in doing so. The application of these management measures by States to activities causing nonpoint pollution is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA).

B. What "Management Practices" Are

In addition to specifying management *measures*, this chapter also lists and describes management *practices* for illustrative purposes only. While State programs are required to specify management *measures* in conformity with this guidance, State programs need not specify or require the implementation of the particular management *practices* described in this document. However, as a practical matter, EPA anticipates that States the management measures generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices listed in this document have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measures. EPA has also used some of these practices, or appropriate combinations of these practices, as a basis for estimating the effectiveness, costs, and economic impacts of achieving the management measures. (Economic impacts of the management measures are addressed in a separate document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*)

EPA recognizes that there is often site-specific, regional and national variability in the selection of appropriate practices, as well as in the design constraints and pollution control effectiveness of practices. The list of practices for each management measure is not all-inclusive and does not preclude States or local agencies from using other technically sound practices. In all cases, however, the practice or set of practices chosen by a State needs to achieve the management measure.

C. Scope of This Chapter

This chapter addresses six categories of sources of agricultural nonpoint pollution that affect coastal waters:

(1) Erosion from cropland;
(2) Confined animal facilities;
(3) The application of nutrients to cropland;
(4) The application of pesticides to cropland;
(5) Grazing management; and
(6) Irrigation of cropland.

Each category of sources (with the exception of confined animal facilities, which has two management measures) is addressed in a separate section of this guidance. Each section contains (1) the management measure; (2) an applicability statement that describes, when appropriate, specific activities and locations for which the measure is suitable; (3) a description of the management measure's purpose; (4) the basis for the management measure's selection; (5) information on the effectiveness of the management measure and/or of practices to achieve the measure; (6) information on management practices that are suitable, either alone or in combination with other practices, to achieve the management measure; and (7) information on costs of the measure and/or practices to achieve the measure.

D. Relationship of This Chapter to Other Chapters and to Other EPA Documents

1. Chapter 1 of this document contains detailed information on the legislative background for this guidance, the process used by EPA to develop this guidance, and the technical approach used by EPA in the guidance.

2. Chapter 7 of this document contains management measures to protect wetlands and riparian areas that serve a nonpoint source abatement function. These measures apply to a broad variety of sources, including agricultural sources.

3. Chapter 8 of this document contains information on recommended monitoring techniques (1) to ensure proper implementation, operation, and maintenance of the management measures and (2) to assess over time the success of the measures in reducing pollution loads and improving water quality.

4. EPA has separately published a document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*

5. NOAA and EPA have jointly published guidance entitled *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance.* This guidance contains details on how State Coastal Nonpoint Pollution Control Programs are to be developed by States and approved by NOAA and EPA. It includes guidance on the following:

   - The basis and process for EPA/NOAA approval of state Coastal Nonpoint Pollution Control Programs;
   - How NOAA and EPA expect State programs to provide for the implementation of management measures "in conformity" with this management measures guidance;
   - How States may target sources in implementing their Coastal Nonpoint Pollution Control Programs;

- Changes in State coastal boundaries; and
- Requirements concerning how States are to implement the Coastal Nonpoint Pollution Control Programs.

E. Coordination of Measures

The management measures developed for agriculture are to be used as an overall system of measures to address nonpoint source (NPS) pollution sources on any given site. In most cases, not all of the measures will be needed to address the nonpoint sources at a specific site. For example, many farms or agriculture enterprises do not have animals as part of the enterprise and would not need to be concerned with the management measures that address confined animal facilities or grazing. By the same token, many enterprises do not use irrigation and would not need to use the irrigation water management measure.

Most enterprises will have more than one source to address and may need to employ two or more of the measures to address the multiple sources. Where more than one source exists, the application of the measures is to be coordinated to produce an overall system that adequately addresses all sources for the site in a cost-effective manner.

The agricultural management measures for CZMA are, for the most part, systems of practices that are commonly used and recommended by the U.S. Department of Agriculture (USDA) as components of Resource Management Systems, Water Quality Management Plans, and Agricultural Waste Management Systems. Practices and plans installed under State NPS programs are also included. Many farms and fields, therefore, may already be in compliance with the measures needed to address the nonpoint sources on them. For cases where existing source control is inadequate to achieve conformity with the needed management measures, it may be necessary to add only one or two more practices to achieve conformity. Existing NPS progress must be recognized and appropriate credit given to the accomplishment of our common goal to control NPS pollution. There is no need to spend additional resources for a practice that is already in existence and operational. Existing practices, plans, and systems should be viewed as building blocks for these management measures and may need no additional improvement.

F. Pollutants That Cause Agricultural Nonpoint Source Pollution[1]

The primary agricultural nonpoint source pollutants are nutrients, sediment, animal wastes, salts, and pesticides. Agricultural activities also have the potential to directly impact the habitat of aquatic species through physical disturbances caused by livestock or equipment, or through the management of water. The general pathways for transport of pollutants from agricultural lands to water resources are shown in Figure 2-1 (USDA, 1991). The effects of these pollutants on water quality are discussed below.

1. Nutrients

Nitrogen (N) and phosphorus (P) are the two major nutrients from agricultural land that degrade water quality. Nutrients are applied to agricultural land in several different forms and come from various sources, including:

- Commercial fertilizer in a dry or fluid form, containing nitrogen (N), phosphorus (P), potassium (K), secondary nutrients, and micronutrients;
- Manure from animal production facilities including bedding and other wastes added to the manure, containing N,P,K, secondary nutrients, micronutrients, salts, some metals, and organics;

[1] This section on Pollutants That Cause Agricultural Nonpoint Source Pollution is adapted from USDA-SCS (1983).

R0042590

VOL 12

9284

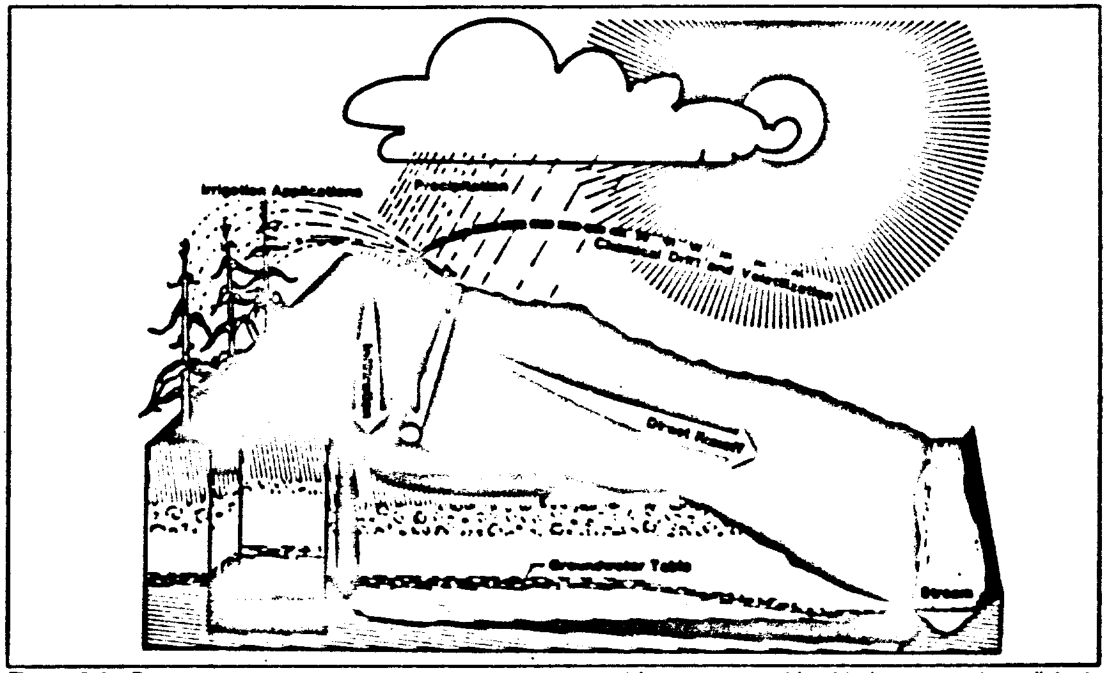

Figure 2-1. Pathways through which substances are transported from agricultural land to become water pollutants (USDA, 1991).

- Municipal and industrial treatment plant sludge, containing N.P.K, secondary nutrients, micronutrients, salts, metals, and organic solids;
- Municipal and industrial treatment plant effluent, containing N.P.K, secondary nutrients, micronutrients, salts, metals, and organics;
- Legumes and crop residues containing N, P, K, secondary nutrients, and micronutrients;
- Irrigation water; and
- Atmospheric deposition of nutrients such as nitrogen and sulphur.

Surface water runoff from agricultural lands to which nutrients have been applied may transport the following pollutants:

- Particulate-bound nutrients, chemicals, and metals, such as phosphorus, organic nitrogen, and metals applied with some organic wastes;
- Soluble nutrients and chemicals, such as nitrogen, phosphorus, metals, and many other major and minor nutrients;
- Sediment, particulate organic solids, and oxygen-demanding material;

VOL 12

9285

R0042591

- Salts; and

- Bacteria, viruses, and other microorganisms.

Ground-water infiltration from agricultural lands to which nutrients have been applied may transport the following pollutants: soluble nutrients and chemicals, such as nitrogen, phosphorus, metals, and many other major and minor nutrients, and salts.

Surface water and ground-water pollutants from organic matter and crop residue decomposition and from legumes growing on agricultural land may include nitrogen, phosphorus, and other essential nutrients found in the residue of growing crops.

All plants require nutrients for growth. In aquatic environments, nutrient availability usually limits plant growth. Nitrogen and phosphorus generally are present at background or natural levels below 0.3 and 0.05 mg/L, respectively. When these nutrients are introduced into a stream, lake, or estuary at higher rates, aquatic plant productivity may increase dramatically. This process, referred to as cultural eutrophication, may adversely affect the suitability of the water for other uses.

Increased aquatic plant productivity results in the addition to the system of more organic material, which eventually dies and decays. The decaying organic matter produces unpleasant odors and depletes the oxygen supply required by aquatic organisms. Excess plant growth may also interfere with recreational activities such as swimming and boating. Depleted oxygen levels, especially in colder bottom waters where dead organic matter tends to accumulate, can reduce the quality of fish habitat and encourage the propagation of fish that are adapted to less oxygen or to warmer surface waters. Highly enriched waters will stimulate algae production, with consequent increased turbidity and color. Algae growth is also believed to be harmful to coral reefs (e.g., Florida coast). Furthermore, the increased turbidity results in less sunlight penetration and availability to submerged aquatic vegetation (SAV). Since SAV provides habitat for small or juvenile fish, the loss of SAV has severe consequences for the food chain. Chesapeake Bay is an example in which nutrients are believed to have contributed to SAV loss.

a. Nitrogen

All forms of transported nitrogen are potential contributors to eutrophication in lakes, estuaries, and some coastal waters. In general, though not in all cases, nitrogen availability is the limiting factor for plant growth in marine ecosystems. Thus, the addition of nitrogen can have a significant effect on the natural functioning of marine ecosystems.

In addition to eutrophication, excessive nitrogen causes other water quality problems. Dissolved ammonia at concentrations above 0.2 mg/L may be toxic to fish, especially trout. Nitrates in drinking water are potentially dangerous, especially to newborn infants. Nitrate is converted to nitrite in the digestive tract, which reduces the oxygen-carrying capacity of the blood (methemoglobinemia), resulting in brain damage or even death. The U.S. Environmental Protection Agency has set a limit of 10 mg/L nitrate-nitrogen in water used for human consumption (USEPA, 1989).

Nitrogen is naturally present in soils but must be added to increase crop production. Nitrogen is added to the soil primarily by applying commercial fertilizers and manure, but also by growing legumes (biological nitrogen fixation) and incorporating crop residues. Not all nitrogen that is present in or on the soil is available for plant use at any one time. For example, in the eastern Corn Belt, it is normally assumed that about 50 percent of applied N is assimilated by crops during the year of application (Nelson, 1985). Organic nitrogen normally constitutes the majority of the soil nitrogen. It is slowly converted (2 to 3 percent per year) to the more readily plant-available inorganic ammonium or nitrate.

The chemical form of nitrogen affects its impact on water quality. The most biologically important inorganic forms of nitrogen are ammonium (NH_4-N), nitrate (NO_3-N), and nitrite (NO_2-N). Organic nitrogen occurs as particulate matter, in living organisms, and as detritus. It occurs in dissolved form in compounds such as amino acids, amines, purines, and urea.

Nitrate-nitrogen is highly mobile and can move readily below the crop root zone, especially in sandy soils. It can also be transported with surface runoff, but not usually in large quantities. Ammonium, on the other hand, becomes adsorbed to the soil and is lost primarily with eroding sediment. Even if nitrogen is not in a readily available form as it leaves the field, it can be converted to an available form either during transport or after delivery to waterbodies.

b. Phosphorus

Phosphorus can also contribute to the eutrophication of both freshwater and estuarine systems. While phosphorus typically plays the controlling role in freshwater systems, in some estuarine systems both nitrogen and phosphorus can limit plant growth. Algae consume dissolved inorganic phosphorus and convert it to the organic form. Phosphorus is rarely found in concentrations high enough to be toxic to higher organisms.

Although the phosphorus content of most soils in their natural condition is low, between 0.01 and 0.2 percent by weight, recent soil test results show that the phosphorus content of most cropped soils in the Northeast have climbed to the high or very high range (Sims, 1992). Manure and fertilizers increase the level of available phosphorus in the soil to promote plant growth, but many soils now contain higher phosphorus levels than plants need (Killorn, 1980; Novais and Kamprath, 1978). Phosphorus can be found in the soil in dissolved, colloidal, or particulate forms.

Runoff and erosion can carry some of the applied phosphorus to nearby water bodies. Dissolved inorganic phosphorus (orthophosphate phosphorus) is probably the only form directly available to algae. Particulate and organic phosphorus delivered to waterbodies may later be released and made available to algae when the bottom sediment of a stream becomes anaerobic, causing water quality problems.

2. Sediment

Sediment affects the use of water in many ways. Suspended solids reduce the amount of sunlight available to aquatic plants, cover fish spawning areas and food supplies, smother coral reefs, clog the filtering capacity of filter feeders, and clog and harm the gills of fish. Turbidity interferes with the feeding habits of fish. These effects combine to reduce fish, shellfish, coral, and plant populations and decrease the overall productivity of lakes, streams, estuaries, and coastal waters. In addition, recreation is limited because of the decreased fish population and the water's unappealing, turbid appearance. Turbidity also reduces visibility, making swimming less safe.

Chemicals such as some pesticides, phosphorus, and ammonium are transported with sediment in an adsorbed state. Changes in the aquatic environment, such as a lower concentration in the overlying waters or the development of anaerobic conditions in the bottom sediments, can cause these chemicals to be released from the sediment. Adsorbed phosphorus transported by the sediment may not be immediately available for aquatic plant growth but does serve as a long-term contributor to eutrophication.

Sediment is the result of erosion. It is the solid material, both mineral and organic, that is in suspension, is being transported, or has been moved from its site of origin by air, water, gravity, or ice. The types of erosion associated with agriculture that produce sediment are (1) sheet and rill erosion and (2) gully erosion. Soil erosion can be characterized as the transport of particles that are detached by rainfall, flowing water, or wind (Figure 2-2). Eroded soil is either redeposited on the same field or transported from the field in runoff.

Sediments from different sources vary in the kinds and amounts of pollutants that are adsorbed to the particles. For example, sheet and rill erosion mainly move soil particles from the surface or plow layer of the soil. Sediment that originates from surface soil has a higher pollution potential than that from subsurface soils. The topsoil of a field is usually richer in nutrients and other chemicals because of past fertilizer and pesticide applications, as well as nutrient cycling and biological activity. Topsoil is also more likely to have a greater percentage of organic matter. Sediment from gullies and streambanks usually carries less adsorbed pollutants than sediment from surface soils.

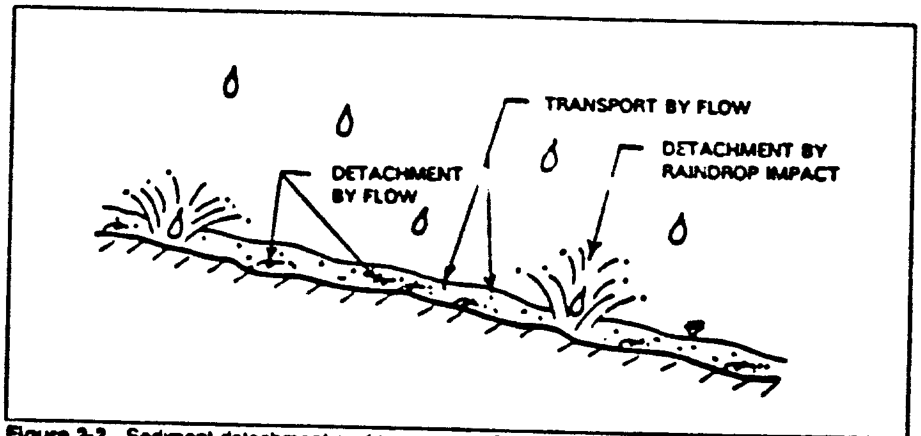

Figure 2-2. Sediment detachment and transport (USEPA, 1981).

Soil eroded and delivered from cropland as sediment usually contains a higher percentage of finer and less dense particles than the parent soil on the cropland. This change in composition of eroded soil is due to the selective nature of the erosion process. For example, larger particles are more readily detached from the soil surface because they are less cohesive, but they also settle out of suspension more quickly because of their size. Organic matter is not easily detached because of its cohesive properties, but once detached it is easily transported because of its low density. Clay particles and organic residues will remain suspended for longer periods and at slower flow velocities than will larger or more dense particles. This selective erosion can increase overall pollutant delivery per ton of sediment delivered because small particles have a much greater adsorption capacity than larger particles. As a result, eroding sediments generally contain higher concentrations of phosphorus, nitrogen, and pesticides than the parent soil (i.e., they are enriched).

3. Animal Wastes

Animal waste (manure) includes the fecal and urinary wastes of livestock and poultry; process water (such as from a milking parlor); and the feed, bedding, litter, and soil with which they become intermixed. The following pollutants may be contained in manure and associated bedding materials and could be transported by runoff water and process wastewater from confined animal facilities:

- Oxygen-demanding substances;
- Nitrogen, phosphorus, and many other major and minor nutrients or other deleterious materials;
- Organic solids;
- Salts;
- Bacteria, viruses, and other microorganisms; and
- Sediments.

Fish kills may result from runoff, wastewater, or manure entering surface waters, due to ammonia or dissolved oxygen depletion. The decomposition of organic materials can deplete dissolved oxygen supplies in water, resulting in anoxic or anaerobic conditions. Methane, amines, and sulfide are produced in anaerobic waters, causing the water to acquire an unpleasant odor, taste, and appearance. Such waters can be unsuitable for drinking, fishing, and other recreational uses.

Solids deposited in waterbodies can accelerate eutrophication through the release of nutrients over extended periods of time. Because of the high nutrient and salt content of manure and runoff from manure-covered areas, contamination of ground water can be a problem if storage structures are not built to minimize seepage.

Animal diseases can be transmitted to humans through contact with animal feces. Runoff from fields receiving manure will contain extremely high numbers of bacteria if the manure has not been incorporated or the bacteria have not been subject to stress. Shellfish closure and beach closure can result from high fecal coliform counts. Although not the only source of pathogens, animal waste has been responsible for shellfish contamination in some coastal waters.

The method, timing, and rate of manure application are significant factors in determining the likelihood that water quality contamination will result. Manure is generally more likely to be transported in runoff when applied to the soil surface than when incorporated into the soil. Spreading manure on frozen ground or snow can result in high concentrations of nutrients being transported from the field during rainfall or snowmelt, especially when the snowmelt or rainfall events occur soon after spreading (Robillard and Walter, 1986). The water quality problems associated with nitrogen and phosphorus are discussed under Section F.1.

When application rates of manure for crop production are based on N, the P and K rates normally exceed plant requirements (Westerman et al., 1985). The soil generally has the capacity to adsorb phosphorus leached from manure applied on land. As previously mentioned, however, nitrates are easily leached through soil into ground water or to return flows, and phosphorus can be transported by eroded soil.

Conditions that cause a rapid die-off of bacteria are low soil moisture, low pH, high temperatures, and direct solar radiation. Manure storage generally promotes die-off, although pathogens can remain dormant at certain temperatures. Composting the wastes can be quite effective in decreasing the number of pathogens.

4. Salts

Salts are a product of the natural weathering process of soil and geologic material. They are present in varying degrees in all soils and in fresh water, coastal waters, estuarine waters, and ground waters.

In soils that have poor subsurface drainage, high salt concentrations are created within the root zone where most water extraction occurs. The accumulation of soluble and exchangeable sodium leads to soil dispersion, structure breakdown, decreased infiltration, and possible toxicity; thus, salts often become a serious problem on irrigated land, both for continued agricultural production and for water quality considerations. High salt concentrations in streams can harm freshwater aquatic plants just as excess soil salinity damages agricultural crops. While salts are generally a more significant pollutant for freshwater ecosystems than for saline ecosystems, they may also adversely affect anadromous fish. Although they live in coastal and estuarine waters most of their lives, anadromous fish depend on freshwater systems near the coast for crucial portions of their life cycles.

The movement and deposition of salts depend on the amount and distribution of rainfall and irrigation, the soil and underlying strata, evapotranspiration rates, and other environmental factors. In humid areas, dissolved mineral salts have been naturally leached from the soil and substrata by rainfall. In arid and semi-arid regions, salts have not been removed by natural leaching and are concentrated in the soil. Soluble salts in saline and sodic soils consist of calcium, magnesium, sodium, potassium, carbonate, bicarbonate, sulfate, and chloride ions. They are fairly easily leached from the soil. Sparingly soluble gypsum and lime also occur in amounts ranging from traces to more than 50 percent of the soil mass.

Irrigation water, whether from ground or surface water sources, has a natural base load of dissolved mineral salts. As the water is consumed by plants or lost to the atmosphere by evaporation, the salts remain and become concentrated in the soil. This is referred to as the "concentrating effect."

The total salt load carried by irrigation return flow is the sum of the salt remaining in the applied water plus any salt picked up from the irrigated land. Irrigation return flows provide the means for conveying the salts to the receiving streams or ground-water reservoirs. If the amount of salt in the return flow is low in comparison to the total stream flow, water quality may not be degraded to the extent that use is impaired. However, if the process of water diversion for irrigation and the return of saline drainage water is repeated many times along a stream or river, water quality will be progressively degraded for downstream irrigation use as well as for other uses.

5. Pesticides

The term *pesticide* includes any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest or intended for use as a plant regulator, defoliant, or desiccant. The principal pesticidal pollutants that may be detected in surface water and in ground water are the active and inert ingredients and any persistent degradation products. Pesticides and their degradation products may enter ground and surface water in solution, in emulsion, or bound to soil colloids. For simplicity, the term *pesticides* will be used to represent "pesticides and their degradation products" in the following sections.

Despite the documented benefits of using pesticides (insecticides, herbicides, fungicides, miticides, nematicides, etc.) to control plant pests and enhance production, these chemicals may, in some instances, cause impairments to the uses of surface water and ground water. Some types of pesticides are resistant to degradation and may persist and accumulate in aquatic ecosystems.

Pesticides may harm the environment by eliminating or reducing populations of desirable organisms, including endangered species. Sublethal effects include the behavioral and structural changes of an organism that jeopardize its survival. For example, certain pesticides have been found to inhibit bone development in young fish or to affect reproduction by inducing abortion.

Herbicides in the aquatic environment can destroy the food source for higher organisms, which may then starve. Herbicides can also reduce the amount of vegetation available for protective cover and the laying of eggs by aquatic species. Also, the decay of plant matter exposed to herbicide-containing water can cause reductions in dissolved oxygen concentration (North Carolina State University, 1984).

Sometimes a pesticide is not toxic by itself but is lethal in the presence of other pesticides. This is referred to as a *synergistic effect*, and it may be difficult to predict or evaluate. *Bioconcentration* is a phenomenon that occurs if an organism ingests more of a pesticide than it excretes. During its lifetime, the organism will accumulate a higher concentration of that pesticide than is present in the surrounding environment. When the organism is eaten by another animal higher in the food chain, the pesticide will then be passed to that animal, and on up the food chain to even higher level animals.

A major source of contamination from pesticide use is the result of normal application of pesticides. Other sources of pesticide contamination are atmospheric deposition, spray drift during the application process, misuse, and spills, leaks, and discharges that may be associated with pesticide storage, handling, and waste disposal.

The primary routes of pesticide transport to aquatic systems are (Maas et al., 1984):

(1) Direct application;
(2) In runoff;
(3) Aerial drift;
(4) Volatilization and subsequent atmospheric deposition; and
(5) Uptake by biota and subsequent movement in the food web.

The amount of field-applied pesticide that leaves a field in the runoff and enters a stream primarily depends on:

(1) The intensity and duration of rainfall or irrigation;
(2) The length of time between pesticide application and rainfall occurrence;
(3) The amount of pesticide applied and its soil/water partition coefficient;
(4) The length and degree of slope and soil composition;
(5) The extent of exposure to bare (vs. residue or crop-covered) soil;

(6) Proximity to streams;
(7) The method of application; and
(8) The extent to which runoff and erosion are controlled with agronomic and structural practices.

Pesticide losses are generally greatest when rainfall is intense and occurs shortly after pesticide application, a condition for which water runoff and erosion losses are also greatest.

The rate of pesticide movement through the soil profile to ground water is inversely proportional to the pesticide adsorption partition coefficient or K_d (a measure of the degree to which a pesticide is partitioned between the soil and water phase). The larger the K_d, the slower the movement and the greater the quantity of water required to leach the pesticide to a given depth.

Pesticides can be transported to receiving waters either in dissolved form or attached to sediment. Dissolved pesticides may be leached to ground-water supplies. Both the degradation and adsorption characteristics of pesticides are highly variable.

6. Habitat Impacts

The functioning condition of riparian-wetland areas is a result of interaction among geology, soil, water, and vegetation. Riparian-wetland areas are functioning properly when adequate vegetation is present to (1) dissipate stream energy associated with high water flows, thereby reducing erosion and improving water quality; (2) filter sediment and aid floodplain development; (3) support denitrification of nitrate-contaminated ground water as it is discharged into streams; (4) improve floodwater retention and ground-water recharge; (5) develop root masses that stabilize banks against cutting action; (6) develop diverse ponding and channel characteristics to provide the habitat and the water depth, duration, and temperature necessary for fish production, waterfowl breeding, and other uses; and (7) support greater biodiversity.

Improper livestock grazing affects all four components of the water-riparian system: banks/shores, water column, channel, and aquatic and bordering vegetation (Platts, 1990). The potential effects of grazing include:

Shore/banks

- Shear or sloughing of streambank soils by hoof or head action.
- Water, ice, and wind erosion of exposed streambank and channel soils because of loss of vegetative cover.
- Elimination or loss of streambank vegetation.
- Reduction of the quality and quantity of streambank undercuts.
- Increasing streambank angle (laying back of streambanks), which increases water width, decreases stream depth, and alters or eliminates fish habitat.

Water Column

- Withdrawal from streams to irrigate grazing lands.
- Drainage of wet meadows or lowering of the ground-water table to facilitate grazing access.
- Pollutants (e.g., sediments) in return water from grazed lands, which are detrimental to the designated uses such as fisheries.

- Changes in magnitude and timing of organic and inorganic energy (i.e., solar radiation, debris, nutrients) inputs to the stream.
- Increase in fecal contamination.
- Changes in stream morphology, such as increases in stream width and decreases in stream depth, including reduction of stream shore water depth.
- Changes in timing and magnitude of stream flow events from changes in watershed vegetative cover.
- Increase in stream temperature.

Channel

- Changes in channel morphology.
- Altered sediment transport processes.

Riparian Vegetation

- Changes in plant species composition (e.g., shrubs to grass to forbs).
- Reduction of floodplain and streambank vegetation including vegetation hanging over or entering into the water column.
- Decrease in plant vigor.
- Changes in timing and amounts of organic energy leaving the riparian zone.
- Elimination of riparian plant communities (i.e., lowering of the water table allowing xeric plants to replace riparian plants).

II. MANAGEMENT MEASURES FOR AGRICULTURAL SOURCES

A. Erosion and Sediment Control Management Measure

Apply the erosion component of a Conservation Management System (CMS) as defined in the Field Office Technical Guide of the U.S. Department of Agriculture - Soil Conservation Service (see Appendix 2A of this chapter) to minimize the delivery of sediment from agricultural lands to surface waters, *or*

Design and install a combination of management and physical practices to settle the settleable solids and associated pollutants in runoff delivered from the contributing area for storms of up to and including a 10-year, 24-hour frequency.

1. Applicability

This management measure is intended to be applied by States to activities that cause erosion on agricultural land and on land that is converted from other land uses to agricultural lands. Agricultural lands include:

- Cropland;
- Irrigated cropland;
- Range and pasture;
- Orchards;
- Permanent hayland;
- Specialty crop production; and
- Nursery crop production.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The problems associated with soil erosion are the movement of sediment and associated pollutants by runoff into a waterbody. See Section I.F.2 of this chapter for additional information regarding problems.

Application of this management measure will reduce the mass load of sediment reaching a waterbody and improve water quality and the use of the water resource. The measure can be implemented by using one of two different strategies or a combination of both. The first, and most desirable, strategy would be to implement practices on the field that would prevent erosion and the transport of sediment from the field. Practices that could be used to accomplish this are conservation tillage, contour strip-cropping, terraces, and critical area planting.

The second strategy is to route runoff from fields through practices that remove sediment. Practices that could be used to accomplish this are filter strips, field borders, grade stabilization structures, sediment retention ponds, water and sediment control basins, and terraces. Site conditions will dictate the appropriate combination of practices for any given situation.

Conservation management systems (CMS) include any combination of conservation practices and management that achieves a level of treatment of the five natural resources (i.e., soil, water, air, plants, and animals) that satisfies criteria contained in the Soil Conservation Service (SCS) Field Office Technical Guide (FOTG), such as a resource management system (RMS) or an acceptable management system (AMS). These criteria are developed at the State level, with concurrence by the appropriate SCS National Technical Center (NTC). The criteria are then applied in the provision of field office technical assistance, under the direction of the District Conservationist of SCS. In-state coordination of FOTG use is provided by the Area Conservationist and State Conservationist of SCS.

The erosion component of a CMS addresses sheet and rill erosion, wind erosion, concentrated flow, streambank erosion, soil mass movements, road bank erosion, construction site erosion, and irrigation-induced erosion. National (minimum) criteria pertaining to erosion and sediment control under an RMS will be applied to prevent long-term soil degradation and to resolve existing or potential off-site deposition problems. National criteria pertaining to the water resource will be applied to control sediment movement to minimize contamination of receiving waters. The combined effects of these criteria will be to both reduce upland soil erosion and minimize sediment delivery to receiving waters.

The practical limits of resource protection under a CMS within any given area are determined through the application of national social, cultural, and economic criteria. With respect to economics, landowners will not be required to implement an RMS if the system is generally too costly for landowners. Instead, landowners may be required to implement a less costly, and less protective, AMS. In some cases, landowner constraints may be such that an RMS or AMS cannot be implemented quickly. In these situations, a "progressive planning approach" may be used to ultimately achieve planning and application of an RMS or AMS. Progressive planning is the incremental process of building a plan on part or all of the planning unit over a period of time. For additional details regarding CMS, RMS, and AMS, see Appendix 2A of this chapter.

It is recognized that implementation of this measure may increase the potential for movement of water and soluble pollutants through the soil profile to the ground water. It is not the intent of this measure to address a surface water problem at the expense of ground water. Erosion and sediment control systems can and should be designed to protect against the contamination of ground water. Ground-water protection will also be provided through implementation of the nutrient and pesticide management measures to reduce and control the application of nutrients and pesticides.

Operation and Maintenance

Continued performance of this measure will be ensured through supporting maintenance operations where appropriate. Since practices are designed to control a specific storm frequency, they may suffer damage when larger storms occur. It is expected that damage will be repaired after such storms and that practices will be inspected periodically. To ensure that practices selected to implement this measure will continue to function as designed and installed, some operational functions and maintenance will be necessary over the life of the practices.

Most structural practices for erosion and sediment control are designed to operate without human intervention. Management practices such as conservation tillage, however, do require "operation consideration" each time they are used. Field operations should be conducted with such practices in mind to ensure that they are not damaged or destroyed by the operations. For example, herbicides should not be applied to any practice that uses a permanent vegetative cover, such as waterways and filter strips.

Structural practices such as diversions, grassed waterways, and other practices that require grading and shaping may require repair to maintain the original design; reseeding may also be needed to maintain the original vegetative cover.

Trees and brush should not be allowed to grow on berms, dams, or other structural embankments. Cleaning of sediment retention basins will be needed to maintain their original design capacity and efficiency.

Filter strips and field borders must be maintained to prevent channelization of flow and the resulting short-circuiting of filtering mechanisms. Reseeding of filter strips may be required on a frequent basis.

3. Management Measure Selection

This management measure was selected based on an evaluation of available information that documents the beneficial effects of improved erosion and sediment control (see Section II.A.4 of this chapter). Specifically, the available information shows that erosion control practices can be used to greatly reduce the quantity of eroding soil on agricultural land, and that edge-of-field practices can effectively remove sediment from runoff before it leaves agricultural lands. The benefits of this management measure include significant reductions in the mass load of sediment and associated pollutants (e.g., phosphorus, some pesticides) entering waterbodies. By reducing the load of sediment leaving a field, downstream water uses can be maintained and improved.

Two options are provided under this management measure that represent best available technology for minimizing the delivery of sediment from agricultural lands to receiving waters. Different management strategies, are employed, however, with the options. The most desirable option is "(1)" since it not only minimizes the delivery of sediment to receiving waters, but also reduces erosion to provide an agronomic benefit. Option "(2)" minimizes the delivery of sediment to receiving waters, but does not necessarily provide the agronomic benefits of upland erosion control. By providing these two options, States are given the flexibility to address erosion and sediment problems in a manner that best reflects State and local needs and preferences.

By designing the measure to achieve contaminant load reduction objectives, the necessary mix of structural and management practices for a given site should not result in undue economic impact on the operator. Many of the practices that could be used to implement this measure may already be required by Federal, State, or local rules (e.g., filter strips or field borders along streams) or may otherwise be in use on agricultural fields. Since many producers may already be using systems that satisfy or partly satisfy the intent of this management measure, the only action that may be necessary will be to recognize the effectiveness of the existing practices and add additional practices, if needed. By building upon existing erosion and sediment control efforts, the time, effort, and cost of implementing this measure will be reduced.

4. Effectiveness Information

The effectiveness of management practices depends on several factors, including:

- The contaminant to be controlled;
- The types of practices or controls being considered; and
- Site-specific conditions.

Management practices or systems of practices must be designed for site-specific conditions to achieve desired effectiveness levels. Practice systems include combinations of practices that provide source control of the contaminant(s) as well as control or reductions in edge-of-field losses and delivery to receiving waters. Table 2-1 provides a gross estimate of practice effectiveness as reported in research literature. The actual effectiveness of a practice will depend exclusively on site-specific variables such as soil type, crop rotation, topography, tillage, and harvesting methods. Even within relatively small watersheds, extreme spatial and temporal variations are common. With this type of variation, the ranges of likely values associated with the reported observations in Table 2-1 are large.

Table 2-1. Relative Gross Effectiveness[a] of Sediment[b] Control Measures (Pennsylvania State University, 1992a)

Practice Category[c]	Runoff[d] Volume	Total[e] Phosphorus (%)	Total[e] Nitrogen (%)	Sediment (%)
Reduced Tillage Systems[f]	—	45	55	75
Diversion Systems[g]	—	30	10	35
Terrace Systems[h]	—	70	20	85
Filter Strips[i]	—	75	70	65

[a] Actual effectiveness depends on site-specific conditions. Values are not cumulative between practice categories.
[b] Includes data where land application of manure has occurred.
[c] Each category includes several specific types of practices.
[d] - indicates reduction; + increase; 0 no change in surface runoff.
[e] Total phosphorus includes total and dissolved phosphorus, total nitrogen includes organic-N, ammonia-N, and nitrate-N.
[f] Includes practices such as conservation tillage, no-till, and crop residue use.
[g] Includes practices such as grassed waterways and grade stabilization structures.
[h] Includes several types of terraces with safe outlet structures where appropriate.
[i] Includes all practices that reduce contaminant losses using vegetative control methods.

The variability in the effectiveness of selected conservation practices that are frequently recommended by SCS in resource planning is illustrated in Table 2-2. This table can be used as a general guide for estimating the effects of these practices on water quality and quantity. The table references include additional site-specific information. Practice effects shown include changes in the water budget, sediment yield, and the movement of pesticides and nutrients. The impacts of variations in climate and soil conditions are accounted for to some extent through the presentation of effectiveness data for different soil-climate combinations. Data were not available for all soils and climates.

Data for the table were obtained from the research literature and include computer model simulation results. Values are reported as the percentage of change in the mass load of a given parameter that can be expected from installing the practice. Changes are determined versus a base condition of a rain-fed, nonleguminous, continuous, row crop (usually corn) that has been cultivated under conventional tillage.

Data from model studies are marked with an "M." For example, *-27M* indicates that the load reduction estimate of 27 percent is derived from a model simulation. Data obtained from plot studies using rainfall simulators are marked with an "S." For example, *+15S* indicates that the estimated load increase of 15 percent is based on a rainfall simulation study.

The range is reported in parentheses, followed by other reported values within the range, set off by commas. For example, *(-32 to +10), -15, +5* denotes a range from a decrease of 32 percent to an increase of 10 percent, with intermediate reported changes of a 15 percent decrease and 5 percent increase. Some practices have a relatively wide range of values because of the variability in climate, soils, and management that occurs with these practices. Although some of the ranges are large, they can usually be attributed to small changes in very small quantities (that the percentage change is great, yet the magnitude of change is small) or to the variability of site-specific conditions.

Table 2-2 contains the following information:

- Column (a) lists the practice and its SCS reporting code number.
- Column (b) lists the climate and a generalized soil classification for the site under consideration.
- Column (c) is the percentage change in surface runoff and deep percolation, components of the water budget, caused by the applied practice.
- Column (d) is the percentage change in sediment load caused by the applied practice.
- Column (e) is the percentage change in the phosphorus load. Two phases of phosphorus are considered: adsorbed and dissolved.
- Column (f) is the percentage change in the load of nitrogen in the adsorbed phase, nitrate in surface runoff, and nitrate in the leachate.
- Column (g) is the percentage change in the pesticide load. The phases of the pesticide listed are (1) strongly adsorbed in surface water, (2) weakly adsorbed in surface water, and (3) weakly adsorbed in the leachate.

5. Erosion and Sediment Control Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Combinations of the following practices can be used to satisfy the requirements of this management measure. The SCS practice number and definition are provided for each management practice, where available. Also included in italics are SCS statements describing the effect each practice has on water quality (USDA-SCS, 1988).

■ a. *Conservation cover (327): Establishing and maintaining perennial vegetative cover to protect soil and water resources on land retired from agricultural production.*

Agricultural chemicals are usually not applied to this cover in large quantities and surface and ground water quality may improve where these material are not used. Ground cover and crop residue will be increased with this practice. Erosion and yields of sediment and sediment related stream pollutants should decrease. Temperatures of the soil surface runoff and receiving water may be reduced. Effects will vary during the establishment period and include increases in runoff, erosion and sediment yield. Due to the reduction of deep percolation, the leaching of soluble material will be reduced, as will be the potential for causing saline seeps. Long-term effects of the practice would reduce agricultural nonpoint sources of pollution to all water resources.

■ b. *Conservation cropping sequence (328): An adapted sequence of crops designed to provide adequate organic residue for maintenance or improvement of soil tilth.*

This practice reduces erosion by increasing organic matter, resulting in a reduction of sediment and associated pollutants to surface waters. Crop rotations that improve soil tilth may also disrupt disease, insect and weed reproduction cycles, reducing the need for pesticides. This removes or reduces the availability of some pollutants in the watershed. Deep percolation may carry soluble nutrients and pesticides to the ground water. Underlying soil

Table 2-2. Effects of Conservation Practices on Water Resource Parameters (USDA-SCS, 1988)

NOTE: Values in the tables are taken from published research, model simulations, and results of simulated rainfall plots. Both the range (in parentheses) and additional values within the range (after parentheses, separated by comma) are presented. The values describe the percentage change in mass loads caused by the use of the practice on a nonirrigated, nonlegume, continuous row crop that has been grown under conventional tillage. Values inside the range are shown behind the range values and are separated by commas (-30,-90), -78. Values from model simulation are marked by an M, e.g., -30M, and values from a rainfall simulator are marked with an S, e.g., -29S. Few data are available for arid conditions and that zone is not included in the table. Not all soil-climate combinations have available reference data. A minus is a decreased value; a plus is an increase.

layers, rock and unconsolidated parent material may block, delay, or enhance the delivery of these pollutants to ground water. The fate of these pollutants will be site specific, depending on the crop management, the soil and geologic conditions.

c. Conservation tillage (329): Any tillage or planting system that maintains at least 30 percent of the soil surface covered by residue after planting to reduce soil erosion by water; or, where soil erosion by wind is the primary concern, maintains at least 1,000 pounds of flat, small-grain residue equivalent on the surface during the critical erosion period.

This practice reduces soil erosion, detachment and sediment transport by providing soil cover during critical times in the cropping cycle. Surface residues reduce soil compaction from raindrops, preventing soil sealing and increasing infiltration. This action may increase the leaching of agricultural chemicals into the ground water.

In order to maintain the crop residue on the surface it is difficult to incorporate fertilizers and pesticides. This may increase the amount of these chemicals in the runoff and cause more surface water pollution.

The additional organic material on the surface may increase the bacterial action on and near the soil surface. This may tie-up and then breakdown many pesticides which are surface applied, resulting in less pesticide leaving the field. This practice is more effective in humid regions.

With a no-till operation the only soil disturbance is the planter shoe and the compaction from the wheels. The surface applied fertilizers and chemicals are not incorporated and often are not in direct contact with the soil surface. This condition may result in a high surface runoff of pollutants (nutrient and pesticides). Macropores develop under a no-till system. They permit deep percolation and the transmittal of pollutants, both soluble and insoluble to be carried into the deeper soil horizons and into the ground water.

Reduced tillage systems disrupt or break down the macropores, incidentally incorporate some of the materials applied to the soil surface, and reduce the effects of wheeltrack compaction. The results are less runoff and less pollutants in the runoff.

d. Contour farming (330): Farming sloping land in such a way that preparing land, planting, and cultivating are done on the contour. This includes following established grades of terraces or diversions.

This practice reduces erosion and sediment production. Less sediment and related pollutants may be transported to the receiving waters.

Increased infiltration may increase the transportation potential for soluble substances to the ground water.

e. Contour orchard and other fruit area (331): Planting orchards, vineyards, or small fruits so that all cultural operations are done on the contour.

Contour orchards and fruit areas may reduce erosion, sediment yield, and pesticide concentration in the water lost. Where inward sloping benches are used, the sediment and chemicals will be trapped against the slope. With annual events, the bench may provide 100 percent trap efficiency. Outward sloping benches may allow greater sediment and chemical loss. The amount of retention depends on the slope of the bench and the amount of cover. In addition, outward sloping benches are subject to erosion form runoff from benches immediately above them. Contouring allows better access to rills, permitting maintenance that reduces additional erosion. Immediately after establishment, contour orchards may be subject to erosion and sedimentation in excess of the now contoured orchard. Contour orchards require more fertilization and pesticide application than did the native grasses that frequently covered the slopes before orchards were started. Sediment leaving the site may carry more adsorbed nutrients and pesticides than did the sediment before the benches were established from uncultivated slopes. If contoured orchards *replace other crop or intensive land use, the increase or decrease in chemical transport from the site may be determined by examining the types and amounts of chemicals used on the prior land use as compared to the contour orchard condition.*

Soluble pesticides and nutrients may be delivered to and possibly through the root zone in an amount proportional to the amount of soluble pesticides applied, the increase in infiltration, the chemistry of the pesticides, organic and clay content of the soil, and amounts of surface residues. Percolating water below the root zone may carry excess solutes or may dissolve potential pollutants as they move. In either case, these solutes could reach ground water supplies and/or surface downslope from the contour orchard area. The amount depends on soil type, surface water quality, and the availability of soluble material (natural or applied).

■ f. Cover and green manure crop (340): A crop of close-growing grasses, legumes, or small grain grown primarily for seasonal protection and soil improvement. It usually is grown for 1 year or less, except where there is permanent cover as in orchards.

Erosion, sediment and adsorbed chemical yields could be decreased in conventional tillage systems because of the increased period of vegetal cover. Plants will take up available nitrogen and prevent its undesired movement. Organic nutrients may be added to the nutrient budget reducing the need to supply more soluble forms. Overall volume of chemical application may decrease because the vegetation will supply nutrients and there may be allelopathic effects of some of the types of cover vegetation on weeds. Temperatures of ground and surface waters could slightly decrease.

■ g. Critical area planting (342): Planting vegetation, such as trees, shrubs, vines, grasses, or legumes, on highly erodible or critically eroding areas (does not include tree planting mainly for wood products).

This practice may reduce soil erosion and sediment delivery to surface waters. Plants may take up more of the nutrients in the soil, reducing the amount that can be washed into surface waters or leached into ground water.

During grading, seedbed preparation, seeding, and mulching, large quantities of sediment and associated chemicals may be washed into surface waters prior to plant establishment.

■ h. Crop residue use (344): Using plant residues to protect cultivated fields during critical erosion periods.

When this practice is employed, raindrops are intercepted by the residue reducing detachment, soil dispersion, and soil compaction. Erosion may be reduced and the delivery of sediment and associated pollutants to surface water may be reduced. Reduced soil sealing, crusting and compaction allows more water to infiltrate, resulting in an increased potential for leaching of dissolved pollutants into the ground water.

Crop residues on the surface increase the microbial and bacterial action on or near the surface. Nitrates and surface-applied pesticides may be tied-up and less available to be delivered to surface and ground water. Residues trap sediment and reduce the amount carried to surface water. Crop residues promote soil aggregation and improve soil tilth.

■ i. Delayed seed bed preparation (354): Any cropping system in which all of the crop residue and volunteer vegetation are maintained on the soil surface until approximately 3 weeks before the succeeding crop is planted, thus shortening the bare seedbed period on fields during critical erosion periods.

The purpose is to reduce soil erosion by maintaining soil cover as long as practical to minimize raindrop splash and runoff during the spring erosion period. Other purposes include moisture conservation, improved water quality, increased soil infiltration, improved soil tilth, and food and cover for wildlife.

j. **Diversion (362): A channel constructed across the slope with a supporting ridge on the lower side (Figure 2-3).**

This practice will assist in the stabilization of a watershed, resulting in the reduction of sheet and rill erosion by reducing the length of slope. Sediment may be reduced by the elimination of ephemeral and large gullies. This may reduce the amount of sediment and related pollutants delivered to the surface waters.

k. **Field border (386): A strip of perennial vegetation established at the edge of a field by planting or by converting it from trees to herbaceous vegetation or shrubs.**

This practice reduces erosion by having perennial vegetation on an area of the field. Field borders serve as "anchoring points" for contour rows, terraces, diversions, and contour strip cropping. By elimination of the practice of tilling and planting the ends up and down slopes, erosion from concentrated flow in furrows and long rows may be reduced. This use may reduce the quantity of sediment and related pollutants transported to the surface waters.

l. **Filter strip (393): A strip or area of vegetation for removing sediment, organic matter, and other pollutants from runoff and wastewater.**

Filter strips for sediment and related pollutants meeting minimum requirements may trap the coarser grained sediment. They may not filter out soluble or suspended fine-grained materials. When a storm causes runoff in excess When the field borders are located such that runoff flows across them in sheet flow, they may cause the deposition of sediment and prevent it from entering the surface water. Where these practice are between cropland and a stream

Figure 2-3. Diversion (USDA-SCS, 1984).

or water body, the practice may reduce the amount of pesticide application drift from entering the surface water of the design runoff, the filter may be flooded and may cause large loads of pollutants to be released to the surface water. This type of filter requires high maintenance and has a relatively short service life and is effective only as long as the flow through the filter is shallow sheet flow.

Filter strips for runoff from concentrated livestock areas may trap organic material, solids, materials which become adsorbed to the vegetation or the soil within the filter. Often they will not filter out soluble materials. This type of filter is often wet and is difficult to maintain.

Filter strips for controlled overland flow treatment of liquid wastes may effectively filter out pollutants. The filter must be properly managed and maintained, including the proper resting time. Filter strips on forest land may trap coarse sediment, timbering debris, and other deleterious material being transported by runoff. This may improve the quality of surface water and has little effect on soluble material in runoff or on the quality of ground water.

All types of filters may reduce erosion on the area on which they are constructed.

Filter strips trap solids from the runoff flowing in sheet flow through the filter. Coarse-grained and fibrous materials are filtered more efficiently than fine-grained and soluble substances. Filter strips work for design conditions, but when flooded or overloaded they may release a slug load of pollutants into the surface water.

■ m. **Grade stabilization structure (410): A structure used to control the grade and head cutting in natural or artificial channels.**

Where reduced stream velocities occur upstream and downstream from the structure, streambank and streambed erosion will be reduced. This will decrease the yield of sediment and sediment-attached substances. Structures that trap sediment will improve downstream water quality. The sediment yield change will be a function of the sediment yield to the structure, reservoir trap efficiency and of velocities of released water. Ground water recharge may affect aquifer quality depending on the quality of the recharging water. If the stored water contains only sediment and chemical with low water solubility, the ground water quality should not be affected.

■ n. **Grassed waterway (412): A natural or constructed channel that is shaped or graded to required dimensions and established in suitable vegetation for the stable conveyance of runoff.**

This practice may reduce the erosion in a concentrated flow area, such as in a gully or in ephemeral gullies. This may result in the reduction of sediment and substances delivered to receiving waters. Vegetation may act as a filter in removing some of the sediment delivered to the waterway, although this is not the primary function of a grassed waterway.

Any chemicals applied to the waterway in the course of treatment of the adjacent cropland may wash directly into the surface waters in the case where there is a runoff event shortly after spraying.

When used as a stable outlet for another practice, waterways may increase the likelihood of dissolved and suspended pollutants being transported to surface waters when these pollutants are delivered to the waterway.

■ o. **Grasses and legumes in rotation (411): Establishing grasses and legumes or a mixture of them and maintaining the stand for a definite number of years as part of a conservation cropping system.**

Reduced runoff and increased vegetation may lower erosion rates and subsequent yields of sediment and sediment-attached substances. Less applied nitrogen may be required to grow crops because grasses and legumes will supply organic nitrogen. During the period of the rotation when the grasses and legumes are growing, they will take up more phosphorus. Less pesticides may similarly be required with this practice. Downstream water temperatures may be lower depending on the season when this practice is applied. There will be a greater opportunity for animal *waste management on grasslands because manures and other wastes may be applied for a longer part of the crop year.*

p. Sediment basins (350): Basins constructed to collect and store debris or sediment.

Sediment basins will remove sediment, sediment associated materials and other debris from the water which is passed on downstream. Due to the detention of the runoff in the basin, there is an increased opportunity for soluble materials to be leached toward the ground water.

q. Contour stripcropping (585): Growing crops in a systematic arrangement of strips or bands on the contour to reduce water erosion.

The crops are arranged so that a strip of grass or close-growing crop is alternated with a strip of clean-tilled crop or fallow or a strip of grass is alternated with a close-growing crop (Figure 2-4).

This practice may reduce erosion and the amount of sediment and related substances delivered to the surface waters. The practice may increase the amount of water which infiltrates into the root zone, and, at the time there is an overabundance of soil water, this water may percolate and leach soluble substances into the ground water.

r. Field strip-cropping (586): Growing crops in a systematic arrangement of strips or bands across the general slope (not on the contour) to reduce water erosion.

The crops are arranged so that a strip of grass or a close-growing crop is alternated with a clean-tilled crop or fallow.

This practice may reduce erosion and the delivery of sediment and related substances to the surface waters. The practice may increase infiltration and, when there is sufficient water available, may increase the amount of leachable pollutants moved toward the ground water.

Since this practice is not on the contour there will be areas of concentrated flow, from which detached sediment, adsorbed chemicals and dissolved substances will be delivered more rapidly to the receiving waters. The sod strips will not be efficient filter areas in these areas of concentrated flow.

s. Terrace (600): An earthen embankment, a channel, or combination ridge and channel constructed across the slope (Figures 2-5 and 2-6).

This practice reduces the slope length and the amount of surface runoff which passes over the area downslope from an individual terrace. This may reduce the erosion rate and production of sediment within the terrace interval. Terraces trap sediment and reduce the sediment and associated pollutant content in the runoff water which enhance surface water quality. Terraces may intercept and conduct surface runoff at a nonerosive velocity to stable outlets, thus, reducing the occurrence of ephemeral and classic gullies and the resulting sediment. Increases in infiltration can cause a greater amount of soluble nutrients and pesticides to be leached into the soil. Underground outlets may collect highly soluble nutrient and pesticide leachates and convey runoff and conveying it directly to an outlet, terraces may increase the delivery of pollutants to surface waters. Terraces increase the opportunity to leach salts below the root zone in the soil. Terraces may have a detrimental effect on water quality if they concentrate and accelerate delivery of dissolved or suspended nutrient, salt, and pesticide pollutants to surface or ground waters.

t. Water and sediment control basin (638): An earthen embankment or a combination ridge and channel generally constructed across the slope and minor watercourses to form a sediment trap and water detention basin.

Contour strip cropping systems can involve up to 10 strips in a field. A strip cropping system could involve the following:

Corn (either for grain and/or silage)

Soybeans

1st year Meadow

Established Meadow (2-4 years)

Oats

Grassed waterway or diversion

Tillage systems may include two kinds in the same year such as chisel plowing for the for crop and moldboard plowing for the oats.

See the following figure showing typical patterns of stripcropping.

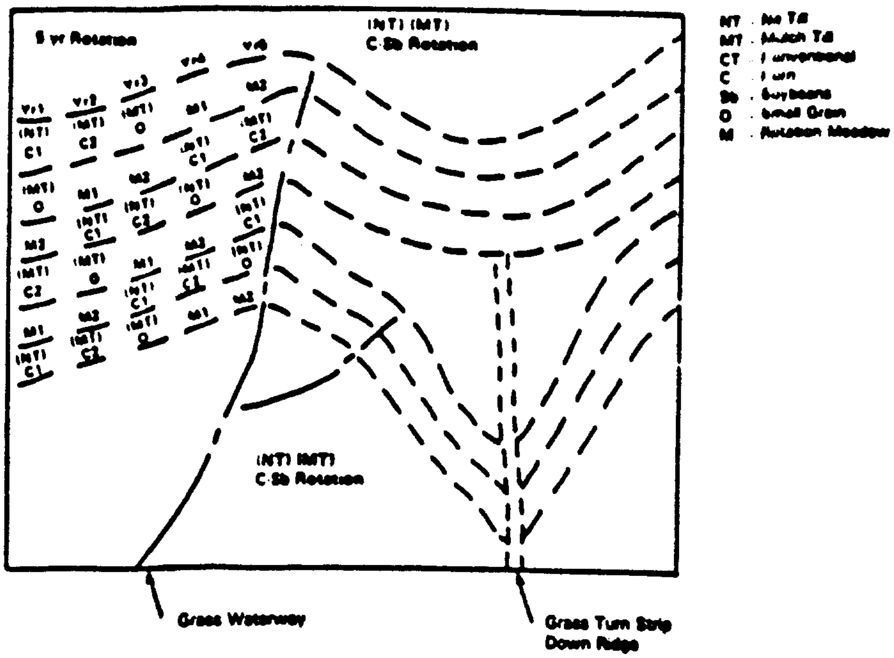

Figure 2-4. Strip-cropping and rotations (USDA-ARS, 1987).

The practice traps and removes sediment and sediment-attached substances from runoff. Trap control efficiencies for sediment and total phosphorus, that are transported by runoff, may exceed 90 percent in silt loam soils. Dissolved substances, such as nitrates, may be removed from discharge to downstream areas because of the increased infiltration. Where geologic condition permit, the practice will lead to increased loadings of dissolved substances toward ground water. Water temperatures of surface runoff, released through underground outlets, may increase slightly because of longer exposure to warming during its impoundment.

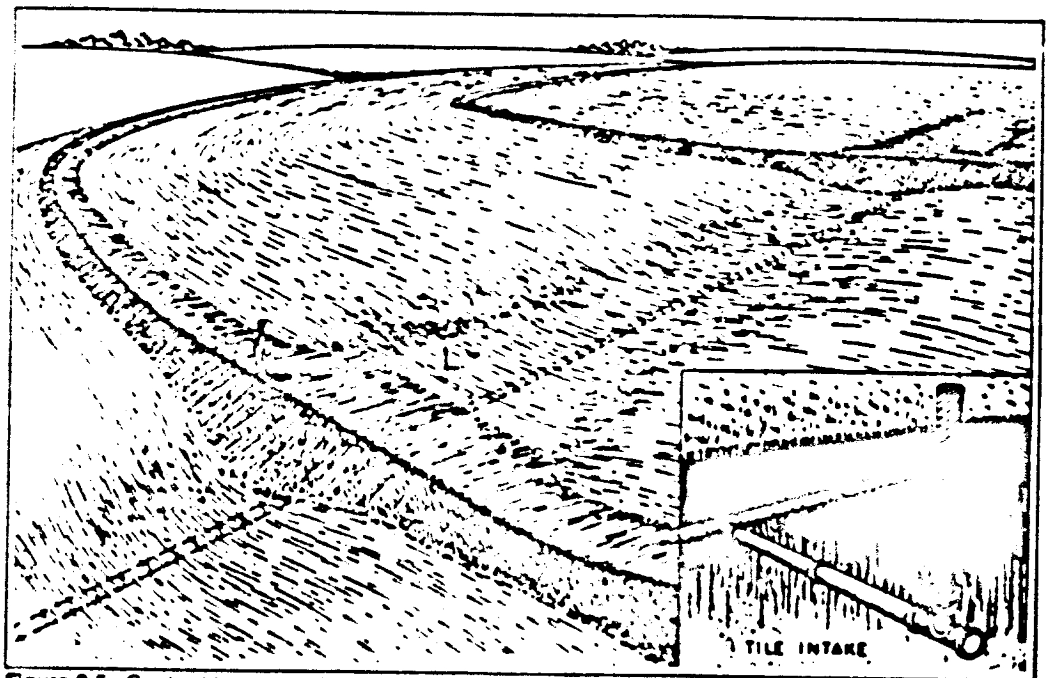

Figure 2-5. Gradient terraces with tile outlets (USDA-SCS, 1984).

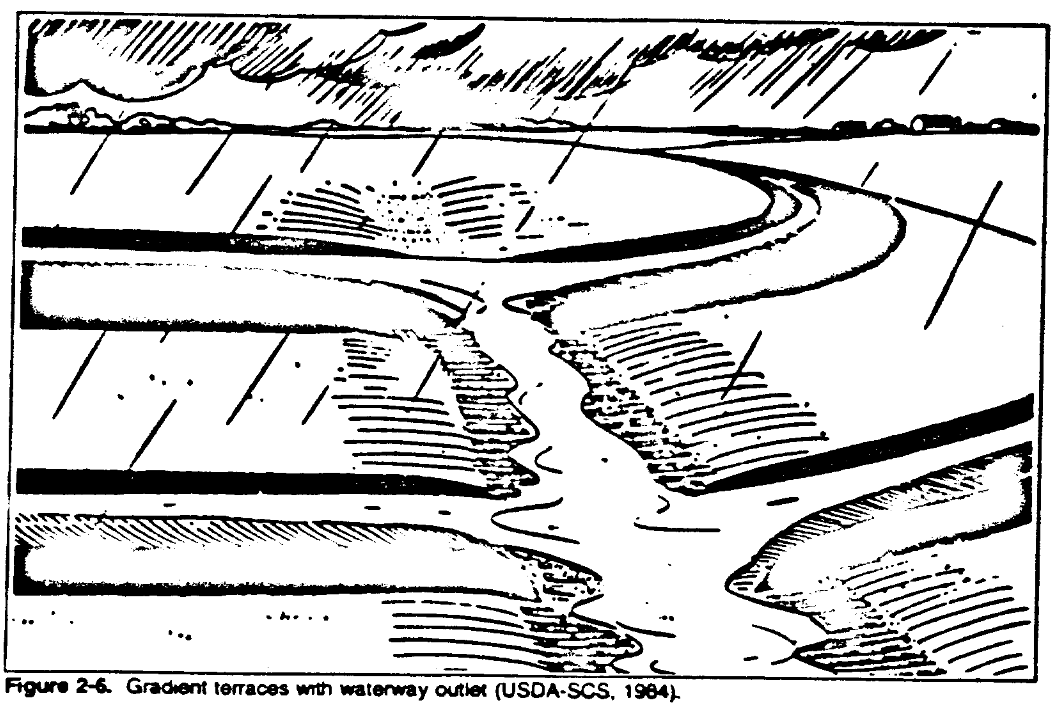

Figure 2-6. Gradient terraces with waterway outlet (USDA-SCS, 1984).

u. Wetland and riparian zone protection

Wetland and riparian zone protection practices are described in Chapter 7.

6. Cost Information

Both national and selected State costs for a number of common erosion control practices are presented in Tables 2-3 through 2-7. The variability in costs for practices can be accounted for primarily through differences in site-specific applications and costs, differences in the reporting units used, and differences in the interpretation of reporting units.

The cost estimates for control of erosion and sediment transport from agricultural lands in Table 2-8 are based on experiences in the Chesapeake Bay Program, but are illustrative of the costs that could be incurred in coastal areas across the Nation. It is important to note that for some practices, such as conservation tillage, the net costs often approach zero and in some cases can be negative because of the savings in labor and energy.

The annual cost of operation and maintenance is estimated to range from zero to 10 percent of the investment cost (USDA-SCS-Michigan, 1988).

[b] Annualized BMP total cost including O&M, planning, and technical assistance costs.
[c] EAC = Equivalent annual cost: annualized total costs for the life span. Interest rate = 10%.
[d] Government incentive costs.
[e] Annualized unit cost per linear foot of constructed waterway.
[f] Units for animal waste are given as $/ton of manure treated.

[illegible]

Limit the discharge from the confined animal facility to surface waters by:

(1) Storing both the facility wastewater *and* the runoff from confined animal facilities that is caused by storms up to and including a 25-year, 24-hour frequency storm. Storage structures should:

(a) Have an earthen lining or plastic membrane lining, or
(b) Be constructed with concrete, or
(c) Be a storage tank;

and

(2) Managing stored runoff and accumulated solids from the facility through an appropriate waste utilization system.

1. Applicability

This management measure is intended for application by States to all new facilities regardless of size and to all new or existing confined animal facilities that contain the following number of head or more:

	Head	Animal Units[2]
Beef Feedlots	300	300
Stables (horses)	200	400
Dairies	70	98
Layers	15,000	150[3]
		495[4]
Broilers	15,000	150[3]
		495[4]
Turkeys	13,750	2,475
Swine	200	80

except those facilities that are required by Federal regulation 40 CFR 122.23 to apply for and receive discharge permits. That section applies to "concentrated animal feeding operations," which are defined in 40 CFR Part 122, Appendix B. In addition, 40 CFR 122.23(c) provides that the Director of an NPDES discharge permit program may designate any animal feeding operation as a concentrated animal feeding operation (which has the effect of subjecting

[2] See *animal unit* in Glossary.

[3] If facility has a liquid manure system, as used in 40 CFR Section 122, Appendix B.

[4] If facility has continuous overflow watering, as used in 40 CFR Section 122, Appendix B.

VOL 12

9314

the operation to the NPDES permit program requirements) upon determining that it is a significant contributor of water pollution. In such cases, upon issuance of a permit, the terms of the permit apply and this management measure ceases to apply.

Under the Coastal Zone Act Reauthorization Amendments, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

A *confined animal facility* is a lot or facility (other than an aquatic animal production facility) where the following conditions are met:

- Animals (other than aquatic animals) have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period, and
- Crops, vegetation forage growth, or post-harvest residues are not sustained in the normal growing season over any portion of the lot or facility.

Two or more animal facilities under common ownership are considered, for the purposes of these guidelines, to be a single animal facility if they adjoin each other or if they use a common area or system for the disposal of wastes.

Confined animal facilities, as defined above, include areas used to grow or house the animals, areas used for processing and storage of product, manure and runoff storage areas, and silage storage areas.

Facility wastewater and runoff from confined animal facilities are to be controlled under this management measure (Figure 2-7). Runoff includes any precipitation (rain or snow) that comes into contact with any manure, litter, or bedding. Facility wastewater is water discharged in the operation of an animal facility as a result of any or all of the following: animal or poultry watering; washing, cleaning, or flushing pens, barns, manure pits, or other animal facilities; washing or spray cooling of animals; and dust control.

2. Description

The problems associated with animal facilities result from runoff, facility wastewater, and manure. For additional information regarding problems, see Section I.F.3 of this chapter.

Application of this management measure will greatly reduce the volume of runoff, manure, and facility wastewater reaching a waterbody, thereby improving water quality and the use of the water resource. The measure can be implemented by using practices that divert runoff water from upslope sites and roofs away from the facility, thereby minimizing the amount of water to be stored and managed. Runoff water and facility wastewater should be routed through a settling structure or debris basin to remove solids, and then stored in a pit, pond, or lagoon for application on agricultural land (Figure 2-8). If manure is managed as a liquid, all manure, runoff, and facility wastewater can be stored in the same structure and there is no need for a debris basin.

For new facilities and expansions to existing facilities, consideration should be given to siting the facility:

- Away from surface waters;
- Away from areas with high leaching potential; and
- In areas where adequate land is available to apply animal wastes in accordance with the nutrient management measure.

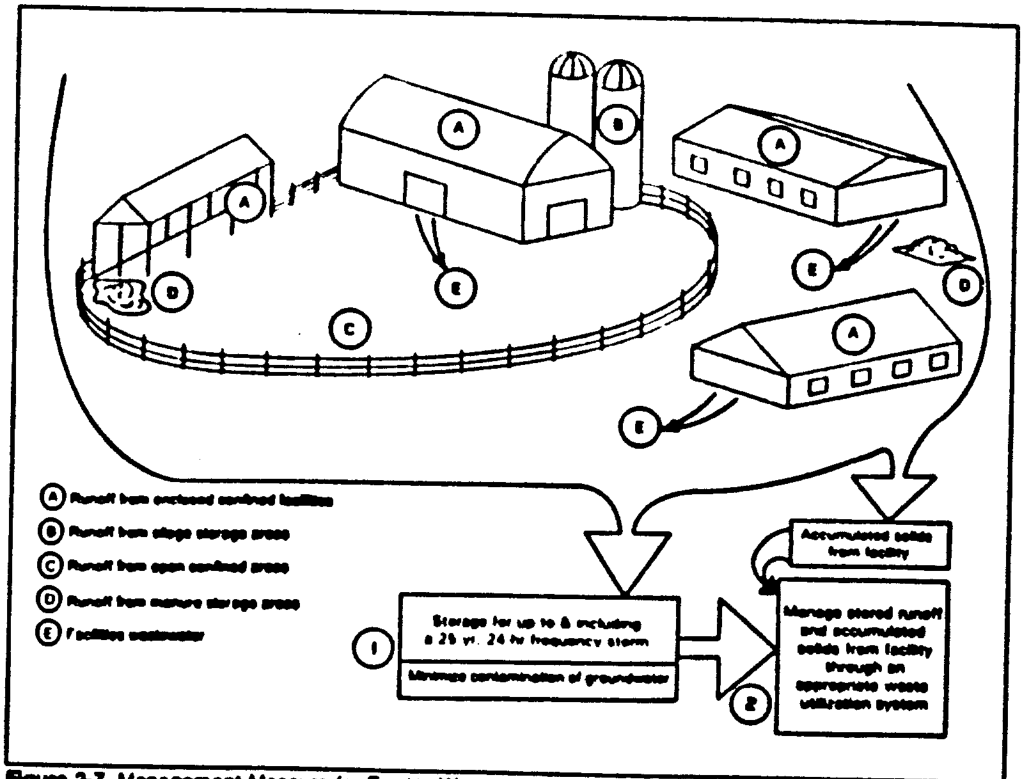

Figure 2-7. Management Measure for Facility Wastewater and Runoff from Confined Animal Facilities (Large Units).

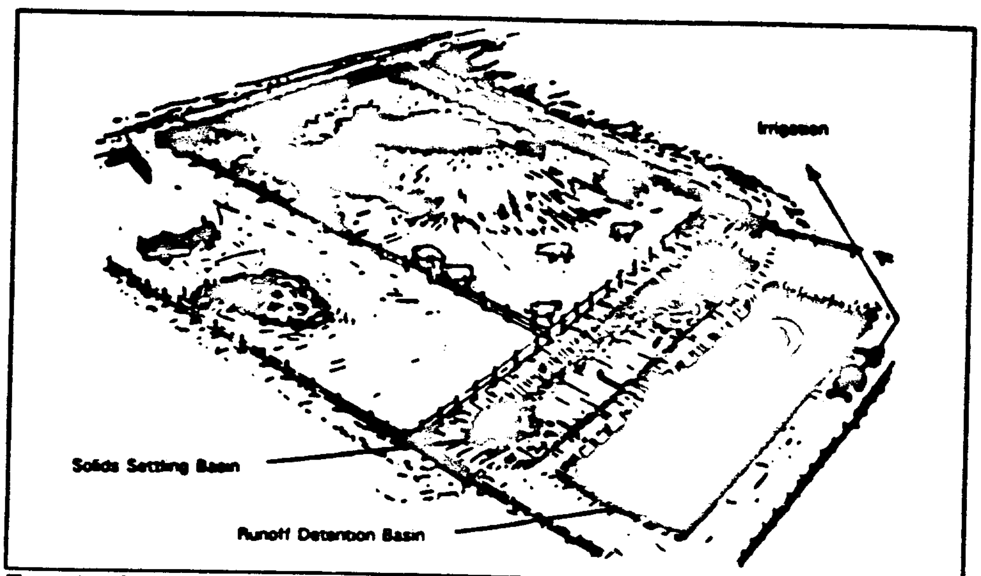

Figure 2-8. Example of manure and runoff storage system (Sutton, 1990).

This management measure does *not* require manure storage structures or areas, nor does it specify required manure management practices. This management measure does, however, address the management of *runoff* from manure storage areas. Manure may be stacked in the confined lot or other appropriate area as long as the storage and management of runoff from the confined lot are in accordance with this management measure. If manure is managed as a solid, any drainage from the storage area or structure area or structure should be routed to the runoff storage system.

When applied to agricultural lands, manure, stored runoff water, stored facility wastewater, and accumulated solids from the facility are to be applied in accordance with the nutrient management measure. An appropriate waste utilization system to minimize impacts to surface water and protect ground water may be achieved through implementation of the SCS Waste Utilization practice (633).

It is recognized that implementation of this measure may increase the potential for movement of water and soluble pollutants through the soil profile to the ground water. It is not the intent of this measure to address a surface water problem at the expense of ground water. Facility wastewater and runoff control systems can and should be designed to protect ground water. Ground-water protection will also be provided by minimizing seepage to ground water, if soil conditions require further protection, and by using the nutrient and pesticide management measures to reduce and control the application of nutrients and pesticides.

Seepage to ground water can be minimized by lining the runoff or manure storage structure with an earthen lining or plastic membrane lining, by constructing with concrete, or by constructing a storage tank. This is not difficult to accomplish and should be achieved in the initial design to reduce costs. For some soils and locations, movement of pollutants to the ground water is not a concern, but site evaluations are needed to determine the appropriate action to take to protect the resources at the site.

Operation and Maintenance of This Measure

Operation

Holding ponds and treatment lagoons should be operated such that the design storm volume is available for storage of runoff. Facilities filled to or near capacity should be drawn down as soon as all site conditions permit the safe removal and appropriate use of stored materials. Solids should be removed from solids separation basins as soon as possible following storm events to ensure that needed solids storage volume is available for subsequent storms.

Maintenance

Diversions will need periodic reshaping and should be free of trees and brush growth. Gutters and downspouts should be inspected annually and repaired when needed. Established grades for lot surfaces and conveyance channels are to be maintained at all times.

Channels should be free of trees and brush growth. Cleaning of debris basins, holding ponds, and lagoons will be needed to ensure that design volumes are maintained. Clean water should be excluded from the storage structure unless it is needed for further dilution in a liquid system.

3. Management Measure Selection

This management measure was selected for larger-sized animal production facilities because it can eliminate the pollutants leaving a facility by storing runoff from storms up to and including the 25-year, 24-hour frequency storm. It also uses practices that reduce the amount of water that comes into contact with animal waste materials. It requires that stored runoff and accumulated solids from the facility are managed through an appropriate waste utilization system. Any stored water, accumulated solids, processed dead animals, or manure are to be applied in accordance with the nutrient management measure.

The size limitations that define a large unit are based on EPA's analysis of the economic achievability of the management measure.

4. Effectiveness Information

The effectiveness of management practices to control contaminant losses from confined livestock facilities depends on several factors including:

- The contaminant(s) to be controlled and their likely pathways in surface, subsurface, and ground-water flows;
- The types of practices (section 5) and how these practices control surface, subsurface, and ground-water contaminant pathways; and
- Site-specific variables such as soil type, topography, precipitation characteristics, type of animal housing and waste storage facilities, method of waste collection, handling and disposal, and seasonal variations. The site-specific conditions must be considered in system design, thus having a large effect on practice effectiveness levels.

The gross effectiveness estimates reported in Table 2-9 simply indicate summary literature values. For specific cases, a wide range of effectiveness can be expected depending on the value and interaction of the site-specific variables cited above.

When runoff from storms up to and including the 24-hour, 25-year frequency storm is stored, there will be no release of pollutants from a confined animal facility via the surface runoff route. Rare storms of a greater magnitude or sequential storms of combined greater magnitude may produce runoff, however. Table 2-10 reflects the occurrence of such storms by indicating less than 100 percent control for runoff control systems.

Table 2-9. Relative Gross Effectiveness[a] of Confined Livestock Control Measures (Pennsylvania State University, 1992a)

Practice[b] Category	Runoff[c] Volume	Total[d] Phosphorus (%)	Total[d] Nitrogen (%)	Sediment (%)	Fecal Coliform (%)
Animal Waste Systems[e]	-	90	80	60	85
Diversion Systems[f]	-	70	45	NA	NA
Filter Strips[g]	-	85	NA	60	55
Terrace System	-	85	55	80	NA
Containment Structures[h]	-	60	65	70	90

NA = not available.
[a] Actual effectiveness depends on site-specific conditions. Values are not cumulative between practice categories.
[b] Each category includes several specific types of practices.
[c] - = reduction; + = increase; 0 = no change in surface runoff.
[d] Total phosphorus includes total and dissolved phosphorus; total nitrogen includes organic-N, ammonia-N, and nitrate-N.
[e] Includes methods for collecting, storing, and disposing of runoff and process-generated wastewater.
[f] Specific practices include diversion of uncontaminated water from confinement facilities.
[g] Includes all practices that reduce contaminant losses using vegetative control measures.
[h] Includes such practices as waste storage ponds, waste storage structures, waste treatment lagoons.

Table 2-10. Effectiveness of Runoff Control Systems (DPRA, 1986)

	Removal Efficiency (%)	
Management Practice	Solids	Phosphorus
Runoff Control System	80 - 90	70 - 95

5. Confined Animal Facility Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Combinations of the following practices can be used to satisfy the requirements of this management measure. The U.S. Soil Conservation Service (SCS) practice number and definition are provided for each management practice, where available. Also included in italics are SCS statements describing the effect each practice has on water quality (USDA-SCS, 1988).

■ a. ***Dikes (356): An embankment constructed of earth or other suitable materials to protect land against overflow or to regulate water.***

Where dikes are used to prevent water from flowing onto the floodplain, the pollution dispersion effect of the temporary wetlands and backwater are decreased. The sediment, sediment-attached, and soluble materials being transported by the water are carried farther downstream. The final fate of these materials must be investigated on site. Where dikes are used to retain runoff on the floodplain or in wetlands the pollution dispersion effects of these areas may be enhanced. Sediment and related materials may be deposited, and the quality of the water flowing into the stream from this area will be improved.

Dikes are used to prevent wetlands and to form wetlands. The formed areas may be fresh, brackish, or saltwater wetlands. In tidal areas dikes are used to stop saltwater intrusion, and to increase the hydraulic head of fresh water which will force intruded salt water out the aquifer. During construction there is a potential of heavy sediment loadings to the surface waters. When pesticides are used to control the brush on the dikes and fertilizers are used for the establishment and maintenance of vegetation there is the possibility for these materials to be washed into the surface waters.

■ b. ***Diversions (362): A channel constructed across the slope with a supporting ridge on the lower side.***

This practice will assist in the stabilization of a watershed, resulting in the reduction of sheet and rill erosion by reducing the length of slope. Sediment may be reduced by the elimination of ephemeral and large gullies. This may reduce the amount of sediment and related pollutants delivered to the surface waters.

■ c. ***Grassed waterway (412): A natural or constructed channel that is shaped or graded to required dimensions and established in suitable vegetation for the stable conveyance of runoff.***

This practice may reduce the erosion in a concentrated flow area, such as in a gully or in ephemeral gullies. This may result in the reduction of sediment and substances delivered to receiving waters. Vegetation may act as a filter *in removing some of the sediment delivered to the waterway, although this is not the primary function of a grassed waterway.*

Any chemicals applied to the waterway in the course of treatment of the adjacent cropland may wash directly into the surface waters in the case where there is a runoff event shortly after spraying.

When used as a stable outlet for another practice, waterways may increase the likelihood of dissolved and suspended pollutants being transported to surface waters when these pollutants are delivered to the waterway.

d. Heavy use area protection (561): Protecting heavily used areas by establishing vegetative cover, by surfacing with suitable materials, or by installing needed structures.

Protection may result in a general improvement of surface water quality through the reduction of erosion and the resulting sedimentation. Some increase in erosion may occur during and immediately after construction until the disturbed areas are fully stabilized.

Some increase in chemicals in surface water may occur due to the introduction of fertilizers for vegetated areas and oils and chemicals associated with paved areas. Fertilizers and pesticides used during operation and maintenance may be a source of water pollution.

Paved areas installed for livestock use will increase organic, bacteria, and nutrient loading to surface waters. Changes in ground water quality will be minor. Nitrate nitrogen applied as fertilizer in excess of vegetation needs may move with infiltrating waters. The extent of the problem, if any, may depend on the actual amount of water percolating below the root zone.

e. Lined waterway or outlet (468): A waterway or outlet having an erosion-resistant lining of concrete, stone, or other permanent material.

The lined section extends up the side slopes to a designed depth. The earth above the permanent lining may be vegetated or otherwise protected.

This practice may reduce the erosion in concentrated flow areas resulting in the reduction of sediment and substances delivered to the receiving waters.

When used as a stable outlet for another practice, lined waterways may increase the likelihood of dissolved and suspended substances being transported to surface waters due to high flow velocities.

f. Roof runoff management (558): A facility for controlling and disposing of runoff water from roofs.

This practice may reduce erosion and the delivery of sediment and related substances to surface waters. It will reduce the volume of water polluted by animal wastes. Loadings of organic waste, nutrients, bacteria, and salts to surface water are prevented from flowing across concentrated waste areas, barnyards, roads and alleys will be reduced. Pollution and erosion will be reduced. Flooding may be prevented and drainage may improve.

g. Terrace (600): An earthen embankment, a channel, or combination ridge and channel constructed across the slope.

This practice reduces the slope length and the amount of surface runoff which passes over the area downslope from an individual terrace. This may reduce the erosion rate and production of sediment within the terrace interval. Terraces trap sediment and reduce the sediment and associated pollutant content in the runoff water which enhances surface water quality. Terraces may intercept and conduct surface runoff at a nonerosive velocity to stable outlets, thus reducing the occurrence of ephemeral and classic gullies and the resulting sediment. Increases in infiltration *can cause a greater amount of soluble nutrients and pesticides to be leached into the soil. Underground outlets may collect highly soluble nutrient and pesticide leachates and convey runoff and conveying it directly to an outlet, terraces may increase the delivery of pollutants to surface waters. Terraces increase the opportunity to leach salts below the root zone in the soil. Terraces may have a detrimental effect on water quality if they concentrate and accelerate delivery of dissolved or suspended nutrient, salt, and pesticide pollutants to surface or ground waters.*

■ *h. Waste storage pond (425): An impoundment made by excavation or earth fill for temporary storage of animal or other agricultural wastes.*

This practice reduces the direct delivery of polluted water, which is the runoff from manure stacking areas and feedlots and barnyards, to the surface waters. This practice may reduce the organic, pathogen, and nutrient loading to surface waters. This practice may increase the dissolved pollutant loading to ground water by leakage through the sidewalls and bottom.

■ *i. Waste storage structure (313): A fabricated structure for temporary storage of animal wastes or other organic agricultural wastes.*

This practice may reduce the nutrient, pathogen, and organic loading to the surface waters. This is accomplished by intercepting and storing the polluted runoff from manure stacking areas, barnyards and feedlots. This practice will not eliminate the possibility of contaminating surface and ground water; however, it greatly reduces this possibility.

■ *j. Waste treatment lagoon (359): An impoundment made by excavation or earth fill for biological treatment of animal or other agricultural wastes.*

This practice may reduce polluted surficial runoff and the loading of organics, pathogens, and nutrients into the surface waters. It decreases the nitrogen content of the surface runoff from feedlots by denitrification. Runoff is retained long enough that the solids and insoluble phosphorus settle and form a sludge in the bottom of the lagoon. There may be some seepage through the sidewalls and the bottom of the lagoon. Usually the long-term seepage rate is low enough, so that the concentration of substances transported into the ground water does not reach an unacceptable level.

■ *k. Application of manure and/or runoff water to agricultural land*

Manure and runoff water are applied to agricultural lands and incorporated into the soil in accordance with the management measures for nutrients.

■ *l. Waste utilization (633): Using agricultural wastes or other wastes on land in an environmentally acceptable manner while maintaining or improving soil and plant resources.*

Waste utilization helps reduce the transport of sediment and related pollutants to the surface water. Proper site selection, timing of application and rate of application may reduce the potential for degradation of surface and ground water. This practice may increase microbial action in the surface layers of the soil, causing a reaction which assists in controlling pesticides and other pollutants by keeping them in place in the field.

Mortality and other compost, when applied to agricultural land, will be applied in accordance with the nutrient management measure. The composting facility may be subject to State regulations and will have a written operation and management plan if SCS practice 317 (composting facility) is used.

VOL 12

9321

■ *m. Composting facility (317): A facility for the biological stabilization of waste organic material.*

The purpose is to treat waste organic material biologically by producing a humus-like material that can be recycled as a soil amendment and fertilizer substitute or otherwise utilized in compliance with all laws, rules, and regulations.

■ *n. Commercial rendering or disposal services*

■ *o. Incineration*

■ *p. Approved burial sites*

6. Cost Information

Construction costs for control of runoff and manure from confined animal facilities are provided in Table 2-11. The annual operation and maintenance costs average 4 percent of construction costs for diversions, 3 percent of construction costs for settlement basins, and 5 percent of construction costs for retention ponds (DPRA, 1992). Annual costs for repairs, maintenance, taxes, and insurance are estimated to be 5 percent of investment costs for irrigation systems (DPRA, 1992).

Table 2-11. Costs for Runoff Control Systems (DPRA, 1992)

Practice[a]	Unit	Cost/Unit Construction ($)[b]
Diversion	foot	2.00
Irrigation		
- Piping (4-inch)	foot	1.75
- Piping (6-inch)	foot	2.25
- Pumps (10 hp)	unit	1,750.00
- Pumps (15 hp)	unit	2,000.00
- Pumps (30 hp)	unit	3,000.00
- Pumps (45 hp)	unit	3,500.00
- Sprinkler/gun (150 gpm)	unit	875.00
- Sprinkler/gun (250 gpm)	unit	1,750.00
- Sprinkler/gun (400 gpm)	unit	3,200.00
- Contracted service to empty retention pond	1,000 gallon	3.00
Infiltration[c]	acre	2,500.00
Manure Hauling	mile per 4.5-ton load	2.15
Dead Animal Composting Facility	cubic foot	5.00
Retention Pond		
- 241 cubic feet in size	cubic foot	2.58
- 2,678 cubic feet in size	cubic foot	1.24
- 28,638 cubic feet in size	cubic foot	0.60
- 267,123 cubic feet in size	cubic foot	0.31
Settling Basin		
- 53 cubic feet in size	cubic foot	4.28
- 488 cubic feet in size	cubic foot	2.74
- 5,088 cubic feet in size	cubic foot	1.71
- 49,950 cubic feet in size	cubic foot	1.08

[a] Expected lifetimes of practices are 20 years for diversions, settling basins, retention ponds, and infiltration areas and 15 years for irrigation equipment.
[b] 1990 dollars. This table does not present annualized costs.
[c] Does not include land costs.

VOL 12

9323

R0042629

[illegible] Management (Small Units)

Design and implement systems that collect solids, reduce contaminant concentrations, and reduce runoff to minimize the discharge of contaminants in both facility wastewater and in runoff that is caused by storms up to and including a 25-year, 24-hour frequency storm. Implement these systems to substantially reduce significant increases in pollutant loadings to ground water.

Manage stored runoff and accumulated solids from the facility through an appropriate waste utilization system.

1. Applicability

This management measure is intended for application by States to all existing confined animal facilities that contain the following number of head:

	Head	Animal Units[3]
Beef Feedlots	50-299	50-299
Stables (horses)	100-199	200-399
Dairies	20-69	28-97
Layers	5,000-14,999	50-149[6]
		165-494[7]
Broilers	5,000-14,999	50-149[6]
		165-494[7]
Turkeys	5,000-13,749	900-2,474
Swine	100-199	40-79

except those facilities that are required by Federal regulation 40 CFR 122.23(c) to apply for and receive discharge permits. 40 CFR 122.23(c) provides that the Director of an NPDES discharge permit program may designate any animal feeding operation as a concentrated animal feeding operation (which has the effect of subjecting the operation to the NPDES permit program requirements) upon determining that it is a significant contributor of water pollution. In such cases, upon issuance of a permit, the terms of the permit apply and this management measure ceases to apply.

Facilities containing fewer than the number of head listed above are not subject to the requirements of this management measure. Existing facilities that meet the requirements of Management Measure B1 for large units are in compliance with the requirements of this management measure. Existing and new facilities that already minimize

[3] See *animal unit* in Glossary.

[6] If facility has a liquid manure system, as used in 40 CFR Section 122, Appendix B.

[7] If facility has continuous overflow watering, as used in 40 CFR Section 122, Appendix B.

the discharge of contaminants to surface waters, protect against contamination of ground water, and have an appropriate waste utilization system may already meet the requirements of this management measure. Such facilities may not need additional controls for the purposes of this management measure.

Under the Coastal Zone Act Reauthorization Amendments, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

A *confined animal facility* is a lot or facility (other than an aquatic animal production facility) where the following conditions are met:

- Animals (other than aquatic animals) have been, are, or will be stabled or confined and fed or maintained for a total of 45 days or more in any 12-month period, and

- Crops, vegetation forage growth, or post-harvest residues are not sustained in the normal growing season over any portion of the lot or facility.

Two or more animal facilities under common ownership are considered, for the purposes of these guidelines, to be a single animal facility if they adjoin each other or if they use a common area or system for the disposal of wastes.

Confined animal facilities, as defined above, include areas used to grow or house the animals, areas used for processing and storage of product, manure and runoff storage areas, and silage storage areas.

Facility wastewater and runoff from confined animal facilities are to be controlled under this management measure (Figure 2-9). Runoff includes any precipitation (rain or snow) that comes into contact with any manure, litter, or bedding. Facility wastewater is water discharged in the operation of an animal facility as a result of any or all of the following: animal or poultry watering; washing, cleaning, or flushing pens, barns, manure pits, or other animal facilities; washing or spray cooling of animals; and dust control.

2. Description

The goal of this management measure is to minimize the discharge of contaminants in both facility wastewater and in runoff that is caused by storms up to and including a 25-year, 24-hour frequency storm by using practices such as solids separation basins in combination with vegetative practices and other practices that reduce runoff and are also protective of ground water.

The problems associated with animal facilities are the control of runoff, facility wastewater, and manure. For additional information regarding problems, see Section I.F.3. of this chapter.

Application of this management measure will greatly reduce the volume of runoff, manure, and facility wastewater reaching a waterbody, thereby improving water quality and the use of the water resource. The measure can be implemented by using practices that divert runoff water from upslope sites and roofs away from the facility, thereby minimizing the amount of water that must be managed (Figure 2-10). Runoff water and facility wastewater from the facility should be routed through a settling structure or debris basin to remove solids. If manure is managed as a liquid, all manure, runoff, and facility wastewater can be stored in the same structure and there is no need for a debris basin.

This management measure does *not* require manure storage structures or areas, nor does it specify required manure management practices. This management measure does, however, address the management of *runoff* from manure

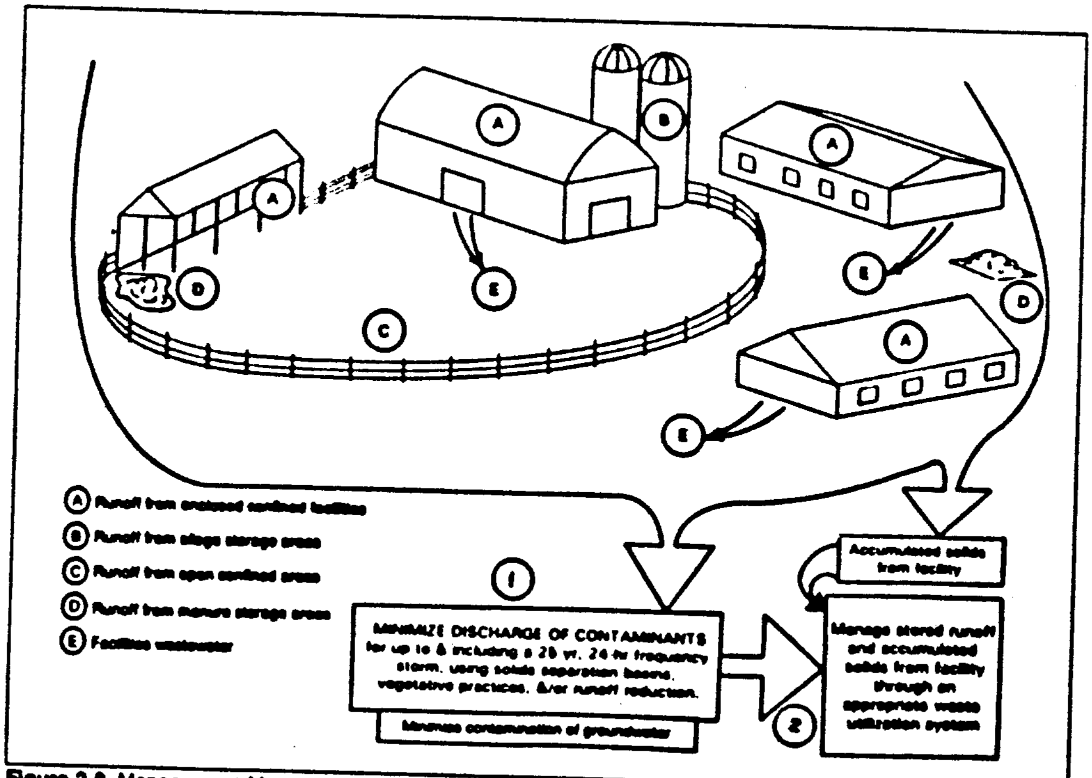

Figure 2-9. Management Measure for Facility Wastewater and Runoff from Confined Animal Facilities (Small Units).

storage areas. Manure may be stacked in the confined lot or other appropriate area as long as the discharge is minimized and any stored runoff is managed in accordance with this management measure. If manure is managed as a solid, any drainage from the storage area or structure should be routed to the runoff control practices.

When applied to agricultural lands, manure, stored runoff water, stored facility wastewater, and accumulated solids from the facility are to be applied in accordance with the nutrient management measure. An appropriate waste utilization system to minimize impacts to surface water and protect ground water may be achieved through implementation of the SCS Waste Utilization practice (633).

It is recognized that implementation of this measure may increase the potential for movement of water and soluble pollutants through the soil profile to the ground water. It is not the intent of this measure to address a surface water problem at the expense of ground water. Facility wastewater and runoff control systems can and should be designed to protect against the contamination of ground water. Ground-water protection will also be provided by minimizing seepage to ground water, if soil conditions require further protection, and by using the nutrient and pesticide management measures to reduce and control the application of nutrients and pesticides. While a nutrient management plan is not required to be implemented on the vegetative control practices themselves, ground water should be protected by taking extreme care to not exceed the capacity of the practices to assimilate nutrients.

When storage structures are used to meet the requirements of this management measure, seepage to ground water can be minimized by lining the runoff or manure storage structure with an earthen lining or plastic membrane lining, by constructing with concrete, or by constructing a storage tank. This is not difficult to accomplish and should be achieved in the initial design to reduce costs. For some soils and locations movement of pollutants to the ground

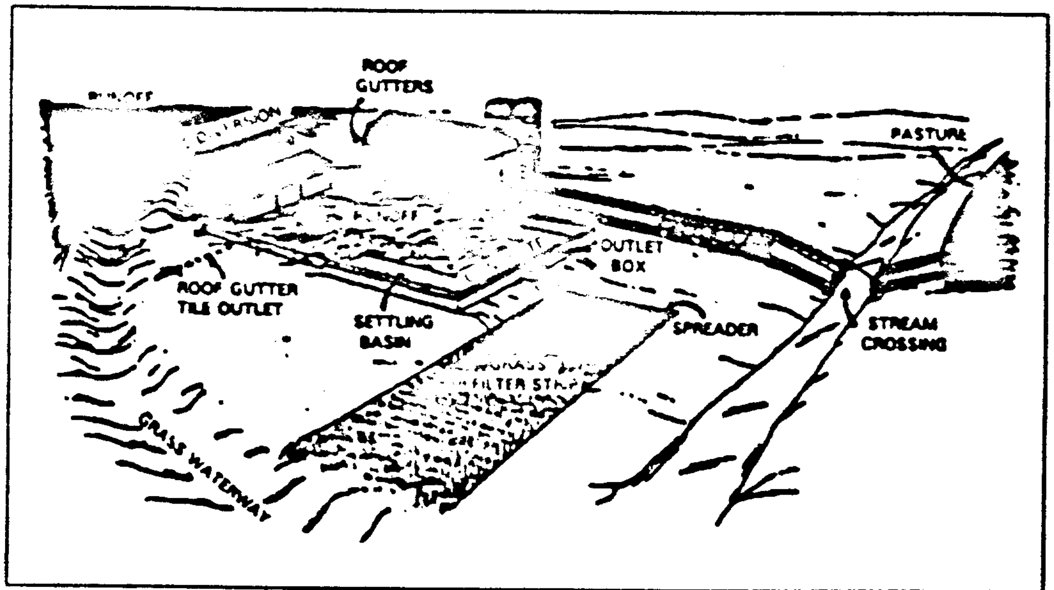

Figure 2-10. Typical barnyard runoff management system (Wisconsin Dept. of Agriculture, Trade and Consumer Protection, 1989).

water is not a concern, but each site must be evaluated and the appropriate action taken to protect the resources at the site.

Operation and Maintenance of This Measure

Operation

Holding ponds and treatment lagoons should be operated such that the design storm volume is available for storage of runoff. Facilities that have filled should be drawn down as soon as all site conditions permit the safe removal and appropriate use of stored materials. Solids should be removed from solids separation basins as soon as possible following storm events to ensure that needed solids storage volume is available for subsequent storms.

Maintenance

Diversions will need periodic reshaping and should be free of trees and brush growth. Gutters and downspouts should be inspected annually and repaired when needed. Established grades for lot surfaces and conveyance channels must be maintained at all times.

Channels must be free of trees and brush growth. Cleaning of debris basins, holding ponds, and lagoons will be needed to ensure that design volumes are maintained. Clean water should be excluded from the storage structure unless it is needed for further dilution in a liquid system.

3. Management Measure Selection

This management measure was selected for smaller-sized animal production facilities based on an evaluation of available information that documents the beneficial effects of improved management of confined livestock facilities. Specifically, the management measure reduces the amount of pollutants leaving a facility by using practices that reduce the amount of water that comes into contact with animal waste materials. It also uses solid removal and filtration of runoff water to remove a significant amount of the pollutants contained in the runoff waters. This can be accomplished without the expense of constructing a runoff storage structure and purchasing the equipment necessary to apply the stored water to the land.

This management measure also requires that stored runoff and accumulated solids from the facility are managed through an appropriate waste utilization system. The size limitations that define a small unit are based on EPA's analysis of the economic achievability of the management measure.

4. Effectiveness Information

The effectiveness information presented for large units (Tables 2-9 and 2-10) also applies to this management measure.

Pollutant loads from runoff caused by storms up to and including the 25-year, 24-hour frequency storm can be reduced by decreasing the potential for runoff contamination (e.g., by keeping accumulations of manure off the open lots), and by removing the contaminants to the fullest extent practicable through vegetative and structural practices (e.g., solids separation devices, sediment basins, filter strips, and constructed wetlands). Pollutant loads can also be reduced by storing and applying the runoff to the land with any manure and facility wastewater in accordance with the nutrient management measure.

Table 2-12 shows reductions in pollutant concentrations that are achievable with solids separation basins that receive runoff from barnyards and feedlots. Concentration reductions may differ from the load reductions presented in Tables 2-9 and 2-10 since loads are determined by both concentration and discharge volume. Solids separation basins combined with drained infiltration beds and vegetated filter strips (VFS) provide additional reductions in contaminant concentrations. The effectiveness of solids separation basins is highly dependent on site variables. Solids separation; basin sizing and management (clean-out); characteristics of VFS areas such as soil type, land slope, length, vegetation type, vegetation quality; and storm amounts and intensities all play important roles in the performance of the system. Appropriate operation and maintenance are critical to success.

Table 2-12. Concentrated Reductions in Barnyard and Feedlot Runoff Treated with Solids Separation

Site Location	Constituent Reduction (%)

5. Confined Animal Facility Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Combinations of the following practices can be used to satisfy the requirements of this management measure. The U.S. Soil Conservation Service (SCS) practice number and definition are provided for each management practice, where available. Also included in italics are SCS statements describing the effect each practice has on water quality (USDA-SCS, 1988).

■ a. ***Waste storage pond (425): An impoundment made by excavation or earth fill for temporary storage of animal or other agricultural waste.***

This practice reduces the direct delivery of polluted water, which is the runoff from manure stacking areas and feedlots and barnyards, to the surface waters. This practice may reduce the organic, pathogen, and nutrient loading to surface waters. This practice may increase the dissolved pollutant loading to ground water by leakage through the sidewalls and bottom.

■ b. ***Waste storage structure (313): A fabricated structure for temporary storage of animal waste or other organic agricultural waste.***

This practice may reduce the nutrient, pathogen, and organic loading to the surface waters. This is accomplished by intercepting and storing the polluted runoff from manure stacking areas, barnyards and feedlots. This practice will not eliminate the possibility of contaminating surface and ground water; however, it greatly reduces this possibility.

■ c. ***Waste treatment lagoon (359): An impoundment made by excavation or earth fill for biological treatment of animal or other agricultural waste.***

This practice may reduce polluted surficial runoff and the loading of organics, pathogens, and nutrients into the surface waters. It decreases the nitrogen content of the surface runoff from feedlots by denitrification. Runoff is retained long enough that the solids and insoluble phosphorus settle and form a sludge in the bottom of the lagoon. There may be some seepage through the sidewalls and the bottom of the lagoon. Usually the long-term seepage rate is low enough, so that the concentration of substances transported into the ground water does not reach an unacceptable level.

■ d. ***Sediment basin (350): A basin constructed to collect and store debris or sediment.***

Sediment basins will remove sediment, sediment associated materials and other debris from the water which is passed on downstream. Due to the detention of the runoff in the basin, there is an increased opportunity for soluble materials to be leached toward the ground water.

■ e. ***Water and sediment control basin (638): An earth embankment or a combination ridge and channel generally constructed across the slope and minor water courses to form a sediment trap and a water detention basin.***

The practice traps and removes sediment and sediment-attached substances from runoff. Trap control efficiencies for sediment and total phosphorus, that are transported by runoff, may exceed 90 percent in silt loam soils. Dissolved substance, such as nitrates, may be removed from discharge to downstream areas because of the increased infiltration. Where geologic condition permit, the practice will lead to increased loadings of dissolved substances toward ground water. Water temperatures of surface runoff, released through underground outlets, may increase slightly because of longer exposure to warming during its impoundment.

f. *Filter strip (393): A strip or area of vegetation for removing sediment, organic matter, and other contaminants from runoff and wastewater.*

Filter strips for sediment and related pollutants meeting minimum requirements may trap the coarser grained sediment. They may not filter out soluble or suspended fine-grained materials. When a storm caused runoff in excess of the design runoff, the filter may be flooded and may cause large loads of pollutants to be released to the surface water. This type of filter requires high maintenance and has a relatively short service life and is effective only as long as the flow through the filter is shallow sheet flow.

Filter strips for runoff from concentrated livestock areas may trap organic material, solids, materials which become adsorbed to the vegetation or the soil within the filter. Often they will not filter out soluble materials. This type of filter is often wet and is difficult to maintain.

Filter strips for controlled overland flow treatment of liquid wastes may effectively filter out pollutants. The filter must be properly managed and maintained, including the proper resting time. Filter strips on forest land may trap coarse sediment, timbering debris, and other deleterious material being transported by runoff. This may improve the quality of surface water and has little effect on soluble material in runoff or on the quality of ground water.

All types of filters may reduce erosion on the area on which they are constructed.

Filter strips trap solids from the runoff flowing in sheet flow through the filter. Coarse-grained and fibrous materials are filtered more efficiently than fine-grained and soluble substances. Filter strips work for design conditions, but when flooded or overloaded they may release a slug load of pollutants into the surface water.

g. *Grassed waterway (412): A natural or constructed channel that is shaped or graded to required dimensions and established in a suitable vegetation for the stable conveyance of runoff.*

This practice may reduce the erosion in a concentrated flow area, such as in a gully or in ephemeral gullies. This may result in the reduction of sediment and substances delivered to receiving waters. Vegetation may act as a filter in removing some of the sediment delivered to the waterway, although this is not the primary function of a grassed waterway.

Any chemicals applied to the waterway in the course of treatment of the adjacent cropland may wash directly into the surface waters in the case where there is a runoff event shortly after spraying.

When used as a stable outlet for another practice, waterways may increase the likelihood of dissolved and suspended pollutants being transported to surface waters when these pollutants are delivered to the waterway.

h. *Constructed wetland (ASCS-999): A constructed aquatic ecosystem with rooted emergent hydrophytes designed and managed to treat agricultural wastewater.*

This is a conservation practice for which SCS has developed technical requirements under a trial program leading to the development of a conservation practice standard.

i. Dikes (356): An embankment constructed of earth or other suitable materials to protect land against overflow or to regulate water.

Where dikes are used to prevent water from flowing onto the floodplain, the pollution dispersion effects of the temporary wetlands and backwater are decreased. The sediment, sediment-attached, and soluble materials being transported by the water are carried further downstream. The final fate of these materials must be investigated on site. Where dikes are used to retain runoff on the floodplain or in wetlands the pollution dispersion effects of these areas may be enhanced. Sediment and related materials may be deposited, and the quality of the water flowing into the stream from this area will be improved.

Dikes are used to prevent wetlands and to form wetlands. The formed areas may be fresh, brackish, or saltwater wetlands. In tidal areas dikes are used to stop saltwater intrusion, and to increase the hydraulic head of fresh water which will force intruded salt water out the aquifer. During construction there is a potential of heavy sediment loadings to the surface waters. When pesticides are used to control the brush on the dikes and fertilizers are used for the establishment and maintenance of vegetation there is the possibility for these materials to be washed into the surface waters.

j. Diversion (362): A channel constructed across the slope with a supporting ridge on the lower side.

This practice will assist in the stabilization of a watershed, resulting in the reduction of sheet and rill erosion by reducing the length of slope. Sediment may be reduced by the elimination of ephemeral and large gullies. This may reduce the amount of sediment and related pollutants delivered to the surface waters.

k. Heavy use area protection (561): Protecting heavily used areas by establishing vegetative cover, by surfacing with suitable materials, or by installing needed structures.

Protection may result in a general improvement of surface water quality through the reduction of erosion and the resulting sedimentation. Some increase in erosion may occur during and immediately after construction until the disturbed areas are fully stabilized.

Some increase in chemicals in surface water may occur due to the introduction of fertilizers for vegetated areas and oils and chemicals associated with paved areas. Fertilizers and pesticides used during operation and maintenance may be a source of water pollution.

Paved areas installed for livestock use will increase organic, bacteria, and nutrient loading to surface waters. Changes in ground water quality will be minor. Nitrate nitrogen applied as fertilizer in excess of vegetation needs may move with infiltrating waters. The extent of the problem, if any, may depend on the actual amount of water percolating below the root zone.

l. Lined waterway or outlet (468): A waterway or outlet having an erosion-resistant lining of concrete, stone, or other permanent material.

The lined section extends up the side slopes to a designed depth. The earth above the permanent lining may be vegetated or otherwise protected.

This practice may reduce the erosion in concentrated flow areas resulting in the reduction of sediment and substances delivered to the receiving waters.

When used as a stable outlet for another practice, lined waterways may increase the likelihood of dissolved and suspended substances being transported to surface waters due to high flow velocities.

m. *Roof runoff management (558): A facility for controlling and disposing of runoff water from roofs.*

This practice may reduce erosion and the delivery of sediment and related substances to surface waters. It will reduce the volume of water polluted by animal wastes. Loadings of organic waste, nutrients, bacteria, and salts to surface water are prevented from flowing across concentrated waste areas, barnyards, roads and alleys. Pollution and erosion will be reduced. Flooding may be prevented and drainage may improve.

n. *Terrace (600): An earthen embankment, a channel, or combination ridge and channel constructed across the slope.*

This practice reduces the slope length and the amount of surface runoff which passes over the area downslope from an individual terrace. This may reduce the erosion rate and production of sediment within the terrace interval. Terraces trap sediment and reduce the sediment and associated pollutant content in the runoff water which enhance surface water quality. Terraces may intercept and conduct surface runoff at a nonerosive velocity to stable outlets, thus reducing the occurrence of ephemeral and classic gullies and the resulting sediment. Increases in infiltration can cause a greater amount of soluble nutrients and pesticides to be leached into the soil. Underground outlets may collect highly soluble nutrient and pesticide leachates and convey runoff and conveying it directly to an outlet, terraces may increase the delivery of pollutants to surface waters. Terraces increase the opportunity to leach salts below the root zone in the soil. Terraces may have a detrimental effect on water quality if they concentrate and accelerate delivery of dissolved or suspended nutrient, salt, and pesticide pollutants to surface or ground waters.

o. *Waste utilization (633): Using agricultural wastes or other wastes on land in an environmentally acceptable manner while maintaining or improving soil and plant resources.*

Waste utilization helps reduce the transport of sediment and related pollutants to the surface water. Proper site selection, timing of application and rate of application may reduce the potential for degradation of surface and ground water. This practice may increase microbial action in the surface layers of the soil, causing a reaction which assists in controlling pesticides and other pollutants by keeping them in place in the field.

Mortality and other compost, when applied to agricultural land, will be applied in accordance with the nutrient management measure. The composting facility may be subject to State regulations and will have a written operation and management plan if SCS practice 317 (composting facility) is used.

p. *Composting facility (317): A facility for the biological stabilization of waste organic material.*

The purpose is to treat waste organic material biologically by producing a humus-like material that can be recycled as a soil amendment and fertilizer substitute or otherwise used in compliance with all laws, rules, and regulations.

q *Commercial rendering or disposal services*

r. *Incineration*

s. *Approved burial site*

6. Cost Information

The construction costs for large units (Table 2-11) also apply to this measure. The annual operation and maintenance costs average 4 percent of construction costs for diversions, 3 percent of construction costs for settlement basins, and 5 percent of construction costs for retention ponds (DPRA, 1992). Annual costs for repairs, maintenance, taxes, and insurance are estimated to be 5 percent of investment costs for irrigation systems (DPRA, 1992).

[illegible]

Develop, implement, and periodically update a nutrient management plan to: (1) apply nutrients at rates necessary to achieve realistic crop yields, (2) improve the timing of nutrient application, and (3) use agronomic crop production technology to increase nutrient use efficiency. When the source of the nutrients is other than commercial fertilizer, determine the nutrient value and the rate of availability of the nutrients. Determine and credit the nitrogen contribution of any legume crop. Soil and plant tissue testing should be used routinely. Nutrient management plans contain the following core components:

(1) Farm and field maps showing acreage, crops, soils, and waterbodies.

(2) Realistic yield expectations for the crop(s) to be grown, based primarily on the producer's actual yield history, State Land Grant University yield expectations for the soil series, or SCS Soils-5 information for the soil series.

(3) A summary of the nutrient resources available to the producer, which at a minimum include:

- Soil test results for pH, phosphorus, nitrogen, and potassium;
- Nutrient analysis of manure, sludge, mortality compost (birds, pigs, etc.), or effluent (if applicable);
- Nitrogen contribution to the soil from legumes grown in the rotation (if applicable); and
- Other significant nutrient sources (e.g., irrigation water).

(4) An evaluation of field limitations based on environmental hazards or concerns, such as:

- Sinkholes, shallow soils over fractured bedrock, and soils with high leaching potential,
- Lands near surface water,
- Highly erodible soils, and
- Shallow aquifers.

(5) Use of the limiting nutrient concept to establish the mix of nutrient sources and requirements for the crop based on a realistic yield expectation.

(6) Identification of timing and application methods for nutrients to: provide nutrients at rates necessary to achieve realistic crop yields; reduce losses to the environment; and avoid applications as much as possible to frozen soil and during periods of leaching or runoff.

(7) Provisions for the proper calibration and operation of nutrient application equipment.

1. Applicability

This management measure is intended to be applied by States to activities associated with the application of nutrients to agricultural lands. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to minimize edge-of-field delivery of nutrients and minimize leaching of nutrients from the root zone. Nutrient management is pollution prevention achieved by developing a nutrient budget for the crop, applying nutrients at the proper time, applying only the types and amounts of nutrients necessary to produce a crop, and considering the environmental hazards of the site. In cases where manure is used as a nutrient source, manure holding areas may be needed to provide capability to avoid application to frozen soil.

This measure may result in some reduction in the amount of nutrients being applied to the land, thereby reducing the cost of production as well as protecting both ground water and surface water quality. However, application of the measure may in some cases cause more nutrients to be applied where there has not been a balanced use of nutrients in the past. This will usually allow all the nutrients to be used more efficiently, thereby reducing the amount of nutrients that will be available for transport from the field during the non-growing season. While the use of nutrient management should reduce the amount of nutrients lost with surface runoff to some degree, the primary control for the transport of nutrients that are attached to soil particles will be accomplished through the implementation of erosion and sediment control practices (Section II.A of this chapter). For information regarding the potential problems caused by nutrients see Section I.F.1 of this chapter.

Operation and Maintenance for Nutrient Management

The use of a nutrient management plan requires accurate information on the nutrient resources available to the producer. Management practices typically used to obtain this information include periodic soil testing for each field; soil and/or tissue testing during the early growth stages of the crop; and testing of manure, sludge, and irrigation water if they are used. The plan may call for multiple applications of nutrients that require more than one field operation to apply the total nutrients needed by the crop.

A nutrient management plan should be reviewed and updated at least once every 3 years, or whenever the crop rotation is changed or the nutrient source is changed. Application equipment should be calibrated and inspected for wear and damage periodically, and repaired when necessary. Records of nutrient use and sources should be maintained along with other management records for each field. This information will be useful when it is necessary to update or modify the management plan.

3. Management Measure Selection

This management measure was selected as a method (1) to minimize the amount of nutrients entering ground water through root zone leaching and entering surface water from edge-of-field delivery and (2) to promote more efficient use of all sources of nutrients that are available to the producer. The practices and concepts that can be used to implement this measure on a given site are those commonly used and recommended by States and USDA for general use on agricultural lands. By implementing the measure using the necessary mix of practices for a given site there should not be a negative economic impact on the operator, and in most cases the impact will be positive. Many of the practices that can be used to implement this measure may already be required by Federal, State, or local rules (e.g., field borders along streams) or may otherwise be in use on agricultural fields. Since many producers may

R0042640

already be using systems that satisfy or partly satisfy the intent of this management measure, the only action that may be necessary will be to determine the effectiveness of the existing practices and add additional practices, if needed. Use of existing practices will reduce the time, effort, and cost of implementing this measure.

4. Effectiveness Information

Following is a summary of information regarding pollution reductions that can be expected from installation of nutrient management practices.

The State of Maryland estimates that average reductions of 34 pounds of nitrogen and 41 pounds of phosphorus per acre can be achieved through the implementation of nutrient management plans (Maryland Department of Agriculture, 1990). These average reductions may be high because they apply mostly to farms that use animal wastes; average reductions for farms that use only commercial fertilizer may be lower. The reduction in the loading of these nutrients to coastal waters is difficult to measure or predict. Field-scale and watershed models, however, can be used to estimate the reduction in nutrients moving to the edges of fields and to ground water.

As of July 1990, the Chesapeake Bay drainage basin States of Pennsylvania, Maryland, and Virginia reported that approximately 114,300 acres (1.4 percent of eligible cropland in the basin) had nutrient management plans in place (USEPA, 1991a). The average nutrient reductions of total nitrogen and total phosphorus were 31.5 and 37.5 pounds per acre, respectively. The States initially focused nutrient management efforts on animal waste utilization. Because initial planning was focused on animal wastes (which have a relatively high total nitrogen and phosphorus loading factor), estimates of nutrient reductions attributed to nutrient management may decrease as more cropland using only commercial fertilizer is enrolled in the program.

In Iowa, average corn yields remained constant while nitrogen use dropped from 145 pounds per acre in 1985 to less than 130 pounds per acre in 1989 and 1990 as a result of improved nutrient management (Iowa State University, 1991b). In addition, data supplied from nitrate soil tests indicated that at least 32 percent of the soils sampled did not need additional nitrogen for optimal yields (Iowa State University, 1991b).

In a pilot program in Butler County, Iowa, 48 farms operating 25,000 acres reduced fertilizer nitrogen use by 240,000 pounds through setting realistic yield goals by soils, giving appropriate crop rotation and manure credits, and some use of the pre-sidedress soil nitrate test (Hallberg et al., 1991). Other data from Iowa showed that in some areas fields have enough potassium and phosphorus to last for at least another decade (Iowa State University, 1991b).

In Garvin Brook, Minnesota, fertilizer management on corn resulted in nitrogen savings of 29 to 49 pounds per acre from 1985 to 1988 (Wall et al., 1989). In this Rural Clean Water Program (RCWP) project, fertilizer management consisted of split applications and rates based upon previous yields, manure application, previous crops, and soil test results.

Berry and Hargett (1984) showed a 40 percent reduction in statewide nitrogen use over 8 years following introduction of improved fertilizer recommendations in Pennsylvania. Findings from the RCWP project in Pennsylvania indicate that, for 340 nutrient management plans, overall recommended reductions (corn, hay, and other crops) were 27 percent for nitrogen, 14 percent for phosphorus, and 12 percent for potash (USDA-ASCS, 1992a). Producers achieved 79 percent of the recommended nitrogen reductions and 45 percent of the recommended phosphorus reductions.

In Vermont, research suggests that a newly introduced, late spring soil test results in about a 50 percent reduction in the nitrogen recommendation compared to conventional technologies (Magdoff et al., 1984). Research in New York and other areas of the Nation documents fertilizer use reductions of 30 to 50 percent for late spring versus preplant and fall applications, with yields comparable to those of the preplant and fall applications (Bouldin et al., 1971).

VOL 12

USDA reports that improved nutrient management has resulted in nitrogen application reductions of 33.1 pounds/acre treated for surface water protection, 28.4 pounds/acre treated for ground water protection, and 62.1 pounds of phosphorus per acre treated for water quality protection in its 16 Water Quality Demonstration Projects and 74 Hydrologic Unit Areas (USDA, 1992). The Hydrologic Unit Areas begun in 1990 show the greatest reductions in fertilizer use per acre (Table 2-13).

A summary of the effectiveness of nutrient management in controlling nitrogen and phosphorus is given in Table 2-14. This summary is based on an extensive search of the published literature.

Table 2-13. Nutrient Reductions Achieved Under USDA's Water Quality Program (USDA, 1992)

5. Nutrient Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Following are practices, components, and sources of information that should be considered in the development of a nutrient management plan:

(1) Use of soil surveys in determining soil productivity and identifying environmentally sensitive sites.

(2) Use of producer-documented yield history and other relevant information to determine realistic crop yield expectations. Appropriate methods include averaging the three highest yields in five consecutive crop years for the planning site, or other methods based on criteria used in developing the State Land Grant University's nutrient recommendations. In lieu of producer yield histories, university recommendations based on interpretation of SCS Soils-5 data may be used. Increased yields due to the use of new and improved varieties and hybrids should be considered when yield goals are set for a specific site.

(3) Soil testing for pH, phosphorus (Figure 2-11), potassium, and nitrogen (Figure 2-12).

(4) Plant tissue testing.

(5) Manure (Figure 2-13), sludge, mortality compost, and effluent testing.

(6) Use of proper timing, formulation, and application methods for nutrients that maximize plant utilization of nutrients and minimize the loss to the environment, including split applications and banding of the nutrients, use of nitrification inhibitors and slow-release fertilizers, and incorporation or injection of fertilizers, manures, and other organic sources.

(7) Use of small grain cover crops to scavenge nutrients remaining in the soil after harvest of the principal crop, particularly on highly leachable soils. Consideration should be given to establishing a cover crop on land receiving sludge or animal waste if there is a high leaching potential. Sludge and animal waste should be incorporated.

(8) Use of buffer areas or intensive nutrient management practices to manage field limitations based on environmentally high risk areas such as:

- Karst topographic areas containing sinkholes and shallow soils over fractured bedrock;
- Lands near surface water;
- High leaching index soils;
- Irrigated land in humid regions;
- Highly erodible soils;
- Lands prone to surface loss of nutrients; and
- Shallow aquifers.

(9) Control of phosphorus losses from fields through a combination of the Erosion and Sediment Control Measure (Section II.A of this chapter) and the Nutrient Management Measure. Limit manure and sludge applications to phosphorus crop needs when possible, supplying any additional nitrogen needs with nitrogen fertilizers or legumes. If this is not practical, route excess phosphorus in manures or sludge to

PRE-SIDEDRESS SOIL NITROGEN TEST FOR CORN QUICKTEST EVALUATION PROJECT

• SOIL TEST INFORMATION AND REPORT FORM •

Best time to call (8 am - 4:30 pm): ________

Please answer all of the following questions about this field:

1. What is the field ID (name or number)? ____________ Corn Height ________ in.
2. What is the expected yield of the corn crop (bu/A or ton/A) in this field? ________
3. What was the previous crop? ____________________

   If this was a forage legume what was the % stand?

   (check one): ☐ 0-25% ☐ 25-50 % ☐ 50-100%
4. Was manure applied to this field? ☐ Yes ☐ No If "yes" answer the following questions:

   When? ☐ Fall ☐ Spring ☐ Both ☐ Daily

   Type? ☐ Cattle ☐ Poultry ☐ Swine ☐ Horse ☐ Sheep

   Estimate manure rate: _____ tons/acre - OR - _____ gallons/acre

   If incorporated how many days were there between spreading and incorporation? ______
5. What is the tillage program on this field? ☐ Conventional Tillage ☐ Minimum Tillage ☐ No-till
6. What would be your normal N fertilizer application rate for this field? ______ lbs. N/acre

fields that will be rotated into legumes, to other fields that will not receive manure applications the following year, or to sites with low runoff and low soil erosion potential.

(10) A narrative accounting of the nutrient management plan that explains the plan and its use.

6. Cost Information

In general, most of the costs are associated with providing additional technical assistance to landowners to develop nutrient management plans. In many instances landowners can actually save money by implementing nutrient management plans. For example, Maryland has estimated (based on the over 750 nutrient management plans that were completed prior to September 30, 1990) that if plan recommendations are followed, the landowners will save an average of $23 per acre per year (Maryland Dept. of Agriculture, 1990). The average savings may be high because most plans were for farms using animal waste. Future savings may be reduced as more farms using commercial fertilizer are included in the program.

In the South Dakota RCWP project, the total cost (1982-1991) for implementing fertilizer management on 46,571 acres was $50,109, or $1.08 per acre (USDA-ASCS, 1991a). In the Minnesota RCWP project, the average cost for fertilizer management for 1982-1988 was $20 per acre (Wall et al., 1989). Assuming a cost of $0.15 per pound of nitrogen, the savings in fertilizer cost due to improved nutrient management on Iowa corn was about $2.25 per acre as rates dropped from 145 pounds per acre in 1985 to about 130 pounds per acre in 1989 and 1990 (Iowa State University, 1991a).

[illegible] Management [illegible]

To reduce contamination of surface water and ground water from pesticides:

(1) Evaluate the pest problems, previous pest control measures, and cropping history;

(2) Evaluate the soil and physical characteristics of the site including mixing, loading, and storage areas for potential leaching or runoff of pesticides. If leaching or runoff is found to occur, steps should be taken to prevent further contamination;

(3) Use integrated pest management (IPM) strategies that:

(a) Apply pesticides only when an economic benefit to the producer will be achieved (i.e., applications based on economic thresholds); and

(b) Apply pesticides efficiently and at times when runoff losses are unlikely;

(4) When pesticide applications are necessary and a choice of registered materials exists, consider the persistence, toxicity, runoff potential, and leaching potential of products in making a selection;

(5) Periodically calibrate pesticide spray equipment; and

(6) Use anti-backflow devices on hoses used for filling tank mixtures.

1. Applicability

This management measure is intended to be applied by States to activities associated with the application of pesticides to agricultural lands. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to reduce contamination of surface water and ground water from pesticides. The basic concept of the pesticide management measure is to foster effective and safe use of pesticides without causing degradation to the environment. The most effective approach to reducing pesticide pollution of waters is, first, to release fewer pesticides and/or less toxic pesticides into the environment and, second, to use practices that minimize the movement of pesticides to surface water and ground water (Figure 2-14). In addition, pesticides should

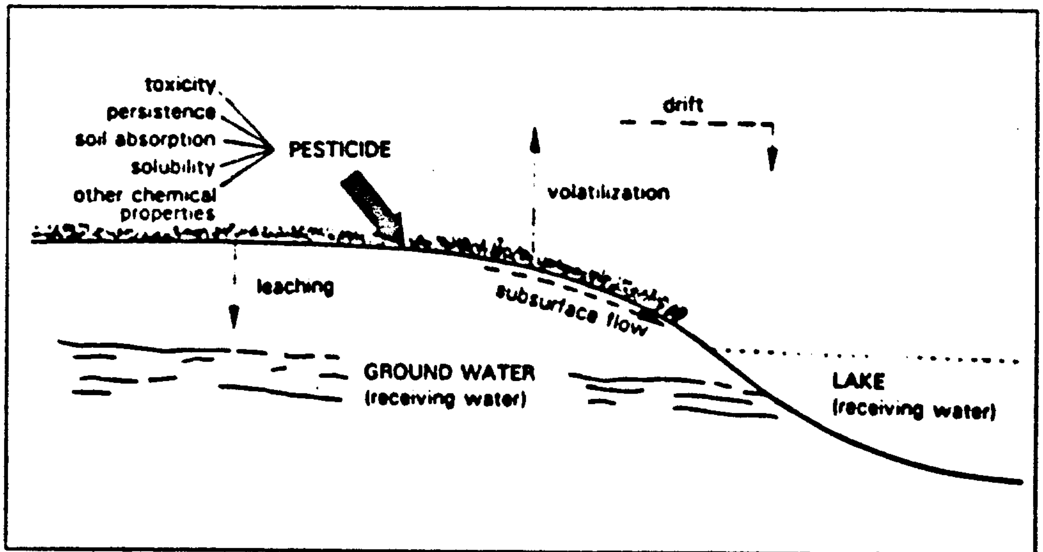

Figure 2-14. Factors affecting the transport and water quality impact of a pesticide (USEPA, 1982).

be applied only when an economic benefit to the producer will be achieved. Such an approach emphasizes using pesticides only when, and to the extent, necessary to control the target pest. This usually results in some reduction in the amount of pesticides being applied to the land, plants, or animals, thereby enhancing the protection of water quality and possibly reducing production costs as well.

