ABSTRACT

This proceedings, ***Stormwater NPDES Related Monitoring Needs***, consists of papers presented at the Engineering Foundation Conference held in Colorado, August 7-12, 1994. The Conference brought together 90 experts in the field of urban stormwater management to discuss the current state of the U.S. Environmental Protection Agency's Nonpoint Pollution Discharge Elimination System (NPDES) regulations related to discharges of urban stormwater, and the monitoring requirements under those regulations. The objective was to summarize the current state of stormwater monitoring with respect to meeting these regulatory requirements, and to lay out an agenda for the future. Technical sessions included: 1) An overview of stormwater monitoring needs; 2) locating illicit connections; 3) system runoff characterization; 4) NPDES compliance monitoring; 5) policy and institutional issues o NPDES monitoring; 6) BMP monitoring for data transferability; 7) monitoring receiving water trends; and 8) stormwater and best management practice (BMP) monitoring. There were also extensive discussions, as well as a number of adhoc meetings. A major conclusion reached by the conferees was that existing monitoring requirements will not yield the information necessary to determine impacts on the environment or to evaluate the effectiveness of BMPs.

FOREWORD

The Urban Water Resources Research Council (UWRRC) of the American Society of Civil Engineers has for 30 years been a leader in the transfer of urban stormwater technology among researchers, practitioners and administrators. One of the principal means of accomplishing this transfer has been through a series of Engineering Foundation Conferences, held in the United States and abroad, as well as International Symposia and technical sessions at professional conferences.

The Council has recognized for some time that there have been numerous concerns related to the monitoring requirements of the current U. S. Environmental Protection Agency NPDES regulations, and particularly those governing discharges of stormwater to the environment. Because of these concerns, and because the Council itself felt that there were many technical and administrative problems with these regulations, the Council organized this Conference on stormwater NPDES related monitoring needs. It was the aim of the Conference to bring together experts in all fields related to these needs, including those from the regulatory agencies and the regulated community. What resulted was a mix of perspectives and expertise representing industry and state and local governments, together with their technical staffs and consultants.

All of the papers presented in the regular sessions were by invitation, and were reviewed and accepted for publication by both the Conference Chairman and by the Proceedings Editor. Papers in Appendix A (Poster Papers) were unsolicited, and only received an editorial review for format, etc. All papers are eligible for discussion in the Journal of the Water Resources Planning and Management Division of the American Society of Civil Engineers (ASCE). All papers are eligible for ASCE awards.

The Proceedings are organized by "session", corresponding to the actual conference sessions. Formal papers are presented first, followed by a session discussion which may include both material presented by an author which is not necessarily in his paper, as well as comments/questions from participants, and the answers to those questions furnished by the author (or, in some cases, by other conference participants).

ACKNOWLEDGEMENTS

The Conference organizers gratefully acknowledge the financial support of the U. S. Environmental Protection Agency and the Engineering Foundation, without which the Conference would not have been possible.

Particular thanks are due to the Conference organizing committee:

Ben Urbonas, Chairman
Michael B. Cook, Co-Chair
Christine B. Andersen, Co-Chair
Harry C. Torno, Proceedings Editor
Charles Beck
David R. Dawdy
William H. Frost
Jiri Marsalek
Tavit Najarian
A. Charles Rowney
Betty Rushton
Shaw L. Yu

These individuals gave generously of their time and energy to insure that the Conference would be a success.

Further thanks are due to the Conference co-sponsors, who provided guidance and support throughout, and especially to Michael Cook, William Swietlik, William Tate, Kevin Weiss and Robert Goo, all members of the EPA Support Group.

Thanks go also to the session Chairpersons, who were responsible for organizing their individual sessions, and ensuring that Conference deadlines were met.

Richard Horner
Marshall Jennings
Jon Sorensen
L. Scott Tucker
John Warwick
Wayne Huber
Larry A. Roesner
Eric Strecker
Ben Urbonas
Jim Wulliman

Particular thanks go to John Doerfer, Rich Horner, Wayne Huber, Larry Roesner, and Harry Torno, who diligently kept notes on the session discussions.

Finally, the Conference organizers would like to acknowledge the efforts of the Engineering Foundation staff - Dr. Charles V. Freiman, Director, Mrs. Barbara Hickernell, Director of Conferences, and Mr. Michael Salgo (ASCE, ex-officio member of the Engineering Foundation Board of Directors), who cheerfully and efficiently provided logistical and administrative support to the Conference.

Overview Summary of the Conference

Ben Urbonas, M.ASCE[1] and Harry C. Torno, M.ASCE[2]

Abstract

The Urban Water Resources Research Council of the American Society of Civil Engineers sponsored an Engineering Foundation Conference on Stormwater NPDES-Related Monitoring Needs, which was held August 7-12, 1994, in Crested Butte, Colorado. The Conference was prompted by concerns that, while we as a nation are spending millions of dollars on stormwater monitoring, we still are not able to predict the effects of stormwater discharges on the environment, particularly in the long term. Moreover, we are faced with even larger expenditures in the future.

The purpose of the Conference was to explore current needs and available technology associated with stormwater monitoring, and to bring together regulators, the regulated community, and their consultants, to determine what we, as professionals and as a nation, need to do to achieve the various goals set forth for stormwater in the Clean Water Act, and the municipal and industrial NPDES regulations that implement that act.

This summary provides a brief overview of the key points raised in the papers presented at the Conference, and of the discussions that surrounded those papers and related matters. The papers and discussions presented a reasonably balanced view from the viewpoint of the regulator, the regulated community, and researchers who are endeavoring both to provide the technical information necessary to meet regulatory requirements at reasonable cost, and to protect the environment.

<u>Introduction</u>

200 or so cities and counties in the U.S. have been required, by Part II of the U. S. Environmental Protection Agency's municipal NPDES separate stormwater discharge permit application, to spend large sums of money (estimated by some at about $60 million) to collect stormwater data. Many questions have been raised about both the validity of the requirement to collect these huge amounts of data, and the validity of the data itself, particularly in terms of evaluating the impacts on the environment and the usefulness of corrective measures which might be required.

For example, the Dallas-Fort Worth area spent approximately $2.9 million to satisfy Federal requirements, and industry in that area may have had to spend even more. It has become apparent that these costs are to a large extent the result of a profound lack of understanding, on the part of both the regulators and the regulated community (including their consultants), of the cost and complexity of obtaining meaningful stormwater quantity and quality data.

The goal of the Conference, therefore, was to bring together the regulated community, along with their experts and consultants, and the regulators, for the purpose of exploring where monitoring technology stands at this time, and determining the monitoring needs related to separate stormwater systems. The exchange that occurred at Crested Butte is documented in these Proceedings, in both the papers that were presented, and in the discussions that ensued. The following discussion summarizes the main issues raised at the Conference.

<u>Thoughts and Observations</u>

There was general agreement that current water quality standards, which tell us little about the <u>environmental health</u> of the nation's receiving waters, may be a significant detriment to the improvement of environmental quality. They are a huge resource drain (time, energy, money), and most stormwater professionals cannot support the requirements of these standards as being cost-effective. Furthermore, the standards impair effective communication between regulators and the regulated community, and confuse issues like what research should be done. Similarly, end-of-pipe measurements of pollutant discharges, which are used in the implementation of the water quality standards, tell us nothing about the impact of those discharges on the environment.

Such standards are not used in Canada or New Zealand, for instance. They choose instead to look at watersheds or basins in their entirety, and to establish, in a holistic sense, pollution control requirements which address overall environmental improvement.

Effective stormwater monitoring, whether physical, chemical or biological, is very difficult and expensive. Currently, NPDES regulations (and the individual

VOL 12

7360

regulators, whose interpretations of those regulations may vary considerably) require permittees to collect vast amounts of stormwater monitoring data. Much of the data collected pursuant to these requirements appears to be inappropriate and of little value, either locally or nationally, either to the regulator or the permittee.

Individuals in regulatory agencies charged with writing regulations and/or permits, and with their implementation, frequently do not have enough training and experience, considering the technical and administrative complexities involved. There is considerable concern on the part of regulated communities and industries that permit writers will continue to use the results of current monitoring, whether meaningful or not, to justify additional monitoring and additional control requirements, and that the costs involved will be prohibitive.

Toxic concentrations of certain pollutants are sometimes found in stormwater, but there is a question about the degree of stress they cause because of:

- The short-term exposure of the biota to these toxicant concentrations (there is, in fact, little data available on the duration of the exposure).
- The form of the constituent that is measured. Most measurements are of total recoverable concentrations of a pollutant, whereas, in reality, the dissolved or ionic form is the real toxicant. For instance, one typically measures total recoverable concentrations of lead, rather than the ionic (toxic) form.

Very little meaningful monitoring is being directed toward measuring the actual effect of stormwater discharges on the short- or long-term health of the environment. Furthermore, there is no consensus on how this monitoring should be done.

Despite considerable research, we have generally been unable to identify reliable indicators (which can substitute for the monitoring of a wide range of pollutants or toxic effects) of pollution or of environmental degradation. The search continues, but we have a long way to go in establishing these indicators, if indeed it can be done at all.

Cause and effect relationships in urban ecosystems will be very difficult to determine. Experiments will need to be designed with each specific site in mind. Rigid national protocols will not help, and may in fact hinder sound local experimental design. It will nonetheless be necessary to have general scientific guidance at the national level so as not to sacrifice good science for regulatory expedience.

Some leading biologists, biochemists, ecologists, etc. have undertaken the study of the effects of urban stormwater discharges on the environment, particularly in

VOL 12

7361

England and the U.S. This involvement, which is critical if the programs alluded to here are to be successful, has already served to broaden the knowledge base, and to facilitate communication between disciplines which have, in the past, not had much interaction.

There is a clear need for large, nationally-funded investigations that can direct sufficient resources, provide sound experimental design, and provide adequate quality control, to, over time, permit environmental scientists and engineers to draw conclusions concerning environmental health, to evaluate alternatives for controlling or improving stormwater quality, and to determine how best to utilize our limited resources to achieve the greatest benefits.

Excellent progress has been made in developing techniques for locating illicit connections, which are a significant source of contamination of stormwater. This progress has been reported in these Proceedings, and in several EPA documents. Despite this progress, however, some further work is still necessary.

Source control of pollutants is a critical fundamental need. All projects which reported lead concentrations from urban runoff, for instance, clearly indicated that lead concentrations are lower now than they were, say, ten years ago, and that these reductions can be directly attributed to the use of lead-free gasoline.

Diazinon continues to be a ubiquitous urban environmental pollutant. Virtually all of the studies reported at the Conference found diazinon present in urban runoff from residential areas - to the extent that there were suggestions that it could be used as an indicator of the presence of this runoff. Thus, it may be necessary to re-evaluate its importance as an environmental pollutant.

Similarly, automobile brake pads and atmospheric deposition seem to be significant sources of copper in stormwater, and programs for their control, similar in nature to the use of unleaded fuel to reduce lead emissions, may be required (and may also be most cost-effective).

Funding constraints at the local and state level are impediments to reaching the goal of a better environment. EPA's estimates of funding requirements have, for the most part, been too low. Local administrators frequently have difficulty in justifying the cost of stormwater monitoring programs to their constituents because there is no perceived benefit - stormwater is not viewed as a serious environmental problem. At the same time, although less federal funds are available (EPA's funding situation is often no better than that of the local communities), local governments still must comply with NPDES regulations.

Despite the many ongoing projects which are evaluating best management practices (BMPs) for the enhancement of stormwater quality, there is a lack of consistency in the way monitoring data are being collected, the type and form of information being reported, and the methods for drawing conclusions (and reporting those conclusions) from the data. Most such evaluations appear to lack a design engineer's perspective, in that they do not permit the use of the information gathered to develop more effective and reliable designs. As a result, the data base available for BMP design is very limited.

There is a consensus that the meaningful monitoring of receiving waters is the most difficult technical problem currently facing us. If these monitoring programs are to provide us with the requisite information on the health of the environment, and on the impacts that stormwater discharges will have on that environment, they must be very carefully designed - both the programs and their physical, chemical and biological components - by environmental scientists in a wide variety of disciplines working in concert with engineers and planners.

There are several excellent examples of well-designed and managed programs in these Proceedings (see papers by Livingston, and by Shaver and Maxted), so it is clear that such projects are possible. They typically require, however, the co-operation of a number of levels of government, of multiple local agencies, and of industry. They must, in addition, have the involvement of the best experts in the engineering and scientific community.

Conclusions

We learned much from each other at Crested Butte about NPDES-related stormwater monitoring. In particular, we learned that, in spite of all that we now know, we understand very little. It is clear that laws, rules, regulations, and best intentions will not change that fact. Only good research programs, involving the best engineering and scientific minds, will improve our level of understanding.

If we are to acquire this understanding, we must stop wasting monitoring resources on the "laundry list" type of monitoring encouraged or required by our current regulations. We must instead move towards well-designed and adequately funded national and regional scientific study programs and research efforts.

WELCOME FROM THE UWRRC AND PERSPECTIVE

Jonathan E. Jones, P.E., M.ASCE[1]

ABSTRACT

This paper briefly summarizes highlights of previous urban water resources-related conferences sponsored by the American Society of Civil Engineers and Engineering Foundation that relate to the issues that will be discussed at this conference.

On behalf of the nearly 100 members of the American Society of Civil Engineers (ASCE) Urban Water Resources Research Council (UWRRC), I welcome you to Crested Butte. I hope that you and the members of your families take advantage of the wonderful recreational opportunities that the area has to offer. The UWRRC appreciates the excellent work of the Conference Organizing Committee. We also sincerely appreciate the financial and other assistance provided by the U.S. Environmental Protection Agency (EPA), Engineering Foundation, and ASCE.

The UWRRC has been a leader in urban stormwater quantity and quality management issues for over 30 years. I thought that it might be instructive to look through the proceedings of previous conferences initiated by the UWRRC to see if the issues/needs that we are talking about in 1994 were identified earlier. Not surprisingly, they were. Consider the following direct quotations from the cited conferences:

1974: URBAN RUNOFF QUANTITY AND QUALITY

Study should be directed to eight specific areas of information needs:

1. Identification and evaluation of sources of pollution reaching urban runoff.

---

[1] Chairman, ASCE UWRRC, and Vice-President, Wright Water Engineers, Inc., Denver, Colorado.

2. Improvement of methods for identifying and measuring the pollutants reaching urban runoff.

3. Determination of conditions relating or affecting the production of specific pollutants, including the time and rate of pollutant production.

4. Application of such information to an expanded program of data collection.

5. Specification of legislation and organizational requirements appropriate to desired methods of control.

6. Determination of any incompatibilities between objectives of urban flood control and control of water quality in urban runoff.

7. Determination of opportunities in sewer design for reducing water quality problems including the effects of non-structural measures.

8. Determination of design factors when treatment of urban runoff is involved. The design problem becomes more complicated. In fact, urban drainage is an entirely new "ball game" when treatment is involved.

1978: WATER PROBLEMS OF URBANIZING AREAS

Priorities identified for immediate research:

1. Sources and effects of urban runoff pollution.
2. Control of non-point source and urban runoff in urban areas.
3. Improve local stormwater management for multiple purposes.
4. Alternative water quality criteria, taking into account effects of urban runoff.
5. Relationship of urban runoff to channel evolution.
6. Relationship of stream corridors to water quality.
7. Predicting eutrophication in urbanizing areas.

8. Management alternatives, including land use control, for lakes and wetlands in urbanizing areas.

9. Impact of alternative funding approaches on water quality strategy.

10. Groundwater management, including protection of recharge areas in urbanizing areas.

11. Demonstrated improvement of institutional arrangements for water management in urban areas.

__1982: STORMWATER DETENTION FACILITIES - PLANNING, DESIGN, OPERATION, AND MAINTENANCE__

Important research needs:

1. Systematic evaluation of the performance of existing detention facilities to relate their effectiveness to basin design characteristics.

2. Research leading to improved understanding and better predictive techniques related to transport and accumulation of pollutants in saturated and unsaturated groundwater systems below detention facilities.

3. Characterization of stormwater pollutants in terms of parameters related to the design and performance of detention facilities.

__1986: URBAN RUNOFF QUALITY - IMPACT AND QUALITY ENHANCEMENT TECHNOLOGY__

Identified research needs:

1. We need to know more about the field performance of some control technologies including vegetative buffer strips, infiltration/exfiltration, wet and dry detention with filtration, and wetlands.

2. Performance criteria should be developed for commonly used materials such as filter cloth, particularly when used as a silt fence.

3. To the extent feasible, control technology failure should be documented and shared.

4. We need additional research to define inspection, maintenance, and operation requirements or tasks and associated costs.

5. The early emphasis on quantity at the expense of quality must not be replaced by a new emphasis on quality at the expense of quantity. We need case study data to highlight the importance of simultaneously addressing quantity and quality.

1989: URBAN STORMWATER QUALITY ENHANCEMENT - SOURCE CONTROL, RETROFITTING, AND COMBINED SEWER TECHNOLOGY

Conference participants developed the following list of prioritized research needs:

1. Receiving water impacts, including development of receiving water quality standards.
2. Real-time monitoring techniques, including water quality, flow, and treatment plant operational parameters.
3. Effects of wet weather flows on treatment plant performance.
4. Rehabilitation of urban streams - techniques for restoring capacity and aesthetic appeal.
5. Pollutant transport and transformation mechanisms in sewers.
6. Evaluation of the performance of treatment devices.
7. Effects of infiltrated runoff on the environment.
8. Review/comparison, on a worldwide basis, of storm and combined sewer regulations and standards.

After reflecting upon these and other conference proceedings, there is clearly a "continuous thread" that runs through the discussion at these conferences. The issues that we were discussing 20 years ago remain relevant and important today.

TRENDS IN NPDES MONITORING FOR STORM WATER

June 1994

by

Michael B. Cook[1], Kevin J. Weiss[2], and William F. Swietlik[3]

INTRODUCTION

Traditionally, monitoring requirements under the National Pollutant Discharge Elimination System (NPDES) program have emphasized analyzing pollutants in discharges at the end the end of the pipe. However, EPA anticipates that a number of recent initiatives will be changing the direction of monitoring in general and, when coupled with the evolving needs of the storm water program, will result in more comprehensive, improved and better integrated approaches to monitoring storm water in the future.

OVERVIEW OF NEW INITIATIVES

EPA is participating in a number of initiatives that will shape and improve the Agency's monitoring and data collection efforts. Five initiatives that will directly impact monitoring in the NPDES storm water program include:

- the Intergovernmental Task Force on Monitoring Water Quality (ITFM)
- the EPA- National Goals Project
- the Office of Water- NPDES Watershed Strategy
- the Office of Water environmental indicators project.
- the Office of Wastewater Management storm water environmental indicators project.

[1] Director, Office of Wastewater Management (4201), United States EPA Headquarters, 401 M Street S.W., Washington DC, 20460.

[2] Storm Water Section (4203), United States EPA Headquarters, 401 M Street S.W., Washington DC, 20460.

[3] Chief, Storm Water Section (4203), United States EPA Headquarters, 401 M Street S.W., Washington DC 20460.

Intergovernmental Task Force on Monitoring Water Quality (ITFM):

The ITFM was established in 1992 to develop a strategy to solve a number of problems associated with water-quality monitoring activities[4]. The Task Force grew out of the recognition that environmental programs are moving beyond single-media, technology-based approaches towards holistic programs based on risk reduction and pollution prevention. As environmental programs change to more holistic risk-based approaches, monitoring needs become more complex, with new emphasis on:

- Watershed, ecosystem and geographically based programs,
- Biological resources, ecology and habitat,
- Nonpoint source remediation programs,
- Wetlands and coasts, and
- Sediment quality.

The mission of the ITFM is to develop and implement an integrated, voluntary, nationwide strategic plan that provides recommendations for achieving effective collection, interpretation, and presentation of water-quality data to improve the availability of information for decision making at all levels of the government. The strategy was developed in 1992[5]. The goal of the strategy is to provide water-quality data that meet the following four objectives:

1) define water quality status and trends;

2) identify existing and emerging water quality problems;

---

[4] The ITFM is a federal/state/tribal partnership with representatives from 20 agencies and organizations. ITMF members include: the Army Corps of Engineers, Department of Energy, National Oceanic and Atmospheric Administration, National Park Service, Office of Management and Budget, Tennessee Valley Authority, U.S. Department of Agriculture, U.S. EPA, U.S. Fish and Wildlife Service/National Biological Survey, U.S. Geological Survey, Arizona, California, Colorado, Delaware River Basin Commission, Florida, New Jersey, Ohio, Potahatomi Community, South Carolina, Washington, and Wisconsin. The ITFM is chaired by EPA, and the USGS is vice chair.

[5] See "Ambient Water-Quality Monitoring in the United States - First Year Review, Evaluation, and Recommendations", ITFM, December 1992.

3) develop and implement policies and programs for water-resource management and regulation; and

4) evaluate water programs effectiveness.

The strategy includes both a national committee to develop monitoring guidelines and standards, and regional committees to tailor those guidelines to regional needs and to encourage agency participation in the strategy. Tasks planned by the national committee are shown in Table 1. Products that have been or are being developed by the ITMF are shown in Table 2.

EPA National Goals Project:

EPA is in the process of developing a set of broad environmental goals for the Agency. The project's goal is to produce, by Earth Day, April 22, 1995, a set of ambitious, realistic and measurable environmental goals to be achieved in the next century. As part of this effort, the Agency has identified three goals which relate to controlling pollutant sources to surface waters: clean surface waters, safe drinking water, and ecological protection. The Agency is in the process of identifying measures that can be used to evaluate progress towards meeting these goals.

In a complementary effort, the Office of Water issued a Strategic Plan to provide a framework for Office of Water goals and measures of success. A key part of this plan are a series of national environmental goals and environmental indicators. The plan also calls for working closely with the States to put together action plans for reporting on these goals and indicators over time.

As part of the plan, the Office of Water has established four major strategic goals for water programs, shown in Figure 1. Each goal contains one or more subgoals:

♦ PROTECT AND ENHANCE PUBLIC HEALTH (meet designated uses)

- Safe Drinking Water
- Safe Fish and Shellfish Consumption

VOL 12

7371

Table 1 - Tasks of the ITFM National Committee

1. Develop, for each monitoring objective, a set of questions to address issues.
2. Develop QA/QC guidelines for all aspects of the strategy.
3. Develop and update a core list of environmental indicators.
4. Determine the comparability of field and laboratory methods.
5. Develop station selection guidelines.
6. Promote data sharing among major information systems.
7. Identify formatting of ancillary data needed to interpret water-quality data.
8. Promote the development and standardization of data-analysis techniques.
9. Develop unified formats for reporting water-quality information.
10. Develop and organize training for personnel of participating agencies.

VOL 12

7372

VOL 12

Table 2 - Products Developed or Being Developed by the ITFM

Product	Description
National Charter	A charter for a permanent national body to guide the implementation of the ITFM recommendations and to facilitate further collaboration of the many Federal, State, Tribal, regional, local, private, and voluntary organizations that are involved in monitoring.
Monitoring Framework	A framework for monitoring water quality which defines the components that a monitoring program should consider in order to ensure that it accomplishes its objectives.
Indicator Selection Criteria	Criteria with which to select parameters that measure progress in achieving water-quality goals.
Environmental Indicators Recommendations	ITFM recommendations of indicators to measure whether water-quality uses designated by the State are being met.
Methods and Data Comparability Council Charter	A charter for a Methods and Data Comparability Council to foster the development and use of performance-based methods of collection and analysis in a manner which will result in the acquisition of data of known quality. The Council will address some of the biggest obstacles to sharing data among monitoring agencies and other users.
Use of Ecoregions, Reference Conditions, and Index Calibration	An examination of reference conditions as a tool in biological assessment, and the use of the ecoregions concept as a way to categorize landscapes on which assessments are carried out.

These products are described in more detail in "Water-Quality Monitoring in the United States-1993 Report of the Intergovernmental Task Force on Monitoring Water Quality," ITFM, January 1994.

7373

R0040681

- Safe Aquatic Recreation

◆ CONSERVE AND ENHANCE ECOSYSTEMS (meet designated uses)

- Biologically Healthy Water Resources

◆ IMPROVE AMBIENT CONDITIONS

- Improved Surface Water Ambient Concentrations of Toxic and Conventional Pollutants
- Ground Waters Meet Water Quality Objectives
- No Net Loss of Wetlands
- Extent of Contaminated Sediments is Reduced

◆ REDUCE POLLUTANT LOADINGS (point and nonpoint sources)

- Reduced Toxic Pollutant Loadings
- Reduced Conventional Pollutant Loadings

NPDES Watershed Strategy:

In March of 1994, EPA issued the NPDES Watershed Strategy. The Strategy is a first step toward the goal of integrating the NPDES program into a comprehensive, multi-program approach to addressing surface water, ground water, and habitat concerns on a watershed basis. The NPDES Watershed Strategy outlines national objectives and implementation activities to (1) integrate NPDES program functions into broader watershed approaches; and (2) support the development of State-wide basin management approaches.

One of the six essential areas identified in the Watershed Strategy is monitoring and assessment. Action items identified in the Strategy to support monitoring and assessment include:

- Develop a State-wide monitoring strategy to assure the most effective targeting of limited monitoring resources and coordinate collection and analysis of NPDES, nonpoint source, and other watershed data.

VOL 12

7374

VOL 12

- Establish point source ambient monitoring requirements where appropriate to support assessment of watershed conditions; this action may provide opportunities for group monitoring plans for multiple discharges to the same basin.

- Promote comparable data collection, analysis, and utilization by all stakeholders (e.g. NPDES, 303(d), 304(l), and 319) through revisions to information collection and management systems (e.g., permit applications and compliance monitoring, PCS, TMDL development, 305(b), NEP, STORET, and water body systems)

As the NPDES program moves further towards embracing the watershed strategy, monitoring in the NPDES storm water program, as in all NPDES program areas, will need to evolve to be fully supportive.

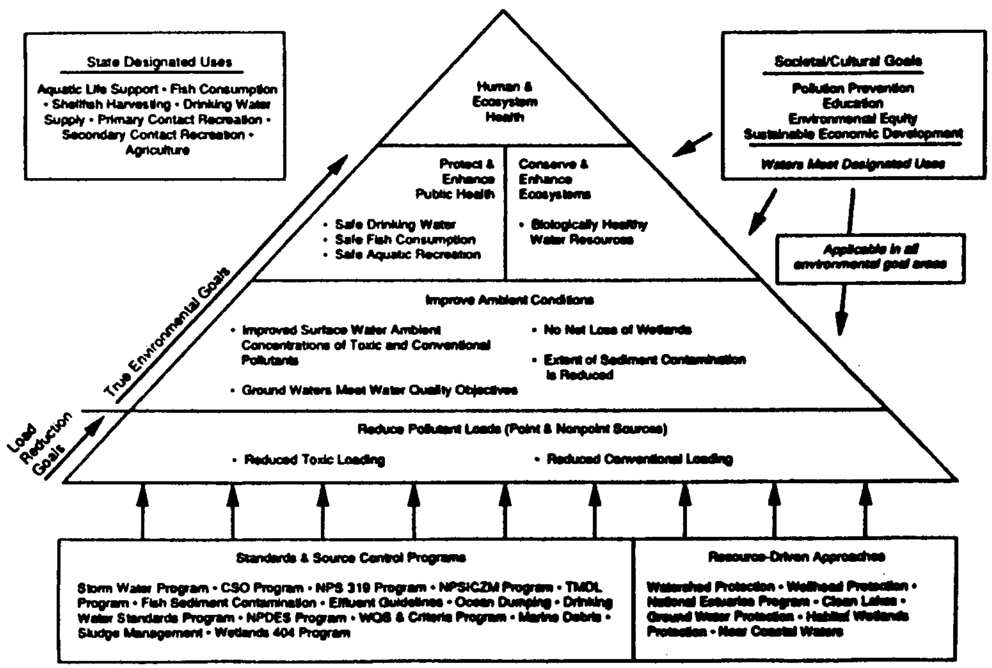
<u>The Office of Water Environmental Indicators Project:</u>

The Office of Water is proposing to evaluate progress in meeting the goals of the Strategic Plan by using a number of environmental and programmatic indicators. These indicators, when adopted, will have a strong influence on the purpose, direction and types of monitoring employed in Office of Water programs in the future. Recommended preliminary indicators for the strategic goals are outlined in Table 3. To complete this effort a significant amount of work remains, including:

- selecting indicators that major participants can agree on,
- establishing a nationwide monitoring and data system that:
  - uses information from various sources to support management systems and report on progress towards national goals,
  - uses comparable collection, reporting and analytical methods,
  - stores data of known quality in systems that can "talk" to each other,

7375

Figure 1 - Office of Water Strategic Goals



- has clear roles and responsibilities and focusses use of available resources from many sources (EPA, other Federal agencies, States, utilities, etc.).

In fiscal year 1995, EPA will be taking two major steps towards implementing the Office of Water Strategic Plan. The first step will be funding a series of State pilot projects to test selected environmental indicators. Eight States[4] will be implementing the pilot projects, lasting 18 to 24 months, using indicators from the list of 33 national indicators developed by EPA. The States will use the indicators to measure success towards reaching the goals of protecting human health, conserving and enhancing ecosystems, improving ambient conditions, and reducing pollutant loadings. These pilot projects will be our first real attempt to test "on the ground" whether the necessary steps to implement and track environmental indicators over time can be successful. The pilots will serve another important purpose--to determine if selected environmental indicators can compliment or substitute over time for some of our current programmatic measures of success for State water programs that are activity-based (such as number of permits issued and enforcement actions taken). We are very pleased with the enthusiasm shown by the States for the environmental indicators pilot project.

The Office of Wastewater Management Storm Water Environmental Indicators Project:

As a complement to the Office of Water environmental indicators effort, the Office of Wastewater Management is initiating a project that will identify and implement environmental indicators specific to the NPDES storm water program.

To accomplish this, EPA is issuing a series of grants to support the selection and implementation of storm water environmental indicators that can be used by municipalities and industries to assess the effectiveness of their storm water control efforts and to possibly provide data for the national environmental indicators tracking system. The project, which will be implemented for the most part in fiscal year 1995, includes:

[4] The States tentatively selected for the pilots are Maine, Delaware, Maryland, Georgia, South Carolina, Wisconsin, Ohio and possibly Nevada. In addition, EPA is considering a local project under the National Estuary Program in Oregon.

- compiling a summary of recent efforts to develop and implement environmental indicators for storm water discharges;
- holding a series of stakeholder meetings around the country to select environmental indicators for the storm water program, including a select list of indicators to be used for national tracking;
- preparing a report on the results of the stakeholder meetings describing the environmental indicators selected and the methodologies and criteria for implementation; and,
- awarding grants for a series of demonstration projects on implementing storm water environmental indicators.

It is the objective of this project that valuable information for selecting and implementing storm water program environmental indicators will be developed which should significantly guide the direction of storm water monitoring in the future.

Upon completion of the storm water environmental indicators demonstration projects, EPA hopes that numerous municipalities and industries will better understand, and be better equipped, to implement effective monitoring strategies for assessing their storm water management programs.

The data that is generated by municipalities, and other sources, if done in a consistent, quality fashion, should be applicable at the national level for tracking and assessing progress of the NPDES storm water program towards accomplishing the Office of Water strategic goals.