The pesticide management measures identify a series of steps or thought processes that producers should use in managing pesticides. First, the pest problems, previous pest control measures, and cropping history should be evaluated. Then the physical characteristics of the soil and the site—including mixing, loading, and storage areas—should be evaluated for potential leaching and/or runoff potential. Integrated pest management (IPM) strategies should be used to minimize the amount of pesticides applied. It is understood that IPM practices are not available for some commodities or in certain regions. An effective IPM strategy should call for pesticide applications only when an economic benefit to the producer will be achieved. In addition, pesticides should be applied efficiently and at times when runoff losses are unlikely.

When pesticide applications are necessary and a choice of materials exists, producers are encouraged to choose the most environmentally benign pesticide products. Users must apply pesticides in accordance with the instructions on the label of each pesticide product. Labels include a number of requirements including allowable use rates; whether the pesticide is classified as "restricted use" for application only by certified and trained applicators; safe handling, storage, and disposal requirements; whether the pesticide can be used only under the provisions of an approved Pesticide State Management Plan; and other requirements. If label requirements include use only under an approved Pesticide State Management Plan, pesticide management measures and practices under the State Coastal Nonpoint Pollution Control Program should be consistent with and/or complement those in EPA-approved Pesticide State Management Plans.

Section 1491 of the 1990 Farm Bill requires users to maintain records of application of restricted use pesticides for a 2-year period after such use. Section 1491 of the 1990 Farm Bill also includes provisions for access to such pesticide records by Federal and State agency staff.

VOL 12

Operation and Maintenance for Pesticide Management

At a minimum, effective pest management requires evaluating past and current pest problems and cropping history; evaluating the physical characteristics of the site; applying pesticides only when an economic benefit to the producer will be achieved; applying pesticides efficiently and at times when runoff losses are unlikely; selecting pesticides (when a choice exists) that are the most environmentally benign; using anti-backflow devices on hoses used for filling tank mixtures; and providing suitable mixing, loading, and storage areas.

Pest management practices should be updated whenever the crop rotation is changed, pest problems change, or the type of pesticide used is changed. Application equipment should be calibrated and inspected for wear and damage each spray season, and repaired when necessary. Anti-backflow devices should also be inspected each spray season and repaired when necessary.

3. Management Measure Selection

This management measure was selected as a method to reduce the amount of pesticides entering ground water and surface water, and to foster effective and safe use of pesticides. The practices and concepts that can be used to implement this measure on a given site are those commonly used and recommended by States and USDA for general use on agricultural lands. When this measure is implemented by using the necessary mix of practices for a given site, there should be a relatively small negative economic impact on the operator's net costs and farm income, and in some cases the impact will be positive (U.S. Environmental Protection Agency, 1992). Many of the practices that can be used to implement this measure may already be required by Federal, State, or local rules, or may otherwise be in use on agricultural fields. Since many producers may already be using systems that satisfy or partly satisfy the intent of this management measure, the only action that may be necessary will be to determine the effectiveness of the existing practices and implement additional practices, if needed. Use of existing practices will reduce the time, effort, and cost of implementing this measure.

4. Effectiveness Information

Following is a summary of available information regarding pollution reductions that can be expected from using various pesticide management practices.

Use of IPM strategies is a key element of the pesticide management measures. Table 2-15 summarizes the findings of several empirical IPM studies on a variety of crops (Virginia Cooperative Extension Service et al., 1987). The summary table indicates that many studies have found IPM to reduce pesticide use. While all these studies indicate a reduction or no change in pesticide use, it is understood that in a small percentage of cases IPM can result in an increased use of pesticides as producers become more aware of what pests are present in the field and then take action to control problems.

Table 2-16 summarizes estimates of reductions in pesticide loss using various management practices and combinations of practices for cotton (North Carolina State University, 1984). These estimates are made at the field level as compared with a hypothetical field using cropping practices that were typical until the late 1970s. The uncertainty of the estimates is a function of the rapid transitions in production methods coupled with the variance among regions and seasons. Traditional sediment and erosion control practices are not as effective on cotton as on corn and soybeans because much cotton is grown on relatively flat land with little or no water erosion problem (Heimlich and Bills, 1984).

Table 2-17 summarizes the estimates of pesticide loss reductions from various management practices and combinations of practices for corn (North Carolina State University, 1984). These estimates are also made at the field level as compared with a hypothetical field using conventional, traditional, or typical cropping practices, realizing that these practices may vary considerably between geographic regions.

Banding of herbicide applications is one of the more recent and promising methods of reducing herbicide applications to corn (NRDC, 1991). Instead of applying herbicides to the entire row, herbicides are applied in a band near to the corn plant. One 3-year study conducted in Iowa on two fields of corn and one of soybeans monitored the effect of different herbicide treatments on yields and herbicide concentrations in tile-drainage water. Over the 3-year period, corn acreage with banded treatments produced equal or slightly higher yields than acreage receiving broadcast herbicides (Baker, 1988). Analysis of water samples for herbicide residues in water beneath herbicide-treated areas revealed that, during this 3-year period, atrazine was detected more often and at higher concentrations in the areas where atrazine was broadcast. Banding of herbicides means, however, that farmers have to rely more extensively on mechanical tillage and cultivation to control weeds.

Table 2-16. Estimates of Potential Reductions in Field Losses of Pesticides for Cotton Compared to a Conventionally and/or Traditionally Cropped Field[a] (North Carolina State University, 1984)

Management Practice	Transport Route(s)	Range of Pesticide Loss Reduction (%)[b]
SWCPs		
Terracing	SR and SL	0 - (20)[c]
Contouring	SR and SL	0 - (20)[c]
Reduced Tillage	SR and SL	-40 - +20 AB
Grassed Waterways	SR and SL	0 - 10 AB
Sediment Basins	SR	0 - 10 AB
Filter Strips	SR	0 - 10 A
Cover Crops	SR and SL	-20 - +10 B
Optimal Application Techniques[d]	All Routes[e]	40 - 80 A
Nonchemical Methods	All Routes	
Scouting Economic Thresholds	All Routes	40 - 65 A 0 - 30 B
Crop Rotations	All Routes	0 - 20 A 10 - 30 B
Pest-Resistant Varieties	All Routes	0 - 80 A 0 - 30 B
Alternative Pesticides	All Routes	80 - 95 A 0 - 20 B

SR = surface runoff
SL = soil leaching

[a] The hypothetical traditionally cropped comparison field uses the following management system:
(1) conventional tillage without other soil and water conservation practices;
(2) aerial application of all pesticides with timing based only on field operation convenience;
(3) ten insecticide treatments annually with a total application of 12 kg/ha based on a prescribed schedule;
(4) cotton grown in 3 out of 4 years; and
(5) long-season cotton varieties.

[b] Assumes field loss reductions are proportional to application rate reductions.
A = insecticides (toxaphene, methylparathion, synthetic pyrethroids).
B = herbicides (trifluralin, fluometron).
Ranges allow for variation in production region, climate, slope and soils.

[c] Refers to estimated increases in movement through soil profile.

[d] Defined for cotton as ground application using optimal droplet or granular size ranges with spraying restricted to calm periods in late afternoon or at night when precipitation is not imminent.

[e] Particularly drift and volatilization.

Table 2-17. Estimates of Potential Reductions in Field Losses of Pesticides for Corn Compared to a Conventionally and/or Traditionally Cropped Field[a] (North Carolina State University, 1984)

Management Practice	Transport Route(s) Affected	Range of Pesticide Loss Reduction (%)[b]
SWCPs	SR and/or SL([c])	
Terracing	SR and/or SL	40 - 75 AB (25[c])
Contouring	SR and/or SL	15 - 55 AB (20[c])
No-till	SR and/or SL	-10 - +40 B 60 - +10 A (10[c])
Other Reduced Tillage	SR and/or SL	-10 - +60 B -40 - +20 A (15[c])
Grassed Waterways	SR	-10 - 20 AB
Sediment Basins	SR	0 - 10 AB
Filter Strips	SR	0 - 10 AB
Cover Crops	SR and/or SL	0 - 20 B[d]
Optimal Application Techniques[e]	All Routes[f]	10 - 20 20 - 40 B
Nonchemical Methods	All Routes	
Adequate Monitoring	All Routes	40 - 66 A
Crop Rotations	All Routes	40 - 70 A 10 - 30 B

SR = surface runoff
SL = soil leaching

[a] The hypothetical field used as the basis for comparison uses the following management system:
(1) conventional tillage without other soil and water conservation practices;
(2) ground application with timing based only on field operation convenience;
(3) little or no pest monitoring; spraying on prescribed schedule; and
(4) corn grown in 3 out of 4 years.

[b] Assumes field loss reductions are proportional to application rate reductions.
A = insecticides (carbofuran and organophosphates)
B = herbicides (Triazine, Alachlor, Butylate, Parquat)
Ranges allow for variation in climate, slope, soils, and types of pesticides used. Ranges for no-till and reduced-till are derived from a combination of increased application rates and decreased runoff losses.

[c] Refers to estimated increases in movement through soil profile.

[d] Cover crops will affect runoff and leaching losses only for pesticides persistent enough to be available over the non-growing season. In the case of pesticides used on corn only the triazine and anilide herbicides will generally meet this criterion.

[e] Defined here for corn as ground application using optimal droplet or granular size ranges, with spraying restricted to calm periods in late afternoon or evening.

[f] Particularly drift and volatilization.

5. Pesticide Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above. The U.S. Soil Conservation Service practice number and definition are provided for management practices, where available.

■ *a. Inventory current and historical pest problems, cropping patterns, and use of pesticides for each field.*

This can be accomplished by using a farm and field map, and by compiling the following information for each field:

- Crops to be grown and a history of crop production;
- Information on soils types;
- The exact number of acres within each field; and
- Records on past pest problems, pesticide use, and other information for each field.

■ *b. Consider the soil and physical characteristics of the site including mixing, loading and storage areas for potential for the leaching and/or runoff of pesticides.*

In situations where the potential for loss is high, emphasis should be given to practices and/or management practices that will minimize these potential losses. The physical characteristics to be considered should include limitations based on environmental hazards or concerns such as:

- Sinkholes, wells, and other areas of direct access to ground water such as karst topography;
- Proximity to surface water;
- Runoff potential;
- Wind erosion and prevailing wind direction;
- Highly erodible soils;
- Soils with poor adsorptive capacity;
- Highly permeable soils;
- Shallow aquifers; and
- Wellhead protection areas.

■ *c. Use IPM strategies to minimize the amount of pesticides applied.*

Following is a list of IPM strategies:

- Use of biological controls:
    - introduction and fostering of natural enemies;
    - preservation of predator habitats; and
    - release of sterilized male insects;
- Use of pheromones:
    - for monitoring populations;
    - for mass trapping;
    - for disrupting mating or other behaviors of pests; and
    - to attract predators/parasites;
- Use of crop rotations to reduce pest problems;
- Use of improved tillage practices such as ridge tillage;

- Use of cover crops in the system to promote water use and reduce deep percolation of water that contributes to leaching of pesticides into ground water;
- Destruction of pest breeding, refuge, and overwintering sites (this may result in loss of crop residue cover and an increased potential for erosion);[8]
- Use of mechanical destruction of weed seed;[8]
- Habitat diversification;
- Use of allelopathy characteristics of crops;
- Use of resistant crop strains;
- Pesticide application based on economic thresholds, i.e., apply pesticides when an economic threshold level has been reached as opposed to applying pesticides in anticipation of pest problems;
- Use of periodic scouting to determine when pest problems reach the economic threshold on each field;
- Use of less environmentally persistent, toxic, and/or mobile pesticides;
- Use of timing of field operations (planting, cultivating, irrigation, and harvesting) to minimize application and/or runoff of pesticides; and
- Use of more efficient application methods, e.g., spot spraying and banding of pesticides.

■ d. *When pesticide applications are necessary and a choice of materials exists, consider the persistence, toxicity, and runoff and leaching potential of products along with other factors, including current label requirements, in making a selection.*

Users must apply pesticides in accordance with the instructions on the label of each pesticide product and, when required, must be trained and certified in the proper use of the pesticide. Labels include a number of requirements including allowable use rates; classification of pesticides as "restricted use" for application only by certified applicators; safe handling, storage, and disposal requirements; restrictions required by State Pesticide Management Plans to protect ground water; and other requirements. If label requirements include use only under an approved State Pesticide Management Plan, pesticide management measures and practices under the State Coastal Nonpoint Program should be consistent with and/or complement those in approved State Pesticide Management Plans.

■ e. *Maintain records of application of restricted use pesticides (product name, amount, approximate date of application, and location of application of each such pesticide used) for a 2-year period after such use, pursuant to the requirements in section 1491 of the 1990 Farm Bill.*

Section 1491 requires that such pesticide records shall be made available to any Federal or State agency that deals with pesticide use or any health or environmental issue related to the use of pesticides, on the request of such agency. Section 1491 also provides that Federal or State agencies may conduct surveys and record the data from individual applicators to facilitate statistical analysis for environmental and agronomic purposes, but in no case may a government agency release data, including the location from which the data was derived, that would directly or indirectly reveal the identity of individual producers. Section 1491 provides that in the case of Federal agencies, access to records maintained under section 1491 shall be through the Secretary of Agriculture, or the Secretary's designee. This section also provides that State agency requests for access to records maintained under section 1491 shall be through the lead State agency so designated by the State.

Section 1491 includes special access provisions for health care personnel. Specifically, when a health professional determines that pesticide information maintained under this section is necessary to provide medical treatment or first aid to an individual who may have been exposed to pesticides for which the information is maintained, upon request persons required to maintain records under section 1491 shall promptly provide record and available label information to that health professional. In the case of an emergency, such record information shall be provided immediately.

[8] Several IPM strategies listed above emphasize the use of mechanical tillage and removal of crop residue cover. Such IPM strategies may result in some producers being out of compliance with the U.S. Department of Agriculture's requirements for highly erodible land, and such producers may need to consider other IPM strategies on such highly erodible land.

Operators may consider maintaining records beyond those required by section 1491 of the 1990 Farm Bill. For example, operators may want to maintain records of *all* pesticides used for each field, i.e., not just restricted use pesticides. In addition, operators may want to maintain records of other pesticide management activities such as scouting records or other IPM techniques used and procedures used for disposal of remaining pesticides after application.

- f. *Use lower pesticide application rates than those called for by the label when the pest problem can be adequately controlled using such lower rates.*

- g. *Consider the use of organic farming techniques that do not rely on the use of synthetically compounded pesticides.*

- h. *Recalibrate spray equipment each spray season and use anti-backflow devices on hoses used for filling tank mixtures.*

Purchase new, more precise application equipment and other related farm equipment (including improved nozzles, computer sensing to control flow rates, radar speed determination, electrostatic applicators, and precision equipment for banding and cultivating) as replacement equipment is needed.

- i. *Integrated crop management system (Pest Management 595): A total crop management system that promotes the efficient use of pesticide and nutrients in an environmentally sound and economically efficient manner.*

6. Cost Information

In general, most of the costs of implementing the pesticide management measure are program costs associated with providing additional educational programs and technical assistance to producers to evaluate pest management needs and for field scouting during the growing season. Producers may actually save money by implementing IPM strategies as indicated by the data in Table 2-15.

Table 2-15 summarizes the findings of several IPM studies on a variety of crops (Virginia Cooperative Extension Service et al., 1987). This summary table indicates that, in general, IPM reduces pesticide use, increases yields, increases net returns, and decreases economic risk.

Table 2-18 shows that IPM scouting costs vary by crop type and by region (USEPA, 1992). High and low scouting costs are given for major crops in each of the coastal regions. These costs reflect variations in the level of service provided by various crop consultants. For example, in the Great Lakes region, the relatively low cost of $4.95 per acre is based on five visits per season at the request of the producer. Higher cost services include scouting and weekly written reports during the growing seasons. Cost differences may also reflect differences in the size of farms (i.e., number of acres) and distance between farms.

The variations in scouting costs between regions and within regions also occur because of differences in the provider of the service. For example, in some States the Cooperative Extension Service provides scouting services at no cost or for a nominal fee. In other areas of the coastal zone, farmer cooperatives have formed crop management associations to provide scouting and crop fertility/pest management recommendations.

Scouting costs also vary by crop type. For example, the data in Table 2-18 indicate that scouting costs for fresh market vegetables are higher than for all other crop types. Scouting services for high-value cash crops, such as fruits and vegetables, must be very intensive given that pest damage is permanent and may make the crop unmarketable.

Costs for erosion and sediment control and for irrigation management are discussed in Sections II.A and II.F, respectively, of this chapter.

Table 2-18. Estimated Scouting Costs (dollars/acre) by Coastal Region and Crop in the Coastal Zone in 1992 (USEPA, 1992)

	Crop						
Coastal Region	Corn	Soybean	Wheat	Rice	Cotton	Fresh Market Vegetables[a]	Hay[b]
Northeast							
Low	5.50	NA	3.75	—	—	25.00	2.50
High	6.25	NA	4.50	—	—	28.00	2.75
Southeast							
Low	5.00	3.25	3.00	8.00	6.00	30.00	2.00
High	6.00	4.00	3.50	12.00	8.00	35.00	3.00
Gulf Coast							
Low	6.00	4.50	—	5.00	6.00	35.00	—
High	8.00	6.50	—	9.00	9.00	40.00	—
Great Lakes							
Low	4.95	4.25	3.75	—	—	—	4.75
High	5.50	5.00	4.00	—	—	—	5.25
West Coast							
Low	NA	NA	3.50	NA	6.75	32.00	NA
High	NA	NA	5.50	NA	9.30	38.00	NA

NA = not available
— = not applicable
[a] Most fresh market vegetables are produced under a regular spraying schedule.
[b] Scouting costs for hay are based on alfalfa insect inspection. The higher cost in the Great Lakes region includes pesticide and soil sampling.

7. Relationship of Pesticide Management Measure to Other Programs

Under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), EPA registers pesticides on the basis of evaluation of test data showing whether a pesticide has the potential to cause unreasonable adverse effects on humans, animals, or the environment. Data requirements include environmental fate data showing how the pesticide behaves in the environment, which are used to determine whether the pesticide poses a threat to ground water or surface water. If the pesticide is registered, EPA imposes enforceable label requirements, which can include, among other things, maximum rates of application, classification of the pesticide as a "restricted use" pesticide (which restricts use to certified applicators trained to handle toxic chemicals), or restrictions on use practices, including requiring compliance with EPA-approved Pesticide State Management Plans (described below). EPA and the U.S. Department of Agriculture Cooperative Extension Service provide assistance for pesticide applicator and certification training in each State.

FIFRA allows States to develop more stringent pesticide requirements than those required under FIFRA, and some States have chosen to do this. At a minimum, management measures and practices under State Coastal Nonpoint Source Programs must not be less stringent than FIFRA label requirements or any applicable State requirements.

EPA's *Pesticides and Groundwater Strategy* (USEPA, 1991b) describes the policies and regulatory approaches EPA will use to protect the Nation's ground-water resources from risks of contamination by pesticides under FIFRA. The objective of the strategy is the prevention of ground-water contamination by regulating the use of certain pesticides (i.e., use according to EPA-approved labeling) in order to reduce and, if necessary, eliminate releases of the pesticide in areas vulnerable to contamination. Priority for protection will be based on currently used and reasonably expected sources of drinking water supplies, and ground water that is closely hydrogeologically connected to surface waters. EPA will use Maximum Contaminant Levels (MCLs) under the Safe Drinking Water Act as "reference points" for water resource protection efforts when the ground water in question is a current or reasonably expected source of drinking water.

The Strategy describes a significant new role for States in managing the use of pesticides to protect ground water from pesticides. In certain cases, when there is sufficient evidence that a particular use of a pesticide has the potential for ground-water contamination to the extent that it might cause unreasonable adverse effects, EPA may (through the use of existing statutory authority and regulations) limit legal use of the product to those States with an acceptable Pesticide State

Management Plan, approved by EPA. Plans would tailor use to local hydrologic conditions and would address:

- State philosophy;
- Roles and responsibilities of State and local agencies;
- Legal and enforcement authority;
- Basis for assessment and planning;
- Prevention measures;
- Ground-water monitoring;
- Response to detections;
- Information dissemination; and
- Public participation.

In the absence of such an approved plan, affected pesticides could not be legally used in the State.

Since areas to be managed under Pesticide State Management Plans and Coastal Nonpoint Pollution Control Programs can overlap, State coastal zone and nonpoint source agencies should work with the State lead agency for pesticides (or the State agency that has a lead role in developing and implementing the Pesticide State Management Plan) in the development of pesticide management measures and practices under both programs. This is necessary to avoid duplication of effort and conflicting pesticide requirements between programs. Further, ongoing coordination will be necessary since both programs and management measures will evolve and change with increasing technology and data.

Section 1491 of the 1990 Farm Bill requires recordkeeping for restricted use pesticides for a 2-year period after such use. Specifically, records of pesticide applications are to include product name, amount, approximate date of application, and location of application of each pesticide used. Section 1491 also specifies the limitations on access to these records by governmental agencies and health care personnel (see practice "e" under "Pesticide Management Practices" for additional information regarding access to such records).

VOL 12

E. Grazing Management Measure

Protect range, pasture and other grazing lands:

(1) By implementing one or more of the following to protect sensitive areas (such as streambanks, wetlands, estuaries, ponds, lake shores, and riparian zones):

(a) Exclude livestock,
(b) Provide stream crossings or hardened watering access for drinking,
(c) Provide alternative drinking water locations,
(d) Locate salt and additional shade, if needed, away from sensitive areas, or
(e) Use improved grazing management (e.g., herding)

to reduce the physical disturbance and reduce direct loading of animal waste and sediment caused by livestock; *and*

(2) By achieving either of the following on all range, pasture, and other grazing lands not addressed under (1):

(a) Implement the range and pasture components of a Conservation Management System (CMS) as defined in the Field Office Technical Guide of the USDA-SCS (see Appendix 2A of this chapter) by applying the progressive planning approach of the USDA-Soil Conservation Service (SCS) to reduce erosion, or
(b) Maintain range, pasture, and other grazing lands in accordance with activity plans established by either the Bureau of Land Management of the U.S. Department of the Interior or the Forest Service of USDA.

9354

1. Applicability

The management measure is intended to be applied by States to activities on range, irrigated and nonirrigated pasture, and other grazing lands used by domestic livestock. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

Range is those lands on which the native vegetation (climax or natural potential plant community) is predominantly grasses, grasslike plants, forbs, or shrubs suitable for grazing or browsing use. Range includes natural grassland, savannas, many wetlands, some deserts, tundra, and certain forb and shrub communities. Pastures are those lands that are primarily used for the production of adapted, domesticated forage plants for livestock. Other grazing lands include woodlands, native pastures, and croplands producing forages.

The major differences between range and pasture are the kind of vegetation and level of management that each land area receives. In most cases, range supports native vegetation that is extensively managed through the control of livestock rather than by agronomy practices, such as fertilization, mowing, irrigation, etc. Range also includes areas that have been seeded to introduced species (e.g., crested wheatgrass), but which are extensively managed like native range. Pastures are represented by those lands that have been seeded, usually to introduced species (e.g., tall fescue) or in some cases to native plants (e.g., switchgrass), and which are intensively managed using agronomy practices and control of livestock.

2. Description

The focus of the grazing management measure is on the riparian zone, yet the control of erosion from range, pasture, and other grazing lands above the riparian zone is also encouraged. Application of this management measure will reduce the physical disturbance to sensitive areas and reduce the discharge of sediment, animal waste, nutrients, and chemicals to surface waters. For information regarding potential problems caused by grazing, see Sections I.F.2 and I.F.6 of this chapter.

The key options to consider (all are not required by this management measure) when developing a comprehensive grazing management approach at a particular location include the development of one or more of the following:

- Grazing management systems. These systems ensure proper grazing use through:
  - Grazing frequency (includes complete rest);
  - Livestock stocking rates;
  - Livestock distribution;
  - Timing (season of forage use) and duration of each rest and grazing period;
  - Livestock kind and class; and
  - Forage use allocation for livestock and wildlife.
- Proper water and salt supplement facilities.
- Livestock access control.
- Range or pasture rehabilitation.

For any grazing management system to work, it must be tailored to fit the needs of the vegetation, terrain, class or kind of livestock, and particular operation involved.

For both pasture and range, areas should be provided for livestock watering, salting, and shade that are located away from streambanks and riparian zones where necessary and practical. This will be accomplished by managing livestock grazing and providing facilities for water, salt, and shade as needed.

Special attention must be given to grazing management in riparian and wetland areas if management measure objectives are to be met. For purposes of this guidance, riparian areas are defined (Mitsch and Gosselink, 1986; Lowrance et al., 1988) as:

> Vegetated ecosystems along a waterbody through which energy, materials, and water pass. Riparian areas characteristically have a high water table and are subject to periodic flooding and influence from the adjacent waterbody.

The health of the riparian system, and thus the quality of water, is dependent on the use, management, and condition of the related uplands. Therefore, the proper management of riparian and wetland ecosystems will involve the correct management of livestock grazing and other land uses in the total watershed.

Conservation management systems (CMS) include any combination of conservation practices and management that achieves a level of treatment of the five natural resources (i.e., soil, water, air, plants, and animals) that satisfies criteria contained in the Soil Conservation Service (SCS) Field Office Technical Guide (FOTG), such as a resource management system (RMS) or an acceptable management system (AMS). These criteria are developed at the State level, with concurrence by the appropriate SCS National Technical Center (NTC). The criteria are then applied in the provision of field office technical assistance, under the direction of the District Conservationist of SCS. In-state coordination of FOTG use is provided by the Area Conservationist and State Conservationist of SCS.

The range and pasture components of a CMS address erosion control, proper grazing, adequate pasture stand density, and range condition. National (minimum) criteria pertaining to range and pasture under an RMS are applied to achieve environmental objectives, conserve natural resources, and prevent soil degradation.

The practical limits of resource protection under a CMS within any given area are determined through the application of national social, cultural, and economic criteria. With respect to economics, landowners will not be required to implement an RMS if the system is generally too costly for landowners. Instead, landowners may be required to implement a less costly, and less protective, AMS. In some cases, landowner constraints may be such that an RMS or AMS cannot be implemented quickly. In these situations, a "progressive planning approach" may be used to ultimately achieve planning and application of an RMS or AMS. Progressive planning is the incremental process of building a plan on part or all of the planning unit over a period of time. For additional details regarding CMS, RMS, and AMS, see Appendix 2A of this chapter.

3. Management Measure Selection

This management measure was selected based on an evaluation of available information that documents the beneficial effects of improved grazing management (see "Effectiveness Information" below). Specifically, the available information shows that (1) aquatic habitat conditions are improved with proper livestock management; (2) pollution from livestock is decreased by reducing the amount of time spent in the stream through the provision of supplemental water; and (3) sediment delivery is reduced through the proper use of vegetation, streambank protection, planned grazing systems, and livestock management.

4. Effectiveness Information

Hubert et al. (1985) showed in plot studies in Wyoming that livestock exclusion and reductions in stocking rates can result in improved habitat conditions for brook trout (Table 2-19). In this study, the primary vegetation was willows, Pete Creek stocking density was 7.88 ac/AUM (acres per animal unit month), and Cherry Creek stocking density was 10 cows per acre.

Platts and Nelson (1989) used plot studies in Utah to evaluate the effects of livestock exclusion on riparian plant communities and streambanks. Several streambank characteristics that are related to the quality of fish habitat were measured, including bank stability, stream shore depth, streambank angle, undercut, overhang, and streambank alteration. The results clearly show better fish habitat in the areas where livestock were excluded (Table 2-20).

Kauffman et al. (1983) showed that fall cattle grazing decreases the standing phytomass of some riparian plant communities by as much as 21 percent versus areas where cattle are excluded, while causing increases for other plant communities. This study, conducted in Oregon from 1978 to 1980, incorporated stocking rates of 3.2 to 4.2 ac/AUM.

Eckert and Spencer (1987) studied the effects of a three-pasture, rest-rotation management plan on the growth and reproduction of heavily grazed native bunchgrasses in Wyoming. The results indicated that range improvement under this otherwise appropriate rotation grazing system is hindered by heavy grazing. Stocking rates on the study plots ranged from 525 to 742 cow-calf AUMs.

Table 2-19. Grazing Management Influences on Two Brook Trout Streams in Wyoming (Hubert et al., 1985)

	Pete Creek (n=3)		Cherry Creek (n=4)	
Parameter	Heavily Grazed (mean)	Lightly Grazed (mean)	Outside Exclosure (mean)	Inside Exclosure (mean)
Width	2.9	2.2[a]	2.9	2.5[a]
Depth	0.07	0.11[b]	0.08	0.09[a]
Width/depth ratio	43	21	37	28[a]
Coefficient of variation in depth	47.3	66.6[a]	57	71
Percent greater than 22 cm deep	9.0	22.3[b]	6.7	21.0[a]
Percent overhanging bank cover	2.7	30.0[a]	24.0	15.3
Percent overhanging vegetation	0	11.7[a]	8.5	18.0
Percent shaded area	0.7	18.3[a]	23.5	28.0
Percent silt substrate	35	52	22	13[a]
Percent bare soil along banks	19.7	13.3	22.6	12.3[a]
Percent litter along banks	7.0	6.0	10.0	6.8[a]

[a] Indicates statistical significance at p<=0.05.
[b] Indicates statistical significance at p<=0.1.

In a literature review, Van Poollen and Lacey (1979) showed that herbage production was greater for managed grazing versus continuous grazing, greater for moderate versus heavy intensity grazing, and greater for light- versus moderate-intensity grazing.

McDougald et al. (1989) tested the effects of moving supplemental feeding locations on riparian areas of hardwood range in California. With stocking rates of approximately 1 ac/AUM, they found that moving supplemental feeding locations away from water sources into areas with high amounts of forage greatly reduces the impacts of cattle on riparian areas (Table 2-21).

Table 2-20. Streambank Characteristics for Grazed Versus Rested Riparian Areas (Platts and Nelson, 1989)

Streambank Characteristic (unit)	Grazed	Rested
Extent (m)	4.1	2.5
Bank stability (%)	32.0	88.5
Stream-short depth (cm)	6.4	14.9
Bank angle (°)	127.0	81.0
Undercut (cm)	6.4	16.5
Overhang (cm)	1.8	18.3
Streambank alteration (%)	72.0	19.0

Table 2-21. The Effects of Supplemental Feeding Location on Riparian Area Vegetation (McDougald et al., 1989)

Practice	Percentage of riparian area with the following levels of residual dry matter in early October		
	Low	Moderate	High
Supplemental feeding located close to riparian areas:			
1982-85 Range Unit 1	48	39	13
1982-85 Range Unit 8	59	29	12
1986-87 Range Unit 8	54	33	13
Supplemental feeding moved away from riparian area:			
1986-87 Range Unit 1	1	27	72

Miner et al. (1991) showed that the provision of supplemental water facilities reduced the time each cow spent in the stream within 4 hours of feeding from 14.5 minutes to 0.17 minutes (8-day average). This pasture study in Oregon showed that the 90 cows without supplemental water spent a daily average of 25.6 minutes per cow in the stream. For the 60 cows that were provided a supplemental water tank, the average daily time in the stream was 1.6 minutes per cow, while 11.6 minutes were spent at the water tank. Based on this study, the authors expect that decreased time spent in the stream will decrease bacterial loading from the cows.

Tiedemann et al. (1988) studied the effects of four grazing strategies on bacteria levels in 13 Oregon watersheds in the summer of 1984. Results indicate that lower fecal coliform levels can be achieved at stocking rates of about 20 ac/AUM if management for livestock distribution, fencing, and water developments are used (Table 2-22). The study also indicates that, even with various management practices, the highest fecal coliform levels were associated with the higher stocking rates (6.9 ac/AUM) employed in strategy D.

Lugbill (1990) estimates that stream protection in the Potomac River Basin will reduce total nitrogen (TN) and total phosphorus (TP) loads by 15 percent, while grazing land protection and permanent vegetation improvement will reduce TN and TP loads by 60 percent. Owens et al. (1982) measured nitrogen losses from an Ohio pasture under a medium-fertility, 12-month pasture program from 1974 to 1979. The results included no measurable soil loss from three watersheds under summer grazing only, and increased average TN concentrations and total soluble N loads from watersheds under summer grazing and winter feeding versus watersheds under summer grazing only (Table 2-23).

Table 2-22. Bacterial Water Quality Response to Four Grazing Strategies (Tiedemann et al., 1988)

Practice	Geometric Mean Fecal Coliform Count
Strategy A: Ungrazed.	40/L
Strategy B: Grazing without management for livestock distribution; 20.3 ac/AUM.	150/L
Strategy C: Grazing with management for livestock distribution: fencing and water developments; 19.0 ac/AUM.	90/L
Strategy D: Intensive grazing management, including practices to attain uniform livestock distribution and improve forage production with cultural practices such as seeding, fertilizing, and forest thinning; 6.9 ac/AUM.	920/L

Table 2-23. Nitrogen Losses from Medium-Fertility, 12-Month Pasture Program (Owens et al., 1982)

Practice	Soil Loss (kg/ha)	Total Sediment N Transport (kg/ha)	Total N Concentration (mg/l)*	Total Soluble N Transport (kg/ha)*
Summer Grazing Only				
Growing season	—	—	3.7	0.4
Dormant season	—	—	1.8	0.1
Year	—	—	3.0	0.5
Summer Grazing - Winter Feeding				
Growing season	251	1.4	4.9	2.5
Dormant season	1,104	6.6	14.6	11.3
Year	1,355	8.0	10.7	13.8

* Five-year average (1974-1979)

Data from a comparison of the expected effectiveness of various grazing and streambank practices in controlling sedimentation in the Molar Flats Pilot Study Area in Fresno County, California indicate that planned grazing systems are the most effective single practice for reducing sheet and rill erosion (Fresno Field Office, 1979). Streambank protection is expected to be the most effective single practice for reducing streambank erosion. Other practices evaluated are proper grazing use, deferred grazing, emergency seeding, and livestock exclusion.

5. Range and Pasture Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

The U.S. Soil Conservation Service practice number and definition are provided for each management practice, where available. Also included in italics are SCS statements describing the effect each practice has on water quality (USDA-SCS, 1988.)

Grazing Management System Practices

Appropriate grazing management systems ensure proper grazing use by adjusting grazing intensity and duration to reflect the availability of forage and feed designated for livestock uses, and by controlling animal movement through the operating unit of range or pasture. Proper grazing use will maintain enough live vegetation and litter cover to protect the soil from erosion; will achieve riparian and other resource objectives; and will maintain or improve the quality, quantity, and age distribution of desirable vegetation. Practices that accomplish this are:

■ a. *Deferred grazing (352): Postponing grazing or resting grazing land for prescribed period.*

In areas with bare ground or low percent ground cover, deferred grazing will reduce sediment yield because of increased ground cover, less ground surface disturbance, improved soil bulk density characteristics, and greater infiltration rates. Areas mechanically treated will have less sediment yield when deferred to encourage re-vegetation. Animal waste would not be available to the area during the time of deferred grazing and there would be less opportunity for adverse runoff effects on surface or aquifer water quality. As vegetative cover increases, the filtering processes are enhanced, thus trapping more silt and nutrients as well as snow if climatic conditions for snow exist. Increased plant cover results in a greater uptake and utilization of plant nutrients.

b. *Planned grazing system (556): A practice in which two or more grazing units are alternately rested and grazed in a planned sequence for a period of years, and rest periods may be throughout the year or during the growing season of key plants.*

Planned grazing systems normally reduce the system time livestock spend in each pasture. This increases quality and quantity of vegetation. As vegetation quality increases, fiber content in manure decreases which speeds manure decomposition and reduces pollution potential. Freeze-thaw, shrink-swell, and other natural soil mechanisms can reduce compacted layers during the absence of grazing animals. This increases infiltration, increases vegetative growth, slows runoff, and improves the nutrient and moisture filtering and trapping ability of the area.

Decreased runoff will reduce the rate of erosion and movement of sediment and dissolved and sediment-attached substances to downstream water courses. No increase in ground water pollution hazard would be anticipated from the use of this practice.

c. *Proper grazing use (528): Grazing at an intensity that will maintain enough cover to protect the soil and maintain or improve the quantity and quality of desirable vegetation.*

Increased vegetation slows runoff and acts as a sediment filter for sediments and sediment attached substances, uses more nutrients, and reduces raindrop splash. Adverse chemical effects should not be anticipated from the use of this practice.

d. *Proper woodland grazing (530): Grazing wooded areas at an intensity that will maintain adequate cover for soil protection and maintain or improve the quantity and quality of trees and forage vegetation.*

This practice is applicable on wooded areas producing a significant amount of forage that can be harvested without damage to other values. In these areas there should be no detrimental effects on the quality of surface and ground water. Any time this practice is applied there must be a detailed management and grazing plan.

e. *Pasture and hayland management (510): Proper treatment and use of pasture or hayland.*

With the reduced runoff there will be less erosion, less sediment and substances transported to the surface waters. The increased infiltration increases the possibility of soluble substances leaching into the ground water.

Alternate Water Supply Practices

Providing water and salt supplement facilities away from streams will help keep livestock away from streambanks and riparian zones. The establishment of alternate water supplies for livestock is an essential component of this measure when problems related to the distribution of livestock occur in a grazing unit. In most western states, securing water rights may be necessary. Access to a developed or natural water supply that is protective of streambank and riparian zones can be provided by using the stream crossing (interim) technology to build a watering site. In some locations, artificial shade may be constructed to encourage use of upland sites for shading and loafing. Providing water can be accomplished through the following Soil Conservation Service practices and the stream crossing (interim) practice (practice "m") of the following section. Descriptions have been modified to meet CZM needs:

f. *Pipeline (516): Pipeline installed for conveying water for livestock or for recreation.*

Pipelines may decrease sediment, nutrient, organic, and bacteria pollution from livestock. Pipelines may afford the opportunity for alternative water sources other than streams and lakes, possibly keeping the animals away from the stream or impoundment. This will prevent bank destruction with resulting sedimentation, and will reduce animal *waste deposition directly in the water. The reduction of concentrated livestock areas will reduce manure solids, nutrients, and bacteria that accompany surface runoff.*

■ g. Pond (378): A water impoundment made by constructing a dam or an embankment or by excavation of a pit or dugout.

Ponds may trap nutrients and sediment which wash into the basin. This removes these substances from downstream. Chemical concentrations in the pond may be higher during the summer months. By reducing the amount of water that flows in the channel downstream, the frequency of flushing of the stream is reduced and there is a collection of substances held temporarily within the channel. A pond may cause more leachable substance to be carried into the ground water.

■ h. Trough or tank (614): A trough or tank, with needed devices for water control and waste water disposal, installed to provide drinking water for livestock.

By the installation of a trough or tank, livestock may be better distributed over the pasture, grazing can be better controlled, and surface runoff reduced, thus reducing erosion. By itself this practice will have only a minor effect on water quality; however when coupled with other conservation practices, the beneficial effects of the combined practices may be large. Each site and application should be evaluated on their own merits.

■ i. Well (642): A well constructed or improved to provide water for irrigation, livestock, wildlife, or recreation.

When water is obtained, if it has poor quality because of dissolved substances, its use in the surface environment or its discharge to downstream water courses the surface water will be degraded. The location of the well must consider the natural water quality and the hazards of its use in the potential contamination of the environment. Hazard exists during well development and its operation and maintenance to prevent aquifer quality damage from the pollutants through the well itself by back flushing, or accident, or flow down the annular spacing between the well casing and the bore hole.

■ j. Spring development (574): Improving springs and seeps by excavating, cleaning, capping, or providing collection and storage facilities.

There will be negligible long-term water quality impacts with spring developments. Erosion and sedimentation may occur from any disturbed areas during and immediately after construction, but should be short-lived. These sediments will have minor amounts of adsorbed nutrients from soil organic matter.

Livestock Access Limitation Practices

It may be necessary to minimize livestock access to streambanks, ponds or lakeshores, and riparian zones to protect these areas from physical disturbance. This could also be accomplished by establishing special use pastures to manage livestock in areas of concentration. Practices include:

■ k. Fencing (382): Enclosing or dividing an area of land with a suitable permanent structure that acts as a barrier to livestock, big game, or people (does not include temporary fences).

Fencing is a practice that can be on the contour or up and down slope. Often a fence line has grass and some shrubs in it. When a fence is built across the slope it will slow down runoff, and cause deposition of coarser grained materials reducing the amount of sediment delivered downslope. Fencing may protect riparian areas which act as sediment traps and filters along water channels and impoundments.

Livestock have a tendency to walk along fences. The paths become bare channels which concentrate and accelerate runoff causing a greater amount of erosion within the path and where the path/channel outlets into another channel. This can deliver more sediment and associated pollutants to surface waters. Fencing can have the effect of concentrating livestock in small areas, causing a concentration of manure which may wash off into the stream, thus causing surface water pollution.

l. *Livestock exclusion (472): Excluding livestock from an area not intended for grazing.*

Livestock exclusion may improve water quality by preventing livestock from being in the water or walking down the banks, and by preventing manure deposition in the stream. The amount of sediment and manure may be reduced in the surface water. This practice prevents compaction of the soil by livestock and prevents losses of vegetation and undergrowth. This may maintain or increase evapotranspiration. Increased permeability may reduce erosion and lower sediment and substance transportation to the surface waters. Shading along streams and channels resulting from the application of this practice may reduce surface water temperature.

m. *Stream crossing (interim): A stabilized area to provide access across a stream for livestock and farm machinery.*

The purpose is to provide a controlled crossing or watering access point for livestock along with access for farm equipment, control bank and streambed erosion, reduce sediment and enhance water quality, and maintain or improve wildlife habitat.

Vegetative Stabilization Practices

It may be necessary to improve or reestablish the vegetative cover on range and pastures to reduce erosion rates. The following practices can be used to reestablish vegetation:

n. *Pasture and hayland planting (512): Establishing and reestablishing long-term stands of adapted species of perennial, biannual, or reseeding forage plants. (Includes pasture and hayland renovation. Does not include grassed waterways or outlets or cropland.)*

The long-term effect will be an increase in the quality of the surface water due to reduced erosion and sediment delivery. Increased infiltration and subsequent percolation may cause more soluble substances to be carried to ground water.

o. *Range seeding (550): Establishing adapted plants by seeding on native grazing land. (Range does not include pasture and hayland planting.)*

Increased erosion and sediment yield may occur during the establishment of this practice. This is a temporary situation and sediment yields decrease when reseeded area becomes established. If chemicals are used in the reestablishment process, chances of chemical runoff into downstream water courses are reduced if application is applied according to label instructions. After establishment of the grass cover, grass sod slows runoff, acts as a filter to trap sediment, sediment attached substances, increases infiltration, and decreases sediment yields.

p. *Critical area planting (342): Planting vegetation, such as trees, shrubs, vines, grasses, or legumes, on highly erodible or critically eroding areas. (Does not include tree planting mainly for wood products.)*

This practice may reduce soil erosion and sediment delivery to surface waters. Plants may take up more of the nutrients in the soil, reducing the amount that can be washed into surface waters or leached into ground water.

During grading, seedbed preparation, seeding, and mulching, large quantities of sediment and associated chemicals may be washed into surface waters prior to plant establishment.

q. *Brush (and weed) management (314): Managing and manipulating stands of brush (and weeds) on range, pasture, and recreation and wildlife areas by mechanical, chemical, or biological means or by prescribed burning. (Includes reducing excess brush (and weeds) to restore natural plant community balance and manipulating stands of undesirable plants through selective and patterned treatments to meet specific needs of the land and objectives of the land user.)*

Improved vegetation quality and the decrease in runoff from the practice will reduce the amount of erosion and sediment yield. Improved vegetative cover acts as a filter strip to trap the movement of dissolved and sediment attached substances, such as nutrients and chemicals from entering downstream water courses. Mechanical brush management may initially increase sediment yields because of soil disturbances and reduced vegetative cover. This is temporary until revegetation occurs.

r. *Prescribed burning (338): Applying fire to predetermined areas under conditions under which the intensity and spread of the fire are controlled.*

When the area is burned in accordance with the specifications of this practice the nitrates with the burned vegetation will be released to the atmosphere. The ash will contain phosphorous and potassium which will be in a relatively highly soluble form. If a runoff event occurs soon after the burn there is a probability that these two materials may be transported into the ground water or into the surface water. When in a soluble state the phosphorous and potassium will be more difficult to trap and hold in place. When done on range grasses the growth of the grasses is increased and there will be an increased tie-up of plant nutrients as the grasses' growth is accelerated.

Selection of Practices

The selection of management practices for this measure should be based on an evaluation of current conditions, problems identified, quality criteria, and management goals. Successful resource management on range and pasture includes appropriate application of a combination of practices that will meet the needs of the range and pasture ecosystem (i.e., the soil, water, air, plant, and animal (including fish and shellfish) resources) and the objectives of the land user.

For a sound grazing land management system to function properly and to provide for a sustained level of productivity, the following should be considered:

- Know the key factors of plant species management, their growth habits, and their response to different seasons and degrees of use by various kinds and classes of livestock.
- Know the demand for, and seasons of use of, forage and browse by wildlife species.
- Know the amount of plant residue or grazing height that should be left to protect grazing land soils from wind and water erosion, provide for plant regrowth, and provide the riparian vegetation height desired to trap sediment or other pollutants.
- Know the range site production capabilities and the pasture suitability group capabilities so an initial stocking rate can be established.
- Know how to use livestock as a tool in the management of the range ecosystems and pastures to ensure the health and vigor of the plants, soil tilth, proper nutrient cycling, erosion control, and riparian area management, while at the same time meeting livestock nutritional requirements.

- Establish grazing unit sizes, watering, shade and salt locations, etc. to secure optimum livestock distribution and proper vegetation use.
- Provide for livestock herding, as needed, to protect sensitive areas from excessive use at critical times.
- Encourage proper wildlife harvesting to ensure proper population densities and forage balances.
- Know the livestock diet requirements in terms of quantity and quality to ensure that there are enough grazing units to provide adequate livestock nutrition for the season and the kind and classes of animals on the farm/ranch.
- Maintain a flexible grazing system to adjust for unexpected environmentally and economically generated problems.
- Special requirements to protect threatened or endangered species.

6. Cost Information

Much of the cost associated with implementing grazing management practices is due to fencing installation, water development, and system maintenance. Costs vary according to region and type of practice. Generally, the more components or structures a practice requires, the more expensive it is. However, cost-share is usually available from the USDA and other Federal agencies for most of these practices.

a. *Grazing Facilities*

Principal direct costs of providing grazing facilities vary from relatively low variable costs of dispersed salt blocks to higher capital and maintenance costs of supplementary water supply improvements. Improving the distribution of grazing pressure by herding or strategically locating grazing facilities to draw cattle away from streamside areas can result in improved utilization of existing forage.

The availability and feasibility of supplementary water development varies considerably between arid western areas and humid eastern areas, but costs for water development, including spring development and pipeline watering, are similar (Table 2-24).

b. *Livestock Exclusion*

Principal direct costs of livestock exclusion are the capital and maintenance costs for fencing to restrict access to streamside areas or the cost of herders to achieve the same results. In addition, there may be an indirect cost of the forage that is removed from grazing by exclusion.

There is considerable difference between multistrand barbed wire, chiefly used for perimeter fencing and permanent stream exclusion and diversions, and single- or double-strand smoothwire electrified fencing used for stream exclusion and temporary divisions within permanent pastures. The latter may be all that is needed to accomplish most livestock exclusion in smaller, managed pastures in the East (Table 2-25).

c. *Improvement/Reestablishment*

Principal direct costs of improving or reestablishing grazing land include the costs of seed, fertilizer, and herbicides needed to establish the new forage stand and the labor and machinery costs required for preparation, planting, cultivation, and weed control (Table 2-26). An indirect cost may be the forage that is removed from grazing during the reestablishment work and rest for seeding establishment.

d. Overall Costs of the Grazing Management Measure

Since the exact combination of practices needed to implement the management measure depends on site-specific conditions that are highly variable, the overall cost of the measure is best estimated from similar combinations of practices applied under the Agricultural Conservation Program (ACP), Rural Clean Water Program (RCWP), and similar activities. Cost data from the ACP programs are summarized in Table 2-27.

E. Irrigation Water Management

To reduce nonpoint source pollution of surface waters caused by irrigation:

(1) Operate the irrigation system so that the timing and amount of irrigation water applied match crop water needs. This will require, as a minimum: (a) the accurate measurement of soil-water depletion volume and the volume of irrigation water applied, and (b) uniform application of water.

(2) When chemigation is used, include backflow preventers for wells, minimize the harmful amounts of chemigated waters that discharge from the edge of the field, and control deep percolation. In cases where chemigation is performed with furrow irrigation systems, a tailwater management system may be needed.

The following limitations and special conditions apply:

(1) In some locations, irrigation return flows are subject to other water rights or are required to maintain stream flow. In these special cases, on-site reuse could be precluded and would not be considered part of the management measure for such locations.

(2) By increasing the water use efficiency, the discharge volume from the system will usually be reduced. While the total pollutant load may be reduced somewhat, there is the potential for an increase in the concentration of pollutants in the discharge. In these special cases, where living resources or human health may be adversely affected and where other management measures (nutrients and pesticides) do not reduce concentrations in the discharge, increasing water use efficiency would not be considered part of the management measure.

(3) In some irrigation districts, the time interval between the order for and the delivery of irrigation water to the farm may limit the irrigator's ability to achieve the maximum on-farm application efficiencies that are otherwise possible.

(4) In some locations, leaching is necessary to control salt in the soil profile. Leaching for salt control should be limited to the leaching requirement for the root zone.

(5) Where leakage from delivery systems or return flows supports wetlands or wildlife refuges, it may be preferable to modify the system to achieve a high level of efficiency and then divert the "saved water" to the wetland or wildlife refuge. This will improve the quality of water delivered to wetlands or wildlife refuges by preventing the introduction of pollutants from irrigated lands to such diverted water.

(6) In some locations, sprinkler irrigation is used for frost or freeze protection, or for crop cooling. In these special cases, applications should be limited to the amount necessary for crop protection, and applied water should remain on-site.

9359

1. Applicability

This management measure is intended to be applied by States to activities on irrigated lands, including agricultural crop and pasture land (except for isolated fields of less than 10 acres in size that are not contiguous to other irrigated lands); orchard land; specialty cropland; and nursery cropland. Those landowners already practicing effective irrigation management in conformity with the irrigation water management measure may not need to purchase additional devices to measure soil-water depletion or the volume of irrigation water applied, and may not need to expend additional labor resources to manage the irrigation system. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to reduce nonpoint source pollution of surface waters caused by irrigation. For the purposes of this management measure, "harmful amounts" are those amounts that pose a significant risk to aquatic plant or animal life, ecosystem health, human health, or agricultural or industrial uses of the water.

A problem associated with irrigation is the movement of pollutants from the land into ground or surface water. This movement of pollutants is affected by the pathways taken by applied water and precipitation (Figure 2-15); the physical, chemical, and biological characteristics of the irrigated land; the type of irrigation system used; crop type; the degree to which erosion and sediment control, nutrient management, and pesticide management are employed; and the management of the irrigation system (Figure 2-16).

Return flows, runoff, and leachate from irrigated lands may transport the following types of pollutants:

- Sediment and particulate organic solids;
- Particulate-bound nutrients, chemicals, and metals, such as phosphorus, organic nitrogen, a portion of applied pesticides, and a portion of the metals applied with some organic wastes;
- Soluble nutrients, such as nitrogen, soluble phosphorus, a portion of the applied pesticides, soluble metals, salts, and many other major and minor nutrients; and
- Bacteria, viruses, and other microorganisms.

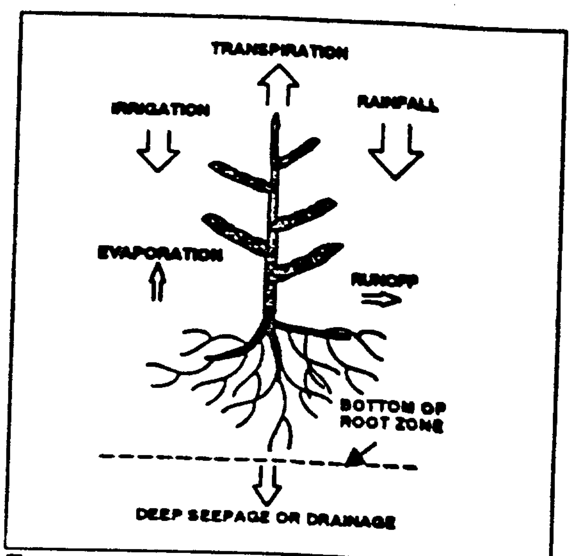

Figure 2-15. Source and fate of water added to a soil system (Evans et al., 1991c).

Transport of irrigation water from the source of supply to the irrigated field via open canals and laterals can be a source of water loss if the canals and laterals are not lined. Water is also transported through the lower ends of canals and laterals because of the flow-through requirements to maintain water levels in them. In many soils, unlined canals and laterals lose water via seepage in bottom and side walls. Seepage water either moves into the ground water through infiltration or forms wet areas near the canal or lateral. This water

VOL 12

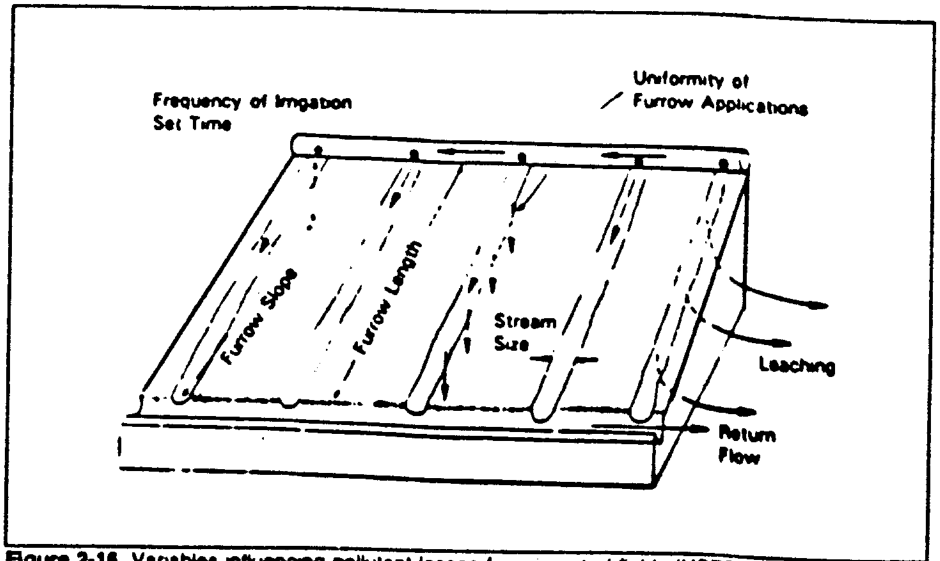

Figure 2-16. Variables influencing pollutant losses from irrigated fields (USEPA, 1982).

will carry with it any soluble pollutants in the soil, thereby creating the potential for pollution of ground or surface water.

Since irrigation is a consumptive use of water, any pollutants in the source waters that are not consumed by the crop (e.g., salts, pesticides, nutrients) can be concentrated in the soil, concentrated in the leachate or seepage, or concentrated in the runoff or return flow from the system. Salts that concentrate in the soil profile must be removed for sustained crop production.

For additional information regarding the problems caused by these pollutants, see Section I.F of this chapter.

Application of this management measure will reduce the waste of irrigation water, improve the water use efficiency, and reduce the total pollutant discharge from an irrigation system. It is not the intent of this management measure to require the replacement of major components of an irrigation system. Instead, the expectation is that components to manage the timing and amount of water applied will be provided where needed, and that special precautions (i.e., backflow preventers, prevent tailwater, and control deep percolation) will be taken when chemigation is used.

Irrigation scheduling is the use of water management strategies to prevent over-application of water while minimizing yield loss due to water shortage or drought stress (Evans et al., 1991d). Irrigation scheduling will ensure that water is applied to the crop when needed and in the amount needed. Effective scheduling requires knowledge of the following factors (Evans et al., 1991c; Evans et al., 1991d):

- Soil properties;
- Soil-water relationships and status;
- Type of crop and its sensitivity to drought stress;
- The stage of crop development;
- The status of crop stress;
- The potential yield reduction if the crop remains in a stressed condition;
- Availability of a water supply; and
- Climatic factors such as rainfall and temperature.

9371

Much of the above information can be found in Soil Conservation Service soil surveys and Extension Service literature. However, all information should be site-specific and verified in the field.

There are three ways to determine when irrigation is needed (Evans et al., 1991d):

- Measuring soil water;
- Estimating soil water using an accounting approach; and
- Measuring crop stress.

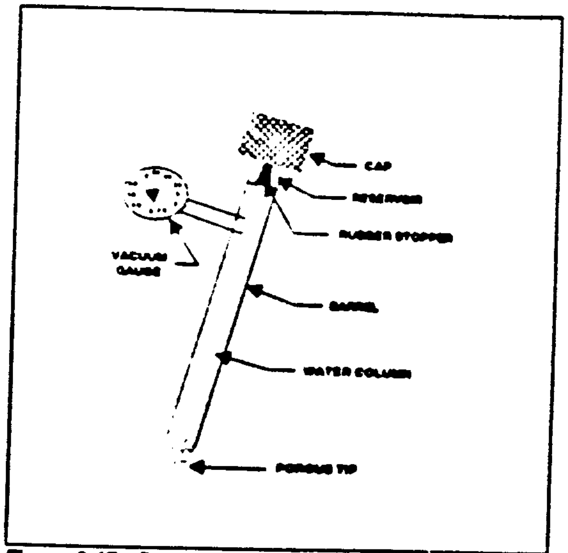

Figure 2-17. Diagram of a tensiometer (Evans et al., 1991b).

Soil water can be measured using a range of devices (Evans et al., 1991b), including tensiometers, which measure soil water suction (Figure 2-17); electrical resistance blocks (also called gypsum blocks or moisture blocks), which measure electrical resistance that is related to soil water by a calibration curve (Figure 2-18); neutron probes, which directly measure soil water; Phene cells, which are used to estimate soil water based on the relationship of heat conductance to soil water content; and time domain reflectometers, which can be used to estimate soil water based on the time it takes for an electromagnetic pulse to pass through the soil. The appropriate device for any given situation is a function of the acreage of irrigated land, soils, cost, and other site-specific factors.

Accounting approaches estimate the quantity of soil water remaining in the effective root zone and can be simple or complex. In essence, daily water inputs and outputs are measured or estimated to determine the depletion volume. Irrigation is typically scheduled when the allowable depletion volume is nearly reached.

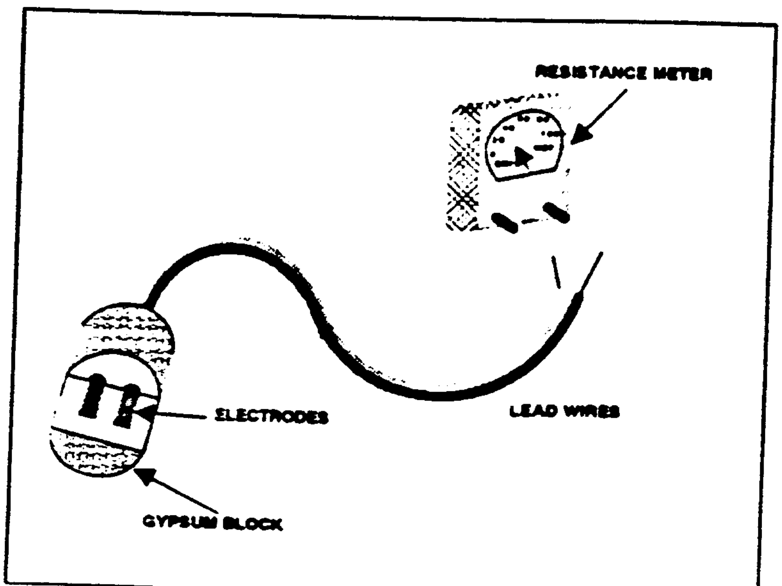

Figure 2-18. Schematic of an electrical resistance block and meter (Evans et al., 1991b).

Once the decision to irrigate has been made, it is important to determine the amount of water to apply. Irrigation needs are a function of the soil water depletion volume in the effective root zone, the rate at which the crop uses water (Figure 2-19), and climatic factors. Accurate measurements of the amount of water applied are essential to maximizing irrigation efficiency. The quantity of water applied

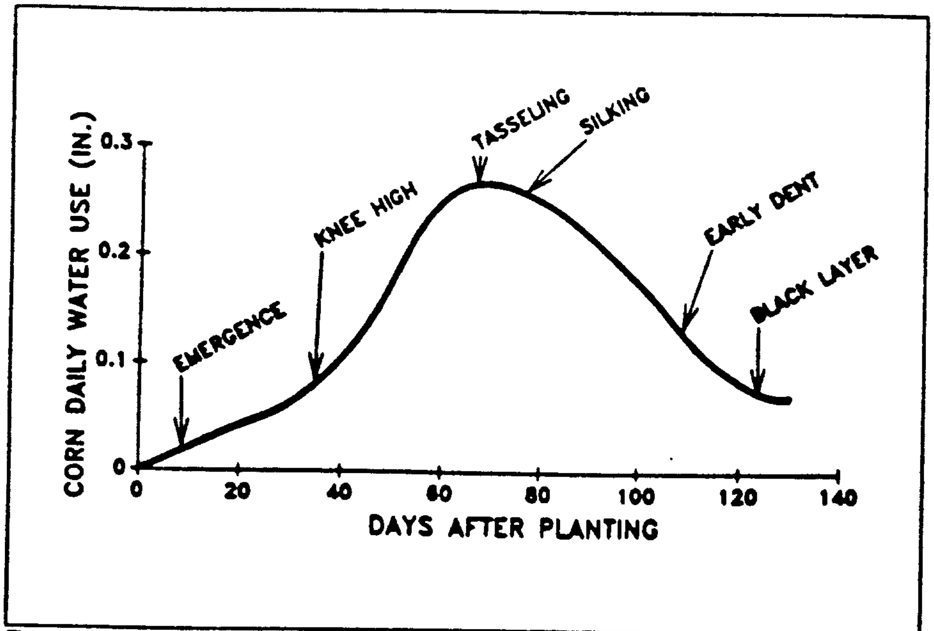

Figure 2-19. Corn daily water use as influenced by stage of development (Evans et al., 1991c).

can be measured by such devices as a totalizing flow meter that is installed in the delivery pipe. If water is supplied by ditch or canal, weirs or flumes in the ditch can be used to measure the rate of flow.

Deep percolation can be greatly reduced by limiting the amount of applied water to the amount that can be stored in the plant root zone. The deep percolation that is necessary for salt management can be accomplished with a sprinkler system by using longer sets or very slow pivot speeds or by applying water during the non-growing season.

Reducing overall water use in irrigation will allow more water for stream flow control and will increase flow for diversion to marshes, wetlands, or other environmental uses. If the source is ground water, reducing overall use will maintain higher ground-water levels, which could be important for maintaining base flow in nearby streams. Reduced water diversion will reduce the salt or pollutant load brought into the irrigation system, thereby reducing the volume of these pollutants that must be managed or discharged from the system.

Although this management measure does not require the replacement of major components of an irrigation system, such changes can sometimes result in greater pollution prevention. Consequently, the following is a broader discussion of the types of design and operational aspects of the overall irrigation system that could be addressed to provide additional control of nonpoint source pollution beyond that which is required by this management measure. Overall, five basic aspects of the irrigation system can be addressed:

(1) Irrigation scheduling;
(2) Efficient application of irrigation water;
(3) Efficient transport of irrigation water;
(4) Use of runoff or tailwater; and
(5) Management of drainage water.

This management measure addresses irrigation scheduling, efficient application, and the control of tailwater when chemigation is used. The efficient transport of irrigation water, the use of runoff or tailwater, and the management of drainage water are additional considerations.

R0042679

VOL 12

9373

Although not a required element of this management measure, the seepage losses associated with canals and laterals can be reduced by lining the canals and laterals, or can be eliminated by conversion from open canals and laterals to pipelines. Flow-through losses will not be changed by canal or lateral lining, but can be eliminated or greatly reduced by conversion to pipelines.

Surface irrigation systems are usually designed to have a percentage (up to 30 percent) of the applied water lost as tailwater. This tailwater should be managed with a tailwater recovery system, but such a system is not required as a component of this management measure unless chemigation is practiced. Tailwater recovery systems usually include a system of ditches or berms to direct water from the end of the field to a small storage structure. Tailwater is stored until it can be either pumped back to the head end of the field and reused or delivered to additional irrigated land. In some locations, there may be downstream water rights that are dependent upon tailwater, or tailwater may be used to maintain flow in streams. These requirements may take legal precedence over the reuse of tailwater.

Well-designed and managed irrigation systems remove runoff and leachate efficiently; control deep percolation; and minimize erosion from applied water, thereby reducing adverse impacts on surface water and ground water. If a tailwater recovery system is used, it should be designed to allow storm runoff to flow through the system without damage. Additional surface drainage structures such as filter strips, field drainage ditches, subsurface drains, and water table control may also be used to control runoff and leachate if site conditions warrant their use. Sprinkler systems will usually require design and installation of a system to remove and manage storm runoff.

A properly designed and operated sprinkler irrigation system should have a uniform distribution pattern. The volume of water applied can be changed by changing the total time the sprinkler runs; by changing the pressure at which the sprinkler operates; or, in the case of a center pivot, by adjusting the speed of travel of the system. There should be no irrigation runoff or tailwater from most well-designed and well-operated sprinkler systems.

The type of irrigation system used will dictate which practices can be employed to improve water use efficiency and to obtain the most benefit from scheduling. Flood systems will generally infiltrate more water at the upper end of the field than at the lower end because water is applied to the upper end of the field first and remains on that portion of the field longer. This will cause the upper end of the field to have greater deep percolation losses than the lower end. Although not required as a component of this management measure, this situation can sometimes be improved by changing slope throughout the length of the field. This type of change may not be practical or affordable in many cases. For example, furrow length can be reduced by cutting the field in half and applying water in the middle of the field. This will require more pipe or ditches to distribute the water across the middle of the field.

3. Management Measure Selection

This management measure was selected based on an evaluation of available information that documents the beneficial effects of improved irrigation management (see Section II.F.4 of this chapter). Specifically, the available information shows that irrigation efficiencies can be improved with scheduling that is based on knowledge of water needs and measurement of applied water. Improved irrigation efficiency can result in the reduction or elimination of runoff and return flows, as well as the control of deep percolation. Secondly, backflow preventers can be used to protect wells from chemicals used in chemigation. In addition, tailwater prevention, or tailwater management where necessary, is effective in reducing the discharge of soluble and particulate pollutants to receiving waters.

By reducing the volume of water applied to agricultural lands, pollutant loads are also reduced. Less interaction between irrigation water and agricultural land will generally result in less pollutant transport from the land and less leaching of pollutants to ground water.

The practices that can be used to implement this measure on a given site are commonly used and are recommended by SCS for general use on irrigated lands. By designing the measure using the appropriate mix of structural and management practices for a given site, there is no undue economic impact on the operator. Many of the practices that can be used to implement this measure (e.g., water-measuring devices, tailwater recovery systems, and backflow preventers) may already be required by State or local rules or may otherwise be in use on irrigated fields. Since many irrigators may already be using systems that satisfy or partly satisfy the intent of the management measure, the only action that may be necessary will be to determine the effectiveness of the existing practices and add additional practices, if needed.

4. Effectiveness Information

Following is information on pollution reductions that can be expected from installation of the management practices outlined within this management measure.

In a review of a wide range of agricultural control practices, EPA (1982) determined that increased use of call periods, on-demand water ordering, irrigation scheduling, and flow measurement and control would all result in decreased losses of salts, sediment, and nutrients (Table 2-28). Various alterations to existing furrow irrigation systems were also determined to be beneficial to water quality, as were tailwater management and seepage control.

Logan (1990) reported that chemical backsiphon devices are highly effective at preventing the introduction of pesticides and nitrogen to ground water. The American Society of Agricultural Engineers (ASAE) specifies safety devices for chemigation that will prevent the pollution of a water supply used solely for irrigation (ASAE, 1989).

Properly designed sprinkler irrigation systems will have little runoff (Boyle Engineering Corp., 1986). Furrow irrigation and border check or border strip irrigation systems typically produce tailwater, and tailwater recovery systems may be needed to manage tailwater losses (Boyle Engineering Corp., 1986). Tailwater can be managed by applying the water to additional fields, by treating and releasing the tailwater, or by reapplying the tailwater to upslope cropland.

The Rock Creek Rural Clean Water Program (RCWP) project in Idaho is the source of much information regarding the benefits of irrigation water management (USDA, 1991). All crops in the Rock Creek watershed are irrigated with water diverted from the Snake River and delivered through a network of canals and laterals. The combined implementation of irrigation management practices, sediment control practices, and conservation tillage has resulted in measured reductions in suspended sediment loadings ranging from 61 percent to 95 percent at six stations in Rock Creek (1981-1988). Similarly, 8 of 10 sub-basins showed reductions in suspended sediment loadings over the same time period. The sediment removal efficiencies of selected practices used in the project are given in Table 2-29.

In California it is expected that drip irrigation will have the greatest irrigation efficiency of those irrigation systems evaluated, whereas conventional furrow irrigation will have the lowest irrigation efficiency and greatest runoff fraction (Table 2-30). Tailwater recovery irrigation systems are expected to have the greatest percolation rate. Plot studies in California have shown that in-season irrigation efficiencies for drip irrigation and Low Energy Precision Application (LEPA) are greater than those for improved furrow and conventional furrow systems (Table 2-31). LEPA is a linear move sprinkler system in which the sprinkler heads have been removed and replaced with tubes that supply water to individual furrows (Univ. Calif., 1988). Dikes are placed in the furrows to prevent water flow and reduce soil effects on infiltrated water uniformity.

Mielke et al. (1981) studied the effects of tillage practice and type of center pivot irrigation on herbicide (atrazine and alachlor) losses in runoff and sediment. Study results clearly show that, for each of three tillage practices studied, low-pressure spray nozzles result in much greater herbicide loss in runoff than either high-pressure or low-pressure impact heads.

5. Irrigation Water Management Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully apply to achieve the management measure described above.

Table 2-28. Summary of Pollutant Impacts of Selected Irrigation Practices[a] (USEPA, 1982)

Practice	Description	T-P[b]	NA-P[c]	T-N[d]	NA-N[e]	A-Pes[f]	NA-Pes[g]	Salts[h]	Sed[i]
Call Period	A minimum length of time allowed to place an order.	-	-	-	-	-	-	-	-
On-Demand Water Ordering	Maximizes scheduling flexibility; however, this encourages less planning.	-/0	-/0	-/0	-/0	-/0	-/0	-/0	-/0
Irrigation Scheduling	Uses meteorological information with soil moisture levels to forecast future irrigations.		-	-	-	-	-	-	-
Conveyance Channel Improvements and Maintenance	Keep canals free of silt deposits and vegetation to maintain capacity. Repair damaged canal banks.	-	-	-	-	-	-	-	-
Improved Management of System Storage	System water storage provides flexibility and efficiency, but it should be minimized to reduce seepage and evaporation.	-	-	-	-	-	-	-	-
Improved Management of Return Flows	Canals should not be operated at capacity at all times with unneeded water spilled into return flows.				-			-	
Seepage Control	Lining canals, ditches, laterals, and watercourses that have high seepage losses with some impermeable material.				-			-	
Flow Measurement and Control	Measure and control flow to ensure adequate application of water while preventing unnecessary and wasteful diversions. To control the flow of water in canals and ditches, structures such as checks, drops, culverts, and field inlet devices are used. Notched weirs or small fiberglass flumes are used to measure the flow of water.	-	-	-	-	-	-	-	-
Cutback Irrigation	Flow volume is adjusted by using a head ditch or delivery pipe, which is adjusted so that a flow is quickly introduced to the end of the furrow and then "cut back" to a "soaking" flow rate. Increases uniformity of application and reduces tailwater, but is only applicable if there is sufficient cross slope.	-	-	-	-	-	-	-	-
Gated Pipe System	Combines features of improved furrow and cutback systems, and can be automatically controlled and coupled with on-demand water availability.	-	-	-	-	-	-	-	-

Practice	Description	T-P[b]	NA-P[c]	T-N[d]	NA-N[e]	A-Pes[f]	NA-Pes[g]	Salts[h]	Sed[i]
Multi-set Irrigation System	Combines features of improved furrow with a shorter length of run by using lateral supply pipes across each field.	-	-	-	-	-	-	-	-
Tailwater Reuse System/Subsurface Drainage	Tile drainage allows collection of surface flows into a water drainage system for control.	-	-	-	-	-	-	-	-
Sprinkler Irrigation	This system includes side-roll, center-pivot, tow-line, and solid-set sprinklers. Sprinkler systems are more efficient than surface irrigation.	-	-	-	-	-	-	-	-
Trickle Irrigation	Water is delivered to individual plants through lines or emitters in order to provide crop plants with nearly optimal soil moisture.	-	-	-	-	-	-	-	-

[a] + = increases in application of control will increase pollutant losses; - = increases in application of control will decrease pollutant losses; 0 = no appreciable effect. Blanks indicate no information presented.
[b] Absorbed phosphorus (total and labile).
[c] Nonabsorbed phosphorus (soluble forms).
[d] Absorbed nitrogen (total N and ammonium).
[e] Nonabsorbed nitrogen (nitrate).
[f] Absorbed pesticide.
[g] Nonabsorbed pesticide.
[h] Salts.
[i] Sediment.

Table 2-29. Sediment Removal Efficiencies and Comments on BMPs Evaluated (USDA, 1991)

Practice	Sediment Removal Efficiency (%)		Comment
	Average	Range	
Sediment basins: field, farm, subbasin	87	75-95	Cleaning costly.
Mini-basins	86[a]	0-95	Controlled outlets essential. Many failed. Careful management required.
Buried pipe systems (incorporating mini-basins with individual outlets into a buried drain)	83	75-95	High installation cost. Potential for increased production to offset costs. Eliminates tailwater ditch. Good control of tailwater.
Vegetative filters	50[a]	35-70	Simple. Proper installation and management needed.
Placing straw in furrows	50	40-80	Labor-intensive without special equipment. Careful management required.

[a] Mean of those that did not fail.

Table 2-30. Expected Irrigation Efficiencies of Selected Irrigation Systems in California (California SWRCB, 1987)

Irrigation System	Irrigation Efficiency (%)	Percolation Fraction (%)	Runoff Fraction (%)
Conventional Furrow	60	17.5	22.5
Gated Pipe	67.5	14.2	18.3
Shorter Run	70	13.3	16.7
Tail Water Recovery	73.2	21.3	5.5
Hand Move Sprinkler	80	8.75	11.3
Lateral Move Sprinkler	87.5	5.5	7.0
Drip	95	4.0	1.0

Table 2-31. Irrigation Efficiencies of Selected Irrigation Systems for Cotton (California SWRCB, 1991)

System	Year	Seasonal Irrigation (in.)	In-Season Distribution Uniformity (%)	In-Season Irrigation Efficiency (%)	In-Season Deep Percolation (in.)
Drip Irrigation	1989	17.82	87	99	2.43
	1990	19.24	81	82	3.98
LEPA (Low Energy Precision Application)	1989	14.21	92	97	2.88
	1990	23.19	92	78.6	6.13
Improved Furrow	1989	20.89	57.5	36	16.9
	1990	16.35	86.5	75.3	6.15
Conventional Furrow	1989	21.26	59.3	36	19.4
	1990	20.00	74	74	9.85

The U.S. Soil Conservation Service practice number and definition are provided for each management practice, where available. Also included in italics are SCS statements describing the effect each practice has on water quality (USDA-SCS, 1988).

Irrigation Scheduling Practices

Proper irrigation scheduling is a key element in irrigation water management. Irrigation scheduling should be based on knowing the daily water use of the crop, the water-holding capacity of the soil, and the lower limit of soil moisture for each crop and soil, and measuring the amount of water applied to the field. Also, natural precipitation should be considered and adjustments made in the scheduled irrigations.

Practices that may be used to accomplish proper irrigation scheduling are:

a. *Irrigation water management (449): Determining and controlling the rate, amount, and timing of irrigation water in a planned and efficient manner.*

Management of the irrigation system should provide the control needed to minimize losses of water, and yields of sediment and sediment attached and dissolved substances, such as plant nutrients and herbicides, from the system. Poor management may allow the loss of dissolved substances from the irrigation system to surface or ground water. Good management may reduce saline percolation from geologic origins. Returns to the surface water system would increase downstream water temperature.

The purpose is to effectively use available irrigation water supply in managing and controlling the moisture environment of crops to promote the desired crop response, to minimize soil erosion and loss of plant nutrients, to control undesirable water loss, and to protect water quality.

To achieve this purpose the irrigator must have knowledge of (1) how to determine when irrigation water should be applied, based on the rate of water used by crops and on the stages of plant growth; (2) how to measure or estimate the amount of water required for each irrigation, including the leaching needs; (3) the normal time needed for the soil to absorb the required amount of water and how to detect changes in intake rate; (4) how to adjust water stream size, application rate, or irrigation time to compensate for changes in such factors as intake rate or the amount of irrigation runoff from an area; (5) how to recognize erosion caused by irrigation; (6) how to estimate the amount of irrigation runoff from an area; and (7) how to evaluate the uniformity of water application.

Tools to assist in achieving proper irrigation scheduling:

b. *Water-measuring device: An irrigation water meter, flume, weir, or other water-measuring device installed in a pipeline or ditch.*

The measuring device must be installed between the point of diversion and water distribution system used on the field. The device should provide a means to measure the rate of flow. Total water volume used may then be calculated using rate of flow and time, or read directly, if a totalizing meter is used.

The purpose is to provide the irrigator the rate of flow and/or application of water, and the total amount of water applied to the field with each irrigation.

c. *Soil and crop water use data: From soils information the available water-holding capacity of the soil can be determined along with the amount of water that the plant can extract from the soil before additional irrigation is needed.*

Water use information for various crops can be obtained from various USDA publications.

The purpose is to allow the water user to estimate the amount of available water remaining in the root zone at any time, thereby indicating when the next irrigation should be scheduled and the amount of water needed. Methods to measure or estimate the soil moisture should be employed, especially for high-value crops or where the water-holding capacity of the soil is low.

Practices for Efficient Irrigation Water Application

Irrigation water should be applied in a manner that ensures efficient use and distribution, minimizes runoff or deep percolation, and eliminates soil erosion.

The method of irrigation employed will vary with the type of crop grown, the topography, and soils. There are several systems that, when properly designed and operated, can be used as follows:

d. *Irrigation system, drip or trickle (441): A planned irrigation system in which all necessary facilities are installed for efficiently applying water directly to the root zone of plants by means of applicators* (orifices, emitters, porous tubing, or perforated pipe) operated under low pressure (Figure 2-20). The applicators can be placed on or below the surface of the ground (Figure 2-21).

Surface water quality may not be significantly affected by transported substances because runoff is largely controlled by the system components (practices). Chemical applications may be applied through the system. Reduction of runoff will result in less sediment and chemical losses from the field during irrigation. If excessive, local, deep percolation should occur, a chemical hazard may exist to shallow ground water or to areas where geologic materials provide easy access to the aquifer.

e. Irrigation system, sprinkler (442): A planned irrigation system in which all necessary facilities are installed for efficiently applying water by means of perforated pipes or nozzles operated under pressure.

Proper irrigation management controls runoff and prevents downstream surface water deterioration from sediment and sediment attached substances. Over irrigation through poor management can produce impaired water quality in runoff as well as ground water through increased percolation. Chemigation with this system allows the operator the opportunity to mange nutrients, wastewater and pesticides. For example, nutrients applied in several incremental applications based on the plant needs may reduce ground water contamination considerably, compared to one application during planting. Poor management may cause pollution of surface and ground water. Pesticide drift from chemigation may also be hazardous to vegetation, animals, and surface water resources. Appropriate safety equipment, operation and maintenance of the system is needed with chemigation to prevent accidental environmental pollution or backflows to water sources.

f. Irrigation system, surface and subsurface (443): A planned irrigation system in which all necessary water control structures have been installed for efficient distribution of irrigation water by surface means, such as furrows, borders, contour levees, or contour ditches, or by subsurface means.

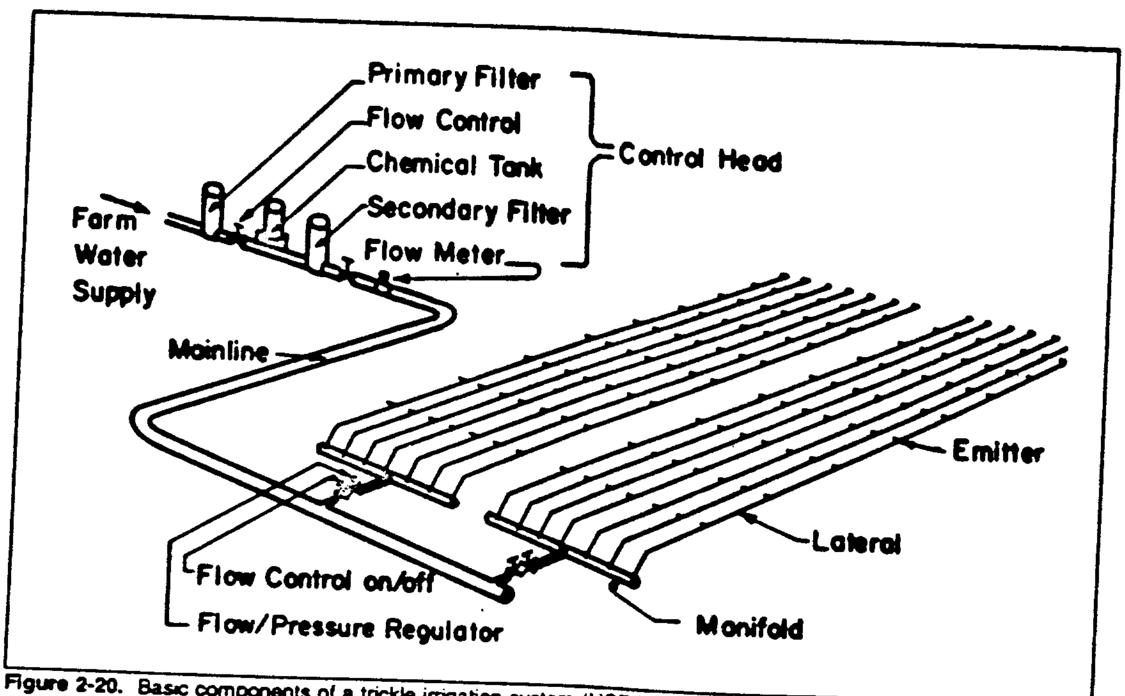

Figure 2-20. Basic components of a trickle irrigation system (USDA-SCS, 1984).

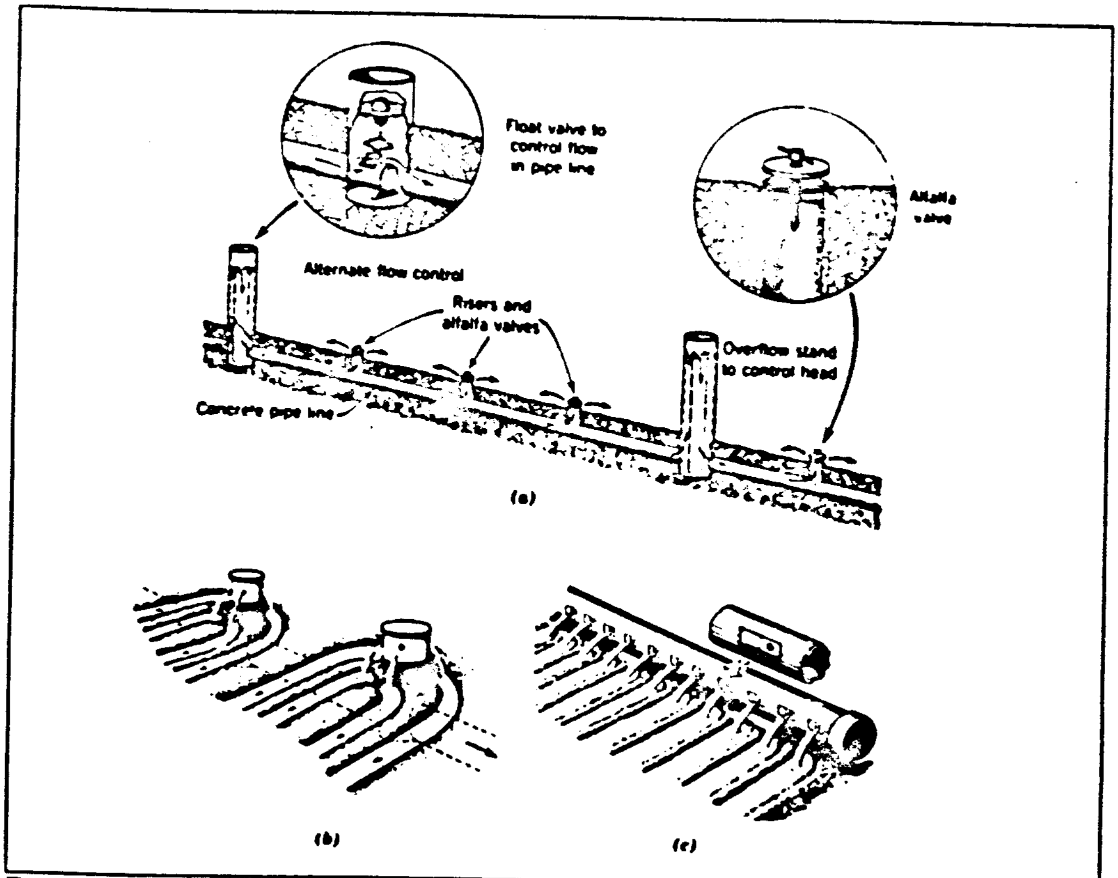

Figure 2-21. Methods of distribution of irrigation water from (a) low-pressure underground pipe, (b) multiple-outlet risers, and (c) portable gated pipe (Schwab et al., 1981).

Operation and management of the irrigation system in a manner which allows little or no runoff may allow small yields of sediment or sediment-attached substances to downstream waters. Pollutants may increase if irrigation water management is not adequate. Ground water quality from mobile, dissolved chemicals may also be a hazard if irrigation water management does not prevent deep percolation. Subsurface irrigation that requires the drainage and removal of excess water from the field may discharge increased amounts of dissolved substances such as nutrients or other salts to surface water. Temperatures of downstream water courses that receive runoff waters may be increased. Temperatures of downstream waters might be decreased with subsurface systems when excess water is being pumped from the field to lower the water table. Downstream temperatures should not be affected by subsurface irrigation during summer months if lowering the water table is not required. Improved aquatic habitat may occur if runoff or seepage occurs from surface systems or from pumping to lower the water table in subsurface systems.

■ g. *Irrigation field ditch (388): A permanent irrigation ditch constructed to convey water from the source of supply to a field or fields in a farm distribution system.*

The standard for this practice applies to open channels and elevated ditches of 25 ft^3/second or less capacity formed in and with earth materials.

Irrigation field ditches typically carry irrigation water from the source of supplying to a field or fields. Salinity changes may occur in both the soil and water. This will depend on the irrigation water quality, the level of water management, and the geologic materials of the area. The quality of ground and surface water may be altered depending on environmental conditions. Water lost from the irrigation system to downstream runoff may contain dissolved substances, sediment, and sediment-attached substances that may degrade water quality and increase water temperature. This practice may make water available for wildlife, but may not significantly increase habitat.

h. *Irrigation land leveling (464): Reshaping the surface of land to be irrigated to planned grades.*

The effects of this practice depend on the level of irrigation water management. If plant root zone soil water is properly managed, then quality decreases of surface and ground water may be avoided. Under poor management, ground and surface water quality may deteriorate. Deep percolation and recharge with poor quality water may lower aquifer quality. Land leveling may minimize erosion and when runoff occurs concurrent sediment yield reduction. Poor management may cause an increase in salinity of soil, ground and surface waters. High efficiency surface irrigation is more probable when earth moving elevations are laser controlled.

Practices for Efficient Irrigation Water Transport

Irrigation water transportation systems that move water from the source of supply to the irrigation system should be designed and managed in a manner that minimizes evaporation, seepage, and flow-through water losses from canals and ditches. Delivery and timing need to be flexible enough to meet varying plant water needs throughout the growing season.

Transporting irrigation water from the source of supply to the field irrigation system can be a significant source of water loss and cause of degradation of both surface water and ground water. Losses during transmission include seepage from canals and ditches, evaporation from canals and ditches, and flow-through water.[9] The primary water quality concern is the development of saline seeps below the canals and ditches and the discharge of saline waters. Another water quality concern is the potential for erosion caused by the discharge of flow-through water. Practices that are used to ensure proper transportation of irrigation water from the source of supply to the field irrigation system *can be found in the USDA-SCS Handbook of Practices, and include: irrigation water conveyance, ditch and canal lining (428); irrigation water conveyance, pipeline (430); and structure for water control (587).*

Practices for Utilization of Runoff Water or Tailwater

The utilization of runoff water to provide additional irrigation or to reduce the amount of water diverted increases the efficiency of use of irrigation water. For surface irrigation systems that require runoff or tailwater as part of the design and operation, a tailwater management practice needs to be installed and used. The practice is described as follows:

i. *Irrigation system, tailwater recovery (447): A facility to collect, store, and transport irrigation tailwater for reuse in the farm irrigation distribution system.*

The reservoir will trap sediment and sediment attached substances from runoff waters. Sediment and chemicals will accumulate in the collection facility by entrapping which would decrease downstream yields of these substances.

---

[9] Flow-through water is water that is never applied to the land but is needed to maintain hydraulic head in the ditch. Flow-through water is also water transported in excess of delivery requirements, carried to reduce the level of management necessary to adjust flows in the ditch for changed delivery locations and amounts. Typically this water (10 - 35 percent of delivery requirements) is applied to fields as excess flow above the requested or billed amount, or returned to the supply stream as delivery system tailwater. Often credit is given by the regulatory agency for this returned water.

Salts, soluble nutrients, and soluble pesticides will be collected with the runoff and will not be released to surface waters. Recovered irrigation water with high salt and/or metal content will ultimately have to be disposed of in an environmentally safe manner and location. Disposal of these waters should be part of the overall management plan. Although some ground water recharge may occur, little if any pollution hazard is usually expected.

Practices for Drainage Water Management

Drainage water from an irrigation system should be managed to reduce deep percolation, move tailwater to the reuse system, reduce erosion, and help control adverse impacts on surface water and groundwater. A total drainage system should be an integral part of the planning and design of an efficient irrigation system. This may not be necessary for those soils that have sufficient natural drainage abilities.

There are several practices to accomplish this:

■ j. *Filter strip (393): A strip or area of vegetation for removing sediment, organic matter, and other pollutants from runoff and waste water.*

Filter strips for sediment and related pollutants meeting minimum requirements may trap the coarser grained sediment. They may not filter out soluble or suspended fine-grained materials. When a storm causes runoff in excess of the design runoff, the filter may be flooded and may cause large loads of pollutants to be released to the surface water. This type of filter requires high maintenance and has a relative short service life and is effective only as long as the flow through the filter is shallow sheet flow.

Filter strips for runoff form concentrated livestock areas may trap organic material, solids, materials which become adsorbed to the vegetation or the soil within the filter. Often they will not filter out soluble materials. This type of filter is often wet and is difficult to maintain.

Filter strips for controlled overland flow treatment of liquid wastes may effectively filter out pollutants. The filter must be properly managed and maintained, including the proper resting time. Filter strips on forest land may trap coarse sediment, timbering debris, and other deleterious material being transported by runoff. This may improve the quality of surface water and has little effect on soluble material in runoff or on the quality of ground water.

All types of filters may reduce erosion on the area on which they are constructed. Filter strips trap solids from the runoff flowing in sheet flow through the filter. Coarse-grained and fibrous materials are filtered more efficiently than fine-grained and soluble substances. Filter strips work for design conditions, but when flooded or overloaded they may release a slug load of pollutants into the surface water.

■ k. *Surface drainage field ditch (607): A graded ditch for collecting excess water in a field.*

From erosive fields, this practice may increase the yields of sediment and sediment-attached substances to downstream water courses because of an increase in runoff. In other fields, the location of the ditches may cause a reduction in sheet and rill erosion and ephemeral gully erosion. Drainage of high salinity areas may raise salinity levels temporarily in receiving waters. Areas of soils with high salinity that are drained by the ditches may increase receiving waters. Phosphorus loads, resulting from this practice may increase eutrophication problems in ponded receiving waters. Water temperature changes will probably not be significant. Upland wildlife habitat may be improved or increased although the habitat formed by standing water and wet areas may be decreased.

■ l. *Subsurface drain (606): A conduit, such as corrugated plastic tile, or pipe, installed beneath the ground surface to collect and/or convey drainage water.*

Soil water outletted to surface water courses by this practice may be low in concentrations of sediment and sediment-adsorbed substances and that may improve stream water quality. Sometimes the drained soil water is high in the *concentration of nitrates and other dissolved substances and drinking water standards may be exceeded. If drainage water that is high in dissolved substances is able to recharge ground water, the aquifer quality may become impaired. Stream water temperatures may be reduced by water drainage discharge. Aquatic habitat may be altered or enhanced with the increased cooler water temperatures.*

■ *m. Water table control (641): Water table control through proper use of subsurface drains, water control structures, and water conveyance facilities for the efficient removal of drainage water and distribution of irrigation water.*

The water table control practice reduces runoff, therefore downstream sediment and sediment-attached substances yields will be reduced. When drainage is increased, the dissolved substances in the soil water will be discharged to receiving water and the quality of water reduced. Maintaining a high water table, especially during the nongrowing season, will allow denitrification to occur and reduce the nitrate content of surface and ground by as much as 75 percent. The use of this practice for salinity control can increase the dissolved substance loading of downstream waters while decreasing the salinity of the soil. Installation of this practice may create temporary erosion and sediment yield hazards but the completed practice will lower erosion and sedimentation levels. The effect of the water table control of this practice on downstream wildlife communities may vary with the purpose and management of the water in the system.

■ *n. Controlled drainage (335): Control of surface and subsurface water through use of drainage facilities and water control structures.*

The purpose is to conserve water and maintain optimum soil moisture to (1) store and manage infiltrated rainfall for more efficient crop production; (2) improve surface water quality by increasing infiltration, thereby reducing runoff, which may carry sediment and undesirable chemicals; (3) reduce nitrates in the drainage water by enhancing conditions for denitrification; (4) reduce subsidence and wind erosion of organic soils; (5) hold water in channels in forest areas to act as ground fire breaks; and (6) provide water for wildlife and a resting and feeding place for waterfowl.

Practices for Backflow Prevention

■ *o. The American Society of Agricultural Engineers recommends, in standard EP409, safety devices to prevent backflow when injecting liquid chemicals into irrigation systems (ASAE Standards, 1989).*

The process of supplying fertilizers, herbicides, insecticides, fungicides, nematicides, and other chemicals through irrigation systems is known as chemigation. A backflow prevention system will "prevent chemical backflow to the water source" in cases when the irrigation pump shuts down (ASAE, 1989).

Three factors an operator must take into account when selecting a backflow prevention system are the characteristics of the chemical that can backflow, the water source, and the geometry of the irrigation system. Areas of concern include whether injected material is toxic and whether there can be backpressure or backsiphonage (ASAE, 1989; USEPA, 1989b).

Several different systems used as backflow preventers are:

(1) **Air gap.** A physical separation in the pipeline resulting in a loss of water pressure. Effective at end of line service where reservoirs or storage tanks are desired.

(2) **Check valve with vacuum relief and low pressure drain.** Primarily used as an antisiphon device (Figure 2-22).

(3) **Double check valve.** Consists of two single check valves coupled within one body and can handle both backsiphonage and backpressure.

(4) **Reduced pressure principle backflow preventer.** This device can be used for both backsiphonage and backpressure. It consists of a pressure differential relief valve located between two independently acting check valves.

(5) **Atmospheric vacuum breaker.** Used mainly in lawn and turf irrigation systems that are connected to potable water supplies. This system cannot be installed where backpressure persists and can be used only to prevent backsiphonage.

6. Cost Information

A cost of $10 per irrigated acre is estimated to cover investments in flow meters, tensiometers, and soil moisture probes (USEPA, 1992; Evans, 1992). Information from North Carolina indicates that the cost of devices to measure soil water ranges from $3 to $4,500 (Table 2-32). Gypsum blocks and tensiometers are the two most commonly used devices.

For quarter-section center pivot systems, backflow prevention devices cost about $416 per well (Stolzenburg, 1992). This cost (1992 dollars) is for (1) an 8-inch, 2-foot-long unit with a check valve inside ($386) and (2) a one-way injection point valve ($30). Assuming that each well will provide about 800-1,000 gallons per minute, approximately 130 acres will be served by each well. The cost for backflow prevention for center pivot systems then becomes approximately $3.20 per acre. In South Dakota, the cost for an 8-inch standard check valve is about $300, while an 8-inch check valve with inspection points and vacuum release costs about $800 (Goodman, 1992). The latter are required by State law. For quarter-section center pivot systems, the cost for standard check valves ranges from about $1.88 per acre (corners irrigated, covering 160 acres) to $2.31 per acre (circular pattern, covering about 130 acres).

Tailwater can be prevented in sprinkler irrigation systems through effective irrigation scheduling, but may need to be managed in furrow systems. The reuse of tailwater downslope on adjacent fields is a low-cost alternative to tailwater recovery and upslope reuse (Boyle Engineering Corp., 1986). Tailwater recovery systems require a suitable

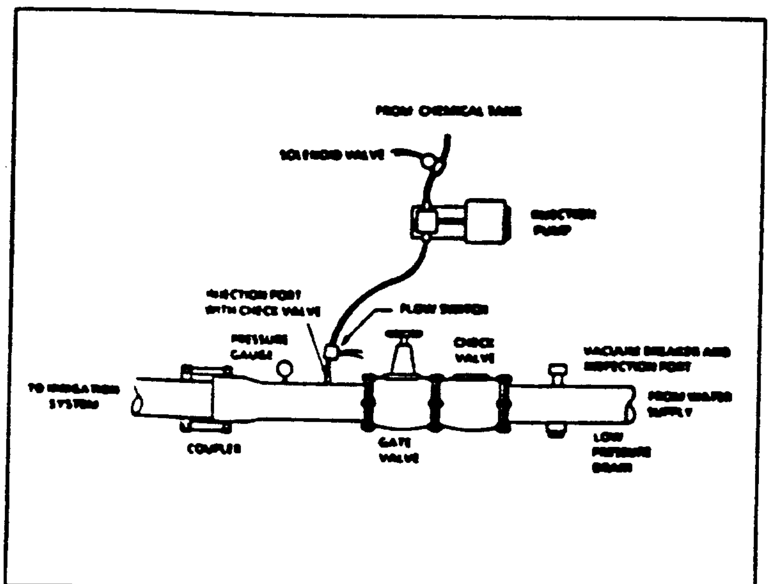

Figure 2-22. Backflow prevention device using check valve with vacuum relief and low pressure drain (ASAE, 1989).

Table 2-32. Cost of Soil Water Measuring Devices

Device	Approximate Cost
Flow meters[a]	$35 to $300, depending on size
Tensiometers[a]	$35 and up, depending on size
Gypsum blocks[a]	$3-4, $200-400 for meter
Neutron Probe[a]	$4,000-4,500
Phene Cell[a]	$4,000-4,500
Flow meters, tensiometers, and soil moisture probes[b]	$10 per irrigated acre

[a] Sneed, 1992.
[b] Evans, 1992.

drainage water receiving facility such as a sump or a holding pond, and a pump and pipelines to return the tailwater for reapplication (Boyle Engineering Corp., 1986). The cost to install a tailwater recovery system was about $125/acre in California (California State Water Resources Control Board, 1987) and $97.00/acre in the Long Pine Creek, Nebraska, RCWP (Hermsmeyer, 1991).

The cost to install irrigation water conservation systems (ASCS practice WC4) for the primary purpose of water conservation in the 33 States that used the practice was about $86.00 per acre served in 1991 (USDA-ASCS, 1992b). Practice WC4 increased the average irrigation system efficiency from 48 percent to 64 percent at an amortized cost of $9.47 per acre foot of water conserved. The components of practice WC4 are critical area planting, canal or lateral, structure for water control, field ditch, sediment basin, grassed waterway or outlet, land leveling, water conveyance ditch and canal lining, water conveyance pipeline, trickle (drip) system, sprinkler system, surface and subsurface system, tailwater recovery, land smoothing, pit or regulation reservoir, subsurface drainage for salinity, and toxic salt reduction. When installed for the primary purpose of water quality, the average installation cost for WC4 was about $52 per acre served. For erosion control, practice WC4 averaged approximately $57 per acre served. Specific cost data for each component of WC4 are not available.

Water management systems for pollution control, practice SP35, cost about $26 per acre served when installed for the primary purpose of water quality (USDA-ASCS, 1992b). When installed for erosion control, SP35 costs about $19 per acre served. The components of SP35 are grass and legumes in rotation, underground outlets, land smoothing, structures for water control, subsurface drains, field ditches, mains or laterals, and toxic salt reduction.

The design lifetimes for a range of salt load reduction measures are presented in Table 2-33 (USDA-ASCS, 1988).

III. GLOSSARY

10-year, 24-hour storm: A rainfall event of 24-hour duration and 10-year frequency that is used to calculate the runoff volume and peak discharge rate to a BMP.

25-year, 24-hour storm: A rainfall event of 24-hour duration and 25-year frequency that is used to calculate the runoff volume and peak discharge rate to a BMP.

Acceptable Management System (AMS): A combination of conservation practices and management that meets resource quality criteria established in the FOTG by the State Conservationist that is feasible within the social, cultural, or economic constraints identified for the resource conditions. It is expected that some degradation may continue to occur for the resource after the AMS is applied (Part 506, Glossary, SCS General Manual).

Adsorption: The adhesion of one substance to the surface of another.

Agronomic practices: Soil and crop activities employed in the production of farm crops, such as selecting seed, seedbed preparation, fertilizing, liming, manuring, seeding, cultivation, harvesting, curing, crop sequence, crop rotations, cover crops, strip-cropping, pasture development, and others (Soil Conservation Society of America, 1982).

Aquifer: A geologic formation or structure that transmits water in sufficient quantity to supply the needs for a water development; usually saturated sands, gravel, fractures, and cavernous and vesicular rock (Soil Conservation Society of America, 1982).

ASCS: Agricultural Stabilization and Conservation Service of USDA.

Animal unit: A unit of measurement for any animal feeding operation calculated by adding the following numbers: the number of slaughter and feeder cattle multiplied by 1.0, plus the number of mature dairy cattle multiplied by 1.4, plus the number of swine weighing over 25 kilograms (approximately 55 pounds) multiplied by 0.4, plus the number of sheep multiplied by 0.1, plus the number of horses multiplied by 2.0 (40 CFR Part 122, Appendix B).

AUM: Animal unit month. A measure of average monthly stocking rate that is the tenure of one animal unit for a period of 1 month. With respect to the literature reviewed for the grazing management measure, an animal unit is a mature, 1,000-pound cow or the equivalent based on average daily forage consumption of 26 pounds of dry matter per day (Platts, 1990). Alternatively, an AUM is the amount of forage that is required to maintain a mature, 1,000-pound cow or the equivalent for a one-month period. See *animal unit* for the NPDES definition.

Backflow prevention device: A safety device used to prevent water pollution or contamination by preventing flow of water and/or chemicals in the opposite direction of that intended (ASAE, 1989).

Best Management Practice (BMP): A practice or combination of practices that are determined to be the most effective and practicable (including technological, economic, and institutional considerations) means of controlling point and nonpoint pollutants at levels compatible with environmental quality goals (Soil Conservation Society of America, 1982).

Broiler: Bird that is raised for its meat production; usually produced in a 7-week period.

Center pivot: Automated sprinkler irrigation achieved by automatically rotating the sprinkler pipe or boom, supplying water to the sprinkler head or nozzle, as a radius from the center of the field to be irrigated (Soil Conservation Society of America, 1982).

Chemigation: The addition of one or more chemicals to the irrigation water.

Chemigated water: Water to which fertilizers or pesticides have been added.

Check valve: A device to provide positive closure that effectively prohibits the flow of material in the opposite direction of normal flow when operation of the irrigation system pumping plant or injection unit fails or is shut down (ASAE, 1989).

Composting: A controlled process of degrading organic matter by microorganisms (Soil Conservation Society of America, 1982).

Conservation management system (CMS): A generic term that includes any combination of conservation practices and management that achieves a level of treatment of the five natural resources that satisfies criteria contained in the Field Office Training Guide (FOTG), such as a resource management system or an acceptable management system (Part 506, Glossary, SCS General Manual).

Cover crop: A close-growing crop grown primarily for the purpose of protecting and improving soil between periods of regular crop production or between trees and vines in orchards and vineyards (Soil Conservation Society of America, 1982).

Crop residue: The portion of a plant or crop left in the field after harvest (Soil Conservation Society of America, 1982).

Crop rotation: The growing of different crops in recurring succession on the same land (Soil Conservation Society of America, 1982).

Defoliant: A herbicide that removes leaves from trees and growing plants (USEPA, 1989a).

Denitrification: The chemical or biochemical reduction of nitrate or nitrite to gaseous nitrogen, either as molecular nitrogen or as an oxide of nitrogen (Soil Conservation Society of America, 1982).

Deposition: The accumulation of material dropped because of a slackening movement of the transporting material—water or wind (Soil Conservation Society of America, 1982).

Desiccant: A chemical agent used to remove moisture from a material or object (Soil Conservation Society of America, 1982).

Dike: An embankment to confine or control water, especially one built along the banks of a river to prevent overflow of lowlands; a levee (Soil Conservation Society of America, 1982).

Diversion: A channel, embankment, or other man-made structure constructed to divert water from one area to another (Soil Conservation Society of America, 1982).

Effluent: Solid, liquid, or gaseous wastes that enter the environment as a by-product of man-oriented processes (Soil Conservation Society of America, 1982).

Empirical: Originating in or relying or based on factual information, observation, or direct sense experience.

EPA: United States Environmental Protection Agency.

Erosion: Wearing away of the land surface by running water, glaciers, winds, and waves. The term erosion is usually preceded by a definitive term denoting the type or source of erosion such as gully erosion, sheet erosion, or bank erosion (Brakensiek et al., 1979).

ES: Extension Service of USDA.

Evaporation: The process by which a liquid is changed to a vapor or gas (Soil Conservation Society of America, 1982).

Fallow: Allowing cropland to lie idle, either tilled or untilled, during the whole or greater portion of the growing season (Soil Conservation Society of America, 1982).

Fertilizer: Any organic or inorganic material of natural or synthetic origin that is added to a soil to supply elements essential to plant growth (Soil Conservation Society of America, 1982).

Field capacity: The soil-water content after the force of gravity has drained or removed all the water it can, usually 1 to 3 days after rainfall (Evans et al., 1991c).

Flume: An open conduit on a prepared grade, trestle, or bridge for the purpose of carrying water across creeks, gullies, ravines, or other obstructions; also used in reference to calibrated devices used to measure the flow of water in open conduits (Soil Conservation Society of America, 1982).

Forb: A broad-leaf herbaceous plant that is not a grass, sedge, or rush.

FOTG: USDA-SCS's Field Office Technical Guide.

Grade: (1) The slope of a road, channel, or natural ground. (2) To finish the surface of a canal bed, roadbed, top of embankment, or bottom of excavation (Soil Conservation Society of America).

Grazing unit: An area of public or private pasture, range, grazed woodland, or other land that is grazed as an entity.

Herbaceous: A vascular plant that does not develop woody tissue (Soil Conservation Society of America, 1982).

Herbicide: A chemical substance designed to kill or inhibit the growth of plants, especially weeds (Soil Conservation Society of America, 1982).

Herding: The guiding of a livestock herd to desired areas or density of distribution.

Holding pond: A reservoir, pit, or pond, usually made of earth, used to retain polluted runoff water for disposal on land (Soil Conservation Society of America, 1982).

Hybrid: A plant resulting from a cross between parents of different species, subspecies, or cultivar (Soil Conservation Society of America, 1982).

Hydrophyte: A plant that grows in water or in wet or saturated soils (Soil Conservation Society of America, 1982).

Incineration: The controlled process by which solids, liquid, or gaseous combustible wastes are burned and changed into gases; the residue produced contains little or no combustible material (Soil Conservation Society of America, 1982).

Inert: A substance that does not react with other substances under ordinary conditions.

Infiltration: The penetration of water through the ground surface into subsurface soil or the penetration of water from the soil into sewer or other pipes through defective joints, connections, or manhole walls (USEPA, 1989a).

Insecticide: A pesticide compound specifically used to kill or control the growth of insects (USEPA, 1989a).

Integrated Pest Management (IPM): A pest population management system that anticipates and prevents pests from reaching damaging levels by using all suitable tactics including natural enemies, pest-resistant plants, cultural management, and the judicious use of pesticides, leading to an economically sound and environmentally safe agriculture.

Irrigation: Application of water to lands for agricultural purposes (Soil Conservation Society of America, 1982).

Irrigation scheduling: The time and amount of irrigation water to be applied to an area.

Karst: A type of topography characterized by closed depressions, sinkholes, underground caverns, and solution channels. See *sinkhole* (Soil Conservation Society of America, 1982).

Lagoon: A reservoir or pond built to contain water and animal wastes until they can be decomposed either by aerobic or anaerobic action (Soil Conservation Society of America, 1982).

Lateral: Secondary or side channel, ditch, or conduit (Soil Conservation Society of America, 1982).

Layer: Bird that is used to produce eggs for broilers, new layers, or consumption.

Leachate: Liquids that have percolated through a soil and that contain substances in solution or suspension (Soil Conservation Society of America, 1982).

Leaching: The removal from the soil in solution of the more soluble materials by percolating waters (Soil Conservation Society of America, 1982).

Legume: A member of a large family that includes many valuable food and forage species, such as peas, beans, peanuts, clovers, alfalfas, sweet clovers, lespedezas, vetches, and kudzu (Soil Conservation Society of America, 1982).

Levee: See *dike*.

Limiting nutrient concept: The application of nutrient sources such that no nutrient (e.g., N, P, K) is applied at greater than the recommended rate.

Livestock: Domestic animals.

Load: The quantity (i.e., mass) of a material that enters a waterbody over a given time interval (Soil Conservation Society of America, 1982).

Manure: The fecal and urinary defecations of livestock and poultry; may include spilled feed, bedding litter, or soil (Soil Conservation Society of America, 1982).

Micronutrient: A chemical element necessary in only extremely small amounts (less than 1 part per million) for the growth of plants (Soil Conservation Society of America, 1982).

NOAA: United States Department of Commerce, National Oceanic and Atmospheric Administration.

Nutrients: Elements, or compounds, essential as raw materials for organism growth and development, such as carbon, nitrogen, phosphorus, etc. (Soil Conservation Society of America, 1982).

Parasites: An organism that lives on or in a host organism during all or part of its existence. Nourishment is obtained at the expense of the host (Soil Conservation Society of America, 1982).

Pasture: Grazing lands planted primarily to introduced or domesticated native forage species that receives periodic renovation and/or cultural treatments such as tillage, fertilization, mowing, weed control, and irrigation. Not in rotation with crops.

Percolation: The downward movement of water through the soil (Soil Conservation Society of America, 1982).

Perennial plant: A plant that has a life span of 3 or more years (Soil Conservation Society of America, 1982).

Permanent wilting point: The soil water content at which healthy plants can no longer extract water from the soil at a rate fast enough to recover from wilting. The permanent wilting point is considered the lower limit of plant-available water (Evans et al., 1991c).

Permeability: The quality of a soil horizon that enables water or air to move through it; may be limited by the presence of one nearly impermeable horizon even though the others are permeable (Soil Conservation Society of America, 1982).

Pesticide: Any chemical agent used for control of plant or animal pests. Pesticides include insecticides, herbicides, fungicides, nematocides, and rodenticides.

Pheromone: A substance secreted by an insect or an animal that influences the behavior or morphological development, or both, of other insects or animals of the same species (Soil Conservation Society of America, 1982).

Plant-available water: The amount of water held in the soil that is available to plants; the difference between field capacity and the permanent wilting point (Evans et al., 1991c).

Pollutant: Dredged spoil, solid waste, incinerator residue, sewage, garbage, sewage sludge, munitions, chemical wastes, biological materials, radioactive materials, heat, wrecked or discarded equipment, rock, sand, cellar dirt, and industrial, municipal, and agricultural waste discharged into water (Section 502(6) of The Clean Water Act as amended by the Water Quality Act of 1987, Pub. L. 100-4).

Range: Land on which the native vegetation (climax or natural potential) is predominantly grasses, grass-like plants, forbs, or shrubs. Includes lands revegetated naturally or artificially when routine management of that vegetation is accomplished mainly through manipulation of grazing. Range includes natural grasslands, savannas, shrublands, most deserts, tundra, alpine communities, coastal marshes, wet meadows, and riparian areas.

Reduced-till: A system in which the primary tillage operation is performed in conjunction with special planting procedures to reduce or eliminate secondary tillage operations (Soil Conservation Society of America, 1982).

Residue: See *crop residue*.

Resource Management System (RMS): A combination of conservation practices and management identified by land or water uses that, when installed, will prevent resource degradation and permit sustained use by meeting criteria established in the FOTG for treatment of soil, water, air, plant, and animal resources (Part 506, Glossary, SCS General Manual).

Return flow: That portion of the water diverted from a stream that finds its way back to the stream channel either as surface or underground flow (Soil Conservation Society of America, 1982).

Riparian area: Vegetated ecosystems along a waterbody through which energy, materials, and water pass. Riparian areas characteristically have a high water table and are subject to periodic flooding and influence from the adjacent waterbody.

Root zone: The part of the soil that is, or can be, penetrated by plant roots (Soil Conservation Society of America, 1982).

Runoff: That part of precipitation, snow melt, or irrigation water that runs off the land into streams or other surface water. It can carry pollutants from the air and land into the receiving waters (USEPA, 1989a).

Salinity: The concentration of dissolved solids or salt in water (Soil Conservation Society of America, 1982).

Savannas: A grassland with scattered trees, either as individuals or clumps; often a transitional type between true grasslands and woodland.

SCS: Soil Conservation Service of USDA.

SCS Soils-5 Information: SCS Soil Interpretation Records data base, which contains a wide variety of soil characteristics and interpretations. Available through the Statistical Laboratory, Iowa State University, Ames, Iowa.

Sediment: The product of erosion processes; the solid material, both mineral and organic, that is in suspension, is being transported, or has been moved from its site of origin by air, water, gravity, or ice (USDA-SCS, 1991).

Sedimentation: The process or act of depositing sediment (Soil Conservation Society of America, 1982).

Seepage: Water escaping through or emerging from the ground along an extensive line or surface as contrasted with a spring, where the water emerges from a localized spot (Soil Conservation Society of America, 1982).

Settleable solids: Solids in a liquid that can be removed by stilling a liquid. Settling times of 1 hour (APHA/AWWA/WPFC, 1975) or more are generally used (Soil Conservation Society of America, 1982).

Sheet flow: Water, usually storm runoff, flowing in a thin layer over the ground surface (Soil Conservation Society of America, 1982).

Silage: A fodder crop that has been preserved in a moist, succulent condition by partial fermentation; such crops include corn, sorghums, legumes, and grasses (Soil Conservation Society of America, 1982).

Sinkhole: A depression in the earth's surface caused by dissolving of underlying limestone, salt, or gypsum; drainage is through underground channels; may be enlarged by collapse of a cavern roof (Soil Conservation Society of America, 1982).

Slope: The degree of deviation of a surface from horizontal, measured as a percentage, as a numerical ratio, or in degrees (Soil Conservation Society of America, 1982).

Sludge: The material resulting from chemical treatment of water, coagulation, or sedimentation (Soil Conservation Society of America, 1982).

Soil profile: A vertical section of the soil from the surface through all its horizons, including C horizons (Soil Conservation Society of America, 1982).

Soil survey: A general term for the systematic examination of soils in the field and in laboratories; their description and classification; the mapping of kinds of soil; the interpretation of soils according to their adaptability for various crops, grasses, and trees; their behavior under use or treatment for plant production or for other purposes; and their productivity under different management systems (Soil Conservation Society of America, 1982).

Soil water depletion volume: The amount of plant-available water removed from the soil by plants and evaporation from the soil surface (Evans et al., 1991c).

Surface water: All water whose surface is exposed to the atmosphere (Soil Conservation Society of America, 1982).

Suspended sediment: The very fine soil particles that remain in suspension in water for a considerable period of time (Soil Conservation Society of America, 1982).

Tailwater: Irrigation water that reaches the lower end of a field (Soil Conservation Society of America, 1982).

Tillage: The operation of implements through the soil to prepare seedbeds and rootbeds, control weeds and brush, aerate the soil, and cause faster breakdown of organic matter and minerals to release plant foods (Soil Conservation Society of America, 1982).

Tilth: The physical condition of the soil as related to its ease of tillage, its fitness as a seedbed, and its impedance to seedling emergence and root penetration (Soil Conservation Society of America, 1982).

Topography: The relative positions and elevations of the natural or man-made features of an area that describe the configuration of its surface (Soil Conservation Society of America, 1982).

USDA: United States Department of Agriculture.

Waste: Material that has no original value or no value for the ordinary or main purpose of manufacture or use; damaged or defective articles of manufacture; or superfluous or rejected matter or refuse (Soil Conservation Society of America, 1982).

Watershed: A drainage area or basin in which all land and water areas drain or flow toward a central collector such as a stream, river, or lake at a lower elevation.

Water table: The upper surface of the ground water or that level below which the soil is saturated with water; locus of points in soil water at which the hydraulic pressure is equal to atmospheric pressure (Soil Conservation Society of America, 1982).

Weir: Device for measuring or regulating the flow of water (Soil Conservation Society of America, 1982).

VOL 12

February 12, 1990

GENERAL MANUAL
450-TCH
AMENDMENT - 4 (PART 401)

SUBJECT: TCH - SCS TECHNICAL GUIDE POLICY

Purpose. To transmit revised Soil Conservation Service (SCS) Field Office Technical Guide (FOTG) policy.

Effective Date. This policy is effective when received.

Background. SCS Field Office Technical Guide policy was revised by 450-GM, Amendment 3, February 1987. As a result of numerous comments received on that policy, the National Technical Guide Committee (NTGC) prepared a draft revision for review by selected states and by technical guide committees at the National Technical Centers. Amendment 4 is the result of comments on the draft.

Explanation. Policy transmitted by this amendment contains guidance by which FOTG are established, changed and maintained. Following are the more important changes from Amendment 3:

1. State and NTC responsibilities in Section 401.01 for maintaining up-to-date information in technical guides have been amplified.

2. The descriptions of the six resource concerns in Section 401.03(b)(3)(iii) have been replaced with descriptions of the five resources: soil, water, air, plants, and animals.

3. Criteria for treatment required to achieve an RMS for each of the five resources have been clearly stated in Section 401.03(b)(iv).

4. The process for developing criteria for treatment required to achieve an Acceptable Management System (AMS), a new concept, has been stated in section 401.03(b)(3)(v).

5. Explanation of the content of the National Handbook for Conservation Practices (NHCP) in Subpart B has been revised to remove redundant statements and clearly states responsibilities for changes in NHCP and for issuance and review of interim standards.

6. Section V of the FOTG, described in section 401.03(b)(5), has been totally revised and is now named "Conservation Effects." Guidance on effects is provided to aid in conservation planning activities.

DIST: GM

9403

VOL 12

9404

Filing Instructions:

1. Remove and discard existing GM 450, Part 401, dated February 1987. (Amendment 3)

2. Replace with the enclosed GM 450, Part 401, dated January 1990.

Directives Cancelled:

1. Remove and discard National Instruction No. 450-301, dated October 5, 1979.

PART 401 - TECHNICAL GUIDES

VOL 12

9405

SUBPART A - POLICY AND RESPONSIBILITIES

401.00 General.

(a) This part states policy for establishing, changing, and maintaining technical guides. It also establishes supporting committees for maintaining those guides.

(b) The Soil Conservation Service (SCS) is responsible for providing national leadership and administration of programs to conserve soil, water, and related resources on the private lands of the Nation. A primary goal is to provide technical assistance to decisionmakers for the planning and implementation of a system of conservation practices and management which achieves a level of natural resource protection that prevents degradation and permits sustainable use. In cases where degradation has already occurred, the goal is to restore the resource to the degree practical to permit sustainable use. Technical guides provide procedures and criteria for the formulation and evaluation of resource management systems which achieve these goals and, when needed, for the formulation and evaluation of acceptable management systems which achieve these goals to the extent feasible.

(c) Technical guides are primary technical references for SCS. They contain technical information about conservation of soil, water, air, and related plant and animal resources. Technical guides used in any office are to be localized so that they apply specifically to the geographic area for which they are prepared. These documents are referred to as Field Office Technical Guides (FOTGs). Appropriate parts of FOTG will be systematically automated as data bases, computer programs, and other electronic-based materials compatible with the Computer Assisted Management and Planning System (CAMPS) are developed.

(d) Technical guides provide:

(1) Soil interpretations and potential productivity within alternative levels of management intensity and conservation treatment;

(2) Technical information for achieving SCS's and the decisionmaker's objectives;

(3) Information for interdisciplinary planning for the conservation of soil, water, and related resources;

(4) A basis for identifying resource management system (RMS) options and, when needed, acceptable management system (AMS) options and components thereof;

(5) Information on effects of resource management systems, acceptable management

systems, and their component practices;

(6) Criteria to evaluate the quality of RMS options, AMS options, and components thereof;

(7) Standards and specifications for conservation practices;

(8) Information for evaluating the economic feasibility of conservation practices and resource management system options;

(9) Information for locating and identifying cultural resources and methods to account for their significance; and

(10) Technical material for training employees.

401.01 Responsibilities.

(a) National Headquarters (NHQ).

(1) The Deputy Chief for Technology has national leadership for policy and procedures for developing and using the FOTG.

(2) The Director, Ecological Sciences Division (ECS), chairs the National Technical Guide Committee (NTGC).

(3) The NTGC makes recommendations to the Deputy Chief for Technology regarding technical guide policy and procedure.

(b) National Technical Centers (NTCs).

(1) NTC directors are responsible for establishing a Technical Guide Committee (TGC) at each NTC.

(2) The TGC provides guidance to states in developing FOTGs.

(3) NTC directors establish procedures to coordinate NTC technical review and concurrence of state developed material that affect either policy or technical aspects in all sections of the FOTG.

(4) The TGC coordinates NTC technical review and concurrence of state developed material as described in (3). The NTC director will inform the state conservationist (STC) of NTC action and comments.

(5) The TGC refers proposed changes in the National Handbook of Conservation Practices (NHCP) to NTGC for action.

(6) NTC provide states with examples of guidance documents for RMS and AMS options, displays of conservation effects, and guidance documents developed to meet specific program requirements. NTC has primary technical oversight.

(7) NTC directors are responsible for coordination and consistency among NTC regions.

(c) State offices.

(1) The state conservationist (STC) is responsible for the development, quality, coordination, use, and maintenance of FOTG in his/her state.

(2) The STC will:

(i) Coordinate FOTG contents across state lines where Major Land Resource Areas are shared to achieve reasonable uniformity between and among states;

(ii) Request appropriate assistance from the NTC director to prepare, revise, and maintain the FOTG and to correlate FOTG contents with adjoining states;

(iii) Submit to the NTC for review and concurrence all state developed materials that affect either policy or technical aspects in all FOTG sections prior to issuance;

(iv) Propose interim standards, variances, or changes in national standards to the NTC director for action;

(v) Establish a state TGC and appoint membership;

(vi) Establish criteria for RMS and AMS with concurrence by the NTC; and

(vii) Establish procedures for maintaining up-to-date data in FOTG. All FOTG material is to be reviewed by the designated state discipline specialist at least once every two years. Material is to be updated as necessary to maintain technical adequacy. Each technical guide subsection described in section 401.03(b) is to contain a table of contents showing the issue date and the date of the last review.

(d) Area offices.

(1) The area conservationist (AC) will:

(i) Coordinate the development, use, and maintenance of FOTG in the field offices supervised;

(ii) Work with the specialists in the state offices to achieve high-quality FOTG; and

(iii) Establish an area-level TGC if necessary.

(e) Field offices.

(1) District conservationists (DC) will:

(i) Take the lead to develop and assemble the FOTG;

(ii) Use and maintain the FOTG in the office(s) they supervise;

(iii) Ensure that all field office technical assistance is based on FOTG contents;

(iv) Identify needed changes and/or additions; and

(v) Request specialist help to make improvements.

(2) All field office employees are responsible for identifying the need for improvements and for informing the DC of those needs.

401.02 National Technical Guide Committee (NTGC).

(a) Membership. The members of the NTGC are:

(1) Director, Ecological Sciences Division (chairperson);
(2) Director, Engineering Division;
(3) Director, Economics and Social Sciences Division;
(4) Director, Soil Survey Division;
(5) Director, Land Treatment Program Division;
(6) Director, Conservation Planning Division;
(7) Director, Watershed Projects Division;
(8) Director, Basin and Area Planning Division;
(9) Director of an NTC (on a 1-year rotation);
(10) Executive Secretary (appointed by the chairperson); and
(11) Chair of National Conservation Practice Standards Subcommittee (NCPSS) (appointed by the NTGC chairperson).
(12) A representative from the Extension Service will be invited to participate in all NTGC meetings.

(b) Responsibilities.

(1) Keep national FOTG policy and procedures current by recommending policy changes to the Deputy Chief for Technology.

(2) Respond to requests for FOTG policy and procedure clarification.
(3) Designate members of the National Conservation Practice Standards Subcommittee.
(4) Act upon recommendations from NCPSS.
(5) Coordinate policy and procedures established to automate FOTG contents and functions in SCS operations.
(6) Create ad hoc subcommittees as necessary.
(7) Receive and act upon requests, recommendations, referrals, and suggestions from the NTC TGC.

(c) NTGC operation.

(1) NTGC will meet quarterly and otherwise as convened by the chairperson.
(2) Materials for consideration by the NTGC will be sent to the chairperson.
(3) Minutes of each meeting will be sent to each member, the Deputy Chiefs for Technology and Programs, and NTC directors.
(4) Matters requiring action will be acted upon within 45 days of receipt.

401.03 Content of technical guides.

(a) Technical guides contain Sections I through V and appropriate subsections. Those sections are:

(1) Section I - General Resource References;

(2) Section II - Soil and Site Information;

(3) Section III - Conservation Management Systems;

(4) Section IV - Practice Standards and Specifications; and

(5) Section V - Conservation Effects.

(b) The following are descriptions of technical guide sections and subsections:

(1) Section I - General Resource References.

This section lists references and other information for use in understanding the field office working area or in making decisions about resource use and management systems. The actual references listed are to be filed to the extent possible in the same location as the FOTG. References kept in other locations will be cross-referenced. The following are subsections of Section I of the FOTG.

(i) Reference lists. These include handbooks, manuals, and reports commonly used in resource conservation planning and implementation activities such as irrigation and drainage guides; the *National List of Scientific Plant Names* (NLSPN); the *National Register of*

VOL 12

9409

VOL 12

Historic Places; published soil surveys; basic water resources information on ground water quality, surface water quality, and water quantity; recreation potential appraisals; natural resource inventories; reports that identify such items as areas susceptible to flooding; river basin reports; seismic zones; and documentation of useful computer models.

(ii) **Cost data.** General reference data on costs, such as cost lists for practice components.

(iii) **Maps.** The SCS National Planning Manual (NPM), Part 507, Exhibits 507.09, contains a list of resource maps that should be included. Water quality problem areas and areas with a potential water quality problem are to be included here.

(iv) **Erosion prediction.** Guidance, data, and SCS approved techniques for predicting soil erosion are to be included here, or appropriately referenced.

(v) **Climatic data.** This subsection contains local climatic data needed for planning conservation management systems and installing conservation practices, such as record low and high temperatures; averages for such items as rainfall, length of growing season, temperatures, wind velocities, hail incidence, and snowfall; water supply data; probability of receiving selected amounts of precipitation by months; and frost-free periods. References should be made to other climatic data in other field office documents.

(vi) **Cultural (archaeological and historic) resource information.** This subsection contains general locational data and documentation suitable for inventory, checking and recording, and conservation planning. The law states that specific locational information, such as site maps, is not to be available to the general public; therefore they should only be referenced in this subsection.

(vii) **Threatened and endangered species list.** This subsection contains information on species of plants and animals that are threatened and endangered and are to be accounted for in conservation planning.

(viii) **Laws.** List of state and local laws, ordinances, or regulations that impact Conservation Management System development and other technical applications such as conservation practice application.

9410

(2) Section II - Soil and Site Information.

Information from the State Soil Survey Database (3SD) will be used as the basis of this section. The 3SD contains current information on soils and their basic interpretations as tailored from the Soil Interpretations Records (SCS-SOI-5). Detailed interpretations of soils will be provided in Section II by state and area specialists.

Interpretations are specific to the soils identified and mapped in the area. Map units to which the interpretations apply are clearly identified by name, symbol(s), or both. New map unit names and symbols resulting from reclassification of soils are cross-referenced to old names and symbols and shown on a list.

Soils are to be described and interpreted to help make decisions about use and management of land. Soil characteristics that limit or affect land use and management are to be identified, and soils are to be rated according to limitations, capability, suitability, and/or potential.

This information may be available in published soil surveys or in the State Soil Survey Database (3SD). A copy of the appropriate sections of soil surveys can be included in the applicable subsections, or reference can be made to the source document maintained in the field office.

The following are subsections of Section II of the FOTG.

(i) Soils legend. This list includes the names of the soil map units and, for each unit, the identification of interpretive groups (if any) of importance in the field office. For map units having two or more soils in their name, interpretive groups are identified for each soil. Where appropriate, the map unit is placed in a group that generally controls the use and management of the area.

If soil surveys of more than one vintage are used, the symbols used in each are to be identified along with appropriate interpretive groups. For remapped areas, only the legend for the most recent mapping is to be used.

(ii) Soil descriptions.

(A) Nontechnical soil descriptions for use with individuals, groups, and units of government are included. Brief references to major limitations e.g., erosion or wetness, and soil potential are a part of each description. Basic information needed to develop these descriptions is in the soil map unit descriptions and in the State Soil Survey Database (3SD).

(B) Technical descriptions of each soil series and of each soil map unit are provided in this section or available in the field office. If such descriptions are maintained as separate material, the source document should be listed here as a reference.

(iii) Detailed soil interpretations. These will be supplied by appropriate technical specialists for all land uses in the field office area. Examples follow:

(A) Cropland interpretations. These include soil interpretive information needed for plant adaptations, yield estimates, and the lists of soil map units that meet the soil requirements for prime farmland and highly erodible land. Interpretations are presented by land capability units, erodibility index, and soil map units in narrative or tabular form as appropriate. Where land capability unit or erodibility index is used, a list of all soil map units in each capability unit or erodibility index is included.

(B) Rangeland, grazed forest land, and native pasture interpretations. The required content of range and native pasture interpretive groupings is outlined in the National Range Handbook. All soils used as rangeland are to be placed in appropriate range sites. Range site descriptions and condition guides for rangeland are included. Grazed forest land and native pasture groupings include references to individual soils, grazing groups, or woodland suitability groups. Interpretations may be presented by individual soil map units or by groups of soil map units.

(C) Forest land interpretations. These are presented by individual soils or by woodland suitability groups (WSG). These interpretations include the woodland class symbol that denotes potential productivity for the indicator species in wood per cubic meters per hectare. Site index and annual productivity estimates in cubic feet per acre, board feet per acre, and/or cords per acre may also be provided for important tree species. The subclass indicates the primary soil or physiographic characteristic that contributes to important hazards or limitations in management. Site index information is also provided for important tree species.

(D) Nonagricultural interpretations. Nonagricultural uses include commercial development, subdivision development, industrial related development, roads and other transportation and transmission systems, and other land uses important to the area.

(E) Recreation interpretations. These include the ratings of soils for recreation uses.

(F) Wildlife interpretations. These are presented by wildlife habitat elements with descriptions of each element.

(G) Pastureland and hayland interpretations. These are arranged by pastureland and hayland suitability groups, capability units, other groupings, or soil map units.

(H) Mined land interpretations. These include interpretations which dictate the limitation to reclamation, revegetation, and maintenance for the different types of mined land.

(I) Windbreak interpretations. These interpretations are made by individual soils or by windbreak suitability groups (WISG). Interpretations provided by the WISG include the soil-adapted species recommended, the predicted height growth in 20 years, and the soil-related limitations.

(J) Engineering interpretations. These include engineering properties, indices, and soil interpretations for engineering uses and practices.
(K) Waste disposal interpretations. These are interpretations related to the suitability of soils for disposal of organic and inorganic wastes.

(L) Water quality and quantity interpretations. These are interpretations related to soil properties affecting water quantity and quality problems and treatments. Included are soil-pesticide interactive ratings and soil ratings for nitrates and soluble nutrients.

(M) **Hydric soils interpretations.** These are interpretations related to the identification and use of wetlands.

(3) Section III - Conservation Management Systems.

The function of SCS is to provide technical assistance to decisionmakers to protect, maintain, and improve soil, water, air, and related plant and animal resources. This section provides guidance for developing resource management systems (RMS) and acceptable management systems (AMS) for a resource area to prevent or treat problems and take advantage of opportunities associated with these resources. This section includes a description of considerations important in conservation planning of soil, water, air, and related plant and animal resources.

(i) **An RMS achieves the goal of preventing resource degradation and permitting sustainable use as stated in 401.00 (b).** An RMS is achieved if criteria for soil, water, air, and related plant and animal resources are met as defined in Section 401.03(b)(3)(iv). This section describes either national criteria or considerations that must be addressed in developing state criteria for achieving an RMS that solve identified onsite and offsite resource problems using best available technology. The concept and use of RMS is defined in the SCS National Planning Manual (NPM). RMS are not to be confused with "conservation systems," as defined in 7 CFR Section 12.2 for treatment of highly erodible land. A conservation system for Food Security Act purposes is an erosion reduction component of an RMS for cropland.

(ii) **SCS helps decisionmakers plan and apply conservation management systems to prevent and/or solve identified onsite and offsite resource problems or conditions and to achieve the decisionmaker's and public objectives.** SCS identifies and documents decisionmaker's objectives, consistent with land capability and sound environmental principles, as part of element 3 (Determining objectives) of the planning process (reference: National Planning Manual). SCS identifies and documents resource problems or conditions as part of element 4 (Providing resource inventory data) of the planning process. As part of element 6 (Developing and evaluating conservation alternatives), information on conservation effects is used to provide suitable options for addressing the decisionmaker's and public objectives.

(iii) **The five resources are soil, water, air, plants, and animals.** Each resource has several considerations important in conservation planning. Additional considerations in a specific state may need to be added to account for wide variations in soils, climate, or topography. A description of the main considerations for each resource follows:

(A) Soil. Considerations for the soil resource are erosion, condition, and deposition.

[1] Erosion. This consideration deals with one or more of the following types or locations of erosion: sheet and rill, wind, concentrated flow (ephemeral gully and classic gully), streambank, soil mass movement (land slips or slides), road bank, construction site, and irrigation-induced. All of these forms of erosion that are identi fied on the site to be planned need to be dealt with in developing treatment options.

VOL 12

9413

[2] Condition. This consideration deals with the chemical and physical characteristics of soil as related to its ease of tillage, fitness as a seedbed, and ability to absorb, store, and release water and nutrients for plants. Aspects of this consideration will improve soil tilth, which reduces soil crusting and compacting; optimize water infiltration; optimize soil organic material; enhance beneficial soil organisms and biological activity; reduce subsidence; and minimize effects of excess natural and applied chemicals and elements such as salt, selenium, boron, and heavy metals. This consideration also deals with the proper and safe land application and utilization of animal wastes, other organics, nutrients, and pesticides.

[3] Deposition. This consideration deals with onsite or offsite deposition of products of erosion, which includes sediment causing damages to land, crops, and property, such as structures and machinery. This consideration also deals with safety hazards and decreased long-term productivity.

(B) Water. Considerations for the water resource are quantity and quality.

[1] Quantity includes:
• proper disposal of water from overland flows or seeps, both natural and man-made;
• management of water accumulations on soil surfaces or in soil profiles and vadose zones;
• optimization of irrigation and precipitation water use;
• dealing with other problems relating to irrigation — water mounding, water supply and distribution, increasing or decreasing water tables;
• management of deep percolation, runoff, and evaporation;
• water storage;
• management of water for wetland protection; and
• sediment deposition in lakes, ponds, streams and reservoirs, and restricted water conveyance capacity.

[2] Quality includes:
• reducing the effects of salinity and sodicity;
• minimizing deep percolation of contaminated water which will lead to unacceptable levels of pollutants in the underlying ground water;
• maintaining acceptable water quality;
• minimizing offsite effects including ground water contamination by pesticides, nutrients, salts, organics, metals and other inorganics, and pathogens; contamination of surface water (streams and lakes) by sediment, pesticides, nutrients, salts, organics, metals and other inorganics; pathogens; fecal coliform; and high temperature;
• reducing the quantity of sediment;
• improving the quality of sediment;
• ensuring that all waters will be free from substances attributable to man-caused nonpoint source discharges in concentrations that:

*settle to form objectionable deposits;
*float as debris, scum, oil or other matter to form nuisances;

VOL 12

9414

R0042720

•produce objectionable color, odor, taste, or turbidity;

•injure, are toxic to, or produce adverse physiological or behavior responses in humans, animals, or plants; or

•produce undesirable aquatic life or result in the dominance of nuisance species.

(C) **Air.** This resource deals with onsite and offsite airborne effects of undesirable odors, windblown particulates, chemical drift, temperature, and wind.

(D) **Plants.** The considerations for the plant resource are suitability, condition, and management.

[1] **Suitability includes:**
- plant adaptation to site; and
- plant suitability for intended use.

[2] **Condition includes:**
- productivity, kinds, amounts, and distribution of plants; and
- health and vigor of plants.

[3] **Management includes:**
- establishment, growth, and harvest (including grazing) of plants;
- agricultural chemical management (pesticides and nutrients); and
- pest management (brush, weeds, insects, and diseases).

(E) **Animals.** This includes wild and domestic animals, both terrestrial and aquatic. The considerations for the animal resource are habitat and management.

[1] **Habitat includes:**
- food;
- cover or shelter; and
- water.

[2] **Management includes:**
- population and resource balance; and
- animal health.

(iv) **Criteria for treatment required to achieve an RMS will be established by SCS.** They are to be stated in either qualitative or quantitative terms for each resource consideration. Where national criteria have not been established, the state conservationist will establish criteria with concurrence by the NTC. Where state and/or local regulations establish more restrictive criteria, these must be used in developing criteria for state and local programs. For example, some state and/or local regulations have established criteria for offsite control of water quality.

(A) **Soil.** Following are the criteria for this resource:

VOL 12

[1] Erosion.

• Estimated sheet and rill or wind erosion rates are reduced to the level that long term soil degradation is prevented and a high level of crop productivity can be sustained economically and indefinitely.

• Erosion from ephemeral or similar gullies is reduced to a level which permits efficient farming operations and sustains long term productivity.

• Irrigation-induced erosion is reduced to a level that sustains long term productivity.

• Other forms of erosion, such as classic gullies, streambank, roadbank, and land-slides, that are identified as needing treatment (and are within the ability of the decisionmaker to treat), are reduced to the degree necessary to protect the resources or threatened man-made improvements.

[2] Condition.

• Soil tilth is maintained or improved;

• Crop production practices return adequate residue within the rotation cycle;

• Soil compaction by machinery, livestock, or other traffic is minimized;

• Water infiltration is optimized so as not to increase sheet and rill erosion;

• Wind forces and soil blowing are controlled below the crop tolerance level of young seedlings;

• Toxic chemicals affecting soil and plants are controlled to levels sufficient to prevent soil degradation and are below the tolerance of adapted crops;

• Application and utilization of animal wastes and other organics are at a rate that the soil, soil microbes and bacteria, and the plant community can assimilate, degrade, or retain the various materials.

9416

[3] Deposition.

• Where existing or potential onsite or offsite deposition problem(s) are identified, the practices applied to the contributing land resolve the identified deposition problem(s).

• State and/or local governments may establish criteria in response to identified deposition problems. These criteria will be used to determine the adequacy of an RMS with regard to offsite effects. This may require the establishment of more restrictive criteria for one or more of the resources to alleviate the problem. Local public perception of an acceptable level could be used where no standards have been established.

• When disposal of animal wastes and other organics is needed, it shall be done in a manner that maintains or enhances the natural resources.

(B) **Water.** In developing criteria for this resource, the state conservationist is to address:

[1] **Quantity.**

• Overland flows and subsurface water conveyed by conservation practices are safely conducted and disposed of through acceptable outlets.

• Water system discharges going from one ownership to another ownership are not changed from natural flow pathways unless needed land and/or water rights have been obtained consistent with local, state, and Federal regulations.

• Water quality aspects associated with outlets are accounted for.

• Appropriate water storage requirements are in accordance with the needs of the planned use.

• Drainage activities are consistent with SCS policy regarding wetland protection.

• For irrigated land, a minimum percentage level of efficiency is achieved or exceeded for each type of irrigation system and management, as stated in the SCS state irrigation guide.

• For land under supplemental irrigation where adequate water supplies exist, or for land under partial irrigation because of water deficiency or lack of seasonal availability or frequency of availability of water, water is applied in the most effective manner, so that the infiltration rate of the soil, the plant needs, and the soil water-holding capacity are not exceeded.

• Vegetation, cropping sequences, and cultural operations are managed for efficient use of precipitation by minimizing water losses to runoff and evaporation, thereby inducing positive effects on the plant-soil moisture relationship, on ground water recharge, and on water yield downstream.

[2] **Quality.**

• Sediment movement is controlled to minimize contamination of receiving waters.

VOL 12

9417

• Percolation below the root zone is managed to minimize contamination of the percolating water and to minimize the negative effects on production.

• Water used for salt leaching and plant temperature modification is applied to minimize adverse effects.

• Acceptable water temperature is maintained.

• Irrigation water and natural precipitation are managed to minimize the movement of nutrients, pesticides, sediment, salts, and animal wastes to offsite surface and ground water.

• Water-based uses, such as aquaculture enterprises and water-based recreation facilities maintain or improve environmental quality.

• Where surface or ground water nutrient and/or pesticide problems or potential problems exist, the selection of appropriate nutrients or pesticides and the timing, chemical forms, and rate and method of application reduce adverse effects. The use of pesticides and nutrients with high potential for polluting water are avoided where site limitations, such as slope, depth to ground water, soil, and material in the vadose zone or aquifer could allow that potential to be realized. Soil-pesticide interactive ratings to identify potential problem situations from surface runoff and/or leaching are used according to FOTG guidelines. Alternative practices or other pest control methods (mechanical, cultural, or biological) or integrated methods are recommended where site limitations exist that increase the probability of degrading water supplies, either below the surface or downstream.

• Agricultural chemical containers and chemicals (including waste oil, fuel, and detergents) are used, handled, and disposed of in compliance with Federal, state, and local laws.

(C) Air. Criteria established by the state conservationist are to address the following onsite and offsite considerations:

• Airborne particulates from agricultural sources do not cause safety, health, machinery, vehicular, or structure problems.

• Local and state regulations are followed in minimizing undesirable odors from agricultural sources.

• Air movement and temperatures are modified when necessary using appropriate vegetative or mechanical means.

• Chemical drift from the application of agricultural chemicals is controlled by adherence to local and state application recommendations and product labels.

(D) **Plants.** Criteria established by the state conservationist are to address the following considerations:

- Plants on all land uses are used, maintained and improved to achieve acceptable production levels to meet conservation, environmental, decisionmaker, and public objectives.

- Nutrient applications for any land use are based on plant nutrient requirements, production requirements, soil test recommendations, soil fertility, soil potential limitations, water budget, and the types of practices planned. Nutrients from all sources (animal waste, crop residue, soil residual, commercial fertilizer, atmospheric-fixed) are considered when calculating the amount of nutrients to apply. Timing, method, and rate of application, and chemical forms of nutrients to be applied are taken into consideration in planning practices.

- Pesticide applications for any land use are applied according to the label recommendation and federal, state, and local regulations.

- On Cropland, crops are grown in a planned sequence that meets conservation, production, and decisionmaker objectives; and weeds, insects, other pests, and diseases are adequately treated.

- On Hayland, dominant native or introduced plant species are appropriate for the forage, agronomic, or commercial use; well adapted to the site; and their stand density is maintained or improved.

- On Native Pasture, herbaceous plants are properly grazed, forage value rating is medium or better, vigor is strong and is commensurate with overstory canopy.

- On Pastureland, dominant plant species are appropriate for the use, adapted to the site, and their stand density is adequate and productivity is maintained or improved.

- On Rangeland, the plant community is managed to meet the needs of the plants and animals in a manner to conserve the natural resources and meet the objectives of the decisionmaker. As a general rule, rangeland in poor or fair ecological range condition is managed for an upward range trend, and rangeland in good or excellent ecological range condition will be managed for a static or upward range trend. In some special situations, poor or fair ecological range condition could be managed for a static range trend to meet special objectives of the decisionmaker as long as there is no degradation of the soil resource.

- On Forest Land, trees are well distributed, vigorous, relatively free of insects, disease, and other damage, and the density of the stand is within 25% of forest stand density guide spacing on a stems-per-acre basis for the particular forest types. Forest Land shall be protected from wildfires and erosion. Forest Land that is grazed shall also be managed to meet the needs of the forage plants, the animals, and the objectives of the decisionmaker.

• On Wildlife Land, Recreation Land, and Other Land, adapted or native plants are of sufficient quantity and quality to improve or protect the defined resource.

• On Urban Land uses, soil cover is maintained using suitable plants or other cover to keep soil erosion within acceptable limits, minimize runoff, and manage infiltration.

(E) Animals. Criteria established by the state conservationist are to address the following considerations:

• The adaptation, kinds, amounts, distribution, health, and vigor of livestock and wildlife are appropriate for the site.

• Adequate quality, quantity and distribution of food are provided for the species of concern.

• Adequate quantity, quality and distribution of wildlife cover for the species of concern are provided. Domestic animals are provided adequate shelter as needed.

• Adequate quantity, quality and distribution of water are provided for the species of concern.

• The decisionmaker's enterprise and the balance between forage production and livestock needs are appropriate.

• Domestic livestock are managed in a manner that meets the needs of the ecosystem, the animal, and that accomplishes the goals and objectives of the decisionmaker.

• Animal wastes and other organic wastes are managed according to an animal waste management plan developed according to SCS standards. Minimum quality criteria are met when the animal waste management plan is applied. Where surface and ground water problems exist from organic waste, bacteria, pathogens, microorganisms, or nutrients, special design considerations for each component will be necessary to eliminate further contamination of runoff or leachates.

(v) An AMS will be established for a resource area in the event that social, cultural, or economic characteristics of the area prevent the feasible achievement of an RMS. An AMS is achieved when soil, water, air, and related plant and animal criteria for the related resource use are established at the level which is achievable in view of the social, cultural, and economic characteristics of the resource area involved.

(A) Social, cultural, and economic considerations are used to establish the level of natural resource protection obtainable and may constrain the resource criteria used in formulating an

R0042726

VOL 12

9420

RMS. Criteria for treatment required to achieve an AMS will be established by SCS. They are to be stated in either qualitative or quantitative terms for each resource consideration. The state conservationist will establish criteria with concurrence by the NTC. Some of these criteria are prescribed by law or statute; e.g., the National Historic Preservation Act. Others are developed through an onsite assessment of social, cultural, and economic factors which define the reasonable and practical degree to which the resource criteria can be achieved. Where regional, state and/or local regulations establish more restrictive criteria, these must be used.

(B) The following criteria are applied to determine the practical limits of resource protection within a resource area and temper the resource criteria to be used in the formulation of an AMS.

(1) Social
- Public health is maintained or improved.
- Treatment level is compatible with community characteristics.
- Treatment level is compatible with clientele characteristics.

(2) Cultural
- Protection of cultural resources is consistent with GM 420, Part 401.

(3) Economic
- Treatment level reflects the ability to pay that is representative of the area.
- Inputs required for conservation treatment are readily available.
- Conservation treatment is consistent with government program participation.

(vi) Additional considerations useful in the planning process to screen or select suitable conservation treatments for individual decisionmakers may include legal, social, cultural, economic, aesthetic, management, and other factors. These are integral to the planning process and are discussed in the National Planning Manual and are displayed in Section V.

(vii) Applications of RMS and AMS Criteria

(A) Several factors may affect the actual level or degree of treatment achieved at a point in time or that is required to be achieved by the decisionmaker. Without legal constraints, the differing cultural, social or economic situation of a decisionmaker usually determines the degree of treatment planned or attained at any point in time. Where an RMS or AMS is not attainable during the present planning effort, the progressive planning approach in NPM 501.04 (d) may be used to ultimately achieve planning and application of an RMS or AMS. Progressive planning is the incremental process of building a plan on part or all of the planning unit consistent with the decisionmaker's ability to make decisions over a period of time. The progression on individual planning units is always toward the planning and implementation of an RMS.

VOL 12

9421

(B) Legislated programs usually have varying authorities and qualifying criteria that may require more or less treatment than RMS or AMS criteria. An example is legislated practices for improving water quality. In this case, the related program manual will establish the criteria to be achieved. These applications must be coordinated across county and state lines and should be for the period of time specified in the law or in the related policies and procedures.

(C) The opportunity for establishing an RMS to achieve the non-degradation and sustainable use goal should be evaluated when ownership, land use, or cropping system changes, or when new technology becomes available.

(D) Decisionmakers may desire to plan treatment in addition to that required to meet RMS or AMS criteria to enhance resource conditions or to serve secondary or tertiary uses or objectives. This additional treatment may include conservation practices or management that contribute to further improvement of water quality; increased production, drainage, or irrigation; enhancement of cultural and environmental values, wildlife habitat, or aesthetics; or improved health and safety.

(viii) RMS, AMS, or other guidance documents will be developed by major land use in the field office area and placed in Section III of each FOTG.

(A) Only enough guidance documents to show examples of the RMS and AMS options to treat the most common identified resource problems for each locally applicable major land use will be developed. NTC will provide specific examples of format for guidance to states in the preparation of guidance documents. Guidance documents are to be developed by states for each FOTG using the NTC format. Guidance documents are to have concurrence of the NTC. NTC directors are to coordinate formats across NTC boundaries.

(B) Guidance documents will present a reasonable number of alternative combinations of practices and management that will meet the criteria for solving resource problems common to that land use.

(C) In developing guidance documents, the effects that alternative practices and combinations of practices and management have on the five resources and on the social, economic, and cultural considerations are to be used. For each guidance document developed, a display of effects of the conservation system should be included in Section V. Guidance on the development and display of effects is provided in Section 401.03(b)(5).

(D) Guidance documents may need to be developed to meet specific program requirements, in which case they are to be clearly labeled to show the program(s) or provision(s) of law to which they apply. These guidance documents may describe management actions in addition to conservation practices that can be carried out to achieve these program purposes.

(ix) Conservation practices are to be installed according to SCS practice standards and specifications. Practice standards and specifications are the same for both RMS and AMS.

(4) Section IV - Practice Standards and Specifications

(i) This section of FOTG contains conservation practice standards and specifications.

(ii) The first item of Section IV is an alphabetical list of conservation practices used by the field office, followed by the practice standards and specifications in the same order. This list will include the date of preparation or revision of each standard, supplement, specification, and interim standard in effect. This list will also show the date of the last review. This list will be revised and reissued each time a change is made in a conservation practice standard, supplement, or specification. See section 401.01(c)(2)(vii).

(iii) Practice standards establish the minimum level of acceptable quality for planning, designing, installing, operating, and maintaining conservation practices. Standards from the National Handbook of Conservation Practices (NHCP) and interim standards are to be used, and will be supplemented by states as needed.

(iv) Practice specifications describe requirements necessary to install a conservation practice so that it functions properly. For most practices in the NHCP, it is necessary to prepare state specifications to fit local soil and climatic conditions. Specifications include some or all of the following: major elements of work to be done; kind, quality, and quantity of materials to be used; essential details of installation; and other technical instructions necessary for installing and maintaining the practice.

(v) See **Part 401 - Subpart B** for policy and procedural details for standards and specifications.

(5) Section V - Conservation Effects

(i) The purpose of this section is twofold:

(A) The first purpose is to provide a repository of data on the effects of conservation activities. Such data are an important part of technical reference material used by SCS and decisionmakers in planning conservation actions. SCS determines the effects of conservation treatments in order to help formulate and facilitate the identification of suitable conservation management systems to protect the resource base and to address the decisionmaker's and society's social, cultural, and economic objectives. The concept of using conservation effects in the decisionmaking process (CED) is elaborated in the National Planning Manual.

(B) The second purpose of this section is to serve as a source of appropriate procedures and methods for collecting, analyzing, and displaying conservation effects data.

(ii) Conservation effects information will typically include the resource setting (i.e., soil, slope, etc.), the specific conservation treatments applied, the kinds, amounts, and timing of actions undertaken by decisionmakers in their operations, and the expected outcome in terms of solving resource problems and meeting social, cultural, and economic objectives.

(A) Effects of conservation may be expressed in either narrative or quantitative terms that represent factual data on experienced or expected results of the specified conservation treatment as applied to the resource setting. Effects of conservation will normally be expressed as a condition or stage of the factors associated with a specified conservation action. For example, typical effects could be: a corn yield of 110 bushels per acre; a USLE erosion rate of 4 tons per acre; irrigation efficiency of 60%; or "a significant reduction in ephemeral gully erosion will occur with this treatment." "Impacts" is a closely related term. An impact is a measure of the change between the stage or condition of one treatment alternative to another. Guidance on the use of effects information in the conservation planning process is contained in the National Planning Manual.

(B) To the extent possible, conservation effects information will include conservation treatments on the five resources and their considerations as described in Section III above.

[1] Examples of effects of conservation treatment on the five resources include but are not limited to:

- Expected effect on sheet and rill, wind, or ephemeral gully erosion.
- Indicators or measures of soil conditions, such as tilth, compaction, and infiltration.
- Where applicable, indicators of soil deposition.
- Measures or indicators of effects on quality and quantity of surface or subsurface waters, such as chemical runoff as influenced by the conservation system.
- Effects on plant conditions and management, such as expected status of range conditions with the indicated range conservation actions.
- Measures of conservation effects on wild and domestic animals, including animal waste uses and effects on the resource base.
- Indicators of effects on air, such as airborne particulates, odors, and chemical drift.

[2] Effects information will also include management, social, cultural, and economic information. Factors such as cost, client acceptability, and physical changes to cultural resource sites associated with the specific conservation treatment component are to be identified. Included, for example, would be:

- Tillage requirements, labor inputs, quantity and costs of inputs, net economic returns, experienced yields, risk management requirements, operation and maintenance requirements, time requirements, cultural resources (archaeological and historic properties), length of life of practices, health and safety, aesthetics, and community effects.

(C) Information developed on conservation effects will vary significantly in scope and detail depending on the resource conditions in the local area as well as upon the needs for technical reference materials to carry out conservation activities in that location.

(iii) Section V of the FOTG should contain summaries of effects data relevant to the field office area. As a minimum, Section V should contain a display of the important effects for decisionmaking for each of the RMS and AMS developed and inserted in Section III. The display should be cross referenced with cropping system, soil map units, and other descriptions of the resource setting and conditions (e.g., precipitation, slope, etc.) that the RMS or AMS was formulated to address in that field office. The format of the display should be easily understandable so as to make the information valuable as ready reference material for the conservation planner and decisionmaker to facilitate planning and decisionmaking. The display will show the degree of resource protection achieved.

(A) Options may be evaluated by simply comparing the differences in the effects of the options.

(B) NTC will provide specific examples of format guidance to states for recording and displaying conservation effects data.

(C) Collection of data on conservation effects is a long term effort to be undertaken as part of the followup element in the planning process. Initial efforts may provide effect information for only the most common situations. Over time, additional resource situations and treatment alternatives will be examined to add depth and breadth to the available conservation effect information.

(D) Information on conservation effects may be refined or updated over time as needed in the local area. The data on conservation effects should be useful to field office personnel in identifying suitable conservation treatment applicable to the area, and serves as technical reference materials when working with decisionmakers in the conservation planning process. (See National Planning Manual Section 508.01).

(iv) Data on conservation effects may be developed by following two general approaches:

(A) The observation and documentation of the experiences of cooperators. Typically, conservationists will make observations of conservation treatments applied by one or more decisionmakers in the first or second year following the application and record the effects experienced. This data can be recorded in conservation field notes and be entered into CAMPS databases. Effects information may also be available from conservation field trials, university research plots, or other trials in the area.

(B) Models of processes impacted by conservation actions can be used to simulate the physical, agronomic, or other effects of treatment systems. Actual results or graphs summarizing results could be developed by state staffs and provided to field offices for inclusion in FOTG. Appropriate models or references to the appropriate models may be stored in FOTG Section V to facilitate use in collecting and analyzing conservation effects data.

(v) Data relating effects of conservation practices on the five resources may be displayed in tabular, narrative, or matrix form. This will be useful in developing RMS or AMS for inclusion in FOTG Section III.

VOL 12

9426

SUBPART B — NATIONAL HANDBOOK OF CONSERVATION PRACTICES

401.10 Purpose.

This subpart sets forth SCS policy for establishing and maintaining a National Handbook of Conservation Practices (NHCP). It also includes directions for variances, changes, interim standards, and adaptations of standards to state and local conditions.

401.11 Content.

(a) The NHCP establishes a national standard for each conservation practice, including:

(1) The official name, definition, code identity, and unit of measurement for the practice;

(2) A concise statement of the scope, purposes (including secondary purposes), conditions where the practice applies, and planning considerations for the practice; and

(3) Criteria for the practice.

(b) For some conservation practices, the NHCP also establishes items for inclusion in state-developed specifications.

(c) The NHCP contains an index of national standards, including:

(1) The practice name and unit.

(2) The SCS technical discipline leader responsible for each practice.

(3) The date of the current standard.

(4) The code number of the standard.

401.12 National Conservation Practice Standards Subcommittee (NCPSS) of National Technical Guide Committee (NTGC).

The National Conservation Practice Standards Subcommittee (NCPSS) of NTGC coordinates and updates the NHCP. The NTGC designates subcommittee members and acts on recommendations from NCPSS.

401.13 Practice standards and specifications.

(a) Practice standards establish the minimum level of acceptable quality of planning, designing, installing, operating and maintaining conservation practices.

(1) NHCP standards are to be used directly within a state, or state supplements can be added as necessary. Because of wide variations in soils, climate, and topography, state conservationists may need to add special provisions or provide more detail in the standards. State laws and local ordinances or regulations may dictate more stringent criteria.

(2) The official practice name, definition, code identity, and unit of measurement are established nationally and are not to be changed. Generally, the statement of scope, purpose, and conditions where a practice applies can be used directly.

(b) Practice specifications establish the technical details and workmanship for the various operations required to install the practice and the quality and extent of the materials to be used.

(1) Specifications enumerate items that apply when adapting the standard to site specific locations, such as considerations of site preparation and protection; instructions for use of materials described in the standard; or guidance for performing installation operations not directly addressed in the standard. Statements in the specifications are not to conflict with the requirements of the standard.

(2) Items to be included in state-developed specifications for a limited number of conservation practices are contained in the NHCP. Specifications for practices are to be developed by states or NTCs and are to consider the wide variations in soils, climate, and topography present in the various states. State developed specifications must be approved by the appropriate discipline specialist and the state conservationist. Specifications are to meet the requirements of state laws and local ordinances or regulations.

(c) National Technical Centers (NTCs) review and concur in supplements to NHCP standards and specifications prepared by a state for use within that state to ensure conformance with NHCP and consistency among states.

401.14 Variances.

Only the directors of the Engineering and/or Ecological Sciences Divisions can approve variances from requirements stated in the NHCP except that approval authority for variations in channel stability requirements has been delegated to the heads of engineering staffs at the NTC (see NEM 210 Section 501.32). Any other request for a variance is to be submitted to the NTGC and is to include recommendations of the appropriate NTC Director. The NTGC will refer the request to the appropriate division for action. Variances, when granted, are for a specific period of time or until the practice standard to which they pertain is revised, whichever is shorter. Variances will include any requirements for monitoring, evaluation, and reporting needed to determine whether or not changes in practice standards are necessary.

401.15 Changes in the National Handbook of Conservation Practices (NHCP).

(a) The NTGC will consider and recommend proposed changes in the NHCP to the Deputy Chief for Technology. Changes will be made by numbered handbook notices issued by the Deputy Chief for Technology.

(b) Each NHCP standard is to be formally reviewed by the NCPSS at least once every five years from the date of issuance or revision to determine if the standard is needed and up-to-date. If revisions are needed, the revised standard will establish the current minimum level of acceptable quality for planning, designing, installing, operating, and maintaining conservation practices.

(c) The NTC reviews all state proposed changes to NHCP and sends recommendations for approval or disapproval to NTGC. Review and approval of technical content of proposed changes is to be made by the Director, Engineering Division, or the Director, Ecological Sciences Division. Review and approval of format with respect to inclusion of items listed in Section 401.11 are to be performed by NTGC.

401.16 Interim standards.

(a) Interim standards are prepared by states or NTC to address problems for which there is no existing standard.

(b) Interim standards are to be approved by the NTC Director.

(c) Interim standards are to be issued for a period not to exceed 3 years. The NTC director can extend the period for further evaluation at the end of this period, and after an analysis of practice performance using the interim standard.

(d) Interim standards will be evaluated by NTC Technical Guide Committees at the end of the 3-year period and, if appropriate, recommendations made to the NTGC for inclusion in the National Handbook of Conservation Practices.

(e) The notice of approval of each interim standard will provide instructions to states regarding evaluation of practice performance.

(f) NTC directors are to send information copies of all interim standards and evaluation reports to NTGC.

CHAPTER 3: Management Measures for Forestry

I. INTRODUCTION

A. What "Management Measures" Are

This chapter specifies management measures to protect coastal waters from silvicultural sources of nonpoint pollution. "Management measures" are defined in section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA) as economically achievable measures to control the addition of pollutants to our coastal waters, which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

These management measures will be incorporated by States into their coastal nonpoint programs, which under CZARA are to provide for the implementation of management measures that are "in conformity" with this guidance. Under CZARA, States are subject to a number of requirements as they develop and implement their Coastal Nonpoint Pollution Control Programs in conformity with this guidance and will have some flexibility in doing so. The application of these management measures by States to activities causing nonpoint pollution is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA).

B. What "Management Practices" Are

In addition to specifying management *measures*, this chapter also lists and describes management *practices* for illustrative purposes only. While State programs are required to specify management *measures* in conformity with this guidance, States programs need not specify or require implementation of the particular management *practices* described in this document. However, as a practical matter, EPA anticipates that the management measures generally will be implemented by applying one or more management practices appropriate to the site, location, type of operation, and climate. The practices listed in this document have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measures. EPA has also used some of these practices, or appropriate combinations of these practices, as a basis for estimating the effectiveness, costs, and economic impacts of achieving the management measures. (Economic impacts of the management measures are addressed in a separate document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*)

EPA recognizes that there is often site-specific, regional, and national variability in the selection of appropriate practices, as well as in the design constraints and pollution control effectiveness of practices. The list of practices for each management measure is not all-inclusive and does not preclude States or local agencies from using other technically sound practices. In all cases, however, the practice or set of practices chosen by a State needs to achieve the management measure.

C. Scope of This Chapter

This chapter contains 10 management measures that address various phases of forestry operations relevant to the control of sources of silvicultural nonpoint pollution that affect coastal waters. A separate measure for forestry operations in forested wetlands is included. These measures are:

(1) Preharvest planning
(2) Streamside management areas
(3) Road construction/reconstruction
(4) Road management
(5) Timber harvesting
(6) Site preparation and forest regeneration
(7) Fire management
(8) Revegetation of disturbed areas
(9) Forest chemical management
(10) Wetland forest management

Each of these topics is addressed in a separate section of this chapter. Each section contains (1) the management measure; (2) an applicability statement that describes, when appropriate, specific activities and locations for which the measure is suitable; (3) a description of the management measure's purpose; (4) the rationale for the management measure's selection; (5) information on the effectiveness of the management measure and/or of practices to achieve the measure; (6) information on management practices that are suitable, either alone or in combination with other practices, to achieve the management measure; and (7) information on costs of the measure and/or of practices to achieve the measure.

Coordination of Measures

The management measures developed for silviculture are to be used as an overall system of measures to address nonpoint source (NPS) pollution sources on any given site. In most cases, not all the measures will be needed to address the NPS sources of a specific site. For example, many silvicultural systems do not require road construction as part of the operation and would not need to be concerned with the management measure that addresses road construction. By the same token, many silvicultural systems do not use prescribed fire and would not need to use the fire management measure.

Most forestry operations will have more than one phase of operation that needs to be addressed and will need to employ two or more of the measures to address the multiple sources. Where more than one phase exists, the application of the measures needs to be coordinated to produce an overall system that adequately addresses all sources for the site and does not cause unnecessary expenditure of resources on the site.

Since the silvicultural management measures developed for the CZARA are, for the most part, a system of practices that are commonly used and recommended by States and the U.S. Forest Service in guidance or rules for forestry-related nonpoint source pollution, there are many forestry operations for which practices or systems of practices have already been implemented. Many of these operations may already achieve the measures needed for the nonpoint sources on them. For cases where existing source control is inadequate, it may be necessary to add only one or two more practices to achieve the measure. Existing NPS progress must be recognized and appropriate credit given to the accomplishment of our common goal to control NPS pollution. There is no need to spend additional resources for a practice that is already in existence and operational. Existing practices, plans, and systems should be viewed as building blocks for these management measures and may need no additional improvement.

D. Relationship of This Chapter to Other Chapters and to Other EPA Documents

1. Chapter 1 of this document contains detailed information on the legislative background for this guidance, the process used by EPA to develop this guidance, and the technical approach used by EPA in the guidance.

2. Chapter 7 of this document contains management measures to protect wetlands and riparian areas that serve a nonpoint source pollution abatement function. These measures apply to a broad variety of nonpoint sources; however, the measures for wetlands described in Chapter 7 are not intended to address silvicultural sources.

Practices for normal silvicultural operations in forested wetlands are covered in Management Measure J of Chapter 3.

3. Chapter 8 of this document contains information on recommended monitoring techniques to (1) ensure proper implementation, operation, and maintenance of the management measures and (2) assess over time the success of the measures in reducing pollution loads and improving water quality.

4. EPA has separately published a document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*

5. NOAA and EPA have jointly published guidance entitled *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance.* This guidance contains details on how State coastal nonpoint pollution control programs are to be developed by States and approved by NOAA and EPA. It includes guidance on:

   - The basis and process for EPA/NOAA approval of State Coastal Nonpoint Pollution Control Programs;
   - How NOAA and EPA expect State programs to specify management measures "in conformity" with this management measures guidance;
   - How States may target sources in implementing their Coastal Nonpoint Pollution Control Programs;
   - Changes in State coastal boundaries; and
   - Requirements concerning how States are to implement Coastal Nonpoint Pollution Control Programs.

E. Background

The effects of forestry activities on water quality have been widely studied, and the need for management measures and practices to prevent silvicultural contributions to water pollution has been recognized by all States with significant forestry activities. Silvicultural activities have been identified as nonpoint sources in coastal area water quality assessments and control programs. Water quality concerns related to forestry were addressed in the 1972 Federal Water Pollution Control Act Amendments and later, more comprehensively, as nonpoint sources under section 208 of the 1977 Clean Water Act and section 319 of the 1987 Water Quality Act. On a national level, silviculture contributes approximately 3 to 9 percent of nonpoint source pollution to the Nation's waters (Neary et al., 1989; USEPA, 1992a). Local impacts of timber harvesting and road construction on water quality can be severe, especially in smaller headwater streams (Brown, 1985; Coats and Miller, 1981; Pardo, 1980). Megahan (1986) reviewed several studies on forest land erosion and concluded that surface erosion rates on roads often equaled or exceeded erosion reported for severely eroding agricultural lands. These effects are of greatest concern where silvicultural activity occurs in high-quality watershed areas that provide municipal water supplies or support cold-water fisheries (Whitman, 1989; Neary et al., 1989; USEPA, 1984; Coats and Miller, 1981).

Twenty-four States have identified silviculture as a problem source contributing to NPS pollution in their 1990 section 305(b) assessments (USEPA, 1992b). Silviculture was the pollution source for 9 percent of NPS pollution to rivers in the 42 States reporting NPS pollution figures in section 305(b) assessments (USEPA, 1992b). States have reported up to 19 percent of their river miles to be impacted by silviculture. On Federal lands, such as national forests, many water quality problems can be attributed to the effects of timber harvesting and related activities (Whitman, 1989). In response to these impacts, many States have developed programs to address NPS pollution from forestry activities.

1. Pollutant Types and Impacts

Without adequate controls, forestry operations may degrade several water quality characteristics in waterbodies receiving drainage from forest lands. Sediment concentrations can increase due to accelerated erosion; water temperatures can increase due to removal of overstory riparian shade; slash and other organic debris can accumulate in waterbodies, depleting dissolved oxygen; and organic and inorganic chemical concentrations can increase due to harvesting and fertilizer and pesticide applications (Brown, 1985). These potential increases in water quality contaminants are usually proportional to the severity of site disturbance (Riekerk, 1983, 1985; Riekerk et al., 1989). Silvicultural NPS pollution impacts depend on site characteristics, climatic conditions, and the forest practices employed. Figure 3-1 presents a model of forest biogeochemistry, hydrology, and stormflow interactions.

Sediment. Sediment is often the primary pollutant associated with forestry activities (Pardo, 1980). Sediment is often defined as mineral or organic solid material that is eroded from the land surface by water, ice, wind, or other processes and is then transported or deposited away from its original location.

Sediment transported from forest lands into waterbodies can be particularly detrimental to benthic organisms and many fish species. When it settles, sediment fills interstitial spaces in lake bottoms or streambeds. This can eliminate essential habitat, covering food sources and spawning sites and smothering bottom-dwelling organisms and periphyton. Sediment deposition also reduces the capacity of stream channels to carry water and of reservoirs to hold water. This decreased flow and storage capacity can lead to increased flooding and decreased water supplies (Golden, et al., 1984).

Suspended sediments increase water turbidity, thereby limiting the depth to which light can penetrate and adversely affecting aquatic vegetation photosynthesis. Suspended sediments can also damage the gills of some fish species, causing them to suffocate, and can limit the ability of sight-feeding fish to find and obtain food.

Turbid waters tend to have higher temperatures and lower dissolved oxygen concentrations. A decrease in dissolved oxygen levels can kill aquatic vegetation, fish, and benthic invertebrates. Increases (or decreases) in water temperature outside the tolerance limits of aquatic organisms, especially cold-water fish such as trout and salmon, can also be lethal (Brown, 1974).

Nutrients. Nutrients from forest fertilizers, such as nitrogen and phosphorus adsorbed to sediments, in solution, or transported by aerial deposition, can cause harmful effects in receiving waters. Sudden removal of large quantities of vegetation through harvesting can also increase leaching of nutrients from the soil system into surface waters and ground waters by disrupting the nitrogen cycle (Likens et al., 1970). Excessive amounts of nutrients may cause enrichment of waterbodies, stimulating algal blooms. Large blooms limit light penetration into the water column, increase turbidity, and increase biological oxygen demand, resulting in reduced dissolved oxygen levels. This process, termed eutrophication, drastically affects aquatic organisms by depleting the dissolved oxygen these organisms need to survive.

Forest Chemicals. Herbicides, insecticides, and fungicides (collectively termed pesticides) used to control forest pests and undesirable plant species, can be toxic to aquatic organisms. Pesticides that are applied to foliage or soils, or are applied by aerial means, are most readily transported to surface waters and ground waters (Norris and Moore, 1971). Some pesticides with high solubilities can be extremely harmful, causing either acute or chronic effects in aquatic organisms, including reduced growth or reproduction, cancer, and organ malfunction or failure (Brown, 1974). Persistent pesticides that tend to sorb onto particulates are also of environmental concern since these relatively nonpolar compounds have the tendency to bioaccumulate. Other "chemicals" that may be released during forestry operations include fuel, oil, and coolants used in equipment for harvesting and road-building operations.

Organic Debris Resulting from Forestry Activities. Organic debris includes residual logs, slash, litter, and soil organic matter generated by forestry activities. Organic debris can adversely affect water quality by causing increased biochemical oxygen demand, resulting in decreased dissolved oxygen levels in watercourses. Logging slash and debris deposited in streams can alter streamflows by forming debris dams or rerouting streams, and can also

VOL 12

9441

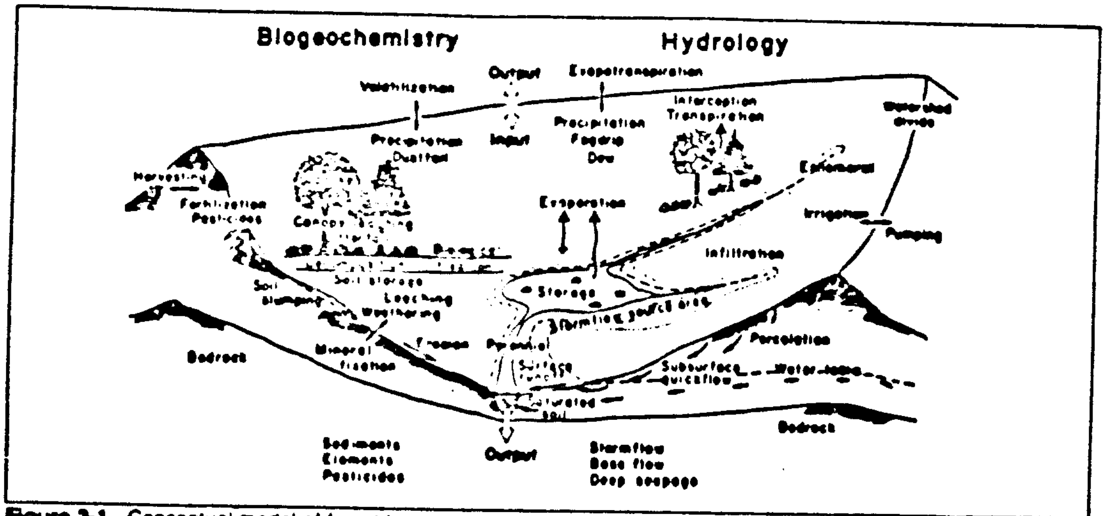

Figure 3-1. Conceptual model of forest biogeochemistry, hydrology and stormflow (Riekerk et al., 1989).

redirect flow in the channel, increasing bank cutting and resulting sedimentation (Dunford, 1962; Everest and Meehan, 1981). In some ecosystems, small amounts of naturally occurring organic material can be beneficial to fish production. Small streams in the Pacific Northwest may be largely dependent on the external energy source provided by organic materials such as leaves and small twigs. Naturally occurring large woody debris in streams can also create physical habitat diversity for rearing salmonids and can stabilize streambeds and banks (Everest and Meehan, 1981; Murphy et al., 1986).

Temperature. Increased temperatures in streams and waterbodies can result from vegetation removal in the riparian zone from either harvesting or herbicide use. These temperature increases can be dramatic in smaller (lower order) streams, adversely affecting aquatic species and habitat (Brown, 1972; Megahan, 1980; Curtis et al., 1990). Increased water temperatures can also decrease the dissolved oxygen holding capacity of a waterbody, increasing biological oxygen demand levels and accelerating chemical processes (Curtis et al., 1990).

Streamflow. Increased streamflow often results from vegetation removal (Likens et al., 1970; Eschner and Larmoyeux, 1963; Blackburn et al., 1982). Tree removal reduces evapotranspiration, which increases water availability to stream systems. The amount of streamflow increase is related to the total area harvested, topography, soil type, and harvesting practices (Curtis et al., 1990). Increased streamflows can scour channels, erode streambanks, increase sedimentation, and increase peak flows.

2. Forestry Activities Affecting Water Quality

The types of forestry activities affecting NPS pollution include road construction and use, timber harvesting, mechanical equipment operation, burning, and fertilizer and pesticide application (Neary et al., 1989).

Road Construction and Use. Roads are considered to be the major source of erosion from forested lands, contributing up to 90 percent of the total sediment production from forestry operations (Rothwell, 1983; Megahan, 1980; Patric, 1976). (See Figure 3-2.) Erosion potential from roads is accelerated by increasing slope gradients on cut-and-fill slopes, intercepting subsurface water flow, and concentrating overland flow on the road surface and in channels (Megahan, 1980). Roads with steep gradients, deep cut-and-fill sections, poor drainage, erodible soils, and road-stream crossings contribute to most of this sediment load, with road-stream crossings being the most frequent

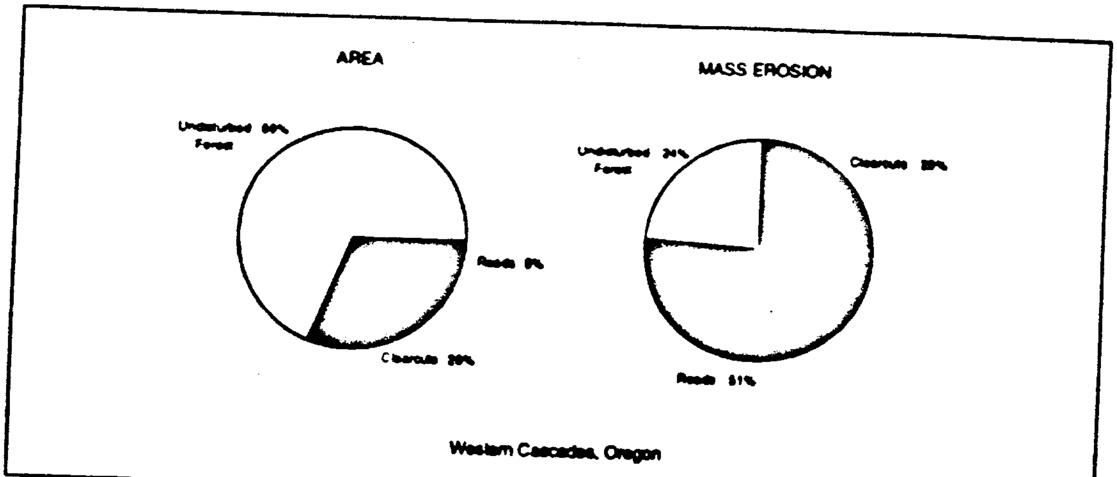

Figure 3-2. Comparison of forest land areas and mass erosion under various land uses (adapted from Sidle, 1989).

sources of erosion and sediment (Rothwell, 1983). Soil loss tends to be greatest during and immediately after road construction because of the unstabilized road prism and disturbance by passage of heavy trucks and equipment (Swift, 1984).

Brown and Krygier (1971) found that sediment production doubled after road construction on three small watersheds in the Oregon Coast Range. Dyrness (1967) observed the loss of 680 cubic yards of soil per acre from the H.J. Andrews Experimental Forest in Oregon due to soil erosion from roads on steep topography. Landslides were observed on all slopes and were most pronounced where forest roads crossed stream channels on steep drainage headwalls. Another example of severe erosion resulting from forestry practices occurred in the South Fork of the Salmon River in Idaho in the winter of 1965, following 15 years of intensive logging and road construction. Heavy rains triggered a series of landslides that deposited sediment on spawning beds in the river channel, destroying salmon spawning grounds (Megahan, 1981). Careful planning and proper road layout and design, however, can minimize erosion and prevent stream sedimentation (Larse, 1971).

Timber Harvesting. Most detrimental effects of harvesting are related to the access and movement of vehicles and machinery, and the skidding and loading of trees or logs. These effects include soil disturbance, soil compaction, and direct disturbance of stream channels. Logging operation planning, soil and cover type, and slope are the most important factors influencing harvesting impacts on water quality (Yobo, 1980). The construction and use of haul roads, skid trails, and landings for access to and movement of logs are the harvesting activities that have the greatest erosion potential.

Surveys of soil disturbance from logging were performed by Hornbeck and others (1986) in Maine, New Hampshire, and Connecticut. They found 18 percent of the mineral soil exposed by logging practices in Maine, 11 percent in New Hampshire, and 8 percent in Connecticut. Megahan (1986) reviewed several studies on forest land erosion and concluded that surface erosion rates on roads often equaled or exceeded erosion reported for severely eroding agricultural lands. Megahan (1986) found that in some cases erosion rates from harvest operations may approach erosion rates from roads and that prescribed burning can accelerate erosion beyond that from logging alone.

Another adverse impact of harvesting is the increase in stream water temperatures resulting from removal of streamside vegetation, with the greatest potential impacts occurring in small streams. However, streamside buffer strips have been shown to minimize the increase in stream temperatures (Brazier and Brown, 1973; Brown and Krygier, 1970).

VOL 12

9444

Regeneration Methods. Regeneration methods can be divided into two general types: (1) regeneration from seedlings, either planted seedlings or existing seedlings released by harvesting, and (2) regeneration from seed, which can be seed from existing trees on or near the site or the broadcast application of seeds of the desired species. In some areas, regeneration with seedlings by mechanical tree planting is often conducted because it is faster and more consistent. Planting approaches relying on seeding generally require a certain amount of mineral soil to be exposed for seed establishment. For this reason, a site preparation technique is usually needed for regeneration by seeding.

Site Preparation. Mechanical site preparation by large tractors that shear, disk, drum-chop, or root-rake a site may result in considerable soil disturbance over large areas and has a high potential to deteriorate water quality (Beasley, 1979). Site preparation techniques that result in the removal of vegetation and litter cover, soil compaction, exposure or disturbance of the mineral soil, and increased stormflows due to decreased infiltration and percolation, all can contribute to increases in stream sediment loads (Golden et al., 1984). However, erosion rates decrease over time as vegetative cover grows back.

Prescribed burning and herbicides are other methods used to prepare sites that may also have potential negative effects on water quality. These activities are discussed below.

Prescribed Burning. Prescribed burning of slash can increase erosion by eliminating protective cover and altering soil properties (Megahan, 1980). The degree of erosion following a prescribed burn depends on soil erodibility, slope, precipitation timing, volume and intensity, fire severity, cover remaining on the soil, and speed of revegetation. Burning may also increase stormflow in areas where all vegetation is killed. Such increases are partially attributable to decreased evapotranspiration rates and reduced canopy interception of precipitation. Erosion resulting from prescribed burning is generally less than that resulting from roads and skid trails and from site preparation that causes intense soil disturbance (Golden et al., 1984). However, significant erosion can occur during prescribed burning if the slash being burned is collected or piled, causing soil to be moved and incorporated into the slash.

Application of Forest Chemicals. Adverse effects on water quality due to forest chemical application typically result from improper chemical application, such as failure to establish buffers around watercourses (Norris and Moore, 1971). Aerial application of forest chemicals has a greater potential to adversely affect water quality, especially if chemicals are applied under improper conditions, such as high winds (Riekerk et al., 1989), or are applied directly to watercourses.

F. Other Federal, State, and Local Silviculture Programs

1. Federal Programs

Forestry activities on Federal lands are predominantly controlled by the U.S. Department of Agriculture (USDA) Forest Service and Department of the Interior (DOI) Bureau of Land Management (BLM). Private entities operating on Federal lands are regulated by timber sales contracts. The Forest Service has developed preventive land management practices and project performance standards (USEPA, 1991). The Agricultural Stabilization and Conservation Service (ASCS) administers the Forestry Incentives Program (FIP) and Stewardship Incentives Program (SIP). Under FIP, ASCS provides cost-share funds to develop, manage, and protect eligible forest land, with emphasis on enhancing water quality, wildlife habitat, and recreational resources, and producing softwood timber. In addition, the Clean Water Act section 404 regulatory program may be applicable to some forestry activities (such as stream crossings) that involve the discharge of dredged or fill material into waters of the United States. However, section 404(f) of the Act exempts most forestry activities from permitting requirements. Regulations describing 404(f) exemptions, as well as applicable best management practices for section 404, have been published by EPA and the U.S. Army Corps of Engineers (40 CFR 232.3). The management measures in this guidance apply only to nonpoint source silvicultural activities. Clean Water Act section 402 regulations for point source permits exempt these nonpoint silvicultural activities (40 CFR 122.27) except for the section 404 requirements discussed above.

2. State Forestry NPS Programs

Most States with significant forestry activities have developed Best Management Practices (BMPs) to control silviculturally-related NPS water quality problems. Often, water quality problems are not due to ineffectiveness of the practices themselves, but to the failure to implement them appropriately (Whitman, 1989; Pardo, 1980).

There are currently two basic types of State forestry NPS programs, voluntary and regulatory. Thirty-five States currently implement voluntary programs, with 6 of these States having the authority to make the voluntary programs regulatory and 10 States backing the voluntary program with a regulatory program for non-compliers (see Table 3-1 for more specific types of programs). Nine States have developed regulatory programs (Essig, 1991).

Voluntary programs rely on a set of BMPs as guidelines to operators (Cubbage et al., 1989). Operator education and technology transfer are also a responsibility of State Forestry Departments. Workshops, brochures, and field tours are used to educate and to demonstrate to operators the latest water quality management techniques. Landowners are encouraged to hire operators who have a working knowledge of State forestry BMPs (Dissmeyer and Miller, 1991). Transfer of information on State NPS controls to landowners is also an important element of these programs.

Regulatory programs involve mandatory controls and enforcement strategies defined in Forest Practice Rules based on a State's Forest Practices Act or local government regulations. These programs usually require the implementation of BMPs based on site-specific conditions and water quality goals, and they have enforceable requirements (Ice, 1985). Often streams are classified based on their most sensitive designated use, such as importance for municipal water supply or propagation of aquatic life. Many water quality BMPs also improve harvesting operation efficiency and therefore can be applied in the normal course of forest harvest operations with few significant added costs (Ontario Ministry of Natural Resources, 1988; Dissmeyer and Miller, 1991). Harvest operation plans or applications to perform a timber harvest are frequently reviewed by the responsible State agency. Erosion and sedimentation control BMPs are also used in these programs to minimize erosion from road construction and harvesting activities.

Present State Coastal Zone Management (CZM) and section 319 programs may already include specific BMP regulations or guidelines for forestry activities. In some States, CZM programs have adopted State forestry regulations and BMPs through reference or as part of a linked program.

3. Local Governments

Counties, municipalities, and local soil and water conservation management districts may also impose additional requirements on landowners and operators conducting forestry activities. In urbanizing areas, these requirements often relate to concerns regarding the conversion of forested lands to urban uses or changes in private property values due to aesthetic changes resulting from forestry practices. In rural areas additional requirements for forestry activities may be implemented to protect public property (roads and municipal water supplies). Local forestry regulations tend to be stricter in response to residents' complaints (Salazar and Cubbage, 1990).

Table 3-1. State Programs by Region and Frequency (Henly and Ellefson, 1987)

NOTE: Water Quality Protection focuses on nonpoint silvicultural sources of pollutants, vegetative buffer strips along waters, road and skid trail design and construction. Reforestation and Timber Management focuses on seed trees and other reforestation forms, timber harvesting system, clearcut size and design. Forest Protection focuses on slash treatment, other wildfire-related treatments, prescribed burn smoke management, herbicide and pesticide application, disease and insect management. Wildlife and Aesthetic Management focuses on wildlife habitat, scenic buffers along roadways, coastal zone management requirements.

Regional Groupings of States: New England-Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island and Vermont; Middle Atlantic-Delaware, Maryland, New Jersey, New York, Pennsylvania and West Virginia; Lake States-Michigan, Minnesota, and Wisconsin; Central States-Illinois, Indiana, Iowa, Kansas, Kentucky, Missouri, Nebraska and Ohio; South Atlantic-North Carolina, South Carolina and Virginia; Southern States-Florida, Georgia, Alabama, Mississippi, Tennessee, Arkansas, Louisiana, Oklahoma and Texas; Pacific States-Alaska, California, Hawaii, Oregon and Washington; N. Rocky Mountain-Idaho, Montana, North Dakota, South Dakota and Wyoming; S. Rocky Mountain-Arizona, Colorado, Nevada, New Mexico and Utah.

II. FORESTRY MANAGEMENT MEASURES

[illegible] Planning

Perform advance planning for forest harvesting that includes the following elements where appropriate:

(1) Identify the area to be harvested including location of waterbodies and sensitive areas such as wetlands, threatened or endangered aquatic species habitat areas, or high- erosion-hazard areas (landslide-prone areas) within the harvest unit.
(2) Time the activity for the season or moisture conditions when the least impact occurs.
(3) Consider potential water quality impacts and erosion and sedimentation control in the selection of silvicultural and regeneration systems, especially for harvesting and site preparation.
(4) Reduce the risk of occurrence of landslides and severe erosion by identifying high-erosion-hazard areas and avoiding harvesting in such areas to the extent practicable.
(5) Consider additional contributions from harvesting or roads to any known existing water quality impairments or problems in watersheds of concern.

Perform advance planning for forest road systems that includes the following elements where appropriate:

(1) Locate and design road systems to minimize, to the extent practicable, potential sediment generation and delivery to surface waters. Key components are:
- **locate roads, landings, and skid trails to avoid to the extent practicable steep grades and steep hillslope areas, and to decrease the number of stream crossings;**
- **avoid to the extent practicable locating new roads and landings in Streamside Management Areas (SMAs); and**
- **determine road usage and select the appropriate road standard.**

(2) Locate and design temporary and permanent stream crossings to prevent failure and control impacts from the road system. Key components are:
- **size and site crossing structures to prevent failure;**
- **for fish-bearing streams, design crossings to facilitate fish passage.**

(3) Ensure that the design of road prism and the road surface drainage are appropriate to the terrain and that road surface design is consistent with the road drainage structures.
(4) Use suitable materials to surface roads planned for all-weather use to support truck traffic.
(5) Design road systems to avoid high erosion or landslide hazard areas. Identify these areas and consult a qualified specialist for design of any roads that must be constructed through these areas.

Each State should develop a process (or utilize an existing process) that ensures that the management measures in this chapter are implemented. Such a process should include appropriate notification, compliance audits, or other mechanisms for forestry activities with the potential for significant adverse nonpoint source effects based on the type and size of operation and the presence of stream crossings or SMAs.

VOL 12

9448

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. The planning process components of this management measure are intended to apply to commercial harvesting on areas greater than 5 acres and any associated road system construction or reconstruction conducted as part of normal silvicultural activities. The component for ensuring implementation of this management measure applies to harvesting and road construction activities that are determined by the State agency to be of a sufficient size to potentially impact the receiving water or that involve SMAs or stream crossings. On Federal lands, where notification of forestry activities is provided to the Federal land management agency, the provisions of the final paragraph of this measure may be implemented through a formal agreement between the State agency and the Federal land management agency. This measure does not apply to harvesting conducted for precommercial thinning or noncommercial firewood cutting.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The objective of this management measure is to ensure that silvicultural activities, including timber harvesting, site preparation, and associated road construction, are conducted without significant nonpoint source pollutant delivery to streams and coastal areas. Road system planning is an essential part of this management measure since roads have consistently been shown to be the largest cause of sedimentation resulting from forestry activities. Good road location and design can greatly reduce the sources and transport of sediment. Road systems should generally be designed to minimize the number of road miles/acres, the size and number of landings, the number of skid trail miles, and the number of watercourse crossings, especially in sensitive watersheds. Timing operations to take advantage of favorable seasons or conditions, avoiding wet seasons prone to severe erosion or spawning periods for fish, is effective in reducing impacts to water quality and aquatic organisms (Hynson et al., 1982). For example, timber harvesting might be timed to avoid periods of runoff, saturated soil conditions, and fish migration and spawning periods.

Preharvest planning should include provisions to identify unsuitable areas, which may have merchantable trees but pose unacceptable risks for landslides or high erosion hazard. These concerns are greatest for steep slopes in areas with high rainfall or snowpack or sensitive rock types. Decomposed granite, highly weathered sedimentary rocks, and fault zones in metamorphic rocks are potential rock types of concern for landslides. Deep soils derived from these rocks, colluvial hollows, and fine-textured clay soils are soil conditions that may also cause potential problems. Such areas usually have a history of landslides, either occurring naturally or related to earlier land-disturbing activities.

Potential water quality and habitat impacts should also be considered when planning silvicultural harvest systems as even-aged (e.g., clearcut, seedtree, shelterwood) or uneven-aged (e.g., group selection or individual tree selection) and planning the type of yarding system. While it may appear to be more beneficial to water quality to use uneven-aged silvicultural stand management because less ground disturbance and loss of canopy cover occur, these factors should also be weighed against the possible effects of harvesting more acres selectively to yield equivalent timber volumes. Such harvesting may require more miles of road construction, which can increase sediment generation and increase levels of road management.

In addition, for uneven-aged systems, yarding in moderately sloping areas is usually done with groundskidding equipment, which can cause much more soil disturbance than cable yarding. For even-aged systems, cable yarding may be used in sloping areas; cable yarding is not widely used for uneven-aged harvesting. Whichever silvicultural system is selected, planning will be required to minimize erosion and sediment delivery to waterbodies. Preharvest planning should address how harvested areas will be replanted or regenerated to prevent erosion and potential impact to waterbodies.

Cumulative effects to water quality from forest practices are related to several processes within a watershed (onsite mass erosion, onsite surface erosion, pollutant transport and routing, and receiving water effects) (Sidle, 1989). Cumulative effects are influenced by forest management activities, natural ecosystem processes, and the distribution of other land uses. Forestry operations such as timber harvesting, road construction, and chemical use may directly affect onsite delivery of nonpoint source pollutants as well as contribute to existing cumulative impairments of water quality.

In areas where existing cumulative effects problems *have already been assessed* for a watershed of concern, the potential for additional contributions to known water quality impairments or problems should be taken into account during preharvest planning. This does not imply that a separate cumulative effects assessment will be needed for each planned forestry activity. Instead, it points to the need to consider the potential for additional contributions to known water quality impairments based on information from previously conducted watershed or cumulative effects assessments. These types of water quality assessments, generally conducted by State or Federal agencies, may indicate water quality impairments in watersheds of concern caused by types of pollutants unrelated to forestry activities. In this case, there would be no potential for additional contributions of those pollutants from the planned forestry activity. However, if existing assessments attribute a water quality problem to the types of pollutants potentially generated by the planned forestry activity, then it is appropriate to consider this during the planning process. If additional contributions to this impairment are likely to occur as a result of the planned activity, this may necessitate adjustments in planned activities or implementation of additional measures. This may include selection of harvest units with low sedimentation risk, such as flat ridges or broad valleys; postponement of harvesting until existing erosion sources are stabilized; and selection of limited harvest areas using existing roads. The need for additional measures, as well as the appropriate type and extent, is best considered and addressed during the preharvest planning process.

Some important sediment sources related to roads are stream crossings, road fills on steep slopes, poorly designed road drainage structures, and road locations in close proximity to streams. Roads through high-erosion-hazard areas can also lead to serious water quality degradation. Some geographical areas have a high potential for serious erosion problems (landslides, major gullies, etc.) after road construction. Factors such as slope steepness, soil and rock characteristics, and local hydrology influence this potential. High-erosion-hazard areas may include badlands, loess deposits, steep and dissected terrain, and areas with existing landslides and are generally recognizable on the ground by trained personnel. Indications of hazard locations may include landslides, gullies, weak soils, unusually high ground water levels, very steep slopes, unvegetated shorelines and streambanks, and major geomorphic changes. Road system planning should identify and avoid these areas.

In most States, high-erosion-hazard areas are limited in extent. In the Pacific Coast States, however, road-related landslides are often the major source of sediment associated with forest management. Erosion hazard areas are often mapped, and these maps are one tool to use in identifying high-erosion-hazard sites. The U.S. Geological Survey has produced geologic hazard maps for some areas. The USDA Soil Conservation Service (SCS) and Agricultural Stabilization and Conservation Service (ASCS), as well as State and local agencies, may also have erosion-hazard-area maps.

Preplanning the timber harvest operation to ensure water quality protection will minimize NPS pollution generation and increase operation efficiency (Maine Forest Service, 1991; Connecticut RC&D Forestry Committee, 1990; Golden et al., 1984). The planning of streamside management area width and extent is also crucial because of SMAs' potential to reduce pollutant delivery. Identification and avoidance of high-hazard areas can greatly reduce the risk of landslides and mass erosion (Golden et al., 1984). Careful planning of road and skid trail system locations will reduce the amount of land disturbance by minimizing the area in roads and trails, thereby reducing erosion and sedimentation (Rothwell, 1978). Studies at Fernow Experimental Forest, West Virginia, demonstrated that good planning reduced skid road area by as much as 40 percent (Kochenderfer, 1970).

Designing road systems prior to construction to minimize road widths, slopes, and slope lengths will also significantly reduce erosion and sedimentation (Larse, 1971). The most effective road system results from planning conducted to serve an entire basin, rather than arbitrarily constructing individual road projects to serve short-term needs (Swift, 1985). The key environmental factors involved in road design and location are soil texture, slope, aspect, climate, vegetation, and geology (Gardner, 1967).

Proper design of drainage systems and stream crossings can prevent system destruction by storms, thereby preventing severe erosion, sedimentation, and channel scouring (Swift, 1984). Removal of excess water from roads will also reduce the potential for grade weakening, surface erosion, and landslides. Drainage problems can be minimized when locating roads by avoiding clay beds, seeps, springs, concave slopes, muskegs, ravines, draws, and stream bottoms (Rothwell, 1978).

Developing a process, or utilizing an existing process, to ensure that the management measures in this chapter are implemented is an important component for forestry nonpoint source control programs. While silvicultural management of forests may extend over long stand rotation periods of 20 to 120 years and cover extensive areas of forestland, the forestry operations that generate nonpoint source pollution, like harvesting and road building, are of relatively short duration and occur in dispersed, often isolated locations in forested areas. Forest harvesting or road building operations are usually operational on a given site only for a period of weeks or months. These operational phases are then followed by the much longer period of regrowth of the stand or the rotation period. Since forestry operations are relatively dispersed and move from site to site within forested areas, it is essential to have some process to ensure implementation of management measures. For example, it is not possible to track the implementation of management measures or determine their effectiveness if there is no way of knowing where or when they might be applied. In the case of monitoring or water quality assessments, correlation of water quality conditions to forestry activities is not possible absent some ability to determine where and to what extent forestry operations are being conducted and whether management measures are being implemented. Because of the dispersed and episodic nature of forestry operations, many States have implemented programs that currently incorporate a process such as notification to ensure implementation and to facilitate evaluation of program implementation and assessment of water quality conditions.

This process has been shown to be a beneficial device for ensuring the implementation of water quality best management practices, particularly for forestry activities. In contrast to the typical forestry situation, nonpoint pollution from urban and agricultural sources is generated from areas and activities that are relatively stationary and repetitive. Because of this, these sources of nonpoint pollution are more apparent and readily addressed than more isolated and episodic forestry operations. Given the unique nature of forestry operations, it is necessary for States to have some mechanism for being apprised of forestry activities in order to uniformly address sources of nonpoint pollution.

This Forestry Management Measure component allows considerable flexibility to States for determining how this provision should be carried out in the coastal zone. For the purposes of this management measure, such a process should include appropriate notification mechanisms for forestry activities with the potential for nonpoint source impacts. It is important to point out that for the purposes of this management measure such a notification process might be either verbal or written and does *not* necessarily require submittal and approval of written preharvest plans (although those States that currently require submittal of a preharvest plan would also fulfill this management measure component for the coastal zone program). States also have flexibility in determining what information should be provided and how this should occur for notification mechanisms. Timing and location of the planned forestry operation are common elements of existing notification requirements and may serve as an acceptable minimum. Existing programs for forestry have found some type of notification of the planned activity to the appropriate State agency to be a very beneficial device for ensuring the implementation of water quality best management practices for silvicultural activities. At least 12 Coastal Zone Management Program States currently require some type of notification, associated with Forest Practices Acts, CWA section 404 requirements, tax incentive or cost share programs, State Forester technical assistance, severance tax filings, stream crossing permits, labor permits, erosion control permits, or land management agency agreements.

3. Management Measure Selection

The rationale for this measure is based on information on the effects of various harvesting practices and the effectiveness and costs of planning, design, and location components addressed in this measure. This measure is also based in part on the experience of some States in using preharvest planning as part of implementation of best management practices.

a. Effectiveness Information

Preharvest planning has been demonstrated to play an important role in the control of nonpoint source pollution and efficient forest management operations. A fundamental component to be considered in timber harvest planning is the selection of the silvicultural system. Research conducted by Beasley and Granillo (1985) demonstrated that selective cutting generated lower water yields and sediment yields than did clearcutting. This is important not only because of the sediment loss, but also because higher stormflows can undercut streambanks and scour channels, reducing channel stability. The data in Table 3-2 show that selective cutting results in sediment yields 2.5 to 20 times less and water yields 1.3 to 2.6 times less than those resulting from clearcutting. As stated previously, the amount and potential water quality impacts of roads needed for each system must also be taken into account.

Methods used for harvesting are closely related to the silvicultural system. Four harvesting methods combined with varying types of management practices to protect water quality, including road location, were compared in a study conducted by Eschner and Larmoyeux (1963) (Table 3-3). Harvesting effects on water quality, as measured by turbidity, were shown to be clearly related to the care taken in logging and planning skid roads. The extensive

Table 3-2. Clearcutting Versus Selected Harvesting Methods (AR) (Beasley and Granillo, 1985)

Water Year	Treatment	Mean Annual Water Yield (cm)	Mean Annual Sediment Losses (kg/ha)
1981	Clearcut	6.4	41
(Preharvest)	Selection	7.4	52
	Control	6.8	52
1982	Clearcut	13.2	264
	Selection	5.1	13
	Control	1.0	4
1983	Clearcut	44.7	63
	Selection	33.8	26
	Control	31.0	19
1984	Clearcut	32.8	83
	Selection	14.5	15
	Control	17.5	46
1985	Clearcut	27.9	73
	Selection	12.3	12
	Control	15.9	17

selection method, combined with some NPS controls (20 percent road grade limits, no skidding in streams, water bars on skid roads), produced higher maximum levels of turbidity than did intensive selection with additional control practices (10 percent road grade limits; skid trails located away from streams). Harvesting by the diameter limit practice without any restrictions on road grades or stream restrictions increased maximum turbidity by 200 times over intensive selection, and commercial clearcutting with no controls increased maximum turbidity by over three orders of magnitude. This study concluded that care taken in preharvest planning of skid roads and logging operations can prevent most potential impairment to water quality.

McMinn (1984) compared a skidder logging system and a cable yarder for their relative effects on soil disturbance (Table 3-4). With the cable yarder, 99 percent of the soil remained undisturbed (the original litter still covered the mineral soil), while the amount of soil remaining undisturbed after logging by skidder was only 63 percent. Beasley, Miller, and Gough (1984) related sediment loss associated with forest roads to the average slope gradient of road segments (Table 3-5). The greater the average slope gradient, the greater the soil loss, ranging from a total of 6.8 tons/acre lost when the slope gradient was 1 percent, to 19.4 tons/acre at 4 percent, to 32.3 tons/acre at 6 percent, to 33.7 tons/acre at 7 percent.

Sidle (1980) found that the impacts of tractor skidding can be lessened through the use of preplanned skid roads and landings designed so that the area disturbed by road construction and the overall extent of sediment compaction at the site are minimized. Sidle (1980) described a study in North Carolina that showed that preplanning roads could result in a threefold decrease in soil compaction at the logging area.

Table 3-3. Effect of Four Harvesting and Road Design Methods on Water Quality (WV, PA) (Eschner and Larmoyeux, 1963)

Watershed Number	Practice	Maximum Turbidity (Turbidity units)	Frequency Distribution of Samples Turbidity Unit Classes: 0 to 10	11 to 99	100 to 999	1000+	Total
			(Number of samples)				
1	Commercial clearcut[a]	56,000	126	40	24	13	203
2	Diameter limit[b]	5,200	171	17	8	7	203
5	Extensive selection[d]	210[c]	195	8	0	0	203
3	Intensive selection[e]	25	201	2	0	0	203
4	Control	15	202	1	0	0	203

Note: Includes regularly scheduled samples and special samples in storm periods.
[a] Skid roads were not planned but were "logger's choice."
[b] Trees over 17 inches DBH were cut. Water bars placed at 2-chain intervals along skid roads.
[c] Not included in frequency distribution. This sample was taken at a time when the other watersheds were not sampled.
[d] Trees over 11 inches DBH were cut. Maximum skid road grade was 20 percent, with water bars installed as needed. Skidding was prohibited in streams.
[e] With intensive selection, trees over 5 inches DBH were cut. Maximum skid road grade was 10 percent. Skidding was prohibited in streams, and roads were located away from streams. Water bars were used as needed, and disturbed areas were stabilized with grass seeding.

Table 3-4. Comparison of the Effect of Conventional Logging System and Cable Miniyarder on Soil (GA) (McMinn, 1984)

Disturbance Class[a]	Cable Skidder (percent)	Miniyarder (percent)
Undisturbed	63	99
Soil exposed	12	1
Soil disturbed	25	0

[a] Undisturbed = original duff or litter still covering the mineral soil.
Exposed = litter and duff scraped away, exposing mineral soil, but no scarification.
Disturbed = Mineral soil exposed and scarified or dislocated.

Table 3-5. Relationship Between Slope Gradient and Annual Sediment Loss on an Established Forest Road[a] (AR) (Beasley, Miller, and Gough, 1984)

Average Slope Gradient of Road Segment (percent)	Soil Deposited[b]		Suspended Solids		Total	
	tons per acre	tons per mile	tons per acre	tons per mile	tons per acre	tons per mile
7	21.6	54.0	12.0	30.0	33.7	84.0
6	10.2	26.7	22.1	57.8	32.3	84.5
4	5.0	11.3	14.4	32.6	19.4	43.8
1	0.2	0.3	6.6	12.4	6.8	12.7

[a] The length of the road segments averaged 330 feet, ranging from 308 to 357 feet. Most of the other physical characteristics of the road were consistent, except the variation in the proportion of backslope to total area. Fill slopes below the road segments were well vegetated. Cut slopes were steep, bare, and actively eroding.
[b] Measured in upslope, inside ditches.

Several researchers have emphasized that prevention is the most effective approach to erosion control for road activities (Megahan, 1980; Golden et al., 1984). Because roads are the greatest source of surface erosion from forestry operations, reducing road surface area while maintaining efficient access is a primary component of proper road design. Careful planning of road layout and design can minimize erosion by as much as 50 percent (Yoho, 1980; Weitzman and Trimble, 1952). This practice has the added benefits of reducing construction, maintenance, and transport costs and increasing forested area for production. Rice et al. (1972) found no increase in sedimentation from a well-designed logging road on gently sloping, stable soils in Oregon except for during the construction period.

Locating roads on low gradients is another planning component that can reduce the impacts of sedimentation. Trimble and Weitzman (1953) presented data showing that lower gradients and shorter road lengths reduce erosion. The same authors, in a 1952 journal article, also presented data showing that reduced gradients in conjunction with water bars can significantly reduce erosion from roads. The data from these two studies are presented in Table 3-6.

b. Cost Information

A cost-benefit analysis by Dissmeyer and others (USDA, 1987) reveals the dramatic, immediate savings from considering water quality during the design phase of a road reconstruction project (Table 3-7). Expertise on soil and water protection provided by a hydrologist resulted in 50 percent of the savings alone. Other long-term economic benefits of careful planning such as longer road life and reduced maintenance costs were not quantified in this analysis.

Table 3-6. The Effect of Skid Road Grade and Length on Road Surface Erosion (WV, PA) (Trimble and Weitzman, 1953)

Skid Road Type (Grade and Length of Slope)	Erosion from Skid Road Surface After Logging		
	Erosion (in)	Average Grade (%)	Average Length (ft)
0-20% grade/0-132 feet	0.4	10	46
21-40% grade/0-132 feet	0.7	29	55
133-264 feet	1.0	35	211

Table 3-7. Costs and Benefits of Proper Road Design (With Water Quality Considerations) Versus Reconstruction (Without Water Quality Considerations) (USDA Forest Service, 1987)

	Without Soil/ Water Input[a]	With Soil/Water Input[a]
Miles of road	3.0	3.0
Reconstruction costs	$796,000	$372,044
Soil/water input costs	--	$800
Immediate benefit (savings) of soil/water input	--	$211,978

[a] Soil/water inputs are design adjustments made by a hydrologist and include narrower road width and steeper road bank cuts in soils of low erodibility and low revegetation potential.

Kochenderfer, Wendel, and Smith (1984) determined the costs for locating four minimum standard roads in the Central Appalachians (Table 3-8). Road location costs increased as the terrain became more difficult (e.g., had a large number of rock outcrops or steep slopes) or required several location changes. Typically, road location costs accounted for approximately 8 percent of total costs.

Ellefson and Miles (1984) performed an economic evaluation of forest practices to curb nonpoint source water pollutants. They presented the cumulative decline in net revenue of 1.2 percent for the practices of skid trail and landing design for a sale with initial net revenue of $124,340.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure discussed above.

a. Harvesting Practices

■ *Consider potential water quality and habitat impacts when selecting the silvicultural system as even-aged (clearcut, seedtree, or shelterwood) or uneven-aged (group or individual selection). The yarding system, site preparation method, and any pesticides that will be used should also be addressed in*

Table 3-8. Characteristics and Road Location[a] Costs of Four "Minimum-Standard" Forest Truck Roads Constructed in the Central Appalachians (Kochenderfer, Wendel, and Smith, 1984)

Road Number	Road Length (miles)	Road Grade (%)	Number of Dips[b]	Culvert Number	Culvert Size (in)	Culvert Length (ft)	Location Costs ($/miles)
1	0.81	6.9	22	1	18	39	585
6	0.78	2.7	15	5	15	135	615
7	0.34	3.7	5	2	15	64	720
8	1.25	2.6	30	0			585

[a] Road location includes the cost to plan, reconnoiter, and lay out 1 mile of road.
[b] Includes natural grade breaks where dozer work is required for outsloping.

preharvest planning. As part of this practice the potential impacts from and extent of roads needed for each silvicultural system should be considered.

- *In warmer regions, schedule harvest and construction operations during dry periods/seasons. In temperate regions, harvest and construction operations may be scheduled during the winter to take advantage of snow cover and frozen ground conditions.*

- *To minimize soil disturbance and road damage, limit operations to periods when soils are not highly saturated (Rothwell, 1978). Damage to forested slopes can also be minimized by not operating logging equipment when soils are saturated, during wet weather, or in periods of ground thawing.*

- *Planned harvest activities or chemical use should not contribute to problems of cumulative effects in watersheds of concern.*

- *Use topographic maps, aerial photography, soil surveys, geologic maps, and rainfall intensity charts to augment site reconnaissance to lay out and map harvest unit; identify and mark, as needed:*
  - *Any sensitive habitat areas needing special protection such as threatened and endangered species nesting areas,*
  - *Streamside management areas,*
  - *Steep slopes, high-erosion-hazard areas, or landslide prone areas,*
  - *Wetlands.*

- *In high-erosion-hazard areas, trained specialists (geologist, soil scientist, geotechnical engineer, wildland hydrologist) should identify sites that have high risk of landslides or that may become unstable after harvest and should recommend specific practices to control harvesting and protect water quality.*

- *Lay out harvest units to minimize the number of stream crossings.*

- *States are encouraged to adopt notification mechanisms that integrate and avoid duplicating existing requirements for notification including severance taxes, stream crossing permits, erosion control permits, labor permits, forest practice acts plans, etc. For example, States may require one preharvest* *plan that the landowner could submit to just one State or local office. The appropriate State agency might encourage forest landowners to develop a preharvest plan. The plan would address the components of this management measure including the area to be harvested, any forest roads to be constructed, and the timing of the activity.*

b. Road System Practices

■ *Preplan skid trail and landing location on stable soils and avoid steep gradients, landslide-prone areas, high-erosion-hazard areas, and poor-drainage areas.*

- Landings should not be located in SMAs.
- New roads and skid trails should not be located in SMAs, except at crossings. Existing roads and landings in the SMA will be closed unless the construction of new roads and landings to access an area will cause greater water quality impacts than the use of existing roads.
- Roads should not be located along stream channels where road fill extends within 50-100 horizontal feet of the *annual* high water level. (Bankfull stage is also used as reference point for this.)

■ *Systematically design transportation systems to minimize total mileage.*

- Weigh skid trail length and number against haul road length and number.
- Locate landings to minimize skid trail and haul road mileage (Rothwell, 1978).

■ *Utilize natural log landing areas to reduce the potential for soil disturbance (Larse, 1971; Yee and Roelofs, 1980).*

■ *Plot feasible routes and locations on an aerial photograph or topographic map to assist in the final determination of road locations.*

Proper design will reduce the area of soil exposed by construction activities. Figure 3-3 presents a comparison of road systems.

■ *In moderately sloping terrain, plan for road grades of less than 10 percent, with an optimal grade between 3 percent and 5 percent. In steep terrain, short sections of road at steeper grades may be used if the grade is broken at regular intervals. Vary road grades frequently to reduce culvert and road drainage ditch flows, road surface erosion, and concentrated culvert discharges (Larse, 1971).*

Gentle grades are desirable for proper drainage and economical construction (Ontario Ministry of Natural Resources, 1988). Steeper grades are acceptable for short distances (200-300 feet), but an increased number of drainage structures may be needed above, on, and below the steeper grade to reduce runoff potential and minimize erosion. In sloping terrain, no-grade road sections are difficult to drain properly and should be avoided when possible.

■ *Design skid trail grades to be 15 percent or less, with steeper grades only for short distances.*

■ *Design roads and skid trails to follow the natural topography and contour, minimizing alteration of natural features.*

This practice will reduce the amount of cut and fill required and will consequently reduce road failure potential. Ridge routes and hillside routes are good locations for ensuring stream protection because they are removed from stream channels and the intervening undisturbed vegetation acts as a sediment barrier. Wide valley bottoms are good routes if stream crossings are few and roads are located outside of SMAs (Rothwell, 1978).

Permanent Haul Road
Temporary Haul Road
Skid Road (or trail)
Bridge (water crossing)
Landing

Plans A, B, and C show three ways to place truck and skid roads on a cutting unit. The comments next to each plan indicate why Plan C is best.

Plan A layout: 2 bridges
4 landings
3 miles of haul road

Comment: Road and bridge construction costs too high. Skid distance too short. Too much steep downhill skidding. Too many landings on too steep land. Two bridges are unnecessary.

Plan B layout: 1 bridge
3 landings
3.5 miles of haul road

Comment: Loop road unnecessary. Skid distances too short. Erosion minimized up hill skidding.

Plan C layout: 1 bridge
2 landings
2 miles of haul road

Comment: Haul road follows high ground. Minimal road construction. Ideal skidding distances. Erosion minimized by uphill skidding. Least number of landings. Only one bridge required.

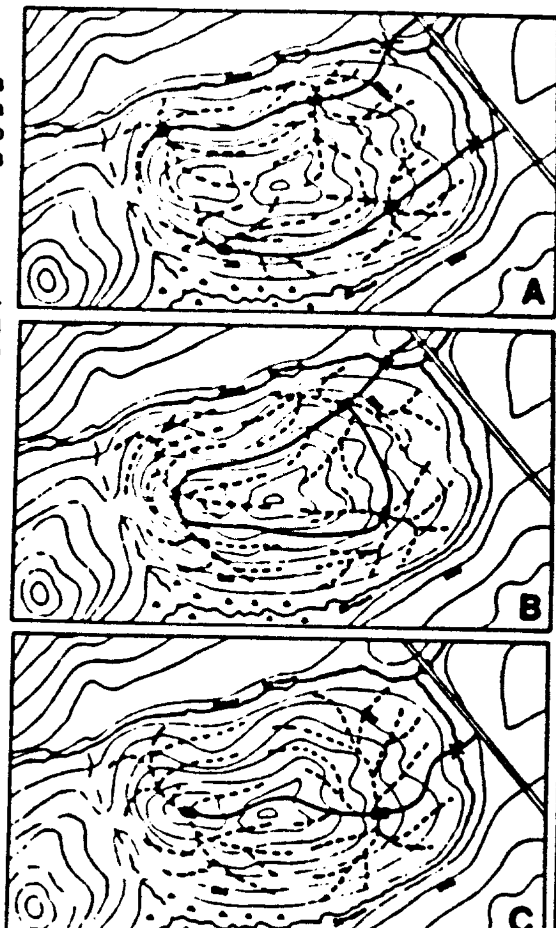

Figure 3-3. How to select the best road layout (Hynson et al., 1982).

■ *Roads in steep terrain should avoid the use of switchbacks through the use of more favorable locations. Avoid stacking roads above one another in steep terrain by using longer span cable harvest techniques.*

■ *Design roads crossing low-lying areas so that water does not pond on the upslope side of the road.*

- Use overlay construction techniques with suitable nonhazardous materials for roads crossing muskegs.
- Provide cross drains to allow free drainage and avoid ponding, especially in sloping areas.

- *Do not locate and construct roads with fills on slopes greater than 60 percent. When necessary to construct roads across slopes that exceed the angle of repose, use full-bench construction and/or engineered bin walls or other stabilizing techniques.*

- *Use full-bench construction and removal of fill material to a suitable location when constructing road prisms on sideslopes greater than 60 percent.*

- *Design cut-and-fill slopes to be at stable angles, or less than the normal angle of repose, to minimize erosion and slope failure potential.*

The degree of steepness that can be obtained is determined by the stability of the soil (Rothwell, 1978). Figure 3-4 depicts proper cut-and-fill construction. Table 3-9 presents an example of stable backslope and fill slope angles for different soil materials.

- Use retaining walls, with properly designed drainage, to reduce and contain excavation and embankment quantities (Larse, 1971). Vertical banks may be used without retaining walls if the soil is stable and water control structures are adequate.
- Balance excavation and embankments to minimize the need for supplemental building material and to maximize road stability.
- Do not use road fills at drainage crossings as water impoundments unless they have been designed as an earthfill dam that may be subject to section 404 requirements. These earthfill embankments should have outlet controls to allow draining prior to runoff periods and should be designed to pass flood flows.

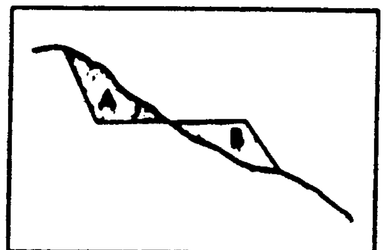

Figure 3-4. Typical side-hill cross section illustrating how cut material, A, equals fill material, B (Rothwell, 1978).

- *Allow time after construction for disturbed soil and fill material to stabilize prior to use (Huff and Deal, 1982). Roads should be compacted and stabilized prior to use. This will reduce the amount of maintenance needed during and after harvesting activities (Kochenderfer, 1970).*

Table 3-9. Stable Back Slope and Fill Slope Angles for Different Soil Materials (Rothwell, 1978)

Back Slopes		Fill Slopes	
Flat ground cuts under 0.9 m	2:1	Common for most soil types	1½:1
Most soil types with ground slopes <55%	1:1	Alluvial soils	2:1
Most soil types with ground slopes >55%	¾:1	Ballast	1:1
Hardpan of soft rock	½:1	Clay	4-1:1
Solid rock	¼:1	Rock, crushed	1-¾:1
		Gravel	1:1
		Sand, moist	1½-1:1
		Sand, saturated	2:1
		Shale	1½:1

VOL 12

■ *Use existing roads, whenever practical, to minimize the total amount of construction necessary.*

Do not plan and construct a road when access to an existing road is available on the opposite side of the drainage. This practice will minimize the amount of new road construction disturbance. However, avoid using existing or past road locations if they do not meet needed road standards (Swift, 1985).

■ *Minimize the number of stream crossings for roads and skid trails. Stream crossings should be designed and sited to cross drainages at 90° to the streamflow.*

■ *Locate stream crossings to minimize channel changes and the amount of excavation or fill needed at the crossing (Furniss et al., 1991). Apply the following criteria to determine the locations of stream crossings (Hynson et al., 1982):*

- Use a streambed with a straight and uniform profile above, at, and below the crossing;
- Locate crossing so the stream and road alignment are straight in all four directions;
- Cross where the stream is relatively narrow with low banks and firm, rocky soil; and
- Avoid deeply cut streambanks and soft, muddy soil.

■ *Choose stream-crossing structures (bridges, culverts, or fords) with the structural capacity to safely handle expected vehicle loads with the least disturbance to the watercourse. Consider stream size, storm frequency and flow rates, intensity of use (permanent or temporary), water quality, and habitat value, and provide for fish passage.*

■ *Select the waterway opening size to minimize the risk of washout during the expected life of the structure.*

9459

Bridges or arch culverts, which retain the natural stream bottom and slope, are preferred over pipe culverts for streams that are used for fish migrating or spawning areas (Figures 3-5 and 3-6). Fish passage may be provided in streams that have wide ranges of flow by providing multiple culverts (Figure 3-7).

■ *Design culverts and bridges for minimal impact on water quality. Size small culverts to pass the 25-year flood, and size major culverts to pass the 50-year flood. Design major bridges to pass the 100-year flood.*

■ *The use of fords should be limited to areas where the streambed has a firm rock or gravel bottom (or where the bottom has been armored with stable material), where the approaches are both low and stable enough to support traffic, where fish are not present during low flow, and where the water depth is no more than 3 feet (Ontario Ministry of Natural Resources, 1988; Hynson et al., 1982).*

■ *For small stream crossings on temporary roads, the use of temporary bridges is recommended.*

Temporary bridges usually consist of logs bound together and suspended above the stream, with no part in contact with the stream itself. This prevents streambank erosion, disturbance of stream bottoms, and excessive turbidity (Hynson et al., 1982). Provide additional capacity to accommodate debris loading that may lodge in the structure opening and reduce its capacity.

■ *When temporary stream crossings are used, remove culverts and log crossings upon completion of operations.*

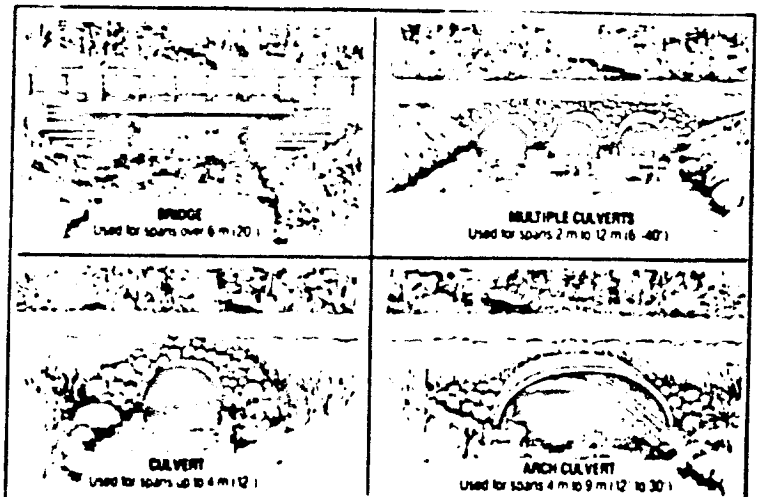

Figure 3-5. Alternative water crossing structures (Ontario Ministry of Natural Resources, 1988).

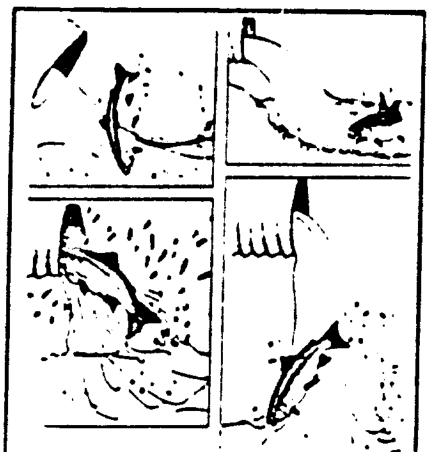

Figure 3-6. Culvert conditions that block fish passage (Yee and Roelofs, 1980).

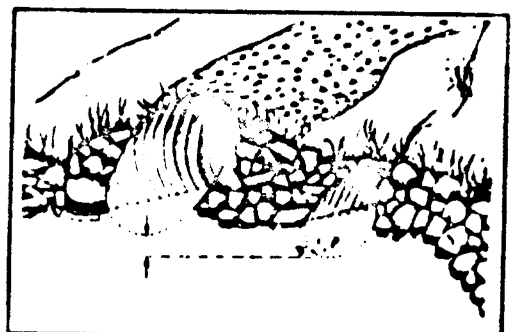

Figure 3-7. Multiple culverts for fish passage in streams that have wide ranges of flows (Hynson et al., 1982).

- *Springs flowing continuously for more than 1 month should have drainage structures rather than allowing road ditches to carry the flow to a drainage culvert.*

- *Most forest roads should be surfaced, and the type of road surface will usually be determined by the volume and composition of traffic, the maintenance objectives, the desired service life, and the stability and strength of the road foundation (subgrade) material (Larse, 1971).*

Figure 3-8 compares roadbed erosion rates for different surfacing materials.

- *Surface roads (with gravel, grass, wood chips, or crushed rocks) where grades increase the potential for surface erosion.*

- *Use appropriately sized aggregate, appropriate percent fines, and suitable particle hardness to protect road surfaces from rutting and erosion under heavy truck traffic during wet periods. Ditch runoff should not be visibly turbid during these conditions. Do not use aggregate containing hazardous materials or high sulfide ores.*

- *Plan water source developments, used for wetting and compacting roadbeds and surfaces, to prevent channel bank and streambed impacts. Access roads should not provide sediment to the water source.*

- *Many States currently utilize some process to ensure implementation of management practices. These processes are typically related to the planning phase of forestry operations and commonly involve some type of notification process. Some States have one or more processes in place which serve as notification mechanisms used to ensure implementation. These State processes are usually associated with either Forest Practices Acts, Erosion Control Acts, State Dredge and Fill or CWA Section 404 requirements, timber tax requirements, or State and Federal incentive and cost share programs. The examples of existing State processes below illustrate some of these which might also be used as mechanisms to ensure implementation of management measures.*

Florida Water Management Districts require notification prior to conducting forestry operations that involve stream crossings. This is required in order to meet the requirements of a State Dredge and Fill general permit, comparable to a CWA section 404 requirement. This notification is usually done by mail, but at least one water management district also allows verbal notification for some types of operations by telephoning an answering machine. In Florida, notification is required for any crossing of "Waters of the State," including wetlands, intermittent streams and creeks, lakes, and ponds. If any of these waters in the State are to be crossed during forestry operations, either by haul roads or by groundskidding, then notification is needed and State BMPs are required by reference in the general permit. Notification is usually provided by mailing in a notification sheet, which says who will conduct the operation and where it will be conducted (see Appendix 3A, Example 3A-1). In addition, information on what type of operation will be conducted, the name of a contact person, and a sketch of the site are included. Use of pesticides for forestry applications in Florida also requires licensing by the State Bureau of Pesticides.

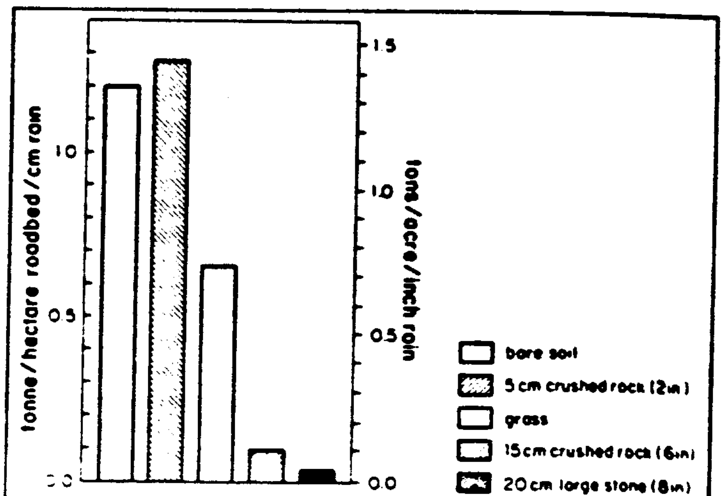

Figure 3-8. Soil loss rates for roadbeds with five surfacing treatments. Roads constructed of sandy loam saprolite (Swift, 1988).

The Oregon Forest Practice Rules require that the landowner or operator notify the State Forester at least 15 days prior to commencement of the following activities: (1) harvesting of forest tree species; (2) construction, reconstruction and improvement of roads; (3) application of pesticides and fertilizers; (4) site preparation for reforestation involving clearing or use of heavy machinery; (5) clearing forest land for conversion to any non-forest use; (6) disposal or treatment of slash; (7) pre-commercial thinning; and (8) cutting of firewood, when the firewood will be sold or used for barrier. The State must approve the activity within 15 days and may require the submittal of a written plan. In addition, the preparation and submittal of a written plan is required for all operations within 100 feet of Class I waters, which are waters that support game fish or domestic uses, or within 300 feet of wetlands and sensitive wildlife habitat areas. Appendix 3A, Example 3A-2 contains a copy of Oregon's Notification of Operation/Application for Permit form. Oregon has developed a system of prioritization for the review and approval of these written plans. In Oregon, notification of intent to harvest is provided to the Department of Revenue through the Department of Forestry for purposes of tax collection. Additional permits for operation of power-driven machinery and to clear rights-of-way for road systems are also required.

New Hampshire does not have a Forest Practices Act, but does have a number of other State processes that serve as notification mechanisms for forestry activities. Prior to conducting forest harvesting, an Intent to Cut Application must be submitted to the Department of Revenue Administration (see Appendix 3A, Example 3A-3). This is required for the timber yield tax, and is filed in order to get a certificate for intent to cut. The Intent to Cut Application must be accompanied by an application for Filling, Dredging or Construction of Structures for those operations that involve the crossing of any freshwater wetland, intermittent or perennial stream, or other surface water. If the activity is not considered a minimum impact, a written plan must be submitted and approved before work may begin. Signature of these applications by the owner or operator adopts by reference the provisions of the State Best Management Practice Handbook. The State Erosion Control Act also requires notification for obtaining a permit for ground-disturbing activities greater than 100,000 square feet. This permit is required prior to commencement of operations. Another State process that entails notification is the provisions for the prevention of pollution from terrain alteration. These provisions require the submission of a plan 30 days before conducting the transport of forest products in or on the border of the surface waters of the State or before significantly altering the characteristics of the terrain in such a manner as to impede the natural runoff or create an unnatural runoff. The State must grant written permission before operations of this type may take place. Each of these existing State mechanisms entails the notification of the State prior to conducting forestry operations. Pesticides licensing is also necessary if the forestry operation involves the application of herbicides or insecticides.

Streamside Management Areas (SMAs)

Establish and maintain a streamside management area along surface waters, which is sufficiently wide and which includes a sufficient number of canopy species to buffer against detrimental changes in the temperature regime of the waterbody, to provide bank stability, and to withstand wind damage. Manage the SMA in such a way as to protect against soil disturbance in the SMA and delivery to the stream of sediments and nutrients generated by forestry activities, including harvesting. Manage the SMA canopy species to provide a sustainable source of large woody debris needed for instream channel structure and aquatic species habitat.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to surface waters bordering or within the area of operations. SMAs should be established for perennial waterbodies as well as for intermittent streams that are flowing during the time of operation. For winter logging, SMAs are also needed for intermittent streams since spring breakup is both the time of maximum transport of sediments from the harvest unit and the time when highest flows are present in intermittent streams.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The streamside management area (SMA) is also commonly referred to as a streamside management zone (SMZ) or as a riparian management area or zone. SMAs are widely recognized to be highly beneficial to water quality and aquatic habitat. Vegetation in SMAs reduces runoff and traps sediments generated from upslope activities, and reduces nutrients in runoff before it reaches surface waters (Figure 3-9, Kundt and Hall, 1988). Canopy species provide shading to surface waters, which moderates water temperature and provides the detritus that serves as an energy source for stream ecosystems. Trees in the SMA also provide a source of large woody debris to surface waters. SMAs provide important habitat for aquatic organisms (and terrestrial species) while preventing excessive logging-generated slash and debris from reaching waterbodies (Corbett and Lynch, 1985).

SMAs need to be of sufficient width to prevent delivery of sediments and nutrients generated from forestry activities (harvest, site preparation, or roads) in upland areas to the waterbody being protected. Widths for SMAs are established by considering the slope, soil type, precipitation, canopy, and waterbody characteristics. To avoid failure of SMAs, zones of preferential drainage such as intermittent channels, ephemeral channels and depressions need to be addressed when determining widths and laying out SMAs. SMAs should be designed to withstand wind damage or blowdown. For example, a single rank of canopy trees is not likely to withstand blowdown and maintain the functions of the SMA.

SMAs should be managed to maintain a sufficient number of large trees to provide for bank stability and a sustainable source of large woody debris. Large woody debris is naturally occurring dead and down woody materials and should not be confused with logging slash or debris. Trees to be maintained or managed in the SMA should provide for large woody debris recruitment to the stream at a rate that maintains beneficial uses associated with fish habitat and stream structure at the site and downstream. This should be sustainable over a time period that is equivalent to that needed for the tree species in the SMA to grow to the size needed to provide large woody debris.

A sufficient number of canopy species should also be maintained to provide shading to the stream water surface needed to prevent changes in temperature regime for the waterbody and to prevent deleterious temperature- or sunlight-related impacts on the aquatic biota. If the existing shading conditions for the waterbody prior to activity are known to be less than optimal for the stream, then SMAs should be managed to increase shading of the waterbody.

To preserve SMA integrity for water quality protection, some States limit the type of harvesting, timing of operations, amount harvested, or reforestation methods used. SMAs are managed to use only harvest and silvicultural methods that will prevent soil disturbance within the SMA. Additional operational considerations for SMAs are addressed in subsequent management measures. Practices for SMA applications to wetlands are described in Management Measure J.

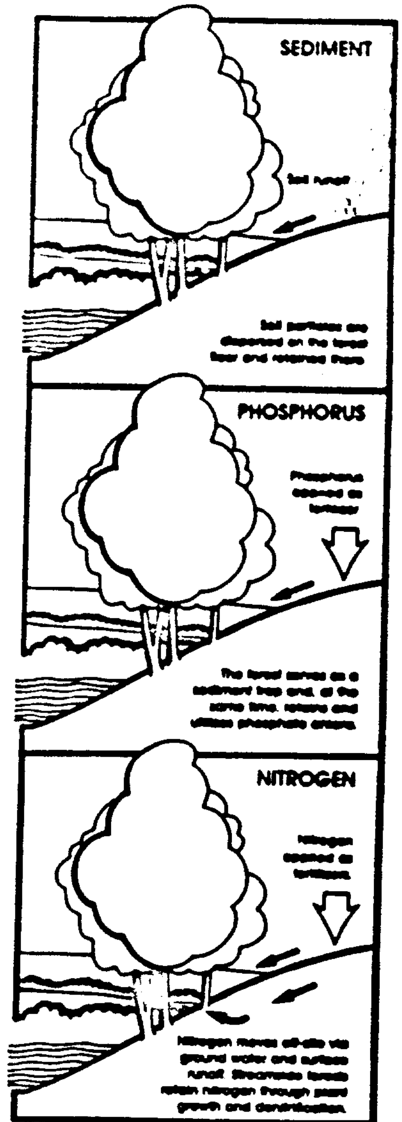

Figure 3-9. SMA pollutant removal processes (Kundt and Hall, 1988).

3. Management Measure Selection

a. Effectiveness Information

The effectiveness of SMAs in protecting streams from temperature increases, large increases in sediment load, and reduced dissolved oxygen was demonstrated by Hall and others (1987) (Table 3-10). Lantz (1971) (Table 3-11) also showed the protection that streamside vegetation and selective cutting gave to both water quality and the cutthroat trout population. A comparison of physical changes associated with logging using three streamside treatments was made by Hartman and others (1987) (Table 3-12). This study was performed to observe the impact of these SMAs on the supply of woody debris essential to the fish population and channel structure. The volume and stability of large woody debris decreased immediately in the most intensive treatment area, decreased a few years after logging in the careful treatment area, and remained stable where streamside trees and other vegetation remained.

Other experimental forest studies have found that average monthly maximum water temperature increases from 3.3 to 10.5 °C following clearcutting (Lynch et. al., 1985). Increases in stream temperature result from increased direct solar radiation to the water surface from the removal of vegetative cover or shading in the streamside area. Stream temperature change depends on the height and density of trees, the width of the waterbody, and the volume of water (stream discharge), with small streams heating up faster than large streams per unit of increased solar radiation (Megahan, 1980). Increased direct solar radiation also shifts the energy sources for stream ecosystems from outside the stream sources, allochthonous organic matter, to instream producers, autochthonous aquatic plants such as algae.

Table 3-10. Comparison of Effects of Two Methods of Harvesting on Water Quality (OR) (Hall et al., 1987)

Watershed	Method	Streamflow	Water Temp.	Sediment	Dissolved Oxygen
Deer Creek	Patch cut with buffer strips (750 acres)	No increase in peak flow	No change	Increases for one year due to periodic road failure	No change
Needle Branch	Clearcut with no stream protection (175 acres)	Small increases	Large changes, daily maximum increase by 30°F, returning to pre-log temp. within 7 years	Five-fold increase during first winter, returning to near normal the fourth year after harvest	Reduced by logging slash to near zero in some reaches; returned to normal when slash removed

Brown and Krygier (1970) report the greatest long-term average temperature response following clearcutting and slash disposal on a small watershed in Oregon. The average monthly temperature increased 14 °F compared to no increase on an adjacent, larger watershed that was clearcut in patches with 50- to 100-foot-wide buffer strips between the logging units and the perennial streams. Lynch and Corbett (1990) report less than a 3 °F mean temperature increase following harvesting, with 100-foot buffer strips along perennial streams. They attribute the increase to an intermittent stream with no protective vegetation that became perennial after harvesting due to increased flow. As a result of this BMP evaluation study, Pennsylvania modified its BMPs to require SMAs along both perennial and intermittent streams.

Another benefit of streamside management areas is control of suspended sediment and turbidity levels. Lynch and others (1985) documented the effectiveness of SMAs in controlling these pollutants (Table 3-13). A combination of practices was applied, including buffer strips and prohibitions for skidding, slash disposal, and road layout in or near streams. Average stormwater-suspended sediment and turbidity levels for the treatment without these practices increased significantly compared to the control and SMA/BMP sites.

Table 3-11. Water Quality Effects from Two Types of Logging Operations in the Alsea Watershed (OR) (Lantz, 1971)

Watershed and Logging Method	Acreage	Oxygen Content	Temperature	Suspended Sediment	Cutthroat Trout Population
Needle Branch; clearcut, streamside vegetation removed	175	Decrease during summer due to debris in water	Increase of maximum from 61°F to 85°F	Increase (largest contribution from roads)	Decrease from 265 to 65 fish in stream ½ mile
Deer Creek; selection cut, streamside vegetation retained	750 30% harvested	Only minor changes, if any			
Flynn Creek; control	500	No changes			

Table 3-12. Summary of Major Physical Changes Within Streamside Treatment Areas (BC) (Hartman et al., 1987)

	Streamside Treatment						
	Leave Strip[a]			Careful[b]	Intensive[c]		
	II	III	IV	VIII	V	VI	VII
Large Debris							
Mean volume (m³/30 m)							
Prelogging	29.6	34.2	37.4	14.3	25.4	26.0	78.2
Postlogging	29.5	50.4	36.4	14.7	23.2	20.0	19.5
Mean number of pieces							
Prelogging	34.0	27.3	32.0	14.2	25.0	25.3	19.8
Postlogging	36.5	27.0	30.0	20.9	27.5	36.2	23.0
Means of stability indices							
Prelogging	54.7	53.0	84.4	82.0	80.2	93.1	98.9
Postlogging	63.3	61.7	61.2	39.0	35.7	43.9	56.2
Small Debris							
Volume							
Prelogging	--	--	--	--	Volume not measured but low. Volume increased after logging and reduced by 90% after 1978 freshet.		--
Postlogging	--	--	--	--			--

Sources: All results except those on substrate change are from Schultz International (1981) and Toews and Moore (1982). The results on substrate change are from Scrivener and Brownlee (1986).

[a] Leave strip treatment included leaving a variable-width strip of vegetation along the stream.

[b] Careful treatment involved clearcutting to the margin of the stream and felling of streambank alder, with virtually no in-channel activity.

[c] Intensive treatment involved clearcutting to the streambank, felling of streambank alder, some yarding of felled trees, and merchantable blowdown from the stream.

Table 3-13. Storm Water Suspended Sediment Delivery for Different Treatments (PA) (Lynch, Corbett, and Mussallem, 1985)

Water Year and Treatment	Annual Average Suspended Sediment in mg/l (Range)
1977	
Forested control	1.7(0.2 - 8.6)
Clearcut-herbicide	10.4(2.3 - 30.5)
Commercial clearcut with BMPs[a]	5.9(0.3 - 20.9)
1978	
Forested control	5.1(0.3 - 33.5)
Clearcut-herbicide	--[b] (1.8 - 38.0)
Commercial clearcut with BMPs[a]	9.3(0.2 - 76.0)

[a] Buffer strips, skidding in streams prohibited, slash disposal away from streams, skid trail and road layout away from streams.

[b] Data not available.

VOL 12

9466

Table 3-14. Average Changes in Total Coarse and Fine Debris of a Stream Channel After Harvesting (OR) (Froehlich, 1973)

Cutting Practice	Natural Debris (tons per hundred feet of channel)	Material Added in Felling (tons per hundred feet of channel)	% Increase
Conventional tree-felling	8.1	47	570
Cable-assisted directional felling	16	14	112
Conventional tree-felling with buffer strip[a]	12	1.3	14

[a] Buffer strips ranged from 20 to 130 feet wide for different channel segments.

Practices such as directional felling are designed to minimize stream and streambank damage associated with increased logging debris in SMAs. Froehlich (1973) provides data on how effective different cutting practices and buffer strips are in preventing debris from entering the stream channel (Table 3-14). Buffer strips were the most effective debris barriers. Narver (1971) investigated the impacts of logging debris in streams on salmonid production and describes threats to fish embryo survival from low dissolved oxygen concentrations and decreased flow velocities in intragravel waters. Erman and others (1977) studied the effectiveness of buffer strips in protecting aquatic organisms and found significant differences in benthic invertebrate communities when logging occurred with buffer strips less than 30 meters wide.

b. Cost Information

In 4 of the 10 areas in Oregon studied by Dykstra and Froelich (1976a), the 55-foot buffer strip was the least costly alternative, yet these researchers concluded that no single alternative is preferable for all sites in terms of costs and that cost analysis alone cannot resolve the question of best stream protection method (Table 3-15).

Dykstra and Froehlich (1976b) also found that increased cable-assisted directional felling costs (68 to 108 percent increase) were offset by savings in channel clean-up costs (only 27 percent as much large debris and 39 percent small debris accumulated in the stream for cable-assisted felling), increased yield from reduced breakage, and reduced yarding costs. They also estimated costs for debris removal from streams to be $300 to clean 5 tons of debris from a 100-foot segment, or about $60 per ton of residue removed.

Table 3-15. Average Estimated Logging and Stream Protection Costs per MBF[a] (OR) (Dykstra and Froehlich, 1976a)

Cutting Practice	Total Cost: Average	Total Cost: Range	Volume Foregone
Conventional felling	$24.78	$21.90 - 29.93	None
Cable-assisted directional felling (1.43% breakage saved within 200-foot stream)	$26.05	$21.36 - 31.24	--
Cable-assisted felling (10% breakage saved)	$24.64	$19.55 - 29.82	--
Buffer strip (55 feet wide)	$23.34	$19.84 - 27.77	0 to 6 percent
Buffer strip (150 feet wide)	$27.15	$24.33 - 30.28	6 to 17 percent

[a] Cost estimates for each of 10 areas studied by Dykstra and Froehlich were averaged for this table.

Lickwar (1989) examined the costs of SMAs as determined by varying slope steepness (Table 3-16) in different regions in the Southeast and compared them to road construction and revegetation practice costs. He found SMAs to be the least expensive practice, in general, and to cost roughly the same independent of slope.

The costs associated with use of alternative buffer and filter strips were also analyzed in an Oregon case study (Olsen, 1987) (Table 3-17) and by Ellefson and Weible (1980). In the Oregon case study, increasing the buffer width from 35 feet on each side of a stream to 50 feet was shown to reduce the value per acre by $103 undiscounted and $75 discounted costs, approximately a 2 percent increase on a harvesting cost per acre of $5,163 undiscounted and $3,237 discounted. Doubling the buffer width from 35 to 70 feet on each side reduced the dollar value per acre by approximately 3 times more, adding approximately 8 percent to the discounted harvesting costs. Ellefson and Weible also analyzed the added cost and rate of return associated with various filter and buffer strip widths. Doubling the width of a filter strip from 30 to 60 feet increases the cost from $12 to $44 per sale and reduces the rate of return by 0.4 percent. Doubling the width of the buffer strip from 30 to 60 feet doubles the cost and reduces the rate of return by 1 percent. Increasing the width of the buffer strip from 30 to 100 feet triples the cost and reduces the rate of return by 2.3 percent.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure discussed above.

■ ***Generally, SMAs should have a minimum width of 35 to 50 feet. SMA width should also increase according to site-specific factors. The primary factors that determine the extension of SMA width are slope, class of watercourse, depth to water table, soil type, type of vegetation, and intensity of management.***

Many States use SMAs. Examples of SMA designation strategies from Florida, North Carolina, Maine, and Washington are presented. Figure 3-10 depicts Florida's streamside management zone (SMZ) designations. Florida's SMZs are divided into a fixed-width primary zone and a variable secondary zone, each of which has its own special management criteria. Table 3-18 presents North Carolina's recommendations for SMZ widths for various types of waterbodies dependent on adjacent upland slope. Maine's recommended filter strip widths are dependent on the land

Table 3-16. Cost Estimates (and Cost as a Percent of Gross Revenues) for Streamside Management Areas (1987 Dollars) (Lickwar, 1989)

Practice Component	Steep Sites[a]		Moderate Sites[b]		Flat Sites[c]	
Streamside Management Zones	$2,061.77	(0.52%)	$2,397.80	(0.51%)	$2,344.08	(0.26%)

[a] Based on a 1,148-acre forest and gross harvest revenues of $399,68. Slopes average over 9 percent.
[b] Based on a 1,104-acre forest and gross harvest revenues of $473,18. Slopes ranged from 4 percent to 8 percent.
[c] Based on a 1,832-acre forest and gross harvest revenues of $899,49. Slopes ranged from 0 percent to 3 percent.

Table 3-17. Cost Impacts of Three Alternative Buffer Strips (OR)[a]: Case Study Results with 640-Acre Base (36 mbf/acre) (Olsen, 1987)

	Scenario I	Scenario II	Scenario III
Average buffer width (feet on each side)	35	50	70
Percent conifers removed	100	60	25
Percent reclassified Class II streams[b]	0	20	80
Harvesting restrictions	Current	New	New

slope between the road and waterbody (Table 3-19). Washington State requires a riparian management zone (RMZ) around all Type 1, 2, and 3 waters where the adjacent harvest cutting is a regeneration cut or a clearcut. A guide for calculating the average width of the RMZ is provided in the Forest Practices Board manual (Washington State Forest Practices Board, 1988)(Figure 3-11).

- *Minimize disturbances that would expose the mineral soil of the SMA forest floor. Do not operate skidders or other heavy machinery in the SMA.*
- *Locate all landings, portable sawmills, and roads outside the SMA.*
- *Restrict mechanical site preparation in the SMA, and encourage natural revegetation, seeding, and handplanting.*
- *Limit pesticide and fertilizer usage in the SMA. Buffers for pesticide application should be established for all flowing streams.*

Table 3-18. Recommended Minimum SMZ Widths (North Carolina Division of Forest Resources, 1989)

Type of Stream or Waterbody	Percent Slope of Adjacent Lands: 0-5	6-10	11-20	21-45	46+
	SMZ Width Each Side (feet)

Public Water Supplies (Streams and Reservoirs)	50	100	150	150	200

■ *Directionally fell trees away from streams to prevent logging slash and organic debris from entering the waterbody.*

■ *Apply harvesting restrictions in the SMA to maintain its integrity.*

Enough trees should be left to maintain shading and bank stability and to provide woody debris. This provision for leaving residual trees can be accomplished in a variety of ways. For example, the Maine Forestry Service (1991) specifies that no more than 40 percent of the total volume of timber 6 inches DBH and greater should be removed in a 10-year period, and the trees removed should be reasonably distributed within the SMA. Florida (1991) recommends leaving a volume equal to or exceeding one-half the volume of a fully stocked stand. The number of residual trees varies inversely with their average diameter (Table 3-20). A shading requirement independent of the volume of timber may be necessary for streams where temperature changes could alter aquatic habitat.