SUMMARY

Several national initiatives will directly impact the future of monitoring in the NPDES storm water program. The Intergovernmental Task Force on Monitoring Water Quality (ITFM) will be recommending that monitoring efforts be more holistic in nature and will be developing national and regional guidelines and standards for monitoring.

* Adequate data exists in the near term to establish baseline information.

The EPA National Goals Project will produce a set of realistic and measurable environmental goals to be achieved in the next century. The Goals Project will involve identifying monitoring that can be used to effectively evaluate progress towards meeting the goals.

Under the new NPDES Watershed Strategy, monitoring and assessment have been identified as an essential element to be addressed. Important objectives of the Strategy are the development of State-wide monitoring strategies to assure the more effective targeting of limited monitoring resources and the coordination of the collection and analysis of data, and the use of receiving water monitoring procedures where appropriate to support assessment of watershed conditions.

The EPA Office of Water is proposing to evaluate progress in meeting the goals of the EPA Strategic Plan by using a number of environmental and programmatic indicators. These indicators, when adopted, will have a strong influence on the purpose, direction and types of monitoring employed in water programs in the future.

Finally, the Office of Water, Office of Wastewater Management is planning the development of a set of environmental indicators that can be used specifically by storm water dischargers to evaluate progress towards meeting the goals of the NPDES storm water program and, more broadly, the strategic goals of the Office of Water.

These initiatives will result in a number of changes to monitoring approaches under the NPDES storm water program in the future. As monitoring requirements under the NPDES storm water program change and evolve, storm water professionals will be presented with unique opportunities to provide insight and expertise on innovative approaches to storm water monitoring at national, State and local levels.

American Public Works Point of View

Christine F. Andersen[1], M.ASCE

Abstract

Public works agencies are responsible for implementing the regulations regarding stormwater in the NPDES program. As such they become the agencies responsible for balancing environmental protection, community interests, political interests, financial constraints and the technical skills and resources necessary to carry out the goals of the Clean Water Act. To carry out this implementation role effectively there is a critical need to build the level of technical knowledge and understanding of stormwater quality and promote opportunities for sharing this information. Pressure for funding at the local level is creating tremendous resistance in communities across the country. Gaining community understanding and support requires the ability to clearly articulate environmental benefits and cost effective application of resource to address local problems. Without grassroots support, communities will become the biggest roadblocks to achieving the goals of the Clean Water Act.

Introduction

Since the reauthorization of the Federal Clean Water Act in 1987, the requirement that municipalities with populations greater than 100,000 obtain NPDES permits for separate storm sewer systems has been implemented. Across the country affected public works agencies responsible for stormwater have been developing

1. Director, Department of Public Works, City of Eugene, 858 Pearl Street, Eugene, OR 97401

stormwater quality programs and seeking permits from state environmental regulatory departments in those NPDES designated states or from EPA. The investment of resource in permit application and the sampling and data base development is significant. The resource requirement for implementation and monitoring of Best Management Practices (BMP's) covered by those permits will require an ongoing commitment.

In the early years following the 1972 adoption of the Federal Water Pollution Control Act when the primary focus of the clean water program was wastewater, up to 90% of the funding required for local agency implementation was provided from federal and state sources. Today, program costs are borne almost entirely at the local level. This fact, along with similar program funding shifts in virtually every area of local government agency programming, has presented real challenges to the implementation of the stormwater NPDES program. Coupled with that challenge is the fact that agencies across the country are scrambling to build stormwater programs based on relatively limited research and experience in the whole area of stormwater monitoring and BMP effectiveness.

Capturing and Sharing Information

Huge data bases of stormwater sampling and BMP monitoring information are being generated across the country through implementation of mandated stormwater programs. It is still uncertain when or how municipalities with populations less than 100,000 will be brought into the stormwater NPDES program. For those 200 or so communities already embarking on their first permit, there is much to learn and share. The focus of this conference is timely and critical to the effective use of the significant resource going into current permit development and implementation. It is essential that communities be able to learn from each other and share information reliably and effectively. In addition, EPA needs to be able to use the information being reported under these permits to base future Clean Water Act changes on improved understanding of stormwater quality problems. The Nationwide Urban Runoff Program (NURP), which served as the basis for the 1987 Clean Water Act amendments covering the stormwater quality program, was relatively limited, covering only 28 cities. The number of communities currently required to be permitted under NPDES and the type of data being generated should result in a far clearer picture of the need for future stormwater program regulatory changes if that data is captured and used effectively.

Not too long ago, it would have been unthinkable to expect communities to take on a research and development role for a problem of this magnitude. Unfortunately, today that is precisely where local communities find themselves. Strategies and techniques are being identified, tested and monitored in the hope that they will result in improved water quality conditions and that it will be feasible to accurately detect environmental improvements.

VOL 12

7383

In many cases, consultants working in partnership with public works agencies are providing the vehicle for technology transfer. Communities are now sharing experiences and information through common consultants, even as the regulatory agencies struggle to develop their own administrative programs. The attendance and participation at this conference reflects both this relationship and the strong common interest in sharing information and learning from other professionals engaged in the development and implementation of stormwater quality programs. This approach has been surprisingly effective but it is not adequate to handle the growing demand and need for transferable information. Authorization and funding of the National Academy of Sciences to evaluate research and development programs and provide an umbrella for better coordination and utilization of colleges and universities in expanding environmental research programs would be important and appropriate steps.

Funding

Program funding is a serious constraint. The issue of unfunded mandates has generated a tremendous local community lobbying effort in Congress and impeded the adoption of the new Clean Water Act. Across the country the demand for funding at the local level to support federal and state mandated programs, as well as those identified by local priorities, is continuing to grow. Revenue limitation initiatives are appearing throughout the states. The strategy used in many communities to implement a stormwater quality program has been the creation of a stormwater utility. That is not a problem-free option and may become even more difficult to initiate and manage over time. As an example, in Oregon there is a statewide initiative measure on the November 1994 ballot that would prohibit any new fees or changes to an existing fee without a public vote. In short, without local support for the implementation of local programs, funding will be more and more at risk. With an eye to the future and the goals of the 1972 Clean Water Act to "restore and maintain the chemical, physical, and biological integrity of the Nation's waters," it is critical to build a foundation of community consensus and support and not rely on the force of federal mandates to achieve these goals.

Building Community Consensus

Gaining community support, particularly where funding is involved, is becoming more and more difficult as public sentiment regarding government and governmental agencies continues to deteriorate. In testimony before the House Subcommittee on Water Resources and Environment this past May, EPA Administrator Carol Browner described the goal of the reauthorized Clean Water Act as "a better, more flexible clean water act that will result in increased protection for our water resources at a lower cost." Flexibility and cost effectiveness are minimum requirements for the achievement of local support. Better understanding of BMP effectiveness and the ability to shift resource from ineffective strategies to other,

VOL 12

7384

more environmentally beneficial ones are basic needs to ensure continued local support. The ability to demonstrate results and contain the otherwise spiraling resource demanded from urban residents are necessities for local program support. The ability to accurately describe the real benefits to a community that are derived from the development, implementation and maintenance of a local stormwater program is critical to gaining and sustaining local support.

Where Do We Go From Here?

The purpose of this conference is to target current needs and future directions. Months and months of work has gone into the drafts of Clean Water Act reauthorization bills that will not make it through Congress this year. Many of the individuals responsible for hammering out language in those bills are at this conference and undoubtedly have perceptions to share about possible next steps. Focusing on common goals for environmental protection and clean water will help to ensure that progress continues to be made as these needs are sorted out.

Overview of Stormwater Monitoring Needs

Kelly A. Cave[1], A.M. ASCE
Larry A. Roesner[2], Ph.D, M. ASCE

Abstract

Runoff pollution studies have attempted to quantify the stormwater pollution load contribution to surface waters since the early 1970s. This paper presents a select summary of what has been learned from previous stormwater monitoring programs and offers recommendations to help guide the future direction of such programs.

Introduction

Since the early 1960s, stormwater runoff has been recognized as a significant source of pollution to the nation's waterways. Since the early 1970s, there has been a growing body of runoff pollution research to quantify the stormwater pollution load contribution to surface waters and to characterize stormwater pollutant generation, transport, and fate. Recently, over 100 U.S. cities and numerous industries collected stormwater runoff data under the Phase I National Pollutant Discharge Elimination System (NPDES) stormwater permitting program. Additional stormwater runoff data will be collected as the Phase I NPDES permits are issued and in other stormwater programs around the world. Stormwater runoff data collection is also likely to be required under the Phase II NPDES program which will be defined this fall.

This paper presents a select summary of what has been learned from previous stormwater monitoring programs and offers recommendations help guide the future direction of such programs.

What We've Learned from the Past

Since the early 1970s, runoff pollution research studies have attempted to quantify the stormwater pollution load contribution to surface waters and to characterize stormwater pollutant generation, transport, and fate. In the late 1970s, the "208 studies" implemented under Section 208 of the Federal Water Pollution Control Act Amendments of 1972 showed that stormwater generally contributed as much as half of the total pollutant load entering U.S. surface waters. This realization led to the U. S. Environmental Protection Agency's (USEPA) development of the Nationwide Urban Runoff Program (NURP) which was initiated to characterize the water quality of urban runoff and the potential for water quality impacts in receiving waters. NURP represents the largest research effort targeting urban stormwater runoff to date. Storm event monitoring was performed at 81 outfalls at 28 cities across the U.S. during the years 1978 through 1983.

The large number of sites monitored under the NURP program represented a wide variety of climatological conditions, land use types, land slopes, and soil types, thereby providing the basis for identifying similarities and differences among sites. Approximately 2,300 storm events were monitored, which corresponds to an average of 28 storms per outfall site. At a particular site, the monitoring was typically conducted over a 12-month period. Urban land uses monitored during the study included. residential, commercial, and limited light industrial. Several of the NURP cities also monitored receiving waters to characterize impacts of urban runoff on receiving water quality. A variety of receiving waters were monitored, including rivers, lakes and estuaries.

The NURP sampling program included a wide range of water quality constituents. For all of the 2,300 storms events monitored, constituents analyzed included total suspended solids (TSS), chemical oxygen demand (COD), biochemical oxygen demand (BOD), total phosphorus, dissolved phosphorus, total Kjeldahl nitrogen (TKN), nitrite + nitrate nitrogen, fecal coliforms, lead, zinc and copper. In addition, a limited number of grab samples were collected during 121 storms and were subsequently analyzed for priority pollutants. At the time, the priority pollutant list included 129 constituents.

The event mean concentration (EMC), which is defined as the total constituent mass in runoff divided by the volume of runoff during a given storm event, was established as the primary water quality statistic in the NURP study. EMCs were estimated at monitoring sites for individual storm events by collecting and analyzing flow-weighted composite samples of runoff generated by each event. At other sites, however, the monitoring consisted of a set of sequential discrete samples collected during a storm event. For these sites, EMCs were calculated by analyzing the hydrographs (flow vs. time) and pollutographs (concentration vs. time) from each storm.

USEPA analysis of the pooled national database from all of the project sites could not explain the variability of the pooled national EMC values by any single factor such as land use, soil type, land slope, climatology or geographic location. These and other transferability evaluations led to the development of a general characterization of urban runoff which can be used nationwide for estimating stormwater pollutant loadings from unmonitored areas. The pooled national NURP urban runoff characterization was recommended for use in planning level water quality studies, unless more localized water quality data are available. Another product of the NURP study was the development of standard monitoring and data analysis approaches which have been used by many subsequent stormwater pollution studies.

Since the NURP study, other stormwater monitoring studies have continued to quantify the pollution load contribution to surface waters and to characterize stormwater pollutant generation, transport, and fate. The U.S. Geological Survey (USGS), for example, has developed an urban storm runoff database consisting of data for over 1,100 storms for 98 urban stations in 20 metropolitan areas. The Federal Highway Administration (FHWA) investigated stormwater runoff loadings from highways by analyzing storm event monitoring data at 31 highway runoff monitoring sites in 11 states during the 1970s and 1980s.

NPDES Stormwater Monitoring

Recently, over 100 U.S. cities and numerous industries were required to collect stormwater runoff data under the Phase I National Pollutant Discharge Elimination System (NPDES) stormwater permitting program. Each Phase I municipality was required to characterize stormwater runoff by monitoring a minimum of 5 "representative" sites during a minimum of 3 storm events. The monitored sites were chosen to characterize discharges representative of commercial, residential, and industrial land use activities of the drainage area contributing to the system. The NPDES sampling protocols were derived from the NURP study. A composite sample from each storm event was analyzed for conventional pollutants (including nutrients, solids, oxygen demand, fecal bacteria) and for priority pollutants (toxic organic and inorganic compounds). Stormwater quality characterization data was based on estimating the EMC from a single flow-weighted composite sample prepared by combining discrete samples collected over the duration of the storm event. The intent of this permit application requirement was to ensure that the system discharges can be appropriately represented by the various existing data bases and to provide a basis for developing a monitoring plan to be implemented as a permit condition.

Use of Existing Data

A comprehensive analysis of all available storm event water quality data collected over the past 15-20 years has not been performed. A comparison of NURP data collected in the early 1980s with the NPDES data collected in 1991 - 1993 in the

VOL 12

7388

State of Michigan is presented below. Three of the NURP studies were located in Michigan (Washtenaw County, Oakland County, and the City of Lansing) with approximately 100 storm events monitored at eleven stations. As part of the NPDES stormwater permit application process, representative outfalls were recently monitored in the Michigan Cities of Warren, Flint, Ann Arbor, and Grand Rapids and at the University of Michigan. The Michigan NPDES data includes EMCs for approximately 75 storm events that were monitored at 27 stations.

The stormwater monitoring data comparisons presented below are based on the lognormal means of the data reported for each site. When data are characterized by infrequent extreme observations, as often happens in water quality monitoring, it is appropriate to apply a lognormal distribution. Studies such as the NURP and FHWA programs described previously have shown that stormwater quality data are best represented by the lognormal distribution. The appropriate statistic to employ for comparisons between individual sites or groups of sites is the median value, because it is less influenced by the small number of large values typical of lognormally distributed data. However, for comparisons with other published data which usually report average values, the mean value is more appropriate.

Table 1 compares the Michigan NPDES EMCs for residential, commercial, and industrial land uses with the Michigan NURP and national NURP EMCs. It should be noted that the NURP sites did not represent any heavy industrial land uses, but rather light industrial park land use. In general, the mean Michigan NPDES EMCs are within the range of EMCs reported under the earlier studies with the exception of lead. For oxygen demand (biochemical oxygen demand (BOD) and chemical oxygen demand (COD)), Michigan NPDES concentrations are generally higher than NURP EMCs for residential and industrial land uses while Michigan NPDES concentrations are lower than NURP for commercial land uses. For total suspended solids (TSS), EMCs reported for the residential and commercial Michigan NPDES sites are as much as 40% lower than NURP EMCs while those for industrial land uses are similar to NURP EMCs. Nutrient (phosphorus and nitrogen) NPDES concentrations are very similar to national NURP EMCs for all three land use categories. However, lead EMCs reported for the Michigan NPDES sites which were monitored during 1991 through 1993 are an order of magnitude lower than those reported in the NURP and other earlier studies which include data collected during the mid-1970s through early 1980s. The primary reason for the decrease in lead EMCs is probably the increased usage of unleaded gasoline.

The previous monitoring studies such as the NURP and the recent NPDES monitoring programs provide stormwater pollution loading data on which to base estimates of stormwater pollutant loadings from a given area. In the case of the Michigan NPDES programs and other programs reviewed, the recent monitoring data compares well with that collected during previous studies. Therefore, continued emphasis on single land use "end-of-pipe" monitoring programs is

NOTES:

(1) Values below the detection limit were analyzed at 50% of the detection limit.

(2) Event mean concentrations assume that the data are lognormally distributed.

(3) Values reported for the Michigan NPDES sites were calculated for 29 single family storm events and 14 multi-family storm events from sites located in the Cities of Ann Arbor, Flint, Grand Rapids, and Warren, and at the University of Michigan during 1992 - 93. Values reported are the averages of the single family and multi-family lognormal means.

(4) Values reported for the Michigan NPDES sites were calculated for 19 commercial storm events from sites located in the Cities of Ann Arbor, Flint, Grand Rapids, and Warren, and at the University of Michigan during 1992 - 1993

(5) Values reported for the Michigan NPDES sites were calculated for 11 industrial storm events from sites located in the Cities of Flint, Warren, and Grand Rapids during 1992.

(6) "Final Report of the Nationwide Urban Runoff Program," (NURP) USEPA, 1983, Tables 6-1 through 6-10 for the Pitt AA-N, Grace N, Grand R. Ot., and Waverly sites and "SEMCOG/Oakland County NURP Project Final Report," SEMCOG, 1983, Table 3 for the combined Beaver Trail and Sylvan Glen sites.

(7) NURP, USEPA, 1983, adapted from Table 6-12.

probably not warranted. However, many of the Phase I NPDES cities are proposing to continue this type of program for the 5-year permit term.

As mentioned previously, a comprehensive analysis of all appropriate storm event water quality data collected over the past 15-20 years has not been performed. We recommend that such analysis be completed to aid in the development of future monitoring programs. For example, the variability in EMCs among NURP sites was greater than any observable variability among geographic regions which made development of land-use specific or regionalized EMC estimates infeasible. Analyses of the NURP data for seasonal differences among EMCs were either not performed or not reported by the NURP team. Clearly these analyses, particularly investigation of regional, geographic, or seasonal differences among EMCs, need to be performed on the larger database of monitoring data available today to guide the direction of future stormwater pollution research.

Objectives of Future Monitoring Programs

Monitoring data collected under the existing Phase I NPDES stormwater permitting program has further supported the premise that stormwater runoff is a significant source of pollution to the nation's waterways. Data collected during development of the Phase I permit programs has been and will be used to aid municipalities and industries in the development and refinement of management programs to reduce stormwater pollutant loadings to U.S. surface waters. Most stormwater management specialists nationwide recognize, however, that effective management programs for protecting our nation's water resources should be based on a watershed basis instead of a jurisdictional basis. This sentiment is also reflected in the recent drafts of the upcoming Clean Water Act (CWA) Reauthorization; both the House and Senate CWA reauthorization bills include language to this effect.

It is our recommendation that nonpoint pollution management plans and the monitoring programs which support their development and implementation should include all nonpoint sources of pollution within a watershed. Many of the NPDES stormwater programs focus exclusively on characterizing stormwater pollution from an industry or a municipality. In urban areas, pollutants from other sources such as atmospheric deposition and contaminated river bottom sediments may also be significant and should be characterized to support a comprehensive management plan.

The current NPDES program relies on "end of pipe" monitoring data to assess the effectiveness of management programs implemented to reduce nonpoint pollution loadings to a receiving water. This approach does not provide local decision-makers with information regarding the performance of individual management measures and programs. We recommend that NPDES monitoring programs also characterize the performance of individual management measures such as detention ponds or source control activities within the watershed investigated. This action

VOL 12

7391

will provide local data to guide the development and refinement of management programs tailored to the characteristics of the local community. In addition, local data on the benefits of requiring costly management measures will aid local decision-makers in the implementation of stormwater management programs.

The overall objective of a nonpoint pollution monitoring program such as those required for NPDES permitting should be to support watershed management decisions by local decision-makers. Specific objectives should be:

1) to refine land use nonpoint pollution loading relationships within a watershed,

2) to provide quantitative information regarding the pollutant removal efficiencies that are achieved by structural and nonstructural best management practices (BMPs),

3) to provide sufficient field data to calibrate and verify pollutant loading estimates, and

4) to conduct special studies to characterize other sources of pollution (e.g., atmospheric deposition, contaminated sediments, biological/habitat assessment) to the extent possible.

Approach for Future Monitoring Programs

The Phase I NPDES stormwater permitting program required collection of monitoring data during the permit application process according to specific protocols outlined in the regulations. During the term of the permit, stormwater quality monitoring is also required but a municipality has more flexibility in devising the monitoring program. The time frame and costs associated with collecting an adequate urban stormwater database for planning, implementing, and evaluating stormwater management plans may, however, exceed the resources available. Consequently, it is recommended that all available existing data from local and regional studies be used. Additional data collection should be carefully planned to ensure that it does not duplicate previous efforts and can be used to augment the existing data. Data collected merely to meet permit requirements may be wasted if it does not support stormwater planning and management needs.

USEPA did not specify minimum standards for the monitoring program to be completed by Phase I municipalities and industries during the 5-year term of the permit but allowed the permitees to design their own programs. A review of monitoring programs proposed by a number of Phase I municipalities revealed that most programs specified continued characterization of land use nonpoint pollution loading relationships within their community by monitoring/sampling at most of the same sites monitored during the permit application process. The number of parameters analyzed, however, is typically substantially reduced from the number required during the permit application process. Further, most proposed programs reviewed specified on the order of 4 storm events sampled per site per year.

Most of the proposed permit term stormwater monitoring programs proposed to date do not include provisions for estimating the pollutant reductions achieved by the structural and nonstructural BMPs (objective 2 above) which already exist in the municipality or which may be implemented as part of a stormwater management plan. For structural BMPs, available pollutant removal performance data shows that pollutant removal efficiencies achieved by BMPs will vary from one storm to the next. After very large storm events or during wet periods, BMPs may exhibit low or negative efficiencies due to insufficient detention times, scour, or resuspension of sediments. Conversely, higher efficiencies may be achieved after smaller storms or during storms that occur after extended dry periods. For nonstructural BMPs, little pollutant removal performance data is available in the literature. For example, few stormwater quality monitoring programs have attempted to document the effectiveness of public education programs aimed at preventing such pollutants as used motor oil and lawn care products from entering receiving waters. Many of the management programs proposed as part of the Phase I NPDES municipal stormwater permit applications submitted to date, however, rely heavily on the use of nonstructural BMPs to reduce stormwater pollutant discharges to the "maximum extent practicable" (MEP) as required in the regulations. Future NPDES monitoring programs should therefore include provisions for defining the effectiveness of management programs implemented and for defining the MEP pollutant reductions for the municipality.

Stormwater monitoring programs to support NPDES stormwater permit programs should be designed to provide a reasonable level of statistical significance on an annual basis as well as over the 5-year permit term. This program design is necessary if regulatory agencies use annual and cumulative data for assessments of the effectiveness of management programs. For many pollutants found in urban runoff, the efficiencies of structural and nonstructural BMP program elements are likely to be on the order of 5% - 10% (nonstructural) up to 50% - 90% (structural). Citywide pollutant loading reductions for typical NPDES stormwater management programs developed to date are likely to be less than 25% for many pollutants under full implementation. In order to demonstrate the progress of local management programs over the 5-year permit term, the estimated mean EMCs from the municipal monitoring database should have a level of accuracy which will reflect reductions due to BMP programs. If the loading reductions achieved by the BMP programs are on the order of 5% - 50%, it will be difficult to draw any meaningful conclusions from the monitoring data if the estimated mean EMCs have a relative error which is much greater than the BMP efficiencies.

Those monitoring programs designed to provide a reasonable level of statistical significance on an annual basis as well as over the 5-year permit term will also demonstrate local benefits of the management program on an annual basis to local decision-makers and the public. Investigations of receiving water quality impacts may also be warranted to aid in management program assessments. The monitoring program should also allow for investigations of seasonal and other bias in the collected data over the 5-year permit term. A monitoring program designed around these recommendations should satisfy both objective 1 above, characterization of land use nonpoint loading relationships within a municipality, and objective 3 above, provide sufficient field data to calibrate and verify pollutant loading estimates as necessary.

In some urban areas, other nonpoint sources of pollution may cause water quality impacts equal to or exceeding those resulting from stormwater pollution loadings. For example, bottom sediments in receiving waters may be heavily contaminated and may introduce significant pollutant loads to the water column. Nonpoint source pollution monitoring programs should investigate such sources to provide data to guide the development of cost-effective watershed management plans. Guidelines for monitoring programs to characterize other nonpoint sources of pollution (objective 4 above) must be developed in accordance with the local situation.

Alternative Approaches for Future Monitoring Programs

There are alternative approaches in addition to monitoring the chemical quality of stormwater, which can be used to generate environmentally relevant information to guide the stormwater control plan for a municipal area. Biological and chemical monitoring of receiving waters enable both the evaluation of receiving water impacts and potential identification of stormwater pollutant sources, although these tools can be most effective when used in conjunction with traditional chemical analysis of stormwater (e.g., end-of-pipe monitoring). One advantage of including receiving water and biological monitoring in a stormwater monitoring program is that stream health can be directly assessed without relying solely on chemical surrogates and highly variable stormwater outfall data. In addition, use of biological monitoring may help address concerns about the aggregate affect of stormwater pollutants as well as the bioavailability of those pollutants. Another benefit of including chemical, biological and receiving water components in a stormwater monitoring program is that it may provide more cost-effective information to guide the direction of local stormwater management plans.

Data Analysis

A critical component of a stormwater monitoring program to support stormwater management plans is effectively utilizing the data collected in order to achieve the program's information goals and monitoring objectives. The conversion of data into information should begin with specified data handling procedures including adherence to quality assurance and quality control protocols. Statistical procedures for analyzing the collected data should be established to ensure that the information generated both matches the ability of the data to yield such

VOL 12

7394

information with confidence and matches the needs and expectations of decision makers. Finally, for NPDES permit monitoring programs, the results of the monitoring program should not be reported independently but as part of the overall report of the progress of the management program. Other information such as how much of the system was served by BMPs and how the results guided management program decisions should be part of the overall management program report to the regulatory agency.

Conclusions

A stormwater monitoring program to support a management plan to protect water resources such as is required under the NPDES stormwater permitting program should be developed on a watershed basis and should be tailored to address as many local sources of nonpoint pollution as possible. The development of the monitoring program should be based on an inventory of all local sources of NPS pollution (e.g., urban runoff, contaminated river bottom sediments) and available local, regional, and national data to characterize those sources. In addition, provision for assessing the success of the management program should be made in the monitoring program. Local data on the pollutant removal efficiencies of preferred structural and nonstructural management practices should be collected to aid local decision-makers in the development, implementation, and refinement of the management program. Investigations of receiving water impacts or biological assessments may also provide valuable data to guide local nonpoint pollution management policies. Most of the recent NPDES monitoring data reviewed compares well with that collected during previous studies. Therefore, continued emphasis on single land use "end-of-pipe" monitoring programs is probably not warranted.

Stormwater monitoring programs to support NPDES stormwater permit programs should be designed to offer a reasonable level of statistical significance on an annual basis and over the entire permit term. This program design is necessary if regulatory agencies use annual and cumulative data for assessments of progress of management programs. This design will also demonstrate local benefits of the management program on an annual basis to local policy-makers and the public. The monitoring program should also allow for investigations of seasonal and other bias in the collected data. A critical component of a stormwater monitoring program to support stormwater management plans is the effective handling and use of the data collected.

Continuing research is also needed in the area of stormwater pollutant generation, transport, and fate. The authors recognize that such research is beyond the scope of the NPDES stormwater permitting program. This research is necessary, however, to develop new management practices in the continuing quest to restore and protect the nation's water resources.

HOW TO MONITOR *ONLY* THE IMPORTANT PARAMETERS

William James[1], P.Eng., F.ASCE

ABSTRACT

On-line ranked sensitivity analysis of complex, continuous, deterministic models allows determination of the important processes, parameters and variables. For this purpose, the model must be complex to the next degree, and the sensitivity analysis must be thorough and complete; e.g. parameters must have been optimized. Written for a drag-and-drop Windows environment, the shell *PCSWMM for Windows* aims especially at sensitivity, calibration and error-analysis (SCEA). SCEA is rendered semi-automatic for the United States Environmental Protection Agency's Storm Water Management Model, supporting about 10^2 differently named, and 10^4 - 10^5 total, parameters for the RUNOFF module alone. Fuzzy logic is used to interpret the ranked parameter sensitivity in various RUNOFF state-variable spaces, and to reduce the scope to a computable effort. An application of the recommended methodology to the Redhill Creek in Hamilton, Ontario, displayed the most significant parameters for three objective functions automatically, and required 33 minutes CPU time on a '486 PC.

INTRODUCTION

In North America and elsewhere, engineers and others are working to restore the damaged environment, especially aquatic habitats and ecosystems that have been displaced or destroyed. Unable (or unwilling) to address the elimination of the root cause of these problems (human population intensification and associated lifestyles), engineers seek instead to prescribe engineering solutions, usually in the form of further but gentler landscape interventions.

To do this, they need first to understand the complex aquatic ecosystems being modified and, typically, degraded. Best available models (BAMs) are accordingly used to help find the cheapest of many potential arrays of assorted best management practices (BMPs), but their inherent complexity renders the model applications uncertain. Field data monitoring is necessary therefore to authenticate the modelling, a troublesome task, since

[1] Professor of Civil and Environmental Engineering, U of Guelph, Ontario, Canada N1G 2W1. email: james@net2.eos.uoguelph.ca Fax 519-767 2770

the methodology for resolving model complexity is still emerging, and few universally-acceptable guidelines exist.

In the end, regulators are pressed to impose blanket and costly monitoring requirements in their search for expediency and uniformity in dealing with the pervading uncertainty. Thus expensive analyses of large numbers of water samples for obscure pollutants has become common if not mandatory. Costs have sky-rocketed and often the results are not useful. As a result, developers, the public, politicians and others are skeptical about the benefits of expensive sampling projects, and of very expensive analyses for trace contaminants.

Fortunately a simple solution is readily at hand: on-line ranked sensitivity analysis to determine which of the important processes, parameters and variables that are relevant to the damaged ecosystem, should be pursued first. Of course, the BAM used in the study must be at least more complex than is required for the current planning, design or operational exercise. In other words, the model should include code explicitly describing all processes that are significantly active in this problem or application. And the sensitivity analysis must be thorough and complete, not the arbitrary and casual task commonly practised today. For example, the parameters must be optimal before being finally ranked for sensitivity, and the procedure must be efficient. For managing the monitoring, continuously computing the ranked sensitivity is a fundamentally important component activity.

Written for a drag-and-drop Windows environment, the shell *PCSWMM4 for Windows* (James, 1994) aims especially at sensitivity, calibration and error-analysis (SCEA) for design applications using large-scale, long-term, continuous modeling at high spatial and temporal resolution. SCEA is rendered semi-automatic for version 4.3 of the United States Environmental Protection Agency's (U.S.EPA's) Storm Water Management Model (SWMM4.3). For a single run of the urban hydrology module (RUNOFF) alone, the shell supports over 10^2 different, and circa 10^4 total, parameters. Fuzzy logic is used to manage the complexity, and to interpret the ranked parameter sensitivity in various RUNOFF state-variable spaces. Here in this paper we deal only with ranked sensitivity; the fuzzy logic is to be published elsewhere later.

BACKGROUND DEVELOPMENT

In accord with common practice, the artificial distinction between *field-data-gathering* on the one hand, and *modeling* for planning, design and operation on the other, is highlighted by this conference. Our very terms of reference at this meeting suggest that there is a dichotomy, that the two activities are somehow separable. They are not. Both are mandated, adopted or indulged for the sole purpose of determining the probable behaviour of an aquatic system, normally as the result of anthropogenic impacts, including modifications aimed at eco-restoration.