Studies by Brazier and Brown (1973) demonstrated that the effectiveness of the SMA in controlling temperature changes is independent of timber volume; it is a complex interrelationship between canopy density, canopy height, stream width, and stream discharge. The Washington State Forest Practices Board (1988) incorporates leave tree and shade requirements in its regulations (Figure 3-12). Shade requirements within the SMA are to leave all nonmerchantable timber that provides midsummer and midday shade to the water surface, and to leave sufficient merchantable timber necessary to retain 50 percent of the summer midday shade. Shade cover is preferably left distributed evenly within the SMA (Figure 3-13). If a threat of blowdown exists, then clumping and clustering of leave trees may be used as long as the shade requirement is met (Figure 3-14).

VOL 12

Guidelines for Calculating Average Width of Riparian Management Zones (RMZ)

Use the following procedures to calculate average width of Eastern Washington riparian management zone (RMZ) when the adjacent harvest cutting is a regeneration cut or clearcut. Average RMZ width is also used to calculate the acreage and number of trees/acre. (See WAC 222-16-010(33) Partial Cut.)

Procedures

1. RMZs are measured separately on each side of streams. Begin at the ordinary high water mark of Type 1, 2 and 3 Waters and measure the horizontal distance to the line where vegetation changes from wetland to upland type, EXCEPT where the distance is less than the minimum or greater than the maximum widths in the rules. (See 7 below and Figure 14.)
2. Width measurements (horizontal distance) are taken at right angles to the stream reach. See WAC 222-30-020(6) for description of Eastern Washington RMZ. Western Washington RMZ is described in WAC 222-30-020(5).
3. Measure width of RMZ at 5 or more similarly spaced intervals.
4. Use 50 feet or greater distance between width measurements. Sample the entire stream reach within the harvest unit.
5. On each end of the stream reach being measured, begin and end width measurements at one-half the interval used for the other measurements. This helps to reduce sampling errors.
6. If the RMZ width varies more than 30 feet in a set of measurements, increase the number of measurements. Try for uniform sampling. Use enough measurements to adequately sample natural variations in width. (See Figure 14.)
7. On Eastern Washington PARTIAL CUTS, a width of less than 30 feet is treated as 30 feet and a width of more than 50 feet is treated as 50 feet when calculating the average RMZ width for leave trees/acre because these distances are specified in the rules. The natural riparian area may be wider or narrower than stated in the rules.

   For other types of cuts, minimum width is measured in the same way as for partial cuts. But the actual width of more than 30 feet is treated up to a maximum of 300 feet. If the riparian area is wider than 300 feet, it is treated as 300 feet.
8. Calculate average width by totaling the widths in feet and dividing by the number of measurements.
9. In Eastern Washington where the adjacent harvest is a regeneration cut or clearcut, RMZs must AVERAGE 50 feet in width.
10. Multiply average RMZ width by its length within the cutting unit to calculate square feet of RMZ. Measure length approximately parallel to stream reach and near outer edge of RMZ.
11. Multiply square feet by 0.000023 to calculate acres or use Acreage Table 6. (Figure 15 describes leave trees and snags for Eastern Washington RMZ.)

VOL 12

5474

R0042780

(1) Follow preharvest planning (as described under Management Measure A) when constructing or reconstructing the roadway.
(2) Follow designs planned under Management Measure A for road surfacing and shaping.
(3) Install road drainage structures according to designs planned under Management Measure A and regional storm return period and installation specifications. Match these drainage structures with terrain features and with road surface and prism designs.
(4) Guard against the production of sediment when installing stream crossings.
(5) Protect surface waters from slash and debris material from roadway clearing.
(6) Use straw bales, silt fences, mulching, or other favorable practices on disturbed soils on unstable cuts, fills, etc.
(7) Avoid constructing new roads in SMAs to the extent practicable.

1. Applicability

This management measure is intended for application by States on lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to road construction/reconstruction operations for silvicultural purposes, including:

- The clearing phase: clearing to remove trees and woody vegetation from the road right-of-way;
- The pioneering phase: excavating and filling the slope to establish the road centerline and approximate grade;
- The construction phase: final grade and road prism construction and bridge, culvert, and road drainage installation; and
- The surfacing phase: placement and compaction of the roadbed, road fill compaction, and surface placement and compaction (if applicable).

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to minimize delivery of sediment to surface waters during road construction/reconstruction projects. Figure 3-15 depicts various road structures addressed by this management measure. Disturbance of soil and rock during road construction/reconstruction creates a significant potential for erosion and sedimentation of nearby streams and coastal waters. Some roads are temporary or seasonal-use roads,

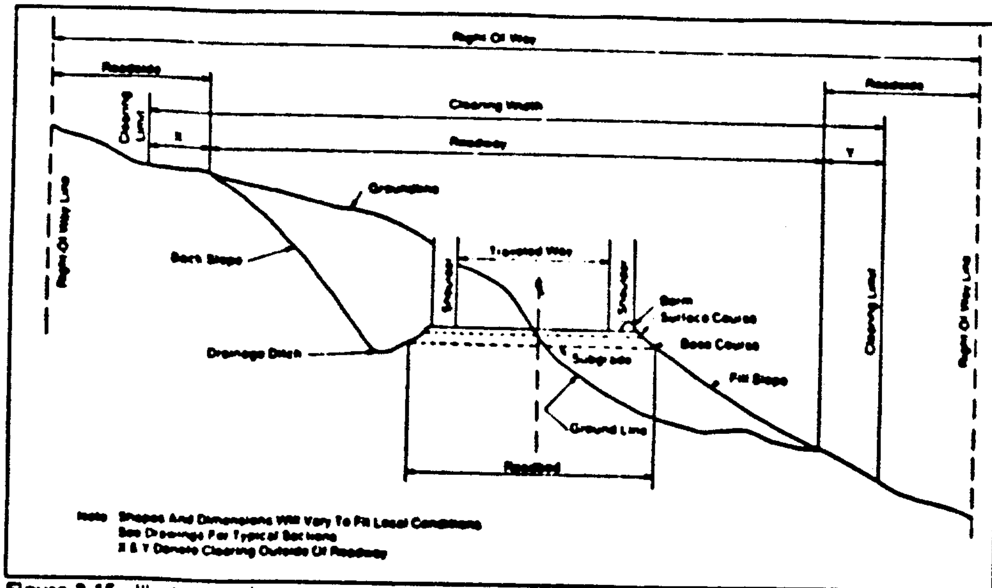

Figure 3-15. Illustration of road structure terms (Hynson et al., 1982).

and their construction does not involve the high level of disturbance generated by permanent, high-standard roads. However, temporary or low-standard roads still need to be constructed in such a way as to prevent disturbance and sedimentation. Brown (1972) stated that road construction is the largest source of silviculture-produced sediment in the Pacific Northwest. It is also a significant source in other regions of the country. Therefore, proper road and drainage crossing construction practices are necessary to minimize sediment delivery to surface waters. Proper road design and construction can prevent road fill and road backslope failure, which can result in mass movements and severe sedimentation. Proper road drainage prevents concentration of water on road surfaces, thereby preventing road saturation that can lead to rutting, road slumping, and channel washout (Dyrness, 1967; Golden et al., 1984). Proper road drainage during logging operations is especially important because that is the time when erosion is greatly accelerated by continuous road use (Kochenderfer, 1970). Figure 3-16 presents various erosion and sediment control practices.

Surface protection of the roadbed and cut-and-fill slopes can:

- Minimize soil losses during storms;
- Reduce frost heave erosion production;
- Restrain downslope movement of soil slumps; and
- Minimize erosion from softened roadbeds (Swift, 1984).

Although there are many commonly practiced techniques to minimize erosion during the construction process, the most meaningful are related to how well the work is planned, scheduled, and controlled by the road builder and those responsible for determining that work satisfies design requirements and land management resource objectives (Larse, 1971).

3. Management Measure Selection

Most erosion from road construction occurs within a few years of disturbance (Megahan, 1980). Therefore, erosion control practices that provide immediate results (such as mulching or hay bales) should be applied as soon as possible to minimize potential erosion (Megahan, 1980). King (1984) found that the amount of sediment produced by road construction was directly related to the percent of the area taken by roads, the amount of protection given to the seeded slopes, and whether the road is given a protective surface (Table 3-21).

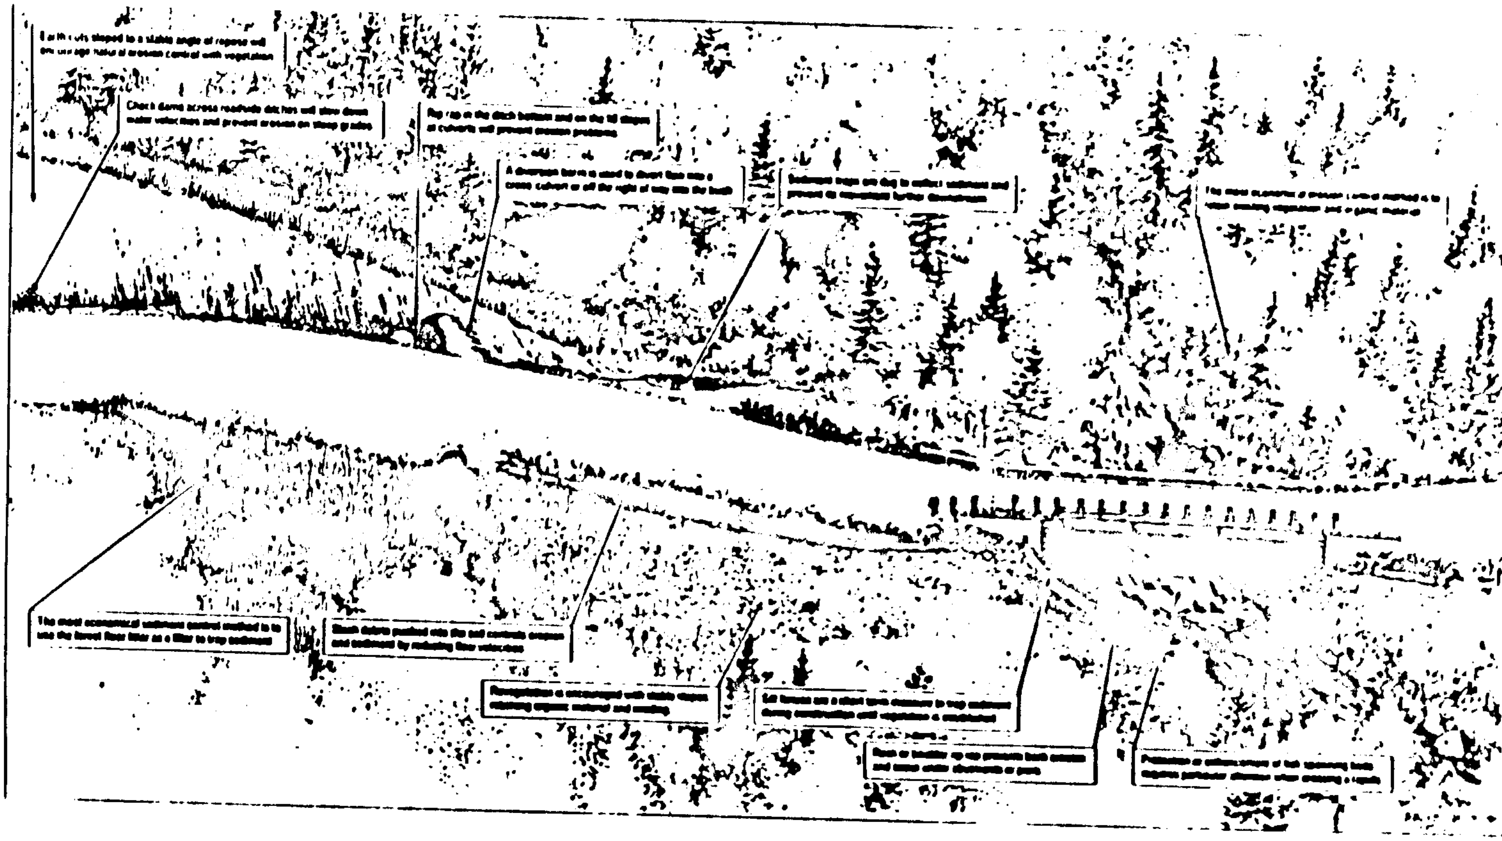

Figure 3-16. Mitigation techniques used for controlling erosion and sediment to protect water quality and fish habitat (Ontario Ministry of Natural Resources, 1988).

Table 3-21. Effects of Several Road Construction Treatments on Sediment Yield (ID) King (1984)

Watershed Area (acres)	Area in Roads (percent)	Treatment	Increase of Annual Sediment Yield* (percent)
207	3.9	Unsurfaced roads; Untreated cut slope; Untreated fill slope	156
161	2.6	Unsurfaced roads; Untreated cut slope dry seeded	130
364	3.7	Surfaced roads; Cut and fill slopes straw mulched and seeded	93
154	1.8	Surfaced roads; Filter windrowed; Cut and fill slopes straw mulched and seeded	53
70	3.0	Surfaced roads; Filter windrowed; Cut and fill slopes hydro-mulched and seeded	25
213	4.3	Surfaced roads; Filter windrowed; Cut and fill slopes hydro-mulched and seeded	19

* Measured in debris basins.

a. Effectiveness Information

The effectiveness of road surfacing in controlling erosion was demonstrated by Kochenderfer and Helvey (1984)(Table 3-22). The data show that using 1-inch crusher-run gravel or 3-inch clean gravel can reduce erosion to less than one-half that of using 3-inch crusher run gravel and to 12 percent that of an ungraveled road surface.

According to Swift (1984b), road cuts and fills are the largest source of sediment once a logging road is constructed. His research showed that planting grass on cut-and-fill slopes of new roads effectively reduced erosion in the southern Appalachians. The combined effectiveness of grass establishment and roadbed graveling was a 97-99 percent reduction in soil loss.

Swift (1986) measured the extent of downslope soil movement for various categories of roadway and slope conditions (Tables 3-23 and 3-24). He found that grassed fill was more effective than mulched fill or bare fill in reducing the downslope movement of soil from newly constructed roads. The author determined grass, forest floor litter, and brush barriers to be effective management practices for reducing downslope sediment.

Megahan (1980, 1987) summarized the results of several studies that echo Swift's conclusions (Table 3-25). The combination of straw mulch with some type of netting to hold it in place reduces erosion by more than 90 percent and has the added benefits of providing immediate erosion control and promoting revegetation. Treating the road surface reduced erosion 70 to 99 percent. Grass seeding alone can control erosion in moist climates, as confirmed by Swift (1984b).

Table 3-22. Effectiveness of Road Surface Treatments in Controlling Soil Losses (WV) (Kochenderfer and Helvey, 1984)

Surface Treatment	Average Annual Soil Losses (tons/acre)*
3-inch clean gravel	5.4
Ungraveled	44.4
3-inch crusher-run gravel	11.4
1-inch crusher-run gravel	5.5

* Six measurements taken over a 2-year time period.

b. Cost Information

The costs associated with construction of rolling dips on roads were estimated by Dubensky (1991) as $19.75 each, with more dips needed as the slope of the road increases.

Ellefson and Miles (1984) determined the decline in net revenue associated with culvert construction, water bar construction, and construction of broad-based dips to be 3.8 percent, 2.3 percent, and 2.4 percent, respectively, for a timber sale with net revenue of $124,340 without these practices. Kochenderfer and Wendel (1980) examined road costs, including bulldozing, construction of drainage dips, culvert installation, and graveling. They concluded that:

(1) Cost to reconstruct a road (including 600 tons of 3-inch clean stone surfacing at $5.74/ton) = *$5,855 per mile*. Cost also included 20.5 hours (25 hours/mile) of D-6 tractor time (for road construction and construction of broad-based drainage dips), 23 hours (28 hours/mile) of JD 450 tractor time to spread gravel and do final dip shaping, and installation of two culverts. Road construction without the stone would have cost *$1,061/mile*.

(2) Cost for a newly constructed road was *$3,673 per mile*, including 200 tons of gravel. Costs included 46.5 hours (57 hours/mile) of D-6 tractor time to bulldoze the road and construct 22 drainage dips. Spreading gravel and final dip shaping required 7.5 hours of JD tractor time. This road, constructed without stone, would have cost *$2,078 per mile*.

The study concluded that road construction costs in terrain similar to the West Virginia mountain area would range from about $2,000/mile with no gravel and few culverts to about $10,000/mile with complete graveling and more frequent use of culverts.

Kochenderfer, Wendel, and Smith (1984) examined the costs associated with road construction of four minimum standard roads in the Appalachians (Table 3-8 gives road characteristics). Excavation costs varied according to site-specific factors (soil type, rock outcrop extent, topography) and increased as the amount of rock needing blasting and the number of large trees to be removed increased. Culvert costs varied according to the size and type of culvert used (Tables 3-26 and 3-27).

Lickwar (1989) studied the costs of various forestry practices in the Southeast. He determined that practices associated with road construction were generally the most expensive, regardless of terrain. The costs for broad-based dips and water bars increased as the terrain steepened, indicating increased implementation of erosion and runoff control practices as slopes increased (Table 3-28). Steeper areas also required additional (nonspecified) road costs that were not necessary in moderate to flat areas.

Table 3-23. Reduction in the Number of Sediment Deposits More Than 20 Feet Long by Grass and Forest Debris (Swift, 1986)

Degree of Soil Protection	Number of Deposits Per 1,000 Feet of Road
Grassed fill, litter and brush burned	13.9
Bare fill, forest litter	9.9
Mulched fill, forest litter	8.1
Grassed fill, forest litter, no brush barrier	6.9
Grassed fill, forest litter, brush barrier	4.5

[a] Percent decrease in erosion compared to similar, untreated sites.
[b] No difference in erosion reduction between these three treatments.
[c] Intermountain Forest and Range Experiment Station, Forestry Sciences Laboratory, Boise, ID.

Unit cost comparisons for surfacing practices (Swift, 1984a) reveal that grass is the least expensive alternative, at $174 per kilometer of road (Table 3-29). Five-centimeter crushed rock cost almost $2000 per kilometer, 15-centimeter gravel cost about $6000, and 20-centimeter gravel cost almost $9000. The author cautions, however, that material costs alone are misleading because an adequate road surface might endure several years of use, whereas a grassed or thinly-graveled surface would need replenishing. Even so, multiple grass plantings may be cheaper and more effective than gravel spread thinly over the roadbed, depending on climate, growing conditions, soil type, and road use (Swift, 1984b). Megahan (1987) found that dry seeding alone cost significantly less than seeding in conjunction with plastic netting (Table 3-30).

Table 3-26. Cost Summary for Four "Minimum-Standard" Forest Truck Roads Constructed in the Central Appalachians[a] (1984 Dollars) (Kochenderfer, Wendel, and Smith, 1984)

Road No.	Costs (dollars/mile)			
	Excavation	Culvert	Labor & Vehicle	Total
1	2,900	371	1,092	5,048
6	4,200	1,043	1,947	7,805

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

- *Follow the design developed during preharvest planning to minimize erosion by properly timing and limiting ground disturbance operations.*

- *Construct bridges and install culverts during periods when streamflow is low.*

- *Avoid construction during egg incubation periods on streams with important spawning areas.*

- *Practice careful equipment operation during road construction to minimize the movement of excavated material downslope as unintentional sidecast.*

- *Compact the road base at the proper moisture content, surfacing, and grading to give the designed road surface drainage shaping.*

■ *Use straw bales, straw mulch, grass-seeding, hydromulch, and other erosion control and revegetation techniques to complete the construction project. These methods are used to protect freshly disturbed soils until vegetation can be established.*

■ *Prevent slash from entering streams or promptly remove slash that accidentally enters streams to prevent problems related to slash accumulations.*

Slash can be useful if placed as windrows along the base of the fill slope. Right-of-way material that is merchantable can also be used by the operator.

■ *Use turnouts, wing ditches, and dips to disperse runoff and reduce road surface drainage from flowing directly into watercourses.*

■ *Install surface drainage controls to remove stormwater from the roadbed before the flow gains enough volume and velocity to erode the surface. Route discharge from drainage structures onto the forest floor so that water will disperse and infiltrate (Swift, 1985). Methods of road surface drainage include:*

- **Broad-based Dip Construction.** A broad-based dip is a gentle roll in the centerline profile of a road that is designed to be a relatively permanent and self-maintaining water diversion structure and can be traversed by any vehicle (Swift, 1985, 1988) (See Figure 3-17). The dip should be outsloped 3 percent to divert stormwater off the roadbed and onto the forest floor, where transported soil can be trapped by forest litter (Swift, 1988). Broad-based dips should be used on roads having a gradient of 10 percent or less. Proper construction requires an experienced bulldozer operator (Kochenderfer, 1970).

- **Installation of Pole Culverts and/or Ditch Relief Culverts.** Culverts are placed at varying intervals in a road to safely conduct water from the ditch to the outside portion of the road. Figures 3-18 and 3-19 highlight the design and installation of pole and pipe culverts, respectively. Culverts often need outlet and inlet protection to keep water from scouring away supporting material and to keep debris from plugging the culvert. Energy dissipators, such as riprap and slash, should be installed at culvert outlets (Rothwell, 1978). Culvert spacing depends on rainfall intensity, soil type, and road grade. Culvert size selection should be based on drainage area size and should be able to handle large flows. Open-top or pole culverts are temporary drainage structures that are most useful for intercepting runoff flowing down road surfaces (Kochenderfer, 1970). They can also be used as a substitute for pipe culverts on roads of smaller operations, if properly built and maintained, but they should not be used for handling intermittent or live streams. Open-top culverts should be placed at angles across a road to provide gradient to the culvert and to ensure that no two wheels of a vehicle hit the ditch at once.

- **Road Outsloping and Grading.** Grade and outslope roadbeds to minimize water accumulation on road surfaces (Kochenderfer, 1970). This practice minimizes erosion and road failure potential. Outsloping involves grading the road so that it slopes downward from the toe of the road cut to the shoulder. The

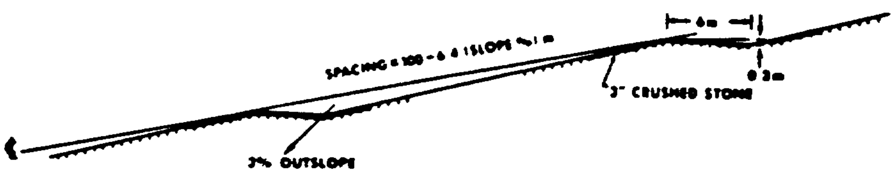

Figure 3-17. Diagram of broad-based dip design for forest access roads (Swift, 1985).

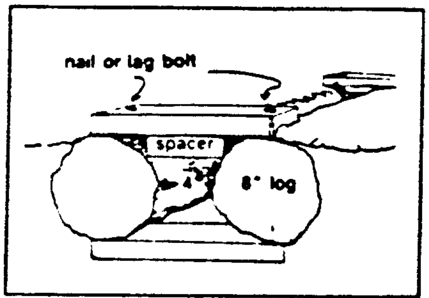

Figure 3-18. Design of pole culverts (Vermont Department of Forests, Parks and Recreation, 1987).

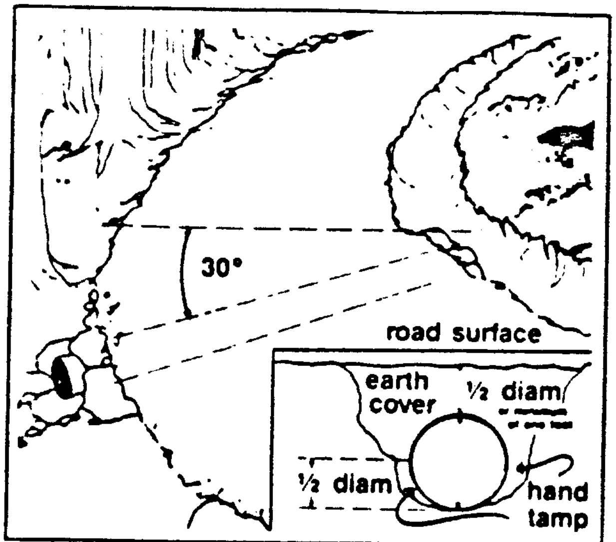

Figure 3-19. Design and installation of pipe culverts (Vermont Department of Forests, Parks and Recreation, 1987).

slope should be about 3-4 percent (Rothwell, 1978). Outsloping the roadbed keeps water from flowing next to and undermining the cut bank, and is intended to spill water off the road in small volumes at many random sites. In addition to outsloping the roadbed, a short reverse grade should be constructed to turn water off the surface. Providing a berm on the outside edge of an outsloped road during construction, and until loose fill material is protected by vegetation, can eliminate fill erosion (Swift, 1985). The effectiveness of outsloping is limited by roadbed rutting during wet conditions. Also, berms may form along the edge of older roadbeds and block drainage (Swift, 1985). Therefore, proper maintenance of these structures is necessary.

- **Ditch and Turnout Construction.** Ditches should be used only where necessary and should discharge water into vegetated areas through the use of turnouts. The less water ditches carry and the more frequently water is discharged, the better. Construct wide, gently sloping ditches, especially in areas with highly erodible soils. Ditches should be stabilized with rock and/or vegetation (Yoho, 1980) and outfalls protected with rock, brush barriers, live vegetation, or other means. Roadside ditches should be large enough to carry runoff from moderate storms. A standard ditch used on secondary logging roads is a triangular section 45 cm deep, 90 cm wide on the roadway side, and 30 cm wide on the cut bank side. Minimum ditch gradient should be 0.5 percent, but 2 percent is preferred to ensure good drainage. Runoff should be frequently diverted into culverts to prevent erosion or overflow (Rothwell, 1978).

■ ***Install appropriate sediment control structures to trap suspended sediment transported by runoff and prevent its discharge into the aquatic environment.***

Methods to trap sediment include:

- **Brush Barriers.** Brush barriers are slash materials piled at the toe slope of a road or at the outlets of culverts, turnouts, dips, and water bars. Brush barriers should be installed at the toe of fills if the fills are located within 150 feet of a defined stream channel (Swift, 1988). Figure 3-20 shows the use of a brush barrier at the toe of fill. Proper installation is important because if the brush barrier is not firmly anchored and embedded in the slope, brush material may be ineffective for sediment removal and may detach to block ditches or culverts (Ontario Ministry of Natural Resources, 1988). In addition to use as brush barriers, slash can be spread over exposed mineral soils to reduce the impact of precipitation events and surface flow.

- **Silt Fences.** Silt fences are temporary barriers used to intercept sediment- laden runoff from small areas. They act as a strainer: silt and sand are trapped on the surface of the fence while water passes through.

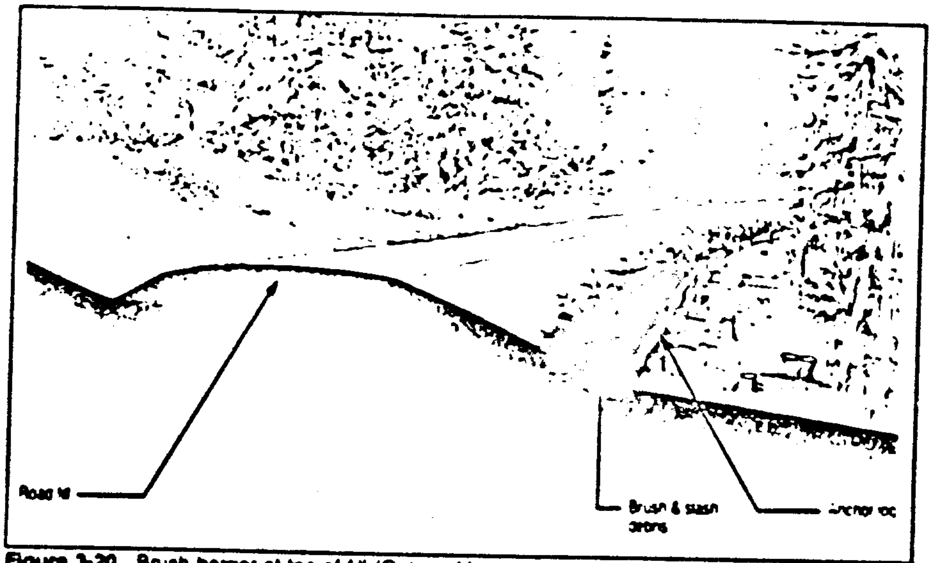

Figure 3-20. Brush barrier at toe of fill (Ontario Ministry of Natural Resources, 1988).

They may consist of woven geotextile filter fabric or straw bales. Silt fences should be installed prior to earthmoving operations and should be placed as close to the contour as possible.

- **Riprap.** Riprap is a layer of rocks or rock fragments placed over exposed soil to protect it from erosive forces. Riprap is generally used only in areas where the velocity of water flow, seriousness of erosion, steepness of slope, or material type prevents satisfactory establishment of vegetation. Stones of suitable size are fitted and implanted in the slope to form a contiguous cover (Figure 3-21). When used near streams, riprap should be extended below the stream channel scour depth and above the high water line. Commonly, a filter cloth or graded filter blanket of small gravel is laid beneath the riprap. Riprap should not be used on slopes that are naturally subject to deep-seated or avalanche-type slide failure. Riprap should be used in conjunction with other slope stabilization techniques and then only if these techniques are ineffective alone. Riprap is not recommended for very steep slopes or fine-grained soils (Hynson et al., 1982).

- **Filter Strips.** Sediment control is achieved by providing a filter or buffer strip between streams and construction activities in order to use the natural filtering capabilities of the forest floor and litter. The Streamside Management Area management measure requires the presence of a filter or buffer strip around all waterbodies.

■ *Revegetate or stabilize disturbed areas, especially at stream crossings.*

Cutbanks and fillslopes along forest roads are often difficult to revegetate (Berglund, 1978). Properly condition slopes to provide a seedbed, including rolling of embankments and scarifying of cut slopes. The rough soil surfaces will provide niches for seeds to lodge and germinate. Seed as soon as possible after disturbance, preferably during road construction or immediately following completion and within the same season (Larse, 1971). Early grassing and spreading of brush or erosion-resisting fabrics on exposed soils at stream crossings are imperative (Swift, 1985). See the Revegetation of Disturbed Areas management measure for a more detailed discussion.

■ *Protect access points to the site that lead from a paved public right-of-way with stone, wood chips, corduroy logs, wooden mats, or other material to prevent soil or mud from being tracked onto the paved road.*

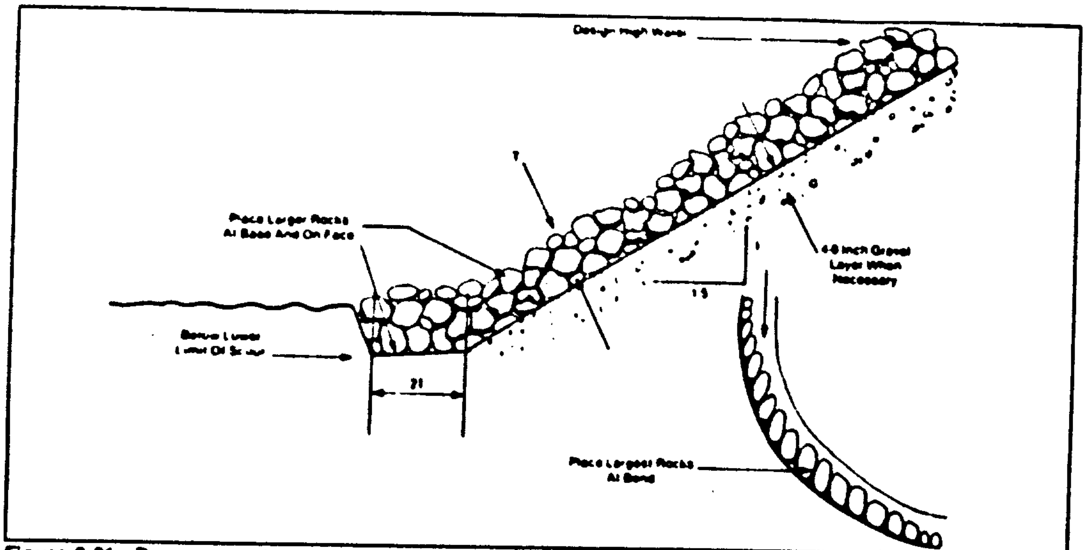

Figure 3-21. Dimensions of typical rock riprap blanket. T equals 1.5 times the diameter of the average size rock. When rock is spherical cobbles, or when machine-placed, T=1.9D (Hynson et al., 1982).

This will prevent tracking of sediment onto roadways, thereby preventing the subsequent washoff of that sediment during storm events. When necessary, clean truck wheels to remove sediment prior to entering a public right-of-way.

■ *Construct stream crossings to minimize erosion and sedimentation.*

Avoid operating machinery in waterbodies. Work within or adjacent to live streams and water channels should not be attempted during periods of high streamflow, intense rainfall, or migratory fish spawning. Avoid channel changes and protect embankments with riprap, masonry headwalls, or other retaining structures (Larse, 1971).

If possible, culverts should be installed within the natural streambeds. The inlet should be on or below the streambed to minimize flooding upstream and to facilitate fish passage. Culverts should be firmly anchored and the earth compacted at least halfway up the side of the pipe to prevent water from leaking around it (Figure 3-22). Both ends of the culvert should protrude at least 1 foot beyond the fill (Hynson et al., 1982). Large culverts should be aligned with the natural course and gradient of the stream unless the inlet condition can be improved and the erosion potential reduced with some channel improvement (Larse, 1971). Use energy dissipators at the downstream end of the culverts to reduce the erosion energy of emerging water. Armor inlets to prevent undercutting and armor outlets to prevent erosion of fill or cut slopes.

■ *Excavation for a bridge or a large culvert should not be performed in flowing water. The water should be diverted around the work site during construction with a cofferdam or stream diversion.*

Isolating the work site from the flow of water is necessary to minimize the release of soil into the watercourse and to ensure a satisfactory installation in a dry environment. Limit the duration of construction to minimize environmental impacts by establishing disturbance limits, equipment limitations, the operational time period when disturbance can most easily be limited, and the use of erosion and sediment controls, such as silt fences and sediment catch basins. Diversions should be used only where constructing the stream crossing structure without diverting the stream would result in instream disturbance greater than the disturbance from diverting the stream. Figure 3-23 portrays a procedure for installing a large culvert when excavation in the channel of the stream would cause sedimentation and increase turbidity.

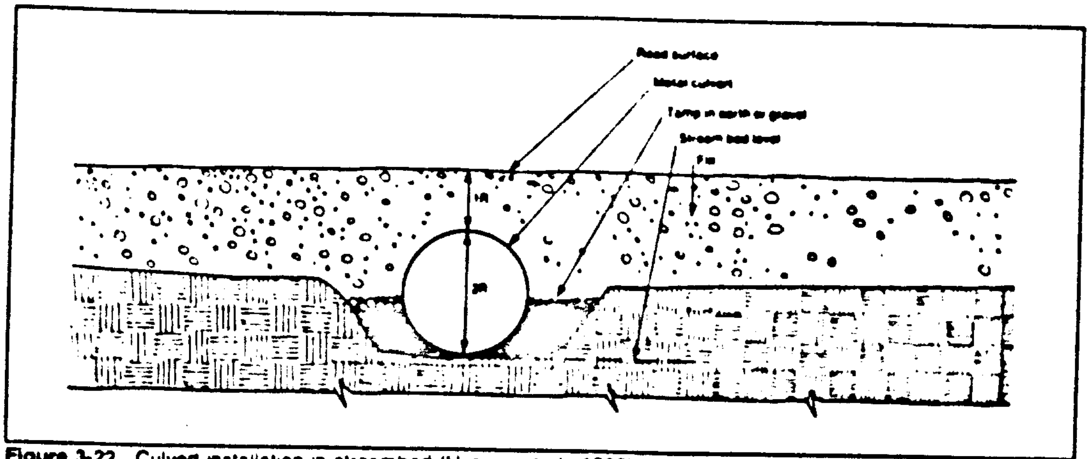

Figure 3-22. Culvert installation in streambed (Hynson et al., 1982).

■ *Compact the fill to minimize erosion and ensure road stability (Hynson et al., 1982).*

During construction, fills or embankments are built up by gradual layering. Compact the entire surface of each layer with a tractor or other construction equipment. If the road is to be grassed, the final layer should not be compacted in order to provide an acceptable seedbed.

■ *Properly dispose of organic debris generated during road construction (Hynson et al., 1982).*

- Stack usable materials such as timber, pulpwood, and firewood in suitable locations and use them to the extent possible. Alternatives for use of other materials include piling and burning, chipping, scattering, windrowing, and removal to designated sites.
- Organic debris should not be used as fill material for road construction since the organic material would eventually decompose and cause fill failure (Hynson et al., 1982; Larse, 1971).
- Debris that is accidently deposited in streams during road construction should be removed before work is terminated.
- All work within the stream channel should be accomplished by hand to avoid the use of machinery in the stream and riparian zone (Hynson et al., 1982).

■ *Use pioneer roads to reduce the amount of area disturbed and ensure stability of the area involved.*

Pioneer roads are temporary access ways used to facilitate construction equipment access when building permanent roads.

- Confine pioneer roads to the construction limits of the surveyed permanent roadway.
- Fit the pioneer road with temporary drainage structures (Hynson et al., 1982).

■ *When soil moisture conditions are excessive, promptly suspend earthwork operations and take measures to weatherproof the partially completed work (Larse, 1971; Hynson et al., 1982).*

Regulating traffic on logging roads during unfavorable weather is an important phase of erosion control. Construction and logging under these conditions destroy drainage structures, plug up culverts, and cause excessive rutting, thereby increasing the amount and the cost of required maintenance (Kochenderfer, 1970).

Locate burn bays away from water and drainage courses.

If the use of borrow or gravel pits is needed during forest road construction, locate rock quarries, gravel pits, and borrow pits outside SMAs and above the 50-year flood level of any waters to minimize the adverse impacts caused by the resulting sedimentation. Excavation should not occur below the water table.

Gravel mining directly from streams causes a multitude of impacts including destruction of fish spawning sites, turbidity, and sedimentation (Hynson et al., 1982). During the construction and use of rock quarries, gravel pits, or borrow pits, runoff water should be diverted onto the forest floor or should be passed through one or more settling basins. Rock quarries, gravel pits, spoil disposal areas, and borrow pits should be revegetated and reclaimed upon abandonment.

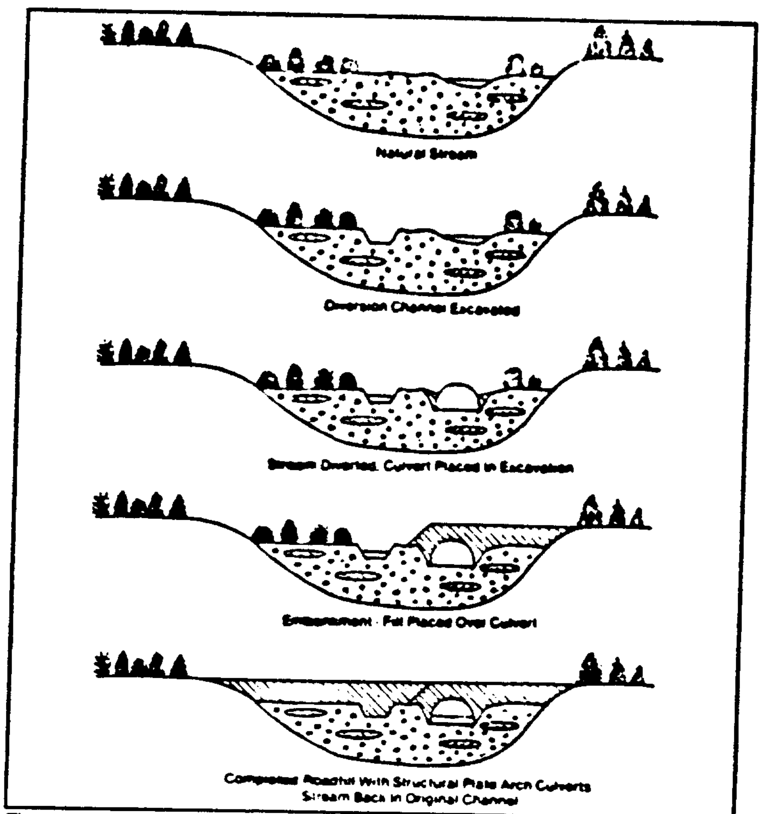

Figure 3-23. Culvert installation using a diversion (Hynson et al., 1982).

(1) Avoid using roads where possible for timber hauling or heavy traffic during wet or thaw periods on roads not designed and constructed for these conditions.
(2) Evaluate the future need for a road and close roads that will not be needed. Leave closed roads and drainage channels in a stable condition to withstand storms.
(3) Remove drainage crossings and culverts if there is a reasonable risk of plugging or failure from lack of maintenance.
(4) Following completion of harvesting, close and stabilize temporary spur roads and seasonal roads to control and direct water away from the roadway. Remove all temporary stream crossings.
(5) Inspect roads to determine the need for structural maintenance. Conduct maintenance practices, when conditions warrant, including cleaning and replacement of deteriorated structures and erosion controls, grading or seeding of road surfaces, and, in extreme cases, slope stabilization or removal of road fills where necessary to maintain structural integrity.
(6) Conduct maintenance activities, such as dust abatement, so that chemical contaminants or pollutants are not introduced into surface waters to the extent practicable.
(7) Properly maintain permanent stream crossings and associated fills and approaches to reduce the likelihood (a) that stream overflow will divert onto roads, and (b) that fill erosion will occur if the drainage structures become obstructed.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to active and inactive roads constructed or used for silvicultural activities.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The objective of this management measure is to manage existing roads to maintain stability and utility and to minimize sedimentation and pollution from runoff-transported materials. Roads that are actively eroding and providing significant sediment to waterbodies, whether in use or not, must be managed. If roads are no longer in use or needed in the foreseeable future, an effective treatment is to remove drainage crossings and culverts if there is a risk of plugging or failure from lack of maintenance. In other cases (e.g., roads in use), it may be more economically viable to periodically maintain crossing and drainage structures.

Sound planning, design, and construction measures often reduce the future levels of necessary road maintenance. Roads constructed with a minimum width in stable terrain, and with frequent grade reversals or dips, require minimum maintenance. However, older roads remain one of the greatest sources of sediment from forest land management. In some locations, problems associated with altered surface drainage and diversion of water from natural channels can result in serious gully erosion or landslides. After harvesting is complete, roads are often forgotten. Erosion problems may go unnoticed until after there is severe resource damage. In western Oregon, 41 out of the 104 landslides reported on private and State forest lands during the winter of 1989-90 were associated with older (built before 1984) forest roads. These landslides were related to both road drainage and original construction problems. Smaller erosion features, such as gullies and deep ruts, are far more common than landslides and very often are related to road drainage.

Drainage of the road prism, road fills in stream channels, and road fills on steep slopes are the elements of greatest concern in road management. Roads used for active timber hauling usually require the most maintenance, and mainline roads typically require more maintenance than spur roads. Use of roads during wet or thaw periods can result in a badly rutted surface, impaired drainage, and excessive sediment leading to waterbodies. Inactive roads, not being used for timber hauling, are often overlooked and receive little maintenance. Many forest roads that have been abandoned may be completely overgrown with vegetation, which makes maintenance very difficult.

Figure 3-24 illustrates some differences between a road with a well-maintained surface, good revegetation, and open drainage structures, and a poorly maintained road.

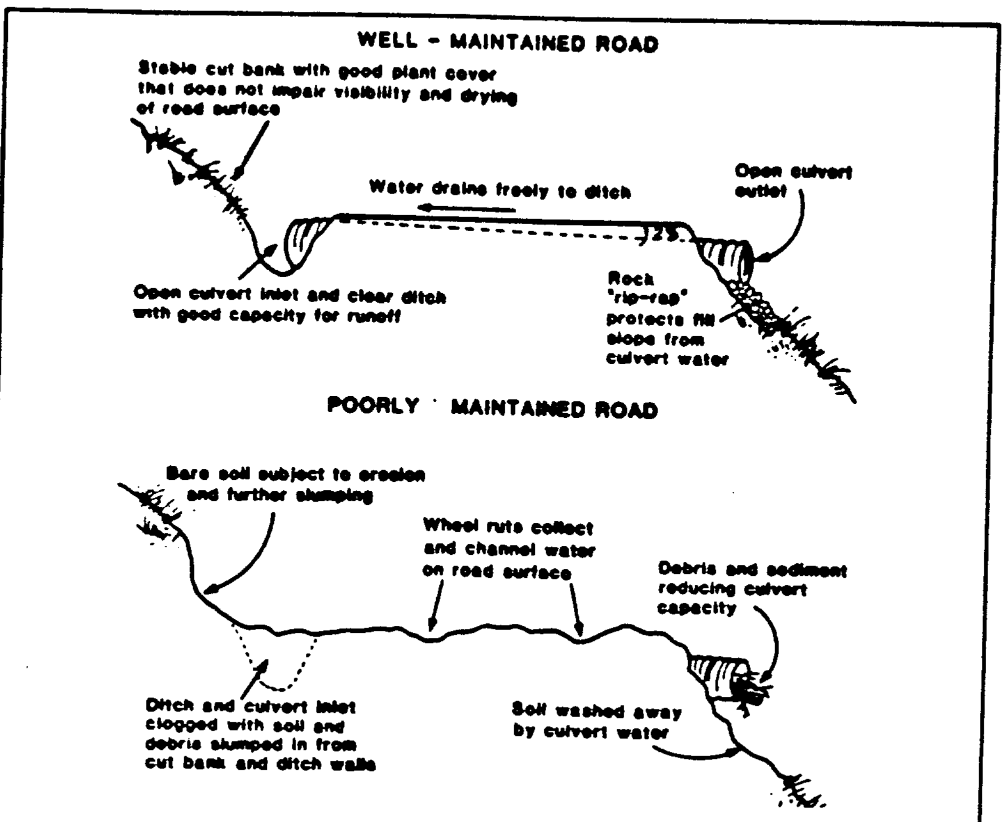

Figure 3-24. Road maintenance examples (Adams, 1991).

VOL 12

3. Management Measure Selection

a. Effectiveness Information

Drainage structures must be maintained to function properly. Culverts and ditches must be kept free of debris that can restrict water flow. Routine cleaning can minimize clogging and prevent flooding, gullying, and washout (Kochenderfer, 1970). Routine maintenance of road dips and surfaces and quick response to problems can significantly reduce road-caused slumps and slides and prevent the creation of berms that could channelize runoff (Oregon Department of Forestry 1981; Ontario Ministry of Natural Resources, 1988).

Proper road/trail closure is essential in preventing future erosion and sedimentation from abandoned roads and skid trails. Proper closure incorporates removal of temporary structures in watercourses, returning stream crossing approaches to their original grades, revegetating disturbed areas, and preventing future access (Kochenderfer, 1970; Rothwell, 1978) Revegetation of disturbed areas protects the soil from raindrop impact and aids soil aggregation, and therefore reduces erosion and sedimentation (Rothwell, 1978).

b. Cost Information

Benefits of proper road maintenance were effectively shown by Dissmeyer and Frandsen (1988). Maintenance costs for road repair were 44 percent greater without implementation of control measures than for installation of BMPs (Table 3-31).

Dissmeyer and Foster (1987) presented an analysis of the economic benefits of various watershed treatments associated with roads (Table 3-32). Specifically, they examined the cost of revegetating cut-and-fill slopes and the costs of various planning and management technical services (e.g., preparing soil and water prescriptions, compiling soils data, and reviewing the project in the field). These costs were compared to savings in construction and maintenance costs resulting from the watershed treatments. Specifically, savings were realized from avoiding problem soils, wet areas, and unstable slopes. The economic analysis showed that the inclusion of soil and water resource management (i.e., revegetating and technical services) in the location and construction of forest roads resulted in an estimated savings of $311 per kilometer in construction costs and $186 per kilometer in maintenance costs.

As part of the Fisher Creek Watershed Improvement Project, Rygh (1990) examined the various costs of ripping and scarification using different techniques. The major crux of Rygh's work was to compare the relative advantages of using a track hoe for ripping and scarification versus the use of large tractor-mounted rippers. He found track hoes to be preferable to tractor-mounted rippers for a variety of reasons, including the following:

- A reduction in furrows and resulting concentrated runoff caused by tractors;
- Improved control over the extent of scarification;
- Increased versatility and maneuverability of track hoes; and
- Cost savings.

Rygh estimated that the cost of ripping with a track hoe ranged from $220 to $406 per mile compared to a cost of $550 per mile for ripping with a D7 or D8 tractor (Table 3-33).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

VOL 12

Table 3-31. Comparison of Road Repair Costs for a 20-Year Period With and Without BMPs[a] (Dissmeyer and Frandsen, 1988)

Maintenance Costs Without BMPs		Costs of BMP Installation	
Equipment	$365	Labor to construct terraces and water diversions	$ 780
Materials (gravel)	122	Materials to revegetate	120
Work supervision	40	Cost of technical assistance	300
Repair cost per 3 years	527	Total cost over 20 years	$1,200
Total cost over 20 years[b]	$2,137		

IRR: 11.2%
PNV: $937
B/C ratio: 1.78 to 1.00 for road BMP installation versus reconstruction/repair.

[a] BMPs include construction of terraces and water diversions, and seeding.
[b] Discounted @ 4%.

Table 3-32. Analysis of Costs and Benefits of Watershed Treatments Associated with Roads (SE U.S.) (Dissmeyer and Foster, 1987)

	Treatment[a]		
	Seed Without Mulch	Seed With Mulch	Hydroseed With Mulch
Costs			
Cost per kilometer ($)	356	569	701
Cost per kilometer for soil and water technical services ($)	62	62	62
Total cost of watershed treatment ($)	418	631	763
Benefits[b]			
Savings in construction costs ($/km)	311	311	311
Savings in annual maintenance costs ($/km)	186	186	186
Benefit/cost (10-year period)	4.4:1	2.9:1	2.4:1

Adapted from West, S., and B.R. Thomas, 1982. Effects of Skid Roads on Diameter, Height, and Volume Growth in Douglas-Fir. *Soil Sci. Soc. Am. J.*, 45:629-632.
[a] Treatments included fertilization and liming where needed.
[b] Cost savings were associated with soil and water resource management in the location and construction of forest roads by avoiding problem soils, wet areas, and unstable slopes. Maintenance cost savings were derived from revegetating cut and fill slopes, which reduced erosion, prolonging the time taken to fill ditch lines with sediment and reducing the frequency of ditch line reconstruction.

■ *Blade and reshape the road to conserve existing surface material; to retain the original, crowned, self-draining cross section; and to prevent or remove berms (except thosedesigned for slope protection) and other irregularities that retard normal surface runoff (Larse, 1971).*

Ruts and potholes can weaken road subgrade materials by channeling runoff and allowing standing water to persist (Rothwell, 1978). Periodic grading of the road surface is necessary to fill in wheel ruts and to reshape the road (Haussman and Pruett, 1978). Maintenance practices must be modified for roads with broad-based dips (Swift, 1985). Maintenance by a motor grader is difficult because scraping tends to fill in the dips, the blade cannot be

9493

Table 3-33. Comparative Costs of Reclamation of Roads and Removal of Stream Crossing Structures (ID) (Rygh, 1990)

Method	Cost (dollar/mile)
Ripping/scarification	
Ripping with D7 or D8 tractor	$550
Scarifying with D8-mounted brush blade	$844
Scarification to 6-inch depth and installation of water bars with track hoe	$1,673
Ripping and slash scattering with track hoe	$440 - $660
Ripping, slash scattering, and water bar installation with track hoe	$812
Ripping with track hoe	$220 - $408

maneuvered to clean the dip outlet, and cut banks are destabilized when the blade undercuts the toe of the slope. Small bulldozers or front-end loaders appear to be more suitable for periodic maintenance of intermittent-use forest roads (Swift, 1988).

■ *Clear road inlet and outlet ditches, catch basins, culverts, and road-crossing structures of obstructions (Larse, 1971).*

Avoid undercutting backslopes when cleaning silt and debris from roadside ditches (Rothwell, 1978). Minimize machine cleaning of ditches during wet weather. Do not disturb vegetation when removing debris or slide blockage from ditches (Larse, 1971; Rothwell, 1978). The outlet edges of broad-based dips need to be cleaned of trapped sediment to eliminate mudholes and prevent the bypass of stormwaters. The frequency of cleaning depends on traffic load (Swift, 1988). Clear stream-crossing structures and their inlets of debris, slides, rocks, and other materials prior to and following any heavy runoff period (Hynson et al., 1982).

■ *Maintain road surfaces by mowing, patching, or resurfacing as necessary.*

Grassed roadbeds carrying fewer than 20-30 vehicle trips per month usually require only annual roadbed mowing and periodic trimming of encroaching vegetation (Swift, 1988).

■ *Remove temporary stream crossings to maintain adequate streamflow (Hynson et al., 1982).*

Failure or plugging of abandoned temporary crossing structures can result in greatly increased sedimentation and turbidity in the stream, and channel blowout.

■ *Wherever possible, completely close the road to travel and restrict access by unauthorized persons by using gates or other barriers (Haussman and Pruett, 1978).*

Where such restrictions are not feasible, traffic should be regulated (Rothwell, 1978).

■ *Install or regrade water bars on roads that will be closed to vehicle traffic and that lack an adequate system of broad-based dips (Kochenderfer, 1970).*

Water bars will help to minimize the volume of water flowing over exposed areas and remove water to areas where it will not cause erosion. Water bar spacing depends on soil type and slope. Table 3-34 contains suggested guidelines for water bar spacing. Water should flow off the water bar onto rocks, slash, vegetation, duff, or other less erodible material and should never be diverted directly to streams or bare areas (Oregon Department of Forestry, 1979a). Outslope closed road surfaces to disperse runoff and prevent closed roads from routing water to streams.

■ *Revegetate to provide erosion control and stabilize the road surface and banks.*

Refer to Revegetation of Disturbed Areas management measure for a more detailed discussion.

■ *Replace open-top culverts with cross drains (water bars, dips, or ditches) to control and divert runoff from road surfaces (Rothwell, 1978; Haussman and Pruett, 1978).*

Open-top culverts are for temporary drainage of ongoing operations. It is important to replace them with more permanent drainage structures to ensure adequate drainage and reduce erosion potential prior to establishment of vegetation on the roadbed.

■ *Periodically inspect closed roads to ensure that vegetational stabilization measures are operating as planned and that drainage structures are operational (Hynson et al., 1982; Rothwell, 1978). Conduct reseeding and drainage structure maintenance as needed.*

Table 3-34. Water Bar Spacing by Soil Type and Slope (Oregon Department of Forestry, 1979a)

Road Grade (percent)	Soil Type		
	Granitic or Sandy	Shale or Gravel	Clay
2	900	1000	1000
4	600	1000	800
6	500	1000	600
6	400	900	500
10	300	600	400
12	200	700	400
15	150	500	300
20	150	300	200
25+	100	200	150

Note: Distances are approximate and should be varied to take advantage of natural features.

E. Timber Harvesting

The timber harvesting management measure consists of implementing the following:

(1) Timber harvesting operations with skid trails or cable yarding follow layouts determined under Management Measure A.

(2) Install landing drainage structures to avoid sedimentation to the extent practicable. Disperse landing drainage over sideslopes.

(3) Construct landings away from steep slopes and reduce the likelihood of fill slope failures. Protect landing surfaces used during wet periods. Locate landings outside of SMAs.

(4) Protect stream channels and significant ephemeral drainages from logging debris and slash material.

(5) Use appropriate areas for petroleum storage, draining, dispensing. Establish procedures to contain and treat spills. Recycle or properly dispose of all waste materials.

For cable yarding:

(1) Limit yarding corridor gouge or soil plowing by properly locating cable yarding landings.

(2) Locate corridors for SMAs following Management Measure B.

For groundskidding:

(1) Within SMAs, operate groundskidding equipment only at stream crossings to the extent practicable. In SMAs, fell and endline trees to avoid sedimentation.

(2) Use improved stream crossings for skid trails which cross flowing drainages. Construct skid trails to disperse runoff and with adequate drainage structures.

(3) On steep slopes, use cable systems rather than groundskidding where groundskidding may cause excessive sedimentation.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to all harvesting, yarding, and hauling conducted as part of normal silvicultural activities on harvest units larger than 5 acres. This measure does not apply to harvesting conducted for precommercial thinnings or noncommercial firewood cutting.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to minimize sedimentation resulting from the siting and operation of timber harvesting, and to manage petroleum products properly.

Logging practices that protect water quality and soil productivity can also reduce total mileage of roads and skid trails, lower equipment maintenance costs, and provide better road protection and lower road maintenance. Careful logging can disturb soil surfaces as little as 8 percent, while careless logging practices can disturb soils as much as 40 percent (Golden et al., 1984). In the Appalachians, skid roads perpendicular to the contour, instead of along the contour, yielded 40 tons of sediment per acre of skid road surface (Hornbeck and Reinhart, 1964). Higher bulk densities and lower porosity of skid road soils due to compaction by rubber-tired skidders result in reduced soil infiltration capacity and corresponding increases in runoff and erosion (Dickerson, 1975). Douglass and Swank (1975) found that poor logging techniques increased sediment production during storms by 10 to 20 times more than sediment production from the undisturbed control watershed. A properly logged watershed experienced only slightly increased sedimentation compared to the undisturbed control watershed.

Locating landings for both groundskidding and cable yarding harvesting systems according to preharvest planning minimizes erosion and sediment delivery to surface waters. However, final siting of landings may need to be adjusted in the field based on site characteristics.

Landings and loading decks can become very compacted and puddled and are therefore a source of runoff and erosion (Golden et al., 1984). Practices that prevent or disperse runoff from these areas before the runoff reaches watercourses will minimize sediment delivery to surface waters. Also, any chemicals or petroleum products spilled in harvest areas can be highly mobile, adversely affecting the water quality of nearby surface waters. Correct spill prevention and containment procedures are therefore necessary to prevent petroleum products from entering surface waters. Designation of appropriate areas for petroleum storage will also minimize water quality impacts due to spills or leakage.

3. Management Measure Selection

This management measure is based on the experience and information gained from studies and from States using similar harvesting practices. Many studies have evaluated and compared the effects of different timber harvest techniques on sediment loss (erosion), soil compaction, and overall ground disturbance associated with various harvesting techniques. The data presented in Tables 3-35 through 3-40 were compiled from many different studies conducted throughout the United States and Canada. Many local factors such as climatic conditions, soil type, and topography affected the results of each study. The studies also examined harvesting techniques under a variety of conditions, including clearcuts, selective cuts, and fire-salvaged areas. However, the major conclusions from the studies on the relative impacts of different timber harvesting techniques on soil erosion and the causes and consequences of ground disturbance remain fairly constant between the studies and enable cross-geographic comparison.

Some of the most significant water quality impacts from logging operations (especially increased sedimentation) result from the actual yarding operations and activities on landings. The critical factors that affect the degree of soil disturbance associated with a particular yarding technique include the amount of disturbance caused by the yarding machinery itself and the amount of road construction needed to support each system. Stone (1973) presented information suggesting that roads may contribute greater than 90 percent of the sedimentation problems associated with logging operations. Therefore, since road areas represent potential erosion sites, it is important to recognize and consider the amount of land used for roads by various logging systems (Sidle, 1980).

a. *Effectiveness Information*

The amount of total soil disturbance varies considerably between the different yarding techniques. Megahan (1980) presented the most comprehensive survey of the available information on these impacts, presenting the data in two ways: soil disturbance associated with the actual yarding operation and soil disturbance associated with the construction of roads needed for the practice (Tables 3-35 and 3-36). The results of his investigation echoed other studies presented in this section and clearly show that aerial and skyline cable techniques are far less damaging than other yarding techniques.

The amount of soil disturbance by yarding depends on the slope of the area, volume yarded, size of logs, and the logging system. Table 3-36 presents data on the extent of soil disturbance associated with particular yarding systems. Megahan's ranking of yarding techniques (from greatest impact to lowest impact) based on percent area disturbed is summarized as follows: tractor (21 percent average), ground cable (21 percent, one study), high-lead (16 percent

Table 3-35. Soil Disturbance from Roads for Alternative Methods of Timber Harvesting (Megahan, 1980)

Logging System (State)	Percent of Logged Area Bared			Reference

average), skyline (8 percent average), jammer in clearcut (5 percent, one study), and aerial techniques (4 percent average).

The amount of road required for different yarding techniques varies considerably. Sidle (1980) defined the amount of land used for haul roads by various logging methods. Skyline techniques require the least amount of road area, with only 2-3.5 percent of the land area in roads. Tractor and single-drum jammer techniques require the greatest amount of road area (10-15 and 18-24 percent of total area, respectively). High-lead cable techniques fall in the middle, with 6-10 percent of the land used for roads. Megahan (1980) concluded that tractor, jammer, and high-lead cable methods result in significantly higher amounts of disturbed soil than do the skyline and aerial techniques.

Sidle (1980) also presented data showing that tractors cause the greatest amount of soil disturbance (35 percent of land area) and soil compaction (26 percent of land area). Sidle (1980) concluded that skyline and aerial balloon techniques created the least disturbance (12 and 6 percent, respectively) and compaction (3 and 2 percent, respectively) (Table 3-37).

Miller and Sirois (1986) compared the land area disturbed by cable, skyline, and groundskidding systems (Table 3-38). They found groundskidding operations to affect 31 percent of the total land area, whereas cable yarding only affected 16 percent of the total land area. Similarly, Patric (1980) found skidders to serve the smallest area per mile of road (20 acres), with skyline yarding serving the largest area per mile of road (80 acres) (Table 3-39).

Table 3-37. Relative Impacts of Four Yarding Methods on Soil Disturbance and Compaction in Pacific Northwest Clearcuts (OR, WA, ID) (Sidle, 1980)

Yarding Method	Bare Soil (%)	Compacted Soil (%)

b. Cost Information

The costs and benefits of rehabilitation of skid trails by planting hardwood, hardwood pine, and shortleaf pine in the southeastern United States were studied by Dissmeyer and Foster (1986). The average rehabilitation cost per acre was $360 and included water barring, ripping or disking, seeding, fertilizing, and mulching where needed (Table 3-40). The benefit/cost ratio of the rehabilitation cost was $1.33 for hardwood, $2.82 for hardwood pine, and $5.07 for shortleaf pine. The real rate of return over inflation ranged from 2.4 to 4.8 percent.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a

Table 3-40. Analysis of Costs and Benefits of Skid Trail Rehabilitation in the Management of Three Southern Timber Types in the Southeast (Dissmeyer and Foster, 1986)

		Timber Type		
	Units	Hardwood	Hardwood Pine	Shortleaf Pine
Rotation	Years	70	60	60
Harvest volume per hectare	m^3	301	350	420
Value per cubic meter	$[b]	28.57	42.86	64.29
Total value of timber per hectare for uncompacted soil	$[b]	8,600	15,001	27,002
Timber volume per acre on skid trails (26% of uncompacted soil)	m^3	78	91	109
Timber volume lost per acre	m^3	223	259	311
Cost per hectare for skid trail rehabilitation[a]	$[b]	900	900	900
Timber volume recovered (75% of loss)	m^3	167	194	233
Value of timber volume recovered	$[b]	4,771	8,315	14,980
Internal rate of return based upon timber volume recovered	%[c]	2.4	3.8	4.8
Net present value of timber volume recovered (@ 2%)	$[b]	1,193	2,538	4,568

practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Harvesting Practices

- *Fell trees away from watercourses, whenever possible, keeping logging debris from the channel, except where debris placement is specifically prescribed for fish or wildlife habitat (Megahan, 1983).*

- *Any tree accidently felled in a waterway should be immediately removed (Huff and Deal, 1982).*

- *Remove slash from the waterbody and place it out of the SMA.*

This will allow unrestricted water flow and protection of the stream's nutrient balance. Remove only logging-generated debris. Leave pieces of large woody debris in place during stream cleaning to preserve channel integrity and maintain stream productivity. Bilby (1984) concluded that indiscriminate removal of large woody debris can adversely affect channel stability. Table 3-41 presents a possible way to determine debris stability.

b. Practices for Landings

- *Landings should be no larger than necessary to safely and efficiently store logs and load trucks.*

- *Install drainage and erosion control structures as necessary.*

Diversion ditches placed around the uphill side of landings minimize accumulation of water on the landing. Landings should have a slight slope to facilitate drainage. Also, adequate drainage on approach roads will prevent road drainage water from entering the landing area.

- *The slope of the landing surface should not exceed 5 percent and should be shaped to promote efficient drainage.*

Table 3-41. General Large Woody Debris Stability Guide Based on Salmon Creek, Washington (Bilby, 1984)

1.a.	If debris is anchored or buried in the streambed or bank at one or both ends or along the upstream face - LEAVE.
1.b.	If debris is not anchored, go to 2.
2.a.	If debris is longer than 10.0 m - LEAVE.
2.b.	If debris is shorter than 10.0 m - go to 3.
3.a.	If debris is greater than 50 cm in diameter - go to 4.
3.b.	If debris is less than 50 cm in diameter - go to 5.
4.a.	If debris is longer than 5.0 m - LEAVE.
4.b.	If debris is shorter than 5.0 m - go to 5.
5.a.	If debris is braced on the downstream side by boulders, bedrock outcrops, or stable pieces of debris - LEAVE.
5.a.	If debris is not braced on the downstream side - REMOVE.

■ *The slope of landing fills should not exceed 40 percent, and woody or organic debris should not be incorporated into fills.*

■ *If landings are to be used during wet periods, protect the surface with a suitable material such as wooden matting or gravel surfacing.*

■ *Install drainage structures for the landings such as water bars, culverts, and ditches to avoid sedimentation. Disperse landing drainage over sideslopes. Provide filtration or settling if water is concentrated in a ditch.*

■ *Upon completion of harvest, clean up landing, regrade, and revegetate (Rothwell, 1978).*

- Upon abandonment, minimize erosion on landings by adequately ditching or mulching with forest litter.
- Establish a herbaceous cover on areas that will be used again in repeated cutting cycles, and restock landings that will not be reused (Megahan, 1983).
- If necessary, install water bars for drainage control.

■ *Locate landings for cable yarding where slope profiles provide favorable deflection conditions so that the yarding equipment used does not cause yarding corridor gouge or soil plowing, which concentrates drainage or causes slope instability.*

■ *Locate cable yarding corridors for streamside management areas following Management Measure B components. Yarded logs should not cause disturbance of the major channel banks of the watercourse of the SMA.*

c. Groundskidding Practices

■ *Skid uphill to log landings whenever possible. Skid with ends of logs raised to reduce rutting and gouging.*

This practice will disperse water on skid trails away from the landing. Skidding uphill lets water from trails flow onto progressively less-disturbed areas as it moves downslope, reducing erosion hazard. Skidding downhill concentrates surface runoff on lower slopes along skid trails, resulting in significant erosion and sedimentation hazard (Figure 3-25). If skidding downhill, provide adequate drainage on approach trails so that drainage does not enter landing.

■ *Skid perpendicular to the slope (along the contour), and avoid skidding on slopes greater than 40 percent.*

Following the contour will reduce soil erosion and encourage revegetation. If skidding must be done parallel to the slope, then skid uphill, taking care to break the grade periodically.

■ *Avoid skid trail layouts that concentrate runoff into draws, ephemeral drainages, or watercourses. Use endlining to winch logs out of SMAs or directionally fell trees so tops extend out of SMAs and trees can be skidded without operating equipment in SMAs. In SMAs, trees should be carefully endlined to avoid soil plowing or gouge.*

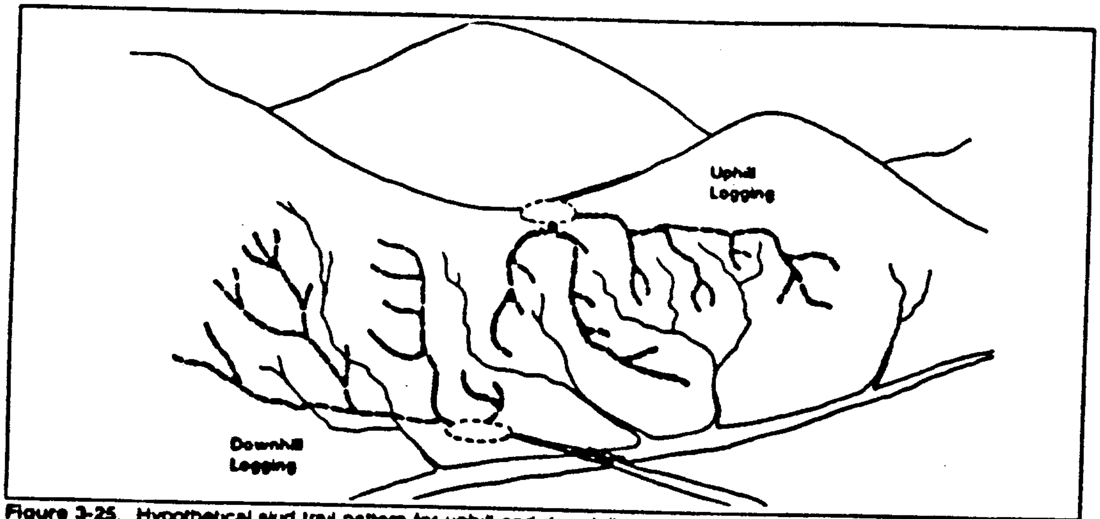

Figure 3-25. Hypothetical skid trail pattern for uphill and downhill logging (Megahan, 1983).

■ *Suspend groundskidding during wet periods, when excessive rutting and churning of the soil begins, or when runoff from skid trails is turbid and no longer infiltrates within a short distance from the skid trail. Further limitation of groundskidding of logs, or use of cable yarding, may be needed on slopes where there are sensitive soils and/or during wet periods.*

■ *Retire skid trails by installing water bars or other erosion control and drainage devices, removing culverts, and revegetating (Rothwell, 1978; Lynch et al, 1985).*

- After logging, obliterate and stabilize all skid trails by mulching and reseeding.
- Build cross drains on abandoned skid trails to protect stream channels or side slopes in addition to mulching and seeding.
- Restore stream channels by removing temporary skid trail crossings (Megahan, 1983).
- Scatter logging slash to supplement water bars and seeding to reduce erosion on skid trails (Lynch et al., 1985).

d. Cable Yarding Practices

■ *Use cabling systems or other systems when groundskidding would expose excess mineral soil and induce erosion and sedimentation.*

- Use high-lead cable or skyline cable systems on slopes greater than 40 percent.
- To avoid soil disturbance from sidewash, use high-lead cable yarding on average-profile slopes of less than 15 percent.

VOL 12

■ *Avoid cable yarding in or across watercourses.*

When cable yarding across streams cannot be avoided, use full suspension to minimize damage to channel banks and vegetation in the SMA.

■ *Yard logs uphill rather than downhill.*

In uphill yarding, log decks are placed on ridge or hill tops rather than in low-lying areas (Megahan, 1983). This creates less soil disturbance because the lift imparted to the logs reduces frictional resistance and the outward radiation of yard trails downhill from the landing disperses runoff evenly over the slope and reduces erosion potential. Downhill yarding should be avoided because it concentrates surface erosion.

e. Petroleum Management Practices

■ *Service equipment where spilled fuel and oil cannot reach watercourses, and drain all petroleum products and radiator water into containers. Dispose of wastes and containers in accordance with proper waste disposal procedures.[1] Waste oil, filters, grease cartridges, and other petroleum-contaminated materials should not be left as refuse in the forest.*

■ *Take precautions to prevent leakage and spills. Fuel trucks and pickup-mounted fuel tanks must not have leaks.*

- Use and maintain seepage pits or other confinement measures to prevent diesel oil, fuel oil, or other liquids from running into streams or important aquifers.
- Use drip collectors on oil-transporting vehicles (Hynson et al., 1982).

■ *Develop a spill contingency plan that provides for immediate spill containment and cleanup, and notification of proper authorities.*

- Provide materials for adsorbing spills, and collect wastes for proper disposal.

9505

[1] The Resource Conservation and Recovery Act (RCRA) regulates the transportation, handling, storage, and disposal of hazardous materials, including petroleum products and by-products.

[illegible]

Confine on-site potential NPS pollution and erosion resulting from site preparation and the regeneration of forest stands. The components of the management measure for site preparation and regeneration are:

(1) Select a method of site preparation and regeneration suitable for the site conditions.
(2) Conduct mechanical tree planting and ground-disturbing site preparation activities on the contour of sloping terrain.
(3) Do not conduct mechanical site preparation and mechanical tree planting in streamside management areas.
(4) Protect surface waters from logging debris and slash material.
(5) Suspend operations during wet periods if equipment used begins to cause excessive soil disturbance that will increase erosion.
(6) Locate windrows at a safe distance from drainages and SMAs to control movement of the material during high runoff conditions.
(7) Conduct bedding operations in high-water-table areas during dry periods of the year. Conduct bedding in sloping areas on the contour.
(8) Protect small ephemeral drainages when conducting mechanical tree planting.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to all site preparation and regeneration activities conducted as part of normal silvicultural activities on harvested units larger than 5 acres.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Regeneration of harvested forest lands not only is important in terms of restocking a valuable resource, but also is important to provide water quality protection from disturbed soils. Tree roots stabilize disturbed soils by holding the soil in place and aiding soil aggregation, decreasing slope failure potential. The presence of vegetation on disturbed soils also slows storm runoff, which in turn decreases erosion.

Leaving the forest floor litter layer intact during site preparation operations for regeneration minimizes mineral soil disturbance and detachment, thereby minimizing erosion and sedimentation (Golden et al., 1984). Maintenance of an unbroken litter layer prevents raindrop detachment, maintains infiltration, and slows runoff (McClurkin et al.,

1987) Mechanical site preparation can potentially impact water quality in areas that have steep slopes and erodible soils and where the prepared site is located near a waterbody. Use of mechanical site preparation treatments that expose mineral soils on steep slopes can greatly increase erosion and landslide potential. Alternative methods, such as drum chopping, herbicide application, or prescribed burning, disturb the soil surface less than mechanical practices (Golden et al., 1984).

Mechanical planting using machines that scrape or plow the soil surface can produce erosion rills, increasing surface runoff and erosion. Natural regeneration, hand planting, and direct seeding minimize soil disturbance, especially on steep slopes with erodible soils (Golden et al., 1984).

3. Management Measure Selection

This measure is based in part on information and experience gained from studies and from the use of similar management practices by States. The information summarized provides comparisons and relative levels of effects and costs for site preparation and regeneration. The majority of the data in Tables 3-42 through 3-46 compare sediment loss or erosion rates for shearing, chopping, root-raking and disking. Many of the data are site-specific, and site characteristics and experimental conditions are provided (when available) in the text below. Regional differences in effects are summarized by Dissmeyer and Stump (1978); however, most of the experimental information is from the Southeast and Texas.

a. Effectiveness Information

Effects of different site preparation techniques depend greatly on care of application and site conditions. Beasley (1979) studied the relative soil disturbance effects of site preparation following clearcutting on three small watersheds in the hilly northern Mississippi Coastal Plain. Slopes were mostly 30 percent or greater. One site was single drum-chopped and burned; one was sheared and windrowed (windrows were burned); and the third was sheared, windrowed, and bedded to contour. The control watershed was instrumented and left uncut. The treatments exposed soil on approximately 40-70 percent of the three watersheds (Table 3-42). A temporary cover crop of clover was sown after site preparation to protect the soil from rainfall impact and erosion. Similar increases in sediment production were measured for the three treatments in the first year after site preparation, with amounts decreasing during the second year except for the bedded site, which was attributed to gully formation from increased stormflow. During the second year, the clover and other vegetation covered 85-95 percent of the surface, effectively decreasing sediment production.

A summary of work on erosion from site preparation by Dissmeyer and Stump is presented in Golden et al. (1984)(Table 3-43). These erosion rates were compiled from the Erosion Data Bank of the U.S. Forest Service and are based on observations throughout the Southeast. The rates reflect soil movement measured at the bottom of the slope, not sediment actually reaching a stream. Therefore, the numbers estimate the worst-case erosion if the stream is located directly at the toe of the slope with no intervening vegetation. Rates are given as tons per acre per year average for 3- to 4-year recovery periods.

The degree of erosion produced by site preparation practices is directly related to the amount of soil disturbed and the percentage of good ground cover remaining. Dissmeyer (1980) showed that disking produced more than twice the erosion rate of any other method (Table 3-44). Bulldozing, shearing, and sometimes grazing were associated with relatively high rates of erosion. Chopping or chopping and burning produced moderate erosion rates. Logging also produced moderate erosion rates in this study when it included the impact of skid and spin roads. The lowest rate of erosion is associated with burning.

Beasley and Granillo (1985) compared stormflow and sediment losses from mechanically and chemically prepared sites in southwest Arkansas (Table 3-45). Mechanical preparation (clearcutting followed by shearing, windrowing, and replanting with pine seedlings) significantly increased sediment losses in the first 2 years after treatment. A subsequent decline in sediment losses in the mechanically prepared watersheds was attributed to rapid growth of ground cover. Windrowing brush into ephemeral drainages and leaving it unburned effectively minimized soil losses

Table 3-42. Deposited, Suspended, and Total Sediment Losses and Percentage of Exposed Soil in the Experimental Watersheds During Water Years 1976 and 1977 for Various Site Preparation Techniques (MS, AR) (Beasley, 1979)

Treatment	Percent of Exposed Soil
Chopped	37
Sheared and windrowed	53
Bedded	69

Treatment	1976 (tons/ha)			1977 (tons/ha)		
	Deposited	Suspended	Total	Deposited	Suspended	Total
Control	--	--	0.62	--	--	0.11
Chopped	2.19	10.34	12.54	0.74	1.58	2.31
Sheared	2.14	10.66	12.80	0.81	1.41	2.22
Bedded	3.26	10.98	14.25	2.18	3.36	5.54

by trapping sediment on-site and reducing channel scouring. Chemical site preparation (herbicides) had no significant effect on sediment losses.

Water quality changes associated with two site preparation methods were studied by Blackburn, DeHaven, and Knight (1982). Table 3-46 shows that shearing and windrowing (which exposed 59 percent of the soil) can produce 400 times more sediment loadings than chopping (which exposed 16 percent of the soil) during site preparation. Total

Table 3-46. Sediment Loss (kg/ha) in Stormflow by Site Treatment from January 1 to August 31, 1981 (TX) (Blackburn, DeHaven, and Knight, 1982)

Treatment	Watershed	Sediment Loss (kg/ha)		
		Suspended	Bedload	Total
Sheared and windrowed	1	815.2	643.5	1,458.7
	2	1,217.0	920.4	2,137.4
	3	736.7	2,270.8	3,007.5
	Mean	923.0	1,278.2	2,201.2
Chopped	5	5.3	0	5.3
	7	10.7	0	10.7
	9	23.2	0	23.2
	Mean	13.1	0	13.1
Undisturbed	4	1.1	0	1.1
	6	7.2	0	7.2
	8	0.8	0	0.8
	Mean	3.0	0	3.0

nitrogen losses were nearly 20 times greater from sheared than from undisturbed watersheds, and three times greater from sheared than from chopped (Table 3-47).

b. Cost Information

The way a site is prepared for reforestation can make a 3- to 14-foot difference in site index for pine in the Southeast (Dissmeyer and Foster, 1987). In an analysis of different site preparation techniques, Dissmeyer and Foster concluded that maintaining site quality yields larger trees and more valuable products (Table 3-48). The heavy site preparation methods required a greater initial investment than did the light site preparation methods, but did not yield a greater harvest. The cost-benefit for light site preparation was a 2.3 percent greater internal rate of return than that for heavy site preparation. Dissmeyer (1986) evaluated the economic benefits of erosion control with respect to different site preparation techniques. Increased timber production and savings in site preparation costs are returns the landowner can enjoy if care is taken to reduce soil exposure, displacement, and compaction (Table 3-49). Using light site preparation techniques such as chopping and light burn reduces erosion, increases the site index and the value of timber, and costs less per unit area treated. Heavy site preparation techniques such as shearing and windrowing remove nutrients, compact soil, increase erosion and site preparation costs, and result in a lower present net value for timber.

Table 3-47. Nutrient Loss (kg/ha) in Stormflow by Site Treatment from January 1 to August 31, 1981 (TX) (Blackburn, DeHaven, and Knight, 1982)

Treatment	Nitrates	Ammonia	Total-N	Ortho-P	Total-P	K	Ca	Mg	Na
Sheared and windrowed	0.227	0.114	2.145	0.033	0.197	4.40	0.72	1.45	1.36
Chopped	0.066	0.042	0.759	0.010	0.012	2.48	1.19	0.71	0.79
Undisturbed	0.001	0.007	0.115	0.001	0.002	0.29	0.19	0.21	0.18

Table 3-48. Analysis of Two Management Schedules Comparing Cost and Site Productivity in the Southeast (Dissmeyer and Foster, 1987)

		Light Site Preparation[a]		Heavy Site Preparation[b]	
Year	Silviculture Treatment	Investment Per Hectare[c]	Wood Produced M³/ha	Investment Per Hectare[c]	Wood Produced M³/ha
1984	Site Prep/Tree Planting	$297		$420	
1999	Thinning	$252	64.2 pulpwood	$180	46.0 pulpwood
2010	Thinning	$256	22.3 saw timber 33.3 pulpwood	$331	5.3 saw timber 22.0 pulpwood
2020	Final Harvest	$2,422	133.5 saw timber 15.2 pulpwood	$2,071	112.3 saw timber 22.0 pulpwood
Present Net Value (@ 4%)		$623		$304	
Internal Rate of Return		12.4%[d]		10.1%	

Adapted from Patterson, T. 1984. Dollars in Your Dirt. *Alabama's Treasured Forests*. Spring: 20-21.

[a] Light site preparation includes chop and light burn or chop with herbicides, and reduces soil exposure and erosion.

[b] Heavy site preparation includes bulldozing or windrowing or shearing and windrowing, and increases erosion and sediment yields over those for light site preparation.

[c] 1984 dollars.

[d] Based on 4% inflation rate assumed.

The U.S. Forest Service (1987) examined the costs of three alternatives to slash treatment: broadcast burn and protection of streamside management zones, yarding of unmerchantable material (YUM) of 15 inches in diameter or more, and YUM of 8 inches in diameter or more (Table 3-50). YUM alternatives cost approximately $435-$820/acre, in comparison to broadcast burning at $900/acre. In addition, the YUM alternatives protect highly erodible soils from direct rainfall and runoff impacts, reduce fire hazards, meet air and water quality standards, and allow for the rapid establishment of seedlings on clearcuts.

Table 3-49. Site Preparation Comparison (VA, SC, NC) (Dissmeyer, 1986)

Treatment	Treatment Cost ($/acre)	Erosion Index[a]
No site preparation	$40	1.0
Burn only	$45	1.1
Single chop and burn	$80	2.3
Double chop and burn	$120	3.0
Single shear and burn	$145	4.3
Shear twice and burn	$170	5.1
Rootrake and disk and burn	$170	16.0
Rootrake and burn	$170	16.0

[a] The index is an expression of relative erosion potential resulting from each treatment.

Table 3-50. Comparison of Costs for Yarding Unmerchantable Material (YUM) vs. Broadcast Burning (OR) (USDA, 1987)

Activity	Broadcast Burn and Protect SMA	YUM 15" in Diameter and No Burn	YUM 8" in Diameter and No Burn
Broadcast burn	$350/acre	N/A	N/A
SMA protection	$450/acre	N/A	N/A
YUM, fell hardwood, lop and scatter	N/A	$305/acre	$700/acre
Planting cost	$100/acre	$130/acre	$120/acre
Totals	$900/acre	$435/acre	$820/acre

Tables 3-51 and 3-52 present comparisons of estimated total costs for different site preparation and regeneration practices, respectively, for which cost-share assistance is provided by the State of Minnesota through its Stewardship Incentives Program (SIP) (Minnesota Department of Natural Resources, 1991). Table 3-53 presents total costs of forest regeneration by various methods, along with the cost-share amount provided by the State of Illinois' SIP.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Site Preparation Practices

■ *Mechanical site preparation should not be applied on slopes greater than 30 percent.*

On sloping terrain greater than 10 percent, or on highly erosive soils, operate mechanical site preparation equipment on the contour.

■ *Mechanical site preparation should not be conducted in SMAs.*

■ *Construct beds along the contour (Huff and Deal, 1982). Avoid connecting beds to drainage ditches or other waterways.*

■ *Use haystack piling where possible instead of windrows.*

Leave sufficient slash and duff on the site to provide good ground cover and minimize erosion from the harvest site. If the soil Basic Erosion Rate (BER) is low, leave at least 40 percent good ground cover; if the BER is medium, leave at least 50 percent good ground cover; if the BER is high, leave at least 60 percent good ground cover.

■ *Minimize incorporation of soil material into windrows and piles during their construction.*

VOL 12

Table 3-51. Estimated Costs for Site Preparation (1991 Costs) (Minnesota Department of Natural Resources, 1991)

Site Preparation Practice	Total Cost[a]
Chemical	$67.00/acre
Mechanical	
Light (includes hand site preparation)	$47.00/acre
Heavy[b]	$107.00/acre
Chemical-Mechanical[b]	$113.00/acre

[a] The costs shown represent the total cost of the practice. Calculations were made by dividing the maximum Federal cost share by 0.75 to get the total cost.
[b] Where slope exceeds 20 percent or primary cover is standing hardwoods greater than 12 inches in diameter, the above may be increased by $40.00 per acre.

Table 3-52. Estimated Costs for Regeneration (1991 Costs) (Minnesota Department of Natural Resources, 1991)

Regeneration Practice	Total Cost[a]
Planting[b]	
Softwoods (when purchased from State nurseries)	$21.00/100 seedlings planted
Hardwoods (when purchased from State nurseries)	$29.00/100 seedlings planted
Softwoods (when purchased from private nurseries)	$28.00/100 seedlings planted
Hardwoods (when purchased from private nurseries)	$41.00/100 seedlings planted
Shrubs	$40.00/100 seedlings planted
Seeding (includes both purchase of seed and seeding)	
Aerial seeding	$23.00/acre
Cyclone seeding	$40.00/acre
Hand or hot cap seeding	$53.00/acre

[a] The costs shown represent the total cost of the practice. Calculations were made by dividing the maximum Federal cost share by 0.75 to get the total cost.
[b] Where planting is to be done on areas of heavy slash from recent harvesting operations or on areas with slopes over 30 percent or on sites having other particularly difficult planting conditions, the limits may be increased an additional $10.00 per 100 seedlings planted and, where the planting has a guaranteed end result, the above rates may be increased by $5.00 per 100 trees planted.

9513

Table 3-53. Cost-Share Information for Revegetation/Tree Planting (Illinois Administrative Code, 1990)

Practice Description	Cost-Share Amount[a]	Total Cost
Tree planting (trees and labor)		
No-cost planting stock	NTE $70.00/acre	$87.50/acre
Purchased planting stock	NTE $170.00/acre	$212.50/acre
Direct seeding (including seed collected or purchased plus labor and any machinery use)	NTE $40.00/acre	$50.00/acre

NTE = not to exceed.
[a] Cost-share amounts represent 80 percent of the actual cost.

This can be accomplished by using a rake or, if use of a blade is unavoidable, keeping the blade above the soil surface and removing only the slash. Rapid site recovery and tree growth are promoted by the retention of nutrient-rich topsoil, and the effectiveness of the windrow in minimizing sedimentation is increased.

■ *Locate windrows and piles away from drainages to prevent movement of materials during high-runoff conditions.*

■ *Avoid mechanical site preparation operations during periods of saturated soil conditions that may cause rutting or accelerate soil erosion.*

■ *Do not place slash in natural drainages, and remove any slash that accidentally enters drainages.*

Slash can clog the channel and cause alterations in drainage configuration and increases in sedimentation. Extra organic material can lower the dissolved oxygen content of the stream. Slash also allows silt to accumulate in the drainage and to be carried into the stream during storm events.

■ *Provide filter strips of sufficient width to protect drainages that do not have SMAs from sedimentation by the 10-year storm.*

b. Practices for Regeneration

■ *Distribute seedlings evenly across the site.*

■ *Order seedlings well in advance of planting time to ensure their availability.*

■ *Hand plant highly erodible sites, steep slopes, and lands adjacent to stream channels (SMAs)(Yoho, 1980).*

■ *Operate planting machines along the contour to avoid ditch formation.*

- Soil conditions (slope, moisture conditions, etc.) should be suitable for adequate machine operation.
- Slits should be closed periodically to avoid channeling flow.

VOL 12

9514

[illegible]

Prescribe fire for site preparation and control or suppress wildfire in a manner which reduces potential nonpoint source pollution of surface waters:

(1) Intense prescribed fire should not cause excessive sedimentation due to the combined effect of removal of canopy species and the loss of soil-binding ability of subcanopy and herbaceous vegetation roots, especially in SMAs, in streamside vegetation for small ephemeral drainages, or on very steep slopes.
(2) Prescriptions for prescribed fire should protect against excessive erosion or sedimentation to the extent practicable.
(3) All bladed firelines, for prescribed fire and wildfire, should be plowed on contour or stabilized with water bars and/or other appropriate techniques if needed to control excessive sedimentation or erosion of the fireline.
(4) Wildfire suppression and rehabilitation should consider possible NPS pollution of watercourses, while recognizing the safety and operational priorities of fighting wildfires.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to all prescribed burning conducted as part of normal silvicultural activities on harvested units larger than 5 acres and for wildfire suppression and rehabilitation on forest lands.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to minimize potential NPS pollution and erosion resulting from prescribed fire for site preparation and from the methods used for wildfire control or suppression.

Prescribed burning is aimed at reducing slash and competition for nutrients among seedlings and protecting against wildfire. Slash burning destroys vegetation that reduces nitrogen-nitrate loadings. If uncontrolled, the burn may reach SMAs or highly erodible soils, causing increased sedimentation and erosion. Prescribed burning causes changes in the chemical cycling of elements by influencing biological and microclimate changes, volatilization, and mineralization processes.

The intensity and severity of burning and the proportion of the watershed burned are the major factors affecting the influence of prescribed burning on streamflow and water quality (Baker, 1990). Fires that burn intensely on steep slopes close to streams and that remove most of the forest floor and litter down to the mineral soil are most likely to adversely affect water quality (Golden et al., 1984). The amount of erosion following a fire depends on the following:

- Amount of ground cover remaining on the soil;
- Steepness of slope;
- Time, amount, and intensity of rainfall;
- Intensity of fire;
- Inherent erodibility of the soil; and
- Rapidity of revegetation.

Mersereau and Dyrness (1972) found slash burning on steep slopes to contribute to surface soil movement by removing litter and vegetation, and baring 55 percent of the mineral soil. Richter and others (1982), however, found that periodic, low-intensity prescribed fires had little effect on water quality in the Atlantic and Gulf coastal plain. Revegetation of burned areas also drastically reduces sediment yield from prescribed burning and wildfires (Baker, 1990).

3. Management Measure Selection

This measure is based in part on information and experience gained from studies and from the use of similar management practices by States. To avoid many of the negative impacts from prescribed burning, Pope (1978) recommends that those in charge of managing the fire construct water diversions on firelines in steep terrain to drain the water away from the burn, leave an adequate strip of undisturbed surface between the prescribed burn area and water sources, and avoid intense fires on soils that are uncohesive and highly erodible.

Dyrness (1963) studied the effects of slash burning in the Pacific Northwest, finding that severe burning decreases soil porosity and infiltration capacity, thus increasing the potential for soil erosion. Clayton (1981) found that after the helicopter logging and broadcast burning of slash in the Idaho batholith, erosion increased approximately 10 times the natural rate for a short period of time as the result of to a high-intensity rain storm and then decreased substantially within the following year.

Feller (1981) examined the effects of (1) clearcutting and (2) clearcutting and slash burning on stream temperatures in southwestern British Columbia. Both treatments resulted in increased summer temperatures as well as daily temperature fluctuations. These effects lasted for 7 years in the case of the clearcut stream but longer in the case of the clearcut and slash-burned stream. Clearcutting increased winter temperatures, while slash burning decreased temperatures. The study concluded that clearcutting and slash burning had a greater impact on stream temperatures than did clearcutting alone.

Biswell and Schultz (1957) found that surface runoff and erosion in northern California ponderosa pine forests are not attributable to prescribed burning. While conducting observations during heavy rains, the authors found that the duff and debris left after burning were effective in maintaining high infiltration and percolation capacity, and they traced surface runoff to bare soil areas caused by human activity. A study by Page and Lindenmuth (1971) examined the effects of prescribed fire on vegetation and sediment on a watershed in the oak-mountain mahogany chaparral of central Arizona. The study found that the average sediment movement from the treated drainages during the 5-year period was 0.30 acre-feet per square mile per year, which is substantially less than the sediment loss of 3.2 acre-feet per square mile per year for the first 5 years following a wildfire in a comparable area in Arizona.

Stednick and others (1982) found increased concentrations of suspended sediments, phosphorus, and potassium in streamflows below the burned area after the slash burning of coastal hemlock-spruce forests of southeastern Alaska. Stream monitoring indicated an immediate flush of elements, followed by a slower release of these elements into surface water. No reduction in the nitrogen content or depth of the soil organic horizon was found, but there were significant reductions in the potassium and magnesium contents of the soil.

Minnesota's Landowner Forest Stewardship Plan (1991) estimates the cost for prescribed burning to be $27/acre.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Prescribed Fire Practices

■ *Carefully plan burning to adhere to weather, time of year, and fuel conditions that will help achieve the desired results and minimize impacts on water quality.*

Evaluate ground conditions to control the pattern and timing of the burn.

■ *Intense prescribed fire for site preparation should not be conducted in the SMA.*

■ *Piling and burning for slash removal purposes should not be conducted in the SMA.*

■ *Avoid construction of firelines in the SMA.*

■ *In prescriptions for burns, avoid conditions requiring extensive blading of firelines by heavy equipment.*

Use handlines, firebreaks, and hose lays to minimize blading of firelines.

■ *Use natural or in-place barriers (e.g., roads, streams, lakes, wetlands) as an acceptable way to minimize the need for fireline construction in situations where artificial construction of firelines will result in excessive erosion and sedimentation.*

■ *Construct firelines in a manner that minimizes erosion and sedimentation and prevents runoff from directly entering watercourses.*

- Locate firelines on the contour whenever possible, and avoid straight uphill-downhill placement.
- Install grades, ditches, and water bars while the line is being constructed.
- Install water bars on any fireline running up and down the slope, and direct runoff onto a filter strip or sideslope, not into a drainage (Huff and Deal, 1982).
- Construct firelines at a grade of 10 percent or less where possible.
- Adequately cross-ditch all firelines at the time of construction (Megahan, 1983).
- Construct simple diversion ditches or turnouts at intervals as needed to direct surface water off the plowed line and onto undisturbed forest cover for dispersion of water and soil particles.
- Construct firelines only as deep and wide as necessary to control the spread of the fire.

■ *Maintain the erosion control measures on firelines after the burn.*

■ *Revegetate firelines with adapted herbaceous species (Megahan, 1983).*

Refer to the Revegetation of Disturbed Areas management measure for more detailed information.

■ *Execute the burn with a trained crew and avoid intense burning.*

Intense burning can accelerate erosion by consuming the organic cover.

■ *Avoid burning on steep slopes with high-erosion-hazard areas or highly erodible soils.*

b. Wildfire Practices

■ *Whenever possible avoid using fire-retardant chemicals in SMAs and over watercourses, and prevent their runoff into watercourses. Do not clean application equipment in watercourses or locations that drain into watercourses.*

■ *Close water wells excavated for wildfire-suppression activities as soon as practical following fire control.*

■ *Provide advance planning and training for firefighters that considers water quality impacts when fighting wildfires. This can include increasing awareness so direct application of fire retardants to waterbodies is avoided and firelines are placed in the least detrimental position.*

VOL 12

5518

[illegible]

Reduce erosion and sedimentation by rapid revegetation of areas disturbed by harvesting operations or road construction:

(1) Revegetate disturbed areas (using seeding or planting) promptly after completion of the earth-disturbing activity. Local growing conditions will dictate the timing for establishment of vegetative cover.
(2) Use mixes of species and treatments developed and tailored for successful vegetation establishment for the region or area.
(3) Concentrate revegetation efforts initially on priority areas such as disturbed areas in SMAs or the steepest areas of disturbance near drainages.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to all disturbed areas resulting from harvesting, road building, and site preparation conducted as part of normal silvicultural activities. Disturbed areas are those localized areas within harvest units or road systems where mineral soil is exposed or agitated (e.g., road cuts, fill slopes, landing surfaces, cable corridors, or skid trail ruts).

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Revegetation of areas of disturbed soil can successfully prevent sediment and pollutants associated with the sediment (such as phosphorus and nitrogen) from entering nearby surface waters. The vegetation controls soil erosion by dissipating the erosive forces of raindrops, reducing the velocity of surface runoff, stabilizing soil particles with roots, and contributing organic matter to the soil, which increases soil infiltration rates. In areas such as the Pacific Northwest, the construction of forest roads without revegetation has led to significant increases in stream sedimentation. According to Carr and Ballard (1980), studies have found that stream sedimentation increased 250 times during the first rainfalls following construction of a 2.5-km logging road within a 100-hectare watershed and remained higher than an undisturbed companion watershed for the next 2 years.

Vegetation can trap and prevent dry ravel from moving further downslope, and it produces organic matter that is incorporated into the soil, increasing infiltration rates (Berglund, 1978). Nutrient and soil losses to streams and lakes also can be reduced by revegetating burned, cut over, or otherwise disturbed areas (Crumrine, 1977). In some cases, double plantings are used: an early planting to establish erosion protection quickly and a later planting to provide more permanent protection (Hynson et al., 1982).

VOL 12

95/9

3. Management Measure Selection

a. Effectiveness Information

This measure is based in part on information and experience gained from studies and from the use of similar management practices by States. Significant reductions in soil erosion have been achieved by revegetating bare cut-and-fill slopes alongside forest roads. A study of forest roadside slopes at two sites on Vancouver Island, Canada, by Carr and Ballard (1980) found revegetation to be an effective management practice in preventing soil erosion. At the control sites where no plant cover was present, the soil eroded to an average depth of 2-3 cm over 7 months, amounting to an estimated soil loss of 345 cubic meters per kilometer of road. In contrast, sites with hydroseeding had a net accumulation of soil material. In terms of practices, a single hydroseeding application of both seed and fertilizer was as effective as sequential hydroseeding application of seed and fertilizer in terms of preventing soil erosion. The practice of mulching on non-gully-prone soils, as a supplement to hydroseeding, was found to be unnecessary because mulch is incorporated into the hydromulch.

Kuehn and Cobourn (1989) studied the Basic Erosion Rate (BER) for soils on commercial forest land in the Eldorado National Forest and concluded that good ground cover is key to reducing erosion. Figure 3-26 demonstrates the relationship between percent ground cover and slope, and the resulting soil loss. Good ground cover is defined as "living plants within 5 feet of the ground and litter or duff with a depth of 2 inches or more."

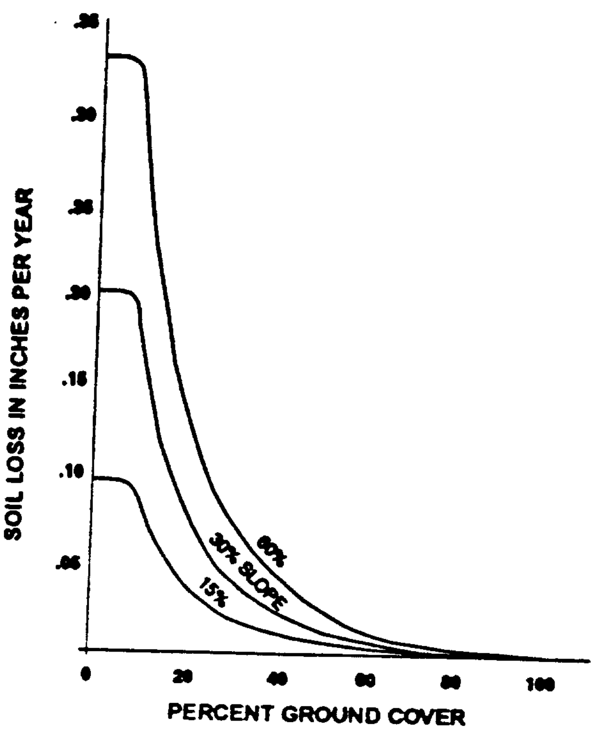

Figure 3-26. Relation of soil loss to good ground cover (Kuehn and Cobourn, 1989).

VOL 12

5520

R0042826

Seeding was also cited by Berglund (1978) as a successful management practice for controlling erosion along forest roads in Oregon. When establishing a revegetation erosion control program, the author suggested that the program address criteria for seed selection, site preparation guidelines, timing of seeding, application methods, fertilization, and mulching. Several guidelines for seed cover, fertilization, and mulching rates were also presented. For example, Berglund suggests that a vegetative cover of 40 percent or more is necessary to significantly reduce soil erosion from disturbed areas.

Bethlahmy and Kidd (1966) described the extent to which revegetation controls erosion from steep road fills as dependent upon the amount of protection given to the seeded slopes (Table 3-54). Seed and fertilizer alone did not control erosion, but the addition of straw mulch reduced erosion by one-eighth to one-half. Adding more protection, netting as well as mulch, reduced erosion by almost 100 percent to nearly negligible levels.

b. Cost Information

Megahan (1987) found the costs of seeding with plastic netting placed over the seeded area to be almost 50 times more than the costs of dry seeding alone (Table 3-55). The economic impacts of other revegetation management measures were estimated by Dubensky (1991)(Table 3-56). Seeding firelines or rough logging roads adds $19.75 per 100 feet of road or fireline. Ripping, shaping, and seeding log decks costs about 178.50 per log deck. Fiber for road and landing maintenance adds $4 per ton used, and water bars add $12.50 each for construction and seeding.

Lickwar (1989) compared the costs for revegetation of disturbed areas for various slope gradients in the Southeast. He found that revegetation costs decreased slightly as slope decreased; however, costs remained fairly high (Table 3-57). Minnesota's Stewardship Incentives Program (SIP) estimated the costs of reestablishment of permanent vegetation to vary from $80.00/acre to $147.00/acre of disturbed area, depending on type of vegetation (Table 3-58).

Table 3-54. Comparison of the Effectiveness of Seed, Fertilizer, Mulch, and Netting in Controlling Cumulative Erosion from Treated Plots on a Steep Road Fill in Idaho (Bethlahmy and Kidd, 1966)

Cumulative Elapsed Time (days)	Cumulative Precipitation (inches)	Control Plot[a]	Group A (seed, fertilizer)		Group B (seed, mulch, fertilizer)		Group C (seed, fertilizer, mulch, netting)		
			Erosion (in 1,000 lb/ac) by Plot Number[b]						
			2	4	3	8	5	6	7
17	1.41	31.9	38.7	38.0	0.1	32.6	0	0	0
80	4.71	70.0	99.2	85.7	7.4	34.6	0.9	0	0.3
157	12.46	72.2	100.2	86.9	11.1	35.1	1.1	0	0.4
200	15.25	79.1	101.0	87.6	11.4	35.7	1.1	0	0.4
255	17.02	82.3	102.8	88.8	11.5	35.8	1.1	0	0.4
322	20.40	84.2	104.7	89.4	11.9	36.0	1.1	0	0.4

[a] The control plot received no treatment at all.
[b] Plot 2 had contour furrows, seed, fertilizer, holes.
Plot 3 had contour furrows, straw mulch, seed, fertilizer, holes.
Plot 4 had polymer emulsion, seed, fertilizer.
Plot 5 had straw mulch, paper netting, seed, fertilizer.
Plot 6 had straw mulch, jute netting, seed, fertilizer.
Plot 7 had seed, fertilizer, straw mulch, chicken wire netting.
Plot 8 had seed, fertilizer, straw mulch with asphalt emulsion.

Table 3-55. Costs of Erosion Control Measures (Megahan, 1987)

Measure[a]	Cost ($/acre)
Dry seeding	124
Plastic netting placed over seeded area	5,662

Table 3-57. Cost Estimates (and Cost as a Percent of Gross Revenues) for Seed, Fertilizer, and Mulch (1987 Dollars) (Lickwar, 1989)

Practice Component	Steep Sites[a]	Moderate Sites[b]	Flat Sites[c]
Seed, fertilizer, and mulch	$13,625.00 (3.41%)	$12,849.95 (2.72%)	$12,258.70 (1.36%)

[a] Based on a 1,148-acre forest and gross harvest revenues of $399,685. Slopes average over 9 percent.
[b] Based on a 1,104-acre forest and gross harvest revenues of $473,182. Slopes ranged from 4 percent to 8 percent.
[c] Based on a 1,832-acre forest and gross harvest revenues of $899,491. Slopes ranged from 0 percent to 3 percent.

Table 3-58. Estimated Costs for Revegetation (1991 Costs) (Minnesota Department of Natural Resources, 1991)

Practice	Total Cost[a]
Establishment of permanent vegetative cover (includes seedbed preparation, fertilizer, chemicals and application, seed, and seeding as prescribed in the plan)	
Introduced grasses	$80.00/acre
Native grasses	$147.00/acre

[a] The costs shown represent the total cost of the practice. Calculations were made by dividing the maximum Federal cost share by 0.75 to obtain the total cost.

4. Practices

As described more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

- *Use seed mixtures adapted to the site, and avoid the use of exotic species (Larse, 1971). Species should consist primarily of annuals to allow natural revegetation of native understory plants, and they should have adequate soil-binding properties.*

The selection of appropriate grasses and legumes is important for vegetation establishment. Grasses vary as to climatic adaptability, soil chemistry, and plant growth characteristics (Berglund, 1978). USDA Soil Service technical guides at the State-wide level are excellent sources of information for seeding mixtures and planting prescriptions (Hynson et al., 1982). The U.S. Forest Service, State foresters, and County Extension agents can also provide helpful suggestions (Kochenderfer, 1970). The use of native species is important and practical. Because non-native species can take over and destroy native vegetation, use of non-native species often results in increased maintenance activities and expense, and plenty of hardy native species are usually available (Hynson et al., 1982). In addition to selecting a seeding mixture, the seeding rate must be determined so that adequate soil protection can be achieved without the excess cost of overseeding. Berglund (1978) describes how to determine seeding rates in *Seeding to Control Erosion Along Forest Roads*.

- *On steep slopes, use native woody plants planted in rows, cordons, or wattles.*

These species may be established more effectively than grass and are preferable for binding soils.

- *Seed during optimum periods for establishment, preferably just prior to fall rains (Larse, 1971).*

Timing will depend on the species to be planted and the schedule of operations, which determines when protection is needed (Hynson et al., 1982).

- *Mulch as needed to hold seed, retard rainfall impact, and preserve soil moisture (Larse, 1971).*

Critical, first-year mulch applications provide the necessary ground cover to curb erosion and aid plant establishment (Berglund, 1978). Many different kinds of mulches can be used to improve conditions for germination (Rothwell, 1978). Various materials, including straw, bark, and wood chips, can be used to temporarily stabilize fill slopes and other disturbed areas immediately after construction. In most cases, mulching is used in combination with seeding and planting to establish stable banks. Both the type and the amount of mulch applied vary considerably between regions and depend on the extent of the erosion potential and the available materials (Hynson et al., 1982). Figure 3-27 is a summary of mulching effectiveness in reducing erosion.

- *Fertilize according to site-specific conditions.*

Fertilization is often necessary for successful grass establishment because road construction commonly results in the removal or burial of fertile topsoil (Berglund, 1978). To determine fertilizer formulations, it is best to compare available nitrogen, phosphorus, potassium, and sulphur in the soils to be treated with the requirements of the species to be sown (Rothwell, 1978). It may be necessary to refertilize periodically after vegetation establishment to maintain growth and erosion control capabilities (Larse, 1971; Berglund, 1978).

■ *Protect seeded areas from grazing and vehicle damage until plants are well established.*

If the stand is over 60 percent damaged, reestablish it following the original specifications.

■ *Inspect all seeded areas for failures, and make necessary repairs and reseed within the planting season.*

■ *During non-growing seasons, apply interim surface stabilization methods to control surface erosion.*

Possible methods include mulching (without seeding) and installation of commercially produced matting and blankets. Alternative methods for planting and seeding include hand operations, the use of a wide variety of mechanical seeders, and hydroseeding (Hynson et al., 1982).

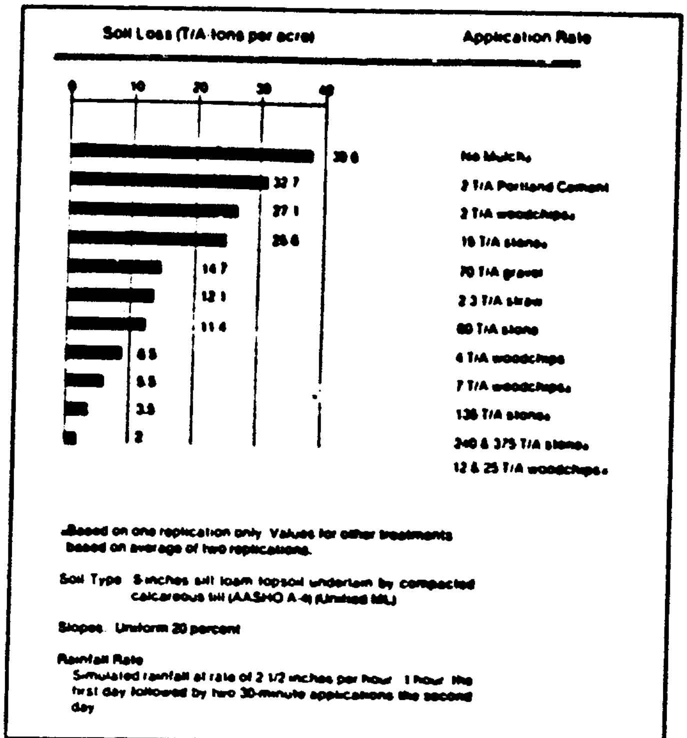

Figure 3-27. Soil losses from a 35-foot long slope by mulch type (Hynson et al., 1982).

Use chemicals when necessary for forest management in accordance with the following to reduce nonpoint source pollution impacts due to the movement of forest chemicals off-site during and after application:

(1) Conduct applications by skilled and, where required, licensed applicators according to the registered use, with special consideration given to impacts to nearby surface waters.
(2) Carefully prescribe the type and amount of pesticides appropriate for the insect, fungus, or herbaceous species.
(3) Prior to applications of pesticides and fertilizers, inspect the mixing and loading process and the calibration of equipment, and identify the appropriate weather conditions, the spray area, and buffer areas for surface waters.
(4) Establish and identify buffer areas for surface waters. (This is especially important for aerial applications.)
(5) Immediately report accidental spills of pesticides or fertilizers into surface waters to the appropriate State agency. Develop an effective spill contingency plan to contain spills.

1. Applicability

This management measure pertains to lands where silvicultural or forestry operations are planned or conducted. It is intended to apply to all fertilizer and pesticide applications (including biological agents) conducted as part of normal silvicultural activities.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Chemicals used in forest management are generally pesticides (insecticides, herbicides, and fungicides) and fertilizers. Since pesticides may be toxic, they must be mixed, transported, loaded, and applied properly and their containers disposed of properly in order to prevent potential nonpoint source pollution. Since fertilizers may also be toxic or may shift the ecosystem energy dynamics, depending on the exposure and concentration, they must also be properly handled and applied.

Pesticides and fertilizers are occasionally introduced into forests to reduce mortality of desired tree species, improve forest production, and favor particular plant species. Many forest stands or sites never receive chemical treatment, and of those that do receive treatment, typically no more than two or three applications are made during an entire tree rotation (40 to 120 years) (Megahan, 1980). Despite the low rate of applications in an area, pesticides can still accumulate within a watershed because there may be many forest sites that receive applications.

Although pesticides and fertilizers are used infrequently in forest operations, they can still pose a risk to the aquatic environment depending on the application technique used (Feller, 1989; Neary, 1985). These chemicals can directly enter surface waters through five major pathways: direct application, drift, mobilization in ephemeral streams, overland flow, and leaching. The input from direct application is the most important source of increased chemical concentrations and is also one of the most easily prevented.

Most adverse water quality effects related to the application of pesticides and fertilizers result from direct application of chemicals to surface waters or from chemical spills (Golden et al., 1984; Fredriksen et al., 1973; Norris and Moore, 1971). Hand application of herbicides generally poses little or no threat to water quality in areas where there is no potential for herbicides to wash into watercourses through gullies (Golden et al., 1984). Norris and Moore (1971) also found that providing buffer areas around streams and waterbodies effectively eliminated adverse water quality effects from forestry chemicals.

3. Management Measure Selection

This measure is based in part on information and experience gained from studies and from use of similar management practices by States. Information on the effects of various pesticide application and fertilization techniques on water quality are summarized in Tables 3-59 through 3-62. Many of the data presented are site-specific or lack clearly specified experimental conditions. However, general trends can be discerned among the studies, and general conclusions on the effectiveness of stream protection practices can be drawn.

a. Pesticide Effects

Most data show that the delivery of pesticides to surface waters from forestry operations is variable, depending on application technique, the presence or absence of buffers, and pesticide characteristics. The studies suggest that negative effects can be greatly reduced by taking precautions to avoid drift or direct application of chemicals to streams and other waterbodies. Norris and Moore (1971) noted that the concentration of 2,4-D in streams after aerial application was one to two orders of magnitude greater in forestry operations without buffers than in areas with buffers (Table 3-59). The elevated concentrations in the nonbuffered area returned to levels comparable to the buffered area after roughly 81 hours from the time of application. Fredriksen and others (1973) noted that in 8 years of monitoring Northwest forest streams for pesticide effects, no herbicide residues were detected in water column samples more than 1 month after aerial application. However, neither aquatic organisms nor sediments were sampled. Herbicide-induced changes in vegetation density and composition may cause indirect effects on streams such as increases in water temperature or nutrient concentration after desiccation of streamside vegetation. Use of unsprayed buffer strips should minimize these effects (Fredriksen et al., 1973).

Riekerk and others (1989) also found that the greatest risk to water quality from pesticide application in forestry operations occurs from aerial applications because of drift, wash-off, and erosion processes. As shown in Table 3-60, they found that aerial applications of herbicides resulted in a surface runoff concentration roughly 3.5 times greater than that of applications to the ground. They suggested that tree injection application methods would be considered the least hazardous for water pollution, but would also be the most labor-intensive.

Norris and others (1991) compiled information from multiple studies that evaluated the peak concentrations of herbicides, insecticides, and fertilizers in soils, lakes, and streams (Table 3-61). These studies were conducted from 1967 to 1987. Norris (1967) found that application of 2,4-D to marshy areas lead to higher-than-normal levels of stream contamination. When ephemeral streams were treated, residue levels of hexazinone and picloram greatly increased with storm-generated flow. Glyphosate was aerially applied (3.3 kg/hectare) to an 8-hectare forest ecosystem in the Oregon Coast Range. The study area contained two ponds and a small perennial stream. All were unbuffered and received direct application of the herbicide. Glyphosate residues were detected for 55 days after application with peak stream concentrations of 0.27 mg/L. It was demonstrated that the concentration of insecticides

Table 3-59. Concentrations of 2,4-D After Aerial Application in Two Treatment Areas (OR) (Norris and Moore, 1971)

Treatment Without Buffers		Treatment With Buffers	
Time After Spraying (hr)	2,4-D (mg/l)	Time After Spraying (hr)	2,4-D (mg/l)
4.7	0.085	5.4	0.001
6.0	0.010	8.7	0.001
7.0	0.026	84.5	0.003
8.0	0.075	168.0	0
9.0	0.059		
13.9	0.051		
26.9	0.003		
37.9	0.009		
78.0	0.008		
80.8	0.001		
168.0	0		

in streams was significantly greater when the chemicals were applied without a buffer strip to protect the watercourse. When streams were unbuffered, the peak concentrations of malathion ranged from 0.037-0.042 mg/L. However, when buffers were provided, the concentrations of malathion were reduced to levels that ranged from undetectable to 0.017 mg/L. The peak concentrations of carbaryl ranged from 0.000-0.0008 mg/L when watercourses were protected with a buffer, but increased to 0.016 mg/L when watercourses were unbuffered.

Another study concluded that the effects of a pellet formulation of picloram applied to an Appalachian mountain forest did not produce any adverse effect on water quality within the 2-year study period (Neary et al., 1985). Similar results were found for a study on the application of sulfometuron methyl in Coastal Plain flatwoods (Neary et al., 1989). These researchers concluded that chemical application should not pose a threat to water quality when chemicals are applied at rates established on the product label and well away from flowing streams.

b. Fertilizer Effects

Moore (1971), as cited in Norris et al. (1991), compared nitrogen loss from a watershed treated with 224 kg urea-N per hectare to nitrogen loss from an untreated watershed. The study demonstrated that the loss of nitrogen from the fertilized watershed was 28.02 kg per hectare while the loss of nitrogen from the unfertilized watershed was only 2.15 kg per hectare (Table 3-62).

Proportional loss				
Percent of total	2.44	0.85	96.71	100.00

the waterbody. The peak concentrations were directly proportional to the amount of open surface water within the treated areas, and increases resulted almost entirely from direct applications to surface water. Megahan (1980) summarized data from Moore (1975), who examined changes in water quality following the fertilization of various forest stands with urea. The major observations from this research are summarized as follows (Megahan, 1980):

- Increases in the concentration of urea-N ranged from very low to a maximum of 44 ppm, with the highest concentrations attributed to direct application to water surfaces.
- Higher concentrations occurred in areas where buffer strips were not left beside streambanks.
- Chemical concentrations of urea and its by-products tended to be relatively short-lived due to transport downstream, assimilation by aquatic organisms, or adsorption by stream sediments.

Based on his literature review, Megahan (1980) concluded that the impacts of fertilizer application in forested areas could be significantly reduced by avoiding application techniques that could result in direct deposition into the waterbody and by maintaining a buffer area along the streambank. Malueg and others (1972) and Hetherington (1985) also presented information in support of Megahan's conclusions.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ *For aerial spray applications maintain and mark a buffer area of at least 50 feet around all watercourses and waterbodies to avoid drift or accidental application of chemicals directly to surface water.*

A wider buffer may be needed for major streams and lakes and for application of pesticides with high toxicity to aquatic life. A 100-foot buffer should be used for aerial applications and a 25-foot buffer used for ground spray. Aerial application methods require careful and precise marking of application areas to avoid accidental contamination of open waters (Riekerk, 1989). For specific applications such as hypo hatchet or wick applicator, buffer area widths used for spray applications may be reduced.

■ *Apply pesticides and fertilizers during favorable atmospheric conditions.*

- Do not apply pesticides when wind conditions increase the likelihood of significant drift.
- Avoid pesticide application when temperatures are high or relative humidity is low because these conditions influence the rate of evaporation and enhance losses of volatile pesticides.

■ *Users must abide by the current pesticide label which may specify: whether users must be trained and certified in the proper use of the pesticide; allowable use rates; safe handling, storage, and disposal requirements; and whether the pesticide can only be used under the provision of an approved Pesticide State Management Plan, management measures and practices for pesticides should be consistent with and/or complement those in the approved Pesticide State Management Plans.*

■ *Locate mixing and loading areas, and clean all mixing and loading equipment thoroughly after each use, in a location where pesticide residues will not enter streams or other waterbodies.*

■ *Dispose of pesticide wastes and containers according to State and Federal laws.*

■ *Take precautions to prevent leaks and/or spills.*

■ *Develop a spill contingency plan that provides for immediate spill containment and cleanup, and notification of proper authorities.*

An adequate spill and cleaning kit that includes the following should be maintained:

- Detergent or soap;
- Hand cleaner and water;
- Activated charcoal, adsorptive clay, vermiculite, kitty litter, sawdust, or other adsorptive materials;
- Lime or bleach to neutralize pesticides in emergency situations;
- Tools such as a shovel, broom, and dustpan and containers for disposal; and
- Proper protective clothing.

■ *Apply slow-release fertilizers, when possible.*

This practice will reduce potential nutrient leaching to ground water, and it will increase the availability of nutrients for plant uptake.

■ *Apply fertilizers during maximum plant uptake periods to minimize leaching.*

■ *Base fertilizer type and application rate on soil and/or foliar analysis.*

To determine fertilizer formulations, it is best to compare available nitrogen, phosphorus, potassium, and sulphur in the soils to be treated with the requirements of the species to be sown (Rothwell, 1978).

■ *Consider the use of pesticides as part of an overall program to control pest problems.*

Integrated Pest Management (IPM) strategies have been developed to control forest pests without total reliance on chemical pesticides. The IPM approach uses all available techniques, including chemical and nonchemical. An extensive knowledge of both the pest and the ecology of the affected environment is required for IPM to be effective.

A more in-depth discussion of IPM strategies and components can be found in the Pesticide management measure section of the Agriculture chapter of this guidance.

Base selection of pesticide on site factors and pesticide characteristics.

These factors include vegetation height, target pest, adsorption to soil organic matter, persistence or half-life, toxicity, and type of formulation.

Check all application equipment carefully, particularly for leaking hoses and connections and plugged or worn nozzles. Calibrate spray equipment periodically to achieve uniform pesticide distribution and rate.

Always use pesticides in accordance with label instructions, and adhere to all Federal and State policies and regulations governing pesticide use.[2]

5. Relationship of Management Measure Components for Pesticides to Other Programs

Under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), EPA registers pesticides on the basis of evaluation of test data showing whether a pesticide has the potential to cause unreasonable adverse effects on humans, animals, or the environment. Data requirements include environmental fate data showing how the pesticide behaves in the environment, which are used to determine whether the pesticide poses a threat to ground water or surface water. If the pesticide is registered, EPA imposes enforceable label requirements, which can include, among other things, maximum rates of application, classification of the pesticide as a "restricted use" pesticide (which restricts use to certified applicators trained to handle toxic chemicals), or restrictions on use practices, including requiring compliance with EPA-approved Pesticide State Management Plans (described below). EPA and the U.S. Department of Agriculture Cooperative Extension Service provide assistance for pesticide applicator and certification training in each State.

FIFRA allows States to develop more stringent pesticide requirements than those required under FIFRA, and some States have chosen to do this. At a minimum, management measures and practices under State Coastal Nonpoint Source Programs must not be less stringent than FIFRA label requirements or any applicable State requirements.

EPA's *Pesticides and Groundwater Strategy* (USEPA, 1991) describes the policies and regulatory approaches EPA will use to protect the Nation's ground-water resources from risks of contamination by pesticides under FIFRA. The objective of the strategy is the prevention of ground-water contamination by regulating the use of certain pesticides (i.e., use according to EPA-approved labeling) in order to reduce and, if necessary, eliminate releases of the pesticide in areas vulnerable to contamination. Priority for protection will be based on currently used and reasonably expected sources of drinking water supplies, and ground water that is closely hydrogeologically connected to surface waters. EPA will use Maximum Contaminant Levels (MCLs) under the Safe Drinking Water Act as "reference points" for water resource protection efforts when the ground water in question is a current or reasonably expected source of drinking water.

The Strategy describes a significant new role for States in managing the use of pesticides to protect ground water from pesticides. In certain cases, when there is sufficient evidence that a particular use of a pesticide has the potential for ground-water contamination to the extent that it might cause unreasonable adverse effects, EPA may (through the use of existing statutory authority and regulations) limit legal use of the product to those States with an acceptable Pesticide State Management Plan, approved by EPA. Plans would tailor use to local hydrologic conditions and would address:

[2] The Federal Insecticide, Fungicide and Rodenticide Act governs the storage and application of pesticides.

- State philosophy,
- Roles and responsibilities of State and local agencies;
- Legal and enforcement authority;
- Basis for assessment and planning;
- Prevention measures;
- Ground-water monitoring;
- Response to detections;
- Information dissemination; and
- Public participation.

In the absence of such an approved Plan, affected pesticides could not be legally used in the State.

Since areas to be managed under Pesticide State Management Plans and Coastal Nonpoint Source Programs can overlap, State coastal zone and nonpoint source agencies should work with the State lead agency for pesticides (or the State agency that has a lead role in developing and implementing the Pesticide State Management Plan) in the development of pesticide management measure components and practices under both programs. This is necessary to avoid duplication of effort and conflicting pesticide requirements between programs. Further, ongoing coordination will be necessary since both programs and management measures will evolve and change with increasing technology and data.

[illegible]

Plan, operate, and manage normal, ongoing forestry activities (including harvesting, road design and construction, site preparation and regeneration, and chemical management) to adequately protect the aquatic functions of forested wetlands.

1. Applicability

This management measure is intended for forested wetlands where silvicultural or forestry operations are planned or conducted. It is intended to apply specifically to forest management activities in forested wetlands and to supplement the previous management measures by addressing the operational circumstances and management practices appropriate for forested wetlands. Chapter 7 provides additional information on wetlands and wetland management measures for other, nonforestry source categories and activities.

Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of this management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

This management measure applies specifically to forest management activities in forested wetlands, including those currently undertaken under the exemptions of section 404(f) (40 CFR, Part 232). Many normal, ongoing forestry activities are exempt under section 404(f)(1) unless recaptured under the provisions of section 404(f)(2). This management measure is not intended to prohibit these silvicultural activities but to reduce incidental or indirect effects on aquatic functions as a result of these activities. Chapter 7 provides additional information on wetlands and wetland management measures for other, nonforestry source categories and activities.

2. Description

Forested wetlands provide many beneficial functions that need to be protected. Among these are floodflow alteration, sediment trapping, nutrient retention and removal, provision of important habitat for fish and wildlife, and provision of timber products (Clairain and Kleiss, 1989). The extent of palustrine (forested) wetlands in the continental United States has declined greatly in the past 40 years due to conversion to other land uses, with a net annual loss of 300,000 acres occurring between 1950 and 1970 (Frayer et al., 1983). Forested wetland productivity is dependent upon hydrologic conditions and nutrient cycling, and alteration of a wetland's hydrologic or nutrient-cycling processes can adversely affect wetland functions (Conner and Day, 1989). Refer to Chapter 7 for a wetland definition and a more complete description of the values and functions of wetlands.

The primary difference between forestry activities on wetland sites as compared to activities on upland sites is the result of flooding that occurs in most wetlands during some or most of the year. Potential impacts of forestry operations in wetlands include:

- Sediment production as a result of road construction and use and equipment operation;

VOL 12

9534

R0042840

- Drainage alteration as a result of improper road construction;
- Stream obstruction caused by failure to remove logging debris;
- Soil compaction caused by operation of logging vehicles during flooding periods or wet weather (skid trails, haul roads, and log landings are areas where compaction is most severe); and
- Contamination from improper application and/or use of pesticides.

The primary adverse impacts associated with road construction in forested wetlands are alteration of drainage and flow patterns, increased erosion and sedimentation, habitat degradation, and damage to existing timber stands. In an effort to prevent these adverse effects, section 404 of the Federal Water Pollution Control Act requires usage of appropriate BMPs for road construction and maintenance in wetlands so that flow and circulation patterns and chemical and biological characteristics are not impaired. Additional section 404(f) BMPs specific to forestry can be found at 40 CFR 232.3.

Harvest planning and selection of the right harvest system are essential in achieving the management objectives of timber production, ensuring stand establishment, and avoiding adverse impacts to water quality and wetland habitat. The potential impacts of reproduction methods and cutting practices on wetlands include changes in water quality, temperature, nutrient cycling, and aquatic habitat (Toliver and Jackson, 1989). Streams can also become blocked with logging debris if SMAs are not properly maintained or if appropriate practices are not employed in SMAs.

Site preparation includes but is not limited to the use of prescribed fire, chemical, or mechanical site preparation. Extensive site preparation on bottoms where frequent flooding occurs can cause excessive erosion and stream siltation. The degree of acceptable site preparation is governed by the amount and frequency of flooding, soil type, and species suitability, and is dependent upon the regeneration method used.

Clean Water Act section 404 establishes a permit program that regulates the discharge of dredged or fill material into waters of the United States, including certain forested areas that meet the criteria for wetlands. Section 404(f)(1) of the Act provides an exemption from the permitting requirement for discharges in waters of the United States associated with normal, ongoing silviculture operations, including such practices as placement of bedding, cultivation, seeding, timber harvesting, and minor drainage. Section 404(f)(2) clarifies that discharges associated with silviculture activities identified at 404(f)(1) as exempt, are not eligible for the exemption if the proposed discharge involves toxic materials or if they would have the effect of converting waters of the United States, including wetlands, to dry land. Regulations implementing section 404(f), as well as describing applicable best management practices for avoiding impairment of the physical, chemical, and biological characteristics of the waters of the United States, were promulgated by EPA at 40 CFR Part 232.

3. Management Measure Selection

Mader and others (1989) assessed the relative impacts of various timber harvesting methods on different parameters in a forested wetland. On-site ecological responses on a clearcut site following timber harvesting with helicopter and rubber-tired skidder systems were compared to a clearcut, harvested, herbicide-treated area and an undisturbed stand in southwest Alabama. They found total nitrogen concentrations in soil water to be significantly lower for the skidder treatment when compared with all other treatments (Table 3-63). Total phosphorus concentrations were also significantly different for the helicopter treatment as compared to the control stand. Sediment accumulation was greatest for the helicopter treatment and least for the herbicide treatment, and all differences between treatments were significant.

Table 3-63. Total Nitrogen and Phosphorus Concentrations in Soil Water, and Sedimentation During Wet Season Flooding[a] (Mader et al., 1989)

Treatment	n[b]	Nutrient Concentration (parts per million)		n	Sediment Accumulation (millimeters)
		TN[c]	TP[d]		
Herbicide	36	11.1 (2.1)	9.8 (2.6)	81	0.7 (0.3)
Skidder	36	7.4 (1.0)	10.1 (2.1)	81	1.2 (0.5)
Helicopter	36	10.6 (1.4)	11.4 (2.0)	81	2.2 (0.6)
Undisturbed	36	11.0 (1.6)	8.8 (2.0)	81	1.1 (0.1)

[a] Values are treatment means (±SE) of nine replications.
[b] n = Number of samples.
[c] TN = Total nitrogen in soil water.
[d] TP = Total phosphorus in soil water.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as apractical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Road Design and Construction Practices

■ *Locate and construct forest roads according to preharvest planning.*

Improperly constructed and located forest roads may cause changes in hydrology, accelerate erosion, reduce or degrade fisheries habitat, and destroy or damage existing stands of timber.

■ *Utilize temporary roads in forested wetlands.*

Permanent roads should be constructed only to serve large and frequently used areas, as approaches to watercourse crossings, or as access for fire protection. Use the minimum design standard necessary for reasonable safety and the anticipated traffic volume.

■ *Construct fill roads only when absolutely necessary for access since fill roads have the potential to restrict natural flow patterns.*

Where construction of fill roads is necessary, use a permeable fill material (such as gravel or crushed rock) for at least the first layer of fill. The use of pervious materials maintains the natural flow regimes of subsurface water. Figures 3-28 and 3-29 demonstrate the impact of impervious and pervious road fills on wetland hydrology. Permeable fill material is not a substitute for using bridges where needed, or for installation of adequately spaced culverts present at all natural drainageways. This practice should be used in conjunction with cross drainage structures to ensure that natural wetland flows are maintained (i.e., so that fill does not become clogged by sediment and obstruct flows (Hynson et al., 1982).

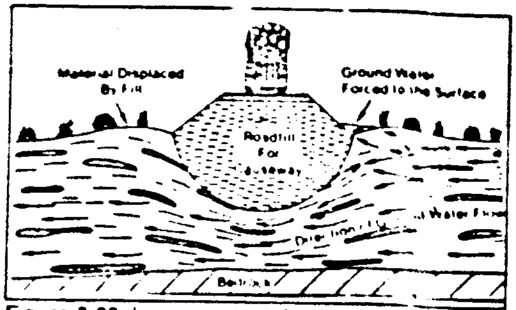

Figure 3-28. Impervious roadfill section placed on wetlands consisting of soft organic sediments with sand lenses. The natural material consolidates and restricts ground-water flow (Hynson et al., 1982).

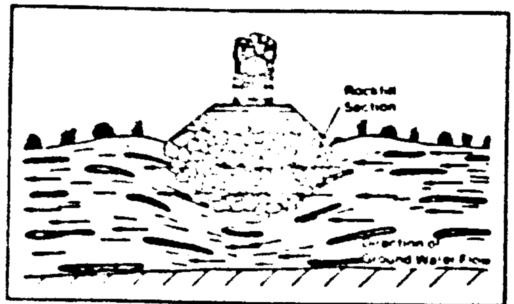

Figure 3-29. Pervious roadfill section on wetland allows movement of ground water through it and minimizes flow changes (Hynson et al., 1982).

■ *Provide adequate cross drainage to maintain the natural surface and subsurface flow of the wetland.*

This can be accomplished through adequate sizing and spacing of water crossing structures, proper choice of the type of crossing structure, and installation of drainage structures at a depth adequate to pass subsurface flow. Bridges, culverts, and other structures should not perceptibly diminish or increase the duration, direction, or magnitude of minimum, peak, or mean flow of water on either side of the structure (Hynson et al., 1982).

■ *Construct roads at natural ground level to minimize the potential to restrict flowing water.*

Float the access road fill on the natural root mat. If the consequences of the natural root mat failing are serious, use reinforcement materials such as geotextile fabric, geo-grid mats, or log corduroy. Figure 3-30 depicts a cross section

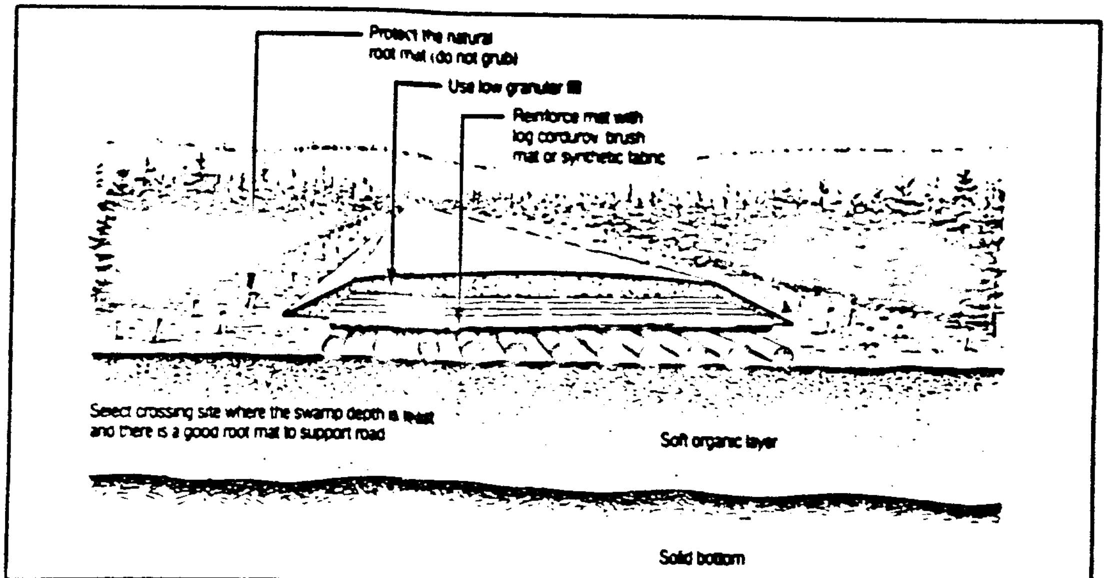

Figure 3-30. Cross section of a wetland road (Ontario Ministry of Natural Resources, 1988).

VOL 12

9537

of the "floating the road" practice. Protect the root mat beneath the roadway from equipment damage. This can be facilitated by diverting through traffic to the edge of the right-of-way, shear-blading stumps instead of grubbing, and using special wide-pad equipment. Also, protect the root mat from damage or puncture by using fill material that does not contain large rocks or boulders.

b. Harvesting Practices

■ *Conduct forest harvesting according to preharvest planning designs and locations.*

Planning and close supervision of harvesting operations are needed to protect site integrity and enhance regeneration. Harvesting without regard to season, soil type, or type of equipment can damage the site productivity; retard regeneration; cause excessive rutting, churning, and puddling of saturated soils; and increase erosion and siltation of streams.

■ *Establish a streamside management area adjacent to natural perennial streams, lakes, ponds, and other standing water in the forested wetland following the components of the SMA management measure.*

■ *Ensure that planned harvest activities or chemical use do not contribute to problems of cumulative effects in watersheds of concern.*

■ *Select the harvesting method to minimize soil disturbance and hydrologic impacts to the wetland.*

In seasonally flooded wetlands, a guideline is to use conventional skidder logging that employs equipment with low-ground-pressure tires, cable logging, or aerial logging (Doolittle, 1990). Willingham (1989) compared cable logging to helicopter logging and concluded that helicopter operations caused less site disturbance, were more economical, and provided greater yield. Table 3-64 depicts harvesting systems recommended by the Florida Division of Forestry by type of forested wetland. These recommendations are based on both water quality and economic considerations. Another alternative is to conduct harvesting during winter months when the ground is frozen.

■ *When groundskidding, use low-ground-pressure tires or tracked machines and concentrate skidding to a few primary skid trails to minimize site disturbance, soil compaction, and rutting.*

■ *When soils become saturated, suspend groundskidding harvesting operations. Use of groundskidding equipment during excessively wet periods may result in unnecessary site disturbance and equipment damage.*

c. Site Preparation and Regeneration Practices

■ *Select a regeneration method that meets the site characteristics and management objectives.*

Choice of regeneration method has a major influence on the stand composition and structure and on the silvicultural practices that will be applied over the life of the stand (Toliver and Jackson, 1989). Natural regeneration may be achieved by clearcutting the existing stand and relying on regeneration from seed from adjacent stands, the cut trees, or stumps and from root sprouts (coppice). Successful regeneration depends on recognizing the site type and its characteristics; evaluating the stocking and species composition in relation to stand age and site capability; planning regeneration options; and using sound harvesting methods. Schedule harvest during the dormant season to take advantage of seed sources and to favor coppice regeneration. Harvest trees at a stump height of 12 inches or less when practical to encourage vigorous coppice regeneration. Artificial regeneration may be accomplished by planting seedlings or direct seeding. Table 3-65 contains the regeneration system recommendations of the Georgia Forestry Association.

Table 3-64. Recommended Harvesting Systems by Forested Wetland Site[a]
(Florida Department of Agriculture and Consumer Services, 1988)

Site Type	Conventional	Conventional with Controlled Access[b]	Cable or Aerial	Barge or High Flotation Boom
Flowing Water				
Mineral Soil				
Alluvial River Bottom	B	A	C	C
Organic Soil				
Black River Bottom	B	A	C	C
Branch Bottom	A[c]	B	C	C
Cypress Strand	B	A	A	A
Muck Swamp	C	A	A	A
Nonflowing Water				
Mineral Soil				
Wet Hammock	B	A	C	C
Organic Soil				
Cypress Dome	B	A	A	A
Peat Swamp	C	A	A	A

A = recommended; B = recommended when dry; C = not recommended.
[a] Recommendations include cost considerations.
[b] Preplanned and designated skid trails and access roads.
[c] Log from the hill (high ground).

Conduct mechanized site preparation and planting sloping areas on the contour.

To reduce disturbance, conduct bedding operations in high-water-table areas during dry periods of the year.

The degree of acceptable site preparation depends on the amount and frequency of flooding, the soil type, and the species suitability.

Minimize soil degradation by limiting operations on saturated soils.

d. Chemical Management Practices

Apply herbicides by injection or application in pellet form to individual stems.

For chemical and aerial fertilizer applications, maintain and mark a buffer area of at least 50 feet around all surface water to avoid drift or accidental direct application.

Avoid application of pesticides with high toxicity to aquatic life, especially aerial applications.

Table 3-65. Recommended Regeneration Systems by Forested Wetland Type (Georgia Forestry Association, 1990)

Type	Natural Regeneration				Artificial Regeneration		
	Clearcut	Group Selection	Shelter Wood	Seed[a] Tree	Mechanical Site Prep.	Plant	Direct Seed
Flood Plains, Terraces, Bottomland							
Black River	A	B	B	C	D	C	C
Red River	A	B	B	C	D	B	B
Branch Bottoms	A	B	B	C	D	C	C
Piedmont Bottoms	A	B	B	C	D	B	B
Muck Swamps	A	C	C	C	D	C	C
Wet Flats							
Pine Hammocks & Savannahs	A	B	B	B	A	A	B
Pocosins or Bays	A	C	B	B	B	B	B
Cypress Strands	A	C	C	C	D	C	C
Cypress Domes: Peat Swamps							
Peat Swamps	A	C	C	C	C	C	C
Cypress Domes	A	C	C	C	D	C	C
Gulfs, Coves, Lower Slopes	A	B	B	C	C	B	C

A = highly effective; B = effective; C = less effective; D = not recommended.
[a] Seed tree cuts are not recommended on first terraces of flood plains, terraces, and bottomland.

■ ***Apply slow-release fertilizers, when possible.***

This practice will reduce the potential of the nutrients leaching to ground water, and it will increase the availability of nutrients for plant uptake.

■ ***Apply fertilizers during maximum plant uptake periods to minimize leaching.***

■ ***Base fertilizer type and application rate on soil and/or foliar analysis.***

To determine fertilizer formulations, it is best to compare available nitrogen, phosphorus, potassium, and sulphur in the soils to be treated with the requirements of the species to be sown.

III. GLOSSARY

Access road: A temporary or permanent road over which timber is transported from a loading site to a public road. Also known as a haul road.

Alignment: The horizontal route or direction of an access road.

Allochthonous: Derived from outside a system, such as leaves of terrestrial plants that fall into a stream.

Angle of repose: The maximum slope or angle at which a material, such as soil or loose rock, remains stable (stable angle).

Apron: Erosion protection placed below the streambed in an area of high flow velocity, such as downstream from a culvert.

Autochthonous: Derived from within a system, such as organic matter in a stream resulting from photosynthesis by aquatic plants.

Bedding: A site preparation technique whereby a small ridge of surface soil is formed to provide an elevated planting or seed bed. It is used primarily in wet areas to improve drainage and aeration for seeding.

Berm: A low earth fill constructed in the path of flowing water to divert its direction, or constructed to act as a counterweight beside the road fill to reduce the risk of foundation failure (buttress).

Borrow pit: An excavation site outside the limits of construction that provides necessary material, such as fill material for embankments.

Broad-based dip: A surface drainage structure specifically designed to drain water from an access road while vehicles maintain normal travel speeds.

Brush barrier: A sediment control structure created of slash materials piled at the toe slope of a road or at the outlets of culverts, turnouts, dips, and water bars.

Buck: To saw felled trees into predetermined lengths.

Buffer area: A designated area around a stream or waterbody of sufficient width to minimize entrance of forestry chemicals (fertilizers, pesticides, and fire retardants) into the waterbody.

Cable logging: A system of transporting logs from stump to landing by means of steel cables and winch. This method is usually preferred on steep slopes, wet areas, and erodible soils where tractor logging cannot be carried out effectively.

Check dam: A small dam constructed in a gully to decrease the flow velocity, minimize channel scour, and promote deposition of sediment.

Chopping: A mechanical treatment whereby vegetation is concentrated near the ground and incorporated into the soil to facilitate burning or seedling establishment.

Clearcutting: A silvicultural system in which all merchantable trees are harvested within a specified area in one operation to create an even-aged stand.

Contour: An imaginary line on the surface of the earth connecting points of the same elevation. A line drawn on a map connecting the points of the same elevation.

Crown: A convex road surface that allows runoff to drain to either side of the road prism.

Culvert: A metal, wooden, plastic, or concrete conduit through which surface water can flow under or across roads.

Cumulative effect: The impact on the environment that results from the incremental impact of an action when added to other past, present, and reasonably foreseeable future actions regardless of what agency or person undertakes such action.

Cut-and-fill: Earth-moving process that entails excavating part of an area and using the excavated material for adjacent embankments or fill areas.

DBH: Diameter at breast height; the average diameter (outside the bark) of a tree 4.5 feet above mean ground level.

Disking (harrowing): A mechanical method of scarifying the soil to reduce competing vegetation and to prepare a site to be seeded or planted.

Diversion: A channel with a supporting ridge on the lower side constructed across or at the bottom of a slope for the purpose of intercepting surface runoff.

Drainage structure: Any device or land form constructed to intercept and/or aid surface water drainage.

Duff: The accumulation of needles, leaves, and decaying matter on the forest floor.

Ephemeral stream: A channel that carries water only during and immediately following rainstorms. Sometimes referred to as a dry wash.

Felling: The process of cutting down standing trees.

Fill slope: The surface formed where earth is deposited to build a road or trail.

Firebreak: Naturally occurring or man-made barrier to the spread of fire.

Fireline: A barrier used to stop the spread of fire constructed by removing fuel or rendering fuel inflammable by use of fire retardants.

Ford: Submerged stream crossing where tread is reinforced to bear intended traffic.

Forest filter strip: Area between a stream and construction activities that achieves sediment control by using the natural filtering capabilities of the forest floor and litter.

Forwarding: The operation of moving timber products from the stump to a landing for further transport.

Geotextile: A product used as a soil reinforcement agent and as a filter medium. It is made of synthetic fibers manufactured in a woven or loose nonwoven manner to form a blanket-like product.

Grade (gradient): The slope of a road or trail expressed as a percentage of change in elevation per unit of distance traveled.

Harvesting: The felling, skidding, processing, loading, and transporting of forest products.

Haul road: See *access road*.

Intermittent stream: A watercourse that flows in a well-defined channel only in direct response to a precipitation event. It is dry for a large part of the year.

Landing (log deck): A place in or near the forest where logs are gathered for further processing or transport.

Leaching: Downward movement of a soluble material through the soil as a result of water movement.

Logging debris (slash): The unwanted, unutilized, and generally unmerchantable accumulation of woody material, such as large limbs, tops, cull logs, and stumps, that remains as forest residue after timber harvesting.

Merchantable: Forest products suitable for marketing under local economic conditions. With respect to a single tree, it means the parts of the bole or stem suitable for sale.

Mineral soil: Organic-free soil that contains rock less than 2 inches in maximum dimension.

Mulch: A natural or artificial layer of plant residue or other materials covering the land surface that conserves moisture, holds soil in place, aids in establishing plant cover, and minimizes temperature fluctuations.

Mulching: Providing any loose covering for exposed forest soils, such as grass, straw, bark, or wood fibers, to help control erosion and protect exposed soil.

Muskeg: A type of bog that has developed over thousands of years in depressions, on flat areas, and on gentle to steep slopes. These bogs have poorly drained, acidic, organic soils supporting vegetation that can be (1) predominantly sphagnum moss; (2) herbaceous plants, sedges, and rushes; (3) predominantly sedges and rushes; or (4) a combination of sphagnum moss and herbaceous plants. These bogs may have some shrub and stunted conifers, but not enough to classify them as forested lands.

Ordinary high water mark: An elevation that marks the boundary of a lake, marsh, or streambed. It is the highest level at which the water has remained long enough to leave its mark on the landscape. Typically, it is the point where the natural vegetation changes from predominantly aquatic to predominantly terrestrial.

Organic debris: Particles of vegetation or other biological material that can degrade water quality by decreasing dissolved oxygen and by releasing organic solutes during leaching.

Outslope: To shape the road surface to cause drainage to flow toward the outside shoulder.

Patch cutting method: A silvicultural system in which all merchantable trees are harvested over a specified area at one time.

Perennial stream: A watercourse that flows throughout a majority of the year in a well-defined channel.

Persistence: The relative ability of a pesticide to remain active over a period of time.

Pioneer roads: Temporary access ways used to facilitate construction equipment access when building permanent roads.

Prescribed burning: Skillful application of fire to natural fuels that allows confinement of the fire to a predetermined area and at the same time produces certain planned benefits.

Raking: A mechanical method of removing stumps, roots, and slash from a future planting site.

Regeneration: The process of replacing older trees removed by harvest or disaster with young trees.

Residual trees: Live trees left standing after the completion of harvesting.

Right-of-way: The cleared area along the road alignment that contains the roadbed, ditches, road slopes, and back slopes.

Riprap: Rock or other large aggregate that is placed to protect streambanks, bridge abutments, or other erodible sites from runoff or wave action.

Rut: A depression in access roads made by continuous passage of logging vehicles.

Salvage harvest: Removal of trees that are dead, damaged, or imminently threatened with death or damage in order to use the wood before it is rendered valueless by natural decay agents.

Sanitation harvest: Removal of trees that are under attack by or highly susceptible to insect and disease agents in order to check the spread of such agents.

Scarification: The process of removing the forest floor or mixing it with the mineral soil by mechanical action preparatory to natural or direct seeding or the planting of tree seedlings.

Scour: Soil erosion when it occurs underwater, as in the case of a streambed.

Seed bed: The soil prepared by natural or artificial means to promote the germination of seeds and the growth of seedlings.

Seed tree method: Removal of the mature timber in one cutting, except for a limited number of seed trees left singly or in small groups.

Selection method: An uneven-aged silvicultural system in which mature trees are removed, individually or in small groups, from a given tract of forestland over regular intervals of time.

Shearing: A site preparation method that involves the cutting of brush, trees, or other vegetation at ground level using tractors equipped with angles or V-shaped cutting blades.

Shelterwood method: Removal of the mature timber in a series of cuttings that extend over a relatively short portion of the rotation in order to encourage the establishment of essentially even-aged reproduction under the partial shelter of seed trees.

Silt fence: A temporary barrier used to intercept sediment-laden runoff from small areas.

Silvicultural system: A process, following accepted silvicultural principles, whereby the tree species constituting forests are tended, harvested, and replaced. Usually defined by, but not limited to, the method of regeneration.

Site preparation: A silvicultural activity to remove unwanted vegetation and other material, and to cultivate or prepare the soil for regeneration.

Skid: Short-distance moving of logs or felled trees from the stump to a point of loading.

Skid trail: A temporary, nonstructural pathway over forest soil used to drag felled trees or logs to the landing.

Slash: See *logging debris*.

Slope: Degree of deviation of a surface from the horizontal, measured as a numerical ratio, as a percent, or in degrees. Expressed as a ratio, the first number is the horizontal distance (run) and the second number is the vertical distance (rise), as 2:1. A 2:1 slope is a 50 percent slope. Expressed in degrees, the slope is the angle from the horizontal plane, with a 90 degree slope being vertical (maximum) and a 45 degree slope being a 1:1 slope

Stand: A contiguous group of trees sufficiently uniform in species composition, arrangement of age classes, and condition to be a homogeneous and distinguishable unit.

Streamside management area (SMA): A designated area that consists of the stream itself and an adjacent area of varying width where management practices that might affect water quality, fish, or other aquatic resources are modified. The SMA is not an area of exclusion, but an area of closely managed activity. It is an area that acts as an effective filter and absorptive zone for sediments; maintains shade; protects aquatic and terrestrial riparian habitats; protects channels and streambanks; and promotes floodplain stability.

Tread: Load-bearing surface of a trail or road.

Turnout: A drainage ditch that drains water away from roads and road ditches.

Water bar: A diversion ditch and/or hump installed across a trail or road to divert runoff from the surface before the flow gains enough volume and velocity to cause soil movement and erosion, and deposit the runoff into a dispersion area. Water bars are most frequently used on retired roads, trails, and landings.

Watercourse: A definite channel with bed and banks within which concentrated water flows continuously, frequently or infrequently.

Windrow: Logging debris and unmerchantable woody vegetation that has been piled in rows to decompose or to be burned; or the act of constructing these piles.

Yarding: Method of transport from harvest area to storage landing.

Examples of State Processes Useful for Ensuring Implementation of Management Measures

3A-1: Examples from Florida

SRWMD PERMIT NUMBER ________
APPLICATION FOR AGRICULTURE OR FORESTRY
GENERAL SURFACEWATER MANAGEMENT PERMIT
FORM 40B-4-1

SUWANNEE RIVER WATER MANAGEMENT DISTRICT
ROUTE 3, BOX 64
LIVE OAK, FLORIDA 32060
TELEPHONE (904) 362-1001

Landowner/Applicant: ________

Address: ________
Street - Route - Box City State Zip Code

Person Responsible: ________

Phone: ________ Beginning Date: ________

Project Location: ________ Location Sketch:
County

____
Township Range Section

____
Parcel ID Number (from County records)

Project Area: ____ Acres owned or in management block

____ Acres in project area (aerial photograph copy with project area outlined is suggested.)

Wetlands Area: ____ Wetland acres in project area

____ Wetland acres affected by the work

Description of the proposed work to include sizes and dimensions: ________

____

____

____

THE GENERAL SURFACEWATER MANAGEMENT PERMIT AUTHORIZED BY SS.40B-4.2010(1), FLORIDA ADMINISTRATIVE CODE (F.A.C.), REQUIRES PERMITTEES TO COMPLY WITH BEST MANAGEMENT AND ACCEPTED CONSERVATION PRACTICES. ADDITIONAL LIMITATIONS AND/OR STANDARDS ARE CONTAINED IN SS.40B-4.2010(1)(C)1. THROUGH 6. A COPY OF CHAPTER 40B-4, F.A.C., AND BEST MANAGEMENT PRACTICES MANUALS ARE AVAILABLE AT NO CHARGE FROM THE DISTRICT, OR QUESTIONS MAY BE DIRECTED TO THE SUWANNEE RIVER WATER MANAGEMENT DISTRICT AT 904/362-1001 OR 1-800-342-1002. A DISTRICT PERMIT DOES NOT RELIEVE A PERMITTEE FROM OBTAINING APPROVALS THAT MAY BE REQUIRED BY ANY UNIT OF LOCAL, STATE, OR FEDERAL GOVERNMENT.

THIS APPLICATION IS NOT TO BE USED FOR SUBDIVISIONS, COMMERCIAL PROJECTS, OR ANY OTHER NON-AGRICULTURAL OR FORESTRY WORK.

Authorization No. ______________________

NORTHWEST FLORIDA WATER MANAGEMENT DISTRICT

FORESTRY AUTHORIZATION NOTIFICATION FORM

Instructions:

1. Deliver or mail to the appropriate District Office identified on the attached sheet at least two (2) working days before commencing activity.
2. Emergency authorizations may be requested by calling the appropriate District Office.
3. See attached sheet for list of qualifying projects, limiting conditions, and District Offices.

Application is for: ☐ Construction ☐ Replacement ☐ Maintenance

Owner's Name: ______________________ Phone: ______________

Address: ____

City: ______________________ State: ____________ Zip: ____________

Agent's Name: ______________________ Phone: ______________

Address: ____

City: ______________________ State: ____________ Zip: ____________

Only the minor works listed in Section 40A-44.052(1), F.A.C. (see attached sheet), may qualify for an authorization. After reviewing the attached list, which letter identifies the minor work you propose? Please circle the appropriate one(s):

A B C D E F

Detailed description of the proposed work, include water quality protection and site stabilization methods: ______________

____

____

Starting Date: ______________

Location of Proposed Work:

County: ______________

Section: ______________

Township: ______________

Range: ______________

Water Body Affected:

____

Location Sketch

A copy of Chapter 40A-44, F.A.C., is available at any District office. A District authorization does not relieve a permittee from obtaining the necessary approvals of any local, state, or federal government.

I have read and will comply with the requirements of Section 40A-44.052, F.A.C. I understand that this Forestry Authorization Notice is available only under limited circumstances as set forth in Section 40A-44.052, F.A.C., and that permittees are required to comply with all limiting conditions listed in Section 40A-44.052, F.A.C.

INSTRUCTIONS FOR FILLING OUT "NOTIFICATION OF OPERATION / APPLICATION FOR PERMITS"

The instructions are numbered to match the numbered form areas. Please print or type the information on the form. Do not fill out any space shaded gray. File notice with the State Forester at least 15 days prior to the date you would like to start operating. A notification is not considered accepted until it is received by the appropriate office. Mail or deliver the form to one of the following offices

Office Address	Phone Number	Office Address	Phone Number
ASTORIA Rt 1 Box 950 97103	325-5451	MOLALLA 14995 S Hwy 211 97038	829-2216

SIDE ONE - Notification of Operation/Application for Permits

1. "County (Enter only one)". Fill in the county where the operation will take place. If an operation spans two or more counties, file a separate notification for each county.

An operation can be any combination of the following activities: harvest of forest crops, road construction or reconstruction; site preparation, chemical application, clearing for land use change, treatment of slashing, pre-commercial thinning; or other activities which require separate explanation.

2. "Check Appropriate Boxes (2A, 2B, 2C, or 2D)" next to the notice you are giving and/or the permit(s) you need.

3. "Person to be contacted in case of Fire Emergency (Designated Representative). Phone No." Print the name and telephone number of the person to contact in case a fire starts on the operation. This person should know what resources you have available to fight the fire, and have the authority to commit those resources in case of a fire.

"Check one box in the left column to indicate who filled out the application."

4. "Operator Information" 5. "Landowner Information" 6. "Timberowner and Harvest Tax Payer." You must fill in either a person's or a company's name, address and phone number. Fill in EITHER the timberowner's Employer Identification number or the timberowner's social security number, not both. The person who owns timber at the time of severance from the stump (harvest) is the timberowner, and is responsible for paying the harvest tax.

7. "Timber Sale Name and/or No." Fill in the sale name and/or number. This information is required for all state and federal timber sales and is optional for private land timber sales.

8. "Western Oregon Private Land Only!" If the timber to be harvested is from public land, do not fill out this portion! If it is from private land, check with the landowner to see whether the timber has been certified under the Western Oregon Small Tract Optional Tax (WOSTOT) law. Timber removed from land certified under WOSTOT is normally exempt from the Western Oregon Severance Tax. If you have checked "Part" or "All", please list the certificate number in the WOSTOT Certificate Number box.

SIDE TWO - Site Information

9. "Activity Codes". There are six columns here. You assign a one- or two-digit unit number, beginning with 1 and going sequentially up to 99. Or, if there is a unit number associated with a state or federal timber sale, use that number in the unit column. A unit can be:

- an operating area with a state or federal sale unit number; or
- a single operating area within a continuous boundary; or
- an operating area with a separate harvest tax number; or
- a separate area within your total operation area on which you plan to conduct a single type of activity (for example, 30 acres of clear cut only).

FORM 629-0-0-1-0000 (Rev. 11/91)

VOL 12

9562

R0042868

In all cases, all activities you plan on that piece of land should be listed under the unit number. For example, road construction activity needed prior to starting a commercial timber harvest should be described under the unit number along with the harvesting activity. If there will be more activities happening in the unit than you can fit on one line straight across, continue on the lines below. Leave a blank under the unit number. See the example below.

Activity Code. Write the codes for all activities taking place in one unit under this heading. Use the numbers, code names and associated methods shown below.

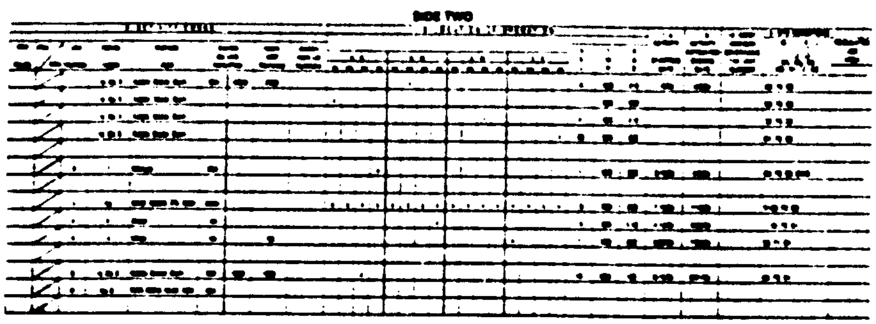
Activity Code	Methods Used	Activity Code	Methods Used
1a. Partial Cut (Partial Cut code must not be used for a pre-commercial thinning operation.)	Cable/Ground/Other	4a. Herbicide Application	Ground/Aerial/Name/Rate/Carrier
1b. Clear Cut	Cable/Ground/Other	4b. Insecticide Application	Ground/Aerial/Name/Rate/Carrier
1c. Cutting only		4c. Rodenticide Application	Ground/Aerial/Name/Rate/Carrier
2a. Road Construction	Dozer/Backhoe/Other	4d. Fertilizer Application	Ground/Aerial/Name/Rate/Carrier
2b. Road Reconstruction	Dozer/Backhoe/Other	5. Clearing for Land Use Change (Local land use rules may apply.)	
3. Site Preparation	Manual/Mechanical/Burning	6. Treatment of Slashing	Burning, Mechanical
		7. Pre-Commercial Thinning	Manual/Chemical
		8. Others	Explain

Write the methods you will use in the "Methods Used" column next to the code for the activity, in the same order as the activity codes are listed. If you need more space, go to the next row down in the same column. Write in the name of the spray product. In Applicant Remarks column list the carrier and rate of application. See the example below.

Quantity Column. Fill in either the acres (A) or lineal feet (F) involved in the activity. The example shows 86 acres of harvest and 3000 ft. of road construction.

Approximate Thousand Board Feet (MBF) Removed. List the approximate MBF to be removed for each unit with commercial timber harvesting.

Government Lot Numbers. List the government lot numbers for each unit. (Not tax lot numbers.)



10. "Location of Operation" (Legal Descriptions). Enter the legal descriptions for each unit number. If you have several rows worth of activities that will take place at one location, REPEAT THE CODES, not the legal descriptions.

11. a. & 11. b. "Activity Starting and Activity Estimated Ending Date". The starting date should be at least 15 days after the date the form is received by the appropriate Department office.

12. "Western Oregon Severance Tax Unit Number". Large landowners will have a list of harvest tax numbers which apply to the site(s).

13. "Site Conditions". Fill in a D, T, and S code for each unit, as shown in the example. Fill in DWS, WG or SW codes when necessary.

D = Distance to Class 1 waters. A Class 1 water is "any portions of streams, lakes, estuaries, significant wetlands, or other waters of the state which are significant for (a) domestic use, including drinking, culinary and other household human use; (b) angling; (c) water dependent recreation; or (d) spawning, rearing or migration of anadromous or game fish."

- D100 = Class 1 waters are within 100 feet of the operation.
- D1 = Class 1 waters are within ¼ mile but greater than 100 feet from the operation.
- D2 = Class 1 waters are within ¼-½ mile of the operation.
- D3 = None within ½ mile.

T = Topography

- T1 is a slope of 0 to 35% (percent)
- T2 is a slope of 35% to 60%
- T3 is a slope greater than 60%

S = Slope Stability

- S1 = No evidence of mass soil movement (landslides, slips, slumps).
- S2 = Evidence of old slides, small failures.
- S3 = Recent or active movement; wet areas.

- DWS = The operation affects a Domestic Water Supply
- WG = The operation takes place in the Willamette Greenway
- SW = The operation takes place near a Scenic Waterway.
- UGB = The operation takes place in an Urban Growth Boundary
- SH = The operation takes place near a Scenic Highway
- CC = The operation will result in a single clearcut or combination of contiguous clearcuts that exceed 120 acres.
- IC2 = The operation takes place near an influential Class II stream.

14. If you request a waiver of the 15 day waiting period, check the box and contact the Forest Practice Forester (FPF). The FPF will decide if a waiver can be granted.

15. a. & 15. b. Print your name in 15. a. and sign your name and write the date in 15. b.

16. ATTACH MAP AND/OR AERIAL PHOTOS! The notification form is not complete unless a map or aerial photo of the operation area is attached!

CHAPTER 4: MANAGEMENT MEASURES FOR URBAN AREAS

VOL 12

9565

I. INTRODUCTION

A. What "Management Measures" Are

This chapter specifies management measures to protect coastal waters from urban sources of nonpoint pollution. "Management measures" are defined in section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA) as economically achievable measures to control the addition of pollutants to our coastal waters, which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

These management measures will be incorporated by States into their coastal nonpoint programs, which under CZARA are to provide for the implementation of management measures that are "in conformity" with this guidance. Under CZARA, States are subject to a number of requirements as they develop and implement their Coastal Nonpoint Pollution Control Programs in conformity with this guidance and will have some flexibility in doing so. The application of these management measures by States to activities causing nonpoint pollution is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA).

B. What "Management Practices" Are

In addition to specifying management *measures*, this chapter also lists and describes management *practices* for illustrative purposes only. While State programs are required to specify management *measures* in conformity with this guidance, State programs need not specify or require the implementation of the particular management *practices* described in this document. However, as a practical matter, EPA anticipates that the management measures generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices listed in this document have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measures. EPA has also used some of these practices, or appropriate combinations of these practices, as a basis for estimating the effectiveness, costs, and economic impacts of achieving the management measures. (Economic impacts of the management measures are addressed in a separate document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.)*

EPA recognizes that there is often site-specific, regional, and national variability in the selection of appropriate practices, as well as in the design constraints and pollution control effectiveness of practices. The list of practices for each management measure is not all-inclusive and does not preclude States or local agencies from using other technically sound practices. In all cases, however, the practice or set of practices chosen by a State needs to achieve the management measure.

C. Scope of This Chapter

This chapter addresses six major categories of sources of urban nonpoint pollution that affect surface waters:

(1) Runoff from developing areas;
(2) Runoff from construction sites;

R0042871

(3) Runoff from existing development;
(4) On-site disposal systems;
(5) General sources (households, commercial, and landscaping); and
(6) Roads, highways, and bridges.

Each category of sources is addressed in a separate section of this guidance. Each section contains (1) the management measure; (2) an applicability statement that describes, when appropriate, specific activities and locations for which the measure is suitable; (3) a description of the management measure's purpose; (4) the basis for the management measure's selection; (5) information on management practices that are suitable, either alone or in combination with other practices, to achieve the management measure; (6) information on the effectiveness of the management measure and/or of practices to achieve the measure; and (7) information on costs of the measure and/or practices to achieve the measure.

D. Relationship of This Chapter to Other Chapters and to Other EPA Documents

1. Chapter 1 of this document contains detailed information on the legislative background for this guidance, the process used by EPA to develop this guidance, and the technical approach used by EPA in the guidance.

2. Chapter 6 of this document contains information and management measures for addressing nonpoint source impacts resulting from hydromodification, which often occurs to accommodate urban development.

3. Chapter 7 of this document contains management measures to protect wetlands and riparian areas that provide a nonpoint source pollution abatement function. These measures apply to a broad variety of sources, including urban sources.

4. Chapter 8 of this document contains information on recommended monitoring techniques to (1) ensure proper implementation, operation, and maintenance of the management measures and (2) assess over time the success of the measures in reducing pollution loads and improving water quality.

5. EPA has separately published a document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*

6. NOAA and EPA have jointly published guidance entitled *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*. This guidance contains details on how State Coastal Nonpoint Pollution Control Programs are to be developed by States and approved by NOAA and EPA. It includes guidance on:

   - The basis and process for EPA/NOAA approval of State Coastal Nonpoint Pollution Control Programs;
   - How NOAA and EPA expect State programs to provide for the implementation of management measures "in conformity" with this management measures guidance;
   - How States may target sources in implementing their Coastal Nonpoint Pollution Control Programs;
   - Changes in State coastal boundaries; and
   - Requirements concerning how States are to implement their Coastal Nonpoint Pollution Control Programs.

VOL 12

E. Overlap Between This Management Measure Guidance for Control of Coastal Nonpoint Sources and Storm Water Permit Requirements for Point Sources

Historically, overlaps and ambiguity have existed between programs designed to control urban nonpoint sources and programs designed to control urban point sources. For example, runoff that originates as a nonpoint source may ultimately may be channelized and become a point source. Potential confusion concerning coverage and implementation of these two programs has been heightened by Congressional enactment of two important pieces of legislation: section 402(p) of the Clean Water Act, which establishes permit requirements for certain municipal and industrial storm water discharges, and section 6217 of CZARA, which requires EPA to promulgate and States to provide for the implementation of management measures to control nonpoint pollution in coastal waters. The discussion below is intended to clarify the relationship between these two programs and describe the scope of the coastal nonpoint program and its applicability to storm water in coastal areas.

1. The Storm Water Permit Program

The storm water permit program is a two-phased program enacted by Congress in 1987 under section 402(p) of the Clean Water Act. Under Phase I, National Pollutant Discharge Elimination System (NPDES) permits are required to be issued for municipal separate storm sewers serving large or medium-sized populations (greater than 250,000 or 100,000 people, respectively) and for storm water discharges associated with industrial activity. Permits are also to be issued, on a case-by-case basis, if EPA or a State determines that a storm water discharge contributes to the violation of a water quality standard or is a significant contributor of pollutants to waters of the United States. EPA published a rule implementing Phase I on November 16, 1990.

Under Phase II, EPA is to prepare two reports to Congress that assess remaining storm water discharges; determine, to the maximum extent practicable, the nature and extent of pollutants in such discharges; and establish procedures and methods to control storm water discharges to the extent necessary to mitigate impacts on water quality. Then, EPA is to issue regulations that designate storm water discharges, in addition to those addressed in Phase I, to be regulated to protect water quality and is to establish a comprehensive program to regulate those designated sources. The program is required to establish (1) priorities, (2) requirements for State storm water management programs, and (3) expeditious deadlines.

These regulations were to have been issued by EPA not later than October 1, 1992. However, because of EPA's emphasis on Phase I, the Agency has not yet been able to complete and issue appropriate regulations as required under section 402(p). The completion of Phase II is now scheduled for October 1993.

2. Coastal Nonpoint Pollution Control Programs

As discussed more fully earlier, Congress enacted section 6217 of CZARA in late 1990 to require that States develop Coastal Nonpoint Pollution Control Programs that are in conformity with the management measures guidance published by EPA.

3. Scope and Coverage of This Guidance

EPA is excluding from coverage under this section 6217(g) guidance all storm water discharges that are covered by Phase I of the NPDES storm water permit program. Thus, EPA is excluding any discharge from a municipal separate storm sewer system serving a population of 100,000 or more; any discharge of storm water associated with industrial activity; any discharge that has already been permitted; and any discharge for which EPA or the State makes a determination that the storm water discharge contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States. All of these activities are clearly addressed by the storm water permit program and therefore are excluded from the Coastal Nonpoint Pollution Control Programs.

9567

EPA is adopting a different approach with respect to other (Phase II) storm water discharges. At present, EPA has not yet promulgated regulations that would designate additional storm water discharges, beyond those regulated in Phase I, that will be required to be regulated in Phase II. It is therefore not possible to determine at this point which additional storm water discharges will be regulated by the NPDES program and which will not. Furthermore, because of the great number of such discharges, it is likely that it would take many years to permit all of these discharges even if EPA allows for relatively expeditious State permitting approaches such as the use of general permits.

Therefore, to give effect to the Congressional intent that coastal waters receive special and expeditious attention from EPA, NOAA, and the States, storm water runoff that potentially may be ultimately covered by Phase II of the storm water permits program is subject to this management measures guidance and will be addressed by the States' Coastal Nonpoint Pollution Control Programs. Any storm water runoff that ultimately is regulated under an NPDES permit will no longer be subject to this guidance once the permit is issued.

In addition, it should be noted that some other activities are not presently covered by the NPDES permit requirements and thus would be subject to a State's Coastal Nonpoint Pollution Control Program. Most importantly, construction activities on sites that result in the disturbance of less than 5 acres, which are not currently covered by Phase I storm water application requirements,[1] are covered by the Coastal Nonpoint Pollution Control Program. Similarly, runoff from wholesale, retail, service, or commercial activities, including gas stations, which are not covered by Phase I of the NPDES storm water program, would be subject instead to a State's Coastal Nonpoint Pollution Control Program. Further, onsite disposal systems (OSDS), which are generally not covered by the storm water permit program, would be subject to a State's Coastal Nonpoint Pollution Control Program.

Finally, EPA emphasizes that while different legal authorities may apply to different situations, the goals of the NPDES and CZARA programs are complementary. Many of the techniques and practices used to control storm water are equally applicable to both programs. Yet, the programs do not work identically. In the interest of consistency and comprehensiveness, States have the option to implement the CZARA section 6217(g) management measures throughout the State's 6217 management area as long as the NPDES storm water requirements continue to be met by Phase I sources in that area.

F. Background

The prevention and control of urban nonpoint source pollution in coastal areas pose a distinctive challenge to the environmental manager. Increasing water quality problems and degraded coastal resources point to the need for comprehensive solutions to protect and enhance coastal water quality. This chapter presents a framework for preventing and controlling urban nonpoint sources of pollution.

Urban runoff management requires that a number of objectives be pursued simultaneously. These objectives include the following:

- Protection and restoration of surface waters by the minimization of pollutant loadings and negative impacts resulting from urbanization;
- Protection of environmental quality and social well-being;
- Protection of natural resources, e.g., wetlands and other important aquatic and terrestrial ecosystems;

[1] On May 27, 1992, the United States Court of Appeals for the Ninth Circuit invalidated EPA's exemption of construction sites smaller than 5 acres from the storm water permit program in *Natural Resources Defense Council* v. *EPA*, 965 F.2d 759 (9th Cir. 1992). EPA is conducting further rulemaking proceedings on this issue and will not require permit applications for construction activities under 5 acres until further rulemaking has been completed.

- Minimization of soil erosion and sedimentation problems;
- Maintenance of the predevelopment hydrologic conditions;
- Protection of ground-water resources;
- Control and management of runoff to reduce/prevent flooding; and
- Management of aquatic and riparian resources for active and passive recreation (APWA, 1981).

1. Urbanization and Its Impacts

Urbanization first occurred in coastal areas and this historical trend continues. Approximately 80 percent of the Nation's population lives in coastal areas. The negative impacts of urbanization on coastal and estuarine waters has been well documented in a number of sources, including the Nationwide Urban Runoff Program (NURP) and the States' §305(b) and §319 reports.

During urbanization, pervious spaces, including vegetated and open forested areas, are converted to land uses that usually have increased areas of impervious surface, resulting in increased runoff volumes and pollutant loadings. While urbanization may enhance the use of property under a wide range of environmental conditions (USEPA, 1977), urbanization typically results in changes to the physical, chemical, and biological characteristics of the watershed. Vegetative cover is stripped from the land and cut-and-fill activities that enhance the development potential of the land occur. For example, natural depressions that temporarily pond water are graded to a uniform slope, increasing the volume of runoff during a storm event (Schueler, 1987). As population density increases, there is a corresponding increase in pollutant loadings generated from human activities. These pollutants typically enter surface waters via runoff without undergoing treatment.

a. Changes in Hydrology

As urbanization occurs, changes to the natural hydrology of an area are inevitable. Hydrologic and hydraulic changes occur in response to site clearing, grading, and the addition of impervious surfaces and maintained landscapes (Schueler, 1987). Most problematic are the greatly increased runoff volumes and the ensuing erosion and sediment loadings to surface waters that accompany these changes to the landscape. Uncontrolled construction site sediment loads have been reported to be on the order of 35 to 45 tons per acre per year (Novotny and Chesters, 1981; Wolman and Schick, 1967; Yorke and Herb, 1976, 1978). Loadings from undisturbed woodlands are typically less than 1 ton per year (Leopold, 1968).

Hydrological changes to the watershed are magnified after construction is completed. Impervious surfaces, such as rooftops, roads, parking lots, and sidewalks, decrease the infiltrative capacity of the ground and result in greatly increased volumes of runoff. Elevated flows also necessitate the construction of runoff conveyances or the modification of existing drainage systems to avoid erosion of streambanks and steep slopes. Changes in stream hydrology resulting from urbanization include the following (Schueler, 1987):

- Increased peak discharges compared to predevelopment levels (Leopold, 1968; Anderson, 1970);
- Increased volume of urban runoff produced by each storm in comparison to predevelopment conditions;
- Decreased time needed for runoff to reach the stream (Leopold, 1968), particularly if extensive drainage improvements are made;
- Increased frequency and severity of flooding;

- Reduced streamflow during prolonged periods of dry weather due to reduced level of infiltration in the watershed; and

- Greater runoff velocity during storms due to the combined effects of higher peak discharges, rapid time of concentration, and the smoother hydraulic surfaces that occur as a result of development.

In addition, greater runoff velocities occur during spring snowmelts and rain-on-snow events in suburban watersheds than in less impervious rural areas (Buttle and Xu, 1988). Major snowmelt events can produce peak flows as large as 20 times initial flow runoff rates for urban areas (Pitt and McLean, 1992).

Figures 4-1 and 4-2 illustrate the changes in runoff characteristics resulting from an increasing percentage of impervious areas. Other physical characteristics of aquatic systems that are affected by urbanization include the total volume of watershed runoff baseflow, flooding frequency and severity, channel erosion and sediment generation, and temperature regime (Klein, 1985).

b. Water Quality Changes

Urban development also causes an increase in pollutants. The pollutants that occur in urban areas vary widely, from common organic material to highly toxic metals. Some pollutants, such as insecticides, road salts, and fertilizers, are intentionally placed in the urban environment. Other pollutants, including lead from automobile exhaust and oil drippings from trucks and cars, are the indirect result of urban activities (USEPA, 1977).

Many researchers have linked urbanization to degradation of urban waterways (e.g., Klein, 1985, Livingston and McCarron, 1992, Schueler, 1987). The major pollutants found in runoff from urban areas include sediment, nutrients, oxygen-demanding substances, road salts, heavy metals, petroleum hydrocarbons, pathogenic bacteria, and viruses. Livingston and McCarron (1992) concluded that urban runoff was the major source of pollutants in pollutant loadings to Florida's lakes and streams. Table 4-1 illustrates examples of pollutant loadings from urban areas. Table 4-2 describes potential sources of urban runoff pollutants.

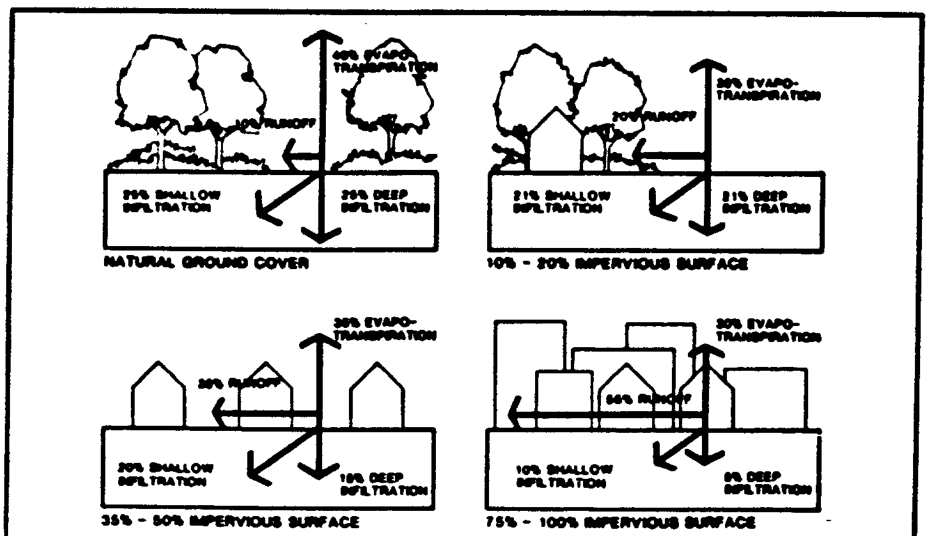

Figure 4-1. Changes in runoff flow resulting from increased impervious area (NC Dept. of Nat. Res. and Community Dev., in Livingston and McCarron, 1992).

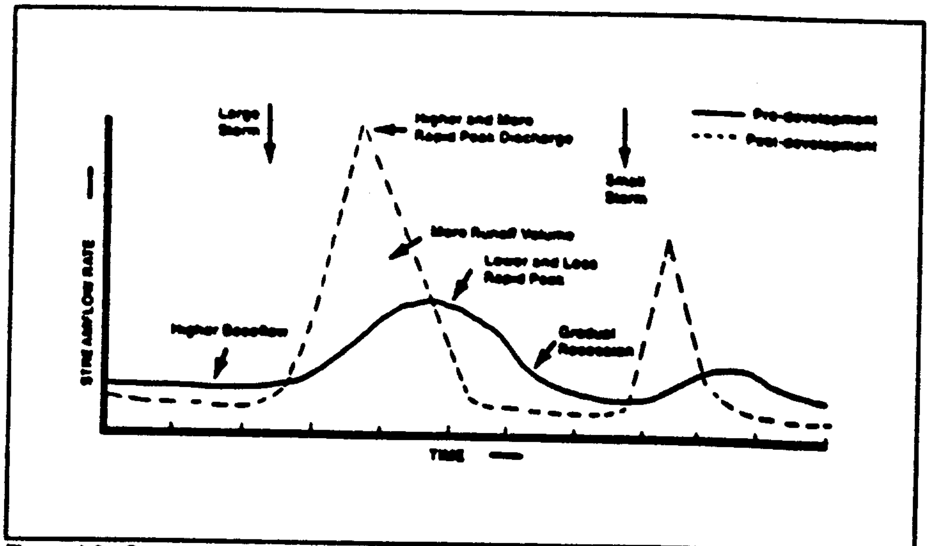

Figure 4-2. Changes in stream hydrology as a result of urbanization (Schueler, 1992).

2. Nonpoint Source Pollutants and Their Impacts

The following discussion identifies the principal types of pollutants found in urban runoff and describes their potential adverse effects (USEPA, 1990).

Sediment. Suspended sediments constitute the largest mass of pollutant loadings to surface waters. Sediment has both short- and long-term impacts on surface waters. Among the immediate adverse impacts of high concentrations of sediment are increased turbidity, reduced light penetration and decreases in submerged aquatic vegetation (SAV) (Chesapeake Implementation Committee, 1988), reduced prey capture for sight-feeding predators, impaired respiration of fish and aquatic invertebrates, reduced fecundity, and impairment of commercial and recreational fishing resources. Heavy sediment deposition in low-velocity surface waters may result in smothered benthic communities/reef systems

Table 4-1. Estimated Mean Runoff Concentrations for Land Uses, Based on the Nationwide Urban Runoff Program (Whalen and Cullum, 1989)

Parameter	Residential	Commercial	Industrial
TKN (mg/l)	0.23	1.5	1.6
$NO_3 + NO_2$ (mg/l)	1.8	0.8	0.93
Total P (mg/l)	0.62	2.29	0.42
Copper (µg/l)	56	50	32
Zinc (µg/l)	254	418	1,063
Lead (mg/l)	293	203	115
COD (mg/l)	102	84	62
TSS (mg/l)	228	168	108
BOD (mg/l)	13	14	62

Table 4-2. Sources of Urban Runoff Pollutants (Adapted from Woodward-Clyde, 1990)

Source	Pollutants of Concern
Erosion	Sediment and attached soil nutrients, organic matter, and other adsorbed pollutants
Atmospheric deposition	Hydrocarbons emitted from automobiles, dust, aromatic hydrocarbons, metals, and other chemicals released from industrial and commercial activities
Construction materials	Metals from flashing and shingles, gutters and downspouts, galvanized pipes and metal plating, paint, and wood
Manufactured products	Heavy metals, halogenated aliphatics, phthalate esters, PAHs, other volatiles, and pesticides and phenols from automobile use, pesticide use, industrial use, and other uses
Plants and animals	Plant debris and animal excrement
Non-storm water connections	Inadvertent or deliberate discharges of sanitary sewage and industrial wastewater to storm drainage systems
Onsite disposal systems	Nutrients and pathogens from failing or improperly sited systems

(CRS, 1991), increased sedimentation of waterways, changes in the composition of bottom substrate, and degradation of aesthetic value. The primary cause of coral reef degradation in coastal areas is attributed to land disturbances and dredging activities due to urban development (Rogers, 1990). Additional chronic effects may occur where sediments rich in organic matter or clay are present. These enriched depositional sediments may present a continued risk to aquatic and benthic life, especially where the sediments are disturbed and resuspended.

Nutrients. The problems resulting from elevated levels of phosphorus and nitrogen are well known and are discussed in detail in Chapter 2 (agriculture).. Excessive nutrient loading to marine ecosystems can result in eutrophication and depressed dissolved oxygen (DO) levels due to elevated phytoplankton populations. Eutrophication-induced hypoxia and anoxia have resulted in fish kills and widespread destruction of benthic habitats (Harper and Gullient, 1989). Surface algal scum, water discoloration, and the release of toxins from sediment may also occur. Species composition and size structure for primary producers may be altered by increased nutrient levels (Hecky and Kilham, 1988; GESAMP, 1989; Thingstad and Sakshaug, 1990).

Occurrences of eutrophication have been frequent in several coastal embayments along the northeast coast (Narragansett and Barnegat Bays), the Gulf Coast (Louisiana and Texas), and the West Coast (California and Washington) (NOAA, 1991). High nitrate concentrations have also been implicated in blooms of nuisance algae in Newport Bay, California (NRC, 1990b). Nutrient loadings in Louisiana coastal waters have decreased productivity, increased hypoxic events, and decreased fisheries yields (NOAA, 1991).

Oxygen-Demanding Substances. Proper levels of DO are critical to maintaining water quality and aquatic life. Decomposition of organic matter by microorganisms may deplete DO levels and result in the impairment of the waterbody. Data have shown that urban runoff with high concentrations of decaying organic matter can severely depress DO levels after storm events (USEPA, 1983). The NURP study found that oxygen-demanding substances can be present in urban runoff at concentrations similar to secondary treatment discharges.

Pathogens. Urban runoff typically contains elevated levels of pathogenic organisms. The presence of pathogens in runoff may result in waterbody impairments such as closed beaches, contaminated drinking water sources, and shellfish bed closings. OSDS-related pathogen contamination has been implicated in a number of shellfish bed closings. Table 4-3 shows the adverse impacts of septic systems and urban runoff on shellfish beds, resulting in closure. This problem may be especially prevalent in areas with porous or sandy soils.

Table 4-3. Percent of Limited or Restricted Classified Shellfish Waters Affected by Types of Pollution (Leonard et al., 1991)

	Septic Systems	Urban Runoff	Ag. Runoff	POTWs	Boats	Industry
North Atlantic	26	23	3	67	17	7
Mid-Atlantic	11	58	12	57	31	20
South Atlantic	34	34	28	44	17	21
Gulf	48	35	8	27	14	14
Pacific	19	36	13	25	15	42
Nationwide	37	38	11	37	18	17

Road Salts. In northern climates, road salts can be a major pollutant in urban areas. Klein (1985) reported on several studies by various authors of road salt contamination in lakes and streams and cases where well contamination had been attributed to road salts in New England. Snow runoff produces high salt/chlorine concentrations at the bottom of ponds, lakes, and bays. Not only does this condition prove toxic to benthic organisms, but it also prevents crucial vertical spring mixing (Bubeck et al., 1971; Hawkins and Judd, 1972).

Hydrocarbons. Petroleum hydrocarbons are derived from oil products, and the source of most such pollutants found in urban runoff is vehicles—auto and truck engines that drip oil. Many do-it-yourself auto mechanics dump used oil directly into storm drains (Klein, 1985). Concentrations of petroleum-based hydrocarbons are often high enough to cause mortalities in aquatic organisms.

Oil and grease contain a wide variety of hydrocarbon compounds. Some polynuclear aromatic hydrocarbons (PAHs) are known to be toxic to aquatic life at low concentrations. Hydrocarbons have a high affinity for sediment, and they collect in bottom sediments where they may persist for long periods of time and result in adverse impacts on benthic communities. Lakes and estuaries are especially prone to this phenomenon.

Heavy Metals. Heavy metals are typically found in urban runoff. For example, Klein (1985) reported on a study in the Chesapeake Bay that designated urban runoff as the source for 6 percent of the cadmium, 1 percent of the chromium, 1 percent of the copper, 19 percent of the lead, and 2 percent of the zinc.

Heavy metals are of concern because of toxic effects on aquatic life and the potential for ground-water contamination. Copper, lead, and zinc are the most prevalent NPS pollutants found in urban runoff. High metal concentrations may bioaccumulate in fish and shellfish and impact beneficial uses of the affected waterbody.

Toxics. Many different toxic compounds (priority pollutants) have been associated with urban runoff. NURP studies (USEPA, 1983) indicated that at least 10 percent of urban runoff samples contained toxic pollutants.

a. Pollutant Loading

Nonpoint source pollution has been associated with water quality standard violations and the impairment of designated uses of surface waters (Davenport, 1990). The 1990 Report to Congress on §319 of the Clean Water Act reported that:

- Siltation and nutrients are the pollutants most responsible for nonpoint source impacts to the Nation's surface waters, and

- Wildlife and recreation, (in particular, swimming, fishing, and shellfishing) are the uses most affected by nonpoint source pollution.

The pollutants described previously can have a variety of impacts on coastal resources. Examples of waterbodies that have been adversely impacted by nonpoint source pollution are varied.

- The Miami River and Biscayne Bay in Florida have experienced loss of habitat, loss of recreational and commercial fisheries, and decrease in productivity partly as the result of urban runoff (SFWMD, 1988).
- Shellfish beds in Port Susan, Puget Sound, Washington, have been declared unsafe for the commercial harvest of shellfish in part because of bacterial contamination from onsite disposal systems (USEPA, 1991).
- Impairment due to toxic pollution from urban runoff continues to be a problem in the southern part of San Francisco Bay (USEPA, 1992).
- Nonpoint sources of pollution have been implicated in degradation of water quality in Westport River, Massachusetts, a tributary of Buzzards Bay. High concentrations of coliform bacteria have been observed after rainfall events, and shellfish bed closures in the river have been attributed to loadings from surface runoff and septic systems (USEPA, 1992).
- In Brenner Bay, St. Thomas, U.S. Virgin Islands, populations of corals and shellfish and marine habitat have been damaged due to increased nutrient and sediment loadings. After several years of rapid urban development, less than 10 percent of original grass beds remain as a result of sediment shoaling, eutrophication, and algae blooms (Nichols and Towle, 1977).

b. Other Impacts

Other impacts not related to a specific pollutant can also occur as a result of urbanization. Temperature changes result from increased flows, removal of vegetative cover, and increases in impervious surfaces. Impervious surfaces act as heat collectors, heating urban runoff as it passes over the impervious surface. Recent data indicate that intensive urbanization can increase stream temperature as much as 5 to 10 degrees Celsius during storm events (Galli and Dubose, 1990). Thermal loading disrupts aquatic organisms that have finely tuned temperature limits. Salinity can also be affected by urbanization.

Freshwater inflows due to increased runoff can impact estuaries, especially if they occur in pulses, disrupting the natural salinity of an area. Increased impervious surface area and the presence of storm water conveyance systems commonly result in elevated peak flows in streams during and after storm events. These rapid pulses or influxes of fresh water into the watershed may be 2 to 10 times greater than normal (ABAG, 1991). This may lead to a decrease in the number of aquatic organisms living in the receiving waters (McLusky, 1989).

The alteration of natural hydrology due to urbanization and the accompanying runoff diversion, channelization, and destruction of natural drainage systems have resulted in riparian and tidal wetland degradation or destruction. Deltaic wetlands have also been impacted by changes in historic sediment deposition rates and patterns. Hydromodification projects designed to prevent flooding may reduce sedimentation rates and decrease marsh aggradation, which would normally offset erosion and apparent changes in sea level within the delta (Cahoon et al., 1983).

3. Opportunities

This chapter was organized to parallel the development process to address the prevention and treatment of nonpoint source pollution loadings during all phases of urbanization. (NOTE: The control of nonpoint source pollution requires the use of two primary strategies: the prevention of pollutant loadings and the treatment of unavoidable loadings. The strategy in this chapter relies primarily on the watershed approach, which focuses on pollution prevention or source reduction practices. While treatment options are an integral component of this chapter, a

VOL 12

9574

R0042880

combination of pollution prevention and treatment practices is favored because planning, design, and education practices are generally more effective, require less maintenance, and are more cost-effective in the long term.)

The major opportunities to control NPS loadings occur during the following three stages of development: the siting and design phase, the construction phase, and the postdevelopment phase. Before development occurs, land in a watershed is available for a number of pollution prevention and treatment options, such as setbacks, buffers, or open space requirements, as well as wet ponds or constructed urban runoff wetlands that can provide treatment of the inevitable runoff and associated pollutants. In addition, siting requirements/restrictions and other land use ordinances, which can be highly effective, are more easily implemented during this period. After development occurs, these options may no longer be practicable or cost-effective. Management Measures II.A through II.C address the strategies and practices that can be used during the initial phase of the urbanization process.

The control of construction-related sediment loadings is critical to maintaining water quality. The implementation of proper erosion and sediment control practices during the construction stage can significantly reduce sediment loadings to surface waters. Management Measures II.A and II.B address construction-related practices.

After development has occurred, lack of available land severely limits the implementation of cost-effective treatment options. Management Measure VI.A focuses on improving controls for existing surface water runoff through pollution prevention to mitigate nonpoint sources of pollution generated from ongoing domestic and commercial activities.

VOL 12

9575

II. URBAN RUNOFF

A. New Development Management Measure

(1) By design or performance:

(a) After construction has been completed and the site is permanently stabilized, reduce the average annual total suspended solid (TSS) loadings by 80 percent. For the purposes of this measure, an 80 percent TSS reduction is to be determined on an average annual basis,* or

(b) Reduce the postdevelopment loadings of TSS so that the average annual TSS loadings are no greater then predevelopment loadings, and

(2) To the extent practicable, maintain postdevelopment peak runoff rate and average volume at levels that are similar to predevelopment levels.

Sound watershed management requires that both structural and nonstructural measures be employed to mitigate the adverse impacts of storm water. Nonstructural Management Measures II.B and II.C can be effectively used in conjunction with Management Measure II.A to reduce both the short- and long-term costs of meeting the treatment goals of this management measure.

* Based on the average annual TSS loadings from all storms less than or equal to the 2-year/24-hour storm. TSS loadings from storms greater than the 2-year/24-hour storm are not expected to be included in the calculation of the average annual TSS loadings.

1. Applicability

This management measure is intended to be applied by States to control urban runoff and treat associated pollutants generated from new development, redevelopment, and new and relocated roads, highways, and bridges. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source (NPS) programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

For design purposes, postdevelopment peak runoff rate and average volume should be based on the 2-year/24-hour storm.

2. Description

This management measure is intended to accomplish the following: (1) decrease the erosive potential of increased runoff volumes and velocities associated with development-induced changes in hydrology; (2) remove suspended solids and associated pollutants entrained in runoff that result from activities occurring during and after development; (3) retain hydrological conditions to closely resemble those of the predisturbance condition; and (4) preserve natural systems including in-stream habitat.[2] For the purposes of this management measure, "similar" is defined as "resembling though not completely identical."

During the development process, both the existing landscape and hydrology can be significantly altered. As development occurs, the following changes to the land may occur (USEPA, 1977):

- Soil porosity decreases;
- Impermeable surfaces increase;
- Channels and conveyances are constructed;
- Slopes increase;
- Vegetative cover decreases; and
- Surface roughness decreases.

These changes result in increased runoff volume and velocities, which may lead to increased erosion of streambanks, steep slopes, and unvegetated areas (Novotny, 1991). In addition, destruction of in-stream and riparian habitat, increases in water temperature (Schueler et al., 1992), streambed scouring, and downstream siltation of streambed substrate, riparian areas, estuarine habitat, and reef systems may occur. An example of predicted effects of increased levels of urbanization on runoff volumes is presented in Table 4-4 (USDA-SCS, 1986). Methods are also available to compute peak runoff rates (USDA-SCS, 1986).

The annual TSS loadings can be calculated by adding the TSS loadings that can be expected to be generated during an average 1-year period from precipitation events less than or equal to the 2-year/24-hour storm. The 80 percent standard can be achieved by reducing, over the course of the year, 80 percent of these loadings. EPA recognizes that 80 percent cannot be achieved for each storm event and understands that TSS removal efficiency will fluctuate above and below 80 percent for individual storms.

Management Measures II.A, II.B, and II.C were selected as a system to be used to prevent and mitigate the problems discussed above. In combination, these three management measures applied on-site and throughout watersheds can be used to provide increased watershed protection and help prevent severe erosion, flooding, and increased pollutant loads generally associated with poorly planned development. Implementation of Management Measures II.B and II.C can help achieve the goals of Management Measure II.A.

Structural practices to control urban runoff rely on three basic mechanisms to treat runoff: **infiltration, filtration, and detention.** Table 4-5 lists specific urban runoff control practices that relate to these and includes information on advantages, disadvantages, and costs. Table 4-6 presents site-specific considerations, regional limitations, operation and maintenance burdens, and longevity for these practices.

---

[2] Several issues require clarification to fully understand the scope and intent of this management measure. First, this management measure applies only to postdevelopment loadings and not to construction-related loadings. Management measure options II.A.(1)(a) and (b) both apply only to the TSS loadings that are generated after construction has ceased and the site has been properly stabilized using permanent vegetative and/or structural erosion and sediment control practices. Second, for the purposes of this guidance, the term *predevelopment* refers to the sediment loadings and runoff volumes/velocities that exist onsite immediately before the planned land disturbance and development activities occur. Predevelopment is not intended to be interpreted as that period before any human-induced land disturbance activity has occurred. Third, management measure option II.A.(1)(b) is not intended to be used as an alternative to achieving an adequate level of control in cases where high sediment loadings are the result of poor management of developed sites (not "natural" sites), e.g., farmlands where the erosion control components of the USDA conservation management system are not used or sites where land disturbed by previous development was not permanently stabilized.

VOL 12

Table 4-4. Example Effects of Increased Urbanization on Runoff Volumes (USDA-SCS, 1986)

Development Scenario	Predicted Runoff
100 percent open space	2.81 inches (baseline)
70 percent of the total area divided into ½-acre lots; each lot is 25 percent impervious; 30 percent of the total area is open space	3.28 inches (24 percent increase)
70 percent of the total area is divided into ½-acre lots; each lot is 35 percent impervious; 30 percent of the total area is open space	3.48 inches (24 percent increase)
30 percent of the total area is divided into ½-acre lots - each lot is 25 percent impervious and contiguous; 40 percent is divided into ½-acre lots - each lot is 50 percent impervious and discontinuous; 30 percent of the total area is open space	3.19 inches (14 percent increase)

Infiltration devices, such as infiltration trenches, infiltration basins, filtration basins, and porous and concrete block pavement, rely on absorption of runoff to treat urban runoff discharges. Water is percolated through soils, where filtration and biological action remove pollutants. Systems that rely on soil absorption require deep permeable soils at separation distances of at least 4 feet between the bottom of the structure and seasonal ground water levels. The widespread use of infiltration in a watershed can be useful to maintain or restore predevelopment hydrology, increase dry-weather baseflow, and reduce bankfull flooding frequency. However, infiltration systems may not be appropriate where ground water requires protection. Restrictions may also apply to infiltration systems located above sole source (drinking water) aquifers. Where such designs are selected, they should be incorporated with the recognition that periodic maintenance is necessary for these areas. Long-term effectiveness in most cases will depend on proper operation and maintenance of the entire system.

9578

NOTE: Infiltration systems, some filtration devices, and sand filters should be installed after construction has been completed and the site has been permanently stabilized. The State of Maryland has observed a high failure rate for infiltration systems. Many of these failures can be attributed to clogging due to sediment loadings generated during the construction process and/or the premature use of the device before proper stabilization of the site has occurred. In cases where construction of the infiltration system is necessary before the cessation of land-disturbing activities, diversions, covers, or other means to prevent sediment-laden runoff from entering and clogging the infiltration system should be used (State of Maryland DNR, personal communication, 1991).

Filtration practices such as filter strips, grassed swales, and sand filters treat sheet flow by using vegetation or sand to filter and settle pollutants. In some cases infiltration and treatment in the subsoil may also occur. After passing through the filtration media, the treated water can be routed into streams, drainage channels, or other waterbodies; evaporated; or percolated into ground water. Sand filters are particularly useful for ground-water protection. The influence of climatic factors must be considered in the process of selecting vegetative systems.

Detention practices temporarily impound runoff to control runoff rates, and settle and retain suspended solids and associated pollutants. Extended detention ponds and wet ponds fall within this category. Constructed urban runoff wetlands and multiple-pond systems also remove pollutants by detaining flows that lead to sedimentation (gravitational settling of suspended solids). Properly designed ponds protect downstream channels by controlling discharge velocities, thereby reducing the frequency of bankfull flooding and resultant bank-cutting erosion. If landscaped and planted with appropriate vegetation, these systems can reduce nutrient loads and also provide terrestrial and aquatic wildlife habitat. When considering the use of these devices, potential negative impacts such as downstream warming, reduced baseflow, trophic shifts, bacterial contamination due to waterfowl, hazards to

Table 4-6. Advantages and Disadvantages of Management Practices

Management Practice	Advantages	Disadvantages	Comparative Cost (Schueler, Kumble, and Heraty, 1992)
Infiltration Basin	• Provides ground-water recharge • Can serve large developments • High removal capability for particulate pollutants and moderate removal for soluble pollutants • When basin works, it can replicate predevelopment hydrology more closely than other BMP options • Basins provide more habitat value than other infiltration systems	• Possible risk of contaminating ground water • Only feasible where soil is permeable and there is sufficient depth to rock and water table • Fairly high failure rate • If not adequately maintained, can be an eyesore, breed mosquitoes, and create undesirable odors • Regular maintenance activities cannot prevent rapid clogging of infiltration basins	Construction cost moderate but rehabilitation cost high
Infiltration Trench	• Provides ground-water recharge • Can serve small drainage areas • Can fit into medians, perimeters, and other unused areas of a development site • Helps replicate predevelopment hydrology, increases dry weather baseflow, and reduces bankfull flooding frequency	• Possible risk of contaminating ground water • Only feasible where soil is permeable and there is sufficient depth to rock and water table • Since not as visible as other BMPs, less likely to be maintained by residents • Requires significant maintenance	Cost-effective on smaller sites. Rehabilitation costs can be considerable.
Vegetated Filter Strip (VFS)	• Low maintenance requirements • Can be used as part of the runoff conveyance system to provide pretreatment • Can effectively reduce particulate pollutant levels in areas where runoff velocity is low to moderate • Provides excellent urban wildlife habitat • Economical	• Often concentrates water, which significantly reduces effectiveness • Ability to remove soluble pollutants highly variable • Limited feasibility in highly urbanized areas where runoff velocities are high and flow is concentrated • Requires periodic repair, regrading, and sediment removal to prevent channelization	Low

Table 4-5. (Continued)

Management Practice	Advantages	Disadvantages	Comparative Cost (Schueler, Kumble, and Heraty, 1992)
Grassed Swale	• Requires minimal land area • Can be used as part of the runoff conveyance system to provide pretreatment • Can provide sufficient runoff control to replace curb and gutter in single-family residential subdivisions and on highway medians • Economical	• Low pollutant removal rates • Leaching from culverts and fertilized lawns may actually increase the presence of trace metals and nutrients	Low compared to curb and gutter
Porous Pavement	• Provides ground-water recharge • Provides water quality control without additional consumption of land • Can provide peak flow control • High removal rates for sediment, nutrients, organic matter, and trace metals • When operating properly can replicate predevelopment hydrology • Eliminates the need for stormwater drainage, conveyance, and treatment systems off-site	• Requires regular maintenance • Possible risk of contaminating ground water • Only feasible where soil is permeable, there is sufficient depth to rock and water table, and there are gentle slopes • Not suitable for areas with high traffic volume • Need extensive feasibility tests, inspections, and very high level of construction workmanship (Schueler, 1987) • High failure rate due to clogging • Not suitable to serve large off-site pervious areas	Cost-effective compared to conventional asphalt when working properly
Concrete Grid Pavement	• Can provide peak flow control • Provides ground-water recharge • Provides water quality control without additional consumption of land	• Requires regular maintenance • Not suitable for area with high traffic volume • Possible risk of contaminating ground water • Only feasible where soil is permeable, there is sufficient depth to rock and water table, and there are gentle slopes	Information not available

Table 4-5. (Continued)

Management Practice	Advantages	Disadvantages	Comparative Cost (Schueler, Kumble, and Heraty, 1992)
Filtration Basin	• Ability to accommodate medium-size development (3-80 acres) • Flexibility to provide or not provide ground-water recharge • Can provide peak volume control	• Requires pretreatment of storm water through sedimentation to prevent filter media from prematurely clogging	Information not available
Water Quality Inlets Catch Basins	• Provide high degree of removal efficiencies for larger particles and debris as pretreatment • Require minimal land area • Flexibility to retrofit existing small drainage areas and applicable to most urban areas	• Not feasible for drainage area greater than 1 acre • Marginal removal of small particles, heavy metals, and organic pollutants • Not effective as water quality control for intense storms • Minimal nutrient removal	Information not available
Water Quality Inlet Catch Basins with Sand Filter	• Provide high removal efficiencies of particulates • Require minimal land area • Flexibility to retrofit existing small drainage areas • Higher removal of nutrient as compared to catch basins and oil/grid separator	• Not feasible for drainage area greater than 5 acres • Only feasible for areas that are stabilized and highly impervious • Not effective as water quality control for intense storms	Information not available
Water Quality Inlet Oil/Grit Separator	• Captures coarse-grained sediments and some hydrocarbons • Requires minimal land area • Flexibility to retrofit existing small drainage areas and applicable to most urban areas • Shows some capacity to trap trash, debris, and other floatables • Can be adapted to all regions of the country	• Not feasible for drainage area greater than 1 acre • Minimal nutrient and organic matter removal • Not effective as water quality control for intense storms • Concern exists over the pollutant toxicity of trapped residuals • Require high maintenance	High, compared to trenches and sand filters

Table 4-6. (Continued)

Management Practice	Advantages	Disadvantages	Comparative Cost (Schueler, Kumble, and Heraty, 1992)
Extended Detention Dry Pond	• Can provide peak flow control • Possible to provide good particulate removal • Can serve large development • Requires less capital cost and land area when compared to wet pond • Does not generally release warm or anoxic water downstream • Provides excellent protection for downstream channel erosion • Can create valuable wetland and meadow habitat when properly landscaped	• Removal rates for soluble pollutants are quite low • Not economical for drainage area less than 10 acres • If not adequately maintained, can be an eyesore, breed mosquitoes, and create undesirable odors	Lowest cost alternative in size range
Wet Pond	• Can provide peak flow control • Can serve large developments; most cost-effective for larger, more intensively developed sites • Enhances aesthetics and provides recreational benefits • Little ground-water discharge • Permanent pool in wet ponds helps to prevent scour and resuspension of sediments • Provides moderate to high removal of both particulate and soluble urban stormwater pollutants	• Not economical for drainage area less than 10 acres • Potential safety hazards if not properly maintained • If not adequately maintained, can be an eyesore, breed mosquitoes, and create undesirable odors • Requires considerable space, which limits use in densely urbanized areas with expensive land and property values • Not suitable for hydrologic soil groups "A" and "B" (SCS classification) • With possible thermal discharge and oxygen depletion, may severely impact downstream aquatic life	Moderate to high compared to conventional storm water detention

Table 4-6. (Continued)

Management Practice	Advantages	Disadvantages	Comparative Cost (Schueler, Kumble, and Heraty, 1992)
Extended Detention Wet Pond	• Can provide peak flow control • Can serve large developments; most cost-effective for larger, more intensively developed sites • Enhances aesthetic and provide recreational benefits • Permanent pool in wet ponds helps to prevent scour and resuspension of sediments • Provides better nutrient removal when compared to wet pond	• Not economical for drainage area less than 10 acres • Potential safety hazards if not properly maintained • If not adequately maintained, can be an eyesore, breed mosquitoes, and create undesirable odors • Requires considerable space, which limits use in densely urbanized areas with expensive land and property values • Not suitable for hydrologic soil groups "A" and "B"(SCS classification) • With possible thermal discharge and oxygen depletion, may severely impact downstream aquatic life	

Table 4-5. (Continued)

Management Practice	Advantages	Disadvantages	Comparative Cost (Schueler, Kumble, and Heraty, 1992)
Constructed Stormwater Wetland	• Can serve large developments; most cost-effective for larger, more intensively developed sites • Provides peak flow control • Enhances aesthetics and provides recreational benefits • The marsh fringe also protects shoreline from erosion • Permanent pool in wet ponds helps to prevent scour and resuspension of sediments • Has high pollutant removal capability	• Not economical for drainage area less than 10 acres • Potential safety hazards if not properly maintained • If not adequately maintained can be an eyesore, breed mosquitoes, and create undesirable odors • Requires considerable space, which limits use in densely urbanized areas with expensive land and property values • With possible thermal discharge and oxygen depletion, may severely impact downstream aquatic life • May contribute to nutrient loadings during die-down periods of vegetation	Marginally higher than wet ponds

Table 4-6. Regional, Site-Specific, and Maintenance Considerations for Structural Practices to Control Sediments in Storm Water Runoff (Schueler et al., 1992)

BMP Option	Size of Drainage Area	Site Requirements	Regional Restrictions	Maintenance Burdens	Longevity
Infiltration basins	Moderate to large	Deep permeable soils	Arid and cold regions	High	Low
Infiltration trenches	Moderate	Same as for infiltration basins			
Vegetated filter strips	Small	Low-density areas with low slopes	Arid and cold regions	Low	Low if poorly maintained
Grassed swales	Small	Low-density areas with <15% slope	Arid and cold regions	Low	High if maintained
Porous pavement	Small	Deep permeable soils, low slopes, and restricted traffic	Arid and cold regions or high wind erosion rates	High	Low
Concrete grid pavement	Small	Same as for porous pavement		Moderate to high	High
Filtration basins and sand filters	Widely applicable	Widely applicable	Arid and cold regions	Moderate	Low to moderate
Water quality inlets	Small	Impervious catchments	Few restrictions	Cleaned twice a year	High
Extended detention ponds	Moderate to large	Deep soils	Few restrictions	Dry ponds have relatively high burdens	High
Wet ponds	Moderate to large	Deep soils	Arid regions	Low	High
Constructed storm water wetlands	Moderate to large	Poorly drained soils, space may be limiting	Arid regions	Annual harvesting of vegetation	High

nearby residents, and nuisance factors such as mosquitoes and odor should be considered. Siting development in wetlands and floodplains should be avoided. Where drainage areas are greater than 250 acres and ponds are being considered, inundation of upstream channels may be of concern.

Constructed wetlands and multiple-pond systems also treat runoff through the processes of adsorption, plant uptake, filtration, volatilization, precipitation, and microbial decomposition (Livingston and McCarron, 1992; Schueler et al., 1992). Multiple-pond systems in particular have shown potential to provide much higher levels of treatment (Schueler et al., 1992). In general, the potential concerns and drawbacks applicable to wet ponds apply to these systems. Many of these systems are currently being designed to include vegetated buffers and deep-water areas to provide habitat for wildlife and aesthetic benefits. Where such designs are selected, they should be incorporated with the recognition that periodic maintenance is necessary. Long-term effectiveness in most cases will depend on proper operation and maintenance of the entire system. Refer to Chapter 7 for additional information on constructed wetlands.

VOL 12

Water quality inlets, like ponds, rely on gravity settling to remove pollutants before ponds discharge water to the storm sewer or other collection system. Water quality inlets are designed to trap floatable trash and debris. When inlets are coupled with oil/grit separators, hydrocarbon loadings from areas with high traffic/parking volumes can be reduced. However, experience has shown that these devices have limited pollutant-removal effectiveness and should not be used unless coupled with frequent and effective clean-out methods (Schueler et al., 1992). Although no costs are currently available, proper maintenance of water quality inlets must include proper disposal of trapped coarse-grained sediments and hydrocarbons. The costs of clean-out and disposal may be significant when contaminated sediments require proper disposal.

Inadequate maintenance is often cited as one of the major factors influencing the poor effectiveness of structural practices. The cost of long-term maintenance should be evaluated during the selection process. In addition, responsibility for maintenance should be clearly assigned for the life of the system. Typical maintenance requirements include:

- Inspection of basins and ponds after every major storm for the first few months after construction and annually thereafter;
- Mowing of grass filter strips and swales at a frequency to prevent woody growth and promote dense vegetation;
- Removal of litter and debris from dry ponds, forebays, and water quality inlets;
- Revegetation of eroded areas;
- Periodic removal and replacement of filter media from infiltration trenches and filtration ponds;
- Deep tilling of infiltration basins to maintain infiltrative capability;
- Frequent (at least quarterly) vacuuming or jet hosing of porous pavements or concrete grid pavements;
- Quarterly clean-outs of water quality inlets;
- Periodic removal of floatables and debris from catch basins, water quality inlets, and other collection-type controls; and
- Periodic removal and proper disposal of accumulated sediment (applicable to all practices). Sediments in infiltration devices need to be removed frequently enough to prevent premature failure due to clogging.

9586

Operation and Maintenance

Proper operation and maintenance of structural treatment facilities is critical to their effectiveness in mitigating adverse impacts of urban runoff. The proper installation and maintenance of various BMPs often determines their success or failure (Reinalt, 1992).

During a field study of 51 urban runoff treatment facilities, the Ocean County, New Jersey, planning and engineering departments determined that the major source of urban runoff problems was a failure of the responsible party to provide adequate facility maintenance. The causes of this failure are complex and include factors such as lack of funding, manpower, and equipment; uncertain or irresponsible ownership; unassigned maintenance responsibility; and ignorance or disregard of potential consequences of maintenance neglect (Ocean County, 1989). The analysis of the field data collected during the study indicated the following trends:

- Bottoms, side slopes, trash racks, and low-flow structures were the primary sources of maintenance problems.

- Infiltration facilities seemed to be more prone to maintenance neglect and were generally in the poorest condition overall.
- Retention facilities appeared to receive the greatest amount of maintenance and generally were in the best condition overall.
- Publicly owned facilities were usually better maintained than those that were privately maintained.
- Facilities located at office development sites were better maintained than those at commercial or institutional sites; facilities in residential areas received average maintenance.
- Highly visible urban runoff facilities were generally better maintained that those in more remote, less visible locations (Ocean County, 1989).

The following program elements should be considered to ensure the proper design, implementation, and operation and maintenance of runoff treatment and control devices (adapted from The State of New Jersey Ocean County Demonstration Study's *Storm Water Management Facilities Maintenance Manual*):

- Adoption, promulgation, and implementation of planning and design standards that eliminate, reduce, and/or facilitate facility maintenance; coordination with other regulatory authorities with jurisdiction over runoff facilities;
- Establishment of a comprehensive design review program, which includes training and education to ensure adequate staff competency and expertise;
- Design standards published in a readily understandable format for all permittees and responsible parties including regulatory authorities; the provision of clear requirements to promote the adoption of planning and standards and expedite facility review and approval;
- Publication of specific obligations and responsibilities of the runoff facility owner/operator including procedures for the identification of owners/operators who will have long-term responsibility for the facility;
- Development of a procedure for addressing maintenance default by negligent owner/operators;
- Periodic review and evaluation of the runoff management program to ensure continued program effectiveness and efficiency;
- Runoff facility construction inspection program; and
- Provisions for public assumption of runoff control facilities.

3. Management Measure Selection

This management measure was selected because of the following factors.

(1) Removal of 80 percent of total suspended solids (TSS) is assumed to control heavy metals, phosphorus, and other pollutants.

(2) A number of coastal States, including Delaware and Florida, and the Lower Colorado River Authority (Texas) require and have implemented a TSS removal treatment standard of at least 80 percent for new development.

(3) Analysis has shown that constructed wetlands, wet ponds, and infiltration basins can remove 80 percent of TSS, provided they are designed and maintained properly. Other practices or combinations of practices can be also used to achieve the goal.

(4) The control of postdevelopment volume and peak runoff rates to reduce or prevent streambank erosion and stream scouring and to maintain predevelopment hydrological conditions can be accomplished using a number of water quality and flood control practices. Many States and local governments have implemented requirements that stipulate that, at a minimum, the 2-year/24-hour storm be controlled.

Management Measure II.A.(1)(b) was selected to provide a descriptive alternative to Management Measure II.A.(1)(a). Where preexisting conditions do not already present a water quality problem, preservation of predevelopment TSS loading levels is intended to promote TSS loading reductions that adequately protect surface waters and are equivalent to or greater than the levels achieved by Management Measure option II.A.(1)(a). In some cases, local conditions (e.g., mountainous areas with arid, steep slopes) may preclude the implementation of Management Measure II.A.(1)(a). Where local conditions do not allow the implementation of BMPs such as grassed swales or detention basins, and preconstruction/predevelopment (existing conditions) TSS loadings from the site are significant, it may not be cost-effective or beneficial to require 80 percent TSS postdevelopment loading reductions. Management Measure option II.A.(1)(b) was provided to allow flexibility where such conditions exist. This flexibility will be especially important in cases where loadings from surrounding undeveloped areas dwarf the TSS loadings generated from the new development. (NOTE: Predevelopment is defined, in the context of Management Measure II.A.(1)(b), as the sediment loadings and runoff volumes/velocities that exist onsite immediately before the planned land disturbance and development occur.)

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Cost and effectiveness information for these practices is shown in Tables 4-7 and 4-8. Many of these practices can be used during site development, but the focus of this section is the abatement of postdevelopment impacts.

a. *Develop training and education programs and materials for public officials, contractors, and others involved with the design, installation, operation, inspection, and maintenance of urban runoff facilities.*

Training programs and educational materials for public officials, contractors, and the public are crucial to implementing effective urban runoff management programs. Contractor certification, inspector training, and competent design review staff are important for program implementation and continuing effectiveness. The State of New Jersey Ocean County Demonstration Study's *Storm Water Management Facilities Maintenance Manual* addresses many of these issues and provides guidance on programmatic elements necessary for the proper operation and maintenance of urban runoff facilities. Several other States and local governments, including Virginia, Maryland, Washington, Delaware, Northeastern Illinois Planning Commission, and the City of Alexandria, Virginia, have developed manuals and training materials to assist in implementation of urban runoff requirements and regulations.

The State of Delaware passed legislation requiring that "all responsible personnel involved in a construction project will have a certificate of attendance at a Departmental sponsored or approved training course for the control of sediment and storm water before initiation of land disturbing activity." The State provides personnel training and educational opportunities for contractors to meet this requirement and has delegated program elements to conservation

[a] References indicate the useful life for infiltration basins and infiltration trenches at 25-50 and 10-15 years, respectively. Because of the high failure rate, infiltration basins are assumed to have useful life span of 25 years and infiltration trenches are assumed to have useful life span of 10 years.
[b] Useful life taken as life of project, assumed to be 50 years.
[c] Incremental cost, i.e., cost beyond that required for conventional asphalt pavement.
[d] Since no information was available for useful life of porous pavement, it was assumed to be similar to that of infiltration trenches.
[e] Since no information was available for useful life of filtration basins it was assumed to be similar to that of infiltration basins.
[f] Frequency of cleaning assumed 2 times per year.

districts, counties, and other agencies. The program has been well received and from February 1991 to July 1991, over 1,100 individuals from 300 companies and organizations participated in the program (Shaver and Piorko, 1992).

b. *Ensure that all urban runoff facilities are operated and maintained properly.*

Once an urban runoff facility is installed, it should receive thorough maintenance in order to function properly and not pose a health or safety threat. Maintenance should occur at regular intervals, be performed by one or more individuals trained in proper inspection and maintenance of urban runoff facilities, and be performed in accordance with the adopted standards of the State or local government (Ocean County, undated). It is more effective and efficient to perform preventative maintenance on a regular basis than to undertake major remedial or corrective action on an as needed basis (Ocean County, undated).

c. *Infiltration Basins*

Infiltration basins are impoundments in which incoming urban runoff is temporarily stored until it gradually infiltrates into the soil surrounding the basin. Infiltration basins should drain within 72 hours to maintain aerobic conditions, which favor bacteria that aid in pollutant removal, and to ensure that the basin is ready to receive the next storm (Schueler, 1987). The runoff entering the basin is pretreated to remove coarse sediment that may clog the surface soil pore on the basin floor. Concentrated runoff should flow through a sediment trap, or a vegetated filter strip may be used for sheet flow.

d. *Infiltration Trenches*

Infiltration trenches are shallow excavated ditches that have been backfilled with stone to form an underground reservoir. Urban runoff diverted into the trench gradually infiltrates from the bottom of the trench into the subsoil and eventually into the ground water. Variations in the design of infiltration trenches include dry wells, pits designed to control small volumes of runoff (such as the runoff from a rooftop), and enhanced infiltration trenches, which are equipped with extensive pretreatment systems to remove sediment and oil. Depending on the quality of the runoff, pretreatment will generally be necessary to lower the failure rate of the trench. More costly than pond systems in terms of cost per unit of runoff treated, infiltration trenches are suited best for drainage areas of less than 5 to 10 acres or where ponds cannot be applied (Schueler et al., 1992).

e. *Vegetated Filter Strips*

Vegetated filter strips are areas of land with vegetative cover that are designed to accept runoff as overland sheet flow from upstream development. They may closely resemble many natural ecotones, such as grassy meadows or riparian forests. Dense vegetative cover facilitates sediment attenuation and pollutant removal. Vegetated filter strips do not effectively treat high-velocity flows and are therefore generally recommended for use in agriculture and low-density development and other situations where runoff does not tend to be concentrated. Unlike grassed swales, vegetated filter strips are effective only for overland sheet flow and provide little treatment for concentrated flows. Grading and level spreaders can be used to create a uniformly sloping area that distributes the runoff evenly across the filter strip (Dillaha et al., 1987). Vegetated filter strips are often used as pretreatment for other structural practices, such as infiltration basins and infiltration trenches. Refer to Chapter 7 of this guidance for additional information.

Filter strips are less effective on slopes of over 15 percent. Periodic inspection, repair, and regrading are required to prevent channelization (Schueler et al., 1992). Inspection is especially important following major storm events. Excessive use of pesticides, fertilizers, and other chemicals should be avoided. To minimize soil compaction, vehicular traffic and excessive pedestrian traffic should be avoided.

A berm of sediment that must be periodically removed may form at the upper edge of grassed filter strips. Mowing of grassed filter strips at a minimum of two to three times per year will maintain a thicker vegetative cover, providing better sediment retention. To avoid impacts on ground-nesting birds, mowing should be limited to spring or fall (USEPA, undated). Harvesting of mowed vegetation will allow for thicker growth and promotes the retention of nutrients that are released during decomposition (Dillaha et al., 1989).

Forested areas directly adjacent to waterbodies should be left undisturbed except for the removal of trees presenting unusual hazards and the removal of small debris near the stream that may be refloated by high water. Periodic harvesting of some trees not directly adjacent to waterbodies removes sequestered nutrients (Lowrance, Leonard, and Sheridan, 1985) and maintains an efficient filter through vigorous vegetation (USEPA, undated). Exposure of forested filter strip soil to direct radiation should be avoided to keep the temperature of water entering waterbodies low, and moist conditions conducive to microbial activities in filter strip soil should be maintained (Nutter and Gaskin, 1989).

f. Grassed Swales

A grassed swale is an infiltration/filtration method that is usually used to provide pretreatment before runoff is discharged to treatment systems. Grassed swales are typically shallow, vegetated, man-made ditches designed so that the bottom elevation is above the water table to allow runoff to infiltrate into ground water. The vegetation or turf prevents erosion, filters sediment, and provides some nutrient uptake (USDA-SCS, 1988). Grassed swales can also serve as conveyance systems for urban runoff and provide similar benefits.

The swale should be mowed at least twice each year to stimulate vegetative growth, control weeds, and maintain the capacity of the system. It should never be mowed shorter than 3 to 4 inches. The established width should be maintained to ensure the continued effectiveness and capacity of the system (Bassler, undated).

g. Porous Pavement and Permeable Surfaces

Porous pavement, an alternative to conventional pavement, reduces much of the need for urban runoff drainage conveyance and treatment off-site. Instead, runoff is diverted through a porous asphalt layer into an underground stone reservoir. The stored runoff gradually exfiltrates out of the stone reservoir into the subsoil. Many States no longer promote the use of porous pavement because it tends to clog with fine sediments (Washington Department of Ecology, 1991). A vacuum-type street sweeper should be used to maintain porous pavement.

Permeable paving surfaces such as modular pavers, grassed parking areas, and permeable pavements may also be employed to reduce runoff volumes and trap vehicle-generated pollutants (Pitt, 1990; Smith, 1981); however, care should be taken when selecting such alternatives. The potential for ground-water contamination, compaction, or clogging due to sedimentation should be evaluated during the selection process. (NOTE: These practices should be selected only in cases where proper operation and maintenance can be guaranteed due to high failure rates without proper upkeep.)

h. Concrete Grid Pavement

Concrete grid pavement consists of concrete blocks with regularly interdispersed void areas that are filled with pervious materials, such as gravel, sand, or grass. The blocks are typically placed on a sand or gravel base and designed to provide a load-bearing surface that is adequate to support vehicles, while allowing infiltration of surface water into the underlying soil.

i. Water Quality Inlets

Water quality inlets are underground retention systems designed to remove settleable solids. Several designs of water quality inlets exist. In their simplest form, catch basins are single-chambered urban runoff inlets in which the bottom has been lowered to provide 2 to 4 feet of additional space between the outlet pipe and the structure bottom for collection of sediment. Some water quality inlets include a second chamber with a sand filter to provide additional removal of finer suspended solids by filtration. The first chamber provides effective removal of coarse particles and helps prevent premature clogging of the filter media. Other water quality inlets include an oil/grit separator. Typical oil/grit separators consist of three chambers. The first chamber removes coarse material and debris; the second chamber provides separation of oil, grease, and gasoline; and the third chamber provides safety relief should blockage occur (NVPDC, 1980). While water quality inlets have the potential to perform effectively, they are not recommended. Maintenance and disposal of trapped residuals and hydrocarbons must occur regularly for these devices to work. No acceptable clean-out and disposal techniques currently exist (Schueler et al., 1992).

j. Extended Detention Ponds

Extended detention (ED) ponds temporarily detain a portion of urban runoff for up to 24 hours after a storm, using a fixed orifice to regulate outflow at a specified rate, allowing solids and associated pollutants the required time to settle out. The ED ponds are normally "dry" between storm events and do not have any permanent standing water. These basins are typically composed of two stages: an upper stage, which remains dry except for larger storms, and a lower stage, which is designed for typical storms. Enhanced ponds are equipped with plunge pools near the inlet, a micropool at the outlet, and an adjustable reverse-sloped pipe as the ED control device (orifice) (NVPDC, 1980; Schueler et al., 1992). Temporary and most permanent ED ponds use a riser with an antivortex trash rack on top to control trash.

k. Wet Ponds

Wet ponds are basins designed to maintain a permanent pool of water and temporarily store urban runoff until it is released at a controlled rate. Enhanced designs include a forebay to trap incoming sediment where it can easily be removed. A fringe wetland can also be established around the perimeter of the pond.

l. Constructed Wetlands

Constructed wetlands are engineered systems designed to simulate the water quality improvement functions of natural wetlands to treat and contain surface water runoff pollutants and decrease loadings to surface waters. Where site-specific conditions allow, constructed wetlands or sediment retention basins should be located to have a minimal impact on the surrounding areas. (The State of Washington requires that constructed wetlands be located in uplands (Washington Department of Ecology, 1992).) In addition, constructed urban runoff wetlands differ from artificial wetlands created to comply with mitigation requirements in that they do not replicate all of the ecological functions of natural wetlands. Enhanced designs may include a forebay, complex microtopography, and pondscaping with multiple species of wetland trees, shrubs, and plants. Additional information on constructed wetlands is provided in Chapter 7.

m. Filtration Basins and Sand Filters

Filtration basins are impoundments lined with filter media, such as sand or gravel. Urban runoff drains through the filter media and perforated pipes into the subsoil. Detention time is typically 4 to 6 hours. Sediment-trapping structures are typically used to prevent premature clogging of the filter media (NVPDC, 1980; Schueler et al., 1992).

Sand filters are a self-contained bed of sand to which the first flush of runoff water is diverted. The runoff percolates through the sand, where colloidal and particulate materials are strained out by the cake of solids that forms, or is placed, on the surface of the media. Water leaving the filter is collected in underground pipes and returned to the stream or channel. A layer of peat, limestone, and/or topsoil may be added to improve removal efficiency.

VOL 12

9598

■ ***n. Educate the public about the importance of runoff management facilities.***

"... the value of a comprehensive public information and education program cannot be overemphasized. Such a program must explain the basis, purpose, and details of the proposal and must convince the public and their elected officials that it is both necessary to implement and beneficial to their interests. It must also explain the fundamentals of storm water management facilities, the vital role they play in our lives, and their need for regular maintenance. This information can be presented through flyers, brochures, posters, and other educational aids. Work sessions and field trips can also be conducted. Signs at facility sites can also be erected. Finally, presentations to planning boards, municipal councils and committees, and county freeholders by storm water management experts can also be of great assistance" (New Jersey, undated).

5. Effectiveness and Cost Information

The box and whisker plot in Figure 4-3 summarizes efficiencies for selected structural TSS removal practices, as reported by Schueler et al., 1992. The whiskers of each box represent the range of reported TSS removal efficiencies. The box ends delimit the 25th and 75th percentiles. The horizontal line represents the median, or 50th percentile. Circles represent outliers. Figure 4-3 and Table 4-7 illustrate the range of removal efficiencies, based on monitoring and modeling studies, for total suspended solids for several of the structural practices. The reviewed literature reported a median TSS removal efficiency above 80 percent for three practices—constructed wetlands, wet ponds, and filtration basins. However, it has been reported that the other practices are capable of achieving 80 percent TSS removal efficiency when properly designed, sited, operated, and maintained. More detailed information on the removal efficiencies of the practices and factors influencing the removal efficiencies is presented in Table 4-7. Costs of the practices are shown in Table 4-8.

In many cases, a systems approach to best management practice (BMP) design and implementation may be more effective. By applying multiple practices, enhanced runoff attenuation, conveyance, pretreatment, and treatment may be attained (Schueler et al., 1992). In addition, regionalization of systems (installing and maintaining a BMP or BMPs for more than one development site) may prove more efficient and cost-effective due to the economies of scale of operating one large system versus several smaller systems.

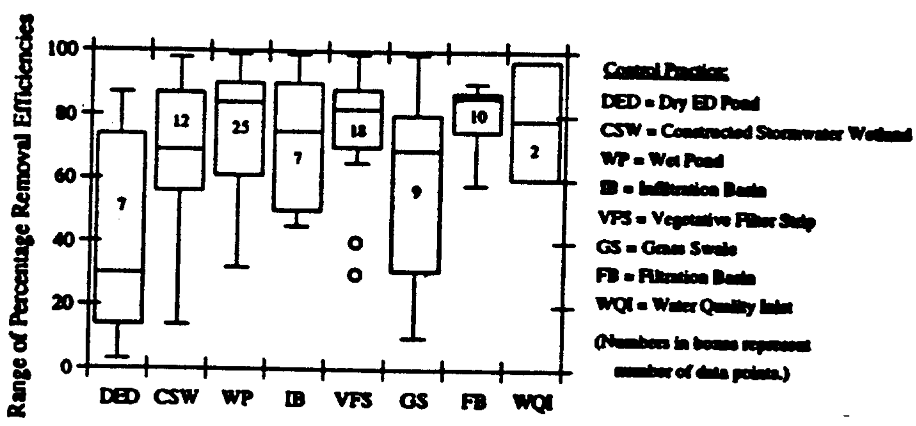

Figure 4-3. Removal efficiencies of selected urban runoff controls for TSS (adapted from Schueler et al., 1992).

Watershed Protection Management Measure

Develop a watershed protection program to:

(1) Avoid conversion, to the extent practicable, of areas that are particularly susceptible to erosion and sediment loss;

(2) Preserve areas that provide important water quality benefits and/or are necessary to maintain riparian and aquatic biota; and

(3) Site development, including roads, highways, and bridges, to protect to the extent practicable the natural integrity of waterbodies and natural drainage systems.

1. Applicability

This management measure is intended to be applied by States to new development or redevelopment including construction of new and relocated roads, highways, and bridges that generate nonpoint source pollutants. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The purpose of this management measure is to reduce the generation of nonpoint source pollutants and to mitigate the impacts of urban runoff and associated pollutants that result from new development or redevelopment, including the construction of new and relocated roads, highways, and bridges. The measure is intended to provide general goals for States and local governments to use in developing comprehensive programs for guiding future development and land use activities in a manner that will prevent and mitigate the effects of nonpoint source pollution.

A watershed is a geographic region where water drains into a particular receiving waterbody. As discussed in the introduction, comprehensive planning is an effective nonstructural tool available to control nonpoint source pollution. Where possible, growth should be directed toward areas where it can be sustained with a minimal impact on the natural environment (Meeks, 1990). Poorly planned growth and development have the potential to degrade and destroy entire natural drainage systems and surface waters (Mantel et al., 1990). Defined land use designations and zoning direct development away from areas where land disturbance activities or pollutant loadings from subsequent development would severely impact surface waters. Defined land use designations and zoning also protect environmentally sensitive areas such as riparian areas, wetlands, and vegetative buffers that serve as filters and trap sediments, nutrients, and chemical pollutants. Refer to Chapter 7 for a thorough description of the benefits of wetlands and vegetative buffers.

Areas such as streamside buffers and wetlands may also have the added benefit of providing long-term pollutant removal capabilities without the comparatively high costs usually associated with structural controls. Conservation or preservation of these areas is important to water quality protection. Land acquisition programs help to preserve areas critical to maintaining surface water quality. Buffer strips along streambanks provide protection for stream ecosystems and help to stabilize the stream and prevent streambank erosion (Holler, 1989). Buffer strips protect and maintain near-stream vegetation that attenuates the release of sediment into stream channels and prevent excessive loadings. Levels of suspended solids increase at a slower rate in stream channel sections with well-developed riparian vegetation (Holler, 1989).

The availability of infrastructure specifically sewage treatment facilities, is also a factor in watershed planning. If centralized sewage treatment is not available, onsite disposal systems (OSDS) most likely will be used for sewage treatment. Because of potential ground-water and surface water contamination from OSDS, density restrictions may be needed in areas where OSDS will be used for sewage treatment. Section VI of this chapter contains a more detailed discussion of siting densities for OSDS.

3. Management Measure Selection and Effectiveness Information

This measure was selected for the following reasons:

(1) Watershed protection is a technique to provide long-term water quality benefits, and many States and local communities already use this practice. Numerous State and local governments have already legislated and implemented detailed watershed planning controls that are consistent with this management measure. For example, Oregon, New Jersey, Delaware, and Florida have passed legislation that requires county and municipal governments to adopt comprehensive plans, including requirements to direct future development away from sensitive areas. Several municipalities and regions, in addition to those in these States, have adopted land use and growth controls, including Amherst, Massachusetts, the Cape Cod region, Norwood, Massachusetts, and Narragansett, Rhode Island.

(2) Setting general water quality objectives oriented toward protection of environmentally sensitive areas and areas that provide water quality benefits allows States flexibility in the pursuit of widely differing water quality priorities and reduces potential conflicts that may arise due to existing State or local program goals and requirements. Although public comments on the May 1991 draft guidance suggested that much more specific criteria should be required, such as minimum setbacks from waterbodies, prohibitions on development on slopes in excess of 45 degrees, and bans on development in floodplains, such prescriptive measures are deemed unreasonable given the need for State and local determination of priorities and program direction.

(3) This measure is effective in producing long-term water quality benefits and lacks the high operation and maintenance costs associated with structural controls.

By protecting those areas necessary for maintaining surface water quality in a natural or near natural state, adverse impacts can be reduced. To illustrate the effectiveness of this management measure, two case studies are presented.

CASE STUDY 1 - RHODE RIVER ESTUARY, CHESAPEAKE BAY, MARYLAND

An evaluation of the impact of the Maryland Critical Area Act on nonpoint source pollution (nutrients and sediment) in surface runoff was completed by modeling three land use scenarios and determining the relative change in nonpoint loadings from the Rhode River Critical Area. Research findings suggest that the implementation of the Act will reduce nonpoint source nutrient and sediment loading by mandating agricultural and urban best management practices (BMPs) and limiting development in forested lands. Figure 4-4 illustrates the predicted nitrogen and phosphorus loadings from various land uses within the watershed under various development scenarios. These predictions are based on the assumption that no structural BMPs are in place.

New development allowed by the Critical Area Act is required to minimize impervious surfaces and reduce nonpoint source pollution through urban BMPs. Results from this study indicate that by limiting the impervious portion of a building site to 15 percent in the Rhode River Estuary, nutrient loadings could be reduced by one-third when compared to similar development without this practice (Houlihan, 1990).

CASE STUDY 2 - ALAMEDA COUNTY, CALIFORNIA

Pollutant loading estimates can be used to evaluate the effectiveness of land planning on controlling nonpoint source pollution. For example, Alameda County, California, has estimated seven pollutant loadings for seven parameters by type of land use, as shown in Table 4-9. By leaving larger areas in open space—through easements, buffers, clustering, or preserves—the potential pollutant loading to San Francisco Bay can be reduced. For example, it is estimated that if 50 percent of a 100-acre parcel designated for residential development is preserved in open space, pollutant loadings for zinc and total suspended solids can be reduced by 50.24 percent and 49.76 percent, respectively, when compared to residential development of the entire 100-acre parcel.

Table 4-9. Load Estimates for Six Land Uses in Alameda County, California (based on average wet weather load, lb/acre; adapted from Woodward-Clyde, 1991)

Land Use	Cadmium	Chromium	Copper	Lead	Nickel	Zinc	Total Suspended Solids

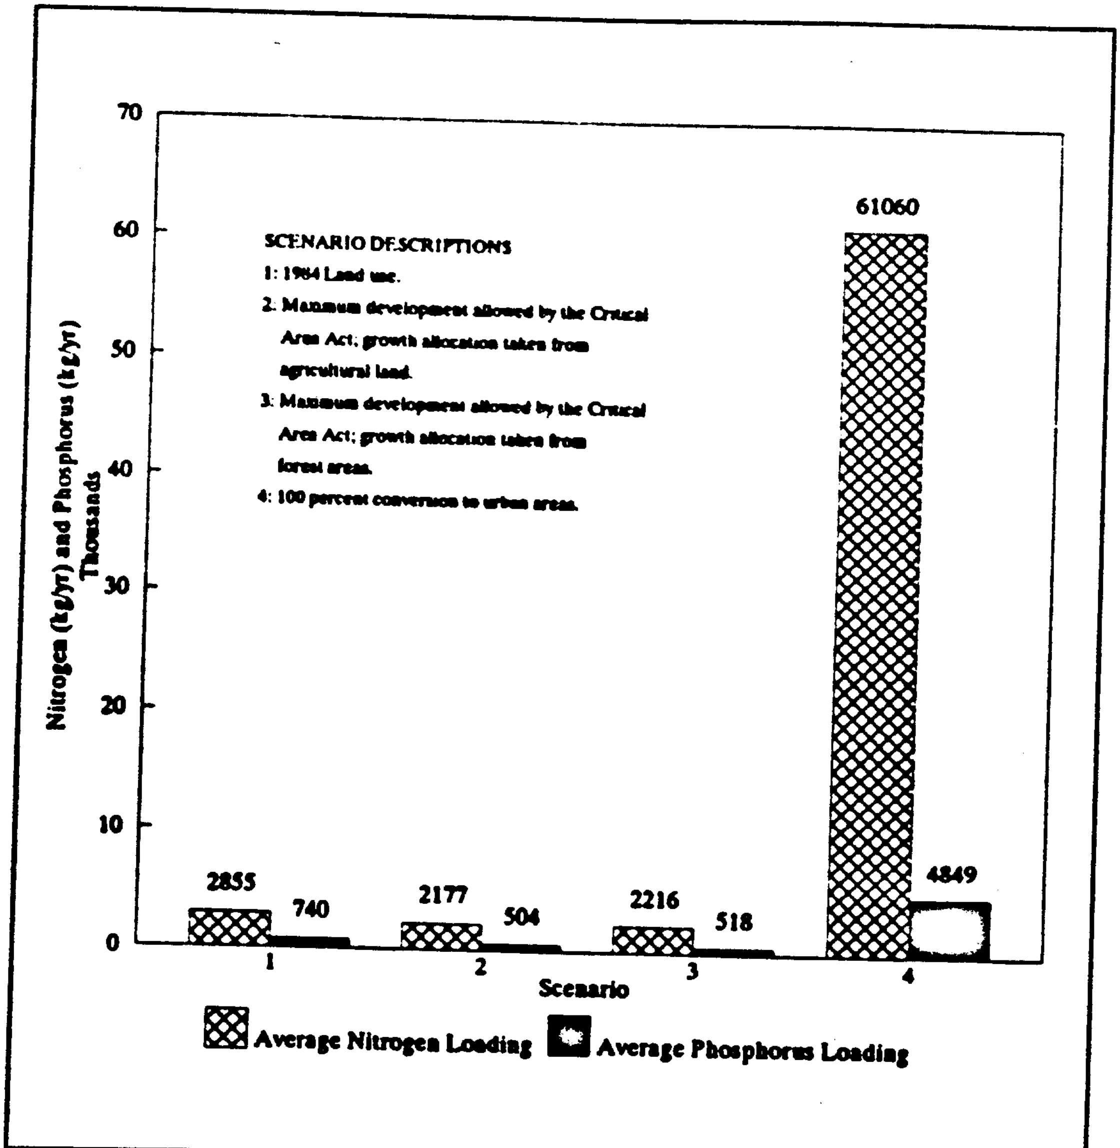

Figure 4-4. Predicted total nitrogen and phosphorus loadings in surface water after runoff from the Rhode River Critical Area under different land use scenarios (Houlihan, 1990).

Considerable uncertainty is associated with the ability to quantify load reductions from various nonstructural practices for controlling nonpoint source pollution (USEPA, 1990). Table 4-10 illustrates the general effectiveness of various planning and site design practices. Many are described in the practices section of this management measure and the Site Development Management Measure.

4. Watershed Protection Practices and Cost Information

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

The most effective way to achieve this management measure is to develop a comprehensive program that incorporates protection of surface waters with programs and plans for guiding growth and development. Planning is an orderly process, and each step builds upon preceding steps. The following practices are part of the process and can be modified to meet the needs of the community. Many of the practices can be incorporated into existing activities being carried out by a local government, such as land planning, zoning, and site plan review. Other activities, such as land acquisition programs, may have to be developed. Where cost and effectiveness information was available, it was included in the discussion of the examples. The general cost and effectiveness of planning programs are described after the practices.

a. *Resource Inventory and Information Analysis*

Before a comprehensive program can be developed, define the watershed boundaries, target areas, and pollutants of concern, and conduct resource inventory and information analysis. These activities can be done by using best available information or collecting primary data, depending on funding availability and the quality of available data. Activities pursued under this process include: assessment of ground-water and surface water hydrology; evaluation of soil type and ground cover; identification of areas with water quality impairments; and identification of environmentally sensitive areas, such as steep or erodible uplands, wetlands, riparian areas, floodplains, aquifer recharge areas, drainage ways, and unique geologic formations. Once environmentally sensitive areas are identified, areas that are integral to the protection of surface waters and the prevention of nonpoint source pollution can be protected.

The following are examples of resource inventory and information analysis programs:

LOCATION	PROGRAM	COST
City of Virginia Beach, Virginia	Three-phase natural areas inventory to help planners and public officials develop practices for resource protection	Phase I (data collection) $13,867; Phase II (field inventory) $54,624; and Phase III (final report) $15,225 (Jenkins, 1991).
Richmond County, Virginia	The Richmond County Resource Information System (RIS) was developed to provide a basis for responsible planning and development of shoreline areas. The compilation and mapping of resource information are part of the county's planning and zoning program.	In 1990, the program was supported by a $39,000 Federal Coastal Zone Management Grant, $45,000 from the Chesapeake Bay Foundation through a Virginia Environmental Endowment Grant, and $96,000 from the county's comprehensive plan budget (Jenkins, 1991).

b. *Development of Watershed Management Plan*

The resource inventory and information analysis component provides the basis for a watershed management plan. A watershed management plan is a comprehensive approach to addressing the needs of a watershed, including land use, urban runoff control practices, pollutant reduction strategies, and pollution prevention techniques.

For a watershed management plan to be effective, it should have measurable goals describing desired outcomes and methods for achieving the goals. Goals, such as reducing pollutant loads to surface water by 25 percent, can be articulated in a watershed management plan. Development and implementation of urban runoff practices, both structural and nonstructural, can be incorporated as methods for achieving the goal. Table 4-11 describes the general steps for developing a watershed management plan.

Table 4-11. Watershed Management: A Step-by-Step Guide (Livingston and McCarron, 1992)

1. **Delineate and map watershed boundary and sub-basins within the watershed.**

2. **Inventory and map natural storm water conveyance and storage systems.**

3. **Inventory and map man-made storm water conveyance and storage system.**
   This includes all ditches, swales, storm sewers, detention ponds, and retention areas and includes information such as size, storage capacity, and age.

4. **Inventory and map land use by sub-basin.**

5. **Inventory and map detailed soils by sub-basin.**

6. **Establish a clear understanding of water resources in the watershed.**
   Analyze water quality, sediment, and biological data. Analyze subjective information on problems (such as citizen complaints). Evaluate waterbody use impairment–frequency, timing, seasonality of problem. Conduct water quantity assessment–low flows, seasonality.

7. **Inventory pollution sources in the watershed.**
   Point sources—location, pollutants, loadings, flow, capacity, etc. Nonpoint sources—type, location, pollutants, loading, etc.
   - land use/loading rate analysis for storm water;
   - sanitary survey for septic tanks;
   - dry flow monitoring to locate illicit discharges

8. **Identify and map future land use by sub-basin.**
   Conduct land use loading rate analyses to assess potential effects of various land use scenarios.

9. **Identify planned infrastructure improvements—5-year, 20-year.**
   Stormwater management deficiencies should be coordinated and scheduled with other infrastructure or development projects.

10. **Analysis.**
    Determine infrastructure and natural resources management needs within each watershed.

11. **Set resource management goals and objectives.**
    Before corrective actions can be taken, a resource management target must be set. The target can be defined in terms of water quality standards; attainment and preservation of beneficial uses; or other local resource management objectives.

12. **Determine pollutant reduction (for existing and future land uses) needed to achieve water quality goals.**

13. **Select appropriate management practices (point source, nonpoint source) that can be used to achieve the goal.**
    Evaluate pollutant removal effectiveness, land owner acceptance, financial incentives and costs, availability of land operation and maintenance needs, feasibility, and availability of technical assistance.

14. **Develop watershed management Plan.**
    Since the problems in each watershed will be unique, each watershed management plan will be specific. However, all watershed plans will include elements such as:
    - existing and future land use plan;
    - master storm water management plan that addresses existing and future needs;
    - wastewater management plan including septic tank maintenance programs;
    - infrastructure and capital improvements plan

Development of a watershed management plan may involve establishing general land use designations that define allowable activities on a parcel of land. For example, land designated for low-density residential use would be limited to a density of two houses per acre, provided that all other regulations and requirements are met. All development activities allowed in a use category should be defined. By guiding uses within the planning areas, impacts to surface waters from urban runoff can be controlled. Those areas identified in the resource inventory and information analysis phase as environmentally sensitive and important to maintaining water quality can be preserved through various measures supported by State or local goals, objectives, and policies.

The following are examples of plan development:

LOCATION	PROGRAM	COST
Florida	• Local governments (counties and incorporated municipalities) were required to develop comprehensive plans based on existing information to guide growth and development in the short term (5 years) and long term (20 to 25 years). • Local plans must be consistent with the State plan and the State Growth Management law. • Each plan must identify environmentally sensitive areas and areas with water quality problems.	Cost information specific to those parts of the plans relating to NPS pollution was not available.
Fairfax County, Virginia	• The Environmental Quality Corridor (EQC) System was established to preserve floodplains, wetlands, shoreline areas, and steep valley slopes. • EQCs are defined in the county's comprehensive plan and identified on the county land use map. • If a parcel of land subject to a zoning or land use designation change contains an EQC, it is set aside by the developer as part of development approval. Since its initiation, tens of thousands of acres have been set aside through the EQC program.	The cost of implementing the program is part of the operating budget of the County Planning Department (Fairfax County Planning Department, personal communication, 1991).
Howard County, Maryland	• A Land Preservation and Recreation Plan was developed as part of the county comprehensive plan. • Open space resources are purchased for preservation and recreation.	The annual cost to update the plan, $25,000, is funded by the State. In FY 1990, the county received $1.14 million in State funds to update the plan and to acquire land (Jenkins, 1991).

c. Plan Implementation

Once critical areas have been identified, land use designations have been defined, and goals have been established to guide activities in the watershed, implementation strategies can be developed. At this point, the requirements of future development are defined. These requirements include, but are not limited to, permitted uses, construction techniques, and protective maintenance measures. Land development regulations may also prescribe natural performance standards; for example, "rates of runoff or soil loss should be no greater than predevelopment

VOL 12

9508

R0042914

conditions" (USEPA, 1977). Listed below are examples of the types of development regulations and other implementation tools that have been successful at controlling nonpoint source pollution.

- *Development of ordinances or regulations requiring NPS pollution controls for new development and redevelopment.*

  These ordinances or regulations should address, at a minimum:

  (1) Control of off-site urban runoff discharges (to control potential impacts of flooding);

  (2) The use of source control BMPs and treatment BMPs;

  (3) The performance expectations of BMPs, specifying design storm size, frequency, and minimum removal effectiveness, as specified by the State or local government;

  (4) The protection of stream channels, natural drainage ways, and wetlands;

  (5) Erosion and sediment control requirements for new construction and redevelopment; and

  (6) Treatment BMP operation and maintenance requirements and designation of responsible parties.