Distinguishing between the two activities places narrow limits on professionalism. Almost by definition, professional engineers are both skilled data-gatherers *and* skilled model-users (i.e. problem-solving designers). In this paper I suggest that all these skills can and should be rolled into one coherent single skill. For example data-gatherermodeller-engineers in the field could use enhanced code with their special models to determine whether the sample about to be taken is worth it, and the same modeller-data-gatherer-engineers at the workstation could use special programs which read the data remotely and are linked to their models to determine whether the process about to be modelled is worth the effort. Such computer programs are only now emerging, and not yet commonly available.

What is needed is a method whereby data gatherers control the modeling, while modelers in turn control the data monitoring. Clearly the special software postulated above would underpin an acceptable methodology, one that keeps the costs of the two components of the study in balance with their expected benefits, the balance to be found in terms of the credibility of the recommended optimal array and capacities of BMPs. In other words, a methodology that relates the effort of the information-processing (monitoring, modeling and their synthesis) on the one hand, to the importance of the restoration effort (planning, design and operational effort to restore the *as-is* or *to-be* damaged ecosystems, often to some *as-was* state) on the other.

Part of the problem may be that funding and resources flow from two different lines in the budget, or through two different departments. (Often the agency responsible for natural resources provides the data-gathering resources, and the agency responsible for the environment, the modeler-analysis resources.) A rule may be tentatively proposed at this stage: *Avoid funding studies where specialists perform only one of the two study components without control of the other.*

VERSION 4.3 OF PCSWMM FOR WINDOWS[1]

Pursuing the benefits of the ever-improving hard- and software environment, the shell (*PCSWMM4 for Windows*) described in this paper was written by Rob James for a drag-and-drop, Windows operating system. So far as is known, this is the only shell to focus especially on sensitivity, calibration and error-analysis (SCEA) for design applications using large-scale (say 1000 and more elements) and long-term (say 75 years) continuous modeling at high resolutions (elements of say 100 ft length, 1 acre extent and integration intervals of 60-seconds); the shell was chiefly written for the currently latest version (4.3) of the United States Environmental Protection Agency (U.S.EPA) program called the Storm Water Management Model (SWMM4; see Huber and Dickinson, 1988). Contrariwise, several papers in the peer-reviewed literature, claim that these specifications are impossible to achieve.

Of course the shell also includes the usual graphics user interfaces that are windows, interactive, menu-driven and pointing-device oriented (GUI-WIMP; note that these gooey wimps are not what they sound like - they were created to be *robust*). Pre- and post-processors for data input and output interpretation are included. But most significantly, SCEA is rendered semi-automatic for approximately 10^2 different hydrologic parameters and a total number of parameters in the order of 10^4, depending

[1]This part of the paper has been abstracted from the user documentation for *PCSWMM for Windows* - see James, 1994.

VOL 12

7399

R0040707

on the processes active, and the spatial resolution. James and James (1993) describe the genesis of PCSWMM4.

Various objective functions, performance evaluation functions and error functions are used in *PCSWMM for Windows*. Since the error analysis is linear, with first and higher order sensitivity gradients, the procedures depend on user-intervention at various levels. Intensive, interactive user-dialog demands that the terms used are carefully defined, especially if they differ in important ways from much of the literature, which has heretofore been understandably loose. So, for clarity, the terms used are once again defined in the following terse discussion:

Modeling has the simple purpose of evaluating the likely performance of potential arrays of various BMPs in an impacted watershed, and determining the "best" array, according to some presumed, prevailing values. If we had prior knowledge of all such performance, sufficient to determine reasonably precise optimal BMP capacities, then modeling would of course be a waste of time. The corollary to this is that, if we had available prior field observations of the performance of all arrays of all types of BMPs for all aquatic systems and physiographies, again we would not need to model. *Because these two alternatives are infeasible, given the inherent complexity, we may conclude that modeling will remain necessary for the forseeable future.*

Processes underlying the BMP performance are imperfectly known, even for the *as-is* system, the best-known of the arrays to be modelled, and thus the computed model output is uncertain. The *to-be* (proposed interventions, the so-called *what-if?* scenarios) and *as-was* systems (pre-development, especially if pre-forest-clearance or pre-agricultural) are even more uncertain. This is especially true of surface water pollutant processes. Field data monitoring is required to validate the models; if the model were certain for all arrays then monitoring would of course be a waste of time. *Because even the best available codes are uncertain models of proposed BMP arrays, field data monitoring will also remain necessary for the forseeable future.*

PCSWMM4 for Windows is a *shell* - code that is written around existing code, usually to provide better human interaction. In this case the existing code is *SWMM4.3* - a collection of programs comprising hundreds of files, hundreds of routines, and scores of thousands of lines of FORTRAN source, object and executable code; more specifically SWMM4.3 refers to the U.S.EPA official issue, compiled and linked using Ryan-McFarland products, and downloaded during or after June, 1994. It makes little sense to test a *program* for SCEA.

On the other hand, a *model* (here a deterministic surface water quality model), is more accurately described as the combination of both 1. a program, together with 2. its input datafiles, such as a SWMM application. A model may have a useful life extending over decades. In this sense, SWMM is a misnomer. Both the program and the model evolve over time. Thus models may become very complex, integrating over time encyclopedic knowledge of component processes as it becomes available, applying it to vast databases as the databases build over time, examining potentially thousands of arrays of best management practices (BMPs) as they are put forward from time-to-time, re-running each array for say 75 years of hydro-meteorologic and physical topo-hydrographic data. A further rule may now be posed: *A model can and should be tested for SCEA and the uncertainty always reported as a part of the computed output. Indeed not to do so, is likely a dereliction in design engineering ethics.*

Chief among the variables in the input data file that distinguish a model, are *parameters* - coefficients that are input, but less likely to form very long time-series at a fine time resolution, and that generally control independent component processes. Some parameters are readily quantified within narrow limits, but others cannot be measured in the field at all - *calibration* is the only way that reasonable values can be estimated for the latter.

An important attribute of parameters is *parameter sensitivity* - the influence of a parameter's value on the model output. Parameters are said to be sensitive when relatively small changes in the value of a parameter significantly affect the computed *objective function*, such as event peak concentration, or event total constituent load. This attribute may be determined by *sensitivity analysis:*

1. varying model coefficients or parameters one at a time, with the amount varied being representative of the uncertainty in the parameter being analyzed,
2. dividing the resulting normalized change in computed response by the dimensionless parameter change, to give the *normalized sensitivity gradient*, and
3. ranking the resulting modulus of the sensitivity gradients, highest to zero, with an explanation for the rank order.

Among the reasons why the modeling exercise is a challenge are:

1. every application is different,
2. every design question poses new hydrologic interventions, and
3. the hydro-met input time-series may for simple problems be sub-divided into at least nine major event-types.

All of these complications materially change the relative sensitivity.

The most important processes are the *dominant processes* - those hydro-pollutional processes, coded into the program, which, when coupled with the input datafile, are active and represent large percentages of contribution to the computed objective function. For example, ground surface infiltration and impervious-area overland-flow are processes coded into SWMM; on urban areas at low rates of rain, impervious-area overland-flow dominates, and ground surface infiltration is utterly insensitive, if considering peak pollutant and flow flux rates. Dominance is related to specific *state variable space* - the combinations of input variables that relate to one or more status variables that most indicate the dominant processes, and that trigger changes of the dominance of those processes, among others that are all coded into the program. Lack of space prevents a discussion here of the fuzzy logic and state variable space approaches used in *PCSWMM4 for Windows*.

Clearly, these procedures encourage users to explore the SCEA for each application and may be said to be *heuristic* - relating to exploratory problem-solving techniques that use self-educating ideas. Dealing with large numbers of processes, sub-spaces, time-series, parameters, objective functions, event types, and performance-evaluation functions can be confusing for novices, and the water quality processes may be more readily understood if they are deemed to be fuzzy. A *fuzzy process* is a process that may be expressed in relative terms, and that has different levels of dominance, dependent on one or more state variables. For example, the modeling of spatially-and-time-averaged (STA) pollutant build-up and wash-off is a fuzzy process when the water transfer rate (such as rainfall droplets or evapo-transpiration) at the ground surface level oscillates from zero to low rates: under these conditions, is *pollutant build-up* or *pollutant wash-off* dominant, or relatively more significant?

Ultimately, the point is to reduce the *error* - the difference between an objective function for a computed and an observed time series. Thus the *best* values of parameters are sought. *Parameter optimization (estimation) or calibration* is a procedure to discover the approximate global optimum of an array of modeling parameters, each of which can only be discovered by estimation, and are not directly measurable in the field, at least not with precision. *Calibration* is completed when a *performance evaluation function*, defined as a measure of degree of fit between measured and computed objective functions, is minimized.

On ethical principles, we deal here only with *continuous modeling* - a simulation that models both the dry and wet processes of pollutant hydrology, with a continuous, long-term record of atmospheric and hydrologic data. In contrast, *event modeling* is a simulation of short, defined storm events using a model that ignores (usually) dry weather processes, and uses subjective start-up conditions. When using events for SCEA, the situation is different from routine event modeling: start-up conditions are known, and certain processes are inactive rather than ignored.

PCSWMM4 for Windows is a *decision support system* - code that manages the simulation system, as opposed to the internal process codes (collectively called the *engine*). This methodology also involves:

error analysis - the computation of the likely error that a computed response may incur;

dissaggregation - the degree to which the physical components of a system are modeled by increasing the number of defined processes;

discretization - the number of spatial components selected to represent the physical system that has been dissaggregated into processes, and the degree to which the physical parameters are averaged (lumped) spatially and temporally;

model complexity - a measure of the number of uncertain parameters in the model. Models should be neither too complex nor too simple for the problem and problem-solving environments.

By *environment* we mean the space with its objects that surrounds a thing that is considered to be more important. Principal among the purposes of the modeling effort is to design an optimum array of *best management practices (BMPs)* - landscape interventions that temporally divert, store or treat urban stormwater runoff to remove pollutants, reduce flooding or provide other amenities.

Finally the method must be *computable* - a simulation that can be performed in a working day (eight hours) using, and providing computed output that can be contained on, typical engineering office workstations, comprising (say) 500 megabyte (Mb) hard disk and a 486-66 motherboard with 16 Mb dynamic memory (DRAM).

VOL 12

SENSITIVITY GRADIENTS

Sensitivity gradients are computed by *PCSWMM4 for Windows* by generating input datafiles that are very large; m times larger than single event runs (m is defined below). Since the constituent pseudo-events are very short, and efficiencies have been made in constructing the datafile, the runs are quite quick, even for datafiles for which m is large, say $m = 10^5$ or larger.

Normalized sensitivity gradients (NSGs) are computed by dividing A, the differences in the computed relative objective function, by B, the relative difference in the input parameter value, for all relevant parameters. All NSGs are accumulated and ranked. Plots are also limited to the most significant parameters, since most parameters have negligible sensitivity. Typical examples are given later.

Time savings are achieved by automatically running the model once, but for m appropriate pseudo-events, where: $m = (aN + 1)$ and N is the number of parameters to be analyzed for sensitivity. For the RUNOFF module:

$$N = \Sigma[(11{*}CA+14)+(8{*}PI)+(3{*}WE)+(20{*}CA)+(5{*}CA)+(6{*}LU+11{*}PO+12{*}CA+4]$$

In this equation, the summation is done over all RUNOFF calls, and the terms in the right hand side refer to the following broad categories of processes: catchments, pipes, weirs, groundwater, erosion and pollutants respectively (snowmelt, pumps and orifices have been excluded here). Variables in these equations are:

- a = 2 for both linear and parabolic sensitivity curves,
- a = 4 for fifth-order sensitivity polynomials,
- CA = number of sub-catchments in each call,
- PI = number of pipes and gutters,
- WE = no. of weirs,
- LU = no. of land uses defined, and
- PO = no. of pollutants.

These equations are given for a single objective function, and only one event type. Although not all objective functions are relevant to all parameters, it should be borne in mind that 20 different objective functions, and nine event types are available, so the theoretically maximum m is of the order of 10^7. Of course the actual number of runs will be much less, and easily computable.

APPLICATION TO THE REDHILL CREEK IN HAMILTON, ONT.

The City of Hamilton's urban drainage system comprises an area of about 120 sq. km which generally drains northward through twenty major combined sewer outfalls to Hamilton Harbour and Coote's Paradise. Three major drainage basins have been identified: Chedoke Creek in the west, Redhill Creek in the east, and the Central Business District incorporating the downtown core.

Redhill Creek consists of three main branches and several smaller tributaries. The watershed lies mainly within the City of Hamilton and the Town of Stoney Creek.

VOL 12

7403

Headwaters of the main branch are located in the south-west corner of the City of Hamilton, above the escarpment, known locally as "the mountain". Flowing first eastward, the creek tumbles over Albion Falls, then meanders northward until it reaches its mouth near the Hamilton Water and Wastewater Treatment Plant, located at the south-east corner of Hamilton Harbour. Finally the Redhill Creek outfalls to Windermere basin, a notoriously-polluted, shallow, receiving water body, part of Hamilton Harbour.

Land-use classification in the datafiles used here was derived in 1984 by Mark Robinson from aerial photographs (Robinson and James, 1984). Redhill Hill Creek covers a drainage area of 66.4 sq. km. Land use within the drainage area has changed over time, from an agricultural base to urban. In 1984, 20% of the area was serviced by a combined sewer system, and 43% of the area was devoted to non-urban activities, located in the upper, southern part of the watershed. Residential and industrial subdivisions are being developed on former fruit and dairy farms. Figure 1 is an outline of the watershed, and Figure 2 shows a schematic of the drainage system. Table 1 gives the datafile used in this study. Parameter values used here are those that were optimized in 1984 against a limited dataset by Robinson (Robinson and James, 1984).

Sensitivity analysis involved running *PCSWMM4 for Windows* three times, once for each of three input functions selected from a library of such input functions:

1. SDHI - short-duration, high-intensity rain,
2. SDLI - short-duration, low-intensity rain, and
3. SDMI - short duration, medium-intensity rain.

Each single run computed NSGs for three objective functions simultaneously:

1. peak flow in CFS,
2. peak BOD concentration in mg/L, and
3. peak suspended solids concentration in mg/L.

Choosing 44 parameters per run that were most likely to be applicable was quite simple, since most of the remaining parameters would be obviously meaningless in this application. Figures 3 to 8 provide the computed ranked sensitivity for the most interesting of these nine cases, using a uniform doubt or uncertainty of 5% for most parameters, for the sake of expediency and illustration here. In this paper, all Figures and Table 1 are presented following this page, and the results and conclusions to be drawn are presented at the end. To save space, Table 2, the list of dominant variables is placed here (in it, STA denotes *spatially-and-time-averaged*):

Table 2: Dominant variables

Variables	*descriptions*	*variables*	*descriptions*
ddfact	= STA pollutant build-up coefficient	g6	= conduit Manning's n
ddpow	= STA pollutant build-up exponent	qfact(1,k)	= STA build-up limit
decay	= STA infiltration rate decay constant	rcoef	= STA washoff coefficient
f1(k,to)	= fraction of another constituent	warea	= area of sub-catchment
gdepth	= conduit start-up depth	washpo	= STA washoff exponent
gylen	= length of curb	wlmax/wlmin	= STA max/min infiltration
gwidth	= conduit invert width, pipe diameter	wstore2	= STA perv. depression storage
g3	= conduit invert slope	ww(3)	= percent imperviousness

RESULTS AND CONCLUSIONS

Figures 3 to 8 rank the variables and thus implicitly the processes in descending order of importance. Large numbers of insensitive processes are revealed, and the dominant processes are few in number. Monitoring effort should be limited to only those fourteen variables that will help calibrate the dominant processes - about 80 parameters are insensitive in this application, and may be ignored.

Figure 3 when compared to Figure 4 illustrates that, for peak flow computations, infiltration parameters are important for SDHI, but not for SDLI rains. Thus good infiltration data are required for flood computations in areas with low imperviousness.

Similarly, when computing peak concentrations of settleable solids and BOD, the input rainfall intensity for short durations has an important influence on the ranking of dominant parameters, as shown by the disparity between Figures 5, 6 and 7 respectively. This should lay to rest the position so often seen in the literature, viz. that the sensitive parameters may be identified for a program, independent of its application.

For example, some surcharging was computed to occur in these Redhill Creek datafile runs, and the rankings show that conduit geometries are important for these cases. When surcharging occurs, computed peak flows are insensitive to all other variables.

For conditions likely to produce high sediment concentrations (high rain rates after prolonged dry weather), data on pollutant build-up are important. Further, according to Figure 8, for peak BOD concentration computed by SWMM-RUNOFF, the only additional parameter of importance, is the fraction that it constitutes of the other pollutant. This is why the other Figures for BOD were not plotted here.

Computational time averaged approximately 11 minutes per run. In other words, the full sensitivity analysis required about 33 minutes on 486-66 microcomputer. The writer considers this to be an insignificant amount of time, considering the value of the information obtained. Even so, these run times were longer than normal, because of the surcharging.

SESSION I: Overview of Stormwater Monitoring Needs

DISCUSSION

Trends in Monitoring for Stormwater
Michael Cook

Tulsa, Oklahoma is the first city issued a Stormwater permit by EPA.

EPA has just undertaken a program to deal with storm sewer overflows - focus over last 20 years has been on wastewater treatment; Agency now hopes to devote more energy to dealing with other forms of pollution. The next increment of control will occur at the local level on a watershed basis.

EPA's Office of Water programs will give more emphasis to NPS, with emphasis on agriculture and mining.

Anecdotal data has been the basis for evaluating the quality of the nation's waters - EPA now looking for a more scientific way to measure the state of water quality.

Groundwater has been a very difficult medium to deal with due to very localized variations in water quality. Current emphasis is on the quality of groundwater used for drinking water supply.

Stormwater Issues

EPA is looking for ways to actually measure improvement in water quality as a result of stormwater pollution control programs. They would like monitoring programs that allow EPA to say "our policy has resulted in a change in water quality." EPA is now holding meetings to identify selected indicators that can be measured. EPA will then give grants to a number of agencies to test their validity.

- Shift from emphasis on water quality monitoring to biological monitoring
- Looking for biological indicators - bioassay, biodiversity, etc.

Questions/Comments

Question: What about funding to continue on-going biomonitoring work?
Answer: Agency needs to look at external research programs that can be used to support EPA efforts. Agency does have some demonstration monies set aside for programs that would look at

biological indicators.

Comment: Reconciliation of use of wetlands for treatment is still an issue - problems tend to be site-specific. Some experts say wetland treatment does not work.

Question: What is "required treatment" for Stormwater?
Answer: Response seemed to be that it was essentially not a problem.

Comment: Regarding mining - EPA is discussing a provision in the Clean Water Act to allow mining industries to assume only partial liability for existing/historic pollution sources.

Comment: Bringing all the different sources of pollution back together under the watershed analysis approach, as proposed in the CWA reauthorization, is difficult, given the history of the CWA in separating sources and dealing with them individually.

American Public Works Point of View
Christine Andersen

We lack the ability to prove clearly the benefits of stormwater management. Therefore, accountability and credibility of municipal agencies and their constituents is a big issue, particularly with respect to environmental programs, i.e. that monies spent on stormwater quality management produce tangible results in terms of improvement of urban waters. This is a particularly acute problem given the reduced levels of state and federal funding.

Concerns of 20 years ago regarding stormwater management are still with us today and not a lot better explained. Not just an engineering problem - requires biological/ecological input as well.

Must come to agreement on how we are going to move forward with storm water management issues. Time is running out and there is no level of agreement. It is imperative that various environmental forces in the community get together in a unified approach.

Review of papers being presented here raises more questions than answers. Still don't know how to interpret data to determine whether or not we are meeting goals.

Pushing those controls that simply meet water quality standards is very expensive, and there is no indication that these actions will meet the community goals for their receiving waters.

Questions/Comments

Question: If you had opportunity, how would you change our approach to monitoring?

Answer: Would change the timing - I would delay it until we had sufficient data to be able to determine with some certainty that the programs we are implementing have some expectation of success.

Question: What about monitoring costs?

Answer: Eugene, Oregon's costs for stormwater management bear no relationship to EPA estimates. Poor quality of these estimates has damaged EPA credibility. Others have had same experience with these estimates.

Answer: Mike Cook - EPA is revisiting requirements for next round of permits (smaller municipalities).

Question: Will current monitoring requirements give us information that will be useful to assess environmental health?

Answer: No. There are many variables, and these are difficult to track.

Overview of Stormwater Monitoring Needs
Kelly A. Cave

CDM is characterizing and comparing (doing statistical analyses on) NPDES data collected for the 30 municipalities for which the firm prepared Stormwater Permits under the EPA Level I program. Results of their study will be made generally available.

Monitoring Program should support watershed management program.

Program should achieve a reasonable level of statistical significance. Continued use of end-of-pipe (EOP) monitoring is not warranted.

Questions/Comments

Comment: CDM's comprehensive analysis of the NURP, USGS, City of Austin, and CDM NPDES studies, will, in effect, redo the NURP statistical analysis.

Comment: We find that Region VI is reluctant to move away from EOP monitoring for land use characterization of stormwater.

Comment: Wisconsin is being blackmailed by cities which have already

VOL 12

7419

invested a lot of money in establishing EOP stations (as a result of having decided to do monitoring). State is somewhat successful in turning them around.

Comment: Oregon is still focusing on EOP monitoring, but trying to move away. Woodward Clyde is currently monitoring some BMPs in Portland (Editor's note - see paper by Eric Strecker in these Proceedings). Oregon does an annual review of data and BMP effectiveness.

Comment: Austin, Texas is still oriented to EOP because of their non-degradation policy. Feels need to enforce pollution reduction from urban runoff.

Comment: In the Rouge River Study (Detroit, Michigan) they are monitoring atmospheric deposition of pollutants.

How to Monitor Only the Important Parameters
William James

We must report model simulations along with uncertainty, rather than as single valued functions, i.e. must show level of significance and confidence intervals associated with predictions. If we fail to do this, we are being "dishonest and unethical."

There is an optimum size for model complexity in view of our ability to accurately simulate processes, and of the uncertainty in the input data we have for planning.

Questions/Comments

Comment: Monitoring and modeling must be coordinated.

Locating Inappropriate Discharges to Storm Drains

Melinda Lalor[1], Robert Pitt[2], Richard Field[3], Edward Thackston[4]

Abstract

This article describes the results of a series of research tasks to develop a procedure to investigate non-stormwater (dry-weather) entries into storm drainage systems (Pitt et al. 1993a, Pitt et al. 1993b). Dry-weather flows discharging from storm drainage systems contribute significant pollutant loadings to receiving waters and although they can originate from many sources, the most significant include sanitary wastewater, industrial and commercial pollutant entries, failing septic tank systems, and vehicle maintenance activities. Protocols are discussed to: characterize the drainage area; locate and identify polluted outfalls; estimate the magnitudes of non-stormwater entries; and locate and correct the non-stormwater entries into the storm drainage system. If these loadings are ignored (e.g., by only considering wet-weather stormwater runoff), only limited improvement in receiving water conditions may occur with stormwater pollution control programs.

Introduction

Current interest in illicit or inappropriate connections to storm drainage systems is an outgrowth of investigations into the larger problem of determining the role urban stormwater runoff plays as a contributor to receiving water

quality problems. The EPA's Storm & Combined Sewer Overflow Pollution Control Research and Nationwide Urban Runoff Programs, respectively helped highlight the problem with data confirming pollution found in urban storm drainage systems. Regulatory requirements such as the National Pollution Discharge Elimination System (NPDES) require certain classes of stormwater discharges to be permitted. Presently, the NPDES requires certain industries (*Federal* 1990) and municipalities with populations of 100,000 or more to conduct investigations to determine the locations of inappropriate dry-weather entries into storm drainage systems.

Waters discharged from stormwater drainage systems often include waters from many non-stormwater sources. A study in Sacramento, California (Montoya 1987) found that slightly less than half the volume of water discharged from a stormwater drainage system was not directly attributable to runoff. Illicit and/or inappropriate entries to the storm drainage system are likely sources of this discharge and can account for a significant amount of the pollutants discharged from storm drainage systems.

The methods described in this paper were developed specifically for detection of pollution sources in dry-weather flow, but are applicable to wet-weather flows as well. It must be noted that during wet-weather flow conditions there will be additional pollutant sources (e.g., roads, roofs, exposed materials storage, etc.).

Origins of Contamination

Common non-stormwater entries include: sanitary wastewater; automobile maintenance and operation waste products; laundry wastewater; household toxic substances and pollutants; accident and spill waste streams; runoff from excessive irrigation; and industrial cooling water, rinse water, and other process wastewater. Although these sources can enter the storm drainage system a variety of ways, they generally result from: (1) direct connections, such as wastewater piping either mistakenly or deliberately connected to the storm drains; or (2) indirect connections, which include infiltration into the storm drainage system and spills received by drain inlets (Pitt et al. 1993a).

Direct connections may be defined as physical connections of sanitary, commercial, or industrial piping that carry untreated or partially treated wastewaters to a separate storm drainage system. Usually unauthorized, whether mistaken or intentional, they represent the most common source of entries to storm drains by industry.

Indirect connections may be defined as infiltration into storm drainage systems and non-storm related discharges to storm catchbasins and inlets. Infiltration most commonly occurs through leaking pipe joints and connections to manholes and catchbasins, as well as pipes damaged by overburden and subsidence. Groundwater and percolating waters may or may not be

VOL 12

7422

contaminated and will be variable in nature since their levels and amounts can be dependent upon rainfall events.

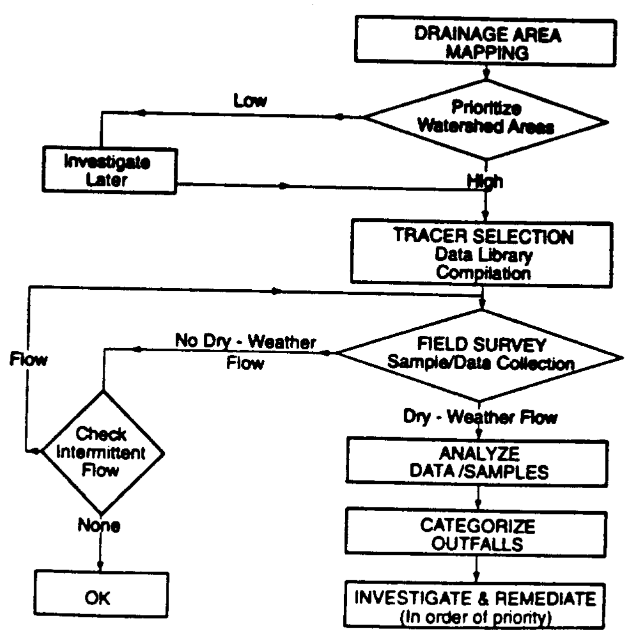
The procedures described in this paper provide an investigative procedure that will allow a user to first determine whether significant non-stormwater entries are present in a storm drain, and then identify the potential source category as an aid to ultimately locating the source.

It is important to emphasize that the removal of inappropriate entries is only one aspect of a comprehensive pollution prevention program required for an effective improvement in receiving water quality.

Procedures

The sequence of "Typical Investigation Steps" is illustrated in Figure 1 and briefly described below.

Figure 1: Typical Investigation Steps



A) Drainage Area Mapping

The mapping exercise is carried out as a desktop operation using existing data/information and field visits to collect additional data/information and/or confirm existing information. It must contain complete descriptions of the drainage areas including: outfall locations, drainage system layout, subcatchment boundaries for each outfall, critical land-use areas, permitted discharges to the storm drainage system, city limits, major streets, streams, etc. Possible sources of information include:

- City records and drainage maps.
- Previous surveys, e.g., sanitary sewer infiltration/inflow and sewer evaluation survey studies.
- Topographic maps.
- Existing GIS (Geographic Information System) data.
- Pre-development stream locations.
- Pre-development site investigations indicating groundwater and water table information.
- Drainage department personnel with knowledge of the area.
- Aerial surveys.

From mapping activities, possible pollutant sources are identified (e.g., industries, landfill sites, areas with septic tank systems, vehicle service stations, industrial sites, etc.) and drainage areas with the highest potential for non-stormwater entry sources are determined. This can assist in setting priorities for field investigation of the outfalls (Pitt et al. 1993a). However, all outfalls will require investigation eventually.

B) Tracer Selection

To detect and identify non-stormwater entries, the dry-weather outfall discharge is analyzed for selected tracers. An ideal tracer should exhibit the following properties:

- Significant difference in concentrations between polluting and non-polluting sources;
- Small variations in concentrations within each likely pollutant source category;
- A conservative behavior (i.e., no significant concentration change due to physical, chemical, and/or biological processes); and
- Ease of measurement with adequate detection limits, good sensitivity and repeatability.

A review of case studies and literature characterizing potential inappropriate entries (e.g., sanitary wastewater, septic tank effluent, laundry wastewater, vehicle wash wastewater, irrigation runoff, etc.) led to the following recommended tracers to identify common pollutant sources in

VOL 12

7424

residential/commercial land use areas :

- Specific conductivity;
- Fluoride and/or hardness;
- Ammonia and/or potassium;
- Detergents and/or fluorescence; and
- Temperature, chlorine, and pH.

The last three parameters do not fit the previously stated criteria, but can indicate extreme instances of pollution. Further details on the recommended tracers are given in Appendix II. If specific chemicals used by industries in the watershed are known, it may be possible to include them as tracers also.

In addition to the parameters described above, relative toxicity can be an important outfall screening parameter. Short-term toxicity tests, (e.g., the Microtox™ test from Microbics, Inc.), are valuable for quickly and cheaply assessing the relative toxicity (to a selected test organism) of different dry-weather flows. These tests can be used to identify outfalls that contain toxic flows which may warrant immediate investigation.

Potential sources of dry weather flows commonly identified within commercial and residential land use areas include spring water, infiltrating shallow ground water, tap water, irrigation runoff from landscaped areas and golf courses, sewage, septic tank discharge, commercial laundry waters, commercial carwash waters, radiator flushing wastes and metal plating bath waters. Obviously, some of these sources would contribute to pollution problems, and some would not. However, all have the potential for showing up in dry-weather flows. Therefore a chemical understanding of each, with respect to the selected tracers, is needed to build a "library" to which outfall dry-weather flows can be compared. To obtain the background information needed to construct such a library, samples are collected directly from the potential sources identified. To the extent possible, samples should come from sources within the study area. For each tracer, the concentration means and standard deviations for all the potential source flows, is calculated. Without this information the likelihood of identifying the pollutant sources is greatly reduced. The selection of a suitable analytical method is discussed later under the "Analysis of Data/Samples" section.

C) Field Survey

Field investigations are used to locate and record all outfalls, and involve physically wadding, boating, etc. the receiving waters in search of all known and unknown outfalls. At each outfall the inspection and sampling should at least include:

- Accurate location of outfall and assignment of ID number;
- Photographs of outfall;
- Outfall discharge flow rate estimate (and note whether continuous or

VOL 12

7425

intermittent discharge);
- Physical inspection and record of outfall characteristics including odor, color, turbidity, floatable matter (fecal matter, sanitary discards, solids, oil sheen, etc.), deposits, stains, vegetation effected by pollutants, damage to outfall structure, and discharge water temperature; and
- Collection of dry-weather discharge samples for tracer analyses in the laboratory (specific conductivity and temperature can be field measured).