- *Infrastructure planning*

  Infrastructure planning is the multiyear scheduling and implementation of public physical improvements (infrastructure), such as roads, sewers, potable water delivery, landfills, public transportation, and urban runoff management facilities. Infrastructure planning can be an effective practice to help guide development patterns away from areas that provide water quality benefits, are susceptible to erosion, or are sensitive to disturbance or pollutant loadings. Where possible, long-term comprehensive plans to prevent the conversion of these areas to more intensive land uses should be drafted and adopted. Infrastructure should be planned for and sited in areas that have the capacity to sustain environmentally sound development. Development tends to occur in response to infrastructure availability, both existing and planned. New development should be targeted for areas that have adequate infrastructure to support growth in order to promote infill development, prevent urban sprawl, and discourage the use of septic tanks where they are inappropriate (International City Management Association, 1979). Infill development may have the added advantage of municipal cost savings.

  To discourage development in the environmentally sensitive East Everglades area, Dade County, Florida, has developed an urban services boundary (USB). In areas outside the USB, the county will not provide infrastructure and has kept land use densities very low. This strategy was selected to prevent urban sprawl, protect the Everglades wetlands (outside of Everglades National Park), and minimize the costs of providing services countywide. The area is defined in the county comprehensive plan, and restrictions have been implemented through the land development regulations (Metro-Dade Comprehensive Development Master Plan, 1988).

  Congress has enacted similar legislation for the protection of coastal barrier islands. In 1981, the availability of Federal flood insurance for new construction on barrier islands was discontinued. In 1982, Congress passed the Coastal Barriers Resources Act, establishing the Coastal Barrier Resource System (CBRS), and terminated a variety of Federal assistance programs for designated coastal barriers, including grants for new water, sewage, and transportation systems. In 1988, similar legislation was passed for the Great Lakes area, adding 112 Great Lakes barrier islands. Additions to the CBRS in 1990 included parts of the Florida Keys, the U.S. Virgin Islands, Puerto Rico, and the Great Lakes (Simmons, 1991).

The result of the legislation and subsequent additions to the CBRS has been the establishment of 1,394,059 acres of barriers that are ineligible for Federal assistance for infrastructure and flood insurance (Simmons, 1991). This Act has helped to guide development away from these sensitive coastal areas to more suitable locations.

- *Local ordinances*

Zoning is the division of a municipality or county into districts for the purpose of regulating land use. Usually defined on a map, the allowable uses within each zone are described in an official document, such as a zoning ordinance. Zoning is enacted for a variety of reasons, including preservation of environmentally sensitive areas and areas necessary to maintain the environmental integrity of an area (International City Management Association, 1979).

Within zoning ordinances, subdivision regulations govern the process by which individual lots of land are created out of larger tracts. Subdivision regulations are intended to ensure that subdivisions are appropriately related to their surroundings. General site design standards, such as preservation of environmentally sensitive areas, are one example of subdivision regulations (International City Management Association, 1979).

Farmland preservation ordinances are another measure that can be implemented to provide open space retention, habitat protection, and watershed protection. Farmland protection may be a less costly means of controlling pollutant loadings than the implementation of urban runoff structural control practices. Much of the farmland currently being converted has soils that are stable and not highly erodible. Conversion of these farmlands often displaces farming activities to less productive, more erodible areas that may require increased nutrient and pesticide applications.

- *Limits on impervious surfaces, encouragement of open space, and promotion of cluster development*

As described earlier, urban runoff contains high concentrations of pollutants washed off impervious surfaces (roadways, parking lots, loading docks, etc.). By retaining the greatest area of pervious surface and maximizing open space, nonpoint source pollution due to runoff from impervious surfaces can be kept to a minimum.

The following are examples of open space requirements and cluster development:

LOCATION	PROGRAM	COST
Brunswick, Maine	• Recently adopted an allowable impervious area threshold of 5 percent of the site to be developed in the defined Coastal Protection Zone. • The remaining 95 percent must be left natural or landscaped.	Accomplished with a $28,000 grant (Brunswick Planning Department, personal communication, 1991).
Commonwealth of Virginia	• Provides general guidance with regard to minimum open space/maximum impervious areas to local governments within the Chesapeake Bay watershed. • While specific requirements are not associated with the guidance, local government plans must contain criteria and must be approved by the Chesapeake Bay Local Assistance Board.	Cost information specific to those parts of the guidance relating to NPS pollution was not available.

LOCATION	PROGRAM	COST
Carroll County, Maryland	• Amended its zoning ordinance to encourage cluster development and preserve open space. • This requirement has been applied to three subdivisions in the county and has resulted in the protection of more than 200 acres of wetlands (Carroll County Planning Department, personal communication, 1991).	Developed using existing county staff and funding.
State of Maryland	• Adopted the Forest Conservation Act of 1991. • Requires all public agency and private landowner submitting a subdivision plan or application for a sediment control permit for an area greater than 40,000 square feet to develop a forest conservation plan for retention of existing forest cover on the site. • Clearing essential to site development is allowed. • The Act also established a forest conservation fund for reforestation projects.	Not available.
Broward County, Florida	• Implements an open space program and encourages cluster development to reduce the amount of impervious surface, to protect water quality, and to enhance aquifer recharge (Broward County, Florida, Land Development Code, 1990).	Developed using existing county staff and funding.
New Hampshire	• Model shoreland protection ordinance. • Encourages grouping of residential units provided a minimum of 50 percent of the total parcel remains as open space.	Not available.

One way to increase open space while allowing reasonable development of land is to encourage cluster development. Clustering entails decreasing the allowable lot size while maintaining the number of allowable units on a site. Such policies provide planners the flexibility to site buildings on more suitable areas of the property and leave environmentally sensitive areas undeveloped. Criteria can be varied.

- *Setback (buffer zone) standards*

In coastal areas, setbacks or buffer zones adjacent to surface waterbodies, such as rivers, estuaries, or wetlands, provide a transition between upland development and waterbodies. The use of setbacks or buffer zones may prevent direct flow of urban runoff from impervious areas into adjoining surface waters and provide pollutant removal, sediment attenuation, and infiltration. Riparian forest buffers function as filters to remove sediment and attached pollutants, as transformers that alter the chemical composition of compounds, as sinks that store nutrients for an extended period of time, and as a source of energy for aquatic life (USEPA, 1992). Setbacks or buffer zones are commonly used to protect coastal vegetation and wildlife corridors, reduce exposure to flood hazards, and protect surface waters by reducing and cleansing urban runoff (Mantell et al., 1990). The types of development allowed in these areas are usually limited to nonhabitable structures and those necessary to allow reasonable use of the property (docks, nonenclosed gazebos, etc.).

Factors for delineating setbacks and buffer zones vary with location and environment and include seasonal water levels, the nature and extent of wetlands and floodplains, the steepness of adjacent topography, the type of riparian vegetation, and wildlife values.

EPA recommends that no habitat-disturbing activities should occur within tidal or nontidal wetlands. In addition, a buffer area should be established that is adequate to protect the identified wetland values. Minimum widths for buffers should be 50 feet for low-order headwater streams with expansion to as much as 200 feet or more for larger streams. In coastal areas, a 100-foot minimum buffer of natural vegetation landward from the mean high tide line helps to remove or reduce sediment, nutrients, and toxic substances entering surface waters (MWCOG, 1991).

Examples of setback or buffer requirements include the following:

LOCATION	PROGRAM	COST
Monroe County, Florida	• Requires a setback of 20 feet from high water on man-made or lawfully altered shorelines for all enclosed structures and 50 feet from the landward extent of mangroves or mean high tide line for natural waterbodies with unaltered shorelines (Monroe County, Florida, Code, Section 9.5-286).	Developed using existing county staff and funding.
Town of Brunswick, Maine	• Requires a buffer of 125 to 300 feet from mean high water within the Coastal Protection Zone (Section 315 of the Brunswick Zoning Ordinance), depending on the slope of the buffer, as designated on the land use map.	Developed using a $28,000 grant (Brunswick Planning Department, personal communication, 1991).
Queen Annes County, Maryland	• Established a standard shore buffer of 300 feet from the edge of tidal water or wetland, 50 percent of which must be forested.	Developed using existing county staff and funding; a bond of surety to cover the cost of implementation is required prior to development (Jenkins, 1991).
Maryland Critical Areas Regulations	• Requires a 25-foot buffer around nontidal wetlands and 100 feet landward of mean high water in tidal areas. • Allowable uses within the setback area are defined in the regulations (Chesapeake Bay Critical Areas Commission, 1988).	Developed as part of the Chesapeake Bay Critical Areas program.
City of Alexandria, Virginia	• Buffers are required as part of the city's Chesapeake Bay Preservation Ordinance. • Applies to all designated Resource Protection Areas (RPAs). • The buffer must achieve 75 percent reduction of sediments and 40 percent reduction of nutrients (100-foot-wide buffer is considered adequate to achieve this standard; smaller widths may be allowed if they are proven to meet the sediment and nutrient removal requirements). • Indigenous vegetation removal is limited to that necessary to provide reasonable sight lines, access paths, general woodlot management, and BMP implementation.	Not available.

LOCATION	PROGRAM	COST
Northeastern Illinois Planning Commission	• Model ordinance • Suggests 75-foot setback from the ordinary high watermark of streams, lakes, ponds, and edge of wetlands or the boundary of the 100-year floodplain (as defined by FEMA), whichever is greater. • Suggests a minimum 25-foot-wide natural vegetation strip from the ordinary highwater mark of perennial and intermittent streams, lakes, ponds, and the edge of wetlands.	Not available

- ***Slope restrictions***

Slope restrictions can be effective tools to control erosion and sediment transport. Erosion rates depend on several site-specific factors including soil type, vegetative cover, and rainfall intensity. In general, as slope increases, there is a corresponding increase in runoff water velocity, which may result in increased erosion and sediment transport to surface waters (Schwab et al., 1981; Dunn and Leopold, 1978). The Maryland Chesapeake Bay Critical Areas Program prohibits clearing on slopes greater than 25 percent (Chesapeake Bay Critical Areas Commission, 1988).

- ***Site plan reviews and approval***

A site plan review involves review of specific development proposals for consistency with the laws and regulations of the local government of jurisdiction. To ensure that natural resources necessary for protecting surface water quality are preserved, inspection of a potential development site should occur. Inspection ensures that the information presented in any application for development approval is accurate and that sensitive areas are noted for preservation. Inspections should also be conducted during and after development to ensure compliance with development conditions. Depending on the size of the local government and the amount of new development occurring, this inspection could be incorporated into the duties of existing staff at minimal additional cost to the local government or could require the addition of staff to conduct onsite inspections and monitoring. The effectiveness of such a program depends on the ability of the inspectors to evaluate property for its natural resource value and the practices used to protect areas necessary for the preservation of water quality.

Development approvals should contain conditions requiring steps to be taken to maintain the environmental integrity of the area and prevent degradation due to nonpoint source pollution, consistent with the goals, objectives, and policies of the comprehensive program and the requirements of the land development regulations. The criteria for new development are outlined as part of a development permit. Examples include the following:

- Areas for preservation or mitigation may be identified, similar to the Fairfax County Environmental Quality Corridor System (page 44).

- The use of nonstructural and structural best management practices described in this chapter for controlling nonpoint source pollution may be a condition of development approval.

- Setbacks and limits on impervious areas may be clearly defined in a condition for development approval, as is being done in the programs discussed earlier such as Monroe County, Florida, Queen Annes County, Maryland, State of Maryland Critical Areas Program, Town of Brunswick, Maine, and the Northeastern Illinois Planning Commission (pages 48 and 49).

- Reduce the use of pesticides and fertilizers on landscaped areas by encouraging the use of vegetation that is adaptable to the environment and requires minimal maintenance. (Xeriscaping is described later in this chapter.)

- *Designation of an entity or individual who is responsible for maintaining the infrastructure, including the urban runoff management systems*

  The responsible party should be trained in the maintenance and management of urban runoff management systems. If desired, the local government could be designated to maintain urban runoff systems, with financial compensation from the developer. Because they are not usually trained in infrastructure maintenance, homeowners groups are not the best entity for monitoring infrastructure for adequacy, especially urban runoff management systems. This responsibility should belong to a responsible party who understands the complexity of urban runoff management systems, can determine when such systems are not functioning properly, and has the resources to correct the problem. Again, this is a duty that the local government can assume, with either existing staff or additional staff, depending on the size of the local government and the amount of new development occurring. The amount of funding needed depends on the size of the local government.

- *Official mapping*

  Official maps can be used to designate and/or protect environmentally sensitive areas, zoning districts, identified land uses, or other areas that provide water quality benefits. When approved by the local governing body, these maps can be used as legal instruments to make land use decisions related to nonpoint source pollution.

- *Environmental impact assessment statements*

  To evaluate the impact that proposed development may have on the natural resources of an area, some counties and municipalities require an environmental assessment as part of the development approval processes. These assessments can be incorporated into the land development regulation process. Areas to be covered include geology, slopes, vegetation, historical features, wildlife, and infrastructure needs (International City Management Association, 1979).

d. Cost of Planning Programs

Cost information was provided for several of the practices discussed in this section. The cost of planning programs depends on a variety of factors, including the level of effort needed to complete and implement a program. As discussed earlier, many of the practices described in this section can be incorporated into ongoing activities of a State or local government.

The Florida legislature funded the development of comprehensive programs and land development regulations required by the Local Government Comprehensive Planning and Land Development Regulation Act (1985). Distribution of funds was based on population according to formulas used for determining funding for the plan and land development regulations. A base amount was given to all counties that requested it. The balance of the monies was allocated to each county in an amount proportionate to its share of the total unincorporated population of all the counties. A similar distribution process was used for local governments. A total of $2.1 million was allocated for plan development; however, not all components of the plans address NPS issues.

The effect of planning programs depends on many variables, including implementation of programs and monitoring of conformance with conditions of development approval.

5. Land or Development Rights Acquisition Practices and Cost Information

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

An effective way to preserve land necessary for protecting the environmental integrity of an area is to acquire it outright or to limit development rights. The following practices can be used to protect beneficial uses.

■ a. *Fee Simple Acquisition/Conservation Easements*

The most direct way to protect land for preservation purposes and associated nonpoint source control functions is fee simple acquisition, through either purchase or donation. Once a suitable area is identified for preservation, the area may be acquired along with the development rights. The more development rights that are associated with a piece of property, the more expensive the property. Many State and local governments and private organizations have programs for purchasing land.

Conservation easements are restrictions put on property that legally restrict the present and future use of the land. For preservation purposes, the easement holder is usually not the owner of the property and is able to control property rights that a landowner could use that might cause adverse impacts to resources on the property. In effect, the property owner gives up development rights within the easement while retaining fee ownership of the property (Mantell et al., 1990; Barrett and Livermore, 1983).

■ b. *Transfer of Development Rights*

The principle of transfer of development rights (TDR) is based on the concept that ownership of real property includes the ownership of a bundle of rights that goes with it. These rights may include densities granted by a certain use designation, environmental permits, zoning approvals, and others. Certain properties have a bigger bundle of rights than others, depending on what approvals have been received by the owner. The TDR system takes all or some of the rights on one piece of property and moves them to another parcel. The purpose of TDRs is to shift future development potential from an area that is determined to be unsuitable for development (sending site) to an area deemed more suitable (receiving site). The development potential can be measured in a variety of ways, including number of dwelling units, square footage, acres, or number of parking spaces. Most TDR systems require a legal restriction for future development on the sending site. TDR programs can be either fixed so that there are only a certain number of sending and receiving sites in an area or flexible so that a sender and receiver can be matched as the situation allows (Mantell et al., 1990; Barrett and Livermore, 1983).

This system is useful for the preservation of those areas thought necessary for maintaining the quality of surface waters in that development rights associated with the environmentally sensitive areas can be transferred to less sensitive areas. There are several examples in the United States where TDRs have been used. Some of the more successful projects involve preservation of the New Jersey Pine Barrens and the Santa Monica Mountains in California. For the TDR concept to work, receiving and sending sites should be identified and evaluated, a program that is simple and flexible should be developed, and the use of the program should be promoted and facilitated (Mantell et al., 1990).

■ c. *Purchase of Development Rights*

R0042921

VOL 12

9 6 / 5

In this process, the rights of development are purchased while the remaining rights remain with the fee title holder. Restrictions in the deed make it clear that the land cannot be developed based on the rights that have been purchased (Mantell et al., 1990).

Howard County, Maryland, has the goal of preserving 20,000 acres of farmland. Development rights are acquired in perpetuity with one-fourth of one percent of the local land transfer tax used as funding. There is no cap on the percent of assessed value that may be considered development value, and payment for development rights may be spread over 30 years to ease the capital gains tax burden on the landowner (Jenkins, 1991).

d. Land Trusts

Land trusts may be established as publicly or privately sponsored nonprofit organizations with the goal of holding lands or conservation easements for the protection of habitat, water quality, recreation, or scenic value or for agricultural preservation. A land trust may also preacquire properties that are conservation priorities if the land trust enters the development market when government funds are not immediately available by acquiring bank funding with the government as guarantor (Jenkins, 1991).

e. Agricultural and Forest Districts

Agricultural or forest districting is an alternative to acquisition of land or development rights. Jurisdictions may choose to allow landowners to apply for designation of land as an Agricultural or Forest District. Tax benefits are received in exchange for a commitment to maintain the land in agriculture, forest, or open space.

Fairfax County, Virginia, taxes land designated as Agricultural or Forest District based on the present use valuation rather than the usual potential use valuation. A commitment to agricultural or forestry activities must be shown, and sound land management practices must be used. The districts are established and renewed for 8-year periods (Jenkins, 1991).

f. Cost and Effectiveness of Land Acquisition Programs

The cost associated with land acquisition programs varies, depending on the desired outcome. If land is to be purchased, the cost will vary depending on the value of the land. An additional cost to be considered is the maintenance of the property once it is in public ownership. Easements and development rights are less expensive, and maintenance of the property is retained by the owner. Depending on the size of the local government, implementation of these programs is usually part of the operating budget of the appropriate agency (planning department or parks and recreation department, for example) and additional operational funding for implementation is dependent on the size of the local government.

The effectiveness of a land acquisition program is determined by the size of the parcel and the difference between predevelopment and potential postdevelopment pollutant loading rates. In addition, wetlands and riparian areas have been shown to reduce pollutant loadings. The acquisition and preservation of these areas can be extremely important to water quality protection and decrease the cost of implementing structural BMPs. However, the use of wetlands for urban runoff treatment, in general, should be discouraged. Where no other alternative exists, States and local governments can target upland areas for acquisition to minimize the impacts to wetlands and preserve the function of wetlands. One option for acquiring land is a public/private partnership. Several examples of such partnerships exist throughout the country. Harford County, Maryland, has targeted areas for purchase of conservation easements. The county staff is working jointly with a local land trust to acquire conservation easements and to educate people in environmentally sound land use practices. The estimated cost for the program is $60,000 per year (Jenkins, 1991). To aid in the establishment of two local land trusts, Anne Arundel County, Maryland, provided $350,000 in seed money for capital expenditures such as land and easement procurement. The county also gives staff assistance to volunteers; additional support comes from contributions of money or land, grants, and fundraisers (Jenkins 1991).

VOL 12

C. Site Development Management Measure

Plan, design, and develop sites to:

(1) Protect areas that provide important water quality benefits and/or are particularly susceptible to erosion and sediment loss;

(2) Limit increases of impervious areas, except where necessary;

(3) Limit land disturbance activities such as clearing and grading, and cut and fill to reduce erosion and sediment loss; and

(4) Limit disturbance of natural drainage features and vegetation.

1. Applicability

This management measure is intended to be applied by States to all site development activities including those associated with roads, highways, and bridges. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to reduce the generation of nonpoint source pollution and to mitigate the impacts of urban runoff and associated pollutants from all site development, including activities associated with roads, highways, and bridges. Management Measure II.C is intended to provide guidance for controlling nonpoint source pollution through the proper design and development of individual sites. This management measures differs from Management Measure II.A, which applies to postdevelopment runoff, in that Management Measure II.C is intended to provide controls and policies that are to be applied during the site planning and review process. These controls and policies are necessary to ensure that development occurs so that nonpoint source concerns are incorporated during the site selection and the project design and review phases. While the goals of the Watershed Protection Management Measure (II.B) are similar, Management Measure II.C is intended to apply to individual sites rather than watershed basins or regional drainage basins. The goals of both the Site Development and Watershed Protection Management Measures are, however, intended to be complementary and the measures should be used within a comprehensive framework to reduce nonpoint source pollution.

Programs designed to control nonpoint source pollution resulting from site development, both during and after construction, should be developed to include provisions for:

- Site plan review and conditioned approval to ensure that the integrity of environmentally sensitive areas and areas necessary for maintaining surface water quality will not be lost;

R0042923

- Requirements for erosion and sediment control plan review and approval prior to issuance of appropriate development permits; and
- Guidance on appropriate pollution prevention practices to be incorporated into site development and use.

In addition to the preceding provisions, where applicable, the following objectives should be incorporated into the site development process:

- During site development, disturb the smallest area necessary to perform current activities to reduce erosion and offsite transport of sediment;
- Avoid disturbance of unstable soils or soils particularly susceptible to erosion and sediment loss, and favor sites where development will minimize erosion and sediment loss;
- Where appropriate, protect and retain indigenous vegetation to decrease concentrated flows and to maintain site hydrology;
- Minimize, to the extent practicable, the percentage of impervious area on-site;
- Properly manage all maintained landscapes to avoid water quality impacts;
- Avoid alteration, modification, or destruction of natural drainage features on-site; and
- Design sites so that natural buffers adjacent to coastal waterbodies and their tributaries are preserved.

The use of site planning and evaluation can significantly reduce the cost of providing structural controls to retain sediment on the development site. Long-term maintenance burdens may also be reduced. Good site planning not only can attenuate runoff from development, but also can improve the effectiveness of the conveyance and treatment components of an urban runoff management system (MWCOG, 1991).

During the site design process, planners should further identify sensitive areas and land forms that may provide water quality protection. These areas should be targeted for preservation or conservation and incorporated into site design. Highly erodible soils should be avoided. By siting development away from erodible soils, it is possible to significantly reduce the amount of erosion, although soil type, topography, vegetation, and climatological conditions affect the degree of erosion resulting from land disturbance activities both during and after construction. In the United States, it has been estimated that human activity causes the transport of nearly 4 billion tons of sediment annually, one-fourth of which eventually reaches the ocean. Sediment loads from developing areas where new construction is occurring can be 5 to 500 times greater than loadings from undeveloped rural areas (Gray, 1972). Natural erosion rates from forested areas or well-sodded prairies are in the range of 0.1 to 1.0 ton of soil per acre per year (Washington Department of Ecology, 1989). Because many nonpoint source pollutants, including heavy metals and nutrients, adsorb to sediments, it is important to limit the volume of sediment leaving a site and entering surface waters.

The Maryland State Highway Administration has developed initiatives to protect sensitive habitats as part of the governor's program to clean up and preserve the Chesapeake Bay. A selection of these initiatives include the following:

- Use of turbidity curtains to protect sensitive sections of a waterway during construction;
- Inspection and maintenance of runoff controls after every storm event;
- Immediate notification of noncompliance and follow-up inspection, when noncompliance occurs;

- A 72-hour stabilization requirement;
- Oversizing of sediment traps and basins depending on right-of-way constraints;
- Innovative scheduling for paving versus vegetative stabilization and implementation of infiltration practices to reduce thermal impacts;
- Minimal clearing of forest areas; and
- Installation of traps and basins prior to grading (Maryland State Highway Administration, 1990).

3. Management Measure Selection

This management measure was selected because the components of the measure have already been implemented, to varying degrees, by State and local governments. For example, the States of California, Maryland, Delaware, and Florida and the local governments of Montgomery, Prince Georges, and Anne Arundel counties in Maryland have implemented these concepts in State or local ordinances and in erosion and sediment control regulations. This measure is intended to provide States and local governments with general guidance on nonpoint source pollution objectives that can be integrated into the site planning process. The components of the management measure were selected to represent the minimum provisions that State and local governments must implement.

This approach was adopted to use existing programs and staff, thereby reducing administrative burdens and implementation costs as much as possible. A significant number of local governments have programs to oversee and review the site development process. In many communities, the costs of implementing this measure within the scope of existing programs may be nominal.

4. Practices and Cost Information for Control of Erosion During Site Development

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. *Erosion and Sediment Control Plans and Programs*

Structural control measures for reducing impacts from erosion during site construction are discussed in the Construction Management Measure. These practices can be implemented as part of plans established in erosion and sediment control ordinances by local government or State laws. A well-thought-out plan for urban runoff management on construction sites can control erosion, retain sediments on the site, and reduce the environmental effects of runoff. In addition to a plan for BMP use, contractors should develop schedules that minimize the area of exposed soil at any given time, particularly during times of heavy or frequent rains. Table 4-12 lists items that should be considered in an erosion and sediment control (ESC) plan. Table 4-13 contains examples of sediment and erosion control requirements implemented at the State and local levels. All temporary erosion and sediment control practices that will be used during the construction phase should be detailed in architectural or engineering drawings to ensure that they are properly implemented. Inclusion of temporary pollution control practices on construction drawings also ensures that their costs are included in the pricing and bidding process (USEPA, 1973).

R0042925

VOL 12

9619

Table 4-12. Items to Consider in Developing an Erosion and Sediment Control Plan (Adapted from Goldman, 1986)

Item	Description
Schedule grading and construction to minimize soil exposure.	• Schedule projects so clearing and grading are done during the dry season or the time of minimum erosion potential. Many parts of the country have a time of year when erosion potential is relatively low and carefully planned construction scheduling could be very effective. • Stage construction so that one area can be stabilized before another is disturbed. This practice reduces the time that an area is left unstabilized.
Retain existing vegetation wherever feasible.	• Clear only those areas that are essential for completing site construction. • Avoid disturbing vegetation on steep slopes or other critical areas and locate material stockpiles, borrow areas, and access roads away from critical areas. • Route construction traffic to avoid existing or newly planted vegetation. • Physically mark off limits of land disturbance with tape, signs, or barriers. This ensures that the bulldozer operator knows the proposed limits of clearing. • Protect natural vegetation with fencing, tree armoring, retaining walls, or tree walls.
Stabilize all denuded areas within 15 calendar days after final grading. Disturbed areas that are inactive and will be exposed to rain for 30 days or more should also be temporarily stabilized.	• During favorable seeding dates and in areas where vegetation can be established, the following should be implemented: - Use seeding and fertilizing in very flat, nonsensitive areas with favorable soils. - Use seeding and mulching for less erosive soil or on moderately steep slopes with moderately erosive soils in relatively sensitive areas. - Use seeding with multiple mulching treatments or sodding for highly erosive soil, very steep slopes, or sensitive areas with highly erosive soils. • If stabilization is required during the time of year that vegetation cannot be established, implement the following practices: - On moderate slopes or soil that is not highly erodible, mulching should be employed. - On steep slopes or highly erodible soils, multiple mulching treatments should be used. • If in high elevation or desert site where grasses cannot survive due to harsh environment, at a minimum, plant native shrubs. • Before stabilizing an area, make sure necessary controls (e.g., diversion of runoff) are in place. • Where practical, stockpile topsoil and reapply to revegetate site. • Cover or stabilize topsoil stockpiles. • For high potential for wind-blown sediment transport, prior to stabilization protect with dust controls such as wind barriers, mulching, tillage, or sprinkling.
Divert runoff away from denuded areas or newly seeded slopes.	• Above disturbed areas, construct dike or swale or install pipe slope drain to intercept runoff and convey it to a permanent channel or storm drain.
Minimize length and steepness of slopes.	• On long or steep disturbed or man-made slopes, construct benches, terraces, or ditches at regular intervals to intercept runoff.

Table 4-12. (Continued)

Item	Description
Prepare drainageways and outlets to handle concentrated or increased runoff.	• Provide lining for any existing or newly constructed channel on-site or off-site so the 2-year storm channel velocity does not cause erosion. • Check dams should be installed on temporary swales that have erosive velocity but due to their short service life cannot support a vegetative lining.
Trap sediment onsite (sediment controls).	• In areas where greater than 5 acres drain to a point, sediment basin should be installed. • In areas where less than 5 acres of concentrated flow leaves the site, silt traps should be installed. • In areas where sheet flow leaves the site and the drainage area is less than 0.5 ac/100 ft of flow, filter fabric fence should be installed. • In areas where sheet flow leaves the site and the drainage area is greater than 0.5 ac/100 ft of flow, perimeter dikes should be installed and flow should be diverted to a sediment trap or sediment basin. • Install inlet protection around all storm drain inlets. • Install construction entrance (gravel pad to collect mud and sediment from wheels) and route all traffic leaving the site to the construction entrance. • Install all sediment controls prior to grading.
Inspect and maintain control measures.	• Remove sediment from sediment traps and filter fence when silted to half capacity. • Inspect and repair, as needed, all controls after each storm event.

NOTE: These are recommendations only and are not intended to be all-inclusive.

VOL 12

Table 4-13. State and Local Construction Site Erosion and Sediment Control Plan Requirements

State or Local Government	General Requirements
Delaware	State law requires erosion and sediment control plans as part of site development approval on construction sites over 5,000 square feet. The State has adopted an ESC handbook. Temporary or permanent stabilization must occur within 14 calendar days of disturbance.
Florida	State law requires erosion and sediment control plans on all construction sites requiring a storm water management permit.
Maine	State law requires ESC plans for construction sitos adjacent to a wetland or waterbody. Measures should ensure that soil is stabilized to prevent erosion of shoreline and siltation of the waterbody. The ESC must prevent the wash of materials into surface waters. Sites must be stabilized at completion of construction or if there is no activity for 7 calendar days. If temporary stabilization is used, permanent stabilization must occur within 30 calendar days; if not, permanent stabilization is required upon completion of construction.
Maryland	State law requires ESC plans for all construction sites over 5,000 square feet. If there is no activity on a construction site for 14 calendar days, the site must be seeded. Permanent stabilization must occur within 7 calendar days.
Michigan	State law requires ESC plans for sites over 1 acre or within 500 feet of a waterbody. Permanent stabilization must occur within 15 calendar days of final grading. Temporary stabilization is required within 30 days if construction activity ceases.
New Jersey	State law requires ESC plans for sites over 5,000 square feet.
North Carolina	State law requires ESC plans on construction sites over 1 acre. Controls must be sufficient to retain the sediment generated by land disturbance activities. Stabilization must occur within 30 working days of completion of any phase of development.
Ohio	State law requires ESC plans for sites larger than 5 acres. Permanent stabilization must occur within 7 calendar days of final grading or when there has been no construction activity on the site for 45 days.
Pennsylvania	State law requires ESC plans for all development; however, the State reviews only plans for sites greater than 25 acres. Sites must be stabilized as soon as possible after grading. Temporary stabilization is required within 70 days if the site will be inactive for more than 30 days. Permanent stabilization is required if the site will be inactive for more than 1 year.
South Carolina	State law requires an ESC plan for all residential, commercial, industrial, or institutional land use, unless specifically exempted. Perimeter controls must be installed, and temporary or permanent stabilization is required for topsoil stockpiles and all other disturbed areas within 7 calendar days of site disturbance.
Virginia	For areas within the jurisdiction of the Chesapeake Bay Preservation Act, no more land is to be disturbed than is necessary to provide for the allowed development. Indigenous vegetation must be preserved to the greatest extent possible.
Washington	State law mandated development of a State storm water management plan, including erosion control provisions. In response, the Department of Ecology is to develop construction activity regulations.

9622

Table 4-13. (Continued)

State or Local Government	General Requirements
King County, WA	King County Code requires submission of a comprehensive plan in accordance with BMPs in King County Conservation District's publication, *Construction and Water Quality: A Guide to Recommended Construction Practices for the Control of Erosion and Sedimentation in King County.*
City of Bellevue, WA	A Temporary Erosion/Sedimentation Control Plan is required for any construction requiring a storm water detention facility or a Clearing and Grading Permit.
Puget Sound Basin, WA	Program Implementation Guidance requires all exposed and unworked soils to be stabilized by suitable application of BMPs. From October 1 to April 30, no soils shall remain unstabilized for more than 2 days. From May 1 to September 30, no soils shall remain unstabilized for more than 7 days. Prior to leaving the site, stormwater runoff shall pass through a sediment pond or sediment trap, or other appropriate BMPs.
Wisconsin	State law requires ESC plans for sites over 4,000 square feet. Permanent or temporary stabilization is required within 7 days.
Colleton County, SC	The county Development Standards Ordinance requires that BMPs be used during development or land-disturbing activity affecting greater than 1 acre. The State's guidelines for BMPs are adopted by reference.
Birmingham, AL	Through the city's Soil and Erosion Sediment Control Code, a clearing and earthwork permit is required for most construction sites over 10,000 square feet. The disturbed area must be stabilized as quickly as practicable.

b. *Phasing and Limiting Areas of Disturbance*

This practice reduces the potential for erosion and can be accomplished by prohibiting clearing and grading from all postdevelopment buffer zones, configuring the site plan to retain high amounts of open space, and using phased construction sequencing to limit the amount of disturbed area at any given time.

c. *Require vegetative stabilization.*

Rapid establishment of a grass or mulch cover on a cleared or graded area at construction sites can reduce suspended sediment levels to surface waters by up to sixfold. Mandatory temporary stabilization of areas left undisturbed for 7 to 14 days is recommended, unless conditions indicate otherwise. Section III.A contains detailed information regarding vegetative stabilization practices.

d. *Minimum Disturbance/Minimum Maintenance*

Minimum disturbance/minimum maintenance is an approach to site development in which clearing and site grading are allowed only within a carefully prescribed building area, preserving and protecting the existing natural vegetation. Landscapes that demand significant amounts of chemical treatment should be avoided. Minimum disturbance/minimum maintenance strategies help minimize nonpoint source impacts associated with the application of fertilizers, pesticides, and herbicides that result from new land development. The retention of existing vegetation may also help maintain predevelopment runoff volumes and peak rates of discharge and thus reduce erosion.

Translation of a concept such as minimum disturbance/minimum maintenance into straightforward numerical standards and criteria is difficult. A certain level of interpretation and judgment is often necessary. Nevertheless, basic standards can be established. Assuming that land use categories have been established through the local land use plans or zoning ordinances, vegetation mapping can be used to illustrate where the proposed development can be constructed with minimal impact on existing vegetation. The area to be disturbed should be identified for all buildings, structures, roads, walkways, and activity areas. The exact dimensions of this disturbance will be subjective and will depend on factors such as lot size and site-specific conditions. For example, a single-family residential development can be constructed with a narrower zone of disturbance than a mall or office park that may require larger construction equipment with greater maneuverability. In general, an extremely conservative zone width would be 10 feet beyond the roof line of a structure or dwelling unit; a more moderate criterion might be 25 feet. Mall sites and large residential developments are typically mass-graded. Limits of Disturbance (LOD) are usually required on all erosion and sediment control plans and are always a function of grading requirements.

Program Implementation Costs

The annual costs of establishing and implementing a minimum disturbance/minimum maintenance (MD/MM) program are estimated below. In some cases, the MD/MM tasks can be incorporated within the framework of the existing land development review process and implementation costs would only be additive. A new program, however, would need trained staff responsible for ensuring that developers properly integrate the requirements for the MD/MM into their respective site plans. The need to inspect sites during construction would also result in additional costs. The annual operating costs of implementing such a program will vary depending on the size of the community and the degree of new development. For a typical program, estimated costs may be approximately $110,000 for one professional staffperson and can be divided as follows:

Professional staff	$ 60,000
Support staff	$ 30,000
Office space	$ 15,000
Office expenses	$ 5,000
Total	$110,000 per year

These figures are based on approximate average salaries and expenses for similar programs.

The manner by which a turf management or landscape control ordinance is developed or implemented varies to some extent, county by county, State by State. The process would reflect county size, the framework of existing government agencies, techniques of governance, and numerous other factors. Costs would vary as well. These specific aspects of the program would be established by any initial studies and establishment of program requirements, as discussed above. Also, as experience is gained by the staff and the minimum disturbance/minimum maintenance concept is better understood by the development community, the need for services might be expected to decrease as the result of increased program operation efficiency.

5. Site Planning Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. *Clustering*

Clustering development is used to concentrate development and construction activity on a limited portion of a site, leaving the remaining portion undisturbed. This allows for the design of more effective erosion and sediment control and urban runoff management plans for the sites, as described in Section II.A. It also provides a mechanism for preserving environmentally sensitive areas and reducing road lengths and impervious parking areas.

VOL 12

9624

R0042930

NOTE: A common belief is that low-density development is more environmentally sound because it results in increased open space. Minimum lot size requirements can result in suburban sprawl. Many of these areas are heavily landscaped and therefore have the potential to contribute significant loadings of nutrients and pesticides to surface waters. In many cases, clustering and infill development may be more environmentally sound strategies. They may also result in a cost savings for municipalities because clustering and infill development usually require less infrastructure, including urban runoff treatment systems. The imposition of density controls may preclude clustering. While minimum lot size requirements are useful in some instances, such as farmland preservation, zoning ordinances should not preclude the implementation of clustered development as an alternative to traditional suburban development.

b. Performance Criteria

Performance criteria for site development contain certain built-in safeguards to protect natural features. Performance criteria often apply not to individual zoning districts but to the site being regulated or protected and set fixed protection levels for specific resources that are not based on general zoning definitions.

c. Site Fingerprinting

The total amount of disturbed area within a site can be reduced by fingerprinting development. Fingerprinting places development away from environmentally sensitive areas (wetlands, steep slopes, etc.), future open spaces, tree save areas, future restoration areas, and temporary and permanent vegetative forest buffer zones. At a subdivision or lot level, ground disturbance is confined to areas where structures, roads, and rights of way will exist after construction is complete.

d. Preserving Natural Drainage Features and Natural Depressional Storage Areas

As discussed in the Watershed Protection Management Measure, natural drainage features should be preserved as development occurs. This can be done at the site planning stage as well as the watershed planning stage and is desirable because of the ability of natural drainage features to infiltrate and attenuate flows and filter pollutants. Depressional storage areas, commonly found as ponded areas in fields during the wet season or large runoff events, serve the purpose of reducing runoff volumes and trapping pollutants. These areas are usually filled and graded as a site is developed. Cluster development can be used to preserve natural drainage features and depressional storage areas and allow for incorporation of these features into a site design (Dreher and Price, 1992).

e. Minimizing Imperviousness

Through the use of various incentives, such as those found in the Maryland Chesapeake Bay Critical Areas 10 Percent Rule, a general strategy of minimizing paved areas can be implemented at the site planning level. Methods used to meet this goal include:

- Reduced sidewalk widths, especially in low-traffic neighborhoods;
- Use of permeable materials for sidewalk construction;
- Mandatory open space requirements;
- Use of porous, permeable, or gritted pavement, where appropriate;
- Reduced building setbacks, which reduces the lengths of driveways and entry walks; and
- Reduced street widths by elimination of onstreet parking (where such action does not pose a safety hazard).

f. Reducing the Hydraulic Connectivity of Impervious Surfaces

Pollutant loading from impervious surfaces may be reduced if the impervious area does not connect directly to an impervious conveyance system. This can be done in at least four ways:

- Route runoff over lawn areas to increase infiltration;

- Discourage the direct connection of downspouts to storm sewers or the discharge of downspouts to driveways or parking lots;

- Substitute swale and pond systems to increase infiltration; and

- Reduce the use of storm sewers to drain streets, parking lots, and back yards (NIPC, 1992)

g. Xeriscape Programs

Xeriscaping is a landscaping concept that maximizes the conservation of water by the use of site-appropriate plants and an efficient watering system and involves the use of landscaping plants that need minimal watering, fertilization, and pesticide application. Xeriscaping can reduce the contribution of landscaped areas to coastal nonpoint source pollution. Xeriscape designs can reduce landscape maintenance by as much as 50 percent, primarily as a result of the following:

- Reduction of water loss and soil erosion through careful planning, design, and implementation;
- Reduction of mowing by limiting lawn areas and using proper fertilization techniques; and
- Reduction of fertilization through soil preparation (Clemson University, 1991).

In 1991, the Florida Legislature adopted a xeriscape law that requires State agencies to adopt and implement xeriscaping programs. The law requires that rules and guidelines for implementation of xeriscaping along highway rights-of-way and on public property associated with publicly owned buildings constructed after July 1, 1992, be adopted. Local governments are to determine whether xeriscaping is a cost-effective measure for conserving water. If so, local governments are to work with the water management districts in developing their xeriscape guidelines. Water management districts will provide financial incentives to local governments for developing xeriscape plans and ordinances. These plans must include:

- Landscape design, installation, and maintenance standards;
- Identification of prohibited plant species (invasive exotic plants);
- Identification of controlled plant species and conditions for their use;
- Specifications for maximum percentage of turf and impervious surfaces allowed in a xeriscaped area;
- Specifications for land clearing and requirements for the conservation of existing native vegetation; and
- Monitoring programs for ordinance implementation and compliance.

There is also a provision in the law requiring local governments and water management districts to promote the use of xeriscape practices in already developed areas through public education programs. California has passed a law requiring all municipalities to consider enacting water-efficient landscape requirements.

III. CONSTRUCTION ACTIVITIES

[illegible]

(1) Reduce erosion and, to the extent practicable, retain sediment onsite during and after construction, and

(2) Prior to land disturbance, prepare and implement an approved erosion and sediment control plan or similar administrative document that contains erosion and sediment control provisions.

1. Applicability

This management measure is intended to be applied by States to all construction activities on sites less than 5 acres in areas that do not have an NPDES permit[3] in order to control erosion and sediment loss from those sites. This management measure does not apply to: (1) construction of a detached single family home on a site of 1/2 acre or more or (2) construction that does not disturb over 5,000 square feet of land on a site. (NOTE: All construction activities, including clearing, grading, and excavation, that result in the disturbance of areas greater than or equal to 5 acres or are a part of a larger development plan are covered by the NPDES regulations and are thus excluded from these requirements.) Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The goal of this management measure is to reduce the sediment loadings from construction sites in coastal areas that enter surface waterbodies. This measure requires that coastal States establish new or enhance existing State erosion and sediment control (ESC) programs and/or require ESC programs at the local level. It is intended to be part of a comprehensive land use or watershed management program, as previously detailed in the Watershed and Site Development Management Measures. It is expected that State and local programs will establish criteria determined by local conditions (e.g., soil types, climate, meteorology) that reduce erosion and sediment transport from construction sites.

Runoff from construction sites is by far the largest source of sediment in urban areas under development (York County Soil and Water Conservation District, 1990). Soil erosion removes over 90 percent of sediment by tonnage in urbanizing areas where most construction activities occur (Canning, 1988). Table 4-14 illustrates some of the

[3] On May 27, 1992, the United States Court of Appeals for the Ninth Circuit invalidated EPA's exemption of construction sites smaller than 5 acres from the storm water permit program in *Natural Resources Defense Council* v. *EPA*, 965 F.2d 759 (9th Cir. 1992). EPA is conducting further rulemaking proceedings on this issue and will not require permit applications for construction activities under 5 acres until further rulemaking has been completed.

measured sediment loading rates associated with construction activities found across the United States. As seen in Table 4-14, erosion rates from natural areas such as undisturbed forested lands are typically less than one ton/acre/year, while erosion from construction sites ranges from 7.2 to over 1,000 tons/acre/year.

Table 4-14. Erosion and Sediment Problems Associated With Construction

Location	Problem	Reference
United States	Sediment loading rates vary from 36.5 to 1,000 ton/ac/yr. These are 5 to 500 times greater than those from undeveloped land. Approximately 600 million tons of soil erodes from developed sites each year. Construction site sediment in runoff can be 10 to 20 times greater than that from agricultural lands.	York County Soil and Water Conservation District, 1990
Franklin County, FL	Sediment yield (ton/ac/yr): forest < 0.5 rangeland < 0.5 tilled 1.4 construction site 30 established urban < 0.5	Franklin County, FL
Wisconsin	Erosion rates range from 30 to 200 ton/ac/yr (10 to 20 times those of cropland).	Wisconsin Legislative Council, 1991
Washington, DC	Erosion rates range from 35 to 45 ton/ac/yr (10 to 100 times greater than agriculture and stabilized urban land uses).	MWCOG, 1987
Anacostia River Basin, VA, MD, DC	Sediment yields from portions of the Anacostia Basin have been estimated at 75,000 to 132,000 ton/yr.	U.S. Army Corps of Engineers, 1990
Washington	Erosion rates range from 50 to 500 ton/ac/yr. Natural erosion rates from forests or well-sodded prairies are 0.01 to 1.0 ton/ac/yr.	Washington Department of Ecology, 1989
Anacostia River Basin, VA, MD, DC	Erosion rates range from 7.2 to 100.8 ton/ac/yr.	USGS, 1978
Alabama North Carolina Louisiana Oklahoma Georgia Texas Tennessee Pennsylvania Ohio Kentucky	1.4 million tons eroded per year. 6.7 million tons eroded per year. 5.1 million tons eroded per year. 4.2 million tons eroded per year. 3.8 million tons eroded per year. 3.5 million tons eroded per year. 3.3 million tons eroded per year. 3.1 million tons eroded per year. 3.0 million tons eroded per year. 3.0 million tons eroded per year.	Woodward-Clyde, 1991

Eroded sediment from construction sites creates many problems in coastal areas including adverse impacts on water quality, critical habitats, submerged aquatic vegetation (SAV) beds, recreational activities, and navigation (APWA, 1991). For example, the Miami River in Florida has been severely affected by pollution associated with upland erosion. This watershed has undergone extensive urbanization, which has included the construction of many commercial and residential buildings over the past 50 years. Sediment deposited in the Miami River channel contributes to the severe water quality and navigation problems of this once-thriving waterway, as well as Biscayne Bay (SFWMD, 1988).

ESC plans are important for controlling the adverse impacts of construction and land development and have been required by many State and local governments, as shown in Table 4-13 (in the Site Development section of this chapter). An ESC plan is a document that explains and illustrates the measures to be taken to control erosion and sediment problems on construction sites (Connecticut Council on Soil and Water Conservation, 1988). It is intended that existing State and local erosion and sediment control plans may be used to fulfill the requirements of this management measure. Where existing ESC plans do not meet the management measure criteria, inadequate plans may be enhanced to meet the management measure guidelines.

Typically, an ESC plan is part of a larger site plan and includes the following elements:

- Description of predominant soil types;
- Details of site grading including existing and proposed contours;
- Design details and locations for structural controls;
- Provisions to preserve topsoil and limit disturbance;
- Details of temporary and permanent stabilization measures; and
- Description of the sequence of construction.

ESC plans ensure that provisions for control measures are incorporated into the site planning stage of development and provide for the reduction of erosion and sediment problems and accountability if a problem occurs (York County Soil and Water Conservation District, 1990). An effective plan for urban runoff management on construction sites will control erosion, retain sediments on site, to the extent practicable, and reduce the adverse effects of runoff. Climate, topography, soils, drainage patterns, and vegetation will affect how erosion and sediment should be controlled on a site (Washington State Department of Ecology, 1989). An effective ESC plan includes both structural and nonstructural controls. Nonstructural controls address erosion control by decreasing erosion potential, whereas structural controls are both preventive and mitigative because they control both erosion and sediment movement.

Typical nonstructural erosion controls include (APWA, 1991; York County Soil and Water Conservation District, 1990):

- Planning and designing the development within the natural constraints of the site;
- Minimizing the area of bare soil exposed at one time (phased grading);
- Providing for stream crossing areas for natural and man-made areas; and
- Stabilizing cut-and-fill slopes caused by construction activities.

Structural controls include:

- Perimeter controls;
- Mulching and seeding exposed areas;
- Sediment basins and traps; and
- Filter fabric, or silt fences.

Some erosion and soil loss are unavoidable during land-disturbing activities. While proper siting and design will help prevent areas prone to erosion from being developed, construction activities will invariably produce conditions where erosion may occur. To reduce the adverse impacts associated with construction, the construction management measure suggests a system of nonstructural and structural erosion and sediment controls for incorporation into an

ESC plan. Erosion controls have distinct advantages over sediment controls. Erosion controls reduce the amount of sediment transported off-site, thereby reducing the need for sediment controls. When erosion controls are used in conjunction with sediment controls, the size of the sediment control structures and associated maintenance may be reduced, decreasing the overall treatment costs (SWRPC, 1991).

3. Management Measure Selection

This management measure was selected to minimize sediment being transported outside the perimeter of a construction site through two broad performance goals: (1) reduce erosion and (2) retain sediment onsite, to the extent practicable. These performance goals were chosen to allow States and local governments flexibility in specifying practices appropriate for local conditions.

While several commentors responding to the draft (May 1991) guidance expressed the need to define "more measurable, enforceable ways" to control sediment loadings, other commentors stressed the need to draft management measures that do not conflict with existing State programs and allow States and local governments to determine appropriate practices and design standards for their communities. These management measures were selected because virtually all coastal States control construction activities to prevent erosion and sediment loss.

The measures were specifically written for the following reasons:

(1) Predevelopment loadings may vary greatly, and some sediment loss is usually inevitable;

(2) Current practice is built on the use of systems of practices selected based on site-specific conditions; and

(3) The combined effectiveness of erosion and sediment controls in systems is not easily quantified.

4. Erosion Control Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Erosion controls are used to reduce the amount of sediment that is detached during construction and to prevent sediment from entering runoff. Erosion control is based on two main concepts: (1) disturb the smallest area of land possible for the shortest period of time, and (2) stabilize disturbed soils to prevent erosion from occurring.

■ a. *Schedule projects so clearing and grading are done during the time of minimum erosion potential.*

Often a project can be scheduled during the time of year that the erosion potential of the site is relatively low. In many parts of the country, there is a certain period of the year when erosion potential is relatively low and construction scheduling could be very effective. For example, in the Pacific region if construction can be completed during the 6-month dry season (May 1 - October 31), temporary erosion and sediment controls may not be needed. In addition, in some parts of the country erosion potential is very high during certain parts of the year such as the spring thaw in northern areas. During this time of year, melting snowfall generates a constant runoff that can erode soil. In addition, construction vehicles can easily turn the soft, wet ground into mud, which is more easily washed offsite. Therefore, in the north, limitations should be placed on grading during the spring thaw (Goldman et al., 1986).

VOL 12

b. Stage construction.

Avoid areawide clearance of construction sites. Plan and stage land disturbance activities so that only the area currently under construction is exposed. As soon as the grading and construction in an area are complete, the area should be stabilized.

By clearing only those areas immediately essential for completing site construction, buffer zones are preserved and soil remains undisturbed until construction begins. Physical markers, such as tape, signs, or barriers, indicating the limits of land disturbance, can ensure that equipment operators know the proposed limits of clearing. The area of the watershed that is exposed to construction is important for determining the net amount of erosion. Reducing the extent of the disturbed area will ultimately reduce sediment loads to surface waters. Existing or newly planted vegetation that has been planted to stabilize disturbed areas should be protected by routing construction traffic around and protecting natural vegetation with fencing, tree armoring, retaining walls, or tree wells.

c. Clear only areas essential for construction.

Often areas of a construction site are unnecessarily cleared. Only those areas essential for completing construction activities should be cleared, and other areas should remain undisturbed. Additionally, the proposed limits of land disturbance should be physically marked off to ensure that only the required land area is cleared. Avoid disturbing vegetation on steep slopes or other critical areas.

d. Locate potential nonpoint pollutant sources away from steep slopes, waterbodies, and critical areas.

Material stockpiles, borrow areas, access roads, and other land-disturbing activities can often be located away from critical areas such as steep slopes, highly erodible soils, and areas that drain directly into sensitive waterbodies.

e. Route construction traffic to avoid existing or newly planted vegetation.

Where possible, construction traffic should travel over areas that must be disturbed for other construction activity. This practice will reduce the area that is cleared and susceptible to erosion.

f. Protect natural vegetation with fencing, tree armoring, and retaining walls or tree wells.

Tree armoring protects tree trunks from being damaged by construction equipment. Fencing can also protect tree trunks, but should be placed at the tree's drip line so that construction equipment is kept away from the tree. The tree drip line is the minimum area around a tree in which the tree's root system should not be disturbed by cut, fill, or soil compaction caused by heavy equipment. When cutting or filling must be done near a tree, a retaining wall or tree well should be used to minimize the cutting of the tree's roots or the quantity of fill placed over the tree's roots.

g. Stockpile topsoil and reapply to revegetate site.

Because of the high organic content of topsoil, it cannot be used as fill material or under pavement. After a site is cleared, the topsoil is typically removed. Since topsoil is essential to establish new vegetation, it should be stockpiled and then reapplied to the site for revegetation, if appropriate. Although topsoil salvaged from the existing site can often be used, it must meet certain standards and topsoil may need to be imported onto the site if the existing topsoil is not adequate for establishing new vegetation.

9631

h. Cover or stabilize topsoil stockpiles.

Unprotected stockpiles are very prone to erosion and therefore stockpiles must be protected. Small stockpiles can be covered with a tarp to prevent erosion. Large stockpiles should be stabilized by erosion blankets, seeding, and/or mulching.

i. Use wind erosion controls.

Wind erosion controls limit the movement of dust from disturbed soil surfaces and include many different practices. Wind barriers block air currents and are effective in controlling soil blowing. Many different materials can be used as wind barriers, including solid board fence, snow fences, and bales of hay. Sprinkling moistens the soil surface with water and must be repeated as needed to be effective for preventing wind erosion (Delaware DNREC, 1989); however, applications must be monitored to prevent excessive runoff and erosion.

j. Intercept runoff above disturbed slopes and convey it to a permanent channel or storm drain.

Earth dikes, perimeter dikes or swales, or diversions can be used to intercept and convey runoff above disturbed areas. An earth dike is a temporary berm or ridge of compacted soil that channels water to a desired location. A perimeter dike/swale or diversion is a swale with a supporting ridge on the lower side that is constructed from the soil excavated from the adjoining swale (Delaware DNREC, 1989). These practices should be used to intercept flow from denuded areas or newly seeded areas to keep the disturbed areas from being eroded from the uphill runoff. The structures should be stabilized within 14 days of installation. A pipe slope drain, also known as a pipe drop structure, is a temporary pipe placed from the top of a slope to the bottom of the slope to convey concentrated runoff down the slope without causing erosion (Delaware DNREC, 1989).

k. On long or steep, disturbed, or man-made slopes, construct benches, terraces, or ditches at regular intervals to intercept runoff.

Benches, terraces, or ditches break up a slope by providing areas of low slope in the reverse direction. This keeps water from proceeding down the slope at increasing volume and velocity. Instead, the flow is directed to a suitable outlet, such as a sediment basin or trap. The frequency of benches, terraces, or ditches will depend on the erodibility of the soils, steepness and length of the slope, and rock outcrops. This practice should be used if there is a potential for erosion along the slope.

l. Use retaining walls.

Often retaining walls can be used to decrease the steepness of a slope. If the steepness of a slope is reduced, the runoff velocity is decreased and, therefore, the erosion potential is decreased.

m. Provide linings for urban runoff conveyance channels.

Often construction increases the velocity and volume of runoff, which causes erosion in newly constructed or existing urban runoff conveyance channels. If the runoff during or after construction will cause erosion in a channel, the channel should be lined or flow control BMPs installed. The first choice of lining should be grass or sod since this reduces runoff velocities and provides water quality benefits through filtration and infiltration. If the velocity in the channel would erode the grass or sod, then riprap, concrete, or gabions can be used.

n. Use check dams.

Check dams are small, temporary dams constructed across a swale or channel. They can be constructed using gravel or straw bales. They are used to reduce the velocity of concentrated flow and, therefore, to reduce the erosion in

VOL 12

9632

a swale or channel. Check dams should be used when a swale or channel will be used for a short time and therefore it is not feasible or practical to line the channel or implement flow control BMPs (Delaware DNREC, 1989).

o. Seed and fertilize.

Seeding establishes a vegetative cover on disturbed areas. Seeding is very effective in controlling soil erosion once a dense vegetative cover has been established. However, often seeding and fertilizing do not produce as thick a vegetative cover as do seed and mulch or netting. Newly established vegetation does not have as extensive a root system as existing vegetation and therefore is more prone to erosion, especially on steep slopes. Care should be taken when fertilizing to avoid untimely or excessive application. Since the practice of seeding and fertilizing does not provide any protection during the time of vegetative establishment, it should be used only on favorable soils in very flat areas and not in sensitive areas.

p. Use seeding and mulch/mats.

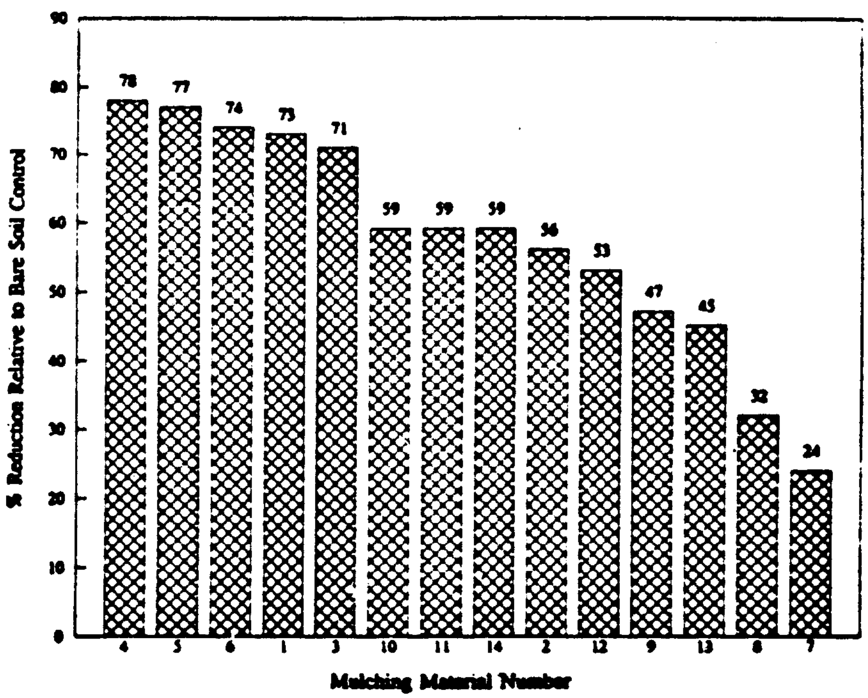
Seeding establishes a vegetative cover on disturbed areas. Seeding is very effective in controlling soil erosion once the vegetative cover has been established. The mulching/mats protect the disturbed area while the vegetation becomes established.

The management of land by using ground cover reduces erosion by reducing the flow rate of runoff and the raindrop impact. Bare soils should be seeded or otherwise stabilized within 15 calendar days after final grading. Denuded areas that are inactive and will be exposed to rain for 30 days or more should also be temporarily stabilized, usually by planting seeds and establishing vegetation during favorable seasons in areas where vegetation can be established. In very flat, non-sensitive areas with favorable soils, stabilization may involve simply seeding and fertilizing. Mulching and/or sodding may be necessary as slopes become moderate to steep, as soils become more erosive, and as areas become more sensitive.

q. Use mulch/mats.

Mulching involves applying plant residues or other suitable materials on disturbed soil surfaces. Mulchs/mats used include tacked straw, wood chips, and jute netting and are often covered by blankets or netting. Mulching alone should be used only for temporary protection of the soil surface or when permanent seeding is not feasible. The useful life of mulch varies with the material used and the amount of precipitation, but is approximately 2 to 6 months. Figure 4-5 shows water velocity reductions that could be expected using various mulching techniques. Similarly, Figure 4-6 shows reductions in soil loss achievable using various mulching techniques. During times of year when vegetation cannot be established, soil mulching should be applied to moderate slopes and soils that are not highly erodible. On steep slopes or highly erodible soils, multiple mulching treatments should be used. On a high-elevation or desert site where grasses cannot survive the harsh environment, native shrubs may be planted. Interlocking ceramic materials, filter fabric, and netting are available for this purpose. Before stabilizing an area, it is important to have installed all sediment controls and diverted runoff away from the area to be planted. Runoff may be diverted away from denuded areas or newly planted areas using dikes, swales, or pipe slope drains to intercept runoff and convey it to a permanent channel or storm drain. Reserved topsoil may be used to revegetate a site if the stockpile has been covered and stabilized.

Consideration should be given to maintenance when designing mulching and matting schemes. Plastic nets are often used to cover the mulch or mats; however, they can foul lawn mower blades if the area requires mowing.



Mulch Material	Characteristics
1	100% wheat straw/top net
2	100% wheat straw/two nets
3	70% wheat straw/30% coconut fiber
4	70% wheat straw/30% coconut fiber
5	100% coconut fiber
6	Nylon monofilament/two nets
7	Nylon monofilament/rigid/bonded
8	Vinyl monofilament/flexible/bonded
9	Curled wood fibers/top net
10	Curled wood fibers/two nets
11	Antiwash netting (jute)
12	Interwoven paper and thread
13	Uncrimped wheat straw – 2,242 kg/ha
14	Uncrimped wheat straw – 4,484 kg/ha

14	Uncrimped wheat straw – 4,484 kg/ha

Figure 4-6. Actual soil loss reductions for different mulch treatments (adapted from Harding, 1990).

r. Use sodding.

Sodding permanently stabilizes an area. Sodding provides immediate stabilization of an area and should be used in critical areas or where establishment of permanent vegetation by seeding and mulching would be difficult. Sodding is also a preferred option when there is a high erosion potential during the period of vegetative establishment from seeding.

s. Use wildflower cover.

Because of the hardy drought-resistant nature of wildflowers, they may be more beneficial as an erosion control practice than turf grass. While not as dense as turfgrass, wildflower thatches and associated grasses are expected to be as effective in erosion control and contaminant absorption. Because thatches of wildflowers do not need fertilizers, pesticides, or herbicides, and watering is minimal, implementation of this practice may result in a cost savings (Brash et al., undated). In 1987, Howard County, Maryland, spent $690.00 per acre to maintain turfgrass areas, compared to only $31.00 per acre for wildflower meadows (Wilson, 1990).

A wildflower stand requires several years to become established; maintenance requirements are minimal once the area is established (Brash et al., undated).

5. Sediment Control Practices[4]

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Sediment controls capture sediment that is transported in runoff. Filtration and detention (gravitational settling) are the main processes used to remove sediment from urban runoff.

a. Sediment Basins

Sediment basins, also known as silt basins, are engineered impoundment structures that allow sediment to settle out of the urban runoff. They are installed prior to full-scale grading and remain in place until the disturbed portions of the drainage area are fully stabilized. They are generally located at the low point of sites, away from construction traffic, where they will be able to trap sediment-laden runoff.

Sediment basins are typically used for drainage areas between 5 and 100 acres. They can be classified as either temporary or permanent structures, depending on the length of service of the structure. If they are designed to function for less than 36 months, they are classified as "temporary"; otherwise, they are considered permanent structures. Temporary sediment basins can also be converted into permanent urban runoff management ponds. When sediment basins are designed as permanent structures, they must meet all standards for wet ponds.

b. Sediment Trap

Sediment traps are small impoundments that allow sediment to settle out of runoff water. Sediment traps are typically installed in a drainageway or other point of discharge from a disturbed area. Temporary diversions can be

[4]Adapted from Goldman (1986).

used to direct runoff to the sediment trap. Sediment traps should not be used for drainage areas greater than 5 acres and typically have a useful life of approximately 18 to 24 months.

c. Filter Fabric Fence

Filter fabric fence is available from many manufacturers and in several mesh sizes. Sediment is filtered out as urban runoff flows through the fabric. Such fences should be used only where there is sheet flow (i.e., no concentrated flow), and the maximum drainage area to the fence should be 0.5 acre or less per 100 feet of fence. Filter fabric fences have a useful life of approximately 6 to 12 months.

d. Straw Bale Barrier

A straw bale barrier is a row of anchored straw bales that detain and filter urban runoff. Straw bales are less effective than filter fabric, which can usually be used in place of straw bales. However, straw bales have been effectively used as temporary check dams in channels. As with filter fabric fences, straw bale barriers should be used only where there is sheet flow. The maximum drainage area to the barrier should be 0.25 acre or less per 100 feet of barrier. The useful life of straw bales is approximately 3 months.

e. Inlet Protection

Inlet protection consists of a barrier placed around a storm drain drop inlet, which traps sediment before it enters the storm sewer system. Filter fabric, straw bales, gravel, or sand bags are often used for inlet protection.

f. Construction Entrance

A construction entrance is a pad of gravel over filter cloth located where traffic leaves a construction site. As vehicles drive over the gravel, mud, and sediment are collected from the vehicles' wheels and offsite transport of sediment is reduced.

g. Vegetated Filter Strips

Vegetated filter strips are low-gradient vegetated areas that filter overland sheet flow. Runoff must be evenly distributed across the filter strip. Channelized flows decrease the effectiveness of filter strips. Level spreading devices are often used to distribute the runoff evenly across the strip (Dillaha et al., 1989).

Vegetated filter strips should have relatively low slopes and adequate length and should be planted with erosion-resistant plant species. The main factors that influence the removal efficiency are the vegetation type, soil infiltration rate, and flow depth and travel time. These factors are dependent on the contributing drainage area, slope of strip, degree and type of vegetative cover, and strip length. Maintenance requirements for vegetated filter strips include sediment removal and inspections to ensure that dense, vigorous vegetation is established and concentrated flows do not occur. Maintenance of these structures is discussed in Section II.A of this chapter.

6. Effectiveness and Cost Information

a. Erosion Control Practices

The effectiveness of erosion control practices can vary based on land slope, the size of the disturbed area, rainfall frequency and intensity, wind conditions, soil type, use of heavy machinery, length of time soils are exposed and unprotected, and other factors. In general, a system of erosion and sediment control practices can more effectively reduce offsite sediment transport than can a single system. Numerous nonstructural measures such as protecting natural or newly planted vegetation, minimizing the disturbance of vegetation on steep slopes and other highly erodible areas, maximizing the distance eroded material must travel before reaching the drainage system, and locating roads away from sensitive areas may be used to reduce erosion.

Table 4-15 contains the available cost and effectiveness data for some of the erosion controls listed above. Information on the effectiveness of individual nonstructural controls was not available. All reported effectiveness data assume that controls are properly designed, constructed, and maintained. Costs have been broken down into annual capital costs, annual maintenance costs, and total annual costs (including annualization of the capital costs).

b. Sediment Control Practices

Regular inspection and maintenance are needed for most erosion control practices to remain effective. The effectiveness of sediment controls will depend on the size of the construction site and the nature of the runoff flows. Sediment basins are most appropriate for drainage areas of 5 acres or greater. In smaller areas with concentrated flows, silt traps may suffice. Where concentrated flow leaves the site and the drainage area is less than 0.5 ac/100 ft of flow, filter fabric fences may be effective. In areas where sheet flow leaves the site and the drainage area is greater than 0.5 acre/100 ft of flow, perimeter dikes may be used to divert the flow to a sediment trap or sediment basin. Urban runoff inlets may be protected using straw bales or diversions to filter or route runoff away from the inlets.

Table 4-16 describes the general cost and effectiveness of some common sediment control practices.

c. Comparisons

Figure 4-7 illustrates the estimated TSS loading reductions from Maryland construction sites possible using a combination of erosion and sediment controls in contrast to using only sediment controls. Figure 4-8 shows a comparison of the cost and effectiveness of various erosion control practices. As can be seen in Figure 4-8, seeding or seeding and mulching provide the highest levels of control at the lowest cost.

Table 4-15. ESC Quantitative Effectiveness and Cost Summary

Practice	Design Constraints or Purpose	Percent Removal of TSS	Useful Life (years)[a]	Construction Cost	Annual Maintenance Cost (as % construction cost)	Total Annual Cost
Sod	Immediate erosion protection where there is high erosion potential during vegetative establishment.	Average: 99% Observed range: 98% - 99% References: Minnesota Pollution Control Agency, 1989; Pennsylvania, 1983 cited in USEPA, 1991	2	Average: $0.2 per ft^2 [$11,300 per acre] Range: $0.1 - $1.1 References: SWRPC, 1991; Schueler, 1987; Virginia, 1980	Average: 5% Range: 5% Reference: SWRPC, 1991	$0.20 per ft^2 $7,500 per acre
Seed	Establish vegetation on disturbed area.	After vegetation established- Average: 90% Observed range: 50% - 100% References: SCS, 1985 cited in EPA, 1991; Minnesota Pollution Control Agency, 1989; Oberts, 1984 cited in City of Austin, 1988; Delaware Department of Natural Resources, 1989	2	Average: $400 per acre Range: $200 - $1000 per acre References: Wisconsin DOT cited in SWRPC, 1991; SWRPC, 1991; Goldman, 1986; Virginia, 1980	Average: 20% Range: 15% - 25% References: Wisconsin DOT cited in SWRPC, 1991; SWRPC, 1991	$300 per acre
Seed and Mulch	Establish vegetation on disturbed area.	After vegetation established- Average: 90% Observed range: 50% - 100% References: SCS, 1985 cited in EPA, 1991; Minnesota Pollution Control Agency, 1989; Oberts, 1984 cited in City of Austin, 1988; Delaware Department of Natural Resources, 1989	2	Average: $1,500 per acre Range: $800 - $3,500 per acre References: Goldman, 1986; Washington DOT, 1990; NC State, 1990; Schueler, 1987; Virginia, 1980; SWRPC, 1991	Average: NA[b] Range: NA References: None	$1,100 per acre

VOL 12

[illegible]

(1) Limit application, generation, and migration of toxic substances;

(2) Ensure the proper storage and disposal of toxic materials; and

(3) Apply nutrients at rates necessary to establish and maintain vegetation without causing significant nutrient runoff to surface waters.

1. Applicability

This management measure is intended to be applied by States to all construction sites less than 5 acres in area and to new, resurfaced, restored, and reconstructed road, highway, and bridge construction projects. This management measure does not apply to: (1) construction of a detached single family home on a site of 1/2 acre or more or (2) construction that does not disturb over 5,000 square feet of land on a site. (NOTE: All construction activities, including clearing, grading, and excavation, that result in the disturbance of areas greater than or equal to 5 acres or are a part of a larger development plan are covered by the NPDES regulations and are thus excluded from these requirements.) Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformance with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

9647

2. Description

The purpose of this management measure is to prevent the generation of nonpoint source pollution from construction sites due to improper handling and usage of nutrients and toxic substances, and to prevent the movement of toxic substances from the construction site.

Many potential pollutants other than sediment are associated with construction activities. These pollutants include pesticides (insecticides, fungicides, herbicides, and rodenticides); fertilizers used for vegetative stabilization; petrochemicals (oils, gasoline, and asphalt degreasers); construction chemicals such as concrete products, sealers, and paints; wash water associated with these products; paper; wood; garbage; and sanitary wastes (Washington State Department of Ecology, 1991).

The variety of pollutants present and the severity of their effects are dependent on a number of factors:

(1) **The nature of the construction activity.** For example, potential pollution associated with fertilizer usage may be greater along a highway or at a housing development than it would be at a shopping center development because highways and housing developments usually have greater landscaping requirements.

(2) **The physical characteristics of the construction site.** The majority of all pollutants generated at construction sites are carried to surface waters via runoff. Therefore, the factors affecting runoff volume,

such as the amount, intensity, and frequency of rainfall; soil infiltration rates; surface roughness; slope length and steepness; and area denuded, all contribute to pollutant loadings.

(3) **The proximity of surface waters to the nonpoint pollutant source.** As the distance separating pollutant-generating activities from surface waters decreases, the likelihood of water quality impacts increases.

a. Pesticides

Insecticides, rodenticides, and herbicides are used on construction sites to provide safe and healthy conditions, reduce maintenance and fire hazards, and curb weeds and woody plants. Rodenticides are also used to control rodents attracted to construction sites. Common insecticides employed include synthetic, relatively water-insoluble chlorinated hydrocarbons, organophosphates, carbamates, and pyrethrins.

b. Petroleum Products

Petroleum products used during construction include fuels and lubricants for vehicles, for power tools, and for general equipment maintenance. Specific petroleum pollutants include gasoline, diesel oil, kerosene, lubricating oils, and grease. Asphalt paving also can be particularly harmful since it releases various oils for a considerable time period after application. Asphalt overloads might be dumped and covered without inspection. However, many of these pollutants adhere to soil particles and other surfaces and can therefore be more easily controlled.

c. Nutrients

Fertilizers are used on construction sites when revegetating graded or disturbed areas. Fertilizers contain nitrogen and phosphorus, which in large doses can adversely affect surface waters, causing eutrophication.

d. Solid Wastes

Solid wastes on construction sites are generated from trees and shrubs removed during land clearing and structure installation. Other wastes include wood and paper from packaging and building materials, scrap metals, sanitary wastes, rubber, plastic and glass, and masonry and asphalt products. Food containers, cigarette packages, leftover food, and aluminum foil also contribute solid wastes to the construction site.

e. Construction Chemicals

Chemical pollutants, such as paints, acids for cleaning masonry surfaces, cleaning solvents, asphalt products, soil additives used for stabilization, and concrete-curing compounds, may also be used on construction sites and carried in runoff.

f. Other Pollutants

Other pollutants, such as wash water from concrete mixers, acid and alkaline solutions from exposed soil or rock, and alkaline-forming natural elements, may also be present and contribute to nonpoint source pollution.

Revegetation of disturbed areas may require the use of fertilizers and pesticides, which, if not applied properly, may become nonpoint source pollutants. Many pesticides are restricted by Federal and/or State regulations.

Hydroseeding operations, in which seed, fertilizers, and lime are applied to the ground surface in a one-step operation, are more conducive to nutrient pollution than are the conventional seedbed-preparation operations, in which fertilizers and lime are tilled into the soil. Use of fertilizers containing little or no phosphorus may be required by local authorities if the development is near sensitive waterbodies. The addition of lime can also affect the pH of sensitive waters, making them more alkaline.

Improper fueling and servicing of vehicles can lead to significant quantities of petroleum products being dumped onto the ground. These pollutants can then be washed off site in urban runoff, even when proper erosion and sediment controls are in place. Pollutants carried in solution in runoff water, or fixed with sediment crystalline structures, may not be adequately controlled by erosion and sediment control practices (Washington Department of Ecology, 1991). Oils, waxes, and water-insoluble pesticides can form surface films on water and solid particles. Oil films can also concentrate water-soluble insecticides. These pollutants can be nearly impossible to control once present in runoff other than by the use of very costly water-treatment facilities (Washington Department of Ecology, 1991).

After spill prevention, one of the best methods to control petroleum pollutants is to retain sediments containing oil on the construction site through use of erosion and sediment control practices. Improved maintenance and safe storage facilities will reduce the chance of contaminating a construction site. One of the greatest concerns related to use of petroleum products is the method for waste disposal. The dumping of petroleum product wastes into sewers and other drainage channels is illegal and could result in fines or job shutdown.

The primary control method for solid wastes is to provide adequate disposal facilities. Erosion and sediment control structures usually capture much of the solid waste from construction sites. Periodic removal of litter from these structures will reduce solid waste accumulations. Collected solid waste should be removed and disposed of at authorized disposal areas.

Improperly stored construction materials, such as pressure-treated lumber or solvents, may lead to leaching of toxics to surface water and ground water. Disposal of construction chemicals should follow all applicable State and local laws that may require disposal by a licensed waste management firm.

3. Management Measure Selection

This management measure was selected based on the potential for many construction activities to contribute to nutrient and toxic NPS pollution.

This management measure was selected because (1) construction activities have the potential to contribute to increased loadings of toxic substances and nutrients to waterbodies; (2) various States and local governments regulate the control of chemicals on construction sites through spill prevention plans, erosion and sediment control plans, or other administrative devices; (3) the practices described are commonly used and presented in a number of best management practice handbooks and guidance manuals for construction sites; and (4) the practices selected are the most economical and effective.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ a. *Properly store, handle, apply, and dispose of pesticides.*

Pesticide storage areas on construction sites should be protected from the elements. Warning signs should be placed in areas recently sprayed or treated. Persons mixing and applying these chemicals should wear suitable protective clothing, in accordance with the law.

VOL 12

9649

Application rates should conform to registered label directions. Disposal of excess pesticides and pesticide-related wastes should conform to registered label directions for the disposal and storage of pesticides and pesticide containers set forth in applicable Federal, State, and local regulations that govern their usage, handling, storage, and disposal. Pesticides and herbicides should be used only in conjunction with Integrated Pest Management (IPM) (see Chapter 2). Pesticides should be the tool of last resort; methods that are the least disruptive to the environment and human health should be used first.

Pesticides should be disposed of through either a licensed waste management firm or a treatment, storage, and disposal (TSD) facility. Containers should be triple-rinsed before disposal, and rinse waters should be reused as product.

Other practices include setting aside a locked storage area, tightly closing lids, storing in a cool, dry place, checking containers periodically for leaks or deterioration, maintaining a list of products in storage, using plastic sheeting to line the storage area, and notifying neighboring property owners prior to spraying.

■ b. *Properly store, handle, use, and dispose of petroleum products.*

When storing petroleum products, follow these guidelines:

- Create a shelter around the area with cover and wind protection;
- Line the storage area with a double layer of plastic sheeting or similar material;
- Create an impervious berm around the perimeter with a capacity 110 percent greater than that of the largest container;
- Clearly label all products;
- Keep tanks off the ground; and
- Keep lids securely fastened.

Oil and oily wastes such as crankcase oil, cans, rags, and paper dropped into oils and lubricants should be disposed of in proper receptacles or recycled. Waste oil for recycling should not be mixed with degreasers, solvents, antifreeze, or brake fluid.

■ c. *Establish fuel and vehicle maintenance staging areas located away from all drainage courses, and design these areas to control runoff.*

Proper maintenance of equipment and installation of proper stream crossings will further reduce pollution of water by these sources. Stream crossings should be minimized through proper planning of access roads. Refer to Chapter 3 for additional information on stream crossings.

■ d. *Provide sanitary facilities for constructions workers.*

■ e. *Store, cover, and isolate construction materials, including topsoil and chemicals, to prevent runoff of pollutants and contamination of ground water.*

■ f. *Develop and implement a spill prevention and control plan. Agencies, contractors, and other commercial entities that store, handle, or transport fuel, oil, or hazardous materials should develop a spill response plan.*

VOL 12

9550

Post spill procedure information and have persons trained in spill handling on site or on call at all times. Materials for cleaning up spills should be kept on site and easily available. Spills should be cleaned up immediately and the contaminated material properly disposed of. Spill control plan components should include:

- Stop the source of the spill.
- Contain any liquid.
- Cover the spill with absorbent material such as kitty litter or sawdust, but do not use straw. Dispose of the used absorbent properly.

g. Maintain and wash equipment and machinery in confined areas specifically designed to control runoff.

Thinners or solvents should not be discharged into sanitary or storm sewer systems when cleaning machinery. Use alternative methods for cleaning larger equipment parts, such as high-pressure, high-temperature water washes, or steam cleaning. Equipment-washing detergents can be used, and wash water may be discharged into sanitary sewers if solids are removed from the solution first. (This practice should be verified with the local sewer authority.) Small parts can be cleaned with degreasing solvents, which can then be reused or recycled. Do not discharge any solvents into sewers.

Washout from concrete trucks should be disposed of into:

- A designated area that will later be backfilled;
- An area where the concrete wash can harden, can be broken up, and then can be placed in a dumpster; or
- A location not subject to urban runoff and more than 50 feet away from a storm drain, open ditch, or surface water.

Never dump washout into a sanitary sewer or storm drain, or onto soil or pavement that carries urban runoff.

h. Develop and implement nutrient management plans.

Properly time applications, and work fertilizers and liming materials into the soil to depths of 4 to 6 inches. Using soil tests to determine specific nutrient needs at the site can greatly decrease the amount of nutrients applied.

i. Provide adequate disposal facilities for solid waste, including excess asphalt, produced during construction.

j. Educate construction workers about proper materials handling and spill response procedures. Distribute or post informational material regarding chemical control.

IV. EXISTING DEVELOPMENT

A. Existing Development Management Measure

Develop and implement watershed management programs to reduce runoff pollutant concentrations and volumes from existing development:

(1) Identify priority local and/or regional watershed pollutant reduction opportunities, e.g., improvements to existing urban runoff control structures;

(2) Contain a schedule for implementing appropriate controls;

(3) Limit destruction of natural conveyance systems; and

(4) Where appropriate, preserve, enhance, or establish buffers along surface waterbodies and their tributaries.

1. Applicability

This management measure is intended to be applied by States to all urban areas and existing development in order to reduce surface water runoff pollutant loadings from such areas. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA).

2. Description

The purpose of this management measure is to protect or improve surface water quality by the development and implementation of watershed management programs that pursue the following objectives:

(1) Reduce surface water runoff pollution loadings from areas where development has already occurred;

(2) Limit surface water runoff volumes in order to minimize sediment loadings resulting from the erosion of streambanks and other natural conveyance systems; and

(3) Preserve, enhance, or establish buffers that provide water quality benefits along waterbodies and their tributaries.

Maintenance of water quality becomes increasingly difficult as areas of impervious surface increase and urbanization occurs. For the purpose of this guidance, urbanized areas are those areas where the presence of "man-made" impervious surfaces results in increased peak runoff volumes and pollutant loadings that permanently alter one or more of the following:[5] stream channels, natural drainageways, and in-stream and adjacent riparian habitat so that predevelopment aquatic flora and fauna are eliminated or reduced to unsustainable levels and predevelopment water quality has been degraded. Increased bank cutting, streambed scouring, siltation damaging to aquatic flora and fauna, increases in water temperature, decreases in dissolved oxygen, changes to the natural structure and flow of the stream or river, and the presence of anthropogenic pollutants that are not generated from agricultural activities, in general, are indications of urbanization.

The effects of urbanization have been well described in the introduction to this chapter. Protection of water quality in urbanized areas is difficult because of a range of factors. These factors include diverse pollutant loadings, large runoff volumes, limited areas suitable for surface water runoff treatment systems, high implementation costs associated with structural controls, and the destruction or absence of buffer zones that can filter pollutants and prevent the destabilization of streambanks and shorelines.

As discussed in Section II.B of this chapter, comprehensive watershed planning facilitates integration of source reduction activities and treatment strategies to mitigate the effects of urban runoff. Through the use of watershed management, States and local governments can identify local water quality objectives and focus resources on control of specific pollutants and sources. Watershed plans typically incorporate a combination of nonstructural and structural practices.

An important nonstructural component of many watershed management plans is the identification and preservation of buffers and natural systems. These areas help to maintain and improve surface water quality by filtering and infiltrating urban runoff. In areas of existing development, natural buffers and conveyance systems may have been altered as urbanization occurred. Where possible and appropriate, additional impacts to these areas should be minimized and if degraded, the functions of these areas restored. The preservation, enhancement, or establishment of buffers along waterbodies is generally recommended throughout the section 6217 management area as an important tool for reducing NPS impacts. The establishment and protection of buffers, however, is most appropriate along surface waterbodies and their tributaries where water quality and the biological integrity of the waterbody is dependent on the presence of an adequate buffer/riparian area. Buffers may be necessary where the buffer/riparian area (1) reduces significant NPS pollutant loadings, (2) provides habitat necessary to maintain the biological integrity of the receiving water, and (3) reduces undesirable thermal impacts to the waterbody. For a discussion of protection and restoration of wetlands and riparian areas, refer to Chapter 7.

Institutional controls, such as permits, inspection, and operation and maintenance requirements, are also essential components of a watershed management program. The effectiveness of many of the practices described in this chapter is dependent on administrative controls such as inspections. Without effective compliance mechanisms and operation and maintenance requirements, many of these practices will not perform satisfactorily.

Where existing development precludes the use of effective nonstructural controls, structural practices may be the only suitable option to decrease the NPS pollution loads generated from developed areas. In such situations, a watershed plan can be used to integrate the construction of new surface water runoff treatment structures and the retrofit of existing surface water runoff management systems.

Retrofitting is a process that involves the modification of existing surface water runoff control structures or surface water runoff conveyance systems, which were initially designed to control flooding, not to serve a water quality improvement function. By enlarging existing surface water runoff structures, changing the inflow and outflow characteristics of the device, and increasing detention times of the runoff, sediment and associated pollutants can be removed from the runoff. Retrofit of structural controls, however, is often the only feasible alternative for improving water quality in developed areas. Where the presence of existing development or financial constraints limits treatment options, targeting may be necessary to identify priority pollutants and select the most appropriate retrofits.

[5] Changes resulting from dam building and "acts of God" such as earthquakes, hurricanes, and unusual natural events (e.g., a 100-year storm), as well as natural predevelopment riverine behavior that results in stream meander and deposition of sediments in sandbars or similar formations, are excluded from consideration in this definition. For additional information, refer to Chapter 6.

Once key pollutants have been identified, an achievable water quality target for the receiving water should be set to improve current levels based on an identified objective or to prevent degradation of current water quality. Extensive site evaluations should then be performed to assess the performance of existing surface water runoff management systems and to pinpoint low-cost structural changes or maintenance programs for improving pollutant-removal efficiency. Where flooding problems exist, water quality controls should be incorporated into the design of surface water runoff controls. Available land area is often limited in urban areas, and the lack of suitable areas will frequently restrict the use of conventional pond systems. In heavily urbanized areas, sand filters or water quality inlets with oil/grit separators may be appropriate for retrofits because they do not limit land usage.

3. Management Measure Selection

Components (1) and (2) of this management measure were selected so that local communities develop and implement watershed management programs. Watershed management programs are used throughout the 6217 management area although coverage is inconsistent among States and local governments (Puget Sound Water Quality Authority, 1986).

Local conditions, availability of funding, and problem pollutants vary widely in developed communities. Watershed management programs allow these communities to select and implement practices that best address local needs. The identification of priority and/or local regional pollutant reduction opportunities and schedules for implementing appropriate controls were selected as logical starting points in the process of instituting an institutional framework to address nonpoint source pollutant reductions.

Cost was also a major factor in the selection of this management measure. EPA acknowledges the high costs and other limitations inherent in treating existing sources to levels consistent with the standards set for developing areas. Suitable areas are often unavailable for structural treatment systems that can adequately protect receiving waters. The lack of universal cost-effective treatment options was a major factor in the selection of this management measure. EPA was also influenced by the frequent lack of funding for mandatory retrofitting and the extraordinarily high costs associated with the implementation of retention ponds and exfiltration systems in developed areas.

The use of retrofits has been encouraged because of proven water quality benefits. (Table 4-17 illustrates the effectiveness of structural runoff controls for developed areas and retrofitted structures.) Retrofits are currently being used by a number of States and local governments in the 6217 management area, including Maryland, Delaware, and South Carolina.

Management measure components (3) and (4) were selected to preserve, enhance, and establish areas within existing development that provide positive water quality benefits. Refer to the New Development and Site Planning Management Measures for the rationale used in selecting components (3) and (4) of this management measure.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ a. ***Priority NPS pollutants should be targeted, and implementation strategies for mitigating the effects of NPS pollutants should be developed.***

■ b. ***Policies, plans, and organizational structures that ensure that all surface water runoff management facilities are properly operated and maintained should be developed. Periodic monitoring and maintenance may be necessary to ensure proper operation and maintenance.***

c. Remnant pervious areas in already-built areas should be subject to enforceable preservation requirements. For example, set green space goals to promote tree plantings and pavement reclamation projects.

d. Developed areas in need of local or regional structural solutions should be identified and put in priority order.

e. Regional structural solutions, retrofit opportunities, and nonstructural alternatives should be identified, inventoried, and put in priority order.

f. Where possible, modify existing surface water runoff management structures to address water quality.

g. As capital resources allow, implement practices such as those in Table 4-17.

5. Effectiveness Information and Cost Information

The following is a general description of various retrofit options and their effectiveness. Since each retrofit situation is different, the costs will depend on site-specific factors such as climate, drainage area, or pollutants. Table 4-17 discusses the effectiveness of several practices often implemented when correcting existing NPS pollution problems in urban areas.

a. Construction or Modification of Pollutant Removal Facilities

Many of the management practices described in Section II of this chapter cannot be used in already urbanized areas because they require space that is typically not available in urbanized areas. However, two types of pollutant removal retrofits can be used to treat runoff: new treatment facilities can be built in limited land space, and existing facilities can be modified to obtain increased water quality benefits.

New Facilities. If there is space available, the management practices described in Section II can be applied to provide water quality benefits. Typically, however, there are space constraints in urbanized areas that will not allow construction of these facilities. Water quality inlets may be appropriate in areas where space is limited and runoff from highly impervious areas such as parking lots must be treated. The effectiveness and costs of these facilities would be similar to those previously discussed. There are several types of water quality inlets—catch basins, catch basins with sand filters, and oil/grit separators. These are described in detail in Section II.

Retrofit of Existing Facilities. In the past, many surface water runoff management facilities were constructed to provide peak volume control; however, no provisions for pollutant removal were provided. These existing facilities can be modified to provide water quality benefits. Two common modifications are dry pond conversion and fringe marsh creation.

- Dry Pond Conversion. Many dry ponds for surface water runoff management that provide peak volume control, but no water quality benefits, have been constructed. Many of these ponds can be modified to provide water quality control. These modifications can include decreasing the size of the outlet to increase the detention of the dry pond. A dry pond's outlet may also be modified to detain a permanent pool of water and thus create a wet pond or extended detention wet pond. Prince George's County, Maryland, has a successful program for urban retrofits. They are usually off-line facilities with forebays, vegetative benches, and deeper portions for storage.

- Fringe Marsh Creation. Aquatic vegetation can be planted along the perimeter of constructed wet ponds or other open water systems to enhance sediment control and provide some biological pollutant uptake.

b. Stabilization of Shorelines, Stream Banks, and Channels

Urbanization can significantly increase the volume and velocity of surface water runoff that has the potential to erode streambanks and channels. This erosion can create high sediment loads in surface water. Streambanks can be stabilized by providing plantings along the streambank or by placing boulders, riprap, retaining walls, or other structural controls in eroding areas. Where feasible, vegetation and other soft practices should be used instead of hard, structural practices. See the Shoreline and Streambank Protection section of Chapter 6 for additional information.

c. Protection and Restoration of Riparian Forest and Wetland Areas

Riparian forests and wetlands are very effective water quality controls. They should be protected and restored wherever possible. Riparian forests can be restored by replanting the banks and floodplains of a stream with native species to stabilize erodible soils and improve surface water and ground water quality. Refer to Chapter 7 for additional information.

Some examples of urban watershed retrofit programs are presented below. The first case study, the Anacostia watershed, involves a developed urban area suffering from multiple NPS pollution impacts. As with many of the examples given, the project has advanced only through the planning and early implementation stages. Therefore, performance data are not currently available.

CASE STUDY 1 - ANACOSTIA WATERSHED, MARYLAND

Opportunities for urban retrofitting are limited in developed watersheds, but they can be implemented through extensive onsite evaluations. For example, between 1989 and 1991 over 125 sites in the 179-square-mile Anacostia watershed in Montgomery County, Maryland, were identified as candidates for retrofitting after extensive on-site evaluation (Schueler et al., 1991). Retrofit options developed in the watershed included source reduction, extended detention (ED) marsh ponds or ED ponds to handle the first flush, additional storage capacity in the open channel, routing of surface water runoff away from sensitive channels, diversion of the first flush to sand-peat filters, and installation of oil/grit separators in the drain network itself. The most commonly used retrofit technique in the Anacostia watershed is the retrofit of existing dry surface water runoff detention or flood control structures to improve their runoff storage and treatment capacity. Existing detention ponds are maintained by excavation, adding to the elevation of the embankment, or by construction of low-flow orifices. The newly created storage is used to provide a permanent pool, extended detention storage, or a shallow wetland. Nearly 20 such retrofits are in some stage of design or construction in the Anacostia watershed.

VOL 12

9659

CASE STUDY 2 - LOCH RAVEN RESERVOIR, MARYLAND
(Stack and Belt, 1989)

Loch Raven Reservoir, a water supply reservoir serving Baltimore, Maryland, had a eutrophication problem due to excessive phosphorus loads. To address this problem, the city examined the effectiveness of its existing phosphorus controls. They found that the more than 24 extended detention dry ponds that had been originally constructed for surface water runoff management had been designed to treat the once-in-10-year or once-in-100-year flood. The extended detention ponds were thus inefficient at treating runoff from frequent storm events, and the city was receiving few water quality benefits from these structures. Modifications, or retrofits, allowed the basins to collect runoff from smaller events and reduce pollutant loadings without affecting their capacity to contain runoff from larger storms.

Difficulties in obtaining permission from private pond owners restricted the number of ponds with planned retrofits to six ponds owned by the county and one privately owned pond. Private owners were concerned about the maintenance costs associated with the retrofits. Changes to the ponds usually involved alteration of the size of the orifice of the low-flow release structure. Computer modeling was used to determine the minimum size that would not interfere with the pond's design criteria (i.e., containing the 2-, 10- and 100-year storms) while providing sufficient detention time to settle the majority of the solids in urban runoff from the more frequent storms. Each retrofit was tailored to the basin's unique outlet and site characteristics, and costs reflect the differences in approach. For example, one of the ponds was modified as an urban runoff wetland for an estimated cost of $27,800. Retrofits of dry ponds were the least expensive, with costs of less than about $2,000. Draining and dredging boosted the cost of retrofitting a wet pond with a clogged low-flow release structure to approximately $13,000.

Monitoring of the performance of the retrofits during 12 storm events measured removal efficiencies for particulate matter of over 90 percent and removal efficiencies for total phosphorus of between 30 and 40 percent. All of the storms monitored were less than the 1-year storm, and detention times ranged from 1 to 5 hours. Trash debris collectors were effective at reducing clogging; thus no maintenance was necessary in the first year of operation.

CASE STUDY 3 - INDIAN RIVER LAGOON, FLORIDA
(Bennett and Heaney, 1991)

Improper surface water runoff drainage practices have degraded the quality of Florida's Indian River Lagoon by increasing the volume of freshwater runoff to the estuarine receiving water, as well as increasing the loading of suspended solids. Draining of wetlands for urban and agricultural development has led to nutrient loading in the lagoon.

The study area, typical of most Florida flatwood watersheds, was selected as a representative drainage catchment. EPA's Storm Water Management Model (SWMM) was used to summarize the relationship between catchment hydrology, channel hydraulics, and pollutant loads. The model, calibrated for the study region, was used to evaluate the effectiveness of the proposed watershed control program and to project performance levels expected after the study region becomes fully developed. The retrofit of multiple structural measures was undertaken as a demonstration-scale project. An existing trunk channel was modified to act as a wet detention basin. Flow from the trunk channel enters a partially disturbed, interdunal, freshwater wetland. The wetland system provides nutrient assimilation, additional water storage capacity, sediment attenuation, and enhanced evapotranspiration. SWMM predicted that the project will remove between 8[illegible] percent and 85 percent of the total suspended solids, depending on the level of future development. The cost of the project in 1989 dollars, including operation and monitoring costs over a 10-year period, was $198,960.

V. ONSITE DISPOSAL SYSTEMS

A. New Onsite Disposal Systems Management Measure

(1) Ensure that new Onsite Disposal Systems (OSDS) are located, designed, installed, operated, inspected, and maintained to prevent the discharge of pollutants to the surface of the ground and to the extent practicable reduce the discharge of pollutants into ground waters that are closely hydrologically connected to surface waters. Where necessary to meet these objectives: (a) discourage the installation of garbage disposals to reduce hydraulic and nutrient loadings; and (b) where low-volume plumbing fixtures have not been installed in new developments or redevelopments, reduce total hydraulic loadings to the OSDS by 25 percent. Implement OSDS inspection schedules for preconstruction, construction, and postconstruction.

(2) Direct placement of OSDS away from unsuitable areas. Where OSDS placement in unsuitable areas is not practicable, ensure that the OSDS is designed or sited at a density so as not to adversely affect surface waters or ground water that is closely hydrologically connected to surface water. Unsuitable areas include, but are not limited to, areas with poorly or excessively drained soils; areas with shallow water tables or areas with high seasonal water tables; areas overlaying fractured bedrock that drain directly to ground water; areas within floodplains; or areas where nutrient and/or pathogen concentrations in the effluent cannot be sufficiently treated or reduced before the effluent reaches sensitive waterbodies;

(3) Establish protective setbacks from surface waters, wetlands, and floodplains for conventional as well as alternative OSDS. The lateral setbacks should be based on soil type, slope, hydrologic factors, and type of OSDS. Where uniform protective setbacks cannot be achieved, site development with OSDS so as not to adversely affect waterbodies and/or contribute to a public health nuisance;

(4) Establish protective separation distances between OSDS system components and groundwater which is closely hydrologically connected to surface waters. The separation distances should be based on soil type, distance to ground water, hydrologic factors, and type of OSDS;

(5) Where conditions indicate that nitrogen-limited surface waters may be adversely affected by excess nitrogen loadings from ground water, require the installation of OSDS that reduce total nitrogen loadings by 50 percent to ground water that is closely hydrologically connected to surface water.

VOL 12

9561

1. Applicability

This management measure is intended to be applied by States to all new OSDS including package plants and small-scale or regional treatment facilities not covered by NPDES regulations in order to manage the siting, design,

R0042967

installation, and operation and maintenance of all such OSDS. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have flexibility in doing so. The application of management measure by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The purpose of this management measure is to protect the 6217 management area from pollutants discharged by OSDS. The measure requires that OSDS be sited, designed, and installed so that impacts to waterbodies will be reduced, to the extent practicable. Factors such as soil type, soil depth, depth to water table, rate of sea level rise, and topography must be considered in siting and installing conventional OSDS.

The objective of the management measure is to prevent the installation of conventional OSDS in areas where soil absorption systems will not provide adequate treatment of effluents containing solids, phosphorus, pathogens, nitrogen, and nonconventional pollutants prior to entry into surface waters and ground water (e.g., highly permeable soils, areas with shallow water tables or confining layers, or poorly drained soils). In addition to soil criteria, setbacks, separation distances, and management and maintenance requirements need to be established to fulfill the requirements of this management measure. Guidance on design factors to consider in the installation of OSDS is available in EPA's *Design Manual for Onsite Wastewater Treatment and Disposal Systems* (1980), currently under revision. This measure also requires that in areas experiencing pollution problems due to OSDS-generated nitrogen loadings, OSDS designs should employ denitrification systems or some other nitrogen removal process that reduces total nitrogen loadings by at least 50 percent. Additionally, hydraulic loadings to OSDS can be reduced by up to 25 percent by installing low-volume plumbing fixtures and enforcing water conservation measures. Garbage disposals are to be discouraged in all new development or redevelopment where conventional OSDS are employed as another means of reducing overloading and ensure proper operation of the OSDS. Regularly scheduled maintenance and pumpout of OSDS will prolong the life of the system and prevent degradation of surface waters.

States need not conduct new monitoring programs or collect new monitoring data to determine whether ground water is closely hydrologically connected to surface water, nor are States expected to determine exactly where the resulting water quality problems are significant. Rather, States are encouraged to make reasonable determinations based upon existing information and data sources.

3. Management Measure Selection

This management measure was selected to address the proper siting, design, and installation of new OSDS in the 6217 management area. OSDS have been identified as contributors of pathogens, nutrients, and other pollutants to ground water and surface waters. Nearly all coastal States have siting regulations establishing criteria for setbacks, separation distances, and percolation rates (Myers, 1991; WCFS, 1992). However, these programs often do not adequately protect surface waters from pollutants generated by OSDS. This management measure was selected to ensure that States comprehensively control new OSDS siting, design, and installation in order to protect surface waters.

The management measure components were selected to address problems known to be associated with OSDS. These management measure components were selected because proper siting of OSDS and the use of setbacks have been identified as effective methods for reducing nutrient and pathogen loadings to ground water and surface waters. All components of this management measure were selected to direct the placement of OSDS away from areas where site conditions are inadequate to allow proper treatment to occur and areas where there is a high potential for subsequent system failures that may cause contamination of waterbodies. In addition, this management measure was selected because siting and density controls can be effective complements to denitrifying systems. However, these requirements alone are often not adequate to protect surface waters, particularly in situations where installation and replacement of OSDS are allowed without thorough consideration of OSDS-related impacts. Periodic reevaluation of these requirements is necessary to ensure protection of surface waters.

Management measure components (1) (a) and (b) were selected to reduce occurrences of hydraulic overloading of conventional OSDS, which may result in inadequate treatment of septic system effluent and contamination of ground water or surface water. When excessive wastewater volumes are delivered to the soil absorption field, failure can occur. In addition, soil saturated with wastewater will not allow oxygen to pass into the soil. Hydraulic overloading often results from changes in water use habits, such as increased family size, the addition of new water-using appliances that require increased water consumption, or high seasonal use. New systems may fail within a few months if water use exceeds the system's capacity to absorb effluent (Mancl, 1985). Water conservation reduces the amount of water an absorption field must accept.

Since numerous States have responded to this concern by adopting low-flow plumbing fixture regulations (Table 4-18), requiring such fixtures is not unreasonable. In addition, a number of States have regulations prohibiting the installation of garbage disposals where OSDS are used. If low-flow plumbing fixtures are used, it is important that OSDS design not be modified to decrease the required septic tank size. The use of smaller septic tanks will negate the advantages of using low-flow plumbing fixtures.

For absorption fields to operate properly, they must have aerobic conditions. Jarrett et al. (1985) stated that 75 percent of the total number of soil absorption field failures could be attributed to hydraulic overloading. High-efficiency plumbing fixtures can reduce the total water load by as much as 60 percent (Jarrett et al., 1985) and reduce the chance of absorption field failure. Table 4-19 illustrates daily water use and pollutant loadings.

Management measure component (5) was selected to abate OSDS nitrogen loadings to surface waters where nitrogen is a cause of surface water degradation. The Chesapeake Bay Program (1990) found that 55 to 85 percent of the nitrogen entering a conventional OSDS can be discharged into ground water. Conventional septic systems account for 74 percent of the nitrogen entering Buttermilk Bay (at the northern end of Buzzard's Bay) in Massachusetts (Horsely Witten Hegeman, 1991). A study of nitrogen entering the Delaware Inland Bays found that a significant portion of the total pollutant load could be attributed to septic systems. The study determined that septic systems accounted for 15 percent, 16 percent, and 11 percent of the nitrogen inputs to Assawoman, Indian River, and Rehoboth Bays, respectively (Reneau, 1977; Ritter, 1986). Alternatives to conventional OSDS that can substantially reduce nitrogen loadings are available.

In 1980, EPA developed a design manual for onsite wastewater treatment and disposal systems. An update of this document is being prepared.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Many of the following practices involve siting and locating OSDS within the 6217 management area. They address issues such as minimum lot size, depth to water table, and site-specific characteristics such as soil percolation rate. Table 4-20 illustrates the variability in State and local requirements for siting of OSDS. The practices were developed to address the issue of siting OSDS given the variable nature of this activity.

■ a. *Develop setback guidelines and official maps showing areas where conditions are suitable for conventional septic OSDS installation.*

VOL 12

Both conventional and alternative OSDS usually include a soil absorption field. These absorption fields require a certain minimum area of soil surrounding the system to effectively remove pathogens and other pollutants. Setbacks from wells, surface waters, building foundations, and property boundaries are necessary to minimize the threat to public health and the environment. The setback should be based on soil type, slope, presence and character of the water table (as defined on a map developed by the implementing agency), and the type of OSDS. Setback guidelines should be set for both traditional and alternative OSDS. The *Design Manual for Onsite Wastewater Treatment and Disposal Systems* (USEPA, 1980) recommends the following setbacks for soil absorption systems, although other increased setbacks may be necessary to protect ground water and surface waters from viral and bacteria transport to account for tidal influences and accommodate sea level rise. (NOTE: Setback distance requirements may vary considerably based on local soil conditions and aquifer properties):

Water supply wells	50 to 100 feet
Surface waters, springs	50 to 100 feet
Escarpments	10 to 20 feet
Boundary of property	5 to 10 feet
Building foundations	10 to 20 feet (30 feet when located up-slope from a building in slowly permeable soils)

For mound systems, the mound perimeter requires down-slope setbacks to make certain that the basal area of the mound is sufficient to absorb the wastewater before it reaches the perimeter of the mound to avoid surface seepage. The *Design Manual for Onsite Wastewater Treatment and Disposal Systems* (USEPA, 1980) provides guidance on setbacks for mound systems.

b. OSDS should be sited, designed, and constructed so that there is sufficient separation between the soil absorption field and the seasonal high water table or limiting layer, depending on site characteristics, including but not limited to hydrology, soils, and topography.

Studies have shown that at least 4 feet of unsaturated soil below the ponded liquid in a soil absorption field is necessary to (1) remove bacteria and viruses to an acceptable level, (2) remove most organics and phosphorus, and (3) nitrify a large portion of the ammonia (University of Wisconsin, 1978). The majority of coastal States already require a minimum separation distance of at least 2 feet (Woodward-Clyde, 1992). Massachusetts requires a minimum separation of 4 feet; 5 feet is required by towns with sensitive surface waters. Several towns on Cape Cod have adopted 5 feet as the minimum. A prescribed minimum distance is necessary to prevent contaminants from directly entering ground water and surface waters. Areas with rapid soil permeabilities (e.g., a percolation rate of less than 5 minutes/inch) may require a greater separation distance. However, because of local variation, these numbers are provided only as guidance.

A study on a barrier island of North Carolina (Carlile et al., 1981) found high concentrations of nitrogen, phosphorus, and pathogens in shallow ground-water wells located beneath septic system soil absorption fields. These high concentrations were suspected to be the result of inadequate separation distance to the water table. Further analysis revealed that, at the design loading rate, a greater separation distance reduced the ground-water concentration of indicator organisms from 4.6 to 2.3 logs, and phosphorus by 93 percent. Nitrogen levels were also reduced, but this improvement (10 percent) was not as dramatic as that observed for bacteria and phosphorus.

c. Require assessments of site suitability prior to issuing permits for OSDS.

Site assessments should be performed to determine the soil infiltration rate, soil pollutant removal capacity, acceptable hydraulic loading rate, and depth to the water table prior to issuing permits for OSDS. Percolation tests are usually performed to determine the soil infiltration rate. However, Hill and Frink (1974) stated that percolation tests are often performed improperly and system failures have resulted from improper siting and inadequate percolation rates. In addition, regulatory values based on acceptable percolation rates vary considerably (e.g., Delaware - 6 to 60 min/in; Georgia - 50 to 90 min/in; Michigan - 3 to 60 min/in; and Virginia - 5 to 120 min/in

9655

Table 4-20. Example Onsite Sewage Disposal System Siting Requirements

State	OSDS Siting Requirement
Florida	With respect to ground-water movement, the State requires that onsite systems must be placed no closer than 75 ft from a private potable water well, 100 ft from a public drinking water well, and 200 ft from a public drinking water well serving a facility with an estimated sewage flow of more than 2,000 gallons per day. Systems must not be located within 5 ft of building foundations or laterally within 75 ft of the mean high water line. Subdivisions and lots where each lot has a minimum area of at least 1/2 acre and either a minimum dimension of 100 ft or a mean of at least 100 ft from the street may be developed with private potable wells or wells serving water systems and onsite sewage disposal systems.
Massachusetts	The State requires that no septic tank shall be closer than 10 ft and no leaching facility shall be closer than 20 ft to surface water supplies; no septic tank shall be closer than 25 ft and no leaching facility shall be closer than 50 ft to watercourses. Onsite systems must be at least 4 ft above ground water.
South Carolina	No State requirement. County requirements vary. For example, the County of Charleston recommends a minimum lot size of 12,500 ft^2 with a 70-ft front on lots with public water supplies and 30,000 ft^2 with a 100-ft front for lots with private water supplies.
Virginia	The Chesapeake Bay Act requires that no sewage system shall be placed within 25 ft of a Resource Preservation Watercourse or within 100 ft of a Resource Management Watercourse. In the event that these requirements cannot be met, the State requires minimum setbacks of 70 ft for shellfish waters, 50 ft for impounded surface waters, and 50 ft for streams.
Washington	The State requires a 1/2- to 1-acre minimum lot size, dependent upon soil type, for areas served by public water supplies and a 1- to 2-acre minimum lot size for septic tank siting, dependent upon soil type, for individual areas served by water supplies and private wells.
Wisconsin	The State requirements of lot areas and widths vary according to percolation rate (measured as time required to percolate 1 inch). For example, for a lot with a private water supply system and a percolation rate of under 10 minutes, a minimum lot area of 20,000 ft^2, a minimum average lot width of 100 ft, and a minimum continuous suitable soil area of 10,000 ft^2 are required before an OSDS can be sited. For areas served by a community water supply system, a lot with a percolation rate of under 10 minutes requires a minimum lot area of 12,000 ft^2, a minimum average lot width of 75 ft, and a minimum continuous suitable soil area of 6,000 ft.

(Woodward-Clyde, 1992). States such as Florida and Mississippi require soil evaluations to determine the suitability of an absorption field. A soil evaluation should also be used in conjunction with percolation test results to determine whether a site is acceptable, and soil percolation requirements should be phased out, if appropriate. These evaluations should examine the organic content of the soil, the grain size distribution, and the structure of the soil. In addition, hydraulic loading should be evaluated to determine the suitability of a site for septic tank use.

A system such as DRASTIC methodology (USEPA, 1987) can also be used to map areas where aquifers may be vulnerable to pollution from OSDS. DRASTIC considers soil permeability, depth to ground water, and aquifer characteristics.

■ *d. If OSDS are sited in areas where conditions indicate that nitrogen-limited waters may be adversely affected by excessive nitrogen loading, minimize densities of development in those areas and require the use of denitrification systems.*

In areas where nitrogen is a problem pollutant, it is important to consider the density of OSDS. As the density of residences increases, lot sizes decrease and impacts (especially from nitrogen) on underlying ground water may intensify. One-half to 5-acre lots are generally the minimal requirement for siting OSDS, but the lot size may need to be larger if nitrogen is a problem pollutant. Limits on the density of absorption fields should also reflect variations in climate (Rutledge et al., undated). In Buzzards Bay, Massachusetts, a minimum lot size of 70,000 square feet was recommended as necessary to avoid nitrogen-induced degradation (Horsely Witten Hegeman, 1991). However, this practice should not preclude implementation of the use of cluster development to retain open areas necessary for controlling NPS pollution.

A number of treatment systems are known to remove nitrogen using denitrification. Such systems include sand and anaerobic upflow filters, and constructed wetlands. These systems are described in practice "f." Most of these systems require nitrification of septic tank effluent as an initial stage of the treatment process. When properly operated, these systems have been shown to have the potential to remove over 50 percent of the total nitrogen from septic tank effluent.

■ *e. Develop and implement local plumbing codes that require practices that are compatible with OSDS use.*

As stated previously, the majority of OSDS soil absorption field failures are attributed to hydraulic overload. Solids loads from garbage disposals can also lead to clogging and failure of an absorption field. To address these problems, plumbing codes that minimize the potential for soil absorption field failure should be implemented.

Plumbing codes that require the use of high-efficiency plumbing fixtures in new development can reduce these water loads considerably. Such high-efficiency fixtures include toilets of 1.5 gallons or less per flush, shower heads of 2.0 gallons per minute (gpm), faucets of 1.5 gpm or less, and front-loading washing machines of up to 27 gallons per 10- to 12-pound load. Implementing these fixtures can reduce total in-house water use by 30 percent to 70 percent (*Consumer Reports* July 1990, February 1991).

■ *f. In areas suitable for OSDS, select, design, and construct the appropriate OSDS that will protect surface waters and ground water.*

Selection of an OSDS should consider site soil and ground-water characteristics and the sensitivity of the receiving water(s) to OSDS effluent. Descriptions and design considerations for systems have been provided below. Table 4-21 contains available cost and effectiveness data for some of these systems. Design and operation and maintenance information on these devices can be found in *Design Manual for Onsite Wastewater Treatment and Disposal Systems* (USEPA, 1980).

Conventional Septic System. A conventional septic system consists of a settling or septic tank and a soil absorption field. The traditional system accepts both greywater (wastewater from showers, sinks, and laundry) and blackwater (wastewater from toilets). These systems are typically restricted in that the bottom invert of the absorption field must be at least 2 feet above the seasonally high water table or impermeable layer (separation distance) and the percolation rate of the soil must be between 1 and 60 minutes per inch. Also, to ensure proper operation, the tank should be pumped every 3 to 5 years. Nitrogen removal of these systems is minimal and somewhat dependent on temperature. The most common type of failure of these systems is from clogging of the absorption field, insufficient separation distance to the water table, insufficient percolation capacity of the soil, and overloading of water.

Mound Systems. Mound systems are an alternative to conventional OSDS and are used on sites where insufficient separation distance or percolation conditions exist. Mound systems are typically designed so the effluent from the

NA - Not available.
[a] Effectiveness values reflect total system reductions including soil absorption fields.
[b] Costs are in 1988 equivalent dollars, and an average household with four occupants was assumed.

septic tank is routed to a dosing tank and then pumped to a soil absorption field that is located in elevated sand fill above the natural soil surface. There is evidence suggesting that pressure dosing provides more uniform distribution of effluent throughout the absorption field and may result in marginally better performance. A major limitation to the use of mounds is slope. In Pennsylvania, elevated sand mound beds are permitted only in areas with slopes less than 8 percent (Mancl, 1985).

Where adequate area is available for subsurface effluent discharge, and permanent or seasonal high ground water is at least 2 feet below the surface, the elevated sand mound may be used in coastal areas. This system can treat septic tank effluent to a level that usually approaches primary drinking water standards for BOD_5, suspended solids, and pathogens by the time the effluent plume passes the property line for single-family dwellings. A mound system will not normally produce significant reductions in levels of total nitrogen discharged, but should achieve high levels of nitrification.

Intermittent Sand Filter. Intermittent sand filters are used in conjunction with pretreatment methods such as septic tanks and soil absorption fields. An intermittent sand filter receives and treats effluent from the septic tank before it is distributed to the leaching field. The sand filter consists of a bed (either open or buried) of granular material from 24 to 36 inches deep. The material is usually from 0.35 to 1.0 mm in diameter. The bed of granular material is underlain with graded gravel and collector drains. These systems have been shown to be effective for nitrogen removal; however, this process is dependent on temperature. Water loading recommendations for intermittent sand filters are typically between 1 and 5 gallons per day/square foot (gpd/ft^2) but can be higher depending on wastewater characteristics. Primary failure of sand filters is from clogging, and the following maintenance is recommended to keep the system performing properly: resting the bed, raking the surface layer, or removing the top surface medium and replacing it with clean medium. In general, the filters should be inspected every 3 to 4 months to ensure that they are operating properly (Otis, undated).

Intermittent sand filters are used for small commercial and institutional developments and individual homes. The size of the facility is limited by land availability. The filters should be buried in the ground, but may be constructed above ground in areas of shallow bedrock or high water tables. Covered filters are required in areas with extended periods of subfreezing weather. Excessive long-term rainfall and runoff may be detrimental to filter performance, requiring measures to divert water away from the system (USEPA, 1980).

Recirculating Sand Filter. A recirculating sand filter is a modified intermittent sand filter in which effluent from the filter is recirculated through the septic tank and/or the sand filter before it is discharged to the soil absorption field. The addition of the recirculation loop in the system may enhance removal effectiveness and allows media size to be increased to as much as 1.5 mm in diameter and allows water loading rates in the range of 3 to 10 gpd/ft^2 to be used. Recirculation rates of 3:1 to 5:1 are generally recommended.

Buried or recirculating sand filters can achieve a very high level of treatment of septic tank effluent before discharge to surface water or soil. This usually means single-digit figures for BOD_5 and suspended solids and secondary body contact standards for pathogens (in practice, 100-900 per 100 ml). Dosed recycling between sand filter and septic tank or similar devices can result in significant levels of nitrification/denitrification, equivalent to between 50 and 75 percent overall nitrogen removal, depending on the recycling ratio. Regular buried or recirculating sand filters may require as much as 1 square foot of filter per gallon of septic tank effluent.

Anaerobic Upflow Filter. An anaerobic upflow filter (AUF) resembles a septic tank filled with 3/8-inch gravel with a deep inlet tee and a shallow outlet tee. An AUF system includes a septic tank, an AUF, a sand filter, and a soil absorption field. As with the sand filter, dose recycling can be used to enhance this system's performance. Hydraulic loading for an AUF is generally in the range of 3 to 15 gpd. An AUF resembles a septic tank or the second chamber of a dual-chambered tank. It should be sized to allow retention times between 16 and 24 hours. There is a high degree of removal of suspended solids and insoluble BOD. Dosed recycling between sand filter and AUF can result in 60 to 75 percent overall nitrogen removal.

A growing body of data at the University of Arkansas and elsewhere suggests that an AUF can provide further treatment of septic tank effluent before discharge to a sand filter. This treatment allows a drastic reduction (by a factor of 8 to 20) in the size of sand filter needed to attain the performance described above, with major reductions in cost (Krause, 1991).

Trenches and Beds. Trenches are typically 1 to 3 feet wide and can be greater than 100 feet long. Infiltration occurs through the bottom and sides of the trench. Each trench contains one distribution pipe, and there may be multiple trenches in a single system. Like conventional septic systems, they require 2 to 4 feet between the bottom of the system and the seasonally high water table or bedrock, and are best suited in sandy to loamy soils where the infiltration rate is 1 to 60 minutes per inch. Gravelly soils or poor-permeability soils (60 to 90 minutes per inch) are not suitable for trench systems. However, where the infiltration rate is greater than 1 minute per inch, 6 inches of loamy soil can be added around the system to create the proper infiltration rate (Otis, undated).

Beds are similar to trenches except that infiltration occurs only through the bottom of the bed. Beds are usually greater than 3 feet wide and contain one distribution pipe per bed. Single beds are commonly used; however, dual beds may be installed and used alternately. The same soil suitability conditions that apply to trenches apply to bed systems.

Trenches are often preferred to beds for a few reasons. First, with equal bottom areas, trenches have five times the sidewall area for effluent absorption; second, there is less soil damage during the construction of trenches; and third, trenches are more easily used on sloped sites.

The effluent from trenches or beds can be distributed by gravity, dosing, or uniform application. Dosing refers to periodically releasing the effluent using a siphon or pump after a small quantity of effluent has accumulated. Uniform application similarly stores the effluent for a short time, after which it is released through a pressurized system to achieve uniform distribution over the bed or trench. Uniform application results in the least amount of clogging.

Maintenance of trenches and beds is minimal. Dual trench or bed systems are especially effective because they allow the use of one system while the other rests for 6 months to a year to restore its effectiveness (Otis, undated).

Water Separation System. A water separation system separates greywater and blackwater. The greywater is treated using a conventional septic system, and the blackwater is contained in a vault/holding tank. The blackwater is later hauled off site for disposal.

For extreme situations or for seasonal residents, some form of separation of toilet wastes from bath and kitchen wastes may be helpful. Most nitrogen discharges in residential wastewater come from human urine. A very efficient toilet (0.8 gallon per flush), if routed to a separate holding tank, would need pumping only three or four times per year even for a family of four permanent residents.

Constructed Wetlands. Constructed wetlands are usually used for polishing of septage effluent that has already had some degree of treatment (processing through a septic tank or other aggregated system). The performance of constructed wetlands will be degraded in colder climates during winter months because of plant die-off and reduction in the metabolic rate of aquatic organisms.

Cluster Systems. For the purposes of this guidance, a cluster system can be defined as a collection of individual septic systems where primary treatment of septage occurs on each site and the resulting effluent is collected and treated to further reduce pollutants. Additional treatment may involve the use of sand filters or AUF, constructed wetlands, chemical treatment, or aerobic treatment. The use of cluster systems may provide advantages due to increased treatment capability and economy of scale.

Evapotranspiration (ET) and Evapotranspiration/Absorption (ETA) Systems. ET and ETA systems combine the process of evaporation from the surface of a bed and transpiration from plants to dispose of wastewater. The wastewater would require some form of pretreatment such as a septic tank. An ET bed usually consists of a liner, drainfield tile, and gravel and sand layers. ET and ETA systems are useful where soils are unsuitable for subsurface disposal, where the climate is favorable to evaporation, and where ground-water protection is essential. In both types of systems, distribution piping is laid in gravel, overlain by sand, and planted with suitable vegetation. Plants can transpire up to 10 times the amount of water evaporated during the daytime. For an ET system to be effective, evaporation must be equal to or greater than the total water input to the system because it requires an impermeable seal around the system. In the United States, this limits use of ET systems to the Southwest. The size of the system depends on the quantity of effluent inflow, precipitation, the local evapotranspiration rate, and soil permeability (Otis, undated). Data were unavailable on this BMP, so its cost and effectiveness were not evaluated.

Vaults or Holding Tanks. Vaults or holding tanks are used to containerize wastewater in emergency situations or other temporary functions. This technology should be discouraged because of high anticipated overloads due to difficult pumping logistics. Such systems require frequent pumping, which can be expensive.

Fixed Film Systems. A fixed film system employs media to which microorganisms may become attached. Fixed film systems include trickling filters, upflow filters, and rotating biological filters. These systems require pretreatment of sewage in a septic tank; final effluent can be discharged to a soil absorption field. Cost and effectiveness data for this BMP were not available.

Aerobic Treatment Units. Aerobic treatment units can be employed on site. A few systems are available commercially that employ various types of aerobic technology. However, these systems require regular supervision and maintenance to be effective. They require pretreatment by a septic tank, and effluent can be discharged to a soil absorption field. Power requirements can be significant for certain types of these packages. Cost and effectiveness data for this BMP were not available.

Sequencing Batch Reactor. A sequencing batch reactor is a modified conventional continuous-flow activated sludge treatment system. Conventional activated sludge systems treat wastewater in a series of separate tanks. Sequencing batch reactors carry out aeration and sedimentation/clarification simultaneously in the same tank. They are designed for the removal of biochemical oxygen demand (BOD) and total suspended solids (TSS) from typical municipal and industrial wastewater at flow rates of less than 5 MGD. Modification to the design of the basic system allows for nitrification and denitrification and for the removal of biological phosphorus to occur.

The sequencing batch reactor is particularly suitable for small flows and for nutrient removal. Sequencing batch reactors can be either used for new developments or connected to existing septic systems. Small reactors can be sited in areas of only a few hundred square feet. While sequencing batch reactor cost and operation and maintenance requirements are greater than those for conventional OSDS, sequencing batch reactors may be suitable alternatives for sites where high-density development and/or unsuitable soils may preclude adequate treatment of effluent.

Sequencing batch reactors can also be used where municipal and industrial wastes require conventional or extended aeration activated sludge treatment. They are most applicable at flow rates of 3000 gpd to 5 MGD but lose their cost-effectiveness at design rates exceeding 10 MGD (USEPA, 1992). Sequencing batch reactors are very useful for the pretreatment of industrial waste and for small flow applications. They are also optimally useful where wastewater is generated for less than 12 hours per day.

Disinfection Devices. In some areas, pathogen contamination from OSDS is a major concern. Disinfection devices may be used in conjunction with the above systems to treat effluent for pathogens before it is discharged to a soil absorption field. Disinfection devices include halogen applicators (for chlorine and iodine), ozonators, and UV applicators. Of these three types, halogen applicators are usually the most practical (USEPA, 1980). Installation of these devices in an OSDS increases the system's cost and adds to the system's operation and maintenance requirements. However, it may be necessary in some areas to install these devices to control pathogen contamination of surface waters and ground water.

(NOTE: The use of disinfection systems should be evaluated to determine the potential impacts of chlorine or iodine loadings. Some States, such as Maryland, have additional requirements or prohibit the use of these processes.)

Massachusetts has adopted a provision of its State Environmental Code that allows for "approval of innovative disposal systems if it can be demonstrated that their impact on the environment and hazard to public health is not greater than that of other approved systems" (310 CMR 15.18). Commonly referred to as Title 5, this legislation requires evaluation of pollutant loadings as well as management requirements prior to approval of alternative systems (Venhuizen, 1992).

g. Design sites so that an area for a backup soil absorption field is planned for in case of failure of the first field.

In preparation of site plans and designs for OSDS, it is recommended that a suitable area be identified and reserved for construction of a second or replacement soil absorption field, in the event that the first fails or expansion is necessary. Oliveri and others (1981) determined that continuously loaded soil absorption fields have a finite life span and that 50 percent of all fields fail within 25 years. Consequently, dual systems or a plan for a backup system is necessary. The area for the backup soil absorption field should be located to facilitate simultaneous or alternate loading of the old and new systems. With trench systems, the area between the original trenches can serve as the replacement area as long as sufficient vertical spacing exists between the trenches.

h. During construction of OSDS, soils should not be compacted in the primary or the backup soil absorption field area.

Care must be taken during the construction of OSDS so that the soil in the absorption field area is not compacted. Compaction could severely decrease the infiltration capacity of the soil and lead to failure of the absorption field.

i. Perform postconstruction inspection of OSDS.

A postconstruction inspection program should be implemented to ensure that OSDS were installed properly. The inspection should ensure that design specifications were followed and that soil absorption field areas were not compacted during construction. Many local governments in Massachusetts require postconstruction inspection for OSDS (Myers, 1991).

5. Effectiveness Information and Cost Information

Cost and effectiveness data on alternative OSDS systems are presented in Table 4-21.

The availability of high-quality, water-efficient plumbing fixtures (1.6-gallon toilets, 1.5-gpm showerheads, etc.) can provide a reduction of 50 percent in residential water use and wastewater volume, at an incremental cost of only about $20 to $100 for new homes. For on-site treatment, the higher influent concentrations are counterbalanced by longer septic tank retention time. This water conservation can allow further reductions in the size of sand filters or other forms of treatment (Krause, 1991).

The elimination of garbage disposals will reduce hydraulic loadings to OSDS and decrease the potential for solids to clog the absorption field, as shown in Table 4-22.

Performance data on sequencing batch reactors show that typical designs can achieve BOD and TSS concentrations of less than 10 mg/L and that modified systems can denitrify to limits of 1 to 2 mg/L NH_3-N (EPA, 1992). Some modified sequencing batch reactors have been shown to exhibit denitrification. Biological phosphorus removal to less than 1.0 mg/L has also been achieved (EPA, 1992).

VOL 12

9674

Table 4-22. Reduction in Pollutant Loading by Elimination of Garbage Disposals

Parameter	Reduction in Pollutant Loading (%)
Suspended Solids	25-40
Biohemical Oxygen Demand	20-28
Total Nitrogen	3.6
Total Phosphorus	1.7

The costs for sequencing batch reactors, adjusted to 1991 dollars, for constructing and operating sequencing batch reactors were determined for several existing systems. The capital costs for six treatment systems were found to range from $1.93 to $30.69/gpd of design flow (USEPA, 1992). The operating costs for three existing systems, based on 1990 average flow rates, ranged from $0.17/gpd to $2.88/gpd (USEPA, 1992).

Costs for a complete mound system, including a septic tank, in the rural Midwest are typically $7,000 installed (Krause, 1991). The cost for a residential septic tank/AUF/sand filter combination in the rural Midwest normally ranges from $3,000 to $4,000 (Krause, 1991). Costs for buried or recirculatng sand filters depend on the filter size and the availability of sand of the proper texture. Costs for a complete system in the rural Midwest may range between $5,000 and $10,000 (Krause, 1991).

VOL 12

B. [illegible] Measure

(1) Establish and implement policies and systems to ensure that existing OSDS are operated and maintained to prevent the discharge of pollutants to the surface of the ground and to the extent practicable reduce the discharge of pollutants into ground waters that are closely hydrologically connected to surface waters. Where necessary to meet these objectives, encourage the reduced use of garbage disposals, encourage the use of low-volume plumbing fixtures, and reduce total phosphorus loadings to the OSDS by 15 percent (if the use of low-level phosphate detergents has not been required or widely adopted by OSDS users). Establish and implement policies that require an OSDS to be repaired, replaced, or modified where the OSDS fails, or threatens or impairs surface waters;

(2) Inspect OSDS at a frequency adequate to ascertain whether OSDS are failing;

(3) Consider replacing or upgrading OSDS to treat influent so that total nitrogen loadings in the effluent are reduced by 50 percent. This provision applies only:

(a) where conditions indicate that nitrogen-limited surface waters may be adversely affected by significant ground water nitrogen loadings from OSDS, and

(b) where nitrogen loadings from OSDS are delivered to ground water that is closely hydrologically connected to surface water.

9676

1. Applicability

This management measure is intended to be applied by States to all operating OSDS. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce. This management measure does not apply to existing conventional OSDS that meet all of the following criteria: (1) treat wastewater from a single family home; (2) are sited where OSDS density is less than or equal to one OSDS per 20 acres; and (3) the OSDS is sited at least 1,250 feet away from surface waters.

2. Description

The purpose of this management measure is to minimize pollutant loadings from operating OSDS. This management measure requires that OSDS be modified, operated, repaired, and maintained to reduce nutrient and pathogen loadings in order to protect and enhance surface waters. In the past, it has been a common practice to site conventional OSDS

R0042982

in coastal areas that have inadequate separation distances to ground water, fractured bedrock, sandy soils, or other conditions that prevent or do not allow adequate treatment of OSDS-generated pollutants. Eutrophication in surface waters has also been attributed to the low nitrogen reductions provided by conventional OSDS designs.

Poorly designed or operating systems can cause ponding of partially treated sewage on the ground that can reach surface waters through runoff. In addition to oxygen-demanding organics and nutrients, these surface sources contain bacteria and viruses that present problems to human health. Viral organisms can persist in temperatures as low as -20 °F, suggesting that they may survive over winter in contaminated ice, later becoming available to ground water in the form of snowmelt (Hurst et al., undated). Although ground-water contamination from toxic substances is more often life-threatening, the majority of ground-water-related health complaints are associated with pathogens from septic tank systems (Yates, 1985).

Where development utilizing OSDS has already occurred, States and local governments have a limited capability to reduce OSDS pollutant loadings. One way to reduce the possibility of failed systems is to required scheduled pumpouts and regular maintenance of OSDS. Frequent inspections and proper operation and maintenance are the keys to achieving the most cost-effective OSDS pollutant reductions. Inspections upon resale or change of ownership of properties are also a cost-effective solution to ensure that OSDS are operating properly and meet current standards necessary to protect surface waters from OSDS-generated pollutants. Where phosphorus is a problem, phosphate bans can reduce phosphorus loadings by 14 to 17 percent (USEPA, 1992). Garbage disposal restrictions and low-volume plumbing fixtures can help ensure that conventional systems continue to operate properly. Low-volume plumbing fixtures have been shown to reduce hydraulic loadings to OSDS by 25 percent.

An option for managing and maintaining OSDS is through wastewater management utilities or districts. From a regulatory standpoint, a wastewater management program can reduce water quality degradation and save the time and money a local government or homeowner may spend maintaining and repairing systems. A variety of agencies are taking on the responsibilities of managing OSDS. Water utilities are the leading decentralized wastewater management agency (Dix, 1992). The following case studies illustrate successful wastewater management programs used where there are OSDS.

CASE STUDY 1 - GEORGETOWN DIVIDE PUBLIC UTILITIES, CALIFORNIA

The Georgetown Divide Public Utility District in California manages water reservoirs, two water treatment plants, an irrigation canal system, and two hydroelectric plants. Approximately 10 percent of the agency's resources are allocated to managing onsite systems in a large subdivision. The utility provides a comprehensive site evaluation program, designs the onsite system for each lot, lays out the system for the contractor, and makes numerous inspections during construction. There is also continued communication between the homeowners and the utility after construction, including scheduled inspections. For the service homeowners pay $12.50 per month for management of single-family systems. Owners of undeveloped lots pay $6.25 per month (Dix, 1992).

CASE STUDY 2 - STINSON BEACH COUNTY WATER DISTRICT, CALIFORNIA

In addition to monitoring the operation of septic tank systems, the Stinson Beach County Water District in California monitors ground water, streams, and sensitive aquatic systems that surround the coastal community to detect contamination from OSDS. Routine monitoring has identified people who use straight pipes and failures due to residents using overloaded systems. Homeowners pay a monthly fee of $12.90, in addition to the cost of construction or repair.

3. Management Measure Selection

This management measure was selected to control OSDS-related pollutant loadings to surface waters. Numerous States have implemented inspection requirements at title transfer, low-volume plumbing fixture regulations, garbage disposal prohibitions, and other requirements. Conventional systems are designed to operate over a specified period of time. At the end of the expected life span, replacement is generally necessary. Because failures of conventional systems may occur if systems are not properly designed and maintained, it is essential that programs are established to inspect and correct failing systems and to reduce pollutant loadings, public health problems, and inconveniences. Low-flow plumbing fixture installations and garbage disposal restrictions should be encouraged because as many as 75 percent of all system failures can be attributed to hydraulic overloading (Jarrett et al., 1985). Failure occurs when a system does not provide the level of treatment that is expected from the specific OSDS design.

National and local studies have indicated that conventional OSDS experience a significant rate of failure. Failure rates typically range between 1 and 5 percent per year (De Walle, 1981). In the State of Washington, high failure rates were observed in coastal regions (failure rates in 1971: King County - 6.1 percent; Gray's Harbor - 3.3 percent; and Skagit County - 2.6 percent). It has also been estimated in various soils of Connecticut that 4 percent of conventional OSDS fail per year. The failure rate in coastal areas may be greater because many systems (such as those in North Carolina) are approved for unsuitable soil conditions (Duda and Cromartie, 1982). Jarrett and others (1985) presented suggestions from several researchers describing the possible causes of high OSDS failure rates. These suggestions include:

- Smearing of trench bottoms during construction;
- Inadequate absorption areas;
- Improperly performed percolation tests;
- Inadequate design;
- Flooding and high water tables;
- Improper construction and installation;
- Inadequate soil permeability; and
- Use of cleaners and additives.

As stated previously, conventional OSDS do not remove nitrogen effectively and OSDS nitrogen loadings have been linked to degraded surface waters and ground water (Chesapeake Bay Program, 1990).

States should consider replacement with denitrifying OSDS in areas with nitrogen-limited waters. While all OSDS should be inspected periodically (at a recommended interval of once every 3 years) and corrected if failing, requiring that denitrifying systems be installed in all cases where existing systems fail to adequately treat nitrogen was deemed unduly burdensome and impractical.

Refer to the selection statement in the New OSDS Management Measure for additional rationale for selections relating to denitrification, garbage disposals, and low-flow plumbing fixtures.

Phosphorus reductions have been implemented in a number of States (see Table 4-23). Significant reductions in phosphorus loadings (14 to 17 percent) have resulted from such phosphate reductions, with nominal increases in costs for phosphate-free detergents.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Virginia	0.5% by weight as elemental P	8.7% by weight as elemental P		1/1/88
Wisconsin	0.5% by weight as elemental P	8.7% by weight as elemental P		1/1/84

a. *Perform regular inspections of OSDS.*

As previously stated, the high degree of failure of OSDS necessitates that systems be inspected regularly. This can be accomplished in several ways. Homeowners can serve as monitors if they are educated on how to inspect their own systems. Brochures can be made available to instruct individuals on how to inspect their systems and the steps they need to take if they determine that their OSDS is not functioning properly. Trained inspectors, such as those in Maine, also can aid in identifying failing systems.

State or local officials should also develop a program for regular inspection. By using utilities and wastewater management programs or agencies, the costs can be kept minimal. At a minimum, systems should be inspected when the ownership of a property is changed. If, prior to the transfer of ownership, the system is found to be deficient, corrective action should be taken. States and localities can also indirectly assess whether OSDS are failing through surface water and ground-water monitoring. If indicator pollutants (e.g., pathogens) are found during the course of monitoring, nearby OSDS should be inspected to determine whether they are the primary source of the indicators. USEPA (1991) has presented a method for tracing effluent from failing septic systems. This method could be followed as part of an indirect inspection program to locate failing systems.

b. Perform regular maintenance of OSDS.

OSDS are not maintenance-free systems. Huang (1983) stated that half of OSDS failures are due to poor operation and maintenance. Most septic tanks are designed so that wastewater is held for 24 hours to allow removal of solids, greases, and fats. Up to 50 percent of the solids retained in the tank decompose naturally by bacterial and chemical action (Mancl and Magette, 1991). However, during normal use, sludge accumulates on the bottom of the tank, leaving less time for the solids in the influent to settle. When little or no settling occurs, the solids move directly to the soil absorption system and may clog (Mancl and Magette, 1991). Consequently, periodic removal of the solids from the tank is necessary to protect the soil absorption system.

Management options for OSDS maintenance include (NSFCH, 1989):

- Maintenance via contract;
- Operating permits;
- Private management systems; and
- Local ordinances/utility management.

Most tanks need to be pumped out every 3 to 5 years; however, several factors need to be considered when determining the frequency of pumping required. These factors include (Mancl and Magette, 1991):

- Capacity of the tank;
- Flow of wastewater (based on family size); and
- Volume of solids in the wastewater (more solids are produced if a garbage disposal is used).

Failure will not occur immediately if a septic system is not pumped regularly; however, continued neglect will cause the system to fail because the soil absorption system is no longer protected from solids and may need to be replaced (at considerable expense).

Table 4-24 shows an estimate of how often a septic tank should be pumped based on tank and household size. The Arlington County, Virginia, Chesapeake Bay Preservation Ordinance requires that all septic tanks be pumped at least once every 5 years.

Alternative OSDS may have maintenance requirements in addition to septic tank pumping. These maintenance requirements are discussed in the descriptions of the systems presented in Management Measure V.A.

c. Retrofit or upgrade improperly functioning systems.

Improperly functioning systems are usually the result of failure of the soil absorption field. Several practices are available to retrofit these failing systems so that they operate properly. The most common reason for failure of the absorption field is hydraulic overload. Jarrett and others (1985) and other researchers have had good success in retrofitting failing systems by combining the construction of backup soil absorption fields with water conservation measures. A backup absorption system is constructed so that water can be diverted from the primary absorption system. The primary system is rested, and in many cases biological activity will unclog the system and aerobic conditions will be restored in the soil. Scheduling is then done to alternate the use of the primary and backup

Table 4-24. Suggested Septic Tank Pumping Frequency (Years) (Cooperative Extension Service - University of Maryland, 1991)

Tank Size (gal)	Household Size (number of people)									
	1	2	3	4	5	6	7	8	9	10
500	5.8	2.6	1.5	1.0	0.7	0.4	0.3	0.2	0.1	-
750	9.1	4.2	2.6	1.8	1.3	1.0	0.7	0.6	0.4	0.3
1,000	12.4	5.9	3.7	2.6	2.0	1.5	1.2	1.0	0.8	0.7
1,250	15.6	7.5	4.8	3.4	2.6	2.0	1.7	1.4	1.2	1.0
1,500	18.9	9.1	5.9	4.2	3.3	2.6	2.1	1.8	1.5	1.3
1,750	22.1	10.7	6.9	5.0	3.9	3.1	2.6	2.2	1.9	1.6
2,000	25.4	12.4	8.0	5.9	4.5	3.7	3.1	2.6	2.2	2.0
2,250	28.6	14.0	9.1	6.7	5.2	4.2	3.5	3.0	2.6	2.3
2,500	31.9	15.6	10.2	7.5	5.9	4.8	4.0	4.0	3.0	2.6

systems (e.g., use of each system 6 months of the year), so that systems in marginally permeable soils can continue to operate properly. Garbage disposals should be eliminated, and low-volume plumbing fixtures should be installed in cases where the absorption field has failed in order to reduce total pollutant and water loads to the field. (Refer to discussion in Management Measure V.A.)

In some cases, either because of improper siting (e.g., inadequate separation distance, proximity to surface water, poor soil conditions, or lack of land available for a backup absorption system) or the inadequacy of conventional OSDS to remove pollutants of concern, the above retrofit practice may not be feasible. In these cases, alternative OSDS, constructed wetlands, filters, or holding tanks may be necessary to adequately protect surface waters or ground water. Descriptions of these systems and their respective effectiveness and cost are provided in Management Measure V.A.

■ d. ***Use denitrification systems where conditions indicate that nitrogen-limited surface waters may be adversely impacted by excessive nitrogen loading.***

As stated previously, even properly functioning conventional OSDS are not effective at removing nitrogen. In areas where nitrogen is a problem pollutant, existing conventional systems should be retrofitted to denitrification OSDS to provide adequate nitrogen removal. Several systems such as sand filters and constructed wetlands have been shown to remove over 50 percent of the total nitrogen from septic tank effluent (see Table 4-21). Descriptions of these types of systems and their effectiveness and cost are presented in Management Measure V.A.

■ e. ***Discourage the use of phosphate in detergents.***

Conventional OSDS are usually very effective at removing phosphorus. However, certain soil conditions, combined with close proximity to sensitive surface waters, can result in phosphorus pollution problems from OSDS. In such cases the use of detergents containing phosphates may need to be discouraged or banned. Low-phosphate detergents are commercially available from a variety of manufacturers with negligible increases in cost. Eliminating phosphates from detergent can reduce phosphorus loads to OSDS by 40 to 50 percent (USEPA, 1980).

■ *f. Eliminate the use of garbage disposals.*

As presented in Table 4-22, eliminating the use of garbage disposals can significantly reduce the loading of suspended solids and BOD to OSDS. Total nitrogen and phosphorus loads may also be slightly reduced because of decreased loadings of vegetative matter and foodstuffs. Eliminating garbage disposals can also reduce the buildup of solids in the septic tank and reduce the frequency of pumping required. Reduction of the solids also provides added protection against clogging of the soil absorption system.

■ *g. Discourage or ban the use of acid and organic chemical solvent septic system additives.*

Organic solvents used as septic system cleaners are frequently linked to pollution from septic systems. Many brands of septic system cleaning solvents are currently on the market. Makers of these solvents, which often contain halogenated and aromatic hydrocarbons, advertise that they reduce odors, clean, unclog, and generally enhance septic system operations. Manufacturers also advertise that cleaning solvents provide an alternative to periodic pumping of septage from septic tanks. However, there is little evidence indicating that these cleaners perform any of the advertised functions. In fact, their use may actually hinder effective septic system operation by destroying useful bacteria that aid in the degradation of waste, resulting in disrupted treatment activity and the discharge of contaminants.

In addition, since the organic chemicals in the solvents are highly mobile in the soils and toxic (some are suspected carcinogens), they can easily contaminate ground water and surface waters and threaten public health. Research on the common septic system cleaner constituents (methylene chloride (MC) and 1,1,1-trichloroethane (TCA), which are listed on EPA's priority pollutant list and for which EPA's Office of Drinking Water has issued health advisories) has shown that application rates recommended by the manufacturer have resulted in high MC and moderate TCA discharges to ground water.

This issue is discussed further in the pollution prevention section.

■ *h. Promote proper operation and maintenance of OSDS through public education and outreach programs.*

This practice is discussed in the pollution prevention section (Section VI).

VI. POLLUTION PREVENTION

Pollution Prevention Management Measure

Implement pollution prevention and education programs to reduce nonpoint source pollutants generated from the following activities, where applicable:

- **The improper storage, use, and disposal of household hazardous chemicals, including automobile fluids, pesticides, paints, solvents, etc.;**
- **Lawn and garden activities, including the application and disposal of lawn and garden care products, and the improper disposal of leaves and yard trimmings;**
- **Turf management on golf courses, parks, and recreational areas;**
- **Improper operation and maintenance of onsite disposal systems;**
- **Discharge of pollutants into storm drains including floatables, waste oil, and litter;**
- **Commercial activities including parking lots, gas stations, and other entities not under NPDES purview; and**
- **Improper disposal of pet excrement.**

1. Applicability

This management measure is intended to be applied by States to reduce the generation of nonpoint source pollution in all areas within the section 6217 management area. The adoption of the Pollution Prevention Management Measure does not exclude applicability of other management measures to those sources covered by this management measure. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

This management measure is intended to prevent and reduce NPS pollutant loadings generated from a variety of activities within urban areas not addressed by other management measures within Chapter 4. Source reduction is considered preferable over waste recycling for pollution reduction (DOI, 1991; USEPA, 1991). Everyday activities have the potential to contribute to nonpoint source pollutant loadings. Some of the major sources include households, garden and lawn care activities, turf grass management, diesel and gasoline vehicles, OSDS, illegal discharges to urban runoff conveyances, commercial activities, and pets and domesticated animals. These sources are described below. By reducing pollutant generation, adverse water quality impacts from these sources can be decreased.

a. Households

Everyday household activities generate numerous pollutants that may affect water quality. Common household NPS pollutants include paints, solvents, lawn and garden care products, detergents and cleansers, and automotive products such as antifreeze and oil. The use and disposal of these products are chronic sources of pollution (Puget Sound Water Quality Authority, 1991). Table 4-25 summarizes estimated pollutant loadings from various household chemicals that may contaminate runoff. These pollutants are typically introduced into the environment due to ignorance on the part of the user or the lack of proper disposal options. Storm drains are commonly mistaken for treatment systems, and significant loadings to waterbodies result from this misconception. Other wastes and chemicals are dumped directly onto the ground (Washington State Department of Ecology, 1990).

b. Improper Disposal of Used Oil

The improper disposal of used oil and antifreeze can significantly degrade surface waters. The Washington Department of Ecology estimated that over 4.5 million gallons of used oil are dumped in Washington State each year. Of this total, 2 million gallons eventually are discharged into the Puget Sound (USEPA, 1988). Such loadings can severely degrade surface waters. One quart of oil can contaminate up to 2 million gallons of drinking water; 4 quarts of oil can form an oil slick approximately 8 acres in size (University of Maryland Cooperative Extension Service, 1987).

Table 4-25. Estimates of Improperly Disposed Used Oil and Household Hazardous Waste

Reference	Chemical and Estimated Amount
USEPA, 1989	Estimated that 40% of used oil from DIYs[a] is poured onto roads, driveways, or yards or into storm sewers (80 million gallons per year).
Hoffman et al., 1980	Survey of Providence, RI, residents revealed that 35% were DIYs. Of this group, 42% used improper disposal methods (30% disposed of used oil by backyard dumping, 7% by dumping into sewers or storm drains, and 5% by pouring onto roads).
Stanek et al., 1987	Survey of Massachusetts households revealed that one-third changed their oil (17% dumped used oil on the ground and 3% discharged used oil into the town sewers); 17% changed their antifreeze (54% used ground disposal and 14% discharged into the sewer). The majority of the 10% who disposed of oil-based paints or pesticides annually used improper methods.
Voorhees and Temple, Baker and Sloane, Inc., 1989	Survey of studies estimated that between 52% and 64% of private vehicle owners are DIYs. Nationally, DIYs have been estimated to generate 193 million gallons of used oil per year. Of this amount, it was estimated that 61% (118 million gallons) was improperly disposed of.
King County Solid Waste Division, 1990	Estimated that 15% to 20% of household hazardous wastes end up in storm drains or runoff. Estimated that one-third of DIYs dump used oil directly into storm drains or onto the ground.
King County Solid Waste Division, 1990	Estimated that 83% of DIYs that changed their antifreeze flushed their car radiators directly into a storm sewer or street.

[a] DIYs - Do-it-yourself oil changers.

c. Landscape Maintenance and Turf Management

The care of landscaped areas, including golf courses, can contribute significantly to nonpoint source pollutant loadings. The application of fertilizers and pesticides in coastal areas can be detrimental to surface waters. After a site is developed, a significant area of maintained landscape may be regularly treated with fertilizer and pesticides. Heavily landscaped areas include residential yards, golf courses, and parks. In the coastal zone, much residential development commonly is sited on unconsolidated coastal plain with sandy soils. Where such soils are present, frequent fertilization, pesticide application, and watering must occur to maintain turf grasses. Turf management programs and landscaping ordinances that require minimum maintenance and minimum disturbance or xeriscaping can effectively reduce these loadings.

In areas where nitrogen is a problem pollutant, measures to control the introduction of nitrogen into runoff and leachate are important. Several studies have been completed that demonstrate the leaching potential of nitrogen from turf. Researchers at Cornell University found that 60 percent of nitrogen applied to turf leached to ground water (Long Island Regional Planning Board, 1984). Shultz (1989) suggests that 50 percent of the nitrogen applications are leached out and not used by plants. A study completed by Exner and others (1991) showed that as much as 95 percent of nitrate applied in late August on an urban lawn was leached below the turf grass root zone. In coastal areas, where soils are highly permeable and ground water and surface waters are hydrologically connected, reduced applications of nutrients may be necessary to control subsurface flow of nutrients into surface waters.

A recent nonpoint source loading analysis (Cahill and Associates, 1991) indicated that 10 percent of the nitrogen and 4 percent of the phosphorus applied annually in a 193-square-mile area (an area approximately 10 miles by 20 miles) of maintained landscaped residential development end up in surface waters as the result of overapplication. A total of 512.7 tons of nitrogen and 49.4 tons of phosphorus enter surface waters from this area. These estimated pollutant delivery rates are conservative. Delivery rates in coastal areas with sandy soils may be much higher. Schultz (1989) found that over 50 percent of the nitrogen in fertilizer leaches from lawns when improperly applied. In addition, the proximity of sources to waterbodies may result in increased loadings. Where waterbodies are nitrogen- or phosphorus-limited, applications of fertilizers should be reduced or prohibited. Fertilizer control programs can effectively reduce nitrogen and phosphorus loadings by encouraging the proper application of nutrients. Fertilizer costs may also be reduced.

A study in Rhode Island concluded that medium-density residential development has the highest loading factor of pesticides and fertilizers of all land uses in the State (RIDEM, 1988). These results echoed the findings of research conducted on the Chesapeake Bay watershed that identified medium- and high-density residential development as having the highest loading factors for nitrogen and phosphorus in the Bay area (Chesapeake Bay Local Advisory Committee, 1989). Table 4-26 shows a summary of results from various studies quantifying application rates of household fertilizers. Table 4-27 summarizes recommended application rates.

Home use is estimated to account for 20 percent of pesticide use in the Puget Sound area, and household users often apply pesticides excessively or in too concentrated a formulation (PSWQA, 1991). The Puget Sound Water Quality

Table 4-26. Summary of Application Rates of Fertilizers from Various Studies

Estimated Application Rates	Reference
3.3 lb/1000 ft² (affluent areas) 1.1 lb/1000 ft² (less affluent areas)	Cornell Water Resources Institute, 1985
2.2 lb/1000 ft²/yr to 3.9 lb/1000 ft²/yr	Long Island Planning Board, 1984
3.03 lb/ft²/yr (Nitrogen) 0.77 lb/ft²/yr (Phosphorus) (New Jersey)	Cahill and Associates, 1992

Table 4-27. Recommended Fertilizer Application Rates

Recommended Rate	Reference
Virginia - No more than 1 lb/1000 ft^2 at any one time — not to exceed 3 lb/1000 ft^2/yr	Hall, personal communication, 1991; No. VA Soil and Water Conservation District, 1991; VA Cooperative Extension, 1991
Virginia — 1.5 to 2 lb/1000 ft^2/yr	Bowling, personal communication, 1991
Long Island — 1 lb/1000 ft^2/yr	Long Island Regional Planning Board, 1984
Long Island — no more than 1 lb/1000 ft^2/yr on mature lawns	Myers, 1988
General — 2 lb/1000 ft^2/yr	Shultz, 1989

Authority summarized available data in a 1990 issue paper on pesticides in the Puget Sound. This research revealed that 50 to 80 percent of all household users apply some form of pesticides for lawn and garden use. EPA Region 10 and the Puget Sound Water Quality Authority (PSWQA, 1990) reviewed data and surveyed pesticide use in 12 counties in the Puget Sound basin and concluded that household pesticide use in 1988 was greater than 213,000 pounds. Unnecessary pesticide loadings to surface waters may result from homeowner overapplication, poor knowledge of proper application techniques, or applications during grass dormancy. Both the PSWQA and the Virginia Cooperative Extension Survey (1991) have determined that such improper use commonly occurs.

Consideration of the potential for exposure and toxic effects of applied fertilizers and pesticides should be an important component of golf course policy decisions. Some of the technical issues concerning intensive management of turf grass include (1) extent of nutrient and pesticide applications, (2) chronic and acute toxicity to nontarget organisms, (3) potential for exposure of nontarget organisms to applied chemicals, (4) use of increasingly scarce water resources for irrigation, (5) potential off-site movement of fertilizers and pesticides, (6) effects of maintenance and storage facilities on soil and water quality, and (7) potential loss of and effects on wetlands resulting from construction and turf grass maintenance (Balogh and Walker, 1992).

While quantitative information is not currently available regarding the effectiveness of fertilizer and pesticide control measures, it can be assumed that application reductions will result in corresponding decreases in pollutant loadings. Table 4-28 provides guidance useful for reducing fertilizer and pesticide use. This guidance was developed by the Northern Virginia Soil and Water Conservation District, the Lake Barcroft Watershed Improvement District, the Northern Virginia Planning District Commission, and the Virginia Cooperative Extension service for use by commercial lawn care companies and households that choose to use commercial lawn care services. This advice, however, is useful for all turf grass management.

d. Yard Trimmings Management

Improper disposal of yard trimmings can lead to increased nutrient levels in runoff. Yard trimmings deposited on street corners may be washed down storm sewers and result in elevated nutrient loadings to surface waters. Proper management of yard trimmings and home composting can reduce the level of nutrients in runoff and decrease overall runoff volumes through the addition of humus to the soil. Increased levels of humus enhance soil permeability, decrease erodibility, and provide nutrients in a less soluble form than commercial fertilizers.

e. Improper Installation and Maintenance of Onsite Disposal Systems

As discussed in Section V of this chapter, failing or improperly sited or designed OSDS may contribute both pathogens and nutrients to surface waters. Many engineers, contractors, surveyors, drain-layers, sanitarians, OSDS installers, waste haulers, building inspectors, local and State officials, and owners of OSDS are insufficiently informed regarding the need for proper siting, design, and maintenance of onsite systems. While a number of States

Table 4-28. Watershed Chemical Control Standards

Nutrient and Pesticide Control Standard	Estimated Savings and Impacts
Decrease fertilizer use.	The average DIY* applies 2 to 4 times the desirable amount of fertilizer. By reducing fertilizer amounts, costs can be reduced accordingly.
Use phosphorus-free or low-phophorus-content fertilizers.	Cost increases $1.00 to $1.50 per household where phosphate-free fertilizer are used. In the Lake Barcroft, Virginia, Water Management District, Natural Lawn estimated a 7,000-pound reduction in fall phosphorus loadings and an 80-85% decrease in spring loadings due to the use of phosphate-free fertilizers (Natural Lawn, personal communication, 1991).
Use slow-release fertilizers.	Organic fertilizers tend to be slow acting and less soluble than chemical fertilizers (Shultz, 1989). Depending on the fertilizer source, conversion to organic fertilizers would reduce costs to $0.00 where compost from a municipal or county facility is used; costs would increase $1.00 per 100 ft^2 for the purchase of commercial organic fertilizer (Cook, 1991)
Test soils to determine appropriate application rates.	Soil tests and fertilizer recommendations range in cost from $0.00 to $5.00 if done by a Cooperative Extension Service. Private soil test labs may charge $30.00 to $45.00 for the service (Carr et al., 1991).
Stagger fertilizer applications instead of using one large application.	Excess fertilizer may leach into ground water if not utilized by plants. Plants have a limited capacity to utilize fertilizer in any one application; fertilizer costs can be reduced by staggered applications so that the bulk of available nutrients are utilized and excess fertilizers are not applied.
Spot-apply pesticides to control broad-leafed weeds.	Natural Lawn Company reports that by switching from blanket applications to spot applications of herbicides, herbicide use can be reduced 85% to 90% (Bonifant, personal communication, 1991). Volume reductions will result in a comparable cost savings.
Mow lawn at the recommended height.	Shultz (1989) and Carr (1991) suggest that proper mowing techniques result in healthier lawns and can reduce pesticide and fertilizer use.
Retain grass clippings on lawns and other areas planted with turf grass.	Research conducted by Starr and DeRoo (1981) on grass grown in low-nitrogen sandy loam soils showed that grass clippings are beneficial as fertilizer for continued grass growth. Use of clippings as fertilizer can enhance grass growth, reduce the need for additional fertilizer, and decrease total fertilizer costs. *(This recommendation is promoted by the Professional Lawn Care Association of America.)*

* DIY - Do-it-yourself lawn caretaker.

currently license OSDS installers and waste haulers in accordance with State health standards, these licensing procedures may be out-of-date. In addition, many of these standards address only limited health-related issues and do not address the complex joint issues of water quality and public health (Myers, 1991).

Many homeowners are unaware of proper OSDS operation and maintenance principles. They often do not know how frequently their septic tanks need to be pumped, what hydraulic load their systems can accommodate, and what should or should not be disposed of in their systems (Huang, 1983). Some homeowners use septic system cleaners containing substances that may contaminate ground water, may provide little to no benefit to the OSDS, and may even be harmful to the system (RIDEM, 1988). Public education programs can help homeowners to prepare, operate, and maintain OSDS and thus help to ensure the continued pollutant removal effectiveness of the OSDS. A variety of brochures and other educational materials regarding OSDS have already been developed, and these materials have been used in many areas to educate the general public about proper OSDS operation and maintenance (e.g., the Chesapeake Bay Region, Puget Sound). State and local agencies should make use of these materials and implement mailing and information dissemination programs. Brochures mailed to homeowners as part of general utility correspondence or as special mailings are also effective. Posters and other materials distributed at libraries can help disseminate this information to the public. Educational and outreach programs should target builders, buyers, system installation contractors, inspectors, and enforcement personnel, in addition to homeowners, realtors, and pumpers.

f. Discharges Into Storm Drains

Significant loadings of NPS pollutants enter surface waters and tributaries via illegal discharges into storm drains. The public unknowingly assumes that storm drains discharge into sanitary sewers, and materials are dumped into storm drains under the assumption that treatment will occur at the sewage treatment plant. Illicit discharges may also be a problem. Public education programs, such as storm drain stenciling, and identification of illicit discharges can be effective tools to reduce pollutant loadings. Sanitary surveys are also a useful method to help managers identify the presence and entry point(s) of illicit discharges or other sources of pollutants to storm sewer systems.

g. Litter

Litter along coastal waterways, estuaries, and inland shorelines has become a significant source of nonpoint source pollution. · Litter, debris, and dumped large solid items impair coastal water quality, as well as the aesthetic and recreational value of coastal waters, and may also be a hazard to wildlife. Storm sewers have been identified as a significant source of marine debris (Younger and Hodge, 1992).

Plastics are the major debris problem in the marine environment. Plastic accounts for 59 percent of the debris collected in coastal cleanup efforts (Younger and Hodge, 1992). Other litter may also be a problem. The State Adopt-a-Highway programs have revealed that beverage cans are the item most frequently removed from the side of roads. These wastes commonly have entered surface waters via storm sewers or swale systems. During 1991-1992, participants in the Virginia Adopt-a-Highway program removed 36,000 cubic yards of debris with volunteer hours valued at $2 million (M. Kornwolf, Virginia Dept. of Transportation, personal communication, 1992).

h. Commercial Activities

Nonpoint source runoff from commercial land areas such as shopping centers, business districts, and office parks, and large parking lots or garages may contain high hydrocarbon loadings and metal concentrations that are twice those found in the average urban area (Woodward-Clyde, 1991). These loadings can be attributed to heavy traffic volumes and large areas of impervious surface on which these pollutants concentrate (Long Island Sound Regional Planning Board, 1982). For example, contributions of lead to the Milwaukee River south watershed have been estimated as 20 to 25 percent from commercial areas and 40 to 55 percent from industrial areas (Wisconsin Department of Natural Resources, 1991). Where activities other than traffic, such as liquids storage and equipment use and maintenance, are associated with specific commercial activities, other pollutants may also be present in runoff. BMPs suited to the control of automotive-related pollutants and any other pollutants associated with specific commercial uses should be used to control their entry into surface waters.

Gas stations, in most communities, are designated as a commercial land use and are subject to the same controls as shopping centers and office parks. However, gas stations may generate high concentrations of heavy metals, hydrocarbons, and other automobile-related pollutants that can enter runoff (Santa Clara Valley Water Control District, 1992). Since gas stations have high potential loadings and pollutant profiles similar to those of industrial sites, the good housekeeping controls used on industrial sites are usually necessary.

i. Pet Droppings

Pet droppings have been found to be important contributors of NPS pollution in estuaries and bays where there are high populations of dogs. Fecal coliform and fecal streptococcal bacteria levels in runoff in several drainage basins in Long Island, New York, can be attributed to the dog population (Long Island Regional Planning Board, 1982). Although dogs cause the more common pet droppings problem, other urban animals, such as domestic or semi-wild ducks, also contribute to NPS pollution where their populations are high enough. Eliminating or significantly reducing the quantity of pet droppings washed into storm drains and hence into surface waters can improve the quality of urban runoff. It has been estimated that for a small bay watershed (up to 20 square miles), 2 to 3 days of droppings from a population of 100 dogs contribute enough bacteria, nitrogen, and phosphorus to temporarily close a bay to swimming and shellfishing (George Heufelder, personal communication, 1992).

The Soil Conservation Service in the Nassau-Suffolk region of New York collected data indicating that domestic animals contribute BOD, COD, bacteria, nitrogen, and phosphorus to ground water and surface waters (Nassau-Suffolk Regional Planning Board, 1978). Runoff containing pet droppings has been found to be responsible for numerous shellfish bed closures in Massachusetts (George Heufelder, personal communication, 1992; Nassau-Suffolk Regional Planning Board, 1978). In New York the large populations of semi-wild White Pekin ducks contribute heavily to runoff problems, while in a Massachusetts study, dog feces alone were found to be sufficient to account for the closures.

3. Management Measure Selection

This management measure was selected to ensure that communities implement solutions that may result in behavioral changes to reduce nonpoint source pollutant loading from the sources listed in the management measure. A number of States and local communities, including Washington, Maryland, Virginia, Florida, and Alameda County, California, are using pollution prevention activities to protect or enhance coastal water quality. Such activities include public education, promotion of alternative and public transportation, proper management of maintained landscapes, pollution prevention, training and urban runoff control plans for commercial sources, and OSDS inspection and maintenance. To allow flexibility, specific controls have not been specified in the management measure. Communities may select practices that best fit local priorities and the availability of funding. In addition, flexibility is necessary to account for community acceptance, which is often the major determinant affecting whether education and outreach activities and administrative mechanisms such as certification and training requirements are practical or effective solutions.

CASE STUDY - ARLINGTON COUNTY, VIRGINIA

Arlington County, Virginia, is drafting a source control plan for "minimizing impacts on its streams, a well as impacts to the Potomac River and the Chesapeake Bay, from pollutants entering the streams from many diverse sources." The plan is aimed at implementing individual programs for controlling sources of nonpoint pollution. Projects include:

Storm drainage master plan;
Educational programs for lawn management;
Evaluation of street sweeping programs;
Stream valley stabilization and restoration;
Evaluation of parking lot and street design requirements;
Land use planning;
Leaf and debris collection;
Household hazardous waste disposal; and
Storm drain stenciling.

4. Practices, Effectiveness Information, and Cost Information

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. *Promote public education programs regarding proper use and disposal of household hazardous materials and chemicals.*

Public education is an important component of this management measure. The provision of information regarding the environmental impacts of common household activities can produce long-term shifts in behavior and may result in significant reductions in household-generated pollutants. School curricula on watershed protection, including nonpoint pollution control, have been developed for elementary and secondary school education programs. An example is the program developed by the Washington State Office of Environmental Education (Puget Sound Water Quality Authority, 1989). Incorporating such programs into regular school curricula is an effective way to educate youth about the importance of environmentally conscious behavior, which in turn can help reduce the need for and cost of technology-based pollution control.

Florida developed a comprehensive Statewide plan for environmental education coordinated by its Council on Comprehensive Environmental Education to be implemented through formal and informal education programs and State agency programs. All teachers receive the training, as well as State agency personnel and school children in grades kindergarten through 12 (Florida Council on Comprehensive Environmental Education, 1987).

Public participation is an effective means of educating the public and is also necessary for successfully creating and implementing a nonpoint pollution control plan. Public involvement should be encouraged during the planning process through attendance at meetings, workshops, and private or group consultations, and by encouraging the public to comment on planning documents. Support for the documents and the plans being developed is fostered through public involvement. Newsletters are an effective means of keeping the public informed of what planning steps are being taken and how the public can become and stay involved. Metropolitan Seattle has printed an educational brochure concerning waste oil disposal in six languages in order to reach a wider audience (Washington State Department of Ecology, 1992).

b. *Establish programs such as Amnesty Days to encourage proper disposal of household hazardous chemicals.*

Recognizing the potential impacts for environmental degradation from the improper disposal of hazardous household materials and chemicals, many communities have implemented programs to collect these chemicals. There has been an exponential growth in the number of such collection programs since the early 1980s. Two programs were in place in 1980; 822 were in place in 1990. The most common type of collection system is a 1-day event at a temporary site (often referred to as an Amnesty Day). More local governments are beginning to sponsor these programs several times a year, and many communities are establishing permanent programs, including retail store drop-off programs, curbside collection, and mobile permanent facilities (Duxbury, 1990). Table 4-29 summarizes the cost and effectiveness of some household chemical collection programs.

In spite of relatively low participation rates, collection programs can have a significant impact on the amount of hazardous chemicals and materials entering the waste stream. It has been estimated that the amount of hazardous chemicals collected in States having approved coastal management programs was approximately 51,000 drums, or 280,500 gallons, in 1990 (extrapolated from Duxbury, 1990).

c. *Develop used oil, used antifreeze, and hazardous chemical recycling programs and site collection centers in convenient locations.*

Household hazardous chemical (HHC) collection programs already exist in many counties throughout the United States. Specific days are usually designated as drop-off days and are advertised through television, newspapers,

Table 4-29. Waste Recycling Cost and Effectiveness Summary

Program Description	Effectiveness	Cost
University of Alabama - Project ROSE[a] • Initiated in 1977 • Focuses on used oil • Includes curbside collection (as part of regular garbage pick-up), collection centers (primarily service stations), and drum placement (in more rural areas) • Involves public outreach program	Of the approximately 17 million gallons of used oil generated annually in Alabama, 8 million gallons (47 percent) was reclaimed in 1990.	Annual budget is $80,000 ($45,000 is spent on public education).
Sunnyvale, CA, Curbside Used Oil Collection[b] • Curbside collection of used oil, along with other recyclable products • Residents provided with gallon containers to hold the oil • Involves large public outreach program	75 to 120 gallons of used oil from 28,000 homes collected daily. A 40 percent increase in participation was observed from FY 87-88 to FY 90-91.	Exact breakdowns were not available. Costs are kept low by incorporating the program into an existing recycling program; public information is distributed by such means as flyers in utility bills and brochures left by city employees such as repair crews and street sweepers.
Seattle, WA, Mobile Permanent Collection System • Established in 1989 by King County Solid Waste Department • 5,000 ft² mobile facility equipped to collect household hazardous materials ("Wastemobile") • Collected material is either recycled, detoxified, or taken to a secured hazardous waste facility • Includes extensive public outreach program	In the first 6 months of operation, 276.8 tons of material was collected; participation was twice that expected (one site recorded 875 cars in 6 days) In the first quarter, 98.3 tons were collected with the following breakdown: • 44.3 tons (45%) paint • 23.1 tons (23.5%) waste oil • 8.6 tons (8.8%) solvents • 5.9 tons (6%) pesticides. The balance was miscellaneous other household wastes.	The Wastemobile cost $110,000. King County has budgeted $1.5 million (including public outreach and staff) over a 28-month period.
San Francisco, CA, Permanent Collection Facility[c] • A permanent household waste site that was initiated as a pilot project • 65 percent of the collected material was recycled or reused	30,730 gallons of hazardous wastes (excluding batteries) were collected the first year. The most common type of waste was paint, which was recycled and used by citizens groups to paint over graffiti.	Operated by the private company that hauls the city's solid waste. Funds are obtained from the residential rate mechanism. The city is responsible for public education, waste disposal, and facility inspection.

[d] Misner, 1990

flyers, and radio. In Arlington County, Virginia, collection during the week is by appointment with a water pollution chemist employed by the county and on one Saturday a month. Other HHC collection programs have once-a-week or once-a-month collection days, and some programs have a single day set aside each year for all HHC collection for the county or region. The waste collected by these programs is usually disposed of by a licensed HHC contractor. Table 4-29 presents program descriptions, effectiveness, and cost information for representative HHC collection programs. Many service stations currently provide used oil and antifreeze recycling facilities for "do-it-yourselfers" to encourage environmentally sound disposal.

d. Encourage proper lawn management and landscaping.

The care of landscaped areas can contribute significantly to NPS pollutant loadings. Results of a telephone survey conducted in 1982 by the Virginia Polytechnic Insitute and State University showed that only 12 to 15 percent of home lawns in Virginia were being managed properly. The majority of homeowners preferred to do their own lawn work; only 8 to 10 percent of the households used commercial lawn care companies. A similar survey conducted on Long Island concluded that in affluent neighborhoods, 72 percent of the respondents used a lawn care service; in the least affluent neighborhoods, no one subscribed to commercial lawn care (Cornell Water Resources Institute, 1985). The extent of nonpoint source pollution from fertilizer application is site-specific and depends on a number of factors, including soil type, application rate, type of fertilizer, precipitation and watering amount, and socioeconomic status of residents. Because most people are not trained in proper fertilization and maintenance application, homeowner lawn care may result in significant amounts of nonpoint source pollution.

To significantly decrease homeowners' pesticide and fertilizer loadings requires a broad-based educational effort. The State Cooperative Extension Service (CES) is one educational vehicle; however, the CES reaches only a small percentage of the population. Mass media approaches are generally the most effective way to reach a large part of the population, though some other possibilities are discussed below (Puget Sound Water Quality Authority, 1991). The following practices are part of proper lawn management and landscaping.

- ***Proper pesticide and herbicide use, and reduced applications***

  While few studies have been conducted to correlate pesticide and herbicide use with adverse effects on marine water quality, the magnitude of potential impacts can be inferred from incidents such as the extensive ground-water contamination in counties bordering the Puget Sound following widespread use of the pesticide ethylene dibromide (EDB) (Puget Sound Water Quality Authority, 1989). Estimates of pesticide use in the Puget Sound area reveal that 20 percent of the volume of pesticides applied is from residential sources and that these applications are typically in excess of recommended amounts or are too concentrated (Puget Sound Water Quality Authority, 1991).

  Maintaining a buffer between surface water and areas treated with pesticides is one method to increase the transport distance and reduce the potential for offsite movement of toxics. Selection of less toxic, mobile, and persistent chemicals with greater selective control of pests is encouraged (Spectrum Research, 1990).

- ***Reduced fertilizer applications and proper application timing***

  Lawn fertilization has been identified as a source of excess nitrogen and phosphorus loadings that may lead to eutrophication. A modeling study of urban runoff pollution conducted in Pennsylvania, Maryland, Washington, DC, and Virginia by Cohn-Lee and Cameron (1991) estimated that the nonpoint source loadings of nutrients were equal to or greater than loadings discharged from POTWs and industries in the Chesapeake Bay area.

  Ground-water contamination also may be of concern especially where interflow exists between surface waters and ground waters. Schultz (1989) found that over 50 percent of the nitrogen in fertilizer leaches from a lawn when improperly applied. NVSWCD et al. (1991) found that up to two-thirds less fertilizer can be applied than is typically recommended by manufacturers. The use of slow-release forms of nitrogen and proper watering may also decrease nonpoint source pollution loadings (Nassau-Suffolk Regional Planning Board, 1978).

- ***Limited lawn watering***

  Nonpoint source runoff from lawns can be reduced by employing efficient watering techniques. Overwatering can increase nitrogen loss 5 to 11 times the amount lost when proper watering strategies are used (Morton et al., 1988).

Soaker hoses and trickle or drip irrigation systems are an alternative to sprinkler systems. These types of systems deliver water at lower rates, which can increase the volume infiltrated, conserve water, and avoid runoff that can be associated with improperly operated sprinkler systems.

- *Use of minimum maintenance/minimum disturbance and IPM methods*

Minimum maintenance/minimum disturbance policies and strategies can effectively reduce land disturbance and associated soil loss and can reduce fertilizer, pesticide, and herbicide loadings. Where new development is occurring, community standards that limit the use of fertilizers or require commercial lawn care companies to use low-impact lawn care practices can decrease NPS loadings. Such practices can be promoted through public education programs for both new and existing developments.

Effective use of IPM strategies can further reduce nonpoint source loadings. Regional soil conservation services, agricultural extension offices, local conservation districts, or the U.S. Department of Agriculture are good sources of information on IPM. A study in Maryland on IPM for street and landscape trees in a planned suburban community demonstrated that pesticide use could be reduced by 79 to 87 percent when spot application techniques were substituted for cover spray techniques. An average annual cost savings of 22 percent also resulted from the program.

Effective IPM Strategies include (Washington State Department of Ecology, 1992):

- Use of natural predators and pathogens;
- Mechanical control;
- Use of native and resistant plantings;
- Maintainenance of proper growing conditions;
- Removal of or substitutions for less-favored pest habitat;
- Timing annual crops to avoid pests;
- Localized use of appropriate chemicals as a last alternative.

- *Xeriscaping*

Xeriscaping, creative landscaping for decreased water, energy, and pesticide/fertilizer inputs, can be used to reduce urban runoff and minimize the application of lawn care products that may adversely impact coastal waters. The use of xeriscaping practices can reduce required lawn maintenance up to 50 percent and reduce watering requirements by 60 percent (Clemson University, 1991). Florida has passed legislation requiring xeriscaping on the grounds of all State buildings. Several other States, including New Jersey and California, actively support xeriscaping efforts. A more detailed discussion of xeriscaping is in Section II.C of this chapter.

- *Reduced runoff potential*

Rainwater from roofs can be infiltrated into the ground in gravel-filled trenches in well-drained soils or collected in rain barrels for later irrigation. Wood decking or brick pavers allow greater infiltration than do solid concrete structures. Landscape terracing reduces runoff and erosion when gardening on slopes (Washington State Department of Ecology, 1992).

- *Training, certification, and licensing programs for landscaping and lawn care professionals*

Training, certification, and licensing programs are an effective method to educate lawn care professionals about potential nonpoint pollution problems associated with fertilizer, pesticide, and herbicide applications. The State Cooperative Extension Service commonly provides these services. Trained lawn care professional can also help educate the general public about the advantages of low-input approaches.

e. *Encourage proper onsite recycling of yard trimmings.*

Home composting promotes onsite recycling of plant nutrients contained in yard trimmings and reduces the potential for nutrients to enter surface waters. Unlike most commercial fertilizers, compost releases nutrients slowly and is a source of trace metals (Hansen and Mancl, 1988). When added as an amendment to lawn or garden soils, compost increases the organic content of the soil, which increases infiltration, reduces runoff, and decreases the need for watering. Sediment and bound nutrients in soils with high organic content are less mobile and less likely to migrate from the site. Compost applications may also result in increased plant health and vigor, allowing for the reduced use of pesticides (Logsdon, 1990).

Home composting programs may result in municipal cost savings. An average suburban yard generates up to 1,500 pounds of yard trimmings per year, most of which is usually landfilled (McNelly, undated). Homeowners should be encouraged to place compost piles or bins away from streams and roadways that may serve as conveyances of leached nutrients. Recycling of grass clippings and mulched leaves should also be encouraged through education programs. The retention of grass clippings and mulched leaves reduces the need for supplemental water and fertilizer inputs.

Suggested backyard composting programs include the following:

- Provide compost bins free or at cost.
- Create pamphlets explaining benefits and methods.
- Start a "Master Composter" program in which graduates receive free equipment and conduct their own workshops.
- Provide credits on waste removal fees to people who compost yard wastes.

f. *Encourage the use of biodegradable cleaners and other alternatives to hazardous chemicals.*

Improperly disposed household cleaners containing nonbiodegradable chemicals have the potential to contaminate surface waters and ground water. OSDS systems may also be adversely impacted by these substances (PSWQA, 1989). The use of nontoxic, biodegradable alternatives, which quickly break down, should be encouraged through public education efforts (Reef Relief, 1992).

g. *Manage pet excrement to minimize runoff into surface waters.*

The Soil Conservation Service in the Nassau-Suffolk region of New York collected data indicating that domestic animals contribute BOD, COD, bacteria, nitrogen, and phosphorus to ground water and surface waters (Nassau-Suffolk Regional Planning Board, 1978). Urban runoff containing pet excrement has been found to be responsible for numerous shellfish bed closures in New York and has been implicated in shellfish bed closures in Massachusetts (George Huefelder, personal communication, 1992; Nassau-Suffolk Regional Planning Board, 1978). In New York, the large populations of semi-wild Pekin ducks contribute heavily to water quality problems. A study in Massachusetts found that dog droppings alone were significant enough to cause shellfish bed closures.

Curb laws, requiring that dogs be walked close to street curbs so they will defecate on the streets near curbs, are intended to ensure that street sweeping operations collect the droppings and prevent them from entering runoff. However, traditional street sweeping has been found to be an ineffective means for controlling fines and soluble NPS pollution and the dog droppings are more often swept into sewers and delivered to bays and estuaries during rain storms (Long Island Regional Planning Board, 1982; 1984; Nassau-Suffolk Regional Planning Board, 1978). Curbing ordinances should therefore be repealed where they are in effect, and laws requiring pet owners to clean up after their pets when they are walked in public areas and to dispose of the droppings properly should be enacted.

Proper cleanup and disposal of canine fecal material and discouragement of public feeding of waterfowl are two ways of potentially controlling the adverse impacts of animal droppings. The following examples from the Long Island Regional Planning Board (1984) illustrate controls for NPS pollution from animal droppings.

Control of NPS pollution from dogs:

- Enactment of "pooper-scooper" laws requiring the removal and proper disposal of dog feces on public property.
- Enforcement of existing "pooper-scooper" and leash laws should be improved in priority target areas where animal feces are known to be an NPS pollution problem.

Control of NPS pollution from horses:

- Instituting zoning ordinances to control the keeping of horses. These ordinances should include:
  - Minimum acreage requirements per horse;
  - Specifying areas where horse waste may be stored; and
  - Designated areas where horses may be kept.
- Limiting the density of horses in deep aquifer recharge areas, in selected shallow aquifer recharge areas, in areas immediately adjacent to surface waters, and where slopes are greater than 5 percent.

Public education programs:

- The Cooperative Extension Service and similar agencies should be encouraged to develop and distribute informational material on all aspects of animal waste problems.

Owners of large animals should use BMPs similar to those for pasture management, including the fencing of animals away from surface waters, avoidance of "overgrazing," "grazing area" rotation, and limited "grazing" when soil is wet. Manure is best stored away from waterbodies on an impervious surface with a cover or roof (Washington State Department of Ecology, 1992).

The following actions can be used to help control the problem of pet excrement:

- Pass regulations controlling the disposal of excrement from domestic animals;
- Enact domestic animal clean-up regulations; and
- Require commercial domestic animal operations (e.g., pet stores, kennels) to implement BMPs for the control and proper disposal of animal excrement.

h. *Use storm drain stenciling in appropriate areas.*

Storm drain stenciling programs can be effective tools to reduce illegal dumping of litter, leaves, and toxic substances down urban runoff drainage systems. These programs also serve as educational reminders to the public that such storm drains often discharge untreated runoff directly to coastal waters.

A successful program was initiated in Anne Arundel County, Maryland. The program was implemented by volunteers to prevent dumping of harmful material into storm drains that ultimately discharge to the Chesapeake Bay. The county's only involvement has been to publicize the program and provide stencils and painting materials.

Approximately 60 to 70 percent of all communities in the county have participated. Several other counties around the Chesapeake Bay have inquired about the program. Data on effectiveness in terms of pounds of pollutant removed were not available; however, an informal survey that occurred after the program was implemented revealed that there is increased public understanding that storm drains should not be used for disposal of hazardous materials and dumping has decreased. Costs were nominal ($7.00 per stencil kit, including paint and brushes; the average neighborhood cost was $40.00) There is a similar program in place in Puget Sound, Washington. The total cost of implementing the stenciling program for the Sound was $2,644.39, including materials and labor. This practice is currently being used in other States and localities, including the Indian River Lagoon, Florida, drainage basin.

■ i. *Encourage alternative designs and maintenance strategies for impervious parking lots.*

Parking lot runoff accounts for a significant percentage of nonpoint source pollution in commercial areas, depending on the proportion of building size to parking lot size. Sweeping is a viable method of reducing this runoff from paved areas. If a lot is rectangular and has no parking bumpers or medians dividing it, the job is easier and less expensive. As indicated in the case study, a computer model proved to be a useful tool in evaluating the effectiveness of pavement sweeping as a method to control one source of nonpoint pollution (Broward County Planning Council, 1982).

CASE STUDY - FORT LAUDERDALE, FLORIDA

Through an EPA Continuing Planning Process Grant, the Broward County Planning Council received funding to conduct a study to determine the effectiveness of parking lot sweeping as a method to abate water pollution. A computer model, utilizing simple and multiple regression equations, was used to simulate the conditions at the study area and to predict the runoff loads from the area due to rainfall. Some results of the study are as follows: for paved commercial parking lots, the 3-day to 28-day sweeping cycle produces a pollutant removal range of 60 percent to 20 percent, respectively; as the quantity of residue increases, sweeper efficiency also increases, and there is a point of diminishing return for pollutant removal by sweeping and for sweeper efficiency in removing pollutant loadings (Broward County Planning Council, 1982).

Equipment types commonly used for street sweeping include abrasive brush and vacuum device sweepers. Both abrasive brush and vacuum sweepers have been shown to be generally inefficient at picking up fine solids of less than 43 microns. Although vacuum sweepers are more effective at removing fine particulates than brush sweepers, they are still generally considered to be inefficient. A newly developed helical brush sweeper that incorporates a steel brush with vacuum has been shown to be more effective at removing fine solids and is currently being evaluated. Although currently used sweeper technologies have been shown to be inefficient at removing fine particulates, their use in conjunction with other BMPs that are effective in trapping fine solids could improve downstream water quality (NVPDC, 1987).

Another promising method of street cleaning that concentrates on oil and grease removal is wet-sweeping. By spraying a small area with water containing biodegradable soaps or detergents that solubilize the oil and grease deposited on pavement surfaces, increased removal can occur with a combination of sweeping and vacuum action. This method, however, is a fairly new concept and requires further testing (Silverman et al., 1986).

Vegetated areas/grassed swales are another method commonly used to reduce pollutant loadings from pavement runoff. These areas can be designed to accept runoff with relatively high oil and grease concentrations from parking lots. Percolation through soil and underlying layers typically results in hydrocarbon filtration and adsorption, and degradation by naturally occurring soil bacteria.

j. *Control commercial sources of NPS pollutants by promoting pollution prevention assessments and developing NPS pollution reduction strategies or plans and training materials for the workplace.*

The opportunities for and advantages of pollution prevention practices vary from industry to industry, location to location, and activity to activity. Therefore, it is important to develop pollution prevention programs tailored specifically to an activity or site. Pollution prevention assessments on a site-by-site basis reduce some wastes and possibly eliminate the generation of other wastes. Such assessments are often necessary for successful pollution prevention programs (DOI, 1991).

States should promote and/or provide pollution prevention training and on-site assessments of individual facilities to help reduce the amount of hazardous wastes entering the environment from households and commercial facilities. A typical assessment for a facility will identify the types of waste produced, appropriate disposal methods and sites, and source reduction techniques. An education program to instruct personnel about proper materials handling and waste reduction strategies is also recommended.

The Alachua County, Florida, Office of Environmental Protection produced a handbook of BMPs to be applied in 12 separate commercial operations. Many of the BMPs are common to more than one type of operation, though specifics are mentioned for each category of activities. The 12 operations mentioned are small and large mechanical repair, dry cleaning, junk yards, photo processing, print and silk screening, machine shops and airport maintenance, boat manufacturing and repair, concrete and mining, agricultural, paint manufacturers and distributors, and plastic manufacturers (Alachua County Office of Environmental Protection, 1991).

The Santa Clara Valley Nonpoint Source Pollution Control Program and the San Jose Office of Environmental Management produced a handbook of BMPs for automobile service stations (Santa Clara Valley Water Control District, 1992). The handbook describes 18 BMPs that can be used to control onsite nonpoint source pollutants. Many of these BMPs require little or no investment for implementation. Most of the BMPs rely on education-induced behavior changes to minimize spills and disposal of chemicals and wastewaters down storm drains. Recycling, spill prevention and response plans, and proper material storage are also covered.

The City of Lacy, Washington, developed guidelines to control NPS pollution impacts from service stations and automotive repair facilities on Puget Sound. These include:

- Straining used solvents and paint thinner for reuse;
- Recycling antifreeze, oil, metal chips, and batteries;
- Properly disposing of wastes, including oils, machine-tool coolant, and batteries;
- Using dry floor cleaners, such as kitty litter or vermiculite; and
- Limiting use of water to clean driveways and walkways.

The city developed educational material for distribution that describes these guidelines, defines procedures for potential hazardous materials problems, and provides the State Hazardous Substance Hotline.

The City of Bellevue, Washington, Storm and Surface Water Utility, in cooperation with local businesses, has conducted a series of workshops aimed at the prevention of nonpoint pollution for automotive, construction, landscaping, food, and building maintenance businesses. The city gives recognition to businesses that attend a workshop and prepare a water quality action program. Videos of the workshops and accompanying manuals are also produced by the City of Bellevue (Washington State Department of Ecology, 1992).

k. *Promote water conservation.*

Excessive use of water contributes to numerous NPS pollution problems, including runoff from fertilized areas, OSDS drainfield failures, and sewage leaks. Water overuse may also contribute indirectly to NPS pollution problems: streams, rivers, and ground water may be excessively drawn down for water supply, decreasing their capacity to absorb pollutant runoff and upsetting their natural flow (Long Island Regional Planning Board, 1982; Maddaus, 1989). Additional information on water conservation is contained in the OSDS section of this chapter.

l. Discourage the use of septic system additives.

A 1980 EPA study identified 23 priority pollutants that are likely to be disposed of down household drains. Disposal of these chemicals into OSDS may impair OSDS function and contaminate ground water. Septic system cleaners are included in this category. There is little scientific evidence that septic system cleaners are effective in improving the function of septic systems. Many of the septic system cleaners contain chemicals such as chlorinated hydrocarbons, aromatic organic compounds, and acids and bases that may have an adverse affect on the biological treatment system and that may also pollute ground water. Many of these chemicals are also highly persistent in the ground water. Studies of ground-water contamination in New York and Connecticut have monitored these compounds in ground water and have found that (1) the septic system additives are not effective in improving the treatment systems and (2) the additives pass into ground water in relatively unaltered form (RIDEM, 1988).

Many States and local governments have adopted legislation prohibiting the use of septic system cleaning solvents, including the States of Maine and Delaware, the New Jersey Pinelands Regional Planning Commission, and several jurisdictions in Massachusetts. Rhode Island prohibits the disposal of acids or organic chemical solvents in septic systems and specifically discourages the use of septic tank cleaners. The State of Connecticut Department of Environmental Protection has taken the process one step further by banning the sale and use of cleaning solvents and also implementing the law through press releases, statewide surveys, direct manufacturer contact, and contact with the State Retail Merchants Association.

m. Encourage litter control.

While street sweeping historically has been found to provide little benefit in reducing fines and pollutants associated with small particulates because of outdated sweeping equipment and irregular sweeping frequencies, litter control can be an effective means to improve the quality of urban runoff. Both the Baltimore and Long Island Nationwide Urban Runoff Program (NURP) projects found that litter control substantially influenced the quality of runoff from urban areas (Myers, 1989). Suggestions for controlling litter include:

- Encouraging businesses to keep the streets in front of their buildings free of litter;
- Developing local ordinances restricting or prohibiting food establishments from using disposable food packaging, especially plastics, styrofoam, and other floatables;
- Implementing "bottle bills" and mandatory recycling laws;
- Providing technical and financial assistance for establishing and maintaining community waste collection programs;
- Distributing public education materials on the benefits of recycling; and
- Developing "user-friendly" ways for recycling, such as curbside pick-up, voluntary container buy-back systems, and drop-off recycling centers.

n. Promote programs such as Adopt-a-Stream to assist in keeping waterways free of litter and other debris.

Such programs can eliminate much of the floatable debris found in coastal waters and their tributaries. These programs involve volunteers who pick up trash along designated streambeds. Several successful programs similar to these are being implemented in Maryland, Alaska, Virginia, North Carolina, and Washington. The International

Coastal Cleanup, the largest coastal cleanup effort in the country, is coordinated by the Center for Marine Conservation (CMC). With the use of data cards, plastic gloves, and trash bags, 130,152 volunteers cleared 4,347 miles of beaches and waterways of 2,878,913 pounds of trash during the 1991 cleanup effort (Younger and Hodge, 1992).

In addition to the visible benefits of such clean-up efforts, these programs offer valuable educational opportunities for volunteers and provide a significant amount of data on the amounts and types of debris being found in waterways. The sources of various types of debris can be traced as well. Debris can be traced to a specific company or organization based on labeling or marking. Where possible, CMC contacts these organizations about the finding of their debris, informs them of the problems caused by marine debris, and asks them to join the battle against the debris problem. From the 1990 CMC coastal clean-up effort, approximately 150 organizations were identified and contacted. As a result, the majority of organizations responded positively by printing educational "Do not litter" slogans on their products, and several launched internal investigations into current waste-handling procedures (Younger and Hodge, 1992).

■ o. ***Promote proper operation and maintenance of OSDS through public education and outreach programs.***

Many of the problems associated with improper use of OSDS may be attributed to lack of knowledge on operation and maintenance of onsite systems. Training courses for installers and inspectors and education materials for homeowners on proper maintenance may reduce some of the incidences of OSDS failure.

VII. ROADS, HIGHWAYS, AND BRIDGES

NOTE: Management Measures II.A and II.B of this chapter also apply to planning, siting, and developing roads and highways.[a]

[illegible]

Plan, site, and develop roads and highways to:

(1) Protect areas that provide important water quality benefits or are particularly susceptible to erosion or sediment loss;

(2) Limit land disturbance such as clearing and grading and cut and fill to reduce erosion and sediment loss; and

(3) Limit disturbance of natural drainage features and vegetation.

1. Applicability

This measure is intended to be applied by States to site development and land disturbing activities for new, relocated, and reconstructed (widened) roads (including residential streets) and highways in order to reduce the generation of nonpoint source pollutants and to mitigate the impacts of urban runoff and associated pollutants from such activities. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The best time to address control of NPS pollution from roads and highways is during the initial planning and design phase. New roads and highways should be located with consideration of natural drainage patterns and planned to avoid encroachment on surface waters and wet areas. Where this is not possible, appropriate controls will be needed to minimize the impacts of NPS runoff on surface waters.

This management measure emphasizes the importance of planning to identify potential NPS problems early in the design process. This process involves a detailed analysis of environmental features most associated with NPS pollution, erosion and sediment problems such as topography, drainage patterns, soils, climate, existing land use, estimated traffic volume, and sensitive land areas. Highway locations selected, planned, and designed with consideration of these features will greatly minimize erosion and sedimentation and prevent NPS pollutants from entering watercourses during and after construction. An important consideration in planning is the distance between

[a] Management measure II.A applies only to runoff that emanates from the road, highway, and bridge right-of-way. This management measure does not apply to runoff and total suspended solid loadings from upland areas outside the road, highway, or bridge project.

a highway and a watercourse that is needed to buffer the runoff flow and prevent potential contaminants from entering surface waters. Other design elements such as project alignment, gradient, cross section, and the number of stream crossings also must be taken into account to achieve successful control of erosion and nonpoint sources of pollution. (Refer to Chapter 3 of this guidance for details on road designs for different terrains.)

The following case study illustrates some of the problems and associated costs that may occur due to poor road construction and design. These issues should be addressed in the planning and design phase.

> ***CASE STUDY - ANNAPOLIS, MARYLAND***
>
> Poor road siting and design resulted in concentrated runoff flows and heavy erosion that threatened several house foundations adjacent to the road. Sediment-laden runoff was also discharged into Herring Bay. To protect the Chesapeake Bay and the nearby houses, the county corrected the problem by installing diversions, a curb-and-drain urban runoff conveyance, and a rock wall filtration system, at a total cost of $100,000 (Munsey, 1992).

3. Management Measure Selection

This management measure was selected because it follows the approach to highway development recommended by the American Association of State Highway and Transportation Officials (AASHTO), Federal Highway Administration (FHWA) guidance, and highway location and design guidelines used by the States of Virginia, Maryland, Washington, and others.

Additionally, AASHTO has location and design guidelines (AASHTO, 1990, 1991) available for State highway agency use that describe the considerations necessary to control erosion and highway-related pollutants. Federal Highway Administration policy (FHWA, 1991) requires that Federal-aid highway projects and highways constructed under direct supervision of the FHWA be located, designed, constructed, and operated according to standards that will minimize erosion and sediment damage to the highway and adjacent properties and abate pollution of surface water and ground-water resources.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. *Consider type and location of permanent erosion and sediment controls (e.g., vegetated filter strips, grassed swales, pond systems, infiltration systems, constructed urban runoff wetlands, and energy dissipators and velocity controls) during the planning phase of roads, highway, and bridges. (AASHTO, 1991; Hartigan et al., 1989)*

b. *All wetlands that are within the highway corridor and that cannot be avoided should be mitigated. These actions will be subject to Federal Clean Water Act section 404 requirements and State regulations.*

■ c. *Assess and establish adequate setback distances near wetlands, waterbodies, and riparian areas to ensure protection from encroachment in the vicinity of these areas.*

Setback distances should be determined on a site-specific basis since several variables may be involved such as topography, soils, floodplains, cut-and-fill slopes, and design geometry. In level or gently sloping terrain, a general rule of thumb is to establish a setback of 50 to 100 feet from the edge of the wetland or riparian area and the right-of-way. In areas of steeply sloping terrain (20 percent or greater), setbacks of 100 feet or more are recommended. Right-of-way setbacks from major waterbodies (oceans, lakes, estuaries, rivers) should be in excess of 100 to 1000 feet.

■ d. *Avoid locations requiring excessive cut and fill. (AASHTO, 1991)*

■ e. *Avoid locations subject to subsidence, sink holes, landslides, rock outcroppings, and highly erodible soils. (AASHTO, 1991; TRB, Campbell, 1988)*

■ f. *Size rights-of-way to include space for siting runoff pollution control structures as appropriate. (AASHTO, 1991; Hartigan, et al., 1989)*

Erosion and sediment control structures (extended detention dry ponds, permanent sediment traps, catchment basins, etc.) should be planned and located during the design phase and included as part of the design specifications to ensure that such structures, where needed, are provided within the highway right-of-way.

■ g. *Plan residential roads and streets in accordance with local subdivision regulations, zoning ordinances, and other local site planning requirements (International City Managers Association, Model Zoning/Subdivision Codes). Residential road and street pavements should be designed with minimum widths.*

Local roads and streets should have right-of-way widths of 36 to 50 feet, with lane widths of 10 to 12 feet. Minimum pavement widths for residential streets where street parking is permitted range from 24 to 28 feet between curbs. In large-lot subdivisions (1 acre or more), grassed drainage swales can be used in lieu of curbs and gutters and the width of paved road surface can be between 18 and 20 feet.

■ h. *Select the most economic and environmentally sound route location. (FHWA, 1991)*

■ i. *Use appropriate computer models and methods to determine urban runoff impacts with all proposed route corridors. (Driscoll, 1990)*

Computer models to determine urban runoff from streets and highways include TR-55 (Soil Conservation Service model for controlling peak runoff); the P-8 model to determine storage capacity (Palmstrom and Walker); the FHWA highway runoff model (Driscoll et al., 1990); and others (e.g., SWMM, EPA's stormwater management model; HSP continuous simulation model by Hydrocomp, Inc.).

■ j. *Comply with National Environmental Policy Act requirements including other State and local requirements. (FHWA, T6640.8A)*

■ k. *Coordinate the design of pollution controls with appropriate State and Federal environmental agencies. (Maryland DOE, 1983)*

■ *i. Develop local official mapping to show location of proposed highway corridors.*

Official mapping can be used to reserve land areas needed for public facilities such as roads, highways, bridges, and urban runoff treatment devices. Areas that require protection, such as those which are sensitive to disturbance or development-related nonpoint source pollution, can be reserved by planning and mapping necessary infrastructure for location in suitable areas.

5. Effectiveness Information and Cost Information

The most economical time to consider the type and location of erosion, sediment, and NPS pollution control is early in the planning and design phase of roads and highways. It is much more costly to correct polluted runoff problems after a road or highway has already been built. The most effective and often the most economical control is to design roads and highways as close to existing grade as possible to minimize the area that must be cut or filled and to avoid locations that encroach upon adjacent watercourses and wet areas. However, some portions of roads and highways cannot always be located where NPS pollution does not pose a threat to surface waters. In these cases, the impact from potential pollutant loadings should be mitigated. Interactive computer models designed to run on a PC are available (e.g., FHWA's model, Driscoll et al., 1990) and can be used to examine and project the runoff impacts of a proposed road or highway design on surface waters. Where controls are determined to be needed, several cost-effective management practices, such as vegetated filter strips, grassed swales, and pond systems, can be considered and used to treat the polluted runoff. These mitigating practices are described in detail in the discussion on urban developments (Management Measure IV.A).

B. Management Measure for Bridges

Site, design, and maintain bridge structures so that sensitive and valuable aquatic ecosystems and areas providing important water quality benefits are protected from adverse effects.

1. Applicability

This management measure is intended to be applied by States to new, relocated, and rehabilitated bridge structures in order to control erosion, streambed scouring, and surface runoff from such activities. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

This measure requires that NPS runoff impacts on surface waters from bridge decks be assessed and that appropriate management and treatment be employed to protect critical habitats, wetlands, fisheries, shellfish beds, and domestic water supplies. The siting of bridges should be a coordinated effort among the States, the FHWA, the U.S. Coast Guard, and the Army Corps of Engineers. Locating bridges in coastal areas can cause significant erosion and sedimentation, resulting in the loss of wetlands and riparian areas. Additionally, since bridge pavements are extensions of the connecting highway, runoff waters from bridge decks also deliver loadings of heavy metals, hydrocarbons, toxic substances, and deicing chemicals to surface waters as a result of discharge through scupper drains with no overland buffering. Bridge maintenance can also contribute heavy loads of lead, rust particles, paint, abrasive, solvents, and cleaners into surface waters. Protection against possible pollutant overloads can be afforded by minimizing the use of scuppers on bridges traversing very sensitive waters and conveying deck drainage to land for treatment. Whenever practical, bridge structures should be located to avoid crossing over sensitive fisheries and shellfish-harvesting areas to prevent washing polluted runoff through scuppers into the waters below. Also, bridge design should account for potential scour and erosion, which may affect shellfish beds and bottom sediments.

3. Management Measure Selection

This management measure was selected because of its documented effectiveness and to protect against potential pollution impacts from siting bridges over sensitive waters and tributaries in the coastal zone. There are several examples of siting bridges to protect sensitive areas. The Isle of Palms Bridge near Charleston, South Carolina, was designed without scupper drains to protect a local fishery from polluted runoff by preventing direct discharge into the waters below. In another example, the Louisiana Department of Transportation and Development specified stringent requirements before allowing the construction of a bridge to protect destruction of fragile wetlands near New Orleans. A similar requirement was specified for bridge construction in the Tampa Bay area in Florida (ENR, 1991).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Additional erosion and sediment control management practices are listed in the construction section for urban sources of pollution (Management Measure IV.A).

- a. *Coordinate design with FHWA, USCG, COE, and other State and Federal agencies as appropriate.*

- b. *Review National Environmental Policy Act requirements to ensure that environmental concerns are met (FHWA, T6640.8A and 23 CFR 771).*

- c. *Avoid highway locations requiring numerous river crossings. (AASHTO, 1991)*

- d. *Direct pollutant loadings away from bridge decks by diverting runoff waters to land for treatment.*

Bridge decks should be designed to keep runoff velocities low and control pollutant loadings. Runoff waters should be conveyed away from contact with the watercourse and directed to a stable storm drainage, wetland, or detention pond. Conveyance systems should be designed to withstand the velocities of projected peak discharge.

- e. *Restrict the use of scupper drains on bridges less than 400 feet in length and on bridges crossing very sensitive ecosystems.*

Scupper drains allow direct discharge of runoff into surface waters below the bridge deck. Such discharges can be of concern where the waterbody is highly susceptible to degradation or is an outstanding resource such as a spawning area or shellfish bed. Other sensitive waters include water supply sources, recreational waters, and irrigation systems. Care should be taken to protect these areas from contaminated runoff.

- f. *Site and design new bridges to avoid sensitive ecosystems.*

Pristine waters and sensitive ecosystems should be protected from degradation as much as possible. Bridge structures should be located in alternative areas where only minimal environmental damage would result.

- g. *On bridges with scupper drains, provide equivalent urban runoff treatment in terms of pollutant load reduction elsewhere on the project to compensate for the loading discharged off the bridge.*

5. Effectiveness Information and Cost Information

Effectively controlling NPS pollutants such as road contaminants, fugitive dirt, and debris and preventing accidental spills from entering surface waters via bridge decks are necessary to protect wetlands and other sensitive ecosystems. Therefore, management practices such as minimizing the use of scupper drains and diverting runoff waters to land for treatment in detention ponds and infiltration systems are known to be effective in mitigating pollutant loadings. Tables 4-7 and 4-8 in Section II provide cost and effectiveness data for ponds, constructed wetlands, and filtration devices.

Management Measure for Construction Projects

(1) Reduce erosion and, to the extent practicable, retain sediment onsite during and after construction and

(2) Prior to land disturbance, prepare and implement an approved erosion control plan or similar administrative document that contains erosion and sediment control provisions.

1. Applicability

This management measure is intended to be applied by States to new, replaced, restored, and rehabilitated road, highway, and bridge construction projects in order to control erosion and offsite movement of sediment from such project sites. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Erosion and sedimentation from construction of roads, highways, and bridges, and from unstabilized cut-and-fill areas, can significantly impact surface waters and wetlands with silt and other pollutants including heavy metals, hydrocarbons, and toxic substances. Erosion and sediment control plans are effective in describing procedures for mitigating erosion problems at construction sites before any land-disturbing activity begins. Additional relevant practices are described in Management Measures III.A and III.B of this chapter.

Bridge construction projects include grade separations (bridges over roads) and waterbody crossings. Erosion problems at grade separations result from water running off the bridge deck and runoff waters flowing onto the bridge deck during construction. Controlling this runoff can prevent erosion of slope fills and the undermining failure of the concrete slab at the bridge approach. Bridge construction over waterbodies requires careful planning to limit the disturbance of streambanks. Soil materials excavated for footings in or near the water should be removed and relocated to prevent the material from being washed back into the waterbody. Protective berms, diversion ditches, and silt fences parallel to the waterway can be effective in preventing sediment from reaching the waterbody.

Wetland areas will need special consideration if affected by highway construction, particularly in areas where construction involves adding fill, dredging, or installing pilings. Highway development is most disruptive in wetlands since it may cause increased sediment loss, alteration of surface drainage patterns, changes in the subsurface water table, and loss of wetland habitat. Highway structures should not restrict tidal flows into salt marshes and other coastal wetland areas because this might allow the intrusion of freshwater plants and reduce the growth of salt-tolerant species. To safeguard these fragile areas, the best practice is to locate roads and highways with sufficient setback distances between the highway right-of-way and any wetlands or riparian areas. Bridge construction also can impact water circulation and quality in wetland areas, making special techniques necessary to accommodate construction. The following case study provides an example of a construction project where special considerations were given to wetlands.

> **CASE STUDY - BRIDGING WETLANDS IN LOUISIANA**
>
> To provide protection for an environmentally critical wetland outside New Orleans, the Louisiana Department of Transportation and Development (DOTD) required a special construction technique to build almost 2 miles of twin elevated structures for the Interstate 310 link between I-10 and U.S. Route 90. A technique known as "end-on" construction was devised to work from the decks of the structures, building each section of the bridge from the top of the last completed section and using heavy cranes to push each section forward one bay at a time. The cranes were also used to position steel platforms, drive in support pilings, and lay deck slabs, alternating this procedure between each bay. Without this technique, the Louisiana DOTD would not have been permitted to build this structure. The twin 9,200-foot bridges took 485 days to complete at a cost of $25.3 million (*Engineering News Record*, 1991).

3. Management Measure Selection

This management measure was selected because it supports FHWA's erosion and sediment control policy for all highway and bridge construction projects and is the administrative policy of several State highway departments and local governmental agencies involved in land development activity. Examples of erosion and sediment controls and NPS pollutant control practices are described in AASHTO guidelines and in several State erosion control manuals (AASHTO, 1991; North Carolina DOT, 1991; Washington State DOT, 1988). A detailed discussion of cost-effective management practices is available in the urban development section (Section II) of this chapter. These example practices are also effective for highway construction projects.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Additional erosion and sediment control management practices are listed in the construction section (Section III) of this chapter.

■ a. *Write erosion and sediment control requirements into plans, specifications, and estimates for Federal aid construction projects for highways and bridges (FHWA, 1991) and develop erosion control plans for earth-disturbing activities.*

Erosion and sediment control decisions made during the planning and location phase should be written into the contract, plans, specifications, and special provisions provided to the construction contractor. This approach can establish contractor responsibility to carry out the explicit contract plan recommendations for the project and the erosion control practices needed.

■ b. *Coordinate erosion and sediment controls with FHWA, AASHTO, and State guidelines.*

Coordination and scheduling of the project work with State and local authorities are major considerations in controlling anticipated erosion and sediment problems. In addition, the contractor should submit a general work schedule and plan that indicates planned implementation of temporary and permanent erosion control practices, including shutdown procedures for winter and other work interruptions. The plan also should include proposed methods of control on restoring borrow pits and the disposal of waste and hazardous materials.

c. Install permanent erosion and sediment control structures at the earliest practicable time in the construction phase.

Permanent or temporary soil stabilization practices should be applied to cleared areas within 15 days after final grade is reached on any portion of the site. Soil stabilization should also be applied within 15 days to denuded areas that may not be at final grade but will remain exposed to rain for 30 days or more. Soil stabilization practices protect soil from the erosive forces of raindrop impact and flowing water. Temporary erosion control practices usually include seeding, mulching, establishing general vegetation, and early application of a gravel base on areas to be paved. Permanent soil stabilization practices include vegetation, filter strips, and structural devices.

Sediment basins and traps, perimeter dikes, sediment barriers, and other practices intended to trap sediment on site should be constructed as a first step in grading and should be functional before upslope land disturbance takes place. Structural practices such as earthen dams, dikes, and diversions should be seeded and mulched within 15 days of installation.

d. Coordinate temporary erosion and sediment control structures with permanent practices.

All temporary erosion and sediment controls should be removed and disposed of within 30 days after final site stabilization is achieved or after the temporary practices are no longer needed. Trapped sediment and other disturbed soil areas resulting from the disposition of temporary controls should be permanently stabilized to prevent further erosion and sedimentation (AASHTO, 1991).

e. Wash all vehicles prior to leaving the construction site to remove mud and other deposits. Vehicles entering or leaving the site with trash or other loose materials should be covered to prevent transport of dust, dirt, and debris. Install and maintain mud and silt traps.

f. Mitigate wetland areas destroyed during construction.

Marshes and some types of wetlands can often be developed in areas where fill material was extracted or in ponds designed for sediment control during construction. Vegetated strips of native marsh grasses established along highway embankments near wetlands or riparian areas can be effective to protect these areas from erosion and sedimentation (FHWA, 1991).

g. Minimize the area that is cleared for construction.

h. Construct cut-and-fill slopes in a manner that will minimize erosion.

Cut-and-fill slopes should be constructed in a manner that will minimize erosion by taking into consideration the length and steepness of slopes, soil types, upslope drainage areas, and ground-water conditions. Suggested recommendations are as follows: reduce the length of long steep slopes by adding diversions or terraces; prevent concentrated runoff from flowing down cut-and-fill slopes by containing these flows within flumes or slope drain structures; and create roughened soil surfaces on cut-and-fill slopes to slow runoff flows. Wherever a slope face crosses a water seepage plane, thereby endangering the stability of the slope, adequate subsurface drainage should be provided.

i. Minimize runoff entering and leaving the site through perimeter and onsite sediment controls.

j. Inspect and maintain erosion and sediment control practices (both on-site and perimeter) until disturbed areas are permanently stabilized.

k. Divert and convey offsite runoff around disturbed soils and steep slopes to stable areas in order to prevent transport of pollutants off site.

l. After construction, remove temporary control structures and restore the affected area. Dispose of sediments in accordance with State and Federal regulations.

m. All storm drain inlets that are made operable during construction should be protected so that sediment-laden water will not enter the conveyance system without first being filtered or otherwise treated to remove sediment.

5. Effectiveness Information and Cost Information

The detailed cost and effectiveness information presented under the construction measure for urban development is also applicable to road, highway, and bridge construction. See Tables 4-15 and 4-16 in Section III.

[illegible]

(1) Limit the application, generation, and migration of toxic substances;

(2) Ensure the proper storage and disposal of toxic materials; and

(3) Apply nutrients at rates necessary to establish and maintain vegetation without causing significant nutrient runoff to surface water.

1. Applicability

This management measure is intended to be applied by States to new, resurfaced, restored, and rehabilitated road, highway, and bridge construction projects in order to reduce toxic and nutrient loadings from such project sites. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The objective of this measure is to guard against toxic spills and hazardous loadings at construction sites from equipment and fuel storage sites. Toxic substances tend to bind to fine soil particles; however, by controlling sediment mobilization, it is possible to limit the loadings of these pollutants. Also, some substances such as fuels and solvents are hazardous and excess applications or spills during construction can pose significant environmental impacts. Proper management and control of toxic substances and hazardous materials should be the adopted procedure for all construction projects and should be established by erosion and sediment control plans. Additional relevant practices are described in Management Measure III.B of this chapter.

3. Management Measure Selection

This management measure was selected because of existing practices that have been shown to be effective in mitigating construction-generated NPS pollution at highway project sites and equipment storage yards. In addition, maintenance areas containing road salt storage, fertilizers and pesticides, snowplows and trucks, and tractor mowers have the potential to contribute NPS pollutants to adjacent watercourses if not properly managed (AASHTO, 1988, 1991a). This measure is intended to safeguard surface waters and ground water from toxic and hazardous pollutants generated at construction sites. Examples of effective implementation of this measure are presented in the section on construction in urban areas. Several State environmental agencies are using this approach to regulate toxic and hazardous pollutants (Florida DER, 1988; Puget Sound Basin, 1991).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

The practices that are applicable to this management measure are described in Section III.B.

5. Effectiveness Information and Cost Information

The detailed cost and effectiveness data presented in the Section III.A of this chapter describing NPS controls for construction projects in urban development areas are also applicable to highway construction projects.

F. Management Measure for Operation and Maintenance

Incorporate pollution prevention procedures into the operation and maintenance of roads, highways, and bridges to reduce pollutant loadings to surface waters.

1. Applicability

This management measure is intended to be applied by States to existing, restored, and rehabilitated roads, highways, and bridges. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measures and will have some flexibility in doing so. The application of measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Substantial amounts of eroded material and other pollutants can be generated by operation and maintenance procedures for roads, highways, and bridges, and from sparsely vegetated areas, cracked pavements, potholes, and poorly operating urban runoff control structures. This measure is intended to ensure that pollutant loadings from roads, highways, and bridges are minimized by the development and implementation of a program and associated practices to ensure that sediment and toxic substance loadings from operation and maintenance activities do not impair coastal surface waters. The program to be developed, using the practices described in this management measure, should consist of and identify standard operating procedures for nutrient and pesticide management, road salt use minimization, and maintenance guidelines (e.g., capture and contain paint chips and other particulates from bridge maintenance operations, resurfacing, and pothole repairs).

3. Management Measure Selection

This management measure for operation and maintenance was selected because (1) it is recommended by FHWA as a cost-effective practice (FHWA, 1991); (2) it is protective of the human environment (Puget Sound Water Quality Authority, 1989); (3) it is effective in controlling erosion by revegetating bare slopes (AASHTO, 1991b); (4) it is helpful in minimizing polluted runoff from road pavements (Transportation Research Board, 1991); and (5) both Federal (Richardson, 1974) and State highway agencies (Minnesota Pollution Control Agency, 1989; Pitt, 1973) advocate highway maintenance as an effective practice for minimizing pollutant loadings.

Maintenance of erosion and sediment control practices is of critical importance. Both temporary and permanent controls require frequent and periodic cleanout of accumulated sediment. Any trapping or filtering device, such as silt fences, sediment basins, buffers, inlets, and check dams, should be checked and cleaned out when approximately 50 percent of their capacity is reached, as determined by the erodible nature of the soil, flow velocity, and quantity of runoff. Seasonal and climatic differences may require more frequent cleanout of these structures. The sediments removed from these control devices should be deposited in permanently stabilized areas to prevent further erosion and sediment from reaching drainages and receiving streams. After periods of use, control devices may require replacement of deteriorated materials such as straw bales and silt fence fabrics, or restoration and reconstruction of sediment basins and riprap installations.

Permanent erosion controls such as vegetated filter strips, grassed swales, and velocity dissipators should be inspected periodically to determine their integrity and continued effectiveness. Continual deterioration or damage to these controls may indicate a need for better design or construction.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully apply to achieve the management measure described above.

■ a. *Seed and fertilize, seed and mulch, and/or sod damaged vegetated areas and slopes.*

■ b. *Establish pesticide/herbicide use and nutrient management programs.*

Refer to the Management Measure for Construction Site Chemical Control in this chapter.

■ c. *Restrict herbicide and pesticide use in highway rights-of-way to applicators certified under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) to ensure safe and effective application.*

■ d. *The use of chemicals such as soil stabilizers, dust palliatives, sterilants, and growth inhibitors should be limited to the best estimate of optimum application rates. All feasible measures should be taken to avoid excess application and consequent intrusion of such chemicals into surface runoff.*

■ e. *Sweep, vacuum, and wash residential/urban streets and parking lots.*

■ f. *Collect and remove road debris.*

■ g. *Cover salt storage piles and other deicing materials to reduce contamination of surface waters. Locate them outside the 100-year floodplain.*

■ h. *Regulate the application of deicing salts to prevent oversalting of pavement.*

■ i. *Use specially equipped salt application trucks.*

■ j. *Use alternative deicing materials, such as sand or salt substitutes, where sensitive ecosystems should be protected.*

■ k. *Prevent dumping of accumulated snow into surface waters.*

■ l. *Maintain retaining walls and pavements to minimize cracks and leakage.*

■ m. *Repair potholes.*

■ n. *Encourage litter and debris control management.*

o. Develop an inspection program to ensure that general maintenance is performed on urban runoff and NPS pollution control facilities.

To be effective, erosion and sediment control devices and practices must receive thorough and periodic inspection checks. The following is a suggested checklist for the inspection of erosion and sediment controls (AASHTO Operating Subcommittee on Design, 1990):

- Clean out sediment basins and traps; ensure that structures are stable.
- Inspect silt fences and replace deteriorated fabrics and wire connections; properly dispose of deteriorated materials.
- Renew riprapped areas and reapply supplemental rock as necessary.
- Repair/replace check dams and brush barriers; replace or stabilize straw bales as needed.
- Regrade and shape berms and drainage ditches to ensure that runoff is properly channeled.
- Apply seed and mulch where bare spots appear, and replace matting material if deteriorated.
- Ensure that culverts and inlets are protected from siltation.
- Inspect all permanent erosion and sediment controls on a scheduled, programmed basis.

p. Ensure that energy dissipators and velocity controls to minimize runoff velocity and erosion are maintained.

q. Dispose of accumulated sediment collected from urban runoff management and pollution control facilities, and any wastes generated during maintenance operations, in accordance with appropriate local, State, and Federal regulations.

r. Use techniques such as suspended tarps, vacuums, or booms to reduce, to the extent practicable, the delivery to surface waters of pollutants used or generated during bridge maintenance (e.g., paint, solvents, scrapings).

s. Develop education programs to promote the practices listed above.

5. Effectiveness Information and Cost Information

Preventive maintenance is a time-proven, cost-effective management approach. Operation schedules and maintenance procedures to restore vegetation, proper management of salt and fertilizer application, regular cleaning of urban runoff structures, and frequent sweeping and vacuuming of urban streets have effective results in pollution control. Litter control, clean-up, and fix-up practices are a low-cost means for eliminating causes of pollution, as is the proper handling of fertilizers, pesticides, and other toxic materials including deicing salts and abrasives. Table 4-30 presents summary information on the cost and effectiveness of operation and maintenance practices for roads, highways, and bridges. Many States and communities are already implementing several of these practices within their budget limitations. As shown in Table 4-30, the use of road salt alternatives such as calcium magnesium acetate (CMA) can be very costly. Some researchers have indicated, however, that reductions in corrosion of infrastructure, damage to roadside vegetation, and the quantity of material that needs to be applied may offset the higher cost of CMA. Use of road salt minimization practices such as salt storage protection and special salt spreading equipment reduces the amount of salt that a State or community must purchase. Consequently, implementation of these practices can pay for itself through savings in salt purchasing costs. Similar programs such as nutrient and pesticide management can also lead to decreased expenditures for materials.

CMA Eligible for Matching Funds

Calcium magnesium acetate (CMA) is now eligible for Federal matching funds under the Bridge Program of the Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991. The Act provides 80 percent funding for use of CMA on salt-sensitive bridges in order to protect against corrosion and to extend their useful life. CMA can also be used to protect vegetation from salt damage in environmentally sensitive areas.

Table 4-30. Effectiveness and Cost Summary for Roads, Highways, and Bridges Operation and Maintenance Management Practices

Management Practice	% Removal						Cost
	TSS	TP	TN	COD	Pb	Zn	
MAINTAIN VEGETATION							
For Sediment Control							Natural succession allowed to occur -
Average:	90	NA	NA	NA	NA	NA	Avg: $100/ac/year

[a]Measured as reduction in salt.
[b]Measured as reduction of all pollutants.

[illegible]

Develop and implement runoff management systems for existing roads, highways, and bridges to reduce runoff pollutant concentrations and volumes entering surface waters.

(1) Identify priority and watershed pollutant reduction opportunities (e.g., improvements to existing urban runoff control structures; and

(2) Establish schedules for implementing appropriate controls.

1. Applicability

This management measure is intended to be applied by States to existing, resurfaced, restored, and rehabilitated roads, highways, and bridges that contribute to adverse effects in surface waters. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal NPS programs in conformity with this management measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

This measure requires that operation and maintenance systems include the development of retrofit projects, where needed, to collect NPS pollutant loadings from existing, reconstructed, and rehabilitated roads, highways, and bridges. Poorly designed or maintained roads and bridges can generate significant erosion and pollution loads containing heavy metals, hydrocarbons, sediment, and debris that run off into and threaten the quality of surface waters and their tributaries. In areas where such adverse impacts to surface waters can be attributed to adjacent roads or bridges, retrofit management projects to protect these waters may be needed (e.g., installation of structural or nonstructural pollution controls). Retrofit projects can be located in existing rights-of-way, within interchange loops, or on adjacent land areas. Areas with severe erosion and pollution runoff problems may require relocation or reconstruction to mitigate these impacts.

Runoff management systems are a combination of nonstructural and structural practices selected to reduce nonpoint source loadings from roads, highways, and bridges. These systems are expected to include structural improvements to existing runoff control structures for water quality purposes; construction of new runoff control devices, where necessary to protect water quality; and scheduled operation and maintenance activities for these runoff control practices. Typical runoff controls for roads, highways, and bridges include vegetated filter strips, grassed swales, detention basins, constructed wetlands, and infiltration trenches.

3. Management Measure Selection

This management measure was selected because of the demonstrated effectiveness of retrofit systems for existing roads and highways that were constructed with inadequate nonpoint source pollution controls or without such controls. Structural practices for mitigating polluted runoff from existing highways are described in the literature (Silverman, 1988).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

- a. ***Locate runoff treatment facilities within existing rights-of-way or in medians and interchange loops.***
- b. ***Develop multiple-use treatment facilities on adjacent lands (e.g., parks and golf courses).***
- c. ***Acquire additional land for locating treatment facilities.***
- d. ***Use underground storage where no alternative is available.***
- e. ***Maximize the length and width of vegetated filter strips to slow the travel time of sheet flow and increase the infiltration rate of urban runoff.***

5. Effectiveness Information and Cost Information

Cost and effectiveness data for structural urban runoff management and pollution control facilities are outlined in Tables 4-15 and 4-16 in Section III and discussed in Section IV of this chapter and are applicable to determine the cost and effectiveness of retrofit projects. Retrofit projects can often be more costly to construct because of the need to locate the required structures within existing space or the need to locate the structures within adjacent property that requires purchase. However, the use of multiple-use facilities on adjacent lands, such as diverting runoff waters to parkland or golf courses, can offset this cost. Nonstructural practices described in the urban section also can be effective in achieving source control. As with other sections of this document, the costs of loss of habitat, fisheries, and recreational areas must be weighed against the cost of retrofitting control structures within existing rights-of-way.

6. Pollutants of Concern

Table 4-31 lists the pollutants commonly found in urban runoff from roads, highways, and bridges and their sources. The disposition and subsequent magnitude of pollutants found in highway runoff are site-specific and are affected by traffic volume, road or highway design, surrounding land use, climate, and accidental spills.

The FHWA conducted an extensive field monitoring and laboratory analysis program to determine the pollutant concentration in highway runoff from 31 sites in 11 States (Driscoll et al., 1990). The event mean concentrations (EMCs) developed in the study for a number of pollutants are presented in Table 4-32. The study also indicated that for highways discharging into lakes, the pollutants of major concern are phosphorus and heavy metals. For highways discharging into streams, the pollutants of major concern are heavy metals—cadmium, copper, lead, and zinc.

Table 4-31. Highway Runoff Constituents and Their Primary Sources

Constituents	Primary Sources
Particulates	Pavement wear, vehicles, atmosphere, maintenance
Nitrogen, Phosphorus	Atmosphere, roadside fertilizer application
Lead	Leaded gasoline (auto exhaust), tire wear (lead oxide filler material, lubricating oil and grease, bearing wear)
Zinc	Tire wear (filler material), motor oil (stabilizing additive), grease
Iron	Auto body rust, steel highway structures (guard rails, bridges, etc.), moving engine parts
Copper	Metal plating, bearing and bushing wear, moving engine parts, brake lining wear, fungicides and insecticides
Cadmium	Tire wear (filler material), insecticide application
Chromium	Metal plating, moving engine parts, break lining wear
Nickel	Diesel fuel and gasoline (exhaust), lubricating oil, metal plating, bushing wear, brake lining wear, asphalt paving
Manganese	Moving engine parts
Cyanide	Anticake compound (ferric ferrocyanide, sodium ferrocyanide, yellow prussiate of soda) used to keep deicing salt granular
Sodium, Calcium, Chloride	Deicing salts
Sulphate	Roadway beds, fuel, deicing salts
Petroleum	Spills, leaks or blow-by of motor lubricants, antifreeze and hydraulic fluids, asphalt surface leachate

In colder regions where deicing agents are used, deicing chemicals and abrasives are the largest source of pollutants during winter months. Deicing salt (primarily sodium chloride, NaCl) is the most commonly used deicing agent. Potential pollutants from deicing salt include sodium chloride, ferric ferrocyanide (used to keep the salt in granular form), and sulfates such as gypsum. Table 4-33 summarizes potential environmental impacts caused by road salt. Other chemicals used as a salt substitute include calcium magnesium acetate (CMA) and, less frequently, urea and glycol compounds. Researchers have differing opinions on the environmental impacts of CMA compared to those of road salt (Chevron Chemical Company, 1991; Salt Institute, undated; Transportation Research Board, 1991).

VOL 12

Table 4-32. Pollutant Concentrations in Highway Runoff (Driscoll et al., 1990)

Pollutant	Event Mean Concentration for Highways With Fewer Than 30,000 Vehicles/Day[a] (mg/L)	Event Mean Concentration for Highways With More Than 30,000 Vehicles/Day[a] (mg/L)
Total Suspended Solids	41	142
Volatile Suspended Solids	12	39
Total Organic Carbon	8	25
Chemical Oxygen Demand	49	114
Nitrite and Nitrate	0.46	0.76
Total Kjeldahl Nitrogen	0.87	1.83
Phosphate Phosphorus	0.16	0.40
Copper	0.022	0.054
Lead	0.080	0.400
Zinc	0.080	0.329

[a]Event mean concentrations are for the 50% median site.

Table 4-33. Potential Environmental Impacts of Road Salts

Environmental Resource	Potential Environmental Impact of Road Salt (NaCl)
Soils	May accumulate in soil. Breaks down soil structure, increases erosion. Causes soil compaction that results in decreased permeability.
Vegetation	Osmotic stress and soil compaction harm root systems. Spray causes foliage dehydration damage. Many plant species are salt-sensitive.
Ground Water	Mobile Na and Cl ions readily reach ground water. Increases NaCl concentration in well water, as well as alkalinity and hardness.
Surface Water	Causes density stratification in ponds and lakes that can prevent reoxygenation. Increases runoff of heavy metals and nutrients through increased erosion.
Aquatic Life	Monovalent Na and Cl ions stress osmotic balances. Toxic levels: Na - 500 ppm for stickleback; Cl - 400 ppm for trout.
Human/Mammalian	Sodium is linked to heart disease and hypertension. Chlorine causes unpleasant taste in drinking water. Mild skin and eye irritant. Acute oral LD_{50} in rats is approximately 3,000 mg/kg (slightly toxic).

VOL 12

VIII. GLOSSARY

Unless otherwise noted, the source of these definitions is *Glossary of Environmental Terms and Acronym List* (USEPA, 1989).

Bankfull event (also bankfull discharge): A flow condition in which streamflow completely fills the steam channel up to the top of the bank. In undisturbed watersheds, the discharge condition occurs on average every 1.5 to 2 years and controls the shape and form of natural channels. (Schueler, 1987)

Berm: An earthen mound used to direct the flow of runoff around or through a best management practice (BMP) (Schueler, 1987).

Constructed urban runoff wetlands: Those wetlands that are intentionally created on sites that are not wetlands for the primary purpose of wastewater or urban runoff treatment and are managed as such. Constructed wetlands are normally considered as part of the urban runoff collection and treatment system.

Conveyance system: The drainage facilities, both natural and human-made, which collect, contain, and provide for the flow of surface water and urban runoff from the highest points on the land down to a receiving water. The natural elements of the conveyance system include swales and small drainage courses, streams, rivers, lakes, and wetlands. The human-made elements of the conveyance system include gutters, ditches, pipes, channels, and most retention/detention facilities (Washington Department of Ecology, 1992).

Denitrification: The anaerobic biological reduction of nitrate nitrogen to nitrogen gas.

Discharge: Outflow; the flow of a stream, canal, or aquifer. One may also speak of the discharge of a canal or stream into a lake, river, or ocean. (Hydraulics) Rate of flow, specifically fluid flow; a volume of fluid passing a point per unit of time, commonly expressed as cubic feet per second, cubic meters per second, gallons per minute, gallons per day, or millions of gallons per day. (Washington Department of Ecology, 1992)

Drainage basin: A geographic and hydrologic subunit of a watershed (Washington Department of Ecology, 1992).

Ecosystem: The interacting system of a biological community and its nonliving environmental surroundings.

Erosion: The wearing away of the land surface by wind or water. Erosion occurs naturally from weather or runoff but can be intensified by land-clearing practices related to farming, residential or industrial development, road building, or timber cutting.

Forebay: An extra storage space provided near an inlet of a BMP to trap incoming sediments before they accumulate in a pond BMP (Schueler, 1987).

Heavy metals: Metallic elements with high atomic weights, e.g., mercury, chromium, cadmium, arsenic, and lead. They can damage living things at low concentrations and tend to accumulate in the food chain.

Illicit discharge: All nonurban runoff discharges to urban runoff drainage systems that could cause or contribute to a violation of State water quality, sediment quality, or ground-water quality standards, including but not limited to sanitary sewer connections, industrial process water, interior floor drains, car washing, and greywater systems (Washington Department of Ecology, 1992).

Impervious surface: A hard surface area that either prevents or retards the entry of water into the soil mantle as under natural conditions prior to development and/or a hard surface area that causes water to run off the surface in greater quantities or at an increased rate of flow from the flow present under natural conditions prior to development. Common impervious surfaces include, but are not limited to, rooftops, walkways, patios, driveways, parking lots,

9722

storage areas, concrete or asphalt paving, gravel roads, packed earthen materials, and oiled, macadam, or other surfaces that similarly impede the natural infiltration of urban runoff. Open, uncovered retention/detention facilities shall not be considered as impervious surfaces. (Washington Department of Ecology, 1992)

Invasive exotic plants: Non-native plants having the capacity to compete and proliferate in introduced environments (Washington Department of Ecology, 1992).

Land conversion: A change in land use, function, or purpose (Washington Department of Ecology, 1992).

Land-disturbing activity: Any activity that results in a change in the existing soil cover (both vegetative and nonvegetative) and/or the existing soil topography. Land-disturbing activities include, but are not limited to, demolition, construction, clearing, grading, filling, and excavation. (Washington Department of Ecology, 1992)

Local government: Any county, city, or town having its own incorporated government for local affairs (Washington Department of Ecology, 1992).

Municipal separate storm sewer systems: Any conveyance or system of conveyance that is owned or operated by the State or local government entity, is used for collecting and conveying storm water, and is not part of a publicly owned treatment works (POTW), as defined in EPA 40 CFR Part III (Washington Department of Ecology, 1992).

Onsite disposal system (OSDS): Sewage disposal system designed to treat wastewater at a particular site. Septic tank systems are common OSDS. (Washington Department of Ecology, 1992)

Organophosphate: Pesticide chemical that contains phosphorus; used to control insects. Organophosphates are short-lived, but some can be toxic when first applied.

Postdevelopment peak runoff: Maximum instantaneous rate of flow during a storm, after development is complete (Washington Department of Ecology, 1992).

Retrofit: The creation or modification of an urban runoff management system in a previously developed area. This may include wet ponds, infiltration systems, wetland plantings, streambank stabilization, and other BMP techniques for improving water quality and creating aquatic habitat. A retrofit can consist of the construction of a new BMP in a developed area, the enhancement of an older urban runoff management structure, or a combination of improvement and new construction. (Schueler et al., 1992)

Soil absorption field: A subsurface area containing a trench or bed with clean stones and a system of distribution piping through which treated sewage may seep into the surrounding soil for further treatment and disposal.

Turbidity: A cloudy condition in water due to suspended silt or organic matter.

Urban runoff: That portion of precipitation that does not naturally percolate into the ground or evaporate, but flows via overland flow, underflow, or channels or is piped into a defined surface water channel or a constructed infiltration facility (Washington Department of Ecology, 1992).

Vegetated buffer: Strips of vegetation separating a waterbody from a land use with potential to act as a nonpoint pollution source; vegetated buffers (or simply buffers) are variable in width and can range in function from a vegetated filter strip to a wetland or riparian area.

Watershed: The land area that drains into a receiving waterbody.

Wetlands: Areas that are inundated or saturated by surface or ground water at a frequency and duration to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions; wetlands generally include swamps, marshes, bogs, and similar areas. (This definition is consistent with the Federal definition at 40 CFR 230.3; December 24, 1989. As amendments are made to the wetland definition, they will be considered applicable to this guidance.)

Xeriscaping: A horticultural practice that combines water conservation techniques with landscaping; also known as dry landscaping (Clemson University Cooperative Extension Service, 1991).

CHAPTER 5: Management Measures for Marinas and Recreational Boating

I. INTRODUCTION

A. What "Management Measures" Are

This chapter specifies management measures to protect coastal waters from sources of nonpoint pollution from marinas and recreational boating. "Management measures" are defined in section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990 (CZARA) as economically achievable measures to control the addition of pollutants to our coastal waters, which reflect the greatest degree of pollutant reduction achievable through the application of the best available nonpoint pollution control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

These management measures will be incorporated by States into their coastal nonpoint programs, which under CZARA are to provide for the implementation of management measures that are "in conformity" with this guidance. Under CZARA, States are subject to a number of requirements as they develop and implement their coastal nonpoint pollution control programs in conformity with this guidance and will have some flexibility in doing so. The application of these management measures by States to activities causing nonpoint pollution is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA).

B. What "Management Practices" Are

In addition to specifying management *measures*, this chapter also lists and describes management *practices* for illustrative purposes only. While State programs are required to specify management *measures* in conformity with this guidance, State programs need not specify or require the implementation of the particular management *practices* described in this document. However, as a practical matter, EPA anticipates that the management measures generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices listed in this document have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measures. EPA has also used some of these practices, or appropriate combinations of these practices, as a basis for estimating the effectiveness, costs, and economic impacts of achieving the management measures. (Economic impacts of the management measures are addressed in a separate document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*)

EPA recognizes that there is often site-specific, regional, and national variability in the selection of appropriate practices, as well as in the design constraints and pollution control effectiveness of practices. The list of practices for each management measure is not all-inclusive and does not preclude States or local agencies from using other technically sound practices. In all cases, however, the practice or set of practices chosen by a State needs to achieve the management measure.

C. Scope of This Chapter

This chapter addresses categories of sources of nonpoint pollution from marinas and recreational boating that affect coastal waters. This chapter specifies 15 management measures grouped under two broad headings: (1) siting and design and (2) operation and maintenance.

VOL 12

9746

Each category of sources is addressed in a separate section of this guidance. Each section contains (1) the management measure(s); (2) an applicability statement that describes, when appropriate, specific activities and locations for which the measure is suitable; (3) a description of the management measure's purpose; (4) the basis for the management measure's selection; (5) information on management practices that are suitable, either alone or in combination with other practices, to achieve the management measure; (6) information on the effectiveness of the management measure and/or of practices to achieve the measure; and (7) information on costs of the measure and/or practices to achieve the measure.

D. Relationship of This Chapter to Other Chapters and to Other EPA Documents

1. Chapter 1 of this document contains detailed information on the legislative background for this guidance, the process used by EPA to develop this guidance, and the technical approach used by EPA in this guidance.

2. Chapter 7 of this document contains management measures to protect wetlands and riparian areas that serve a nonpoint source abatement function. These measures apply to a broad variety of sources, including marinas and recreational boating sources.

3. Chapter 8 of this document contains information on recommended monitoring techniques to (1) ensure proper implementation, operation, and maintenance of the management measures and (2) assess over time the success of the measures in reducing pollution loads and improving water quality.

4. EPA has separately published a document entitled *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*

5. NOAA and EPA have jointly published guidance entitled *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*. This guidance contains details on how State Coastal Nonpoint Pollution Control Programs are to be developed by States and approved by NOAA and EPA. It includes guidance on the following:

   - The basis and process for EPA/NOAA approval of State Coastal Nonpoint Pollution Control Programs;
   - How NOAA and EPA expect State programs to provide for the implementation of management measures "in conformity" with this management measures guidance;
   - How States may target sources in implementing their Coastal Nonpoint Pollution Control Programs;
   - Changes in State coastal boundaries; and
   - Requirements concerning how States are to implement their Coastal Nonpoint Pollution Control Programs.

E. Problem Statement

Marinas and recreational boating are increasingly popular uses of coastal areas. The growth of recreational boating, along with the growth of coastal development in general, has led to a growing awareness of the need to protect waterways. In the Coastal Zone Management Act (CZMA) of 1972, as amended, Congress declared it to be national policy that State coastal management programs provide for public access to the coasts for recreational purposes. Clearly, boating and adjunct activities (e.g., marinas) are an important means of public access. When these facilities are poorly planned or managed, however, they may pose a threat to the health of aquatic systems and may pose other environmental hazards. Ensuring the best possible siting for marinas, as well as the best available design and construction practices and appropriate operation and maintenance practices, can greatly reduce nonpoint source (NPS) pollution from marinas.

Because marinas are located right at the water's edge, there is often no buffering of the release of pollutants to waterways. Adverse environmental impacts may result from the following sources of pollution associated with marinas and recreational boating:

- Poorly flushed waterways where dissolved oxygen deficiencies exist;
- Pollutants discharged from boats;
- Pollutants transported in storm water runoff from parking lots, roofs, and other impervious surfaces;
- The physical alteration or destruction of wetlands and of shellfish and other bottom communities during the construction of marinas, ramps, and related facilities; and
- Pollutants generated from boat maintenance activities on land and in the water.

The management measures described in this chapter are designed to reduce NPS pollution from marinas and recreational boating. Effective implementation will avoid impacts associated with marina siting, prevent the introduction of nonpoint source pollutants, and/or reduce the delivery of pollutants to water resources.

Pollution prevention should be at the fore of any NPS management strategy. It is expected that each coastal State's decision on implementation of these management measures will be based on a management strategy that balances the need for protecting the coastal environment and the need to provide adequate public access to coastal waters.

F. Pollutant Types and Impacts

A marina can have significant impacts on the concentrations of pollutants in the water, sediment, and tissue of organisms within the marina itself. Although sources of pollutants outside the marina are part of the problem, marina design, operation, and location appear to play crucial roles in determining whether local water quality is impacted (NCDEM, 1991).

Marina construction may alter the type of habitat found at the site. Alterations can have both negative and positive effects. For example, a soft-bottom habitat (i.e., habitat characterized by burrowing organisms and deposit feeders) could be replaced with a habitat characterized by fouling organisms attached to the marina pilings and bulkhead. These fouling organisms, however, may attract other organisms, including invertebrates and juvenile fish.

The presence of a marina is not necessarily an indicator of poor water quality. In fact, many marinas have good water quality. Despite this, they may still have degraded biological resources and contaminated sediments resulting from bioaccumulation in organisms and adhesion of pollutants to sediments. A brief summary of some of the impacts that can be associated with marina and boating activities is presented below.

1. Toxicity in the Water Column

Pollutants from marinas can result in toxicity in the water column, both lethal and sublethal, related to decreased levels of dissolved oxygen and elevated levels of metals and petroleum hydrocarbons. These pollutants may enter the water through discharges from boats or other sources, spills, or storm water runoff.

Low Dissolved Oxygen. The organics in sewage discharged from recreational boats require dissolved oxygen (DO) to decompose. The biological oxygen demand (BOD) of a waterbody is a measure of the DO required to decompose sewage and other organic matter (Milliken and Lee, 1990). Accumulation of organic material in sediment will result in a sediment oxygen demand (SOD) that can negatively impact water column DO. The effect of boat sewage on

DO can be intensified in temperate regions because the peak boating season coincides with the highest water temperatures and thus the lowest solubilities of oxygen in the water and the highest metabolism rates of aquatic organisms. (As temperature increases, dissolved oxygen levels decrease.) Cardwell and Koons (1981) recorded significant decreases in DO in several northwestern marinas in the late summer and early fall, which are the peak times of marina use. Nixon et al. (1973) measured lower DO levels in an area of marina development than in an adjacent undeveloped bay of similar size. An intensive study in several North Carolina marinas showed significant decreases in DO concentration compared to ambient concentrations in the receiving waterbody. These decreases in DO were thought to result from high SOD within the marinas and poor flushing resulting from improper marina design (NCDEM, 1990).

Metals. Metals and metal-containing compounds have many functions in boat operation, maintenance, and repair. Lead is used as a fuel additive and ballast and may be released through incomplete fuel combustion and boat bilge discharges (NCDEM, 1991). Arsenic is used in paint pigments, pesticides, and wood preservatives. Zinc anodes are used to deter corrosion of metal hulls and engine parts. Copper and tin are used as biocides in antifoulant paints. Other metals (iron, chrome, etc.) are used in the construction of marinas and boats.

Many of these metals/compounds are found in marina waters at levels that are toxic to aquatic organisms. Copper is the most common metal found at toxic concentrations in marina waters (NCDEM, 1990, 1991). Dissolved copper was detected at toxic concentrations at several marinas within the Chesapeake Bay (Hall et al., 1987). The input of copper via bottom paints and scrapings has been shown to be quite significant (Young et al., 1974). Tin in the form of butyltin, an extremely potent biocide, has been detected at toxic levels within marina waters nationwide (Stephenson et al., 1986; Maguire, 1986; Grovhoug et al., 1986; Stallard et al., 1987). The use of butyltins in bottom paint is now regulated, and butyltins cannot be used on nonaluminum recreational boats under 25 meters in length. High levels of zinc, chromium, and lead were also detected in waters within North Carolina marinas (NCDEM, 1990). Table 5-1 presents results of a recent study of boatyard hull pressure-washing wastewater in the Puget Sound area that revealed concentrations of metals and other pollutants that are of concern to environmental regulators (METRO, 1992a).

Petroleum Hydrocarbons. McMahon (1989) found elevated concentrations of hydrocarbons in marina waters and attributed them to refueling activities and bilge or fuel discharge from nearby boats.

2. Increased Pollutant Levels in Aquatic Organisms

Aquatic organisms can concentrate pollutants in the water column through biological activity. Copper and zinc concentrations in oysters were significantly higher in oysters in South Carolina and North Carolina marinas than at reference sites (NCDEM, 1991; SCDHEC, 1987). Increased levels of copper, cadmium, chromium, lead, tin, zinc, and PCBs were found in mussels from southern California marina waters (CARWQCB, 1989; Young et al., 1979). Three months after planting, concentrations of lead, zinc, and copper in oysters transplanted to several Australian marinas were two to three times higher than those of control sites (McMahon, 1989). Concentrations of copper in a green algae and the fouling community were significantly higher in a Rhode Island marina area than in adjacent control areas (Nixon et al., 1973). Several polynuclear aromatic hydrocarbons were detected in oyster tissue at marinas in South Carolina (Marcus and Stokes, 1985; Wendt et al., 1990).

3. Increased Pollutant Levels in Sediments

Many of the contaminants found in the storm water runoff of marinas do not dissolve well in water and accumulate to higher concentrations in sediments than in the overlying water. Contaminated sediments may, in turn, act as a source from which these contaminants can be released into the overlying waters. Benthic organisms—those organisms that live on the bottom or in the sediment—are exposed to pollutants that accumulate in the sediments and may be affected by this exposure or may avoid the contaminated area.

Metals. Copper is the major contaminant of concern because most common antifouling paint preparations contain cuprous oxide as the active biocide component (METRO, 1992a). In most cases metals have a higher affinity for sediments than for the water column and therefore tend to concentrate there. A recent Puget Sound area study of

VOL 12

9749

R0043055

wastewater from boat hull pressure washing found that suspended solids accounted for 96 percent of the copper, 94 percent of the lead, and 83 percent of the zinc in the wastewater (see Table 5-1 for concentrations). Most of the metal concentrations were associated with particles less than 60 microns in size, resulting in their settling out of solution slowly (METRO, 1992a). Stallard et al. (1987) noted that the sediments of nearly every California marina tested had high concentration of butyltins. Marina sites in North Carolina had significantly higher levels of arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc than did reference sites (NCDEM, 1991). McMahon (1989) found significantly higher concentrations of copper, lead, zinc, and mercury in the sediments at a marina site than in the parent waterbody. Within the marina, higher levels of copper and lead were found near a maintenance area drain and fuel dock, suggesting the drain as a source of copper and lead and the fuel dock as a possible source of lead. Sediments at most stations within Marina Del Rey were sufficiently contaminated with copper, lead, mercury, and zinc to affect fish and/or invertebrates, especially at the larval or juvenile stage (Soule et al., 1991). Researchers thought that this contamination might account for the absence of more sensitive species and the low diversity within the marina. However, the extent of the sediment contamination resulting from marina-related activities was unclear.

Petroleum Hydrocarbons. Petroleum hydrocarbons, particularly polynuclear aromatic hydrocarbons (PAHs), tend to adsorb to particulate matter and become incorporated into sediments. They may persist for years, resulting in exposure to benthic organisms. Voudrias and Smith (1986) reported that sediments from two Virginia creeks with marinas contained significantly higher levels of hydrocarbons than did control sites. The North Carolina Division of Environmental Management (NCDEM, 1990) found PAHs in the sediments of six marinas, all of which had fuel docks. Nearby reference areas did not appear to be affected. Marcus et al. (1988) found an increase in PAHs in the sediments of two South Carolina marinas. Sources of petroleum hydrocarbons were identified as the origin of

Table 5-1. Boatyard Pressure-washing Wastewater Contaminants and Regulatory Limits in the Puget Sound Area (METRO, 1992)

				Permit Limit Values

Arsenic	mg/L	0.08	0.1	4.0	3.6	0.136	0.720

[a] Values are based on analysis of 18 samples.
[b] Oil and grease not detected by visible inspections.
[c] No limit set or known for this parameter.
[d] No monitoring requirements, but limits will be based on water-quality criteria.
[e] Tin regulated by restrictions on the application of tributyltin paints.
[f] Limit values based on 8/13/91 draft of the Boatyard General NPDES Permit.

sediment contamination within several Australian marinas; however, a well-flushed marina in this study did not have an increase in sediment hydrocarbons (McMahon, 1989). This finding supports the supposition that sufficient flushing within a marina basin prevents build-up of pollutants in marina sediments.

4. Increased Levels of Pathogen Indicators

Studies conducted in Puget Sound, Long Island Sound, Narragansett Bay, North Carolina, and Chesapeake Bay have shown that boats can be a significant source of fecal coliform bacteria in areas with high boat densities and low hydrologic flushing (NCDEM, 1990; Sawyer and Golding, 1990; Milliken and Lee, 1990; Gaines and Solow, 1990; Seabloom et al., 1989; Fisher et al., 1987). Fecal coliform levels in marinas and mooring fields become elevated near boats during periods of high boat occupancy and usage. NOAA identified boating activities (the presence of marinas, shipping lanes, or intracoastal waterways) as a contributing source in the closure to harvesting of millions of acres of shellfish-growing waters on the east coast of the United States (Leonard et al., 1989).

5. Disruption of Sediment and Habitat

Boat operation and dredging can destroy habitat; resuspend bottom sediment (resulting in the reintroduction of toxic substances into the water column); and increase turbidity, which affects the photosynthetic activity of algae and estuarine vegetation. Paulson and Da Costa (1991) demonstrated that propeller-induced flows can contribute significantly to bottom scour in shallow embayments and may have adverse effects on water clarity and quality. The British Waterways Board (1983) noted that propeller-driven boats may impact the aquatic environment and result in bank erosion. Waterways with shallow water environments would be affected as follows:

(1) The propeller would cut off or uproot water plants growing up from the bottom, and

(2) The propeller agitation of the water (propwash) would disturb the sediments, creating turbidity that would reduce the light available for photosynthesis of plants, impact feeding and clog the breathing mechanisms of aquatic animals, and smother animals and plants.

EPA (1974) noted a resuspension of solids from the bottom and disturbance to aquatic macrophytes following boating activity. Changes in turbidity were dependent on water depth, motor power, operational time and type, and nature of sediment deposits. The increase in turbidity was generally accompanied by an increase in organic carbon and phosphorus concentrations. However, the possible contribution of these nutrients to eutrophication was not determined. The biological communities of rivers may be impacted by boat traffic, which can increase turbidity; resuspend sediments that move into backwaters; create changes in waves, velocity, and pressure; and increase shoreline erosion (USFWS, 1982).

Dredging may alter the marina and the adjacent water by increasing turbidity, reducing the oxygen content of the water, burying benthic organisms, causing disruption and removal of bottom habitat, creating stagnant areas, and altering water circulation (Chmura and Ross, 1978). Some of these impacts (e.g., turbidity and reduced DO) are temporary and without long-term adverse effects. Dredging is addressed under CWA section 404 and associated regulations and is therefore not discussed further in this chapter.

6. Shoaling and Shoreline Erosion

Shoaling and shoreline erosion result from the physical transport of sediment due to waves and/or currents. These waves and currents may be natural (wind-induced, rainfall runoff, etc.) or human-induced (alterations in current regimes, boat wakes, etc.).

The British Waterways Board (1983) noted that when vessel-generated waves reach the shallow margins of a waterway, they can erode the banks and the bed, tending to wash away fringing plants and their associated animal life. The Waterways Board also found that a substantial volume of the sediment that results in shoaling comes from bank erosion and that removal of this material by dredging is a costly recurrent expense, especially where boat traffic causes extensive bank erosion. Factors influencing vessel-generated shoreline erosion include the distance of the boat from shore, boat speed, side slopes, sediment type, and depth of the waterway (Camfield et al., 1980; Sorensen, 1986; Zabawa and Ostrom, 1980).

G. Other Federal and State Marina and Boating Programs

1. NPDES Storm Water Program

The storm water permit program is a two-phase program enacted by Congress in 1987 under section 402(p) of the Clean Water Act. Under Phase I, National Pollutant Discharge Elimination System (NPDES) permits are required to be issued for municipal separate storm sewers serving large or medium-sized populations (greater than 250,000 or 100,000 people, respectively), and for storm water discharges associated with industrial activity such as certain types of marinas. Permits are also to be issued, on a case-by-case basis, if EPA or a State determines that a storm water discharge contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States. EPA published a rule implementing Phase I on November 16, 1990.

a. Which marinas are regulated by the NPDES Storm Water Program?

Under the NPDES Storm Water Program, discharge permits are required for point source discharges of storm water from certain types of marinas. A point source discharge of storm water is a flow of rainfall runoff in some kind of discrete conveyance (a pipe, ditch, channel, swale, etc.).

If a marina is primarily in the business of renting boat slips, storing boats, cleaning boats, and repairing boats, and generally performs a range of other marine services, it is classified under the storm water program (using the Standard Industrial Classification (SIC) system developed by the Office of Management and Budget) as a SIC 4493. Marinas classified as SIC 4493 are the type that may be regulated under the storm water program and may be required to obtain a storm water discharge permit.