Intermittent flows will be more difficult to confirm and sample. Additional field visits, use of automatic samplers, and/or flow damming or screening techniques must be utilized for detecting and obtaining samples of intermittent flows.

D) Analyses of Data/Samples

The recommended analytical procedures and associated equipment in Appendix III have been selected based on laboratory and field testing of analytical methods using the following criteria:
- Appropriate detection limits;
- Freedom from interferences;
- Good analytical precision (repeatability);
- Low cost and good durability; and
- Minimal operator training.

For consistent results the analyses should be carried out in the laboratory and not in the field, except for temperature and specific conductivity. Field analyses may be conducted for pH by using portable pH meters or litmus paper depending upon the degree of accuracy required and time constraints. Note that pH is a support tracer and not a primary parameter (see Appendix II for further detail).

The analysis methods selected must provide adequate detection limits (i.e., measurement of the lowest required concentration) and precision (i.e., consistent results). Methods found suitable for residential/commercial land use areas are recommended in Appendix III. These, methods should be checked for suitability at the proposed study site. In order to estimate the required detection limit, it is necessary to know or estimate the tracer mean concentration and standard deviation. The median multiplier values given below, when used in conjunction with the median and coefficient of variation (COV = standard deviation/mean) of the tracer in the more dilute flow, provide a quick and conservative estimate of the detection limit required. These median multipliers were derived from the assessment of a large number of probability calculations. This method is illustrated below:

VOL 12

7426

R0040734

COV Value	Median Multiplier For Detection Limit
Low (<0.5)	0.80
Medium (0.5 to 1.25)	0.23
High (>1.25)	0.12

Example: COV <0.5
median concentration = 0.5 mg/L
detection limit required = 0.5 x 0.8 = 0.4 mg/L

The analytical precision, defined as the repeatability of the analytical method, is also an important consideration. It is determined by repeated analyses of a stable standard, conducting replicate analyses on the samples, or by analyzing known standard additions to samples. Precision is expressed as the standard deviation of the multiple analysis results.

E) Categorize Outfalls

Outfalls must be categorized and subsequently prioritized so that a plan of action can be developed. Naturally, the most toxic and dangerous outfalls need to be eliminated first, especially considering the limited availability of funds in today's strained economic climate. The above analysis of the dry-weather flows provides data to help categorize the outfalls into three groups: 1) pathogenic or toxic pollution, 2) nuisance or aquatic life threatening pollution, 3) unpolluted.

The pathogenic and toxic pollutants can cause illness upon water contact or consumption and significant water treatment problems for downstream consumers, especially if the pollutants are soluble metal and organic toxicants. These pollutants may originate from sanitary, commercial, and/or industrial wastewater non-stormwater entries. Additional residential area activities with a pollution potential include, household toxicant disposal, automobile engine de-greasing and oil disposal, and excessive use of chemical pesticides.

Nuisance and aquatic life threatening pollutants include laundry wastewaters, irrigation runoff carrying heavy loads of fertilizers, vehicle washwaters, construction site dewatering, washing of concrete ready-mix trucks, etc. These pollutants can cause: excessive algal growths; tastes and odors in downstream water supplies; offensive coarse solids and floatables; and noticeably colored, turbid, or odorous waters.

Unpolluted discharge from stormwater outfalls can originate from natural springs feeding urban creeks that have been converted to storm drains, infiltrating groundwater, infiltrating domestic waterline leakage, etc.

Outfalls must be visited, observations made, and all dry-weather flows sampled and tested in order to correlate flows with potential sources. Five methods for analyzing outfall dry-weather flow data/observations have been tested. These methods range from relatively simple reviews of physical

VOL 12

7427

indicators for outfall contamination, to more sophisticated methods requiring computer modeling for evaluation. Methods 1 and 2 attempt only to distinguish between contaminated and uncontaminated flows, while methods 3 through 5 are useful in identifying the likely sources from which dry-weather flows are originating.

Physical Indicators of Contamination

Indicators of contamination (negative indicators) are clearly apparent visual or physical parameters indicating obvious problems that are readily observable at the outfall during the field screening activities. The direct examination of outfall characteristics for unusual conditions of flow, odor, color, turbidity, floatables, deposits/stains, vegetation conditions, and damage to drainage structures is the simplest method of identifying grossly contaminated dry-weather outfall flows. While this procedure doesn't necessarily identify the flow source, some sources may be identifiable based on recognizable odors or floatables, for example. Pearson Correlation results indicated that high turbidity (lack of clarity) and odors appeared to be the most useful physical indicators of contamination when contamination was defined by toxicity and the presence of detergents. Observable parameters cannot be relied upon as a sole method for the evaluation of outfalls. A contaminated discharge may not be visible and can only be determined by other methods (Lalor 1993, Pitt et al. 1993a).

Detergents as Indicators of Contamination

Results from Mann-Whitney U tests during method development indicated that pure streams from any of the dry-weather flow sources investigated in this research could be correctly classified as clean or contaminated based only on the measured value of any one of the following parameters: detergents, color, or conductivity. Color and conductivity were present in samples from clean sources as well as contaminated sources, but their levels of occurrence were significantly different between the two groups (Lalor 1993). If pure streams from only one source were expected to make up outfall flows, the level of color or conductivity measured could be used to distinguish contaminated form clean outfalls. However, since this is commonly not the case, measured levels in outfalls with multiple sources could fall within acceptable levels even though a contaminating source was contributing to the flow. etergents, on the other hand, can be used to distinguish between clean and contaminated outfalls simply by their presence or absence. "Presence" translates to the lower limit of detection for the HACH detergent test kit, which is 3.29 times the standard deviation, or 0.06 mg/L of detergents. This reduces the probability of a false nondetection or a false detection to 5% (Standard Methods 1989).

VOL 12

7428

Flow Chart for Most Significant Flow Component Identification

Figure 2 is a flow chart describing an analysis strategy which may be used to identify the major component of dry-weather flow samples in residential and commercial areas. This method does not attempt to distinguish among all potential sources of dry-weather flow identified earlier, but rather the following four groups of flow are identified: (1) tap waters (tap water, irrigation water and rinse water), (2) natural waters (spring water and shallow ground water), (3) sanitary wastewaters (sanitary sewage and septic tank discharge), and (4) wash waters (commercial laundry waters, commercial car wash waters, radiator flushing wastes, and plating bath wastewaters).

The use of this method would not only allow outfall flows to be categorized as contaminated or uncontaminated, but would allow outfalls carrying sanitary wastewaters to be identified as such. These outfalls could then receive highest priority for further investigation leading to source control.

This flow chart was designed for use in residential and /or commercial areas only. Investigations in industrial or industrial/commercial land use areas must be approached in an entirely different manner (EPA 1993).

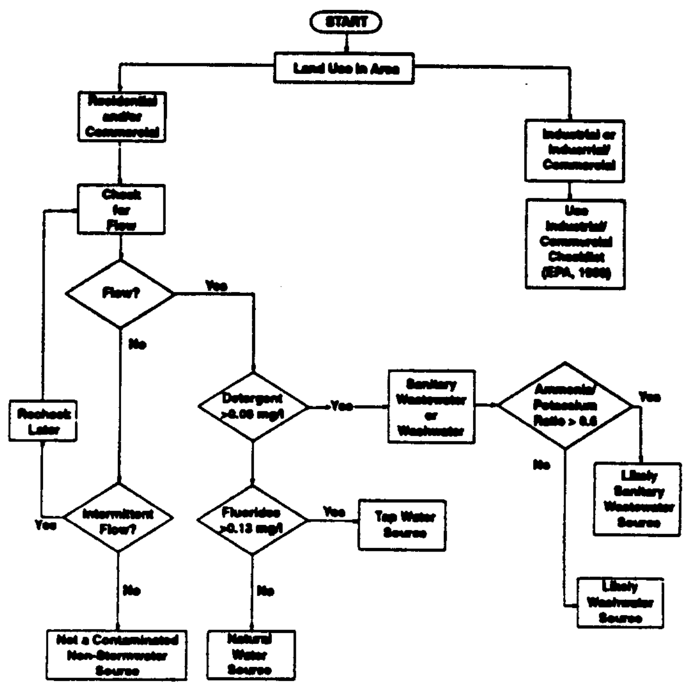
In residential and/or commercial areas, all outfalls should be located and examined. The first indicator is the presence or absence of dry-weather flow. If no dry-weather flow exists at an outfall, then indications of intermittent flows must be investigated. Specifically, stains, deposits, odors, unusual stream-side vegetation conditions, and damage to outfall structures can all indicate intermittent non-stormwater flows. However, frequent visits to outfalls over long time periods, or the use of other monitoring techniques, may be needed to confirm that only stormwater flows occur (Pitt et al. 1993a). If intermittent flow is not indicated, then the outfall probably does no have a contaminated non-stormwater source. The other points on the flow chart serve to indicate if a major contaminating source is present, or if the water is uncontaminated (Lalor 1993). Component contributions cannot be quantified using this method, and only the "most contaminated" type of source present will be identified. Sources are ranked from lowest to highest based on their contamination potential in the following way: (1) Natural water sources, (2) Tap water sources, (3) Wash water sources, (4) Sanitary wastewater sources. Numerical values presented in the flow chart were developed from source flow data collected during method development in Birmingham, Alabama (Lalor 1993). Values should be verified for other locales.

If more specific source information is desired, a more complex approach is necessary. Algorithms based on the simultaneous solution of a series of chemical mass balance equations have been developed to predict the most likely flow source, or sources, making up an outfall sample, and are discussed in the following paragraphs. The degree of accuracy achievable will depend greatly

VOL 12

7429

Figure 2: Flow Chart for Most Significant Flow Component Identification



upon the extent of local tracer data gathered to describe potential source flows.

Chemical Mass Balance at Outfalls: Matrix Algebra Solution

Flow contributions from various sources may be estimated by using a 'receptor model' based on a set of chemical mass balance equation. Such models, which assess the contributions from various sources based on observations at sampling sites (the 'receptors'), have been applied to the investigation of air pollution sources for over 20 years. The characteristic "signatures" of the different types of sources, as identified in the library of source flow data developed in the study area, allows the development of a set of mass balance equations. These equations describe the measured concentrations in an outfall's flow as a linear combination of the contributions from the different potential sources. A major requirement for this method is the physical and chemical characterization of waters collected directly from potential sources of dry-weather flow. This allows concentration patterns for the parameters of interest to be established for each type of source. If these patterns are different for each source, the observed concentrations at the outfall will be a linear combination of the concentration patterns from the different component sources, each weighted by a source strength term (m_n). This source strength term would indicate the fraction of outfall flow originating from each likely source. By measuring a number of parameters equal to, or greater than, the number of potential source types, the source strength term could be obtained by solving a set of chemical mass balance equations of the type:

$$C_p = \sum_n m_n x_{pn}$$

where C_p is the concentration of parameter p in the outfall flow and x_{pn} is the concentration of parameter p in source type n. As noted above, the m_n term represents the fraction contribution of flow from source type n affecting the outfall dry weather flow. The selection of parameters for measurement should reflect evaluated parameter usefulness.

Chemical Mass Balance at Outfalls with Monte Carlo Sampling

The Monte Carlo method goes one step further than the matrix algebra solution by allowing the variation within the library values for each source type to be considered. Instead of using a single value (i.e. mean value) to represent the parameter concentration (C_p) for each likely type of source flow, a Monte Carlo simulation is used to randomly select values from a statistical distribution. Monte Carlo sampling is a traditional method of sampling randomly across an entire input variable distribution. Any value across the range of the distribution is possible, although the sampling is influenced by the relative probability assigned to each value. The more probable values will have a greater chance of

VOL 12

7431

R0040739

being selected. (Lalor 1993).

Based on samples collected from known sources, probability distributions are calculated, for each parameter (conductivity, fluoride, hardness, etc.), within each potential source flow. Distributions considered in this procedure include normal, log-normal, and uniform. Local source flow quality monitoring is necessary to obtain this information, as discussed previously.

Monte Carlo simulation generates sets of concentration values based on the mean, coefficient of variation, and distribution of each parameter within each source. A set of equations is established for each set of sampled concentration values generated by the Monte Carlo simulation. The fraction of flow from each potential source is calculated by solving each set of equations. These flow values are then stored. Multiple trials are used to calculate the most probable sources of contaminants for each outfall.

F. Investigation and Remediation

The investigation of pollutant sources involves upstream surveys to progressively narrow the drainage area(s) of concern and locate the pollutant source(s). Upstream surveys can take a number of forms including:

1) Analysis of dry-weather flow at strategically designated upstream manholes and/or access points which includes all or some of the methods and parameters measured at the outfall;
2) In-depth watershed evaluation of potential sources, achieved by developing on information gained during mapping and tracer data collection; and
3) Localized surveys by visual inspection, TV camera survey, and smoke and dye tests.

In some of the case studies investigated, correcting problems only at the most contaminated outfalls resulted in insufficient receiving water quality improvements. Therefore after the contaminated outfalls have been identified, most of them are likely to require correction if receiving water quality recovery is to be affected. However, categorizing the outfalls allows the most serious outfalls to be recognized and corrective action to be initially concentrated in the most cost-effective manner.

For an effective improvement in receiving water quality (assuming a problem exists), the investigation and correction of only illicit stormwater entries is unlikely to solve the problem. Dry-weather flows are only one source of pollutants and an effective improvement may require a comprehensive investigation and remediation program covering wet-weather induced flows as well.

VOL 12

7432

Discussion and Conclusions

The main purpose of the research from which this paper emanated was to develop and test an effective screening methodology to identify storm sewer outfalls which are contaminated by illicit discharges in residential and commercial land use areas. Stormwater outfall screening methods presented here were tested in residential and commercial land use areas only. Techniques appropriate for industrial land use areas are discussed in *Investigation of Inappropriate Pollutant Entries Into Storm Drainage Systems* (EPA 1993).

Each of the screening methodologies evaluated is based on the location and investigation of stormwater outfalls with dry-weather flows. Consideration must be given to the potential of outfalls to carry intermittent discharges. Intermittent discharges are not inconsequential, and are likely to be missed during infrequent outfall screening visits. Care should be taken to note evidence of intermittent discharges, such as unusual sediments, stains, odors, or abnormal vegetative growth around outfalls.

Additionally, field work associated with this research confirms the importance of investigating all storm water outfalls and direct discharge pipes encountered, not just those within a specific size range. Some of the most contaminated flows encountered were issuing from small pipes (Lalor 1993).

The use of negative physical indicators of contamination alone, such as color, odor, lack of clarity, and the presence of floatables or deposits, resulted in a high false negative rate of 20%, and a false positive rate of 10%. Examination of outfalls for negative indicators of contamination identified only the most grossly contaminated commercial outfalls. Outfalls carrying sanitary wastewaters in mixtures with uncontaminated waters, one of the most serious concerns, were frequently missed using this method.

Testing dry-weather flows in residential and commercial areas for only the parameters identified by EPA as minimum requirements, (pH, chlorine, copper, phenols and detergents), can be used to accurately categorize outfalls as contaminated or uncontaminated. This determination in fact can be based simply on the presence or absence of detergents (lower limit of detection 0.06 mg/L as MBAS). During this research effort in Birmingham, Alabama, all flows from contaminated outfalls contained detergents, while all flows from uncontaminated outfalls did not. No false positives or false negatives resulted from the use of this method. No further prioritization of outfalls was possible using only the parameters identified by EPA. However, in residential and commercial areas, pH, total chlorine, total copper, and total phenols could be useful in identifying industrial discharges not previously known to exist within the drainage area (EPA 1993).

Testing for fluoride, ammonia, and potassium, in addition to detergents, allowed for further prioritization of outfalls, by identifying the outfalls most likely to be contaminated by sanitary wastewaters, wash waters, or relatively clean tap water sources. Using the flow chart presented in Figure 2, the most serious contaminating source can usually be identified for each outfall, whether or not the flow is a mixture originating from several sources. In flows issuing from a single source, the sole flow component can be identified. n multiple source flows which include at least one contaminating source, a contaminated source can be identified as long as it comprises at least approximately 10% of the flow. In mixed flows, contaminating sanitary wastewaters may be incorrectly identified as wash water when they contribute less than about 25% of the flow. This depends on the ratio of ammonia to potassium in both the sanitary wastewater and the other flow sources. The use of the flow chart in this research resulted in no false negatives, no false positives, and further, the correct identification of the most contaminated source contributing to each outfall analyzed (Lalor 1993).

The use of chemical mass balance equations as a means of identifying all sources contributing to flow at a given outfall is appealing in theory. However, this research indicated that the amount of variation present within potential sources of dry-weather flow, as well as the likelihood of unexpected and thus uncharacterized flows, especially in commercial areas, made this method ineffective for use in this application. Possible additional modification to the chemical masss balance program, such as allowing for the inclusion of more equations than unknowns, variable weighting, and the linking of variables with relatively high correlation coefficients, could improve its effectiveness (Wilson 1958). However, these modifications are not likely to fully compensate for the highly variable character of many of the potential dry-weather flows which will be encountered in this application. The amount of time and effort required to adequately identify and characterize potential sources also decreases the economic advantage of this method over wide-scales dye testing. Use of the chemical mass balance method in this research, with no threshold for program noise, resulted in a false positive rate of 40%, and no false negatives. Further, the most contaminated contributor to flow was incorrectly identified 70% of the time.

Defining a threshold level, based on analysis of many samples from known sources, and disregarding identified flow contributors below this level, reduced the false positive rate to zero while maintaining a false negatives rate of zero. However, the most contaminated contributor to flow was still incorrectly identified 50% of the time, making this method less useful for prioritizing outfalls than the simpler flow chart approach.

In summary, the following screening methodology is suggested. All stormwater outfalls and direct discharge pipes should be located. All dry-weather flows should be sampled, regardless of the size of the pipe. Evidence of intermittent flows should be noted, and the affected outfalls should be visited again. The flow chart in Figure 2 should be used as a guide for interpreting screening data. It is extremely important to determine the fluoride, ammonia,

VOL 12

and potassium values for ground, surface, and tap waters in the local study area, if outfall screening data is to be interpreted with confidence. Outfall samples collected should be tested first for detergents. If desired, samples testing negative for detergents could be tested for fluoride, to identify flows from relatively clean tap water sources. Samples testing positive for detergents should be tested for ammonia and potassium. A high ammonia-to-potassium ratio indicates those outfalls most likely to carry flows from sanitary wastewater sources. These outfalls sources receive the highest priority for source correction measures.

7435

Appendix II: Recommended Tracer Parameters

Specific Conductivity- Specific conductivity can be used as an indicator of dissolved solids (i.e., ions). The variation between water and wastewater sources can be substantial enough to indicate the source of a dry-weather flow, and because the measurement is easy, quick, and cheap it is a suggested tracer.

Fluoride- Fluoride concentration should be a reliable indicator of potable water where fluoride levels in the raw water supply are adjusted to consistent levels and where groundwater has low natural fluoride levels.

Hardness- Hardness may be useful in distinguishing between natural and treated waters (like fluoride), as well as between clean treated waters and waters that have been subjected to domestic use. It should be noted that hardness of waters varies considerably from place to place, with groundwaters generally being harder than surface waters.

Ammonia/Ammonium- The presence or absence of ammonia (NH_3), or ammonium ion (NH_4+), has been commonly used as a chemical indicator for prioritizing sanitary wastewater cross-connection drainage problems. Ammonia should be useful in identifying sanitary wastes and distinguishing them from commercial water sources.

Potassium- Greater potassium concentrations have been noted for sanitary wastewater compared to potable water during studies reviewed. These potassium increases following domestic water usage reveal its potential as a tracer parameter.

Surfactants and Fluorescence- Surfactants from detergents used in household and industrial laundering and other cleaning operations results in high concentrations in wastewater. Anionic surfactants account for approximately two thirds of the total surfactants used in detergents in the U.S., and are commonly measured as Methylene Blue Active Substances (MBAS).

Water fluorescence is also an indicator of detergent residue in waters. Most detergents contain fabric whiteners which cause substantial fluorescence.

pH- The pH of most dry-weather flow sources is close to neutral (pH = 7). However, pH values may be extreme (below 6 and above 9) in certain inappropriate commercial and industrial flows or where groundwaters contain dissolved minerals. If unusual pH values are observed, then the drainage system needs to be carefully evaluated. Note that pH values are a power function and

VOL 12

7436

therefore flow contributions cannot be proportioned in the same way concentration values can.

Temperature- An elevated temperature of a receiving water can indicate contamination, particularly in cold weather. Sanitary wastewater and cooling water are examples of sources in which temperature elevation may be noted.

Total Available Chlorine- Chlorine is not stable in water, especially in the presence of organic compounds. The chlorine demand of contaminated water can be very large, with chlorine concentrations decreasing to very small values after short periods of time. The presence of chlorine in dry-weather flow could indicate a significant and very close potable water flow source or industrial discharges. (Pitt et al. 1993a).

Appendix III: Recommended Tracer Analysis Methods

Specific Conductivity and Temperature- Field measure using a multi-parameter SCT meter from YSI. Both specific conductivity and temperature must be calibrated against standard specific conductivity solutions and a standard thermometer.

Fluoride- Lab. analysis using a field spectrophotometer and evacuated reagent and sample vessels (HACH DR/2000™ and AccuVac™ ampules using SPADNS reagent, without distillation). The samples should be filtered through a 0.45 μ membrane filter (e.g., Millipore™ filter) before analysis to minimize color interference.

Hardness- Lab. analysis using a field-titrimetric kit (HACH Digital Titrator Model 16900). Filter as for Fluoride.

Ammonia- Lab. analysis using a direct Nesslerization procedure and spectrophotometer (HACH DR/2000™ Nessler method, but without sample distillation). Filter as for Fluoride.

Potassium- Lab. analysis using either a spectrophotometer (HACH DR/2000™ Tetraphenylborate method), or a flame atomic absorption spectrophotometer (if available). Filter as for Fluoride.

Surfactants- Lab. analysis using a simple comparative colormetric (color wheel) method (from the HACH Company). Filter as for Fluoride. This procedure to be conducted under a laboratory fume hood.

VOL 12

7437

Fluorescence- Lab. analysis fluorometer (Turner model 111). The fluorometer has general purpose filters and lamps and should be operated at the most sensitive setting (number one aperture).

pH- Lab. measurement using a standard laboratory pH meter after accurate calibration using at least two buffer solutions bracketing the expected sample pH value. Field measurements can be made utilizing pH meters or litmus paper depending upon degree of accuracy required and time constraints.

Chlorine- Total available chlorine was determined with the DPD method using a HACH DR/2000™ spectrometer with AccuVac™ ampules.

Water color- Lab. measurement using a simple comparative colormetric (color wheel) field test kit from the HACH Company. Apparent color (unfiltered samples), expressed in HACH color units.

Turbidity- Lab. measurement using a HACH Nephelometer.

Toxicity screening- Microtox™ (from Microbics) toxicity screening for relative toxicity values. The 100 percent screening test was most commonly used. If the light output decrease after 25 minutes (the I_{25} value) was greater than 50 percent, then the standard Microtox test was used to determine the sample dilution required for a 50 percent light decrease (the EC_{50} value). (Field et al. 1993a).

FINDING ILLICIT CONNECTIONS & DISCHARGES WITH P³IL

John D. Minor[1], B.Sc.,M.Sc.

Abstract

The City of Scarborough is a lower tier (area) municipality of 172 square kilometres, population of about 550,000 and borders on the north shore of Lake Ontario. About 85% of the area is fully developed with 7 distinct areas zoned as Industrial Districts (16% of total area). About 400 known ICI sites have stormwater discharges (70% are in Industrial Districts). The City is drained by three watercourses which receive stormwater from 826 outfalls. Thirty-two large outfalls discharge directly to Lake Ontario. Storm outfall and up-pipe pollution prevention efforts utilize aproximately 6,000 manhours per year. Analytic laboratory costs average $35,000 CDN per year. Equipment costs average $15,000 CDN per year. First year start up costs approximate $200,000 CDN for 70% of total area. No stormwater discharge permits are issued in Scarborough except for "once-thru cooling water" to storm. All storm water quality is specified by a Sewer Use Bylaw on a concentration basis, not load. All outfalls, drainage areas and pipes have been digitally mapped. Watercourses are monitored at select locations during dry and wet weather, and on a seasonal basis. Specific storm drainage areas receive intensive investigation. Outfall problems are identified by chemical, biological and visual criteria. Problem outfall (storm sewerage) investigative techniques include visual, biological degradation, chemical and physical assessment. Discharge characterization techniques using flow meters, non-intrusive sensors, video cameras, absorbent sticks/pads (for petroleum), dye testing, smoke testing and pressure testing assist in problem verification. Finding illicit connections and discharges requires dedicated Programs with Procedures that may be executed with Intuition and occasionally Luck (P³IL).

Introduction

Storm water issues in the Province of Ontario have received increased profile and priority since the early 1980's. The Ontario Ministry of Environment and Energy

[1] Manager of Water Resources, City of Scarborough, 300 Consilium Place, Suite 1000, Scarborough, Ontario M1H 3G2 CANADA

(MOEE) and the Ontario Ministry of Natural Resources (MNR) regulate all issues on a province-wide basis. Provincial agencies, such as Conservation Authorities, regulate some water issues on specific watershed bases.

The MOEE regulates predominantly water quality issues, and permits the taking of water from surface and groundwater sources. The MNR regulates water as a habitat and resource issue. Conservation Authorities focus on water quantity control, flood and erosion issues. Legislative authority over storm water related issues rests predominantly in the:

- Ontario Water Resources Act (enforced by MOEE)
- Environmental Protection Act (enforced by MOEE)
- Federal Fisheries Act (as enforced by Provincial MNR)

However, other legislative acts have impact on water discharge (quantity and quality) issues. The Building Code Act (1990) includes regulations pertaining to plumbing and drainage specifications for private lots and some industrial activities.

As environmental concerns and public awareness increased in the mid 1980's, the specific legislation and regulations of the late 1970's and early 1980's have been "enhanced" (with many well intentioned Interim Guidelines.... and Draft Interim Guidelines .....) without amending the legislation. The bottom line of all regulations pertaining to discharges of storm water to the environment is that the owner (or controlling party) of the discharge is deemed to be responsible.

The City of Scarborough (172 square kilometres, population 550,000) owns and operates all sewer conveyances. The City does not own or operate sewage treatment services; treatment is provided by the upper tier Metropolitan Toronto Regional government. All storm sewer conveyances discharge at outfalls or ditches (approximately 825 in Scarborough) into the local waterway (environment). Hence, the City of Scarborough is responsible for local discharge quality issues. Currently no storm water discharge permit or approval process at the municipal level (other than to allow once-thru cooling water on a site by site basis) is practiced. No specific revenues are generated on storm water; general "sewage rates" are calculated on potable water consumption .

The MOEE proposed program of Municipal Industrial Strategy for Abatement (MISA, 1986) includes detailed specifications for quantity and quality of discharge to the environment from seven industrial sectors and the municipal sector. Many of the "direct" discharge sectors (industrial) have been phased in by 1994. The final sector (municipal with "indirect" dischargers) has yet to be brought forward.

Some Regional and Area municipalities, in preparation for MISA and other proposed by-law enhancements, have undertaken waterway and outfall evaluations. The MOEE has provided varying levels of financial assistance through subsidy programs.

Municipalities within the Great Lakes Basin area of Ontario have been provided

VOL 12

7440

with yet another challenge by the Canada-U.S. Great Lakes Water Quality Agreement under the International Joint Commission (IJC). Forty-three specific "Areas of Concern" were identified in the Great Lakes Basin. The Metropolitan Toronto and Region (which includes the City of Scarborough as an area municipality) was specifically identified and a Remedial Action Plan (Metro RAP, 1994) has been created. Action plans proposed in the RAP include specific Trace and Disconnect Programs for cross connections in both Residential and Industrial/Commercial/Institutional (ICI) locations.

Clearly, the intent to improve storm water discharges in Ontario has now been conveyed to public and political audiences, as well as to the municipal and private ICI corporations.
In response to this intent and scrutiny, the owner of a discharge (outfall) must carefully provide a blended response to:

- public expectation
- political promises
- regulatory requirements/due-diligence
- budgetary constraints

Such a blended response must carefully compare the benefits between short term projects and long term programs.

The City of Scarborough has developed a series of programs dedicated to pollution control and storm water issues. Finding and correcting illicit connections is a major component of these programs. These programs have specific procedures that, on occasion, may be augmented with intuition and luck.

Experience supports the premise that the most successful ventures into storm water issues should start with the creation of a long term program having specific descriptions of:

- intent (including long term environmental benefit, corporate due-diligence and regulatory compliance)
- objectives that are open to public and regulatory scrutiny, endorsement and support
- goals (measurable actions or parameters used for determining program progress)
- budgetary and staffing requirements

<u>Program Creation</u>

Short term ventures, seasonal projects and site specific actions all have immediate political and public appeal because dollars are quickly spent and visible action is taken. The long term success of these ventures, however, may not be readily appreciated, achieved or even verified. A program for finding and correcting illicit connections should be part of a larger, and well promoted and managed, outfall and watercourse management strategy.

At the municipal government level, the long term success and survival of the program requires a complete understanding, clear documentation and disclosure of the true intent and goals of the program. Specifically, the ideal program should;

i) be created and considered as a long term program and not as a project of a few years duration.

ii) clearly state the obvious environmental problem(s) and associated human health risks so that officials and the public have (and continue to have) a high level of comfort with budgetary and staffing issues.

iii) state realistic goals, with realistic schedules that will be reported on annually.

iv) have annual review procedures for staffing and budgetary requirements, and actively seek funding from existing or new senior government subsidies.

The City of Scarborough currently enjoys strong political and public support for its programs. This is very important to program longevity and funding as no discharge permit or approval process (and associated revenues) currently exists. All program funding is achieved through tax based annual budgets.

Program Components

A successful investigation program should be carefully and completely planned before field efforts begin; field implementation should be phased in over two years. Implementation schedules should be carefully scrutinized and reassessed throughout the second year.

Phase I

To avoid lost time, effort and incorrect assessments, the first phase should be primarily administrative with minimal fieldwork. Specifically;

i) Watershed areas should be mapped with associated overlays of street grid and sewer layout (including both sanitary and storm). A Geographic Information System (GIS) with digitized mapping facilities can provide an ideal format.

ii) Each watershed area should be mapped with locations and identification codes of all storm discharge locations (outfalls, ditches, infiltration pits/lagoons, significant overland flow routes).

iii) A drainage map for each storm drainage area, serviced by an individual discharge outfall, should be constructed with site specific identification of:
- all manholes (maintenance holes) and catchbasins
- combined sewer areas
- combined sewer overflow (CSO) locations
- sanitary pumping station overflow and forcemain locations
- septic or holding tank sites (areas not serviced by sanitary sewer)

VOL 12

7442

iv) Each drainage area map can then be enhanced with:
- industrial zones/districts
- specific industrial sites
- once-thru cooling water discharge locations
- major transportation corridors and industrial traffic routes
- individual lateral connections to the sewers may also be identified if historic connection cards and a digitized Sewer Inventory Maintenance System (SIMS) are available

Phase II

Field verification of outfall location, size and construction material should commence at the end of Phase I and continue throughout Phase II. Specifically,

i) attention should focus on access routes, access hazards/restrictions. Instructions to staff for access by gates/grates should be coded.

ii) each outfall should be photographed and coded for specific outfall identification.

iii) all outfalls (and drainage areas) should be ranked by size of pipe (hence approximate size of drainage area) and potential number of lateral connections.

iv) lateral connections can also be ranked by size and/or by code for street catchbasin, residential lot, ICI lot, etc.

Phase III

Field assessments should always be conducted by teams (minimum 2 persons per team) where each person is fully trained and certified (when appropriate) in
- confined space access
- first aid/CPR
- road closure and traffic control procedures
- sampling procedures
- chain of custody procedures
- data logging

Screening procedures should be conducted in progression as follows:
- outfall assessment
- up-pipe investigation
- focus on specific sewer branch and lateral connection
- verification and documentation for correction and/or legal action

Outfall Assessment Procedure

a) Visual assessment for solids, odour, colour, oil and grease "sheen", paper and rags, structural damage and acid erosion, can be enhanced with visual clues of biological degradation/enhancement (loss or proliferation of aquatic vegetation, macrophytes or invertebrates in the immediate area of the receiving water).

VOL 12

7443

VOL 12

b) sample parameters should include field measurement of
- flow rate (L/sec)
- temperature (°C)
- dissolved oxygen (mg/L)
- pH
- conductivity (μmho's/cm)

c) Grab samples should be taken if flow is greater than a trigger limit (ie. O.1 L/sec). Analysis of samples should include parameters in Fig. 1.

Figure 1: SAMPLE PARAMETERS AND THRESHOLDS USED TO SELECT OUTFALLS FOR UP-PIPE INVESTIGATION

Parameter		Threshold	Units
Escherichia Coli	(EC)	10,000	/100 mL
Faecal Coliforms	(FC)	50,000	/100 mL
Faecal Streptococci	(FS)	50,000	/100 mL
Pseudomonas Aeruginosa	(PA)	100	/100 mL
Total Kjeldahl Nitrogen	(TKN)	5.0	mg/L
Total Phosphorus	(TP)	1.0	mg/L
Copper	(CU)	1.0	mg/L
Zinc	(ZN)	1.0	mg/L
Lead	(PB)	1.0	mg/L
Cadmium	(CD)	1.0	mg/L
Chromium	(CR)	1.0	mg/L
pH	(pH)	6.0>pH>9.5	
Total Solids	(TS)	1000	mg/L
Dissolved oxygen	(DO_2)	<5	mg/L
Temperature	(Temp)	>45	°C
Biochemical Oxygen Demand	(BOD5)	5.0	mg/L

Additional parametres may include:
- Oil/Grease reported as i) animal/vegetable
  ii) mineral/synthetic
- Chemical parameter(s) specifically related to local ICI

Characterization of outfalls is the most labour intensive and costly activity of the program. It is also a very important activity (second only to finding and removing a cross connection) and must be carefully documented for compliance and enforcement issues, long term trend analysis and watershed loading estimates.

Bacterial data should be reported as a geometric mean count per 100 ml sample volume.

7444

R0040752

Chemical concentrations should be reported as flow weighted mean concentrations (FWM); this removes some bias associated with extreme variations in flow rates,

$$FWM = \frac{(\Sigma_1^n q_i c_i)/n}{(\Sigma_1^n q_i)/n}$$

where q_i = flow rate during the i^{th} sample
c_i = concentration of parameter in the i^{th} sample
n = number of samples collected for parameter

Load calculations should be expressed as an arithmetic average load (L),

$$L = (\Sigma_1^n q_i c_i)/n$$

All visual data should be summarized and ranked by presence/absence criteria. All chemical and physical data should be summarized and ranked by concentration.

Outfalls having visible problems plus chemical and physical data in exceedance of threshold values should be prioritized for immediate up-pipe testing.
Outfalls having no visible problems may have chemical or physical problems. Ranking by FWM and loadings will assist in prioritizing specific outfalls for up-pipe investigation.

Up-pipe Investigation Procedures

Always use the same investigation team on a prioritized outfall. Personal insight, experience and continuity of field procedures are very important in minimizing time and cost. Intuition should be considered but always verified by sampling.

The goal of up-pipe testing is to determine which leg of sewer (between sequential manholes) is receiving the offending discharge.

Regardless of the residential or ICI nature of the drainage area, visual clues and bacterial testing provide the most effective initial investigation because:

- visual clues of rags, paper, oil/grease and solids are readily seen in flow or on benching in manholes and pipes
- bacterial tests are usually reported in 24 to 36 hours (compared to 2 to 3 weeks for chemical tests)
- residential cross connections are usually whole house or basement washroom in origin; bacterial counts will be high (E.C. $> 10^4$) with only some measurable chemical parameters
- industrial whole building or unit cross connections usually include locker and washroom facilities (industrial sites with multiple sewer connections will require visual and chemical testing after bacterial cross-connects are removed)

In an area which is predominantly ICI or is known to have specific chemical users, chemical tests specific for that area will result in better investigation progress but cost significantly more in analytic costs and extended turn around times.

In areas having mixed residential and ICI, especially in large areas serviced by storm pipes >700 mm, the visual and bacterial tests should always be investigated and solved first. After bacterial sources are removed, chemical testing can proceed without interference from alternate sources.

Sampling Location and Frequency

a) Manhole entry locations and sampling frequencies are best determined by the knowledgeable field team.

In small drainage areas (pipes <700mm dia.), 5 to 7 manhole entries for visual and bacterial testing should provide a good definition of problem area.

In larger drainage areas (pipes >700 mm dia.) the first sampling effort may require 10 to 12 manhole entries to successfully sample major intersections and pipe branches.

b) Based upon the visual and first series of bacterial results, subsequent sample runs should include 3 to 5 sequential manholes in the suspect pipe branch.

Typically, visual clues become more evident as one gets closer to the site. Within 200 to 300 metres of the source, average EC:FC:FS:PA counts are $\geq 10^4:10^4:10^4:10^2$. Typical storm sewers and outfalls having no sanitary sewage input have average EC:FC:FS:PA counts $\leq 10^3:10^3:10^3: 10^1$.

c) When the affected leg of sewer has been identified, it must be verified by visual, bacterial and chemical testing (with flow estimates) in the upstream and downstream manholes.

d) Once verified, the difficult task of identifying the exact point of discharge to the sewer can be undertaken;
   i) Residential areas require house by house dye testing of sanitary facilities. This is laborious and typically <50% of buildings are accessible on any given day of effort. Repeated returns to the area may accomplish up to 85% of building testing but rarely is 100% access acquired without sending registered letters and pre-arranging after-hour/weekend testing.
   ii) ICI areas are significantly easier to dye test because they have

fewer lateral connections and usually have control manholes for direct access. Large individual ICI site cross connections can result from:

- site or building expansion over existing outdoor drains and catchbasins
- outside storage area and loading and receiving bays may not have spill containment facilities

iii) When access problems occur in residential sites or certain ICI sites, alternate tests may be progressively used:

- smoke tests in sanitary sewer
- smoke tests in storm sewer
- video camera (in-pipe) to find and observe offending lateral
- dye testing rain water leaders

Difficult Scenarios

Scenario #1: No definite leg of sewer (between sequential manholes) can be identified after 3 or 4 sample runs. The investigation team should suspect;

i) faulty structure or integrity of sewers which allows contaminants to escape from the sanitary sewer, cross bedding material and infiltrate the storm sewer. Pressure testing the sanitary sewer is a suitable verification test under these circumstances.

ii) more than one source of contaminant exists, however, sources are intermittent because of shiftwork or weekend schedules.

iii) the offending party has observed investigation teams efforts and has altered business schedule to avoid detection.

To deal with issue ii) and iii) the investigation team should leave the area for about a week, then return and install auto samplers that collect discrete hourly samples. These auto samplers may be augmented with flow loggers or pH sensors to help define the timing of discharges into the branch sewer.

Scenario #2: Full investigation and in-pipe video reveals no lot lateral connection (typically a chemical, not bacterial problem). The investigation team should suspect;

i) spills or illegal dumping into roadside catchbasins or utility chambers. Catchbasin sumps and chambers should be checked for evidence. Surveillance of the area using time delay video recordings or unmarked vehicles may prove successful.

VOL 12

7447

ii) infiltration into storm pipe during rain events or seasonal high groundwater that is moving contaminants from adjacent lands (landfill sites, industrial site, septic beds, etc.) To verify this problem, a series of boreholes and subsequent soil/water testing should be conducted in the immediate vicinity. Positive results may lead to a large scale and costly remedial effort at source and in the utility trench.

Documentation

The initial phases of program creation (mapping, coding locations, etc.) will become the backbone of a successful program. Proper and complete documentation of all efforts, observations and findings must be carefully and securely filed.

Strict supervision of field staff and their documentation is also necessary. The "thrill of the chase" usually expedites the finding of the cross connection. Concurrent poor documentation may inhibit the correction of the alleged problem especially if the owner becomes adversarial; the good luck of quickly finding the source may turn to bad luck.

Outfall characterization data and cross connection efforts will complement other watershed or stormwater management program efforts. Proper documentation and filing of data will help explain variations in local watercourse conditions. This documentation is essential in maintaining a high level of comfort with government officials and the public.

Summary

The Program and Procedures have been created, and are currently used, in the City of Scarborough. They have evolved (and sometimes regressed) over the years, hence the current program contents have been polished with hindsight.

The creation of a similar program must have full and accurate disclosure of financial and staff requirements from its inception. Failure to properly budget and control expenditures, even if many cross connections are found and corrected, will jeopardize the survival of the program.

Start up costs, in the first year, need not be excessive. Scarborough contracted Phase I (without digitizing), Phase II and Phase III (only outfall characterization) for 70% of the City (554 outfalls) in 1986 for about $200,000 CDN (Gartner Lee, 1987). In subsequent years, staff have digitized most of original Phase I, II work and have conducted Phase I, II, III on the remaining 280 outfalls (250 outfalls in the combined sewer area having 72 CSO's).

VOL 12

7448

Phase III cross connection efforts continue year round utilizing about 6,000 manhours per year. Annual equipment costs, since 1987, have averaged $15,000 CDN per year. Analytic laboratory costs average $35,000 CDN per year.

Phase III outfall characterization is being repeated on a five year schedule with certain outfalls visited more frequently based upon complaints (or spill occurrences) and as verification after a cross connection correction.

Typically, the first and second year of the Phase III effort reveal the greatest number of cross connections per unit effort as gross visual problems (ie. bean sprouts, oil/grease, fish scales/eyes, acid erosion, etc.) are assessed and quickly traced. Subsequent efforts, dealing with clear water chemical problems require significantly more effort and cost. Success per unit effort is maximized by having a dedicated program and specific procedures with allowance for intuition and luck.

Positive reporting to City officials and the public on initial successes and subsequent follow up efforts is very important. It should be stressed that cross connections can appear at any time and place and that only with a long term program can storm water and waterways be maintained to the public and regulatory standards.

Acknowledgements

Commissioner Michael A. Price, P.Eng., FICE, and former commissioner R.K. Brown, P.Eng. of the City of Scarborough Works and Environment Department provided continued support and encouragement for this and other environmental programs. Environmental Services Director, R.T.Quinn, P.Eng. has provided consistent budgetary, staffing and moral support for this program on an annual basis. Funding assistance for start up of the program was provided by the Ontario Ministry of Environment and Energy.

SESSION II: Locating Illicit Connections

DISCUSSION

Locating Inappropriate Discharges to Storm Drains
Melinda Lalor, Robert Pitt, Richard Field and Edward Thackston

No questions or comments.

Finding Illicit Connections and Discharges with P*IL
John Minor

Approach is to sample outlets for a variety of pollutants and then rank them by the percentage of pollutant load contributed by the individual outlet. The municipality then works to remove the illicit connections from the systems that contribute the most pollution.

Do not neglect the smaller pipes, since they often have the worst water quality.

50% of illegal connections require court action to get removed (could this be because they are industrial and commercial?). Need to collect up to a week's worth of data to document sufficiently for court action. Video is becoming increasingly accepted by the court.

Private homes receive 50-100% reimbursement for removal of illegal connections.

Court win ratio is about 50% - therefore about 75% get fixed.

A high percentage of the original illegal connections have been removed. There are still a number remaining, but the pollution from them is small, compared to what was originally there. The real question is "how far do we go in removing illegal connections"?

(No Paper in Proceedings)
John Bingham

Showed the Stonebrook area of Boston, which is a system that has been separated, and which feeds into a combined sewer area. Purpose of the monitoring program was to define the relative contribution of the stormwater system to dry weather pollution load from Stonebrook, i.e. find sanitary connections to stormwater system.

Study was made to identify cross-connections and other sources in the watershed. Analyzed for color, ammonia, fluoride and detergents.

Hach kits were used, and they found that ammonia was the most useful indicator for distinguishing between wastewater and stormwater.

Found about 1 mgd total of raw sewage flowing directly into the Charles River.

Panel Discussion/Questions/Comments

Question: If the storm drain is on private property, it can be difficult to verify and enforce removal of illegal connections.
Answer: Ontario has purchased the right-of-way for all its sewers.

Comment: Contaminated cooling water has chemicals that are not easy to find with simple test kits.

Comment: Pitt also found this - chemicals were generally concentrated tap water, but you have to look for specific tracers, such as rust inhibitors. Cu might be used.

Comment: (Cave) These discharges are falling through the cracks. Region I now has an ordinance, as does California.

Question: Did Bingham filter samples?
Answer: Yes, tested filtered and unfiltered samples, and found no real difference in measured concentrations except for fluoride. However, they recommend filtration of all samples anyway, to remove interferences for colorimetric tests.

Comment: Used Hach kits and got many false negatives on Cl from unfiltered samples. Pitt observed that Cl is not a good indicator for anything.

Question: How do you deal with illegal dumping problems?
Answer: Must collect a sample - which is the largest problem. This may involve building a dam, or setting up some special sampling equipment to collect intermittent flows.

Question: Were criteria developed based on receiving water quality criteria (largest concentration may not have largest environmental impact)?
Answer: Generally, no, but we are trying to move to this.

Comment: For those starting an illicit connections study, do not begin with sampling, but rather gather up as much existing data as possible.

Comment: An EPA User's Manual on detecting illicit connections is available from Richard Field.

Comment: A public information program can be very helpful - public has many eyes (although it may require considerable staff time to check out citizen reports).

NPDES MONITORING - ATLANTA, GEORGIA REGION

P. Michael Thomas,[1] Scott L McClelland,[2]

INTRODUCTION

The impact of stormwater runoff on urban streams is becoming more significant as urban areas continue to expand and as treated wastewater discharge quality is improving. Urban stormwater runoff can contain significant amounts of various pollutants including bacteria, sediments, nutrients and heavy metals (U.S. EPA, 1983). The urbanization or development of a watershed can have a variety of impacts on the stream, including increased flooding, streambank erosion and pollutant export (Schueler, 1987). As a result, the U.S. Congress affirmed in the 1987 Clean Water Act Amendments, that stormwater pipes are point sources of pollution and must be permitted through the NPDES permit program. This paper describes a regional stormwater monitoring plan developed and implemented in the Atlanta Region to comply with NPDES rules and to characterize local stormwater discharges.

<u>Coordinated Regional Response</u> - After the U.S. Environmental Protection Agency (EPA) issued the final stormwater permit rules in 1990, the Georgia Environmental Protection Division (EPD) announced that they would issue a uniform region-wide permit for a five county Metro-Atlanta area of Clayton, Cobb, DeKalb, Fulton and Gwinnett Counties. EPD defined this area as a large municipality, despite the fact that it contains over 40 governments ranging in population from 2,642 (Palmetto) to 468,000 (unincorporated DeKalb County). The population for the entire five county area was 2,218,600 in 1990. The result of EPD's action meant that small cities who had never heard of the NPDES stormwater program, had six months to prepare their Part I application. EPD's rationale for this action was that all these jurisdictions were contributing to violations of water quality standards in Atlanta area rivers and streams.

The local governments joined together with the regional planning agency, the Atlanta Regional Commission, to form the Atlanta Region Storm Water

---

[1] Principal Environmental Planner, Atlanta Regional Commission, 3715 Northside Parkway, 200 Northcreek, Suite 300, Atlanta, Georgia 30327

[2] Associate, Camp Dresser & McKee, Inc., One Tampa Center, Suite 1750, Tampa, Florida 33602

Management Task Force to develop efficient and consistent stormwater permit applications. EPD's strategy was to issue a single permit for the five county area allowing each government to apply independently or as a coapplicant with a larger government. This resulted in 21 independent or lead applicants and 16 coapplicants (Table 1). By coordinating activities and sharing resources, the local governments were able to reduce the resources required in all aspects of the application process including the stormwater characterization work. The Task Force members also worked together to develop a regional approach for a long-term stormwater monitoring plan.

TABLE 1. Independent or lead applicants and coapplicants to the region-wide NPDES stormwater permit for the Metropolitan Atlanta area and their 1990 population.

Independent Applicants		Lead Applicant & Coapplicants	
Government	Population	Government	Population
Cobb County	453,400*	Clayton County	142,000*

Union City	8,483	Norcross	6,034
		Sugar Hill	4,598

*Population listed is for the unincorporated portion of the County

DESIGN OF THE REGIONAL MONITORING PLAN

To comply with the permit application requirements, a regional characterization plan was developed and each major government was assigned appropriate sampling responsibilities. A number of different governments and agencies were involved in instrumenting these sites and collecting information from appropriate storm events. The data collected from each site were compiled and used to develop local stormwater event mean concentrations and pollutant loading estimates for the Region.

NPDES Monitoring - The rules promulgated by the U.S. EPA, required that each permit applicant collect "quantitative data from representative outfalls" of stormwater runoff. The objectives of this sampling work can be summarized as follows:

a) determine the type and magnitude of pollutants in stormwater runoff; and
b) relate the water quality characteristics to land use type.

An important consideration was to collect enough samples to develop statistically valid event mean concentrations for each pollutant by land use (the rules require that three storm events be sampled at each site). Also, it may be important to collect samples during different seasons to determine if there are seasonal fluctuations in stormwater quality.

Sampling Site Selection - One of the first issues addressed by the Task Force was to determine how many sites should be monitored and who would be responsible for instrumenting the sites and collecting and analyzing the samples. The EPA rules required that each applicant select five to 10 representative outfalls for collection of samples for three storm events. It was obvious that five sites for the entire Region was not adequate and that five sites for each of the 21 independent applicants was excessive. The compromise developed by the Task Force was to locate an average of five sites in each county for a minimum of 25 sites. ARC staff developed a method of allocating the responsibility for these sites among the permit applicants based on population and employment as an estimate of the relative amount of stormwater runoff that would be generated by each jurisdiction. The allocation of sites resulted in the five counties and four largest cities being assigned from one to six sampling sites each. The smaller cities, which lack the resources to conduct this type of work, were not assigned a sampling site but were asked to share in the cost of the monitoring work based on the percentage of their population in their respective county.

After the number of sites per government was selected, general site locations were determined based on existing monitoring networks, land use and watershed characteristics. Specific monitoring sites were then located based on size of the drainage area, type and continuity of land use and use of stormwater pipe or stream sites. Existing local government stream monitoring sites were utilized where possible. Sites were then visited and evaluated based on accessibility, safety, security and suitability for flow measurement and sample collection. Hydraulic factors considered for stream sites included open-channel sites with existing stage-discharge relations or sites where adequate stage-discharge relations could be established, stable channel conditions, and adequate distance from major tributaries to allow for complete mixing. Other general site considerations included avoiding sites having steep slopes, poor visibility, and heavy traffic.

VOL 12

7455

Most of the sites were located in the Chattahoochee River basin because more of the five county area lies within this basin than any other and because this river is of great significance to the region, providing over 70% of our water supplies. Figure 1 shows the general location of the 27 sites. Because land use is the main factor that impacts the quality of stormwater runoff and is often used in models to predict stormwater quality (ARC, 1992c), sampling sites were selected to represent the major land uses in the area (Table 2). Where possible, small drainage areas which represented a single land use were chosen.

FIGURE 1. Stormwater Sampling Locations in the Atlanta Region

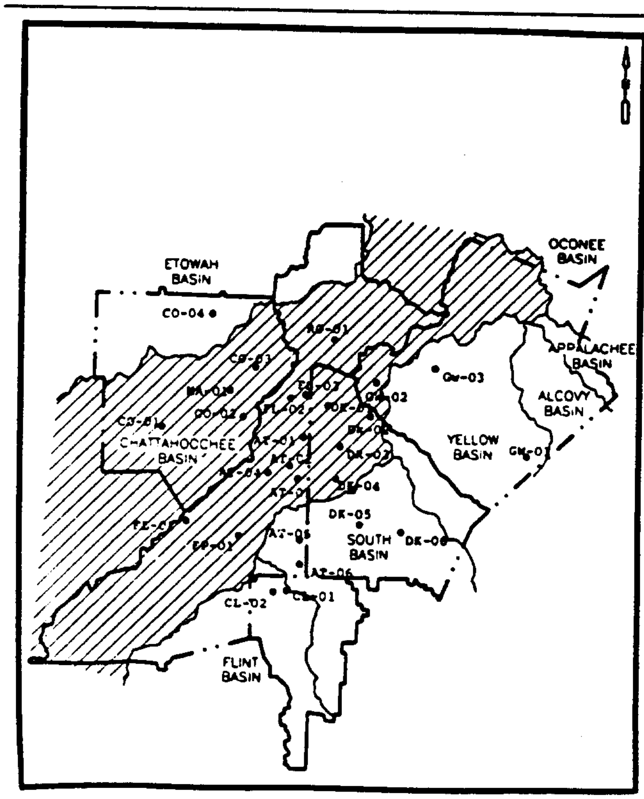

TABLE 2. Sampling Site Description and Land Use Category

Station Number	Site Description	Land Use Category
AT-01	Outfall - Tributary to Nancy Creek - parking lot of large shopping mall, draining commercial land use area.	Commercial
AT-02	Outfall - Tributary to Peachtree Creek - parking lot and roadway, area of commercial and light industrial land use.	Commercial
AT-03	Outfall - Tributary to Clear Creek - draining single family residential area.	Residential
AT-04	Outfall - Tributary to South River - draining a light industrial park.	Industrial
AT-05	Outfall - Tributary to South River - draining an area of industrial land use.	Industrial
AT-06	Outfall - Tributary to Chattahoochee River - draining an area of industrial and transportation land use.	Industrial
CL-01	Junction Box - Tributary to Flint River - draining an area of heavy industry.	Industrial
CL-02	Outfall - Flint River, Clark Howell Highway - draining commercial, business and transportation land use.	Commercial
CO-01	Stream - Olley Creek Tributary to Sweetwater Creek - draining an area of industrial and commercial activity including a closed sanitary landfill.	Commercial
CO-02	Outfall - Unnamed Tributary to Rottenwood Creek - draining a commercial/business park area.	Commercial
CO-03	Outfall - Tributary to Sope Creek - draining moderate density residential area.	Residential
CO-04	Stream - Noonday Creek Tributary to Lake Allatoona - draining an area of residential and commercial land uses.	Residential
DK-01	Stream - Bubbling Creek Tributary to Nancy Creek - draining an area of public parks and residential land uses.	Residential

DATA COLLECTION

A regional consultant was selected (Camp, Dresser & McKee, Inc.) by the Task Force to develop standard operating procedures for the monitoring program and to conduct most of the sampling work. The use of the regional consultant allowed the work to be done quickly and consistently. Some of the large local governments were able to use their own staffs to conduct part of the monitoring work. As the local governments move from the permit application phase to the long-term monitoring program, most will conduct the work with their own staff. Table 3 lists who was responsible for conducting the sampling and lab analysis in each jurisdiction. The involvement of many different parties in the sampling program raises a concern over the consistency of the data collected. The use of the standard operating procedures and the use of the same analytical laboratory for 63% of the sample analyses reduced inconsistencies.

[1]The Regional Consultant (Reg. Cons.) was Camp Dresser & McKee, Inc. The City of Atlanta utilized a different lead consultant but used the same subconsultants as Camp Dresser & McKee did for sample collection and analysis.

Representative Storm Event Criteria - The EPA rules required that each applicant collect samples of stormwater runoff. The rules recommended that "representative storm events" be sampled which met the following criteria:

- the storm event must be greater than 0.1 inches in magnitude;
- the event must be at least 72 hours from the previously measurable event (>0.1 inches);
- where feasible, the variance of event duration and total rainfall should not exceed 50 percent of the average or median rainfall event; and
- the three storm events must be one month apart.

VOL 12

7459

These criteria were proposed to insure that "representative" storm events are sampled and that a preceding dry period is provided to allow a normal period of pollutant deposition on land surfaces.

A statistical evaluation of long-term rainfall records for the Atlanta Region conducted by ARC determined that only an average of 6.2 storms per year would meet these criteria (ARC, 1992a). An additional analysis was conducted to determine if expanding the criteria to ±75% of depth and duration would significantly improve the number of acceptable events. The result was an increase to an average of 14 events per year which still was not a practical operating criteria once the actual sampling work began. Seasonal differences in rainfall patterns and the required 30 day period between events made collection of samples from an acceptable storm event very difficult. The Task Force requested a modification of storm event criteria from EPD and received approval to sample any storm event of a depth of 0.1 inches or more with a 72-hour dry period preceding it. No restrictions were placed on duration of the storm event or the time period between sampling events.

Site Instrumentation - All 27 sites were instrumented in a similar manner, although several organizations were responsible for this activity. A typical site instrumented by the U.S. Geological Survey for DeKalb County consisted of a tipping-bucket rain gage, a staff-type gage, and a stream-stage-shaft-encoder, automatic sampler, and datalogger housed in a monitoring shelter. The equipment was purchased by DeKalb County and maintained for operational readiness during the study by the USGS. Repair and replacement costs to structures and equipment were the responsibility of DeKalb County.

A typical site instrumented by the regional consultant included either a tipping bucket or totalizing rain gage, an automatic sampler with integral data logger and a temporary equipment shelter. Both ISCO and American-SIGMA samplers were used, depending on the preference of the local participating agency. Equipment was either purchased by the local agency and operated by the consultant, or leased and operated by the consultant. All maintenance during the program was provided by the consultant.

Sample Collection and Analysis Procedures - At the DeKalb County/USGS sites the datalogger was programmed at each site to record data at 1-min. intervals once a rainfall threshold of 0.1 in. was met or exceeded. A theoretical culvert rating was programmed into the datalogger which converted the recorded stages into discharges. The datalogger then triggered the automatic samplers each time about 10 percent of the estimated storm volume passed the site. Runoff samples were withdrawn from the stream over the storm hydrograph by the automatic samplers and composited into one sample that represented the water quality conditions for the storm event. For a typical rainfall event, procedures were to activate the rainfall and stream-stage recorders at the sites to be sampled prior to the impending storm. The automatic samplers were checked and outfitted with 2.5 gal. containers. When the rainfall amount at each site reached 0.1 in., the datalogger would begin to collect rainfall and stage data at 1-min. intervals. When the stream

VOL 12

7460

stage reached a preset level (activation level), the volume of water flowing by the site was computed from the recorded stage and accumulated by the datalogger. The datalogger would then trigger the sampler at increments of about 10 percent of storm volume, and the sampler would pump 2 liters of water into the composite bottle. During sampling of the runoff period, ten 2 liter sub-samples were collected in two 2.5 gal. containers. The samples were chilled with ice during the sample collection period and prior to processing. In addition to storm-composite samples, grab samples for measurement of water temperature and pH, and the analysis of cyanide, oil and grease, volatile organic compounds (VOCs), and phenols were collected by hand on the rising side of the storm hydrograph. Water temperature and pH were determined at the site. Grab samples were delivered to DeKalb County Water Quality Lab immediately after collection for the analysis of selected constituents.

Composite samples collected by the automated sampler were processed by the USGS at the District Office. Processing included splitting the composite sample into appropriate bottles using a 16 liter teflon-lined churn splitter, filtering and preserving samples. Processed samples were delivered to DeKalb County Water Quality Lab for inorganic analysis and shipped to the USGS lab in Denver for organic analysis.

Sample collection procedures for the sites administered by the regional consultant were similar to the USGS procedures. Samplers were programmed to collect a sample at equal intervals of flow based on the estimated flow that would be generated from a 0.1 inch rainfall event and the minimum amount of sample required for laboratory analysis. Each sampler was programmed with a theoretical stage-discharge curve and set to initiate sampling when a threshold level was reached.

When a rainfall event alert was issued, each site was visited to check the equipment and activate the battery powered sample. Composite sampling was then initiated automatically when the threshold flow was reached. Grab samples were taken on the rising side of the storm hydrograph. During the grab sample visit, field analysis were made and recorded, the automatic sampler was checked for proper operation, and ice was added to chill the samples of the storm duration. Grab samples were also chilled or fixed in the field. Eventually, composite samples were delivered to the laboratory at the end of the sotrm event. All sample processing including splitting of alloquats, filtering, preserving and analysis was done by the contract laboratory. Typically, all analyses were completed and reported within three weeks.

Several different laboratories were involved in the analysis of the stormwater samples but the majority of the analysis was conducted by a private lab used by the regional consultant. Other labs included the USGS National Water Quality Laboratory, the DeKalb County Water Quality Control Laboratory and the Cobb Water System Laboratory. All laboratories used EPA approved methods for sample analysis. Each sample was analyzed for the full list of over 100 parameters required in the NPDES permit application rules.

VOL 12

7461

Experience with stormwater runoff sampling in previous studies indicates that about 10 attempts at storm sampling are needed to successfully collect one storm event sample. The USGS found that once equipment problems were solved, such as problems with the datalogger and rainfall recorder, and the criteria for suitable storms were eased, that the success rate for sampling was about 90 percent of the events sampled.

Quality Control of Sampling and Analysis - A quality assurance plan was developed and implemented for this study to ensure that data collected were in accordance with accepted industry standards. The USGS developed a plan to ensure that data were collected in accordance with the U.S. Environmental Protection Agency's program requirements for stormwater sampling and that met the technical standards of the Water Resources Division of the USGS. The USGS plan addressed, in part, quality assurance measures for sample handling procedures, chain-of-custody procedures, and analytical methods that included quality control (QC) samples, and evaluation and reporting of QC data. The quality-control procedures provide a mechanism for control and evaluation of the data quality during the project, and define the data quality for the constituents in terms of precision and accuracy.

The regional consultant and local governments involved in sample collection and analysis used similar QC procedures which are documented in the regional Standard Operating Procedures Manual (ARC, 1992b) prepared by the regional consultant.

SAMPLING RESULTS

For the 81 site events (27 sites sampled three times each), the storm durations ranged from 0.5 hours to 26.4 hours and storm magnitudes ranged from 0.12 inches to 4.22 inches. Table 4 shows information on the storm events sampled during this program.