A marina that is classified as a SIC 4493 is required to obtain an NPDES storm water discharge permit if vehicle maintenance activities such as vehicle (boat) rehabilitation, mechanical repairs, painting, fueling, and lubrication or equipment cleaning operations are conducted at the marina. The storm water permit will apply only to the point source discharges of storm water from the maintenance areas at the marinas. Operators of these types of marinas should consult the water pollution control agency of the State in which the marina is located to determine how to obtain a storm water discharge permit.

b. Which marinas are not regulated by the NPDES Storm Water Program?

Marinas classified as SIC 4493 that are *not* involved in equipment cleaning or vehicle maintenance activities are not covered under the storm water program. Likewise, a marina, regardless of its classification and the types of activities conducted, that has no point source discharges of storm water, is also not regulated under the NPDES storm water program. In addition, some marinas are classified SIC code 5541 - marine service stations and are also not regulated under the NPDES Storm Water Program. These types of marinas are primarily in the business of selling fuel *without vehicle maintenance or equipment cleaning operations.*

c. What marina activities are covered by this guidance?

EPA has not yet promulgated regulations that would designate additional storm water discharges, beyond those regulated in Phase I, that will be required to be regulated in Phase II. Therefore, marina discharges that are not covered under Phase I, including those discharges that potentially may be ultimately covered by Phase II of the storm water permits program, are covered by this management measures guidance and will be addressed by the Coastal Nonpoint Pollution Control Programs. Any storm water discharge at a marina that ultimately is issued an NPDES permit will become exempt from this guidance and from the Coastal Nonpoint Pollution Control Program at the time that the permit is issued.

2. Other Regulatory Programs

The management measures for marinas do not address discharge of sanitary waste from vessels. They do, however, specify a measure to require that new marinas be designed to include pumpout stations and other facilities to handle sanitary waste from marine toilets, also referred to as marine sanitation devices (MSDs), and another measure to ensure that these facilities are properly maintained.

Vessels are not required to be equipped with an MSD. If a boat does have an MSD, however, the MSD has to meet certain standards set by EPA as required by CWA section 312. In addition to EPA standards for MSDs, EPA may allow a State to prohibit all discharges (treated or untreated) from MSDs, thus declaring the area a "no-discharge zone." Any State may apply to the EPA Administrator for designation of a "no-discharge zone" in some or all of the waters of the State; however, EPA must ensure that these waters meet certain tests before granting the application.

The siting and permitting process to which marinas are subject varies from State to State. State and Federal agencies both play a role in this process. Under section 10 of the Rivers and Harbors Act of 1899, the U.S. Army Corps of Engineers (USACE) regulates all work and structures in navigable waters of the United States. Under section 404 of the Clean Water Act, USACE permits are issued or denied to regulate discharges of dredged or fill materials in navigable waters of the United States, including wetlands.

All coastal States with Federally-approved coastal zone management programs can review Federal permit applications, and some States regulate dredge and fill, marshlands, or wetlands permitting for marina development. All States with Federally-approved coastal programs have the authority to object to section 10/section 404 permits if the proposed action is inconsistent with the State's coastal zone management program. Some States require permits for the use of State water bottomlands. States have authority under the Clean Water Act to issue section 401 water quality certifications for Federally-permitted actions as part of their water quality standards program.

The Food and Drug Administration (FDA) has established fecal coliform standards for certified shellfish-growing waters. Each coastal State regulates its own shellfish sanitation program under the National Shellfish Sanitation Program. States must participate if they wish to export shellfish across State lines. Various approaches are used to comply.

Some States also have a State coastal zone management permit providing them authority over development activities in areas located within their defined coastal zone. Alternatively, or in addition to this permitting authority, some States have regulatory planning authority in given areas of the coast, allowing them to influence the siting of marinas, if not their actual design and construction.

Finally, Massachusetts has developed a Harbor Planning Program, and other States (e.g., Connecticut, Rhode Island, New York, and Oregon) are developing similar programs. Municipalities participating in the program develop Harbor Management Plans. The plans must be consistent with approved coastal zone management plans, and they offer benefits such as giving municipalities greater influence over licensing of State tidelands and priority consideration for grants. The plans recommend comprehensive, long-term management programs that help municipalities balance conservation and development, address pollution impacts on a cumulative rather than piecemeal basis, and resolve conflicts over water-dependent and non-water-dependent uses of the waterfront.

H. Applicability of Management Measures

The management measures in this chapter are intended to be applied by States to control impacts to water quality and habitat from marina siting, construction (both new and expanding marinas), and operation and maintenance, as well as boat operation and maintenance. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source (NPS) programs in conformity with the management measures and will have some flexibility in doing so. The application of these management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*.

The management measures for marinas are applicable to the facilities and their associated shore-based services that support recreational boats and boats for hire. The following operations/facilities are covered by the management measures of this chapter:

- Any facility that contains 10 or more slips, piers where 10 or more boats may tie up, or any facility where a boat for hire is docked;
- Boat maintenance or repair yards that are adjacent to the water;
- Any Federal, State, or local facility that involves recreational boat maintenance or repair that is on or adjacent to the water;
- Public or commercial boat ramps;
- Any residential or planned community marina with 10 or more slips; and
- Any mooring field where 10 or more boats are moored.

Many States already use a 5- to 10-slip definition for marinas. The 10-slip definition for marinas is also based on Federal legislation that implements MARPOL (the International Convention for the Prevention of Pollution from Ships). This legislation requires adequate waste disposal facilities for ships at facilities with 10 or more slips. This guidance is not intended to address shipyards where extensive repair and maintenance of larger vessels occur. Such facilities are subject to NPDES point source and storm water permitting requirements.

Certain types of changes or additions to existing marinas may produce insignificant differences in impacts from such marinas, while other types of changes and expansions may have a far greater effect. Activities that alter the design, capacity, purpose, or use of the marina are subject to the siting and design management measures. The States are to define: (1) activities that significantly change the physical configuration or construction of the marina, (2) activities that significantly change the number of vessels accommodated, or (3) the operational changes that significantly change the potential impacts of the marina. Potential changes to marinas may be treated in the same manner as new marinas; i.e., the changes to the marina would be subject to applicable siting and design management measures.

The management measures for siting and design are applicable to new marinas. Application of the management measures to expanding marinas should be done on a case-by-case basis and should hinge on the potential for the expansion to impact water quality and important habitat. For example, an expanding marina would not be required to implement the flushing, water quality assessment, or shoreline stabilization management measures if the expansion involved only an increase in the number of parking spaces. The storm water runoff management measure is the only siting and design measure that is always applicable to existing and expanding marinas, as well as new marinas.

One method that has been used successfully by several States to determine whether an alteration/expansion is significant is to set a marina perimeter when the marina is constructed. Thereafter, alterations that occur within that perimeter (such as dock reconfiguration) are considered not significant. Another method that States have used is to set a limit, such as a 25 percent increase in the number of slips or a set number of slips (e.g., an increase of more than five slips is considered significant). Rhode Island has successfully implemented a combination of these methods (Rhode Island Coastal Resources Management Program, Section 300.4).

Changes to a marina may also result from catastrophic natural disasters such as hurricanes and severe flooding. It is possible, in smaller marinas, that efforts to rebuild need not be subject to all siting and design management measures.

II. SITING AND DESIGN

Siting and design are among the most significant factors affecting a marina's potential for water quality impacts. The location of a marina—whether it is open (located directly on a river, bay, or barrier island) or semi-enclosed (located on an embayment or other protected area)—affects its circulation and flushing characteristics. Circulation and flushing can also be influenced by the basin configuration and orientation to prevailing winds. Circulation and flushing play important roles in the distribution and dilution of potential contaminants. The final design is usually a compromise that will provide the most desirable combination of marina capacity, services, and access, while minimizing environmental impacts, dredging requirements, protective structures, and other site development costs. The objective of the marina siting and design management measures is to ensure that marinas and ancillary structures do not cause direct or indirect adverse water quality impacts or endanger fish, shellfish, and wildlife habitat both during and following marina construction.

Many factors influence the long-term impact a marina will have on water quality within the immediate vicinity of the marina and the adjacent waterway. Initial marina site selection is the most important factor. Selection of a site that has favorable hydrographic characteristics and requires the least amount of modification can reduce potential impacts. Because marina development can result in reduced levels of dissolved oxygen, many waters with average dissolved oxygen concentrations barely at or below State standards may be unsuitable for marina development.

9755

A. Marina Flushing Management Measure

Site and design marinas such that tides and/or currents will aid in flushing of the site or renew its water regularly.

1. Applicability

This management measure is intended to be applied by States to new and expanding[1] marinas. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The term *flushing* or *residence time* is often misused in that a single number (e.g., 10 days) is sometimes given to describe the flushing time of an estuary or harbor. In actuality, the flushing time ranges from zero days at the boundary to possibly several weeks, depending on location within the marina waterbody.

Maintaining water quality within a marina basin depends primarily on flushing as determined by water circulation within the basin (Tsinker, 1992). If a marina is not properly flushed, pollutants will concentrate to unacceptable levels in the water and/or sediments, resulting in impacts to biological resources (McMahon, 1989; NCDEM, 1990, 1991). In tidal waters, flushing is primarily due to tidal advective mixing and is controlled by the movement of the tidal prism into and out of the marina waterbody. A large tidal prism relative to the mean total volume of the waterbody indicates a large potential for flushing because more of the "old" water has a chance to become mixed with the "new" water outside the boundary or opening to the waterbody.

In nontidal coastal waters, such as the Great Lakes, wind drives circulation in the adjacent waterbody, causing a velocity shear between the marina basin and the adjacent waterbody and thereby producing one or more circulation cells (vortices). Such cells can have a flushing effect on water within a marina. The current created by local wind conditions is influenced by its persistence in terms of velocity and direction. The depth of the affected water layer is controlled by temperature and how the salinity changes with depth. Several hours of consistent wind are required for full development of wind-driven currents. These currents can be 2 percent of the wind's velocity and are generally downwind in most shallow areas (Tobiasson and Kollmeyer, 1991). In many situations wind-driven currents will provide adequate flushing of marina basins.

The degree of flushing necessary to maintain water quality in a marina should be balanced with safety, vessel protection, and sedimentation. Wave energy should be dissipated adequately to ensure that boater safety and protection of vessels are not at risk. The protected nature of marina basins can result in high sedimentation rates in waters containing high concentrations of suspended solids. Methods for assessing and mitigating sedimentation rates are available (NRC, 1987).

[1] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

3. Management Measure Selection

The measure was selected because it has been shown that adequate flushing will greatly reduce or eliminate the potential for stagnation of water in a marina and will help maintain biological productivity and aesthetics (Tsinker, 1992; SCCC, 1984). Presented below are some illustrative examples of flushing guidelines in different coastal regions and different conditions. In areas where tidal ranges do not exceed 1 meter, as in the southeastern United States, a flushing reduction (the amount of a conservative substance that is flushed from the basin) of 90 percent over a 24-hour period has been recommended. For example, a flushing analysis for a proposed marina/canal on the St. Johns River, Florida, was conducted to predict how an effluent would disperse and to determine the configuration that would provide for maximum flushing of a hypothetical conservative pollutant (Tetra Tech, 1988). The selected design provided the recommended flushing reduction of 90 percent over a 24-hour period. This study showed that employing modeling to demonstrate how to achieve the recommended flushing rate is effective at avoiding adverse water quality and other environmental impacts. In the Northwest, a minimum flushing reduction of 70 percent per day was judged to be adequate (Cardwell and Koons, 1981). The 70 percent value, which represents the overall mean flushing rate for the marina basin, was based on the prevailing 1.82-meter tidal range for a 24-hour period. However, if the marina was in a protected area, such as an estuary or embayment, where tidal ranges never attain 1.82 meters, then a minimum flushing reduction of approximately 85 percent per day was recommended.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ a. *Site and design new marinas such that the bottom of the marina and the entrance channel are not deeper than adjacent navigable water unless it can be demonstrated that the bottom will support a natural population of benthic organisms.*

Existing water depths can affect the entire marina layout and design. Therefore, if depth information is not available, bathymetric surveys should be conducted in the proposed marina basin area as well as in those areas that will be used as channels, whether existing or proposed (Schluchter and Slotta, 1978). Flushing rates in marinas can be maximized by proper design of the entrance channel and basins. For example, in areas of minimal or no tides, marina basin and channel depths should be designed to gradually increase toward open water to promote flushing (USEPA, 1985a). Otherwise, isolated deep holes where water can stagnate may be created (SCCC, 1984).

Good flushing alone does not guarantee that a marina's deepest waters will be renewed on a regular basis. Several studies have concluded that deep canals and holes deeper than adjacent waters are not adequately flushed by tidal action or by wind-generated forces and thus cause stagnant or semi-stagnant conditions (Walton, 1983; Barada and Partington, 1972). Lower layers in canals and basins can act as traps for fine sediment and organic detritus and exhibit low dissolved oxygen concentrations. Lower-layer stagnation can occur in holes of depths less than 10 feet (Murawski, 1969). The low DO concentrations, resulting from an oxygen demand exerted by resuspended sediments and decaying organic matter, can impact aquatic life in the warmer months when the normal DO concentration is lower because of higher temperatures (Sherk, 1971). Fine sediments trapped in deep holes may form a thin surface ooze, which gives poor internal oxygen circulation and leads to oxygen reduction both within the sediments and in the overlying water (USEPA, 1976).

■ b. *Design new marinas with as few segments as possible to promote circulation within the basin.*

Flushing efficiency for a marina is inversely proportional to the number of segments. For example, a one-segment marina will not flush as well as a marina in open water, a two-segment marina will not flush as well as a one-

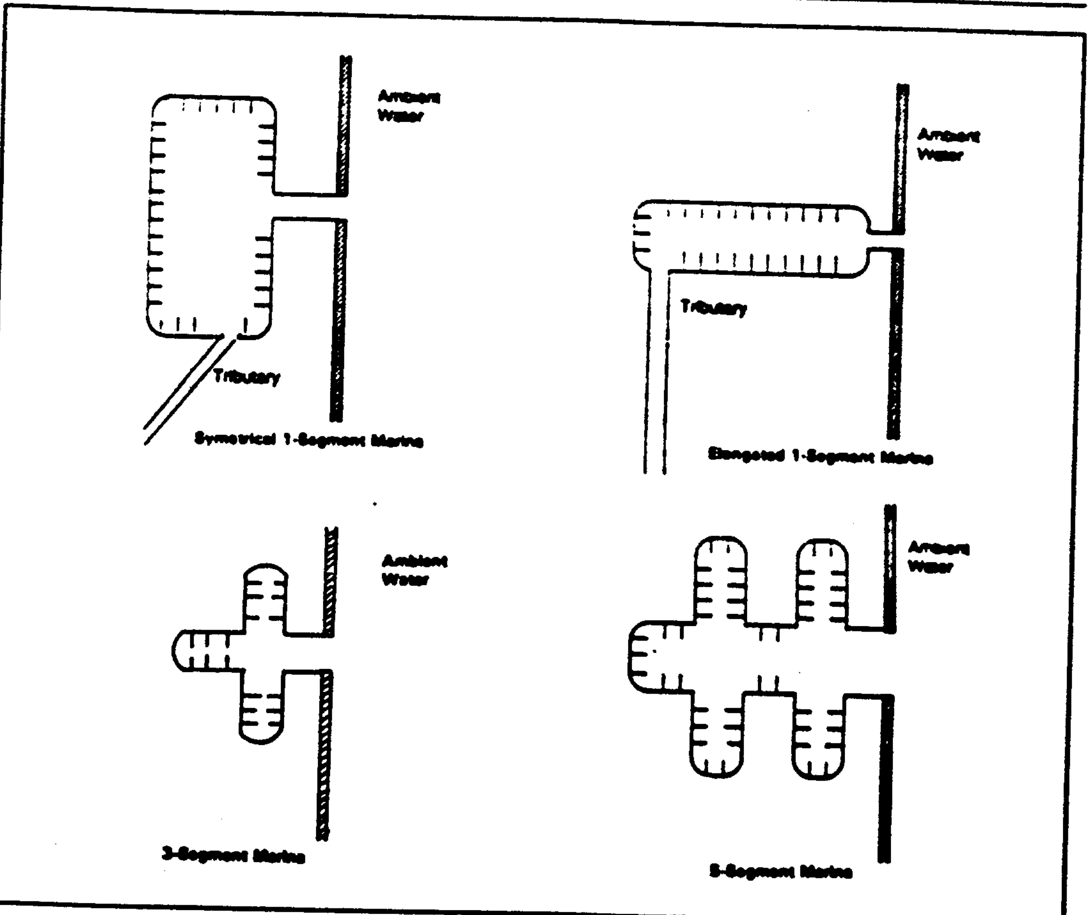

Figure 5-1. Example marina designs (adapted from DNREC, 1990).

segment marina, and so forth. Figure 5-1 presents examples of marinas with one segment and more than one segment. The physical configuration of the proposed marina as determined by the orientation of the marina toward the natural water flow can have a significant effect on the flushing capacity of the waterway. The ideal situation is one in which the distance between the exchange boundary and the inner portion of the basin is minimized. As the shape of the basin becomes more elongated (i.e., more than one segment) with respect to total surface area, the tidal advective or other dispersive mixing processes become more confined along a single flow path, and it takes longer for a water particle originating in the inner part of the basin to travel the greater distance to the boundary.

The marina's aspect ratio (the ratio of its length to its breadth) should be used as a guideline for marina basin design with respect to flushing. This ratio should be greater than 0.33 and less than 3.0, preferably between 0.5 and 2.0 (Cardwell and Koons, 1981). For rectangular marinas with one entrance connected directly to the source waterbody, the length-to-breadth ratio should be between 0.5 and 3.0 to eliminate secondary circulation cells where mixing and tidal flushing are reduced (McMahon, 1989).

Marina configurations that promote flushing exhibit, in general, better dissolved oxygen conditions than those with restrictions or stagnant areas such as improper entrance channel design, bends, and square corners (NCDEM, 1990). These areas also tend to trap sediment and debris. If debris are allowed to collect and settle to the bottom, an oxygen demand will be imposed on the water and water quality will suffer. Therefore, square corners should be avoided in critical downwind or similar areas where this is most likely to be a problem. If square corners are unavoidable because of other considerations, then points of access should be provided in those corners to allow for easy cleanout of accumulated debris.

In tidal waters, marina design should replace conventional rectangular boat basin geometry with curvilinear geometry to eliminate the stagnation effects of sharp-edged corners and to exploit the natural hydraulic patterns of flow and prevent the occurrence of areas where flushing is negligible (Cardwell and Koons, 1981). By combining these elements in the design of a marina, analytical studies have suggested that a strong internal basin circulation system could develop, resulting in acceptable water quality levels (Layton, 1991).

c. *Consider other design alternatives in poorly flushed waterbodies (open marina basin over semi-enclosed design; wave attenuators over a fixed structure) to enhance flushing.*

In selecting a marina site and developing a design, consideration of the need for efficient flushing of marina waters should be a prime factor along with safety and vessel protection. For example, sites located on open water or at the mouth of creeks and tributaries usually have higher flushing rates. These sites are generally preferable to sites located in coves or toward the heads of creeks and tributaries, locations that tend to have lower flushing rates.

In poorly flushed waterbodies, special arrangements may be necessary to ensure adequate overall flushing. In these areas, selection of an open marina design and/or the use of wave attenuators should be considered. Open marina designs have no fabricated or natural barriers, which tend to restrict the exchange of water between ambient water and water within the marina area. Wave attenuators improve flushing rates because water exchange is not restricted. They are also attractive because they do not interfere with the bottom ecology or aesthetic view. Other advantages include their easy removal and minimization of potential interference with fish migration and shoreline processes (Rogers et al., 1982).

The effectiveness of wave attenuators is usually dependent on their mass (Tobiasson and Kollmeyer, 1991). The greater the horizontal and draft dimensions, the greater their displacement and effectiveness. Floating wave attenuators have limitations on their use in extreme wave fields, and site-specific studies should be performed as to their suitability.

d. *Design and locate entrance channels to promote flushing.*

Entrance channel alignment should follow the natural channel alignment as closely as possible to increase flushing. Any bends that are necessary should be gradual (Dunham and Finn, 1974). In areas where the tidal range is small, it is recommended that the marina's entrance be designed as wide as possible to promote flushing while still providing adequate protection from waves (USEPA, 1985a). In areas where the tidal range is large, however, a single narrow entrance channel, if properly designed, has proven to provide adequate flushing (Layton, 1991).

Entrance channel design and placement can alleviate potential water quality problems. In tidal and nontidal waters, marina flushing rates are enhanced by wind action when entrance channels are aligned parallel to the direction of prevailing winds because wind-generated currents can mix basin water and facilitate circulation between the basin and the adjacent waterway (Christensen, 1986).

Shoaling may be significant in areas of significant bed load transport if the entrance channel is located perpendicular to the waterway. Increased shoaling could require extensive maintenance dredging of the channel or create a sill at the entrance to the marina basin. Shoaling at the marina entrance can lead to water quality problems by reducing flushing and water circulation within the basin (Tetra Tech, 1988; USEPA, 1985a). In Panama City, Florida, a study of bathymetric surveys before and after the construction of an artificial inlet showed that the areas of deposition and erosion in the natural bay rapidly changed as a result of alterations of channel positions and depths (Johnston, 1981).

The orientation and location of a solitary entrance can impact marina flushing rates and should be given consideration along with other factors impacting flushing. When a marina basin is square or rectangular, a single entrance at the center of a marina produces better flushing than does a single corner-located asymmetric entrance (Nece, 1981). This results in part because the jet entering the marina on the flood tide is able to circumnavigate a greater length of the sub-basin perimeter associated with each of the two gyres than it could in a single-gyre basin with an asymmetric entrance. If the marina basin is circular, an off-center entrance channel will promote better circulation. Off-center entrance channels also promote better circulation in circular canals.

e. Establish two openings, where appropriate, at opposite ends of the marina to promote flow-through currents.

Where water-level fluctuations are small, alternatives in addition to the ones previously discussed should be considered to ensure adequate water exchange and to increase flushing rates (Dunham and Finn, 1974). An elongated marina situated parallel to a tidal river can be adequately flushed using two entrances to establish a flow-through current so that wind-generated currents or tidal currents move continuously through the marina. In situations where both openings cannot be used for boat traffic, a smaller outlet onto an adjacent waterbody can be opened solely to enhance flushing. In other situations a buried pipeline has been used to promote flushing.

f. Designate areas that are and are not suitable for marina development; i.e., provide advance identification of waterbodies that do and do not experience flushing adequate for marina development.

For example, the physical characteristics of some small tidal creeks result in poor flushing and increased susceptibility to water quality problems (Klein, 1992). These characteristics include:

- Bottom configuration — Flushing is retarded when a depression exists that is lower than the entrance to the waterway.
- Entrance configuration — A constricted entrance will decrease flushing.
- Tributary inflow — Higher freshwater inflow will increase flushing.
- Tidal range — Increased tidal range will increase flushing.
- Shape of the waterway — As the configuration of a waterway becomes more convoluted and irregular, flushing tends to decrease.

VOL 12

B. Water Quality Assessment Management Measure

Assess water quality as part of marina siting and design.

1. Applicability

This management measure is intended to be applied by States to new and expanding[2] marinas. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Assessments of water quality may be used to determine whether a proposed marina design will result in poor water quality. This may entail predevelopment and/or postdevelopment monitoring of the marina or ambient waters, numerical or physical modeling of flushing and water quality characteristics, or both. Cost impacts may preclude a detailed water quality assessment for marinas with 10 to 49 slips (See *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters.*) A preconstruction inspection and assessment can still be expected, however. Historically, water quality assessments have focused on two parameters: dissolved oxygen (DO) and pathogen indicators. The problems resulting from low DO in surface waters have been recognized for over a century. The impacts of low DO concentrations are reflected in an unbalanced ecosystem, fish mortality, and odor and other aesthetic nuisances. DO levels may be used as a surrogate variable for the general health of the aquatic ecosystem (Thomann and Mueller, 1987). Coastal States use pathogen indicators, such as fecal coliform bacteria (*Escherichia coli*) and enterococci, as a surrogate variable for assessing risk to public health through ingestion of contaminated water or shellfish (USEPA, 1988) and through bathing (USEPA, 1986).

Dissolved Oxygen. Three important factors support the use of DO as an indicator of water quality associated with marinas. First, low DO is considered to pose a significant threat to aquatic life. For example, fish and invertebrate kills due to low DO are well known and documented (Cardwell and Koons, 1981). Second, DO is among the few variables that have been measured historically with any consistency. A historical water quality baseline is extremely useful for predicting the impacts of a proposed marina. Third, DO is fundamentally important in controlling the structure—and, in some areas, the productivity—of biological communities.

Pathogen Indicators. Marinas in the vicinity of harvestable shellfish beds represent potential sources for bacterial contamination of the shellfish. Siting and construction of a marina or other potential source of human sewage contiguous to beds of shellfish may result in closure of these beds. Also, nearby beaches and waters used for bathing should be considered.

Fecal coliform bacteria, *Escherichia coli*, and enterococci are used as indicators of the pathogenic organisms (viruses, bacteria, and parasites) that may be present in sewage. These indicator organisms are used because no reliable and

9761

[2] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

cost-effective test for pathogenic organisms exists. Water quality assessments can be used to ensure that water quality standards supporting a designated use are not exceeded. For example, in waters approved for shellfish harvesting, a marina water quality assessment could be used to document potential fecal coliform concentrations in the water column in excess of the standard of 14 organisms MPN (most probable number) per 100 milliliters of water. This standard should not be exceeded in areas where the exceedance would result in the closure of harvestable or productive shellfish beds. Many States have adopted EPA's 1986 ambient water quality criteria for bacteria, which recommend *E. coli* and enterococci as indicators of pathogens for freshwater and marine bathing.

3. Management Measure Selection

Selection of this measure was based on the widespread use and proven effectiveness of water quality assessments in the siting and design of marinas. The North Carolina Department of Environmental Management conducted a postdevelopment study to characterize the water quality conditions of several marinas and to provide data that can be used to evaluate future marina development (NCDEM, 1990). The sampling program demonstrated that marina water quality monitoring studies are effective at assessing potential water quality impacts from coastal marinas. Water quality assessments have been used successfully at a variety of other proposed marina locations nationwide to determine potential water quality impacts (USEPA, 1992b). Many States require water quality assessments of proposed marina development (Appendix 5A). Marinas with 10 to 49 slips may not be able to afford monitoring or modeling. (See *Economic Impacts of EPA Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters*.) In such instances a preconstruction inspection and assessment can still be performed. Dredging requires a River and Harbor Act section 10 permit from the U.S. Army Corps of Engineers (USACE). If there is discharge into waters of the United States after dredging, then a CWA section 404 permit is required. A CWA section 401 Water Quality Certification is required from the State before a section 404 permit is issued by the USACE.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Two effective techniques are available to evaluate water quality conditions for proposed marinas. In the first technique, a water quality monitoring program that includes predevelopment, during-development, and postdevelopment phases can be used to assess the water quality impacts of a marina. In the second approach, effective assessment can be accomplished through numerical modeling that includes predevelopment and postconstruction model applications.

Numerical modeling can be used to study impacts associated with several alternatives and to select an optimum marina design that avoids and minimizes impacts to both water quality and habitats existing at the site (e.g., Rive St. Johns Canal study and Willbrook Island marina). A combination of field surveys and numerical modeling studies may be necessary to identify all environmental concerns and to avoid or minimize marina impacts on both water quality conditions and nearby shellfish habitat.

■ a. *Use a water quality monitoring methodology to predict postconstruction water quality conditions.*

A primary objective for use of a water quality assessment is to ensure that the 24-hour average dissolved oxygen concentration and the 1-hour (or instantaneous) minimum dissolved oxygen concentration both inside the proposed marina and in adjacent ambient waters will not violate State water quality standards or preclude designated uses.

VOL 12

9762

The first step in a marina water quality assessment should be the evaluation and the characterization of existing water quality conditions. Before an analysis of the potential impacts of future development is made, it should be determined whether current water quality is acceptable, marginal, or substandard. The best way to assess existing water quality is to measure it. Acceptable water quality data may already have been collected by various government organizations. Candidate organizations include the U.S. Geological Survey, the USACE, State and local water quality control and monitoring agencies, and engineering and oceanographic departments of local universities.

The second step in a marina water quality assessment is to set design standards in terms of water quality. In most States, the water quality is graded based on DO content, and a standard exists for the 24-hour average concentration and an instantaneous minimum concentration. A State's water quality standard for DO during the critical season may be used to set limits of acceptability for good water quality.

The best way to assess marina impacts on water quality is to design a sampling strategy and physically measure dissolved oxygen levels. During the sampling, sediment oxygen demand and other data that may be used to estimate dissolved oxygen levels using numerical modeling procedures can be collected (USEPA, 1992c, 1992d). A postdevelopment field program may include dye-release and/or drogue-release studies (to verify circulation patterns) and a water quality monitoring program. Data collected from such studies may be used to assist in the prediction of water quality or circulation at other potential marina sites.

Sampling programs are effective methods to evaluate the potential water quality impacts from proposed marinas. The main objective of a preconstruction sampling program is to characterize the water surrounding the area in the vicinity of the proposed marina. Another objective of a preconstruction sampling program is to provide necessary information for modeling investigations (e.g., Tetra Tech, 1988).

■ *b. Use a water quality modeling methodology to predict postconstruction water quality conditions.*

Water quality monitoring can be expensive, and therefore a field monitoring approach may not be practical. The use of a numerical model may be the most economical alternative. However, all models require some field data for proper calibration. A better and more cost-effective approach would be a combination of both water quality monitoring and numerical modeling (Tetra Tech, 1988).

Modeling techniques are used to predict flushing time and pollutant concentrations in the absence of site-specific data. A distinct advantage of numerical models over monitoring studies is the ability to easily perform sensitivity analyses to establish a set of design criteria. Limits of water quality acceptability, flushing rates, and sedimentation rates must be known before quantifying the limit of geometric parameters to comply with these standards. Numerical models can be used to evaluate different alternative designs to determine the configuration that would provide for maximum flushing of pollutants. Models can also be used to perform sensitivity analysis on the selected optimum design.

In 1982, preconstruction numerical modeling studies were conducted to investigate whether a proposed marina in South Carolina would meet the State water quality standards after construction. Modeling results indicated that the proposed Wexford Marina would meet water quality standards (Cubit Engineering, 1982). The marina was approved and constructed. Follow-up monitoring studies were conducted to evaluate preconstruction model predictions (USEPA, 1986). The monitoring results indicated that shellfish harvesting standards were being met, thereby validating the preconstruction modeling study.

EPA Region 4 recently completed an in-depth report on marina water quality models (USEPA, 1992c). The primary focus of the study was to provide guidance for selection and application of computer models for analyzing the potential water quality impacts (both DO and pathogen indicators) of a marina. EPA reviewed a number of available methods and classified them into three categories: simple methods, mid-range models, and complex models. Simple methods are screening techniques that provide only information on the average conditions in the marina. Screening methods do not provide spatial or time-varying water quality predictions, and therefore it is recommended that these methods be used with open marina designs and/or marinas sited in areas characterized by good flushing rates and good water quality conditions (USEPA, 1992c). In addition, simple models are not suitable where marina flushing is controlled by the prevailing wind, requiring the application of more advanced models, such as WASP4.

In poorly flushed areas and in marinas with a complex design, a more advanced method will identify those areas where water quality standards may be violated. The complex methods are also capable of predicting spatial and time-variant water quality conditions and provide the complete water quality picture inside a proposed marina. In general, advanced models are more effective and more appropriate than simple screening methods in assessing environmental impacts associated with marina siting and design (USEPA, 1992c).

Costs associated with applying a numerical model or conducting a water quality monitoring program range from 0.1 to 2.0 percent of the total marina development project cost. Table 5-2 provides cost information by marina, size, State, and year built. These factors should all be considered when comparing a particular cost associated with a specific item. For example, costs associated with the water quality monitoring program for Barbers Point Harbor and Marina complex were estimated at $56,000. On the other hand, the cost of the water quality monitoring program for the Beacons Reach marina, North Carolina, was $3,000. It was only when a full environmental assessment was conducted (e.g., North Point and Barbers Point marina complex) that costs were higher. In addition, several models have been recommended as appropriate tools to assess potential water quality impacts from coastal marinas (USEPA, 1992c, 1992d). The cost associated with applying the simple model is on the order of $1,000, whereas the cost associated with the advanced model is in the range of $25,000 to $100,000. Siting and design practices to reduce environmental impacts were frequently part of a larger design/environmental study. Costs for a total environmental assessment of a proposed marina ranged from 1 percent to 5 percent of the total project cost.

c. *Perform preconstruction inspection and assessment.*

A preconstruction inspection and assessment may be affordable in place of detailed water quality monitoring or modeling for marinas with 10 to 49 slips. The River and Harbor Act of 1899 section 10 and Clean Water Act section 404 permit application process requires applicants to present to the USACE information necessary for a water quality assessment. An expert knowledgeable in water quality and hydrodynamics may assess potential impacts using available information and site inspection.

Table 5-2. Cost Summary of Selected Marina Siting Practices (USEPA, 1992b)

Marina/Project Name and Location	Years	Scope of Work	Cost (x $1000)
North Point Marina Illinois (1,493 slips)	1963-1989	Full environmental assessment	100
		Construction cost	39,000
Point Roberts Marina Washington (1,000 slips)	1976-1978	Environmental studies (physical and numerical modeling, littoral drift, and biological studies)	300
		Postconstruction water quality monitoring program (including dye release and drogue)	10
		Construction cost	6,000
Barbers Point Harbor and Marina Complex (Retrofit) Hawaii	1981-1985	Physical model	650
		Numerical model (both 2D and 3D)	100
		Botanical survey	15
		Baseline water quality monitoring program	56
		Total construction	140,000
Marina Water Quality Modeling Study	1990	Numerical model applications to 3 Southeast marinas	30
		Data collection	22
Rive St. Johns Canal Florida	1988	Littoral studies and data collection	20
		Numerical model study	30
North Carolina Coastal Marina Water Quality Assessment	1989	Water quality monitoring program[a]	3
		Dye study[b]	3
		Numerical modeling studies	0.5
Wilbrook Island Marina (200 slips) South Carolina	1990	Water quality modeling study	10
Coastal Water Quality Assessment (NCDEM) North Carolina	1989	Monitoring program[c]	3
		Numerical modeling application[b]	0.5
		Dye study (flushing)[c]	3
Wexford Marina South Carolina	1982 and 1986	Numerical model application	—[d]
		Numerical model application	—[d]

[a] Cost estimate is per marina site.

Habitat Assessment Management Measure

Site and design marinas to protect against adverse effects on shellfish resources, wetlands, submerged aquatic vegetation, or other important riparian and aquatic habitat areas as designated by local, State, or Federal governments.

1. Applicability

This management measure is intended to be applied by States to new and expanding[3] marinas where site changes may impact on wetlands, shellfish beds, submerged aquatic vegetation (SAV), or other important habitats. The habitats of nonindigenous nuisance species, such as some clogging vegetation or zebra mussels, are not considered important habitats. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Coastal marinas are often located in estuaries, one of the most diverse of all habitats. Estuaries contain many plant and animal communities that are of economic, recreational, ecological, and aesthetic value. These communities are frequently sensitive to habitat alteration that can result from marina siting and design. Biological siting and design provisions for marinas are based on the premise that marinas should not destroy important aquatic habitat, should not diminish the harvestability of organisms in adjacent habitats, and should accommodate the same biological uses (e.g., reproduction, migration) for which the source waters have been classified (Cardwell et al., 1980). Important types of habitat for an area, such as wetlands, shellfish beds, and submerged aquatic vegetation (SAV), are usually designated by local, State, and Federal agencies. In most situations the locations of all important habitats are not known. Geographic information systems are used to map biological resources in Delaware and show promise as a method of conveying important habitat and other siting information to marina developers and environmental protection agencies (DNREC, 1990).

3. Management Measure Selection

The selection of this measure was based on its widespread use in siting and design and the fact that proper siting and design can reduce short-term impacts (habitat destruction during construction) and long-term impacts (water quality, sedimentation, circulation, wake energy) on the surrounding environment (USEPA, 1992b). Currently, 50 percent of the coastal States minimize adverse impacts caused by siting and design by requiring a habitat assessment prior to siting a marina, and an additional 40 percent require a habitat assessment under special conditions (Appendix 5A).

[3] See Section I.H (General Applicability) for additional information on expansions of existing marinas.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. *Conduct surveys and characterize the project site.*

The first step in achieving compatibility between coastal development and coastal resources is to properly characterize the proposed project site. The site's physical properties and water quality characteristics must be assessed. To minimize potential impacts, available habitat and seasonal use of the site by benthos, macroinvertebrates, and ichthyofauna should be evaluated. Once these data are assembled, it becomes possible to identify environmental risks associated with development of the site. Through site-design modifications, preservation of critical or unique habitat, and biological/chemical/physical monitoring, it is possible to minimize the direct and indirect impacts associated with a specific waterfront development (USEPA, 1985a). To properly evaluate development applications for projects at the periphery of critical or endangered habitat areas, it may be necessary to conduct on-site visits and surveys to determine the distribution of critical habitat such as spawning substrate and usage by spawning fish.

Based on data compiled primarily by the New Jersey Department of Environmental Protection (NJDEP) prior to construction, it was concluded that a large proposed marina (Port Liberte) could have a serious environmental impact on resident and transient fish and macroinvertebrates. Loss of unique habitat, water quality degradation, and disturbance of contaminated sediments were some of the more severe anticipated impacts. Following a comprehensive NJDEP review process, the developer modified the site plan and phased construction activities, thereby satisfying the concerns of the various environmental regulatory agencies and minimizing potential direct and indirect impacts (Souza et al., 1990). Follow-up monitoring established that the management practices were effective in avoiding impacts to important fishery habitat.

b. *Redevelop coastal waterfront sites that have been previously disturbed; expand existing marinas or consider alternative sites to minimize potential environmental impacts.*

Proper marina site selection is a practice that can minimize adverse impacts on nearby habitats. For example, the selected site for North Point Marina in Illinois was not a suitable environment for either floral or faunal habitat because of high erosion rates, high ground-water conditions, and the high potential for flooding (Braam and Jansen, 1991). Despite the surrounding environment, this site was thought to be suitable for marina development because the site had been previously disturbed. Within existing urban harbors where the shorelines have been modified previously by bulkheading and filling, there will be many opportunities to site recreational boating facilities with minimal adverse environmental consequences (Goodwin, 1988).

Alternative site analysis may be used to demonstrate that a chosen site is the most economic and environmentally suitable. Alternative site/design analysis has been found effective at reducing potential impacts from many proposed marinas. The proposed Rive St. Johns Canal, Willbrook Island, and John Wayne marinas used this practice and demonstrated the effectiveness of analyzing alternative sites and designs to minimize environmental impacts. For example, eight design alternatives were considered for the John Wayne marina. The selected alternative reduced tideland alteration, biological destruction, and stream diversion. This was accomplished by moving the marina basin nearly 1,000 feet north of the original site and reducing the basin capacity (Holland, 1986). Five alternatives were considered for the Rive St. Johns Canal. The selected site avoided impacts to wetland habitats and has better flushing characteristics. The Willbrook study considered five alternatives, and the site selected successfully minimized impacts to submerged aquatic vegetation and wetlands.

c. Employ rapid bioassessment techniques to assess impacts to biological resources.

Rapid bioassessment techniques, when fully developed, will provide cost-effective biological assessments of potential marina development sites. Rapid bioassessment uses biological criteria and is based on comparing the community assemblages of the potential development site to an undisturbed reference condition. Biological criteria or biocriteria describe the reference condition of aquatic communities inhabiting unimpaired waterbodies (USEPA, 1992a). These methods consist of community-level assessments designed to evaluate the communities based on a variety of functional and structural attributes or metrics. Rapid bioassessment protocols for freshwater streams and rivers were published in 1989 for macroinvertebrates and fish to provide States with guidelines for conducting cost-effective biological assessments (USEPA, 1989). Development of similar protocols for application in estuaries and near coastal areas is under way (USEPA, 1992a).

Scores from rapid bioassessments may be used to determine the biological integrity of a site. Sites that are comparable to pristine conditions, with complete assemblages of species, should not be developed as marinas because of the unavoidable impacts associated with such development. The level of effort required to characterize a site will depend on the specific protocol (level of detail required and organisms used) employed. The time needed to perform a rapid bioassessment in freshwater streams varied from 1.5-3 hours to 5-10 hours for benthos and 3 to 17 hours for fish (USEPA, 1989).

d. Assess historic habitat function (e.g., spawning area, nursery area, migration pathway) to minimize indirect impacts.

Washington State issued siting and tidal height provisions (WDF, 1971, 1974) to ensure that bulkheads do not destroy spawning of surf smelt habitat and increase the vulnerability of juvenile salmon. In addition, marina breakwaters may disrupt the migration pattern of migratory fish, such as salmon. The design of marinas should consider the migration, survival, and the harvestability of food fish and shellfish.

e. Minimize disturbance to indigenous vegetation in the riparian area.

A riparian area is defined as:

> Vegetated ecosystems along a waterbody through which energy, materials, and water pass. Riparian areas characteristically have a high water table and are subject to periodic flooding and influence from the adjacent waterbody. These systems encompass wetlands, uplands, or some combination of these two land forms. They will not in all cases have all of the characteristics necessary for them to be classified as wetlands.[4]

Riparian areas are generally more productive habitat, in both diversity and biomass, than adjacent uplands because of their unique hydrologic condition. Many important processes occur in the riparian zone, including the following:

- Because of their linear form along waterways, riparian areas process large fluxes of energy and materials from upstream systems as well as from ground-water seepage and upland runoff.
- They can serve as effective filters, sinks, and transformers of nutrients, eroded soils, and other pollutants.
- They often appear to be nutrient transformers that have a net import of inorganic nutrient forms and a net export of organic forms.

Chapter 7 of this document, which also requires protection of riparian areas when they have significant nonpoint pollution control value, contains a more detailed discussion of riparian functions.

[4] This definition is adapted from the definition offered previously by Mitsch and Gosselink (1986) and Lowrance et al. (1988).

f. Encourage the redevelopment or expansion of existing marina facilities that have minimal environmental impacts instead of new marina development in habitat areas that local, State, or Federal agencies have designated important.

One method to avoid new marina development in areas containing important habitat is the purchase of development rights of existing marinas or important habitat. In the case of preserving an existing marina (thus avoiding the impacts associated with developing new marinas), the government pays the difference (if there is one) between the just value and the water-dependent value and owns the rights to develop the property for other uses. This approach provides instant liquidity for the marina owner, who keeps the profits derived from all marina assets even though the government may have paid 80 to 90 percent of the value of the land. This would in theory offset the inability to sell the marina for non-water-dependent activities and decrease marina development in areas containing important habitat. The purchase of development rights and conservation easements for land containing important habitat or NPS control values is discussed in Chapter 4. In the Broward County (Florida) Comprehensive Plan, expansion of existing marina facilities is preferred over development of new facilities (Bell, 1990).

g. Develop a marina siting policy to discourage development in areas containing important habitat as designated by local, State, or Federal agencies.

Establishing a marina siting policy is an efficient and effective way to control habitat degradation and water pollution impacts associated with marinas. Creating such a policy involves:

- Establishing goals for coastal resource use and protection;
- Cataloging coastal resources; and
- Analyzing existing conditions and problems, as well as future needs.

A siting policy benefits the environment, the public, regulatory agencies, and the marina industry. Examples of such benefits include:

- Impacts to and destruction of environmentally sensitive areas (such as wetlands, fish nursery areas, and shellfish beds) are avoided by directing development to sites more appropriate for marina development;
- Coastal resources (such as submerged aquatic vegetation and beaches) are protected;
- Cumulative impacts from numerous pollution sources are more easily assessed;
- Coastal development and economic growth are balanced with environmental protection, and the continued viability of water-dependent uses is ensured;
- The needs of the marina industry and rights of public access are accounted for;
- The permitting process is streamlined;
- Regulatory efforts are coordinated; and
- Interjurisdictional consistency is improved.

Many States already address coastal resource and development needs through coastal zone management plans, growth management plans, critical area programs, and other means. The following examples illustrate the high level of acceptance such planning has achieved and the variety of program types upon which a marina siting policy could be built:

- Twelve States have established critical area programs that protect public health and safety, the quality of natural features, scenic value, recreational opportunities, and the historical and cultural significance of coastal areas (Myers, 1991).

- North Carolina has a water use classification system to assist in the implementation of land use policies. Coastal areas are designated for preservation, conservation, or development (Clark, 1990).

- Massachusetts has a Harbor Management Program, wherein municipalities devise specific harbor management plans consistent with State goals (Massachusetts Coastal Zone Management, 1988).

- The Narragansett Bay Project, part of EPA's National Estuary Program, recognizes land use planning as the key to accomplishing many goals, including controlling NPS pollution, protecting and restoring habitat, and preserving public access and recreational opportunities (Myers, 1991).

- The Cape Cod Commission found that unplanned growth over the last several decades has limited public access, displaced marinas and boatyards in favor of non-water-dependent uses, encroached on fishermen's access, degraded water quality, destroyed habitat, and created use conflicts (Cape Cod Commission, 1991).

Shoreline Stabilization Management Measure

Where shoreline erosion is a nonpoint source pollution problem, shorelines should be stabilized. Vegetative methods are strongly preferred unless structural methods are more cost effective, considering the severity of wave and wind erosion, offshore bathymetry, and the potential adverse impact on other shorelines and offshore areas.

1. Applicability

This management measure is intended to be applied by States to new and expanding[3] marinas where site changes may result in shoreline erosion. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The establishment of vegetation as a primary means of shore protection has shown the greatest success in low-wave-energy areas where underlying soil types provide the stability required for plants and where conditions are amenable to the sustaining of plant growth. Under suitable conditions, an important advantage of vegetation is its relatively low initial cost. The effectiveness of vegetation for shore stabilization varies with the amount of wave reduction provided by the physiography and offshore bathymetry of the site or with the degree of wave attenuation provided by structural devices. Identification of the cause of the erosion problem is essential for selecting the appropriate technique to remedy the problem. Methods for determining the potential effectiveness of stabilizing a site with indigenous vegetation are presented in Chapter 7.

Some structural methods to stabilize shorelines and navigation channels are bulkheads, jetties, and breakwaters. They are designed to dissipate incoming wave energy. While structures can provide shoreline protection, unintended consequences may include accelerated scouring in front of the structure, as well as increased erosion of unprotected downstream shorelines.

Among structural techniques, gabions, riprap, and sloping revetments dissipate incoming wave energy more effectively and result in less scouring. Bulkheads are appropriate in some circumstances, but where alternatives are appropriate they should be used first. Costs and design considerations of these and other structural methods for controlling shoreline erosion are presented in Chapter 6.

[3] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

3. Management Measure Selection

Selection of this measure was based on the demonstrated effectiveness of vegetation and structural methods to mitigate shoreline erosion and the resulting turbidity and shoaling (see Chapters 6 and 7). Also, it is in the best interest of marina operators to minimize shoreline erosion because erosion may increase sedimentation and the frequency of dredging in the marina basin and channel(s).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Detailed information on practices and the cost and effectiveness of structural and vegetative practices can be found in Chapters 6 and 7, respectively.

E. Storm Water Runoff Management Measure

Implement effective runoff control strategies which include the use of pollution prevention activities and the proper design of hull maintenance areas.

Reduce the average annual loadings of total suspended solids (TSS) in runoff from hull maintenance areas by 80 percent. For the purposes of this measure, an 80 percent reduction of TSS is to be determined on an average annual basis.

1. Applicability

This management measure is intended to be applied by States to new and expanding[6] marinas, and to existing marinas for *at least* the hull maintenance areas.[7] If boat bottom scraping, sanding, and/or painting is done in areas other than those designated as hull maintenance areas, the management measure applies to those areas as well. This measure is not applicable to runoff that enters the marina property from upland sources. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The principal pollutants in runoff from marina parking areas and hull maintenance areas are suspended solids and organics (predominately oil and grease). Toxic metals from boat hull scraping and sanding are part of, or tend to become associated with, the suspended solids (METRO, 1992a). Practices for the control of these pollutants can be grouped into three types: (1) filtration/infiltration, (2) retention/detention, and (3) physical separation of pollutants. A further discussion of storm water runoff controls can be found in Chapter 4.

The proper design and operation of the marina hull maintenance area is a significant way to prevent the entry of toxic pollutants from marina property into surface waters. Recommended design features include the designation of discrete impervious areas (e.g., cement areas) for hull maintenance activities; the use of roofed areas that prevent rain from contacting pollutants; and the creation of diversions and drainage of off-site runoff away from the hull maintenance area for separate treatment. Source controls that collect pollutants and thus keep them out of runoff include the use of sanders with vacuum attachments, the use of large vacuums for collecting debris from the ground, and the use of tarps under boats that are being sanded or painted.

The perviousness of non-hull maintenance areas should be maximized to reduce the quantity of runoff. Maximizing perviousness can be accomplished by placing filter strips around parking areas. Swales are strongly recommended for the conveyance of storm water instead of drains and pipes because of their infiltration and filtering characteristics.

---

[6] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

[7] Hull maintenance areas are areas whose primary function is to provide a place for boats during the scraping, sanding, and painting of their bottoms.

VOL 12

9773

Technologies capable of treating runoff that has been collected (e.g., wastewater treatment systems and holding tanks) may be used in situations where other practices are not appropriate or pretreatment is necessary. The primary disadvantages of using such systems are relatively high costs and high maintenance requirements. Some marinas are required to pretreat storm water runoff before discharge to the local sewer system (Nielsen, 1991). Washington State strongly recommends that marinas pretreat hull-cleaning wastewater and then discharge it to the local sewer system (METRO, 1992b).

The annual TSS loadings can be calculated by adding together the TSS loadings that can be expected to be generated during an average 1-year period from precipitation events less than or equal to the 2-year/24-hour storm. The 80 percent standard can be achieved, by reducing over the course of the year, 80 percent of these loadings. EPA recognizes that 80 percent cannot be achieved for each storm event and understands that TSS removal efficiency will fluctuate above and below 80 percent for individual storms.

3. Management Measure Selection

The 80 percent removal of TSS was selected because chemical wastewater treatment systems, sand filters, wet ponds, and constructed wetlands can all achieve this degree of pollutant removal if they are designed properly and the site is suitable. Source controls can also reduce final TSS concentrations in runoff. Table 5-3 presents summary information on the effectiveness, cost, and suitability of the practices listed below. The discussion under each practice presents factors to be considered when selecting a specific practice(s) for a particular marina site.

The 80 percent removal of TSS is applicable to the hull maintenance area only. Although pollutants in runoff from the remaining marina property are to be considered in implementing effective runoff pollution prevention and control strategies for all marinas, existing marinas may be unable to economically treat storm water runoff by retention/detention or filtration/infiltration technologies because of treatment system land requirements and the likely need to collect and transfer runoff from marina shoreline areas (at lower elevations) to upland areas for treatment. Also, marina property may be developed to such an extent that space is not available to build the detention/ retention structures. In other situations, the soil type and groundwater levels may not allow sufficient infiltration for trenches, swales, filter strips, etc. The measure applies to all new and existing marina hull maintenance areas because it allows for runoff control of a smaller, more controlled area and also because the runoff from these hull maintenance areas contain higher levels of toxic pollutants (CDEP, 1991; and METRO, 1992a).

In addition, many of the available practices are currently being employed by States to control runoff from marinas and other urban nonpoint sources (Appendix 5A).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ *a. Design boat hull maintenance areas to minimize contaminated runoff.*

Boat hull maintenance areas can be designed so that all maintenance activities that are significant potential sources of pollution can be accomplished over dry land and under roofs (where practical), allowing the collection and proper disposal of debris, residues, solvents, spills, and storm water runoff. Boat hull maintenance areas can be specified with signs, and hull maintenance should not be allowed to occur outside these areas. The use of impervious surfaces (e.g., cement) in hull maintenance areas will greatly enhance the collection of sandings, paint chips, etc. by vacuuming or sweeping.

Table 5-3. Stormwater Management Practice Summary Information

Practice - Characteristics	Pollutants Controlled	Removal Efficiencies (%)	Use with Other Practices	Cost	Retrofit Suitability	References	Pretreatment of Runoff Recommended
Sand Filter	TSS TP TN Fecal Col Metals	60-90 0-80 20-40 40 40-80	Yes	$1 - 11 per ft^3 of runoff	Medium	City of Austin, 1990; Schueler 1991; Tull 1990	Yes

b. *Implement source control practices.*

Source control practices prevent pollutants from coming into contact with runoff. Sanders with vacuum attachments are effective at collecting hull paint sandings (Schlomann, 1992). Encouraging the use of such sanders can be accomplished by including the price of their rental in boat haul-out and storage fees, in effect making their use by marina patrons free. Vacuuming impervious areas can be effective in preventing pollutants from entering runoff. A schedule (e.g., twice per week during the boating season) should be set and adhered to. Commercial vacuums are available for approximately $765 to $1065 (Dickerson, 1992), and approximately one machine is needed at a marina of 250 slips or smaller. Tarpaulins may be placed on the ground prior to placement of a boat in a cradle or stand and subsequent sanding/painting. The tarpaulins will collect paint chips, sanding, and paint drippings and should be disposed of in a manner consistent with State policy.

c. *Sand Filter*

Sand filters (also known as filtration basins) consist of layers of sand of varying grain size (grading from coarse sand to fine sands or peat), with an underlying gravel bed for infiltration or perforated underdrains for discharge of treated water. Figure 5-2 shows a conceptual design of a sand filter system. Pollutant removal is primarily achieved by "straining" pollutants through the filtering media and by settling on top of the sand bed and/or a pretreatment pool.

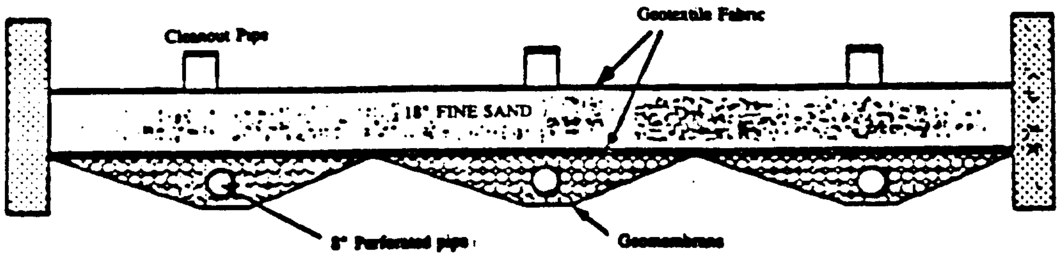

Figure 5-2. Conceptual design of a sand filter system (Austin, Texas, 1991).

Detention time is typically 4 to 6 hours (City of Austin, 1990), although increased detention time will increase effectiveness (Schueler et al., 1992). Sand filters may be used for drainage areas from 3 to 80 acres (City of Austin, 1990). Sand filters may be used on sites with impermeable soils since the runoff filters through filter media, not native soils. The main factors that influence removal rates are the storage volume, filter media, and detention time. Three different designs may be appropriate for marina sites: off-line sedimentation/filtration basins, on-line sand/sod filtration basins, and on-line sand basins. Performance monitoring of these designs produced average removal rates of 85 percent for sediment, 35 percent for nitrogen, 40 percent for dissolved phosphorous, 40 percent for fecal coliform, and 50 percent to 70 percent for trace metals (Schueler et al., 1992).

Sand filters become clogged with particulates over time. In general, clogging occurs near the runoff input to the sand filter. Frequent manual maintenance is required of sand filters, primarily raking, surface sediment removal, and removal of trash, debris, and leaf litter. Sand filters appear to have excellent longevity because of their off-line design and the high porosity of sand as a filtering medium (Schueler et al., 1992). Construction costs have been estimated at $1.30 to $10.50 per cubic foot of runoff treated (Tull, 1990). Significant economies of scale exist as sand filter size increases (Schueler et al., 1992). Maintenance costs are estimated to be approximately 5 percent of construction cost per year (Austin DPW, 1991, in Schueler et al., 1992).

d. Wet Pond

Wet ponds are basins designed to maintain a permanent pool of water and temporary storage capacity for storm water runoff (see Figure 5-3). The permanent pool enhances pollutant removal by promoting the settling of particulates, chemical coagulation and precipitation, and biological uptake of pollutants and is normally 1/2 to 1 inch in depth per impervious acre. Wet ponds are typically not used for drainage areas less than 10 acres (Schueler, 1987). Pond liners are required if the native soils are permeable or if the bedrock is fractured. Design parameters of concern include geometry, wet pond depth, area ratio, volume ratio, and flood pool drawdown time. Ponds may be designed to include shallow wetlands, thereby enhancing pollutant removal. Pollutant removal ranges are presented in Table 5-3. Removal rates of greater than 80 percent for total suspended solids were achieved in many studies (Schueler et al., 1992). Pollutant removal is primarily a function of the ratio of pond volume to watershed size (USEPA, 1986).

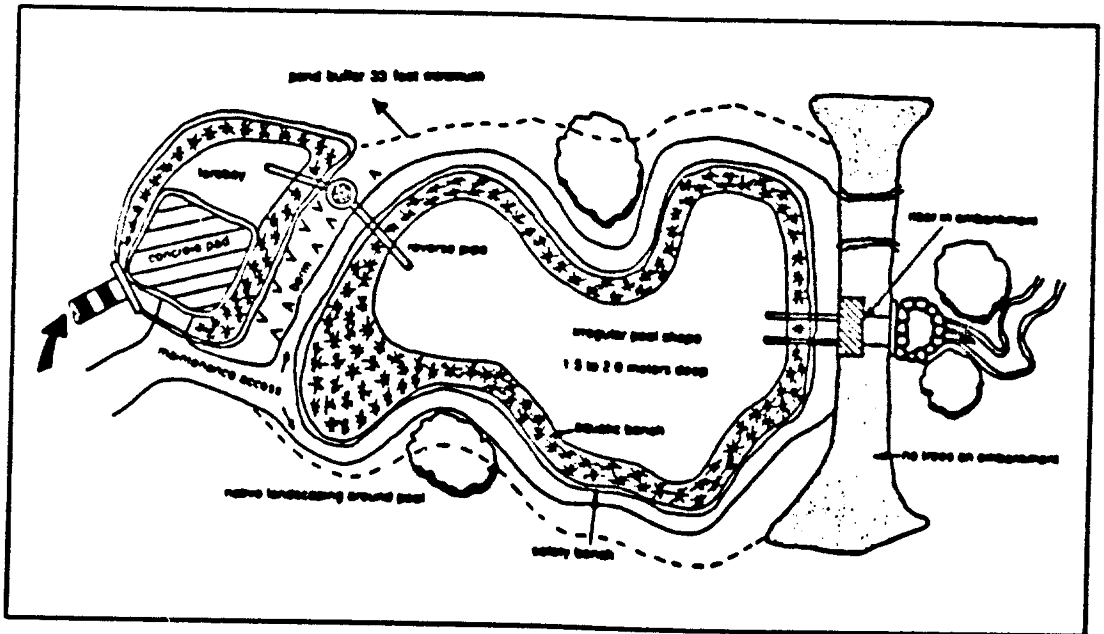

Figure 5-3. Schematic design of an enhanced wet pond system (Schueler, 1991).

A low level of routine maintenance, including tasks such as mowing of side slopes, inspections, and clearing of debris from outlets, is required. Wet ponds can be expected to lose approximately 1 percent of their runoff storage capacity per year as a result of sediment accumulation. To maintain the pollutant removal capacity of the pond, periodic removal of sediment is necessary. A recommended sediment cleanout cycle is every 10 to 20 years (British Columbia Research Corp., 1991). With proper maintenance and replacement of inlet and outlet structures every 25 to 50 years, wet ponds should last in excess of 50 years (Schueler, 1987). A review of capital costs for wet ponds revealed costs of $349 to $823 per acre treated and annual maintenance costs of 3 percent to 5 percent of the capital cost (Schueler, 1987).

e. Constructed Wetland

A complete discussion of created wetlands can be found in Chapter 7. Summary information on pollutant removal efficiencies, cost, etc. is presented in Table 5-3.

f. Infiltration Basin/Trench

Infiltration practices suitable for storm water treatment include basins and trenches. Figures 5-4 and 5-5 show examples of infiltration basins and trenches. Like porous pavement, infiltration practices reduce runoff by increasing ground-water recharge. Prior to infiltration, runoff is stored temporarily at the surface, in the case of infiltration basins, or in subsurface stone-filled trenches.

Infiltration devices should drain within 72 hours of a storm event and should be dry at other times. The maximum contributing drainage area should not exceed 5 acres for an individual infiltration trench and should range from 2 to 15 acres for an infiltration basin (Schueler et al., 1992).

Pretreatment to remove coarse sediments and PAHs is necessary to prevent clogging and diminished infiltration capacity over time. The application of infiltration devices is severely restricted by soils, water table, slope, and

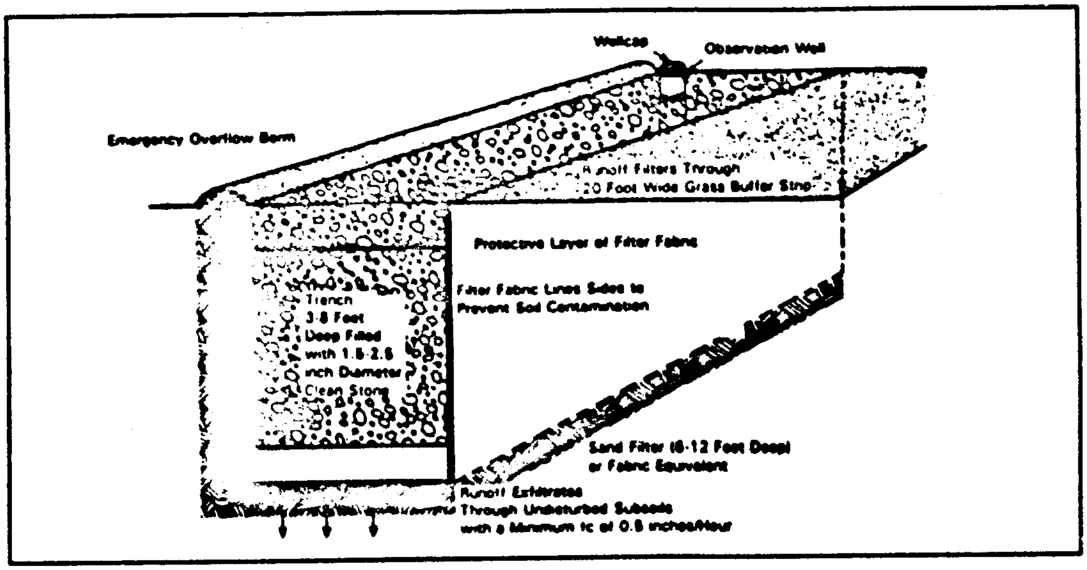

Figure 5-4. Schematic design of a conventional infiltration trench (Schueler, 1987).

contributing area conditions. The sediment load from marina hull maintenance areas may limit the applicability of infiltration devices in these areas. Infiltration devices are not practical in soils with field-verified infiltration rates of less than 1/2 inch per hour (Schueler et al., 1992). Soil borings should be taken well below the proposed bottom of the trench to identify any restricting layers and the depth of the water table. Removal of soluble pollutants in

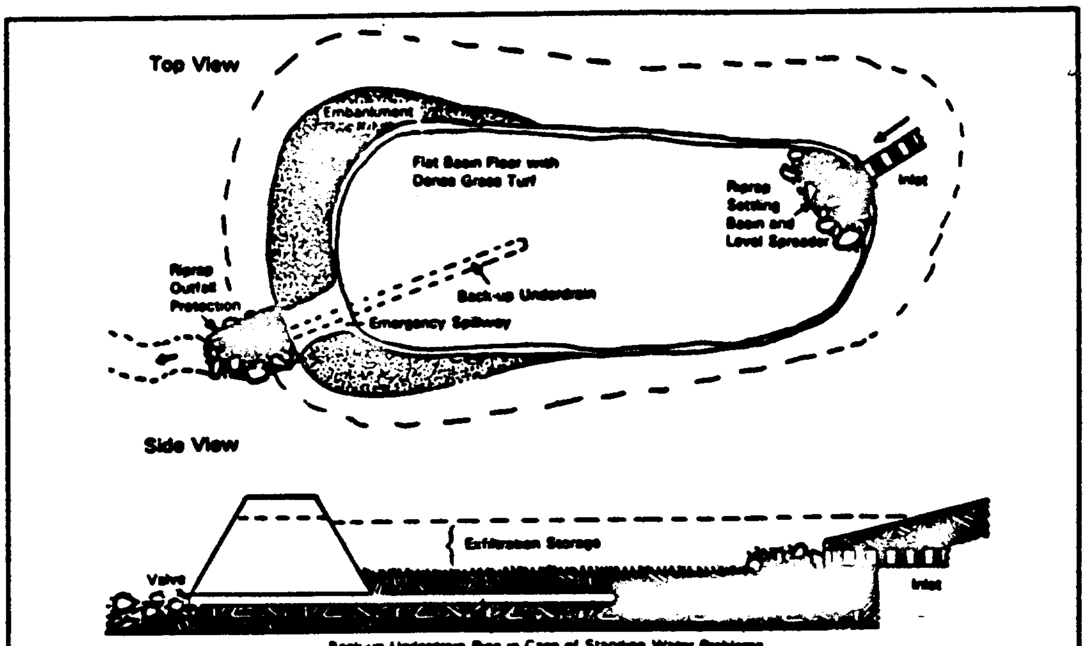

Figure 5-5. Schematic design of an infiltration basin (Schueler, 1987).

VOL 12

infiltration devices relies heavily on soil adsorption, and removal efficiencies are lowered in sandy soils with limited binding capacity. Schueler (1987) reported a sediment removal efficiency of 95 percent, 60 percent to 75 percent removal of nutrients, and 95 percent to 99 percent removal of metals using a 2-year design storm. Other effectiveness data are presented in Table 5-3.

Infiltration basins and trenches have had high failure rates in the past (Schueler et al., 1992). A geotechnical investigation and design of a sound and redundant pretreatment system should be required before construction approval. Routine maintenance requirements include inspecting the basin after every major storm for the first few months after construction and annually thereafter to determine whether scouring or excessive sedimentation is reducing infiltration. Infiltration basins must be mowed twice annually to prevent woody growth. Tilling may be required in late summer to maintain infiltration capacities in marginal soils (Schueler, 1987). Field studies indicate that regular maintenance is not done on most infiltration trenches/basins, and 60 percent to 70 percent were found to require maintenance. Based on longevity studies, replacement or rehabilitation may be required every 10 years (Schueler et al., 1992). Proper maintenance of pretreatment structures may result in increased longevity. Reported costs for infiltration devices (Table 5-3) varied considerably based on runoff storage volume. Annual maintenance costs varied from 3 percent to 5 percent of capital cost for infiltration basins and from 5 percent to 10 percent for infiltration trenches.

g. Chemical and Filtration Treatment Systems

Chemical treatment of wastewater is the addition of certain chemicals that causes small solid particles to adhere together to form larger particles that settle out or can be filtered. Filtration systems remove suspended solids by forcing the liquid through a medium, such as folded paper in a cartridge filter (METRO, 1992b). A recent study showed that such treatment systems can remove in excess of 90 percent of the suspended solids and 80 percent of most toxic metals associated with hull pressure-washing wastewater (METRO, 1992a). The degree of treatment necessary may be dependent on whether the effluent can be discharged to a sewage treatment system. The cost of a homemade system for a small boatyard to treat 100 gallons a day was estimated at $1,560. The cost of larger commercial systems capable of treating up to 10,000 gallons a day was estimated at $3000 to $50,000 plus site preparation. The solid waste generated by these treatment systems may be considered hazardous waste and may be subject to disposal restrictions.

h. Vegetated Filter Strip

A complete discussion of vegetated filter strips can be found in Chapter 7. Summary information on pollutant removal efficiencies, cost, etc. is presented in Table 5-3.

i. Grassed Swale

Grassed swales are low-gradient conveyance channels that may be used in marinas in place of buried storm drains. To effectively remove pollutants, the swales should have relatively low slope and adequate length and should be planted with erosion-resistant vegetation. Swales are not practical on very flat grades or steep slopes or in wet or poorly drained soils (SWRPC, 1991). Grassed swales can be applied in areas where maximum flow rates are not expected to exceed 1.5 feet per second (Horner et al., 1988). The main factors influencing removal efficiency are vegetation type, soil infiltration rate, flow depth, and flow travel time. Properly designed and functioning grassed swales provide pollutant removal through filtering by vegetation of particulate pollutants, biological uptake of nutrients, and infiltration of runoff. Schueler (1987) suggests the use of check dams in swales to slow the water velocity and provide a greater opportunity for settling and infiltration. Swales are designed to deal with concentrated flow under most conditions, resulting in low pollutant removal rates (SWRPC, 1991). Removal rates are most likely higher under low-flow conditions when sheet flow occurs. This may help to explain that the reported percent removal for TSS varied from 0 to greater than 90 percent (W-C, 1991). Wanielista and Yousef (1986) stated that swales are a useful component in a storm water management system and removal efficiencies can be improved by designing swales to infiltrate and retain runoff. Swales should be used only as part of a storm water management system and may be used with the other practices listed under this management measure.

9780

Maintenance requirements for grassed swales include mowing and periodic sediment cleanout. Surveys by Horner et al. (1988) and in the Washington area indicate that the vast majority of swales operate as designed with relatively minor maintenance. The primary maintenance problem was the gradual build-up of soil and grass adjacent to roads, which prevents the entry of runoff into swales. The cost of a grassed swale will vary depending on the geometry of the swale (height and width) and the method of establishing the vegetation (see Table 5-3). Construction costs for grassed swales are typically less than those for curb-and-gutter systems. Regular maintenance costs for conventional swales are minimal. Cleanout of sediments trapped behind check dams and spot vegetation repair may be required (Schueler et al., 1992).

j. Porous Pavement

Porous pavement has a layer of porous top course covering an additional layer of gravel. A crushed stone-filled ground-water recharge bed is typically installed beneath these top layers. The runoff infiltrates through the porous asphalt layer and into the underground recharge bed. The runoff then exfiltrates out of the recharge bed into the underlying soils or into a perforated pipe system (see Figure 5-6). When operating properly, porous pavement can replicate predevelopment hydrology, increase ground-water recharge, and provide excellent pollutant removal (up to 80 percent of sediment, trace metals, and organic matter). The use of porous pavement is highly constrained and requires deep and permeable soils, restricted traffic, and suitable adjacent land uses. Pretreatment of runoff is necessary to remove coarse particulates and prevent clogging and diminished infiltration capacity.

The major advantages of porous pavement are (1) it may be used for parking areas and therefore does not use additional site space and (2) when operating properly, it provides high long-term removal of solids and other pollutants. However, significant problems exist in the use of porous pavement. Porous pavement sites have a high failure rate (75 percent) (Schueler et al., 1992). High sediment loads and oil result in clogging and eventual failure of the system. Therefore, porous pavement is not recommended for treatment of runoff from hull cleaning/maintenance areas. Porous pavement is appropriate for low-intensity parking areas where restrictions on use (no heavy trucks) and maintenance (no deicing chemicals, sand, or improper resurfacing) can be enforced. Quarterly vacuum sweeping and/or jet hosing is needed to maintain porosity. Field data, however, indicate that this routine maintenance practice is not frequently followed (Schueler et al., 1992).

The cost of porous pavement should be measured as the incremental cost, or the cost beyond that required for conventional asphalt pavement (up to 50 percent more). To determine the full value of porous pavement, however, the savings from reducing land consumption and eliminating storm systems such as curbs, inlets, and pipes should be considered (Cahill Associates, 1991). Also, the additional cost of directing pervious area runoff around porous pavement should be considered. Maintenance of porous pavement consists of quarterly vacuum sweeping and may be 1 percent to 2 percent of the original construction costs (Schueler et al., 1992). Other maintenance costs include rehabilitation of clogged systems. In a Maryland study, 75 percent of the porous pavement systems surveyed had partially or totally clogged within 5 years. Failure was attributed to inadequate construction techniques, low permeable soils and/or restricting layers, heavy vehicular traffic, and resurfacing with nonporous pavement materials (Schueler et al., 1992).

k. Oil-Grit Separators

Oil-grit separators (see Figure 5-7) may be used to treat water from small areas where other measures are infeasible and are applicable where activities contribute large loads of grease, oil, mud, sand, and trash to runoff (Steel and McGhee, 1979). Oil-grit separators are mainly suitable for oil droplets 150 microns in diameter or larger. Little is known regarding the oil droplet size in storm water; however, droplets less than 150 microns in diameter may be more representative of storm water (Romano, 1990). Basic design criteria include providing 200-400 cubic feet of oil storage per acre of area directed to the structure. The depth of the oil storage should be approximately 3-4 feet, and the depth of grit storage should be approximately 1.5-2.5 feet minimum under the oil storage. Application is limited to highly impervious catchments that are 2 acres or smaller.

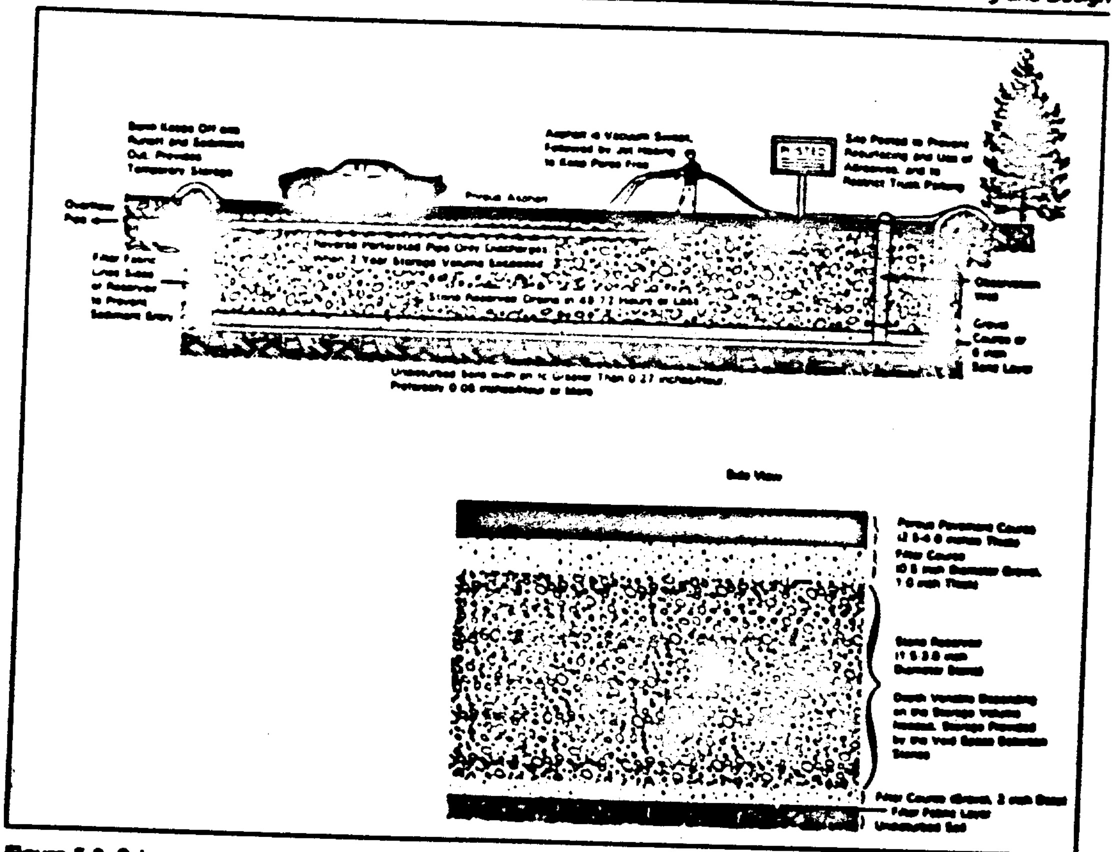

Figure 5-6. Schematic design of a porous pavement system (Schueler, 1987).

Actual pollutant removal occurs only when the chambers are cleaned out. Re-suspension limits long-term removal efficiency if the structure is not cleaned out. Periodic inspections and maintenance of the structure should be done at least twice a year (Schueler, 1987). With proper maintenance, the oil/grit separator should have at least a 50-year life span.

I. Holding Tanks

Simply put, holding tanks act as underground detention basins that capture and hold storm water until it can receive treatment. There are generally two classes of tanks: first flush tanks and settling tanks (WPCF, 1989). First flush tanks are used when the time of concentration of the impervious area is 15 minutes or less. The contents of the tank are transported via pumpout or gravity to another location for treatment. Excess runoff is discharged via the upstream overflow outlet when the tank is filled. Settling tanks are used when a pronounced first flush is not expected. A settling tank is similar to a primary settling tank in that only treated flow is discharged. The load to the clarifier overflow is usually restricted to about 0.2 ft^3/sec/ac of impervious area. If the inflow exceeds this, upstream overflows are activated. Settling tanks require periodic cleaning.

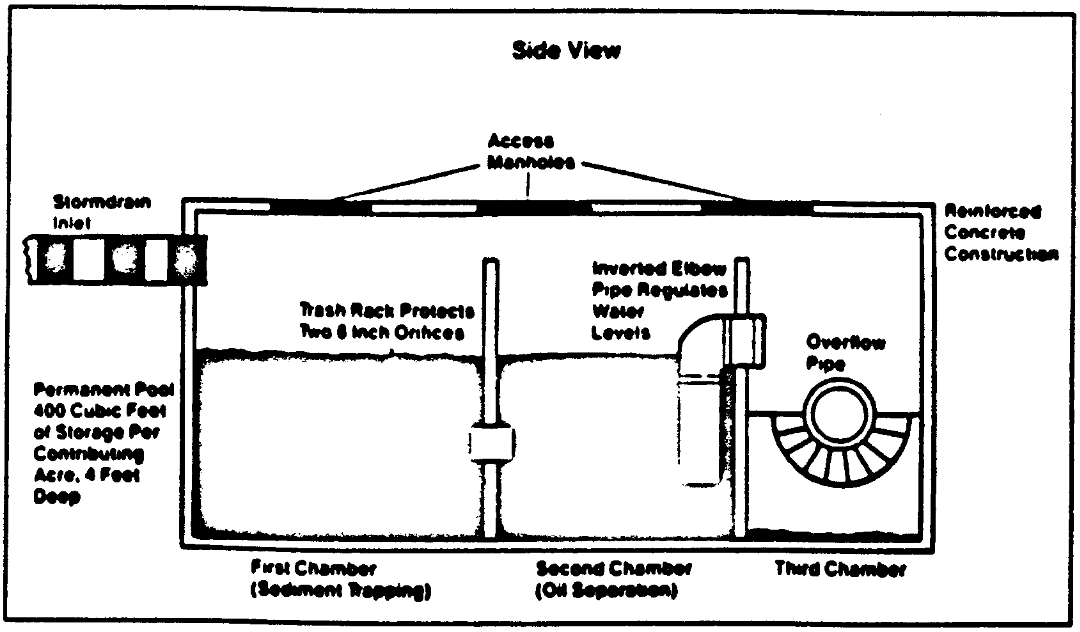

Figure 5-7. Schematic design of a water quality inlet/oil grit separator (Schueler, 1987).

m. Swirl Concentrator

A swirl concentrator is a small, compact solids separation device with no moving parts. During wet weather the unit's outflow is throttled, causing the unit to fill and to self-induce a swirling vortex. Secondary flow currents rapidly separate first flush settleable grit and floatable matter (WPCF, 1989). The pollutant matter is concentrated for treatment, while the cleaner, treated flow discharges to receiving waters. Swirl concentrators are intended to operate under high-flow regimes and may be used in conjunction with settling tanks. EPA published a design manual for swirl and helical bend pollution control devices (USEPA, 1982). However, monitoring data reveal that swirls built in accordance with this manual should be operated at lesser flows than the design indicates to achieve the desired efficiency (Pisano, 1989). Total suspended solids and BOD concentration removal efficiencies in excess of 60 percent have been reported, particularly under first flush conditions (WPCF, 1989). In another report removal effectiveness of total suspended solids from current U.S. swirls varied from a low of 5.2 percent to a high of 36.7 percent excluding first flush, 32.6 percent to 80.6 percent for first flush only, and 16.4 percent to 33.1 percent for entire storm events (Pisano, 1989). Removal efficiencies are dependent on the initial concentrations of pollutants, flow rate, size of structure, when the sumps in the catchments were cleaned, and other parameters (WPCF, 1989; and Pisano, 1989).

n. Catch Basins

Catch basins with flow restrictors may be used to prevent large pulses of storm water from entering surface waters at one time. They provide some settling capacity because the bottom of the structure is typically lowered 2 to 4 feet below the outlet pipe. Above- and below-ground storage is used to hold runoff until the receiving pipe can handle the flow. Temporary surface ponding may be used to induce infiltration and reduce direct discharge. Overland flow can be induced from sensitive areas to either sink discharge points or other storage locations. Catch basins with flow restrictors are not very effective at pollutant removal by themselves (WPCF, 1989) and should be used in conjunction with other practices. Removal efficiencies for larger particles and debris are high and make catch basins attractive as pretreatment systems for other practices. The traps of catch basins require periodic cleaning and maintenance.

Cleaning catch basins can result in large pulses of pollutants in the first subsequent storm if the method of cleaning results in the disturbance and breaking up of residual matter and some material is left in the catch basin (Richards et al., 1981). With proper maintenance, a catch basin should have at least a 50-year life span (Schueler et al., 1992).

o. Catch Basin with Sand Filter

A catch basin with sand filter consists of a sedimentation chamber and a chamber filled with sand. The sedimentation chamber removes coarse particles, helps to prevent clogging of the filter medium, and provides sheet flow into the filtration chamber. The sand chamber filters smaller-sized pollutants. Catch basins with sand filters are effective in highly impervious areas, where other practices have limited usefulness. The effectiveness of the sediment chamber for removal of the different particles depends on the particles' settling velocity and the chamber's length and depth. The effectiveness of the filtration medium depends on its depth.

Catch basins with sand filters should be inspected at least annually, and periodically the top layer of sand with deposition of sediment should be removed and replaced. In addition, the accumulated sediment in the sediment chamber should be removed periodically (Shaver, 1991). With proper maintenance and replacement of the sand, a catch basin with sand filter should have at least a 50-year life span (Schueler et al., 1992).

p. Adsorbents in Drain Inlets

While there is some tendency for oil and grease to sorb to trapped particles, oil and grease will not ordinarily be captured by catch basins, holding tanks, or swirl concentrators. Adsorbent material placed in these structures in a manner that will allow sufficient contact between the adsorbent and the storm water will remove much of the oil and grease load of runoff (Silverman and Stenstrom, 1989). In addition, the performance of oil-grit separators could be enhanced through the use of adsorbents. An adsorbent/catch basin system that treats the majority of the grease and oil in storm water runoff could be designed, and annual replacement of the adsorbent would be sufficient to maintain the system in most cases (Silverman et al., 1989). Manufacturers report that their products are able to sorb 10 to 25 times their weight in oil (Industrial Products, 1991; Lab Safety, 1991). The cost of 10 pillows, 24 inches by 14 inches by 5 inches (total weight 24 pounds), is approximately $85 to $93 (Lab Safety, 1991).

Fueling Station Design Management Measure

Design fueling stations to allow for ease in cleanup of spills.

VOL 12

1. Applicability

This management measure is intended to be applied by States to new and expanding[1] marinas where fueling stations are to be added or moved. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Spillage is a source of petroleum hydrocarbons in marinas (USEPA, 1985a). Most petroleum-based fuels are lighter than water and thus float on the water's surface. This property allows for their capture if petroleum containment equipment is used in a timely manner.

3. Management Measure Selection

Selection of this measure is based on the preference for pollution prevention in the design of marinas rather than reliance on control of material that is released without forethought as to how it will be cleaned up. The possibility of spills during fueling operations always exists. Therefore, arrangements should be made to contain pollutants released from fueling operations to minimize the spread of pollutants through and out of the marina.

9785

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Locate and design fueling stations so that spills can be contained in a limited area.

The location and design of the fueling station should allow for booms to be deployed to surround a fuel spill. Pollutant reduction effectiveness and the cost of the design of fueling areas are difficult to quantify. When designing a new marina, the additional costs of ensuring that the design incorporates effective cleanup considerations should be minimal.

[1] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

b. Design a Spill Contingency Plan.

A Spill Contingency Plan must be developed for fuel storage and dispensation areas. The plan must meet local and State requirements and must include spill emergency procedures, including health and safety, notification, and spill containment and control procedures. Marina personnel must be properly trained in spill containment and control procedures.

c. Design fueling stations with spill containment equipment.

Appropriate containment and control materials must be stored in a clearly marked, easily accessible cabinet or locker. The cabinet or locker must contain absorbent pads and booms, fire extinguishers, a copy of the Spill Contingency Plan, and other equipment deemed suitable. Easily used effective oil spill containment equipment is readily available from commercial suppliers. Booms that can be strung around the spill, absorb up to 25 times their weight in petroleum products, and remain floating after saturation are available at a cost of approximately $160 for four booms 8 inches in diameter and 10 feet long with a weight of 40 pounds (Lab Safety, 1991). Oil-absorbent sheets, rolls, and pillows are also available at comparable prices.

VOL 12

C. Sewage Facility Management Measure

Install pumpout, dump station, and restroom facilities where needed at new and expanding marinas to reduce the release of sewage to surface waters. Design these facilities to allow ease of access and post signage to promote use by the boating public.

1. Applicability

This management measure is intended to be applied by States to new and expanding[9] marinas in areas where adequate marine sewage collection facilities do not exist. Marinas that do not provide services for vessels that have marine sanitation devices (MSDs) do not need to have pumpouts, although dump stations for portable toilets and restrooms should be available. This measure does not address direct discharges from vessels covered under CWA section 312. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Three types of onshore collection systems are available: fixed point systems, portable/mobile systems, and dedicated slipside systems. Information on the installation and operation of sewage pumpout stations is available from the State of Maryland (MDDNR, 1991).

EPA Region I determined that, in general, a range of one pumpout facility per 300-600 boats with holding tanks (type III MSDs) should be sufficient to meet the demand for pumpout services in most harbor areas (USEPA, 1991b). EPA Region 4 suggested one facility for every 200 to 250 boats with holding tanks and provided a formula for estimating the number of boats with holding tanks (USEPA, 1985a). The State of Michigan has instituted a no-discharge policy and mandates one pumpout facility for every 100 boats with holding tanks.

According to the 1989 American Red Cross Boating Survey, there were approximately 19 million recreational boats in the United States (USCG, 1990). About 95 percent of these boats were less than 26 feet in length. A very large number of these boats used a portable toilet, rather than a larger holding tank. Given the large percentage of smaller boats, facilities for the dumping of portable toilet waste should be provided at marinas that service significant numbers of boats under 26 feet in length.

Two of the most important factors in successfully preventing sewage discharge are (1) providing "adequate and reasonably available" pumpout facilities and (2) conducting a comprehensive boater education program (USEPA, 1991b). The Public Education Management Measure presents additional information on this subject. One reason that pumpout use in Puget Sound is higher than that in other areas could be the extensive boater education program established in that area.

[9] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

9787

R0043093

Chemicals from holding tanks may retard the normal functioning of septic systems. Information on septic systems can be found in Chapter 4. Neither the chemicals nor the concentration of marine wastes has proven to be a problem for properly operating public sewage treatment plants.

3. Management Measure Selection

Measure selection is based on the need to reduce discharges of sanitary waste and the fact that most coastal States and many localities already require the installation of pumpout facilities and restrooms at all or selected marinas (Appendix 5A). Other States encourage the installation and use of pumpouts through grant programs and boater education.

In a Long Island Sound study, only about 5 percent of the boats were expected to use pumpouts. Given the low documented usage by boaters at marinas with pumpouts, the time, inconvenience, and cost associated with pumpouts were determined to be more of a deterrent to use than was lack of availability of facilities (Tanski, 1989). A Puget Sound study found that 35 percent of the boats responding to a survey had holding tanks (type III MSDs). Eighty percent of these boats had y-valves that allowed illegal discharge. About half of these boats used pumpouts. The boaters surveyed felt that the most effective methods to ensure proper disposal of boat waste would be the improvement of waste-disposal facilities and boater education (Cheyne and Carter, 1989). Another Puget Sound study found that the problem of marine sewage waste could best be addressed through containment of wastes onboard the vessel and subsequent onshore disposal through the provision of adequate numbers of clean, accessible, economical, and easily used pumpout stations (Seabloom et al., 1989). Designation and advertisement of no-discharge zones can also increase boater use of pumpout facilities (MDDNR, 1991).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. *Fixed-Point Systems*

Fixed-point collection systems include one or more centrally located sewage pumpout stations (see Figure 5-8). These stations are generally located at the end of a pier, often on a fueling pier so that fueling and pumpout operations can be combined. A boat requiring pumpout services docks at the pumpout station. A flexible hose is connected to the wastewater fitting in the hull of the boat, and pumps or a vacuum system move the wastewater to an onshore holding tank, a public sewer system, a private treatment facility, or another approved disposal facility. In cases where the boats in the marina use only small portable (removable) toilets, a satisfactory disposal facility could be a dump station.

b. *Portable Systems*

Portable/mobile systems are similar to fixed-point systems and in some situations may be used in their place at a fueling dock. The portable unit includes a pump and a small storage tank. The unit is connected to the deck fitting on the vessel, and wastewater is pumped from the vessel's holding tank to the pumping unit's storage tank. When the storage tank is full, its contents are discharged into a municipal sewage system or a holding tank for removal by a septic tank pumpout service. In many instances, portable pumpout facilities are believed to be the most logistically feasible, convenient, accessible (and, therefore, used), and economically affordable way to ensure proper disposal of boat sewage (Natchez, 1991). Portable systems can be difficult to move about a marina and this factor should be considered when assessing the correct type of system for a marina. Another portable/mobile pumpout unit that is an emerging technology and is popular in the Great Salt Pond in Block Island, New York, is the radio-

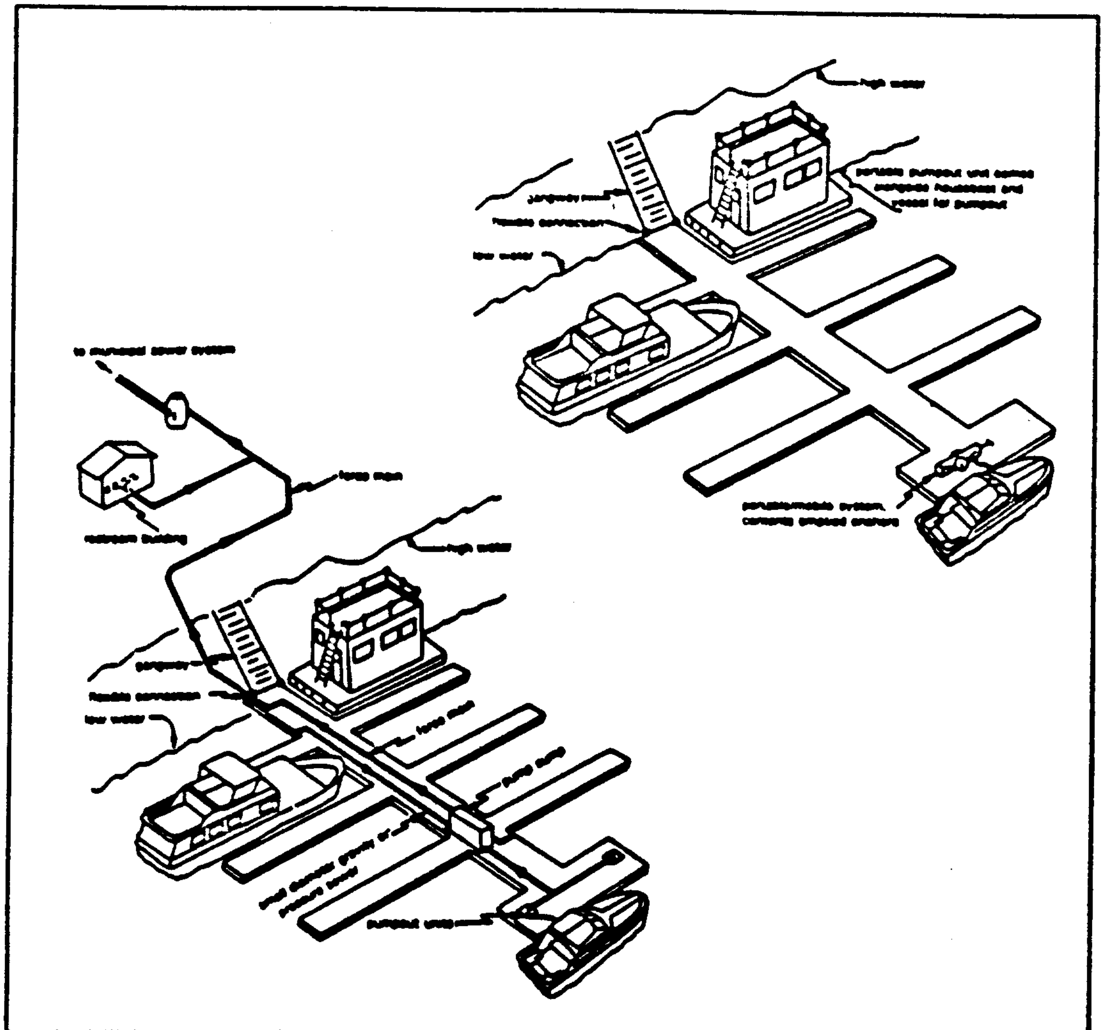

Figure 5-8. Examples of pumpout devices.

dispatched pumpout boat. The pumpout boat goes to a vessel in response to a radio-transmitted request, pumps the holding tank, and moves on to the next requesting vessel. This approach eliminates the inconvenience of lines, docking, and maneuvering vessels in high-traffic areas.

Costs associated with pumpouts vary according to the size of the marina and the type of pumpout system. Table 5-4 presents 1985 cost information for three marina sizes and two types of pumpout systems (USEPA, 1985a). More recent systems are less expensive, with a homemade portable system costing less than $250 in parts and commercial portable units available for between $2,000 and $4,000 (Natchez, 1991).

c. *Dedicated Slipside Systems*

Dedicated slipside systems provide continuous wastewater collection at a slip. Slipside pumpout should be provided to live-aboard vessels. The remainder of the marina can still be served by either marina-wide or mobile pumpout systems.

Table 5-4. Annual Per Slip Pumpout Costs for Three Collection Systems[a] (USEPA, 1985a)

	Marina-Wide	Portable/Mobile	Slipside
Small Marina (200 slips)			
Capital Costs	15[b]	15[c]	102[b]
O&M Costs	110	200	50
Total Cost/Slip/Year	125	215	152
Medium Marina (500 slips)			
Capital Costs	17	10	101
O&M Costs	90	160	40
Total Cost/Slip/Year	107	170	141
Large Marina (2000 slips)			
Capital Costs	16	10	113
O&M Costs	80	140	36
Total Cost/Slip/Year	96	150	149

[a] 1985 data; all figures in dollars.
[b] Based on 12% interest, 15 years amortization.
[c] 12% interest, 15 years on piping; 12% interest, 15 years on portable units.

d. Adequate Signage

Marina operators should post ample signs prohibiting the discharge of sanitary waste from boats into the waters of the State, including the marina basin, and also explaining the availability of pumpout services and public restroom facilities. Signs should also fully explain the procedures and rules governing the use of the pumpout facilities. An example of an easily understandable sign that has been used to advertise the availability of pumpout facilities is presented in Figure 5-9 (Keko, Inc., 1992).

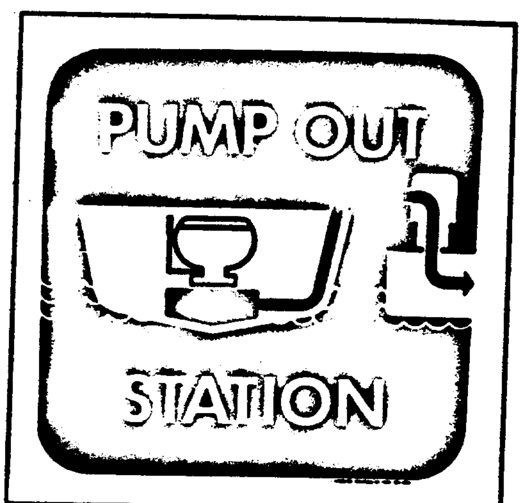

Figure 5-9. Example signage advertising pumpout availability (Keko, Inc., 1992).

III. MARINA AND BOAT OPERATION AND MAINTENANCE

During the course of normal marina operations, various activities and locations in the marina can generate polluting substances. Such activities include waste disposal, boat fueling, and boat maintenance and cleaning; such locations include storage areas for materials required for these activities and hull maintenance areas (METRO, 1992a; Tobiasson and Kollmeyer, 1991). Of special concern are substances that can be toxic to aquatic biota, pose a threat to human health, or degrade water quality.[1] Paint sandings and chippings, oil and grease, fuel, detergents, and sewage are examples (METRO, 1992a; Tobiasson and Kollmeyer, 1991).

It is important that marina operators and patrons take steps to control or minimize the entry of these substances into marina waters. For the most part, this can be accomplished with simple preventative measures such as performing these activities on protected sites, locating servicing equipment where the risk of spillage is reduced (see Siting and Design section of this chapter), providing adequate and well-marked disposal facilities, and educating the boating public about the importance of pollution prevention. The benefit of effective pollution prevention to the marina operator can be measured as the relative low cost of pollution prevention compared to potentially high environmental clean-up costs (Tobiasson and Kollmeyer, 1991).

For those planning to build a marina, attention to the environmental concerns of marina operation during the marina design phase will significantly reduce the potential for generating pollution from these activities. For existing marinas, minor changes in operations, staff training, and boater education should help protect marina waters from these sources of pollution. The management measures that follow address the control of pollution from marina operation and maintenance activities.

VOL 12

A. Solid Waste Management Measure

Properly dispose of solid wastes produced by the operation, cleaning, maintenance, and repair of boats to limit entry of solid wastes to surface waters.

1. Applicability

This management measure is intended to be applied by States to new and expanding[2] marinas. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Marina operators are responsible for determining what types of wastes will be generated at the marina and ensuring proper disposal. Marina operators are thus responsible for the contents of their dumpsters and the management of solid waste on their property. Hazardous waste should never be placed in dumpsters. Liquid waste should not be mixed with solid waste but rather disposed of properly by other methods (see Liquid Waste Management Measure).

3. Management Measure Selection

This measure was selected because marinas have shown the ability to minimize the entry of solid waste into surface waters through implementation of some or all of the practices. Marinas generate a variety of solid waste through the activities that occur on marina property and at their piers. If adequate disposal facilities are not available there is a potential for disposal of solid waste in surface waters or on shore areas where the material can wash into surface waters. Marina patrons and employees are more likely to properly dispose of solid waste if given adequate opportunity and disposal facilities. Under Federal law, marinas and port facilities must supply adequate and convenient waste disposal facilities for their customers (NOAA, 1988).

9792

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

---

[2] Refer to Section I.H (General Applicability) for additional information on expansions of existing marinas.

a. *Perform boat maintenance/cleaning above the waterline in such a way that no debris falls into the water.*

This subject is also addressed under the Boat Cleaning Management Measure later in this chapter.

b. *Provide and clearly mark designated work areas for boat repair and maintenance. Do not permit work outside designated areas.*

c. *Clean hull maintenance areas regularly to remove trash, sandings, paint chips, etc.*

Vacuuming is the preferred method of collecting these wastes.

d. *Perform abrasive blasting within spray booths or plastic tarp enclosures to prevent residue from being carried into surface waters. If tarps are used, blasting should not be done on windy days.*

e. *Provide proper disposal facilities to marina patrons. Covered dumpsters or other covered receptacles are preferred.*

While awaiting transfer to a landfill, dumpsters in which items such as used oil filters are stored should be covered to prevent rain from leaching material from the dumpster onto the ground.

f. *Provide facilities for the eventual recycling of appropriate materials.*

Recycling of nonhazardous solid waste such as scrap metal, aluminum, glass, wood pallets, paper, and cardboard is recommended wherever feasible. Used lead-acid batteries should be stored on an impervious surface, under cover, and sent to or picked up by an approved recycler. Receipts should be retained for inspection.

VOL 12

9793

Fish Waste Management Measure

promote sound fish waste management through a combination of fish-cleaning restrictions, public education, and proper disposal of fish waste.

1. Applicability

This management measure is intended to be applied by States to marinas where fish waste is determined to be a source of water pollution. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Fish waste can result in water quality problems at marinas with large numbers of fish landings or at marinas that have limited fish landings but poor flushing. The amount of fish waste disposed of into a small area such as a marina can exceed that existing naturally in the water at any one time. Fish waste decomposes, which requires oxygen. In sufficient quantity, disposal of fish waste can thus be a cause of dissolved oxygen depression as well as odor problems (DNREC, 1990; McDougal et al., 1986).

3. Management Measure Selection

This measure was selected because marinas have shown the ability to prevent fish-waste-induced water quality or aesthetic problems through implementation of the identified practices. Marinas that cater to patrons who fish a large amount can produce a large amount of fish waste at the marina from fish cleaning. If adequate disposal facilities are not available, there is a potential for disposal of fish waste in areas without enough flushing to prevent decomposition and the resulting dissolved oxygen depression and odor problems. Marina patrons and employees are more likely to properly dispose of fish waste if told of potential consequences and provided adequate and convenient disposal facilities. States require, and many marinas have already implemented, this management measure (Appendix 5A).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Establish fish-cleaning areas.

Particular areas can be set aside or designated for the cleaning of fish, and receptacles can be provided for the waste. Boaters and fishermen should be advised to use only these areas for fish cleaning, and the waste collected in the receptacles should be disposed of properly.

b. Issue rules governing the conduct and location of fish-cleaning operations.

Marinas can issue rules regarding the cleaning of fish at the marina, depending on the type of services offered by the marina and its clientele. Marinas not equipped to handle fish wastes may prohibit the cleaning of fish at the marina; those hosting fishing competitions or having a large fishing clientele should establish fish-cleaning areas with specific rules for their use and should establish penalties for violation of the rules.

c. Educate boaters regarding the importance of proper fish-cleaning practices.

Boaters should be educated about the problems created by discarding their fish waste into marina waters, proper disposal practices, and the ecological advantages of cleaning their fish at sea and discarding the wastes into the water where the fish were caught. Signs posted on the docks (especially where fish cleaning has typically been done) and talks with boaters during the course of other marina operations can help to educate boaters about marina rules governing fish waste and its proper disposal.

d. Implement fish composting where appropriate.

A law passed in 1989 in New York forbids discarding fish waste, with exceptions, into fresh water or within 100 feet of shore (White et al., 1989). Contaminants in some fish leave few alternatives for disposing of fish waste, so Cornell University and the New York Sea Grant Extension Program conducted a fish composting project to deal with the over 2 million pounds of fish waste generated by the salmonid fishery each year. They found that even with this quantity of waste, if composting was properly conducted the problems of odor, rodents, and maggots were minimal and the process was effective (White et al., 1989). Another method of fish waste composting described by the University of Wisconsin Sea Grant Institute is suitable for amounts of compost ranging from a bucketful to the quantities produced by a fish-processing plant (Frederick et al., 1989).

C. Liquid Material Management Measure

Provide and maintain appropriate storage, transfer, containment, and disposal facilities for liquid material, such as oil, harmful solvents, antifreeze, and paints, and encourage recycling of these materials.

1. Applicability

This management measure is intended to be applied by States to marinas where liquid materials used in the maintenance, repair, or operation of boats are stored. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

This management measure minimizes entry of potentially harmful liquid materials into marina and surface waters through proper storage and disposal. Marina operators are responsible for the proper storage of liquid materials for sale and for final disposal of liquid wastes, such as waste fuel, used oil, spent solvents, and spent antifreeze. Marina operators should decide how liquid waste material is to be placed in the appropriate containers and disposed of and should inform their patrons.

3. Management Measure Selection

This measure was selected because marinas have shown the ability to prevent entry of liquid waste into marina and surface waters. Marinas generate a variety of liquid waste through the activities that occur on marina property and at their piers. If adequate disposal facilities are not available, there is a potential for disposal of liquid waste in surface waters or on shore areas where the material can wash into surface waters. Marina patrons and employees are more likely to properly dispose of liquid waste if given adequate opportunity and disposal facilities. The practices on which the measure is based are available. Many coastal States already have mandatory or voluntary programs that satisfy this management measure (Appendix 5A).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ a. *Build curbs, berms, or other barriers around areas used for the storage of liquid material to contain spills. Store materials in areas impervious to the type of material stored.*

To contain spills, curbs or berms should be installed around areas where liquid material is stored. The berms or curbs should be capable of containing 10 percent of the liquid material stored or 110 percent of the largest container, whichever is greater (WADOE, 1991). There should not be drains in the floor. Implementation of this practice will prevent spilled material from directly entering surface waters. The cost of 6-inch cement curbs placed around a cement pad is $10 to $14 per linear foot (Means, 1990). The cost of a temporary spill dike capable of absorbing 50 liters of material (5 inches in diameter and 30 feet long) is approximately $110 (Lab Safety, 1991).

■ b. *Separate containers for the disposal of waste oil; waste gasoline; used antifreeze; and waste diesel, kerosene, and mineral spirits should be available and clearly labeled.*

Waste oil includes waste engine oil, transmission fluid, hydraulic fluid, and gear oil. A filter should be drained before disposal by placing the filter in a funnel over the appropriate waste collection container. The containers should be stored on an impermeable surface and covered in a manner that will prevent rainwater from entering the containers. Containers should be clearly marked to prevent mixing of the materials with other liquids and to assist in their identification and proper disposal. Waste should be removed from the marina site by someone permitted to handle such waste, and receipts should be retained for inspection.

Care should be taken to avoid combining different types of antifreeze. Standard antifreeze (ethylene glycol, usually identifiable by its blue or greenish color) should be recycled. If recycling is not available, propylene-glycol-based anti-freeze should be used because it is less toxic when introduced to the environment. Propylene glycol is often a pinkish hue (Gannon, 1990). Many States, including Maryland, Washington, and Oregon, have developed programs to encourage the proper disposal of used antifreeze.

Fifty-five-gallon closed-head polyethylene or steel drums approved for shipping hazardous and nonhazardous materials are available commercially at a cost of approximately $50 each. Open-head steel drums (approximately $60 each) with self-closing steel drum covers (approximately $90 each) may also be used (Lab Safety, 1991). A package of five labels that may be affixed to drums (10 inches by 10 inches) costs approximately $10.

■ c. *Direct marina patrons as to the proper disposal of all liquid materials through the use of signs, mailings, and other means.*

If individuals within a marina collect, contain, and dispose of their own liquid waste, signs and education programs (see Public Education Management Measure) should direct them to proper recycling and disposal options.

Petroleum Control Management Measure

Reduce the amount of fuel and oil from boat bilges and fuel tank air vents entering marina and surface waters.

1. Applicability

This management measure is intended to be applied by States to boats that have inboard fuel tanks. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Fuel and oil are commonly released into surface waters during fueling operations through the fuel tank air vent, during bilge pumping, and from spills directly into surface waters and into boats during fueling. Oil and grease from the operation and maintenance of inboard engines are a source of petroleum in bilges.

3. Management Measure Selection

This measure was selected because (1) the practices have shown the ability to minimize the introduction of petroleum from fueling and bilge pumping and thus prevent a visible sheen on the water's surface and (2) New York State requires the installation of fuel/air separators on new boats. Boaters and fuel station attendants often inadvertently spill fuel when "topping off" fuel tanks. They know the tank is full when fuel comes out of the mandatory air vent. This is preventable by the use of attachments on the air vent that suppress overflowing. Boat bilges have automatic and manual pumps that empty directly to marina or surface waters. When activated, these pumps often cause direct discharge of oil and grease from operation and maintenance of inboard engines. Oil-absorbing bilge pads contain oil and grease and prevent their discharge.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. ***Use automatic shut-off nozzles and promote the use of fuel/air separators on air vents or tank stems of inboard fuel tanks to reduce the amount of fuel spilled into surface waters during fueling of boats.***

During the fueling of inboard tanks fuel can be spilled into surface waters due to overfilling the fuel tank. An automatic shut-off nozzle is partially effective in reducing the potential for overfilling, but often during fueling operations fuel overflows from the air vent on the fuel tank of the boat. Attachments for vents on fuel tanks, which act as fuel/air separators, are available commercially. These devices release air and vapor but contain overflowing fuel. The State of New York passed a law in 1990 that requires that all boats sold in New York after January 1, 1994, have air vents on their fuel tanks that are designed to prevent fuel overflows or spills. The commercial cost of these devices is approximately $85 per unit. Marinas can make these units available in their retail stores and post notices describing their spill prevention benefits and availability.

■ b. *Promote the use of oil-absorbing materials in the bilge areas of all boats with inboard engines. Examine these materials at least once a year and replace as necessary. Recycle them if possible, or dispose of them in accordance with petroleum disposal regulations.*

Marina operators can advertise the availability of such oil-absorbing material or can include the cost of installation of such material in yearly dock fees. Marina operators can also insert a clause in their leasing agreements that boaters will use oil-absorbing material in their bilges. Pillows/pads that absorb oils and petroleum-based products and not water are available. These pillows/pads absorb up to 12 times their weight in oil and cost approximately $40 for a package of 10 (Lab Safety, 1991).

VOL 12

E. Boat Cleaning Management Measure

For boats that are in the water, perform cleaning operations to minimize, to the extent practicable, the release to surface waters of (a) harmful cleaners and solvents and (b) paint from in-water hull cleaning.

1. Applicability

This management measure is intended to be applied by States to marinas where boat topsides are cleaned and marinas where hull scrubbing in the water has been shown to result in water or sediment quality problems. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

This measure minimizes the use and release of potentially harmful cleaners and bottom paints to marina and surface waters. Marina employees and boat owners use a variety of boat cleaners, such as teak cleaners, fiberglass polishers, and detergents. Boats are cleaned over the water or onshore adjacent to the water. This results in a high probability of some of the cleaning material entering the water. Boat bottom paint is released into marina waters when boat bottoms are cleaned in the water.

9800

3. Management Measure Selection

This measure was selected because marinas have shown the ability to prevent entry of boat cleaners and harmful solvents as well as the release of bottom paint into marina and surface waters. The practices on which the measure is based are available, minimize entry of harmful material into marina waters, and still allow boat owners to clean their boats.

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ a. ***Wash the boat hull above the waterline by hand. Where feasible, remove the boat from the water and perform cleaning where debris can be captured and properly disposed of.***

b. Detergents and cleaning compounds used for washing boats should be phosphate-free and biodegradable, and amounts used should be kept to a minimum.

c. Discourage the use of detergents containing ammonia, sodium hypochlorite, chlorinated solvents, petroleum distillates, or lye.

d. Do not allow in-the-water hull scraping or any process that occurs underwater to remove paint from the boat hull.

The material removed from boat hulls treated with antifoulant paint contains high levels of toxic metals (see Table 5-1).

Public Education Management Measure

Public education/outreach/training programs should be instituted for boaters, as well as marina owners and operators, to prevent improper disposal of polluting material.

1. Applicability

This management measure is intended to be applied by States to all environmental control authorities in areas where marinas are located. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The best method of preventing pollution from marinas and boating activities is to educate the public about the causes and effects of pollution and methods to prevent it. One of the primary reasons for the success of existing programs is the widespread support for these efforts. Measuring the efficiency of the separate practices of public education and outreach programs can be extremely difficult. Programs need to be examined in terms of long-term impacts.

Creating a public education program should involve user groups and the community in all phases of program development and implementation. The program should be suited to a specific area and should use creative promotional material to spread its message. General information on how to educate and involve the public can be found in *Managing Nonpoint Pollution: An Action Plan Handbook for Puget Sound Watersheds* (PSWQA, 1989) and *Dealing with Annex V - Reference Guide for Ports* (NOAA, 1988).

3. Management Measure Selection

Measure selection is based on low cost (Table 5-5), proven effectiveness, availability, and widespread use by many States (Appendix 5A).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

Table 5-5. Approximate Costs for Educational and Promotional Material (NOAA, 1988)

Item	Quantity	Cost
Brochures	10,000	2,100
Posters	5,000	500
Decals	6,000	900
Coloring Books	3,000	1,000
Stickers	20,000	450
Signs (wood)	20	800
Litter bags	8,000	1,400
Litter bags (beach cleanup)	2,000	free
Slide shows	5	250
Photo displays	9	1,000
Sweatshirts	288	2,200
Hats	432	1,100
Notices	40	25
Videotaped programs (copies)	4	200
Radio PSAs (copies, 7 announcements)	25	250
TV Public Service Announcements (copies)	6	200
Advertisements, newspaper	2	350
Advertisements, TV	2 weeks	200
Total		12,925

NOTE: Additional costs (about $2500) were involved in the development of the TV and radio public service announcements and brochures and in the acquisition of the rights to some art and photographic materials.

a. Signage

Interpretive and instructional signs placed at marinas and boat-launching sites are a key method of disseminating information to the boating public. The Chesapeake Bay Commission recommended that Bay States develop and implement programs to educate the boating public to stimulate increased use of pumpout facilities (CBC, 1989). The commission found that "boater education on this issue can be substantially expanded at modest expense."

Appropriate signage to direct boaters to the nearest pumpout facility to alert boaters to its presence would very likely stimulate increased used of pumpout facilities. Signs can be provided to marinas and posted in areas where recreational boats are concentrated. Ten-inch-square aluminum signs are available commercially for approximately $12 each (Lab Safety, 1991).

VOL 12

b. Recycling/Trash Reduction Programs

A New Jersey marina issued reusable tote bags with the marina's name printed on the side. The bags were used repeatedly to transport groceries and to store recyclable materials for proper disposal (Bleier, 1991). Newport, Oregon, instituted a recycling program that was not immediately successful but has since achieved increased boater compliance (Bleier, 1991). The Louisiana and New Hampshire Sea Grant Programs both instituted successful public education programs designed to reduce the amount of marine debris discarded into surface waters (Doyle and Barnaby, 1990). The $17,000 cost of the New Hampshire demonstration program included project organization, distribution of a season's supply of trash bags, advertising material, and project monitoring. More than 90 percent of the 91 participating boats indicated that they had made a commitment to reducing marine pollution.

c. Pamphlets or Flyers, Newsletters, Inserts in Billings

The Washington State Parks and Recreation Commission designed a multifaceted public education program and is working with local governments and boating groups to implement the program and evaluate its effectiveness. The program encourages the use of MSDs and pumpout facilities, discourages impacts to shellfish areas, and provides information to boaters and marina operators about environmentally sound operation and maintenance activities. The Commission has prepared written materials, given talks to boating groups, participated in events such as boat shows, and developed signs for placement at marinas and boat launches. Printed material includes a map of pumpout facilities, a booklet on boat pollution, a pamphlet on plastic debris, and articles on the effects of boating activities. Written material can be made available at marinas, supply stores, or other places frequently visited by boaters. Approximate costs of some educational and promotional materials used in a Newport, Oregon, program are presented in Table 5-5 (NOAA, 1988). Written material describing the importance of boater cooperation in solving the problems associated with marine discharges could be included with annual boat registration forms, and cooperative programs involving State environmental agencies and boaters' organizations could be established.

d. Meetings/Presentations

Presentations at local marinas or other locations are a good way to discuss issues with boaters and marina owners and operators. The New Moon Project in Puget Sound is a public education program that is attempting to increase use of portable sewage pumpouts. This effort has included workshops and seminars for boaters, marina operators, and harbor masters. The presentations have produced interest from marina operators who want to participate and boaters who want additional material (NYBA, 1990). Presentations can also present the positive aspects of marinas and successful case studies of pollution prevention and control.

9804

VOL 12

[illegible]

Ensure that sewage pumpout facilities are maintained in operational condition and encourage their use.

1. Applicability

This management measure is intended to be applied by States to marinas where marine sewage disposal facilities exist. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

The purpose of this measure is to reduce the release of untreated sewage into marina and surface waters.

3. Management Measure Selection

This measure was selected because it is effective in preventing failure of pumpouts and discourages improper disposal of sanitary wastes. Also, many pumpouts are not properly maintained, limiting their use. The Maryland Department of Natural Resources (MDDNR, 1991) provides operation and maintenance information on pumpouts to marina owners and operators in an effort to increase availability and use of pumpouts. Many other States inspect pumpout facilities to ensure that they are in operational condition (Appendix 5A).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

■ a. *Arrange maintenance contracts with contractors competent in the repair and servicing of pumpout facilities.*

■ b. *Develop regular inspection schedules.*

■ c. *Maintain a dedicated fund for the repair and maintenance of marina pumpout stations. (Government-owned facilities only)*

9805

d. Add language to slip leasing agreements mandating the use of pumpout facilities and specifying penalties for failure to comply.

e. Place dye tablets in holding tanks to discourage illegal disposal.

Boating activities that result in excessive fecal coliform bacteria levels can be addressed through the placement of a dye tablet in the holding tanks of all boats entering the adversely impacted waterbody. This practice was employed in Avalon Harbor, California, after moored boats were determined to be the source of problem levels of fecal coliform bacteria. Upon entering the harbor, a harbor patrol officer boards each vessel and places dye tablets in all sanitary devices. The officer then flushes the devices to ensure that the holding tanks do not leak. During the first 3 years of implementation, this practice detected 135 violations of the no-discharge policy and was extremely successful at reducing pollution levels (Smith et al., 1991). One tablet in approximately 60 gallons of water will give a visible dye concentration of one part per million. The cost of the tablets is approximately $30 per 200 tablets (Forestry Suppliers, 1992).

Boat Operation Management Measure

Restrict boating activities where necessary to decrease turbidity and physical destruction of shallow-water habitat.

1. Applicability

This management measure is intended to be applied by States in non-marina surface waters where evidence indicates that boating activities are impacting shallow-water habitats. Under the Coastal Zone Act Reauthorization Amendments of 1990, States are subject to a number of requirements as they develop coastal nonpoint source programs in conformity with this measure and will have some flexibility in doing so. The application of management measures by States is described more fully in *Coastal Nonpoint Pollution Control Program: Program Development and Approval Guidance*, published jointly by the U.S. Environmental Protection Agency (EPA) and the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce.

2. Description

Boat operation can resuspend bottom sediment, resulting in the reintroduction of toxic substances into the water column. It can increase turbidity, which affects the photosynthetic activity of algae and submerged aquatic vegetation (SAV). SAV provides habitat for fish, shellfish, and waterfowl and plays an important role in maintaining water quality through assimilating nutrients. It also reduces wave energy, protecting shorelines and bottom habitats from erosion. Replacing SAV once it has been uprooted or eliminated from an area is difficult, and the science of replacing it artificially is not well-developed. It is therefore important to protect existing SAV. Boat operation may also cut off or uproot SAV, damage corals and oyster reefs, and cause other habitat destruction. The definition of shallow-water habitat should be determined by State policy and should be dependent upon the ecological importance and sensitivity to direct and indirect disruption of the habitats found in the State.

3. Management Measure Selection

This measure was selected because some areas are not suitable for boat traffic due to their shallow water depth and the ecological importance and sensitivity to disruption of the types of habitats in the area. Excluding boats from such areas will minimize direct habitat destruction. Establishing no-wake zones will minimize the indirect impacts of increased turbidity (e.g., decreased light availability).

4. Practices

As discussed more fully at the beginning of this chapter and in Chapter 1, the following practices are described for illustrative purposes only. State programs need not require implementation of these practices. However, as a practical matter, EPA anticipates that the management measure set forth above generally will be implemented by applying one or more management practices appropriate to the source, location, and climate. The practices set forth below have been found by EPA to be representative of the types of practices that can be applied successfully to achieve the management measure described above.

a. Exclude motorized vessels from areas that contain important shallow-water habitat.

Many areas of shallow SAV exhibit troughs (areas of no vegetation) due to the action of boat propellers. This can result in increased erosion of the SAV due to the loss of bottom cover cohesion. SAV should be protected from boat or propeller damage because of its high habitat value.

b. Establish and enforce no-wake zones to decrease turbidity.

No-wake zones should be used in place of speed zones in shallow surface waters for reducing the turbidity caused by boat traffic. Motorboats traveling at relatively slow speeds of 6 to 8 knots in shallow waters can be expected to produce waves at or near the maximum size that can be produced by the boats. The height of a wave is directly proportional to the depth of water in which the wave will disturb the bottom (e.g., a taller wave will disturb the bottom of water deeper than a shorter wave). Bottom sediments composed of fine material will be resuspended and result in turbidity. In areas of high boat traffic, boat-induced turbidity can reduce the photosynthetic activity of SAV. Chapter 6 contains additional information on how to implement this practice.

IV. GLOSSARY

Bathymetric: Pertaining to the depth of a waterbody.

Bed load transport: Sediment transport along the bottom of a waterbody due to currents.

Benthic: Associated with the sea bottom.

Biocriteria: Biological measures of the health of an environment, such as the incidence of cancer in benthic fish species.

BOD: Biochemical oxygen demand; the quantity of dissolved oxygen used by microorganisms in the biochemical oxidation of organic matter and oxidizable inorganic matter by aerobic biological action.

Circulation cell: See *gyre*.

Conservative pollutant: A pollutant that remains chemically unchanged in the water.

Critical habitat: A habitat determined to be important to the survival of a threatened or endangered species, to general environmental quality, or for other reasons as designated by the State or Federal government.

DO: Dissolved oxygen; the concentration of free molecular oxygen in the water column.

Drogue-release study: A study of currents and circulation patterns using objects, or drogues, placed in the water at the surface or at specified depths.

Dye-release study: A study of dispersion using nontoxic dyes.

Exchange boundary: The boundary between one waterbody, e.g., a marina, and its parent waterbody; usually the marina entrance(s).

Fecal coliform: Bacteria present in mammalian feces, used as an indicator of the presence of human feces, bacteria, viruses, and pathogens in the water column.

Fixed breakwater: A breakwater constructed of solid, stationary materials.

Floating breakwater: A breakwater constructed to possess a limited range of movement.

Flushing time: Time required for a waterbody, e.g., a marina, to exchange its water with water from the parent waterbody.

Gyre: A mass of water circulating as a unit and separated from other circulating water masses by a boundary of relatively stationary water.

Hydrographic: Pertaining to ground or surface water.

Ichthyofauna: Fish.

Macrophytes: Plants visible to the naked eye.

Mathematical modeling: Predicting the performance of a design based on mathematical equations.

Micron: Micrometer; one-one millionth (0.000001) of a meter.

NCDEM DO model: A mathematical model for calculating dissolved oxygen concentrations developed by the North Carolina Division of Environmental Management (NCDEM).

No-discharge zone: An area where the discharge of polluting materials is not permitted.

NPDES: National Pollutant Discharge Elimination System. A permitting system for point source polluters regulated under section 402 of the Clean Water Act.

Numerical modeling: See *mathematical modeling.*

Nutrient transformers: Biological organisms, usually plants, that remove nutrients from water and incorporate them into tissue matter.

Organics: Carbon-containing substances such as oil, gasoline, and plant matter.

PAH: Polynuclear aromatic hydrocarbon; multiringed carbon molecules resulting from the burning of fossil fuels, wood, etc.

Physical modeling: Using a small-scale physical structure to simulate and predict the performance of a full-scale structural design.

Rapid bioassessment: An assessment of the environmental degradation of a waterbody based on a comparison between a typical species assemblage in a pristine waterbody and that found in the waterbody of interest.

Removal efficiency: The capacity of a pollution control device to remove pollutants from wastewater or runoff.

Residence time: The length of time water remains in a waterbody. Generally the same as *flushing time.*

Riparian: For the purposes of this report, riparian refers to areas adjoining coastal waterbodies, including rivers, streams, bays, estuaries, coves, etc.

Sensitivity analysis: Modifying a numerical model's parameters to investigate the relationship between alternative [marina] designs and water quality.

Shoaling: Deposition of sediment causing a waterbody or location within a waterbody to become more shallow.

Significant: A quantity, amount, or degree of importance determined by a State or local government.

SOD: Sediment oxygen demand; biochemical oxygen demand of microorganisms living in sediments.

Suspended solids: Solid materials that remain suspended in the water column.

Tidal prism: The difference in the volume of water in a waterbody between low and high tides.

Tidal range: The difference in height between mean low tide and mean high tide.

Velocity shear: Friction created by two masses of water moving in different directions or at different speeds in the same direction.

WASP4 model: A generalized modeling system for contaminant fate and transport in surface waters; can be applied to BOD, DO, nutrients, bacteria, and toxic chemicals.