Impact of Land Use on Stormwater Quality - A review of the sampling results by land use category illustrates some apparent differences among land uses (Table 5). However, the differences may not be statistically significant because of the highly variable nature of stormwater quality. Surprisingly, residential land use appears to have more of an impact on some constituents than commercial and industrial land uses. Residential areas were characterized by much higher concentrations of total suspended solids, copper, fecal coliform and fecal streptococcus bacteria. Industrial areas were characterized by much higher concentrations of dissolved phosphorus and zinc. Commercial areas had much

VOL 12

7464

higher concentrations of total kjeldahl nitrogen. Of the 16 parameters detected at each site, average concentrations were higher in residential areas for nine parameters. However, as described below, some of the higher values in residential areas may be explained by the number of sampling locations located in streams rather than direct outfall pipes. Seven of the ten stream sampling sites were in residential areas.

For comparison purposes, the Atlanta Region stormwater quality data are compared to the results of EPA's Nationwide Urban Runoff Program (NURP) studies (1983) and some of the recent sample results from the Florida Part 2 NPDES Stormwater Permit Application wet weather sampling. The Florida data were compiled by Camp, Dresser and McKee, Inc. (CDM) from Jacksonville, Orlando, St. Petersburg, Sarasota County and Palm Beach County.

Residential - Table 6 shows a summary of analytical data collected during three storm events at nine residential sites for classic pollutants and metals (27 data points). Also shown are results from the NURP study for residential land uses. In

summary, the data are highly variable with the standard deviations (Table 5) frequently approaching or exceeding the means. The minimum observed values for most constituents were at or below the detection limits so that most of the averages shown on the table are slightly high.

Concentrations of constituents measured in samples from residential land uses are very comparable to NURP data: average concentrations for all of the Atlanta Region data fall within the NURP concentration ranges and almost all of the averages are at the low end of the NURP ranges. The only exception is BOD which is about in the middle of the NURP range.

Analytical results for the Atlanta Region and Florida Part 2 studies are similar for the classic pollutants except for TSS. The Atlanta Region data show an average TSS (574 mg/l) which is 10 times higher than the TSS in Florida Part 2 data (54 mg/l). This difference and others, in stormwater quality between the Atlanta Region and Florida data may be due largely to differences in soil characteristics. The Atlanta Region is in the Piedmont physiographic province, which is characterized by highly erodible, clay soils. These soils provide a good substrate for adsorption of pollutants and can be easily transported into nearby streams. The Florida sites, located in the coastal plain, are generally characterized by sandy soils and minimal slopes which minimizes soil erosion and transport into nearby streams. The metal concentrations in the Florida data (Table 6) are considerably less than the concentrations in the Atlanta Region data including concentrations for lead and copper, which are less than the minimum values observed in the Atlanta Region data.

Of the other pollutants detected in samples from the Atlanta Region residential sites, the most frequently occurring was phenol. Phenol was detected in 15 of 27 samples. Chromium was the second most frequently detected (13 of 27), followed by tetrachloroethylene (11 of 27), and toluene, methylchoride, chlordane and diazinon (each 6 of 27). However, of these pollutants, concentrations were generally low with only phenol and chlordane being detected in concentrations in excess of State water quality standards.

Commercial - Table 7 shows the analytical results for the classic pollutants and metals for the commercial land uses. As for the residential land uses, there were 27 events (3 storms at 9 sites). The data were highly variable with large standard deviations and the minimums were generally below the detection limits.

Oxygen demand, solids and nutrient concentrations for, the Atlanta Region data were generally lower that the NURP data although the differences in concentrations are not significant at one standard deviation. Concentrations of lead, copper and zinc for the Atlanta Region data are less than for the NURP data, with lead being 10 times less and copper and zinc about three times less. The lower lead may be attributable to the elimination of lead from gasoline. Since commercial land uses are heavily influenced by parking lots, the lower values for copper and zinc may also be attributed to changes in automotive technology; however, no clear conclusion can be drawn.

In comparison to the Florida Part 2 data, concentrations of parameters in the commercial data, unlike the residential data, are similar for most parameters. The major differences in concentrations are for total nitrogen (TKN plus NO_2+NO_3) and cadmium. Total nitrogen concentrations for the Atlanta Region data is 3.24 mg/l compared to 2.29 mg/l in the Florida data. Average Cadmium concentrations in the Florida data are 10 times less than the Atlanta Region data.

Several other trace metals and organic compounds were detected in individual samples but none of the data sets contained a sufficient number of detections to develop a reliable event mean concentration (EMC).

TABLE 7. Summary of Analytical Results for Commercial Land Uses

Constituent	Units	Atlanta Region Average	NURP Average	Florida* NPDES Average

Fecal Streptococcus	MPN/100 ml	6,800		

Note: Based on data from Jacksonville, Orlando, St. Petersburg, Sarasota County and Palm Beach County NPDES Stormwater Permit Applications (1992-93).

Industrial - As with the other land use categories, 27 samples were collected from industrial land use sites. Also, as with the others, the data were highly variable with the standard deviations often approaching or exceeding the means. Table 8 shows mean values for the industrial sites in the Atlanta Region. The Atlanta Region, NURP and Florida Part 2 data are similar except for zinc which was about five times higher in the NURP and Florida NPDES values.

Contrary to the commercial land uses, nutrients are similar in all datasets, and the cadmium concentrations for the Florida data is about seven times smaller than for the Atlanta Region data. In every case, the concentrations of metals in the NURP data are higher than for either the Atlanta Region or Florida Part 2 data.

As with the commercial land use, other constituents were detected in individual samples but too infrequently to compute a reliable EMC. The most frequently detected compounds were phenol and bis(2-ethyl-hexyl)phthalate (seven detects each).

TABLE 8. Summary of Analytical Results for Industrial Land Uses

Constituent	Units	Atlanta Region Average	NURP Average	Florida* NPDES Average
BOD	mg/l	16	10	12

Comparison of Results to State Water Quality Standards - The Georgia EPD has developed instream water quality standards for over 100 different pollutants. These standards apply to all levels of flow, including wet weather flows. The Georgia EPD has also defined State Waters in such a way as to include water in an enclosed stormwater pipe as "waters of the State" for which the instream water quality standards would theoretically apply.

VOL 12

7467

Table 9 shows the number of times that pollutant concentrations in a storm event sample for this study exceeded water quality standards. The parameter that was most often detected above water quality standards was fecal coliform bacteria. Lead, copper and zinc were also often found in concentrations in excess of water quality standards. Concentrations of pollutants in excess of water quality standards were found across all land use types and in stream and outfall sampling sites. It will be extremely difficult for stormwater runoff to ever achieve compliance with water quality standards developed for low flow periods.

Stream Versus Outfall Sampling Sites - As discussed above, 10 of the 27 sampling sites were in small urban streams rather than on a direct pipe discharge. These sites were utilized because local governments had already established monitoring sites and stage-discharge relationships at these locations for existing trend monitoring programs and because of the existing historical data available at these sites. It can be noted in Table 9 that for lead, copper and fecal coliform, a much greater percentage of the samples from the stream sites exceeded the instream water quality standards. Also a number of organic pollutants were detected in the samples from stream sites that exceeded water quality standards, such as chlordane and phenol (Table 10). Concentrations of chlordane and phenol were not found at these levels in the direct pipe discharges.

The specific reason for the generally higher concentrations in samples from streams compared to samples from direct-pipe discharges is unknown. It could be the result of several factors, including the resuspension of contaminated sediments in the stream bed or in runoff, or saturated soil water flow into the stream channel from residential lawns, industrial or commercial sites.

Implications for Long-Term Monitoring Programs - The stormwater quality data reported in this paper was collected over a short period of time, primarily to provide information for development of the NPDES permit application. To learn more about the nature of stormwater quality and the impacts of land use and best management practices and to comply with the NPDES permit, long-term monitoring programs should be developed and implemented. This long-term program should be structured to identify water quality trends and evaluate the effectiveness of BMPs, including structural controls.

Additional sampling would provide a large database and hopefully, reduce the statistical variability of the data in order to detect statistical trends or differences between land uses. Although instream sampling sites are useful for detecting general water quality trends and watershed-wide program impacts, continued sampling of direct outfall pipes is needed to better quantify pollutant concentrations and loads coming directly from the municipal storm sewer system.

Development of Pollutant Loadings - The Watershed Management Model developed by Camp, Dresser & McKee (CDM-WMM) was chosen by the Task Force to develop estimates of pollutant loadings. The CDM-WMM model was specifically developed for planning-level estimates of system-wide pollutant loads. The most recent version contains estimates of the 12 pollutants required by the NPDES regulation. Using Lotus 1-2-3 as a model platform, CDM-WMM calculates annual loads and flows based upon land uses, imperviousness, and land use specific event mean concentrations. The model uses 12 land use categories with associated literature-based EMCs and imperviousness. For the purposes of the Atlanta Region, 10 of these land uses were used for the load estimates with Cropland being combined with Agriculture and Wetlands being combined with Water.

The model estimates annual runoff volume from the pervious and impervious areas of each land use category, annual rainfall, and runoff coefficients, as follows:

$$R_L = [C_P + (C_I - C_P)\ IMP_L]I$$

where R_L = annual runoff for land use L (in/yr);
C_P = pervious area runoff coefficient (0.20);
C_I = impervious area runoff coefficient (0.95);
IMP_L = fractional imperviousness of land use L; and,
I = annual rainfall (in/yr).

The total annual runoff for the municipality is the sum of the R_L for all of the 10 land uses. Based upon available information (ARC, 1992a), the annual average runoff-producing rainfall for this area is 46.8 inches using the Atlanta Airport gage.

The load estimates are then calculated using the land use specific EMCs, runoff and area of the land use within the watershed:

$$M_L = 0.2266\ EMC_L\ R_L\ A_L$$

where M_L = the annual load from land use L (lb/yr);
0.2266 = a conversion factor;
EMC_L = the EMC for land use L (mg/l); and,
A_L = the area of land use L (acres).

As above, the total annual load for the watershed is the sum of the M_L for all of the 10 land uses. It can be seen that this model can easily be used for seasonal estimates as long as seasonal rainfall and justifiable seasonal EMCs are available.

As an added feature in the CDM-WMM model, for future assessments, the model can estimate the change in load resulting from the use of regional best management practices (BMP), such as wet or dry detention ponds, retention ponds, etc. The model can adjust the pollutant load for a BMP as follows:

$$M_L' = M_L\ \left(1 - \frac{A_{BMP}}{A_L}\ REM\right)\ A_L$$

where M_L' = the BMP-reduced load from land use L (lb/yr);
A_{BMP} = the area of land use L draining to the BMP (acres); and,

REM = the removal efficiency of the BMP for the pollutant.

This feature can be used to estimate the effectiveness of watershed pollution control plans as well as test various strategic pollution reduction alternatives.

Comparison of the EMCs measured as part of the Atlanta Region study and the EMCs from the CDM-WMM model shows that for the oxygen demanding substances, sediment, and nutrients, the EMCs are comparable. The CDM-WMM EMC for TDS is high and the model EMCs for lead and zinc are considerably higher than the measured ones. On the other hand, the model EMCs for cadmium are low compared to the measured results. This is a result of the availability of EMC data for the development of the CDM-WMM model. Only limited EMC studies were available and the literature basis of the data focused primarily on the NURP studies. It should be noted that due to the lack of timely storms, the estimate of pollutant loads had to be completed before the Atlanta Region sampling work was complete. For this reason, and because the CDM-WMM EMCs are generally high, the predicted loads from the municipal storm sewer system probably represent an upper limit of pollutant discharges. The estimated pollutant loads also represent loads from the entire political jurisdiction rather than just the area draining to the municipal system because these drainage areas have not been adequately identified.

SUMMARY

The Atlanta Region governments were successful in implementing a regional stormwater sampling program. These same governments are now involved in implementing a regionally-coordinated long-term monitoring program. During the NPDES permit application sampling program, we were successful in determining the type and magnitude of pollutants in stormwater and how to measure them, however, there is still more to learn about their relationship to land use. With regard to stormwater quality, the following is apparent:

- stormwater runoff often contains pollutants in concentrations in excess of Georgia's instream water quality standards;
- stormwater runoff quality in the Metro-Atlanta area is comparable to national stormwater quality statistics;
- stormwater characteristics vary by land use but the variability of stormwater quality is so great that it will require much more data from drainage areas composed of a single land use type to statistically validate those differences.

With regard to stormwater sampling procedures, we learned the following:

- the EPA recommended "representative storm event" criteria were not practical for this region;
- once new equipment problems are resolved and reasonable storm event criteria are established, sampling success can reach 90% of all attempts.

VOL 12

7471

This information will be valuable in implementing the long-term stormwater sampling program but because of the inherent difficulties involved in wet weather sampling and the variability of stormwater quality, it will require a longer sampling history to confidently make conclusions about stormwater quality that can be used with confidence in developing potentially expensive stormwater management programs. Also, sites with a single land use type should be selected; Some of the drainage areas for the sites sampled in this study did not contain a single predominant land use type.

It is recommended that EPA continue to be flexible in the implementation of stormwater monitoring and management programs as we continue to learn more about this problem. It also evident that even though local stormwater quality data may be comparable to national averages, strong regional differences may occur based on natural factors such as rainfall patterns and soil characteristics. Therefore, programs that work well in one region may be impractical or ineffective in others due to these differences.

NPDES Monitoring - Dallas- Fort Worth, Texas Area

Samuel W. Brush[1]
Marshall E. Jennings, F. ASCE[2]
P. Jonathan Young, M. ASCE[3]
Harry C. McWreath[4]

INTRODUCTION

Cities in the Dallas-Ft Worth, Texas (DFW) area, as have approximately 250 cities and urban counties in the United States, have been responding to the November 16, 1990 final rule regarding stormwater permitting on a system-wide basis for municipal separate storm sewer systems, sometimes referred to as MS4 permitting. The permits, when accepted by a U.S. Environmental Protection Agency (USEPA) Region or a delegated state agency, will be processed in the National Pollution Discharge Elimination System (NPDES). Hence, the permitting effort, is frequently referred to as NPDES permitting for MS4 cities. The published rule is found in USEPA (1990) and the guidance information for the stormwater aspect of the rule is available USEPA (1992).

SCOPE OF NPDES MONITORING, NATIONWIDE AND DFW AREA

The NPDES permitting effort is a very significant national effort that seeks to define and control urban stormwater and dry-weather water quality in cities of 100,000 population or more. It is estimated that the scope of the national effort involves:

[1] Environmental Planner, North Central Texas Council of Governments, P.O. Box 5888, Arlington, Texas 76005-5888
[2] Engineer, U.S. Geological Survey, 8011 Cameron Rd., Building A, Austin, Texas 78754
[3] Engineer, Alan Plummer and Associates, Inc., 841 West Mitchell, Arlington, Texas 76013-2506
[4] Hydrologist, U.S. Geological Survey, P.O. Box 6976, Fort Worth, Texas 76115

- About 250 municipal entities, including cities and urban counties
- About 1250 NPDES monitoring sites
- About 3750 monitored events, each analyzed for more than 140 chemical or other constituents
- About 670,000 laboratory analyses (about 34,000 analyses were obtained in the DFW area
- About $35 to $50M in cost to cities

The NPDES monitoring and related activities during the period 1990 to present have largely been involved with data characterization, building upon previous USEPA-mandated monitoring efforts. By late 1994, most MS4 cities will commence a five-year compliance monitoring program which may require 2-3 times the cost and effort expended in the data characterization phase above. In addition, USEPA will, after 1997, most likely extend the NPDES permitting obligation to cities with populations less than 100,000.

Because of the significance of NPDES permitting in the DFW area, the North Central Texas Council of Governments, like many other councils of government in the nation, organized a Regional Urban Storm Water Management Task Force (RUSWMTF) to unify the many technical, policy, and fiscal aspects of NPDES permitting. To directly oversee technical aspects of NPDES monitoring, RUSWMTF established a Storm Water Quality Subcommittee, with membership from the cities, the Trinity River Authority (TRA), and the Texas Department of Transportation (TXDOT). Cities subject to the regulations in the DFW area include Dallas and Ft. Worth, with populations over 250,000 and Arlington, Garland, Irving, Mesquite, and Plano with populations of 100,000 or more.

This paper describes the work to date of the DFW Regional Urban Stormwater Management Task Force, with the assistance of NCTCOG, in meeting the requirements of NPDES permitting. Unique among Texas cities and perhaps the nation, is the concept of a *regional NPDES monitoring network* for the DFW area. The *regional concept* has been approved by USEPA Region 6 because the MS4 permitting authority for NPDES has not yet been delegated to the state of Texas.

STUDY AREA

The Dallas-Fort Worth, Texas area is located in north-central Texas and has a population of 3.3 million according to the 1990 census. The region is hydrologically part of the upper Trinity River basin including major tributaries of the West Fork Trinity, Elm Fork Trinity and East Fork Trinity all of which meet in the DFW metroplex. The average annual discharge of the USGS streamflow station, Trinity River near Rosser, downstream of the DFW metroplex, is about 2,900 cubic feet per second. Mean annual precipitation at the long term weather station in Fort Worth is 30.6 inches for the period 1961-1990 while the comparable mean annual precipitation at Dallas is 33.6 inches. The study area is located primarily within Collin, Tarrant, and Dallas counties and includes an urban watershed network of 95 sub-basins.

Figure 1 shows the DFW study area and the cities subject to the NPDES permitting regulations. Also shown are smaller communities in the metroplex and the locations of the 26 municipal NPDES monitoring locations. Four TXDOT monitoring locations, now in operation, are not shown.

PREVIOUS DFW AREA STUDIES

Urban storm water studies have been undertaken in the DFW area since the late 1940's when urban gaging began on the 8-square mile Turtle Creek watershed in Dallas. Early urban hydrology studies were concerned with urban flooding and flood-plain management. Through the years, a significant data base on urban watershed rainfall and runoff has accrued. See for example, USGS (1976). With increasing concern by local agencies and the State of Texas over water quality problems in the Trinity River, the emphasis was expanded to include urban stormwater-quality, e.g. Trinity River Authority (1978), Alan Plummer and Associates et. al. (1978) in section 208 studies. The DFW area was not included in the Nationwide Urban Runoff Program (NURP) studies.

The report by Alan Plummer and Associates (1994) reviews historical perspectives and sources of urban stormwater data in the DFW area. For example, in the Trinity River Authority (1978) study, eight urban watersheds varying in drainage area from 30 to 300 acres were sampled for four storm events for a range of chemical constituents. In addition, eight nonurban watersheds varying from 3 to 12 acres in drainage area were sampled for about two storm events each. Twelve metals were measured in urban watersheds and ten pesticides were measured at both urban and nonurban sites. The mean values for all sites are shown in Table 1, taken from Alan Plummer and Associates (1994). As seen in Table 1, urban sites tend to have higher mean values for BOD, solids, phosphorus and fecal coliform. The nonurban sites had a mean value for nitrogen that is 60 percent higher than that for urban sites.

The U.S. Geological Survey, in cooperation with local agencies, has collected water-quality data on urban streams in the DFW area for many years. Records are collected at continuous streamgaging stations and at partial record stations. At 11 sites, on larger urban streams in the DFW area, USGS operates sites equipped with continuous (hourly) measurement of pH, temperature, specific conductance and dissolved oxygen. These records, originally established for receiving water monitoring of wastewater enhancement programs, began as early as 1976 and are expected to provide a benefit in documenting impact of urban stormwater in the DFW area in future years. Alan Plummer and Associates (1994) used five USGS monitoring sites with data available from 1986-1990 that have no effects of wastewater discharges or upstream reservoir releases. These data , summarized in Table 2, are from watersheds with drainage areas ranging from 16,000 to 190,000 acres and are characterized by low density urban and nonurban land use. These data may provide "background" information for some constituents when compared with the NPDES monitoring data.

Table 2 -- Mean storm water quality values, USGS Trinity River Basin monitoring stations, Alan Plummer and Associates, Inc. (1994)

The Texas Natural Resource Conservation Commission (TNRCC) has operated 13 monitoring stations in the DFW area on urban streams. However, few of these data were collected during stormwater periods and thus are of limited benefit for comparison with older data bases and the NPDES monitoring results for the DFW area.

Of special concern in the DFW area, is the occurrence of toxic constituents, some of which occur as urban nonpoint sources. According to Alan Plummer and Associates (1994) many of these toxins are known to occur in Trinity River water and sediments and include cadmium, chlordane, chromium, copper, dieldrin, endrin, heptachlor, lead, lindane, and PCB's. Diazinon, apparently occurring due to use for pest control in residential areas, has frequently been found in storm water and in wastewater effluents.

Previous water-quality monitoring in the DFW area for urban storm water quality can be of substantial benefit to current NPDES monitoring programs. The report by Alan Plummer and Associates, Inc. (1994) has set the stage for future analyses. However, it is clear that much needs to be learned about urban stormwater-quality processes in the DFW area and the role that urban stormwater plays in overall water quality in the 95 DFW urban watersheds and the Trinity River.

DFW NPDES MONITORING NETWORK FOR REGIONAL CHARACTERIZATION

According to USEPA guidelines, stormwater events are to be monitored at 5 to 10 sites in each city, three storms per site, each site representing a predominant land use of residential, commercial or industrial land use. The number and kind of each monitored watershed is to be proportional to all typical watersheds draining to stormwater outfalls within the municipal area. The monitored sites must be free of problems associated with illicit connections to sanitary sewers or industrial discharges. A rain-free period of at least 72 hours must precede storm-event sampling in order to allow urban stormwater loads to accumulate on urban surfaces. Special sites will be required to document highway stormwater runoff-quality.

DRY WEATHER FIELD SCREENING

Part 1 of the storm water permit application process required the cities to complete an initial field screening of storm drainage systems during dry weather in order to detect illicit or improper connections to a cities MS4 system. Using a 1/4 mile grid cell system captured in NCTCOG's regional geographic information system, staffs of the seven cities visited at least 500 outfall sites for the two larger cities and at least 250 outfall sites for the five smaller cities. A field screening system developed by the City of Fort Worth, Rattan and McDaniel (1992), was used and two grab samples were collected within 24 hours at each site. For each site, a narrative description of color, odor, turbidity, presence of oil sheen or surface scum and other observations was made. In addition, a field analysis for the estimation of pH, total chlorine, total copper, total phenol, detergents and discharge flow rate were made. A scoring system assigned a numeric value of unity for each parameter detected was then summed into a final score (maximum score was 28)for each outfall site.

Figure 2 shows the dry weather field screen scores for the City of Fort Worth. Overall, the DFW cities found that about 10 percent of outfalls sampled during dry weather conditions produced significant contaminant discharges (scored 7 or more of 28 possible points).

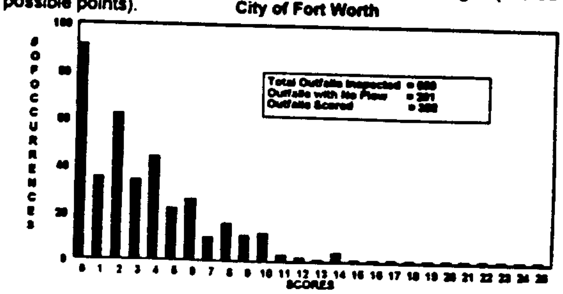

Figure 2 -- Dry weather field screen scores for City of Fort Worth, NCTCOG (1993)

The results of the dry weather field screening have some important implications on storm water quality in the DFW area and for the required wet weather monitoring sites. However, the evidence suggests that illicit *connections* are not prevalent in the DFW area, with sanitary sewage being reported on very few occasions. Illicit *discharges* seem to be a more widespread occurrence, with pollutants probably being generated on land and flowing during both dry and wet periods into MS4 systems. The widespread occurrence of detergents and/or surfactants, NCTCOG (1993), suggests that these constituents may be a major contributor to storm water impacts and therefore represent a challenge for control, due to their spontaneous and erratic appearance. A program of wet weather screening is currently being planned for the DFW area.

Based on the results of the dry weather field screening and the above considerations, RUSWMTF moved forward with the design of the wet weather monitoring network for storm water quality characterization. Assisting RUSWMTF in the design was a regional consultant, Camp Dresser & McKee, Inc. /Alan Plummer and Associates, Inc. (CDM/APAI) and the Texas District, U.S. Geological Survey. The argument was made that the DFW cities, because of their close proximity, lie within a homogeneous hydrologic and climatologic area. This being the case, a cost-effective, regional NPDES monitoring network made more sense than individual city networks. Agreement was reached among the cities and with USEPA Region 6 in Dallas to form a regional network of 30 monitoring sites for the DFW area.

As specified by USEPA, the network must monitor 210 sampled events, the number of events required by USEPA (1990) for 7 cities, each with 10 sites collecting 3 storm events each. However, in recognition of the regional concept, USEPA would allow less than 70 monitoring sites. The USGS suggested that 7 storm events per site would allow an adequate statistical characterization of NPDES monitored data, so the network was designed with 30 monitoring sites each collecting 7 storm events. Of the 30 NPDES monitoring sites, 26 sites were municipal monitoring sites and 4 sites were highway monitoring sites, provided by the Texas Department of Transportation. NPDES monitoring for data characterization, including 182 monitored events, was completed at the 26 municipal sites by June, 1993. Data collection and analysis at the 4 highway monitoring sites is still underway and will not be discussed in this paper.

Following a visit to hundreds of prospective wet-weather monitoring outfall sites across the DFW region and a careful balancing of land-use to be sampled and the ability to obtain good runoff measurements, a tentative DFW NPDES monitoring network was presented and accepted by the RUSWMTF and USEPA Region 6. Figure 3 shows a map of one of the selected monitoring sites, station 08047100 Clear Fork Trinity River Outfall at Oak Hill Circle, Fort Worth, Texas, NCTCOG (1993).

DESCRIPTION OF SITES

As described above, a major goal of the wet-weather monitoring in the data characterization phase of the Part 2 application required by the NPDES permitting rule, was to characterize typical runoff from three broad land use classifications – residential, commercial and industrial. Much study went into the specific site selection, including catchment characteristics, hydraulic factors, accessibility during all hours, and safety. An attempt was made to include a predominance of the single land use sought as well as to include a drainage area of between 10 and 500 acres. Storm-sewer pipe diameters were sought in the range from 4-6 feet or if a box culvert, a size of no more than 8 by 8 feet. A fairly straight and uniform pipe slope was sought for at least 6 pipe diameters upstream from the flow measuring device and an adequate distance was maintained from upstream inflows to allow for complete mixing conditions. Only sites where no problems of substantial backwater conditions, or of unauthorized connections, as determined from the dry-weather screening effort, were considered. In addition, sites with a proximity to sanitary sewers subject to surcharging, were avoided.

WET WEATHER MONITORING

Because the monitoring staff would be collecting samples at any time during the day or night during storm water conditions, sites were selected to minimize high-velocity flow conditions, sewer gases, vehicular traffic, poor visibility lighting and vandalism or crime. Various other considerations were studied before a site was selected, Baldys, et. al (1994).

The final set of wet-weather monitoring sites included 11 residential, 6 commercial, 9 industrial, and 4 highway drainage catchments. Most sites were located at outfall locations while a few were accessible by access to a manhole. The twenty-six monitoring sites were located within the jurisdictional boundaries of the seven cities as follows: Five sites were located in Dallas, five sites in Fort Worth, four sites in Arlington, three sites in Garland, three sites in Irving, three sites in Mesquite, and three sites in Plano. Four additional sites were located along highway right-of-ways, two each in Dallas and Fort Worth. All sites were located and captured in the NCTCOG regional GIS coverages. Figure 1 shows the general locations of the twenty-six municipal monitoring sites in the regional DFW area NPDES network.

Table 3 shows a table of selected watershed characteristics of the municipal NPDES monitoring sites, including impervious area, in percent. Monitoring commenced at these sites in February 1992 with storms having precipitation from 0.2 to 0.9 inches (later raised to 1.5 inches in October 1992 with permission of RUSWMTF and USEPA Region 6) being sampled.

INSTRUMENTATION

The instrumentation for wet weather monitoring, described in Jennings et. al. (1992), is typical of urban storm water instrumentation in use by USGS is other localities. However, USGS urban storm water monitors are significantly different from a normal USGS streamflow monitoring station. Much of this difference is due to rapidity of urban stormwater runoff and due to the fact that small pipes and open channels are typically being monitored in an urban storm water situation. Figure 4 shows a schematic of a typical USGS urban storm water monitoring site with its instrumentation. In the DFW area, the monitoring equipment was located in a sheet metal structure and resembles a utility box familiar to urban areas. Because of the unobtrusive nature of the DFW monitoring structures, little or no vandalism has been experienced during operation of the network.

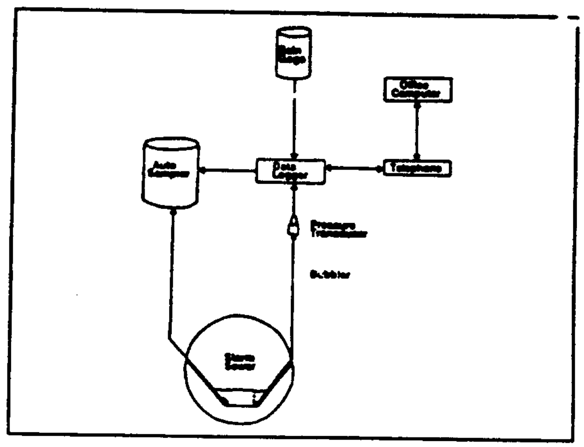

Figure 4 - Schematic of DFW urban stormwater monitoring instrumentation

Equipment for a typical site costs about $15,000 and includes:

- automatic water quality sampler for organic sampling
- controller and datalogger programmed for 1-minute sampling of precipitation and flow
- telephone modem and connected wired or cellular telephone
- 2 or 3 nonsubmersible pressure transducers and gas lines, regulators and sight feeds
- Palmer-Bowlus flume (circular pipes) or V-notch weir (square pipes and open channels)
- tipping bucket raingage
- solar panels, batteries, voltage regulators for AC power

- communication and analysis software
- shelter

Telephone communications with "beeper" alert systems were vital to successful operation due to the fact that the monitoring sites were located over a large area. Not only could a given monitoring station be called to find out if a storm water event was occurring (the stations also called an assigned "storm chief" at all hours when precipitation or flow "triggers" were exceeded), but stormwater data could be efficiently retrieved over the phone line for analysis. This proved useful as an analyst could be graphing rainfall and flow hydrographs soon after samples were retrieved but before a decision was made to process the laboratory samples. Because of the cost of laboratory analyses, quick analysis of the adequacy of the storm data for the event was extremely helpful in deciding whether or not to process the samples.

The automatic sampler contained four one-gallon sample bottles and these were cleaned using the protocols outlined in 40 CFR 136, Part D (USEPA, 1992). The automatic sampler was powered by a 60 amp/hour battery and the sampling line consisted of a stainless steel intake and teflon coated tubing, according to Baldys et. al. , (1994). The sampler intake was typically located just below the flume or weir flow measuring device.

Stage-sensing at the sites included up to three sensing locations per site. In general, for weir sites, only one stage sensor was used. For sites equipped with a Palmer-Bowlus flume as described in Kilpatrick et. al. (1985), typical sites included a stage sensor in the flume approach, and one in the in the throat of the flume. A third stage sensor was located downstream to detect possible flume submergence. The stage sensors were pressure transducers calibrated in the laboratory at temperatures up to 55 degrees Celsius.

Flow measurement was based on laboratory calibrated flumes or known weir flow formula. The flume calibrations and other specifications can be found in Kilpatrick et. al. (1985). The DFW flow measurement conditions fell within the range of the laboratory calibrated flumes and good definition of flow hydrographs at 1-minute time intervals were obtained for all storm events measured. Because the automatic sampler was "pulsed" by the datalogger device, flow volume calculations were continuously made during the storm water event thus allowing flow-weighted sampling by sub-sampling over the hydrograph. Sub samples were taken after a known volume of flow passed the monitoring site. After the storm (sometimes additional bottles were added during longer storm events), a quick assessment was made to see if sampling had adequately occurred over the flow hydrograph and the samples were then processed.

Maintenance was essential to successful operation of each monitoring site and steps were taken to check battery voltage, clean raingages, check communications and data storage devices and software, and make ready all water quality sampling equipment as storm events approached the DFW area.

LABORATORY ANALYSES

When sampling is complete at the DFW NPDES network, more than 34,000 laboratory analyses will have been performed. While the final rule required monitoring for 138 parameters, by use of USGS laboratory schedules at the USGS Central Laboratory in Denver, the actual number of parameters reported is 189. The laboratory analyses performed by USGS fall into seven categories:

- Metals (e.g. arsenic, cadmium, chromium, lead, zinc)
- Volatiles (e.g. benzene, carbon tetrachloride, chloroform, toluene)
- Pesticides (e.g. dieldrin, PCBs, toxaphene, diazinon)
- Acid/Base/neutral organic compounds (e.g. chlorophenol, naphthalene, pyrene)
- Conventional pollutants (e.g. BOD, COD, fecal coliform, oil and grease, phosphorus)
- Additional constituents (e.g. pH, temperature, alkalinity, specific conductance)
- Other (e.g. other organics, not required, but included in a given laboratory schedule)

Water-quality samples were collected using grab sampling methods for 71 constituents while automatic samplers were used for flow-weighted composite samples for 118 other constituents. Water quality samples were processed, packaged and shipped from the USGS office in Fort Worth to the USGS National Water Quality Laboratory (NWQL) in Arvada, CO where most of the laboratory analyses were performed. Total concentrations for thallium, silver, antimony, and cyanide were determined by contract with Rocky Mountain Analytical Laboratory in Denver, CO. Alkalinity, biochemical oxygen demand, fecal coliform and streptococci constituent concentrations were determined locally at the USGS Fort Worth laboratory. Temperature, pH, specific conductance, and the presence of residual chlorine were determined in the field at the time of grab sampling.

According to Baldys et. al. (1994), strict quality control and quality assurance procedures were followed throughout the study. Chain-of-custody procedures, as prescribed by USEPA, were followed with each sample. Equipment blanks for organic constituents as well as matrix spikes were used in the local lab and repeated at NWQL. Trip blanks, used to determine if contamination of the volatile organic samples occurred during transit, and laboratory blanks, used to determine if contamination of the organic samples occurred in the field office during compositing procedures were followed at USGS Fort Worth and at the NWQL, as standard procedure.

PARTNERSHIP FOR FIELD WORK

Because of limited field staff, USGS could operate only about 10 monitoring sites during any particular storm water event. Field staff of the various cities were asked to help with sample retrieval and general monitoring station operation. For safety reasons, at least two people visited monitoring stations and some times three people assisted during night hours. This partnership paid off as shown on Figure 5 which shows a timeline of all storms occurring during 1992 and those storms which were actually sampled.

STORM WATER ANALYSES AND RESULTS

Because storm water was sampled by both grab sampling and by automatic sampler, it is convenient to discuss storm water analyses and results by method of sampling. This is the method of presentation adopted by Baldys et. al. (1994). Brief comments are made concerning unusual occurrences of specific constituents. More details are found in Alan Plummer and Associates, Inc. (1994), NCTCOG (1993) and Baldys et. al. (1994). Alan Plummer and Associates, Inc. (1994) also includes information on the dBase III Plus data base and report generation procedures for the DFW area data.

GRAB SAMPLE CONSTITUENTS

Grab samples were collected primarily by hand dipping at the monitoring station outfall. An attempt was made to collect grab samples early in the storm event. For practical reasons, this was not always possible.

Water Temperature -- Water temperature values varied from 6.5 to 30.0 degrees C. In general water temperatures during storm events did not vary more than 1-2 degrees C.

pH -- Values of pH varied from 6.2 to 9.9. The maximum value occurred at a station with roadbuilding activities in progress.

Cyanide -- Generally below detection limits.

Total phenol -- From below detection limits to a maximum of 58 mg/l at an industrial site.

Oil and grease -- Generally near or below detection limits.

Bacteria -- Fecal streptococcus bacteria concentrations were equal to or greater than those of fecal coliform bacteria. Lowest bacterial concentrations were from industrial land use while median concentrations were highest for residential land use

Volatile-organic compounds (VOC) -- Samples from industrial land use, especially during the first 25 percent of the storm runoff, were more often detected than samples from other land use sites. The most frequently detected VOC was toluene, the 27th largest volume of chemical substance produced in the United States. Benzene and related derivatives were the next most often detected VOC.

VOL 12

7487

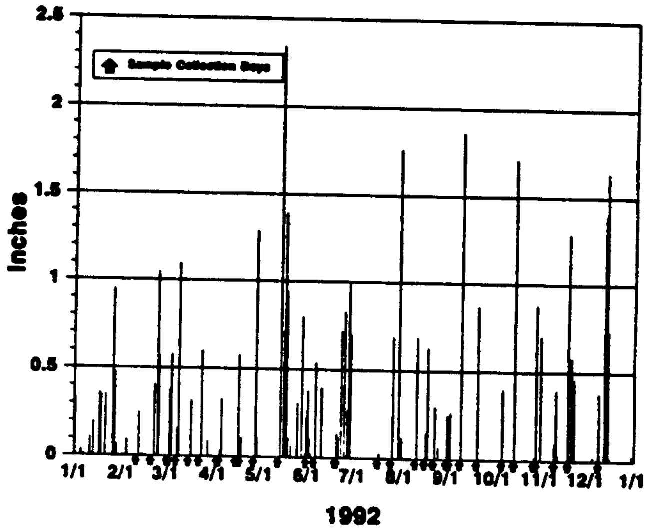

Figure 5 – 1992 storm precipitation in DFW area with indicated sampled events, Alan Plummer and Associates, Inc. (1994)

FLOW-WEIGHTED CONSTITUENTS

Flow-weighted constituents were collected by automatic sampler, generally within the first three hours of the storm water event. There were seven groups of such constituents:

Nutrients – Median concentrations of total nitrogen and total ammonia plus organic nitrogen in samples from residential land uses were significantly greater than for other land uses. Phosphorus concentrations were also higher for residential land use. Lawn care practices are probably responsible for higher nutrient concentrations.

Biochemical and Chemical Oxygen Demand – Samples from industrial land use had the greater median concentration of oxygen demand than for other land uses. Samples from residential land use had the higher median chemical oxygen demand.

Inorganic Compounds – Median suspended sediment concentrations and median dissolved solid concentrations from industrial land use were higher than for other land uses.

Trace metals -- Trace metal concentrations from industrial land use were generally higher. High total arsenic concentrations were detected at one residential site 11 to 35 ug/l with a mean of 22.6 ug/l. One industrial site had very high mean values of total copper (732 ug/l), total lead (133 ug/l), and total zinc (296 ug/l).

Base-Neutral Acid Semi-Volatile Compounds -- Fifty-seven organic constituents for each composite sample were analyzed. The greatest number of detections (96) were from industrial land uses and the fewest number (37) were from residential land uses.

Pesticides -- Diazinon was detected in 92 percent of residential samples, 67 percent of commercial samples and 33 percent of industrial samples. Chlordane and dieldrin were the next most frequently detected pesticide constituent.

Table 4 shows a comparison of the most frequently detected organic constituents for the Nationwide Urban Runoff Program (NURP) of 1978-84 and the DFW area NPDES analyses. Metals such as zinc, lead and copper appear with high frequency of detection in both lists. A paper by Young and others (1994) compares NPDES analyses among several Texas cities.

SPATIAL AND TEMPORAL VARIABILITY OF CONSTITUENTS

Based on a selection of detected constituents in the DFW area, Raines and Baldys (1994) evaluated spatial and temporal characteristics of the monitored data base. The constituents selected were:

chemical oxygen demand
suspended solids
total nitrogen
total phosphorus
total arsenic
total lead
bis (2-ethyljexyl) phthalate
xylene
benzene
chloroform
mesitylene (1,2,4-trimethylbenzene)
biochemical oxygen demand
dissolved solids
total kjeldahl nitrogen
dissolved phosphorus
total copper
total zinc
toluene
pyrene
diazinon
chlordane
fecal coliform
fecal streptococcus

Graphical and statistical analyses were performed designed to explore differences for the constituents between land uses, within land uses, and the effect of seasonality. Techniques found in Helsel and Hirsch (1992), with emphasis on nonparametric statistics, were utilized in the comparisons. For example, figure 6 shows the Kruskal-Wallis results indicating that for many constituents, the seasonal medians are not significantly different for each land use type. Many other tests are given in Raines and Baldys (1994) and are being used in the design of the 5-year DFW compliance monitoring network.

Figure 6 -- Kruskal-Wallis results for median concentrations within each land use by season (after Raines and Baldys, (1994))

CONSTITUENTS FOR USEPA LOAD CALCULATIONS

Twelve constituents were selected by USEPA for load calculations including BOD-5, COD, Total Suspended Solids, Total Dissolved Solids, Total Kejldahl Nitrogen, Nitrate+Nitrite, Total Phosphorus, Dissolved Phosphorus, Total Cadmium, Total Copper, Total Lead, and Total Zinc. For the DFW area, it was decided to add Diazinon to this list of constituents. Figures 7 and 8 show box plots of concentrations for Total Dissolved solids and Diazinon grouped by land use and site.

Event-mean concentrations (EMC's) of twelve constituents and diazinon can be calculated in several ways according to Baldys et. al. (1994): volume-weighted mean concentrations, logarithmic mean concentrations, and arithmetic mean concentrations. A volume-weighted mean concentration over all sites of a given land use is computed by summing the concentration times runoff volume for all storms and dividing by the summation of runoff volumes for all storms. The same procedure is followed for logarithmic mean concentrations except that all storm values for a given land use are transformed to base 10 logarithms prior to the computation. The final value is converted back to original units after computation. The arithmetic mean concentration is the summation of EMC's for each storm for a given land use divided by the total number of observations. Finally, the median , or 50th percentile value for all storms of a given land use can be computed. Table 5 shows the various means and the median by land use for the DFW area. For comparison, the NURP median values, if available, are also shown. The median EMC's for the DFW area are significantly less than NURP median values for BOD, total nitrogen and the trace metals of total copper, lead, and zinc. Cadmium was rarely detected above the detection limit of 1 mg/l. Because of the non-normality of distributions of the concentration values, the median or the log-transformed mean are the better estimates of population mean.

STORM WATER LOADS

Based on monitored data, storm water loads for each storm can be calculated as the product of the observed flow-weighted even-mean concentration and runoff volume, with an appropriate units conversion factor. The local regression storm load equations for constituent loads for the twelve constituent (no value for Cd) are shown in Table 6, based on seven sampled storms at each DFW monitoring site.

Storm load calculations were also performed on three study basins using a deterministic urban watershed model called the Simplified Particle Transport Model (SIMPTM) developed by Sutherland and others (1992). SIMPTM was calibrated at each site using data for four storms and verified with data from three additional storms. SIMPTM provided good results, especially for site-specific results. It is expected that deterministic models such as SIMPTM, will play a role in the site-specific stormwater management studies in the DFW area e.g. evaluation of best management practices.

Table 5 – Mean and median event mean concentrations by land use (after Raines and Baldys, (1994))

The local storm load regression equations were used with long-term rainfall characteristics based on a technique described by Tasker, Gilroy and Jennings (1990) to estimate average annual loads for the 95 sub basins in the DFW area. Comparative analyses were also made using the Watershed Management Model (WMM) developed by Camp Dresser and KcKee, Inc. (1993). The results of the two methods of obtaining DFW area annual stormwater loads is discussed in NTCOG (1993) and is still being evaluated. WMM, a spread sheet-based approach uses run-off coefficients and observed local loading estimates. In general, WMM and USGS methods are comparable.

COD is chemical oxygen demand, BOD is biochemical oxygen demand, SS is suspended solids, DS is dissolved solids, TN is total nitrogen, TKN is total ammonia plus organic nitrogen, TP is total phosphorous, DP is dissolved phosphorous, Cu is total recoverable copper, Pb is total recoverable lead, Zn is total recoverable zinc, and Diaz is total diazinon in storm-runoff load in pounds, b0' is the intercept in the regression model, b1 is the coefficient for the variable TRN (total storm rainfall in inches), b2 is the coefficient for the variable DA (drainage area in square miles), b3 is the coefficient for the variable IA (impervious area as a percentage of total area), b4 is the coefficient for the variable LUI (industrial land use as a percentage of total land use), b5 is the coefficient for the variable LUC (commercial land use as a percentage of total land use), b6 is the coefficient for the variable LUR (residential land use as a percentage of total land use), b7 is the coefficient for the variable LUN (non-urban land use as a percentage of total land use), BCF is the bias correction factor, SE is the standard error of the regression equation in percent, and R^2 adj is the adjusted coefficient of determination, dashes (- -) indicate that the variable is not included; equation form is:

y=b0' (TRN)^b1*(DA)^b2*(IA+1)^b3(LUI+1)^b4(LUC+1)^b5*(LUR+1)^b6(LUN+1)^b7*BCF)

DESIGN OF COMPLIANCE MONITORING NETWORKS

Special Studies, based on results of the DFW area characterization data base, were undertaken by the consultant team and are still in progress. A goal of these studies is to recommend a cost-effective network for the DFW area MS4 cities for the next five years. Concepts other than water-quality monitoring e.g. rapid bioassessment monitoring are also being considered.

Tasker and Raines (1994) have joined the use of the regional regression method of estimating annual loads for the twelve water-quality constituents with a mathematical programming method. Figure 9 shows results of the network analysis for Total Nitrogen load for three 5-year scenarios -- (1) no new stations allowed but stations are added and dropped optimally, (2) thirteen new sites added optimally to existing 26 sites, and (3) twelve fixed sites with optimal addition of 13 new sites. It was assumed that each station was sampled four times per year. Results are being evaluated, however, it is clear that new stations, in general, are the most effective in adding regional information. The analyses shown for loads can also be performed for concentrations.

Based on the network studies, the study team has suggested a proposed monitoring plan as shown in Table 7 to DFW cities. The cities have accepted scenario 3 as shown on this chart.

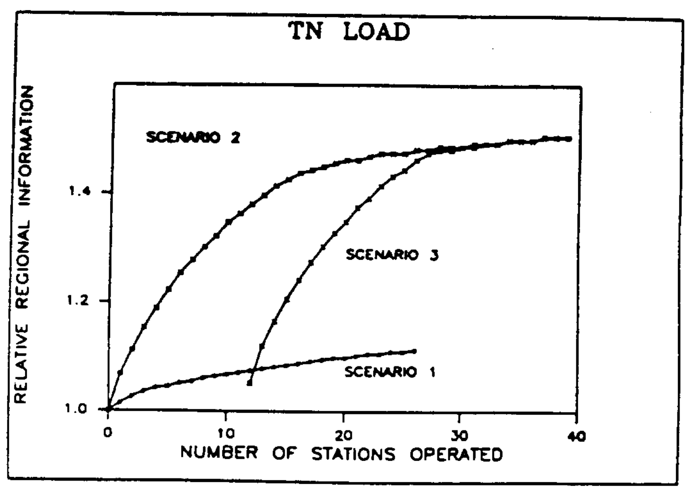

Figure 9 -- Results of network analysis for Total Nitrogen (TN) load (after Tasker and Raines, (1994))

Storm Water NPDES Monitoring in Santa Clara Valley

Terry Cooke[1], David Drury[2], Revital Katznelson[1], Chow Lee[1], Peter Mangarella (M. ASCE)[1], Keith Whitman[2]

Abstract

Results from stormwater monitoring conducted in Santa Clara Valley from 1987 through 1994 are presented. During this period, hydrologic, water quality, and toxicity data have been obtained from a variety of small and large catchments and within storm drains and in streams and rivers. Approximately 200 station-events have been monitored for water quality, primarily focused on heavy metals. Both flow composite and manual grab samples have been obtained. Data presented address water quality characterization, effects of land use on water quality, compliance with water quality objectives, urban versus natural erosional sources of metals, water quality correlations with flow, equilibrium partitioning between dissolved and particulate forms of metals, spatial and temporal differences based on analysis of variance (ANOVA) and analysis of covariance (ANACOVA), power analysis for designing monitoring programs to measure long term trends, and toxicity testing.

Introduction

The Santa Clara Valley is located at the southern end of San Francisco Bay, encompasses about 1800 square kilometers (700 square miles) of which about 50% is urbanized, and has a population of 1.4 million people (Figure 1). The valley contains major cities such as San Jose, as well as "Silicon Valley". The valley is semi-arid with mean annual precipitation on the valley floor of 355 mm (14 in) per year.

In 1986 the San Francisco Regional Water Quality Control Board revised their Basin Plan to require that storm water discharges into the southern portion of San Francisco Bay be characterized and controlled. In response to this requirement, thirteen cities, Santa Clara County, and the Santa Clara Valley Water District

(SCVWD) formed the Santa Clara Valley Nonpoint Source Pollution Control Program (Program). In 1989 the State Water Resources Control Board listed the south Bay as an "impaired water body" as required under Clean Water Act Section 304(L) because water quality standards for heavy metals were frequently exceeded. The Program applied for and received an early NPDES stormwater permit in June 1990.

R0040811

This paper summarizes findings from the extensive monitoring conducted by this program. The first two fiscal years (FY 87-88 and FY 88-89) of monitoring prior to the first permit period included wet weather monitoring at 7 stations that drained different land use areas and wet and dry weather monitoring at 4 waterway stations. These data were used to characterize storm water runoff water quality and to estimate the distribution of annual metals loads to the Bay.

In FY 89-90, monitoring was continued at the four waterway stations to evaluate long term compliance with water quality objectives and at one industrial land use station which was being used as a pilot demonstration project for evaluating the effectiveness of an intense industrial inspection program.

The monitoring activities during the first 5 year permit period (starting in FY 1990) included automatic flow-composite sampling at the four waterway stations. Because the permit required that sampling be conducted at locations which were representative of the discharge, two of these locations were in the largest watersheds in Santa Clara Valley, Guadalupe River and Coyote Creek. For comparison, one sampling station was in a relatively small watershed with a predominantly natural channel, Calabazas Creek, and a fourth was in a constructed channel, Sunnyvale East. The data from these stations are being used to meet the objectives of evaluating water quality trends, and to determine if storm water discharges are in compliance with applicable water quality and toxicity objectives.

To meet other objectives of the monitoring program, monitoring was conducted during the first permit period at two industrial land use stations to characterize storm water quality and to evaluate storm water quality improvements due to the implementation of pollution prevention actions resulting from a pilot inspection program conducted in one of the areas. To characterize storm water quality from transportation corridors, two stations were installed and operated for three years on an eight lane freeway and on a local 4 lane expressway. The Program also evaluated the use of automated flow-composite sampling equipment compared to grab sampling, to ensure that representative samples were being obtained. As part of the grab sampling effort, the Program conducted studies to evaluate how pollutant concentrations vary over the course of a storm event, the duration of water quality exceedences for pollutants during storm events, and whether or not pollutants persist after the event concludes and flows return to pre-storm levels. Toxicity testing was conducted at the land use and transportation stations for two years, and at the waterway stations all five years of the first permit period.

Monitoring Stations

Monitoring stations consisted of two types: stations located in relatively small catchments (typically 10-1,000 hectares) containing predominantly one land use; and stations that drained relatively large watersheds (1,000-30,000 hectares) which contained a mixed land use. The former stations are referred to as "land use" stations and are commonly located in small streams or municipal storm drain pipes. Data from these stations are indicative of urban runoff water quality from urban and non-urban sources and were used to characterize water quality and as input to loading estimates. The latter type of stations, referred to as "waterway or stream stations" were located in larger streams and rivers near the Bay and represented local receiving waters. Data

VOL 12

7504

from these stations were used for compliance and reflect the effects of upstream non-urban areas and stream sediment processes. Table 1 describes the various stations.

TABLE 1
STATION DESCRIPTIONS

Station ID	Type of Station	Location	Principal Land Use	Drainage Area hectares (acres)	Conveyance	Remarks
L1	Land Use	Junction Avenue	industrial park	8.9 (22)	0.76m (30") R.C.P.	Manhole station, with weir installed

S4	Waterway	Coyote Creek	mixed	32,207 (79,552)	natural	SCVWD high-flow gaging station No. 2060

Monitoring Methods

Storm water sampling was generally conducted with automatic flow composite samplers. Station designs varied but generally consisted of ISCO Model 2700 or 3700 automatic samplers, a Campbell Scientific CR-10 data logger and controller, a Druck diaphragm-type pressure transducer, and 10 or 20 liter borosilicate glass bottles to contain the composite samples. Each station was flow rated using established or new flow rating curves or where weirs were installed, appropriate weir equations. Based on the anticipated runoff, the controller was programmed to collect twenty 500 ml sub-samples over the course of the runoff event. Initially stations could only be controlled on site, then telemetry was added to allow remote control and monitoring. This change significantly improved the storm coverage and quality of data obtained.

Manual grab samples were collected for volatile organics, bacteria, and total oil and grease. Manual samples sometimes were obtained for other pollutants to define pollutographs.

Analytical Suite

In the early part of the Program, a full suite of analyses was conducted which included 10 metals for total and dissolved fractions (arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, and zinc), organics (organochlorine pesticides, organophosphate pesticides, volatile organics, semi-volatile organics, total oil and grease, and total organic carbon), and other parameters (pH, hardness, turbidity, and total suspended solids). Parameters that were consistently not detected were dropped from the full suite to a reduced suite of analyses that has become the routine analytical suite for the past 4 years of monitoring. The reduced suite is shown in Table 2.

Note that in Table 2 the method detection limit for mercury was reduced by modifying the analysis techniques in order to quantify mercury levels. Analysis methods were also modified to lower the method detection limits for selenium and PAHs.

Quality Assurance and Quality Control

Since the start of the Program, stringent field and laboratory QA/QC procedures were developed and implemented to ensure high quality data. Field QA/QC includes following strict sampling protocols as specified in standard operating procedures and evaluation of potential contamination through the analysis of field equipment blanks. Laboratory QA/QC addressed:

- Accuracy (analysis of matrix spike recoveries on each batch of samples and quarterly analysis of certified samples)
- Precision (analysis of matrix spike duplicates)
- Contamination (analysis of method blank, and filter blank)
- Holding Time (specified holding times associated with each chemical method)
- Certified Methods of Analysis (EPA or State certified methods of analysis)

Metals Detected

Figure 2 shows the percent of waterway samples in which metals were detected during storm events from 1988 to 1992. Of the metals detected by the total recoverable methods (total metals), cadmium, chromium, copper, lead, nickel and zinc were consistently detected. Total arsenic was detected in 74% of the samples while total mercury, selenium and silver were detected in approximately half the samples. Of the dissolved metals only chromium, copper and zinc were consistently detected.

Monitoring Period: 1988 to 1992

Figure 2 PERCENT OF WATERWAY SAMPLES IN WHICH METALS WERE DETECTED DURING STORM EVENTS

<u>Effects of Land Use on Water Quality</u>

During the first two years of the Program (1987-88,1988-89), monitoring data were collected at seven land use stations (Table 1, stations L1-L7) to characterize water quality from open, residential/commercial, and industrial land uses. To characterize water quality from transportation corridors, two stations were installed and operated for three years on an eight lane freeway and on a local 4 lane expressway (Table 1, stations T1, T2). Figure 3 shows the median concentrations of total cadmium, copper, lead, nickel and zinc at the land use stations and at the waterway stations (Table 1, stations S1-S4).

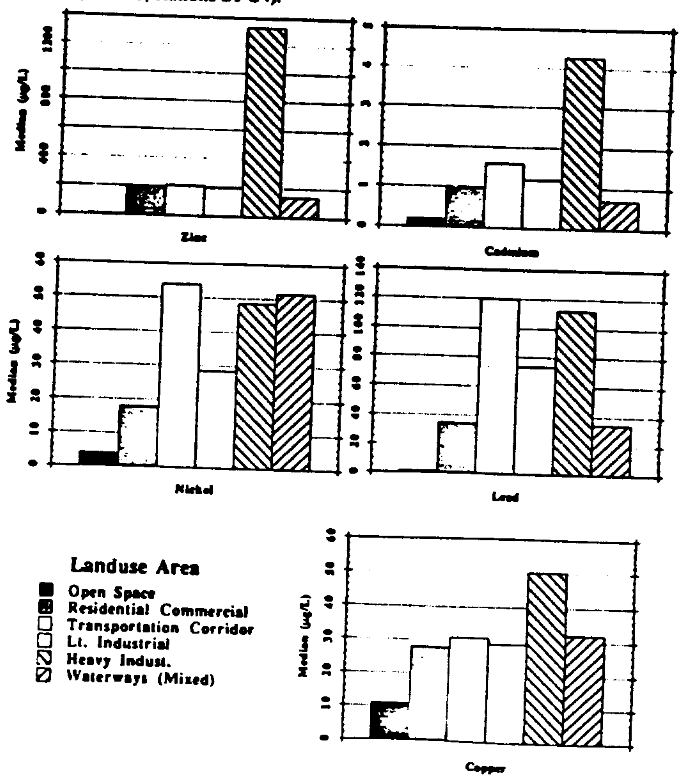

Figure 3 MEDIAN METAL CONCENTRATIONS IN STORM RUNOFF

Total zinc and cadmium at the heavy industrial station were 4 to 6 times higher than concentrations at the other land use areas. (Note: pilot inspection programs implemented in this catchment indicated a source of cadmium and zinc from metal plating operations.) Total cadmium in the other land use areas was only slightly elevated relative to the waterway concentrations. Total lead concentrations were highest at the transportation and heavy industrial stations. Total nickel concentrations were highest at the transportation, heavy industrial, and waterway stations. Total copper concentrations were highest in the heavy industrial station. Total median copper concentrations at the other urbanized land uses are consistently around 30 µg/L/L. Copper concentrations in samples obtained from open space stations were approximately one third of this value suggesting a substantial amount of copper may originate from open space land use areas.

Statistical tests of these data indicate that metals concentrations in samples obtained from open space versus residential/commercial samples versus heavy industrial samples are significantly different. The tests do not show statistically significant differences in concentrations of samples collected in different types of residential areas (eg, single versus multi-family) or between residential and commercial areas (SCVNPS, 1989).

Enrichment of Metals Associated With Suspended Particulates

Metals in storm water runoff are often associated with suspended solids. Metals in these solids may arise from either 'natural' sources (erosion of soils containing minerals) or manmade sources. One measure of the amount of manmade metal in a given sample is the "enrichment factor" defined as the ratio of the suspended metal concentration in a storm water sample collected in an urbanized portion of a watershed to the surficial soils concentrations in upland open areas of that watershed. (The enrichment concept is that if there were no additional input, or "enrichment", of metals from sources other than erosion, the suspended metals concentration would equal upland surficial sediment concentrations and the enrichment factor would be of the order of unity.)

The suspended metal concentration (µg/g) is defined as the ratio of the particulate metal concentration (g/L) to total suspended solids (TSS) concentration (g/L); where the particulate metal concentration (g/L) is the total metal concentration minus the dissolved metal concentration. The suspended metals concentrations are expressed on a dry weight basis (as are TSS values).

Data from Shacklette and Boerngen (1984) for the San Francisco Bay Area were used to characterize upland surficial sediment concentrations. The hills in the

South Bay contains serpentine outcrops as well as other mineral formations which are a source of nickel, copper, chromium, and mercury and metals concentrations in Bay Area soils were in the upper quartile of national data compiled by Shacklette and Boerngen.

Figure 4 shows enrichment factors for a variety of metals and sampling station types. The highest enrichment factors for land use stations are for zinc, lead, and cadmium which have enrichment factors between 10 and 40 for the three urban land use area types. In the waterway stations suspended solids had higher enrichment factors for most metals than bed sediments. Several factors may contribute to the

VOL 12

7510

observed higher enrichment factors in suspended versus bed sediments including differences in particle size.

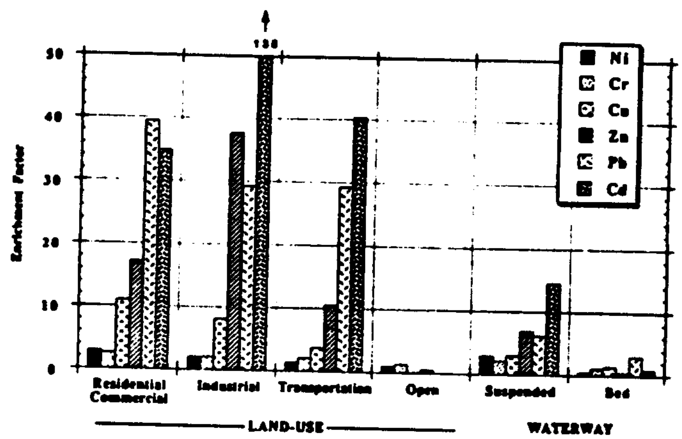

Figure 4 ENRICHMENT FACTORS FOR SUSPENDED SOLIDS

Enrichment analysis is a tool for identifying the relative importance of urban versus upland erosional sources. These results indicate that urban sources for cadmium, lead, and zinc are much larger than upland erosional sources, whereas for copper and nickel both sources are important. Chromium appears to be primarily an erosional source.

Water Quality Flowrate Correlations

There has always been an interest in potential correlations between water quality and flow and efforts at correlation using flow composite data have not been successful. However, grab sampling results for five storm events (28 data points) from the Guadalupe River Station (S3) were successfully correlated with flowrate. Figure 5 shows discrete TSS concentrations versus instantaneous stream flowrate. Linear regression analysis indicated a correlation coefficient of 0.781. The best-fit linear regression equation describing this relationship is:

$$TSS\ (mg/L) = 0.277\ FLOWRATE\ (cfs) + 58.49$$

Because of the high affinity of metals to solids, and since TSS is correlated with flowrate, we tested the relationship between total copper and flowrate.

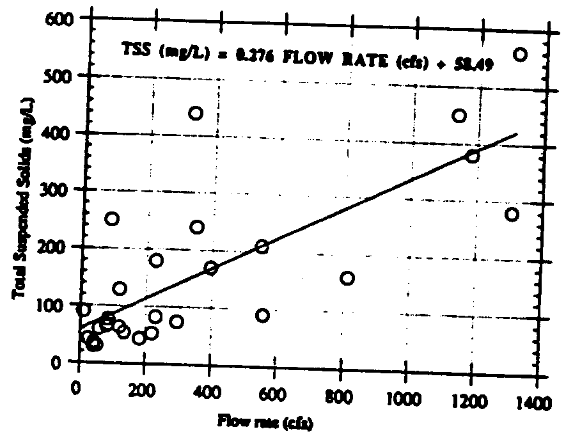

Figure 5 TOTAL SUSPENDED SOLIDS VERSES FLOW RATE IN GUADALUPE RIVER

Figure 6 shows a positive correlation (R^2= 0.820) between total copper concentration (TCu) and flowrate with a best-fit linear regression equation given by:

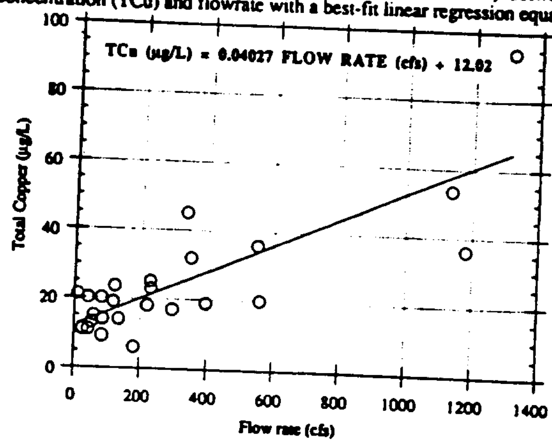

Figure 6 TOTAL COPPER CONCENTRATIONS VERSES FLOW RATE IN GUADALUPE RIVER

VOL 12

7512

R0040820

Equilibrium Partitioning

The form (as well as presence) of pollutants is important as the dissolved form of the constituent is more biologically available than the particulate form . In order to be able to characterize dissolved versus particulate partitioning we examined the applicability of equilibrium partitioning theory to storm water. A sorption isotherm describes the partitioning of chemicals between the dissolved phase and the sorbed phase. Assuming a linear isotherm for dilute solutions yields the following equilibrium partitioning equation (Maidment, 1992):

$$F_{dis} = 1/[1 + (K_d\ TSS)]$$

where

F_{dis} = ratio of dissolved to total concentration
K_d = Distribution coefficient (L/Kg)
TSS = Total Suspended Solids Concentration (μg/L)

When the grab sample data for copper were fitted to this theoretical relationship (Figure 7), there was a significant correlation (R^2=0.937). The distribution coefficient which yielded the best-fit regression curve shown in Figure 7 is 29,079 L/kg.

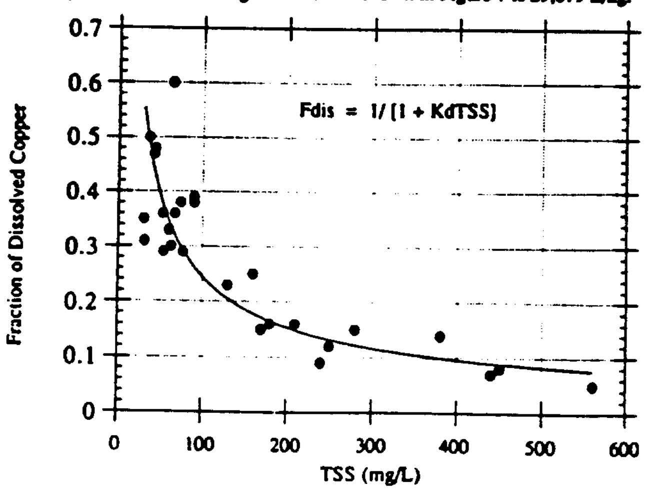

Figure 7 RELATIONSHIP BETWEEN FRACTION DISSOLVED COPPER AND TOTAL SUSPENDED SOLIDS

The distribution coefficient is the ratio of the sorbed concentration (g/Kg) to the dissolved concentration (g/L); therefore the higher the value of K_d, the lower the dissolved fraction. The distribution coefficient for lead is greater than that for zinc

VOL 12

7/5/13

R0040821

which is greater than that for copper. This means that in the sorbed phase, there is a higher fraction of lead than zinc than copper.

In conclusion, these storm water data support the linear isotherm equilibrium partitioning theory and this theory may be applied to estimate the dissolved fraction given the TSS and total concentration. Although not shown, this theory also applied reasonably well to data taken in storm drains (SCVNPS, 1993).

Exceedances of Water Quality Objectives

The metals data from four years of monitoring waterway stations have been compared to water quality objectives contained in the April 1991 California Inland Surface Waters Plan. Since the average storm runoff duration at waterway stations is about 36 hours in Santa Clara Valley, comparison of urban runoff water quality to the freshwater aquatic life1-hour and 4-day objectives are used to "bracket" the actual exposure. The 4-day average objective is referred to as the "chronic" objective, and the 1-hour average objective is referred to as the "acute" objective. Given the duration of storm events, exceedance of an acute objective is considered a better indicator of a potential toxicity problem. In addition, exceedances of objectives by dissolved metal concentrations are considered better indicators of potential toxicity problems than exceedances by total metals concentrations because dissolved metals are more bioavailable.

Table 3 summarizes the water quality objective exceedances for various metals at the four waterway stations using dissolved and total metals data collected during the 90-91, 91-92, 92-93, and 93-94 wet weather seasons. Acute and chronic water quality objectives for total copper and total zinc were consistently exceeded in samples collected from Calabazas Creek (station S1) and Sunnyvale East Channel (S2). The objectives for total zinc were only occasionally exceeded in storm water samples from Guadalupe River (S3) and Coyote Creek (S4). The objectives for total copper were less frequently exceeded, and the concentrations were nearer the objectives, in storm water samples from Guadalupe River and Coyote Creek than in samples from Sunnyvale East Channel and Calabazas Creek. The chronic objectives for total nickel and total lead were always exceeded in samples from Sunnyvale East Channel and Calabazas Creek, and frequently exceeded in samples from Guadalupe River and Coyote Creek. Acute objectives for total lead were rarely exceeded, and acute objectives for total nickel have never been exceeded. Total cadmium has not exceeded acute objectives, and exceeded chronic objectives in 8 of 61 storm samples; the most recent observed exceedance was in October 1991.

Dissolved constituents seldom exceed objectives. Dissolved copper exceeded the chronic objectives in 2 of 42 samples, and has not exceeded acute objectives. Dissolved lead was detected in 10 of 43 samples and one of these ten samples exceeded the chronic objectives; no lead samples exceeded the acute objectives.

Those 304(l) metals of concern that have never exceeded water quality objectives include total mercury (acute objectives only, chronic objectives were lower than the MDL), total selenium, dissolved cadmium, and dissolved zinc. Total silver is generally not detected, and dissolved silver and chromium (VI) have never been detected in storm water samples from the four waterway stations.

VOL 12

7/5/14

Figure 8 compares the total copper data with acute and chronic objectives for the four waterway stations. This figure shows the effect of urbanization on water quality exceedances. Most exceedances occur at the stations (S1 and S2) whose watersheds are smaller and more highly urbanized.

5--5-7

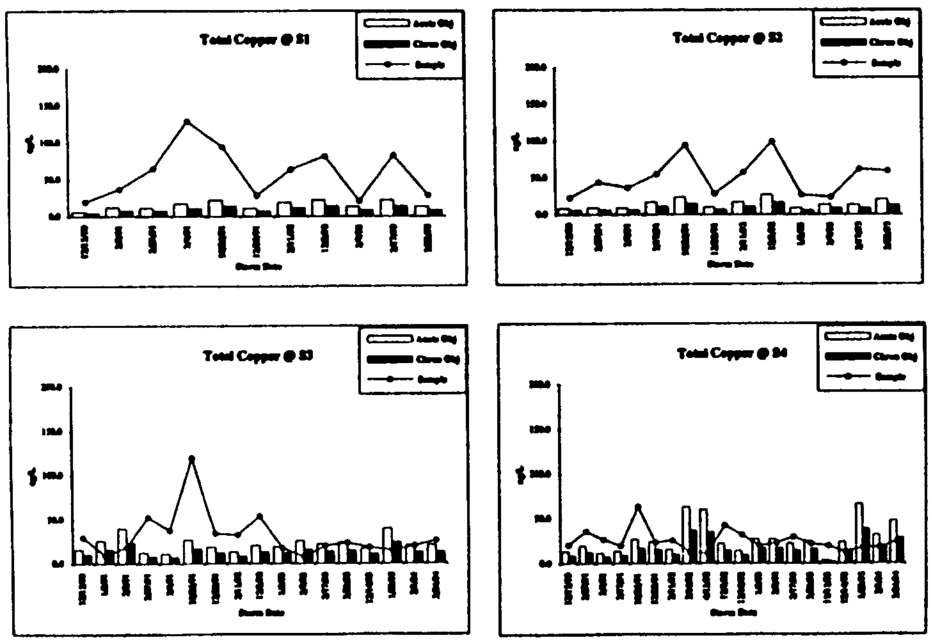

Figure 8 COMPARISON OF TOTAL COPPER CONCENTRATIONS IN STORM WATER SAMPLES TO WATER QUALITY OBJECTIVES AT FOUR WATERWAY STATIONS

Duration Of Water Quality Objective Exceedances

If flow-weighted concentrations exceed the WQOs, it is often assumed that the duration of exceedance equals the duration of the runoff event. In order to test this assumption, the actual duration of exceedance was determined by collecting and analyzing discrete samples during six storm events at the Guadalupe River Station (S3). For each storm event, about six samples were collected over the rising, peak, and receding limb of the hydrograph.

Table 4 shows that the duration of exceedance of acute WQOs for total copper, lead and zinc is always less than the duration of the storm runoff event. The frequency of exceedance varies depending on the metal, and was greatest for copper (5 of 6 events), then zinc (4 of 6), and then lead (2 of 6). For copper, exceedance duration ranged between 8-38 hours or about 20 to 95% of the duration of the storm runoff. For zinc, the exceedance durations ranged between 3-28 hours (8 to 74% of storm runoff duration) and for lead the two exceedances were each 6 hours or 20-25% of the storm runoff duration. For those cases where an exceedance was measured, the average duration of exceedance (expressed as a percent of the storm duration) was approximately 60% for copper, 40% for zinc, and about 20% for lead.

Table 4. Estimated Duration of Exceedance of Acute WQO for Total Copper, Lead, and Zinc

Storm Event	Storm Date	Storm Runoff Duration (Hrs)	COPPER Exceedance Duration of Acute WQO (1)		LEAD Duration of Exceedance of Acute WQO (1)		ZINC Duration of Exceedance of Acute WQO (1)	
			(Hrs)	(%)	(Hrs)	(%)	(Hrs)	(%)
SE11	12/15/90	40	38	95	0	0	28	74
SE13	2/2/91	20	0	0	0	0	0	0
SE14	2/28/91	30	23	77	6	20	10	33

Statistical Analyses

Statistical analysis were used to determine if there were differences in water quality between monitoring stations and between monitoring years. The results were also used to help select future stations for long term monitoring and to determine the number of samples that need be collected to detect a given trend in water quality (power analysis).

Two way analysis of variance (ANOVA) and analysis of covariance (ANACOVA) were used to perform comparisons between stations and years. Parametric procedures (using the actual values of the data) rather than non-parametric procedures (using the ranks of the values) were chosen because they allow the statistical results to be used to determine the number of samples necessary to determine a given difference between years and/or stations (power analysis). Previous data analysis indicated total metals are lognormally distributed and therefore, statistical analyses used log-transformed data.

ANOVA Results - Station Differences

Figure 9 presents total copper box plots for the four waterway stations for samples collected during the permit period. The figure indicates total copper concentrations are highest and more variable in Calabazas Creek (S1) and Sunnyvale East Channel (S2), with lower concentrations and less variability seen in Guadalupe River (S3) and Coyote Creek (S4). The stations with the higher concentrations drain smaller more urbanized watersheds.

The results of the ANOVA statistical analysis (top of Figure 9) indicate Calabazas Creek (S1) had significantly higher total copper concentrations than Guadalupe River (S3) and Coyote Creek (S4) and Sunnyvale East Channel (S2) was significantly higher than Coyote Creek (S4). If the data for the two stations (S1,S2) having the higher concentrations are pooled, these data are significantly higher than the pooled data for stations S3 and S4 ($p=0.002$).

ANACOVA Results - With TSS as Covariant

Much of the total copper in waterways during storms is associated with suspended solids, with the dissolved fraction typically ranging from 15% to 30% of the total concentration (Figure 7). Variations in TSS from event to event may mask apparent station and or year differences. To examine this effect, analysis of covariance (ANACOVA) was used to account for differences in total copper concentrations caused by variations in suspended solid concentrations by including TSS as a covariant. Differences not due to variations in TSS are seen as better indicators of station and year differences.

Station Differences

Figure 10 presents the suspended sediment total copper percentile box plots. The figure indicates the total copper concentrations in suspended sediments are highest in Sunnyvale East Channel, with lower concentrations in Calabazas Creek, Guadalupe River and Coyote Creek. Sunnyvale East Channel is not a natural channel while the other waterways are natural channels with little or no improvements. This suggests that total suspended sediment concentrations are lower in constructed waterways

VOL 12

7518

(because of minimal or no bottom or bank erosion) which, for a given total metals concentration, results in lower copper concentrations in suspended sediments.

Station ID Key

S1 Calabazas Cr.
S2 Sunnyvale E. Channel
S3 Guadalupe River
S4 Coyote Creek

Figure 10 TOTAL COPPER IN SUSPENDED SEDIMENT IN SANTA CLARA VALLEY WATERWAY STATIONS

Results of the ANACOVA statistical comparison are presented at the top of Figure 10. The results indicate Sunnyvale East Channel (S2) had significantly higher total copper concentrations than Calabazas Creek, Guadalupe River and Coyote Creek. Total copper concentrations in Calabazas Creek, Guadalupe River, and Coyote Creek are not significantly different after accounting for differences due to TSS.

Annual Differences

Data from the three similar stations (Calabazas, Guadalupe, and Coyote) were used to conduct a two-way ANACOVA using year and stations as the effects to be tested. The results shown in Figure 11 indicate total copper was significantly lower in 1992 as compared to 1991 (p=0.044). No other significant differences between years were observed. These observed differences may be due to increased rainfall in 1992 (19.5 inches total) as compared to 1990 (11 inches) and 1991 (14 inches) or other factors.

In conclusion, these analyses indicate the advantage of conducting ANACOVA statistical testing taking into account the effects of TSS as a covariate. The results indicate that, by taking into account TSS, differences between stations were illuminated which would otherwise have been masked using an ANOVA analysis. The ANACOVA results also showed a statistically valid annual difference which was not evident in the ANOVA analysis.

Power Analysis for Detection of Long-term Trends

There is considerable interest in storm water monitoring to detect long term trends in water quality that may be associated with BMP implementation. The following describes the application of the statistical tool called power analysis to help address this issue.

The ability to distinguish long-term trends in a dataset is influenced by several factors including the magnitude of the difference to be observed, the amount of variability in the data, the number of samples, and the desired confidence intervals for the statistical tests. The probability of observing a given trend increases when sample size is increased and decreases when variability and/or desired statistical confidence intervals are increased. Additionally, the larger the trend to be observed the higher the probability it will be observed, other factors being equal. The main variables which can be controlled are the number of samples and which stations will be monitored.

Results of the ANOVA statistical testing indicated the four monitoring stations could be grouped into subsets based on total copper concentrations. Each of the subsets contained differing degrees of variability with the Calabazas Creek Sunnyvale East Channel subset (S1&S2) having higher variability than the Guadalupe River Coyote Creek subset (S3&S4). As variability is a factor influencing statistical power, separate power analysis was conducted for each station subset.

Figure 12 presents the results of the power analysis for total copper data collected at the Coyote Creek and Guadalupe River monitoring stations. Presented are the number of samples per year (total for both stations) and the power (probability of detecting the trend) for three projected trends. For example, this figure indicates that, at the 80 percent confidence level, it would take about 22 samples per year to confirm a 40% change over a 10 year period. If the trend analysis were to be conducted at the other two waterway stations where the data are more variable, the analysis shows that about 30 samples would be required.

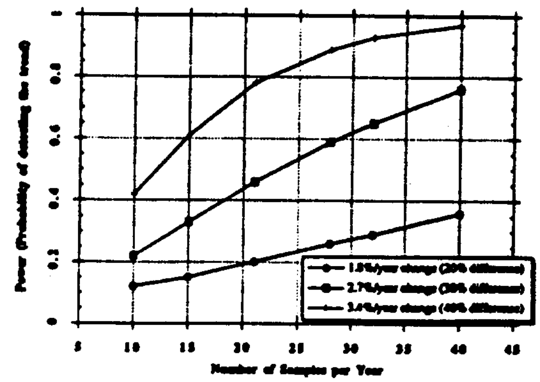

Figure 12 NUMBER OF WATERWAY SAMPLES NEEDED TO DETECT A 10-YEAR TREND IN TOTAL COPPER CONCENTRATIONS IN STORM WATER SAMPLES (Guadalupe and Coyote Stations)

An alternative power analysis was conducted using the ANACOVA statistical results which examines differences in total copper caused by factors other than changes in total suspended solids (Figure 13).

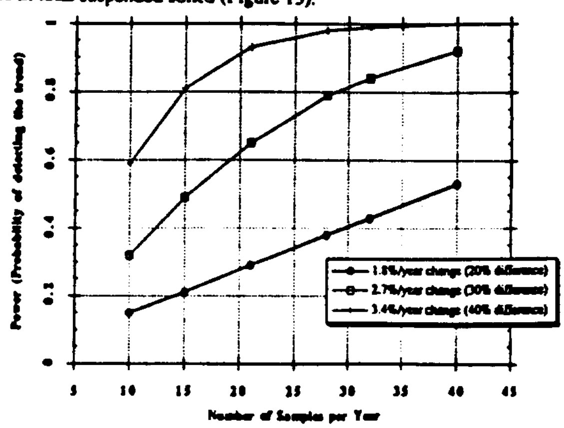

Figure 13 NUMBER OF WATERWAY SAMPLES NEEDED TO DETECT A 10-YEAR TREND IN TOTAL COPPER BASED ON ANACOVA USING TSS (Calabazas, Guadalupe, and Coyote Stations)

VOL 12

7523

When compared to the previous power analysis presented in Figure 12 it is apparent that changes in TSS-corrected total copper are easier to detect using the ANACOVA model, reflecting the lower unexplained error after changes due to TSS are taken into account. (For example, 15 samples per year are sufficient to detect a 40% change).

The disadvantage to using the ANACOVA model is that it is more difficult to relate the observed differences to actual changes in pollutant concentrations and loads. The advantage of the model is that, by correcting for changes in TSS in individual storms, some of the influence due to changes in stream hydrology during individual storms is taken into account and annual differences due to other factors may become more apparent.

Toxicity Testing

The purpose of toxicity monitoring was to characterize toxicity at different land use stations and to provide a long term assessment of toxicity (frequency and intensity) in waterway stations. Storm water samples were collected in Santa Clara County during several winters. Some of these were used in chronic, 7-day toxicity tests with *Ceriodaphnia dubia* (USEPA,1989), and some were used for further characterization employing toxicity identification evaluations (TIE) phase I protocols (USEPA, 1988).

The results of chronic toxicity tests are presented in Figure 14, arranged by categories of toxicity intensities. The legend lists the categories in ascending order of intensity (F being more intensive than A) and defines each toxicity category. The mortality endpoint is based on how long it took for a sample to cause mortality of 50% of the test organisms, and samples were assigned to one of three groups: extremely toxic (F, less than 24 hours), highly toxic (E, 1-4 days), or moderately toxic (C and D, 4-7 days). Impaired reproduction (or lack of reproductive effect) was assessed for all samples that did not cause mortality within 5-7 days, using the average number of offspring per female per reproductive day (OFRD) as compared to control OFRD. Moderately toxic samples were assigned to category D if they did not impair reproduction and to category C if they did. Samples which did not kill the organisms but caused impaired reproduction were defined as non-lethal (category B), and samples that did not have any deleterious effect were categorized as non-toxic (category A). Generally, the term "acute toxicity" for *C. dubia* refers to toxic effects delineated in categories E and F (mortality within four days), while the term "chronic toxicity" refers to situations encountered in categories B, C, and D.

Samples from various stations revealed distinctly different distribution among toxicity categories (Figure 14). In the heavy industry station (L-2), all of the samples collected during 1991-1993 were extremely toxic (category F). All samples collected at residential and commercial areas in 1989 caused mortality, and half were extremely toxic. The majority (80%) of the waterway stations samples collected during 1989-1994 were lethal to *C. dubia* (categories D, E and F), but only 20% were extremely toxic. It is important to emphasize that moderately toxic and non-lethal samples from residential, commercial, and mixed land use catchments did not inhibit reproduction of *C. dubia*, except for one unusual event (SE-27) in which all samples collected in Santa Clara Valley impaired reproduction. On the other hand, most of the transportation stations samples inhibited reproduction, and were categorized either as moderately toxic (category C) or non-lethal (category B).

VOL 12

7524

R0040832

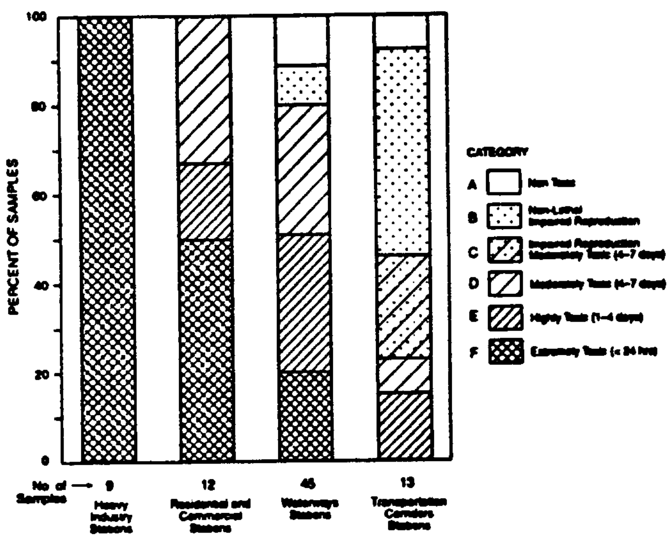

Figure 14. CATEGORIES OF TOXICITY OBSERVED IN DIFFERENT LAND-USE STATIONS IN SANTA CLARA VALLEY

Figure 15 shows the relative intensities of toxicity as measured in Coyote Creek (Station S4, Table 1) during three years of monitoring. The white upper portion of each bar represents the median time to lethality (LT_{50}), which is the duration of exposure that killed 50% of the test animals. The shorter the LT_{50} the higher the toxicity. The duration of the entire test is 7 days (168 hours). To more easily visualize variations in toxicity, we have defined a relative toxicity intensity unit that equals 168 hours minus LT_{50}, shown by the lower darker part of each bar. Taller dark portions mean higher intensity of toxicity, and absence of a dark portion means that toxicity was not detected at all. As can be seen in Figure 15, the variability in toxicity between storm events is very high, and due to this variability it is difficult to see a trend. However, toxicity was detected in autumn and spring storms more often than in mid-winter storms. The environmental significance of laboratory toxicity tests using sensitive non-native organisms is unclear. But the fact that the actual runoff duration in waterway stations is consistently less that the observed LT_{50}s suggests that storm water may not be creating toxic conditions in the tributary streams.

TIE testing has been conducted in a limited way, in part because such tests require highly toxic samples that have not been observed in waterway samples since 1991. TIE tests (3 samples) from industrial stations showed that dissolved metals accounted for a substantial portion of the toxicity observed. This is consistent with the fact that, at industrial stations, dissolved metals also exceeded WQOs and the toxicity intensity correlated with the magnitude of the exceedance.

At waterway stations (5 samples) and transportation stations (1 sample) the major causes of toxicity were non-polar organics (e.g., pesticides or hydrocarbons), or metal-organic complexes. This is consistent with the lack of exceedances of WQOs by dissolved metals and lends support to the appropriateness of dissolved (rather than total) concentrations as the preferred indicator of acute toxicity (Cooke and Lee, 1993). Instead of metals, pesticides, particularly diazinon, have been implicated as a major cause of toxicity in urban runoff samples from residential areas in Alameda County (S.R. Hansen, personal communication) and in the Central Valley (Connor et al, 1994).

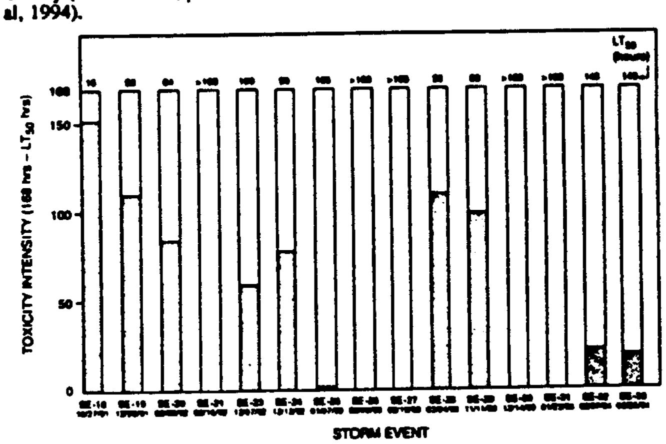

Figure 15. INTENSITY OF TOXICITY AT COYOTE CREEK STATION (S4) DURING THREE YEARS OF MONITORING

<u>Conclusions</u>

(1) The effects of land use on water quality is statistically significant only when data are pooled into the following broad land use categories: open, residential/commercial, and heavy industrial. No statistically significant differences in water quality have been determined for data sets within these broad land use categories.

(2) Enrichment analysis indicates that urban sources of cadmium, lead, and zinc are much larger than upland erosional sources, whereas for copper and nickel both sources are important. Chromium appears to be primarily an erosional source.

(3) Discrete grab sample water quality data correlate with flow whereas past attempts with correlations using flow composite data have been largely unsuccessful.

(4) Linear Isotherm equilibrium partitioning theory applies to storm water samples in alluvial streams and to a lesser extent in storm drains. This theory is very useful in predicting the dissolved versus particulate fraction of metals which is important in evaluating the potential toxicity and treatability of the sample.

(5) Exceedances of acute water quality objectives have not been observed with dissolved metals data and only 2 copper samples (out of 42) exceeded the chronic objectives. Toxicity data indicate that toxicity does not correlate with total concentrations of the metals and that toxicity is not reduced by filtering the sample. These results support the current EPA recommendations (EPA, 1993) that dissolved forms of metals are preferred for evaluating compliance with water quality objectives.

(6) If total metals data is used to evaluate compliance, grab sample data indicate that the duration of exceedance is 20-60 % of the storm event duration depending on the metal.

(7) Evaluating differences between stations and between years appears to be facilitated if one uses ANACOVA analysis using TSS as a covariate. This effectively eliminates hydrologic effects associated with increased TSS (and implicitly increased flows). This analysis indicated that water quality in a watershed where the channels have been significantly improved (e.g., lined with concrete) was statistically different from water quality collected in natural watersheds.

(8) The results of a power analysis to design a monitoring program to detect potential long term trends in water quality shows that accounting for TSS as a covariate could reduce the sampling burden. Nonetheless the number of samples per year required to measure trends are large (eg. 20-40 samples) and it is questionable whether such resources should be applied, especially every year. The authors suggest that monitoring resources should be balanced between compliance and trends analysis versus focused special studies of limited duration.

(9) Toxicity effects have been characterized in six categories depending on the type of effect (mortality and/or reproduction) and time scale of effect. Based on this classification, toxicity testing data indicate that runoff from different land uses exhibit different levels of toxicity to *Ceriodaphnia dubia*. The most toxic samples were found in industrial land use areas, and the least toxic were collected at transportation corridors. However, samples from transportation corridors specifically inhibited reproduction of *C. dubia*.

The cause of toxicity also varied. Data suggest that dissolved metals are the principal cause of observed toxicity at the heavy industrial station whereas at waterway stations the cause appears to be related to non-polar organics or metal-organic complexes. Pesticides, particularly, diazinon, have been implicated in storm water monitoring conducted in other areas of the state.

Future Direction Of Monitoring Program

The two major watersheds, Guadalupe River and Coyote Creek, will continue to be monitored annually for five storm events per year to evaluate long term trends in water quality and to determine if storm water discharges are in compliance with water quality and toxicity objectives. Sunnyvale East Channel and Calabazas Creek will be monitored every other year to meet these objectives, and to provide comparative data. The program will continue to conduct studies to evaluate control measure effectiveness, such as the development of BMPs for the control of pollutants from urban parking lots, scheduled for completion in December 1995. Toxicity testing will continue, but new approaches to evaluating the causes of observed toxicity will be implemented to better understand this complex environmental issue.

In addition to taking a more targeted approach specifically to stormwater quality monitoring, the Program will initiate efforts in the next permit period to expand the scope and purpose of monitoring. New monitoring objectives include greater emphasis on source identification, integrating monitoring into the goals of public education and participation, and expanding the scope of monitoring as a component of watershed management.

The Program recently completed a pilot Citizen Monitoring Project and will be supporting an expansion of this throughout the Santa Clara Valley in an effort to encourage public education and participation and to help prevent illegal dumping through increased community awareness. A pilot watershed-based sediment sampling and analysis project will be conducted in late 1994 to test such an approach to source identification, with particular emphasis on potential erosion and sediment management measures to reducing total copper loads to South San Francisco Bay. Finally, the Program, in cooperation with the Bay Area Stormwater Management Agencies Association and the San Francisco Estuary Institute, will be developing comprehensive watershed monitoring goals, objectives, protocols, and data management and analysis guidelines. A watershed monitoring approach will then be implemented in the Santa Clara Valley during the next permit term as component of watershed management.

Acknowledgements

The authors would like to express their appreciation to the member agencies of the Santa Clara Valley Nonpoint Source Pollution Control Program for supporting this work. We particularly wish to thank Mr. Roger James who, as Chair of the Program Management Committee during the 1st Permit Period, established a proactive program. Kinnetic Laboratories Incorporated (KLI) designed, installed, and maintained the equipment and collected the samples. Special appreciation is given to the field crews who collected these data under often difficult conditions. Marty Stevenson and Richard Mattison of KLI were key players in executing the field program. Toxscan, Inc. Laboratories conducted the chemical analyses and toxicity testing. Josephine Shum of SCVWD assisted in toxicity testing data interpretation. Marco Lobascio of Woodward Clyde assisted in designing and implementing the data management system. Michael Paquet of Woodward Clyde assisted in coordinating the field work and tracking weather.

SESSION III: System Runoff Characterization

DISCUSSION

NPDES Monitoring - Atlanta, Georgia Region
P. Michael Thomas and Scott McClelland

Finding - Average EMC for any pollutant from any land use is always close to the minimum observed value. Also, there was no statistical difference in the average EMC between land uses for any pollutant.

Finding - 14 parameters exceeded WQS. Fecal coliform in 44%, metals (lead copper, zinc and cadmium), chlordane and bis-2-ethylhexyl-phthalate.

Finding - Standards more frequently violated in stream samples than in end-of-pipe samples. 43% of stream samples exceeded lead standards, while end of pipe samples were much less - possibly due to resuspension of solids (Note: Still comparing measured chemical quality to WQS).

The storm event criteria recommended by EPA were not practical in Atlanta. Atlanta has short intense thunderstorms; can meet volume criteria, but not duration.

Questions/Comments

Question: Why the State designation of storm drains as waters of the state?
Answer: This is just the way it is defined in Georgia state law.

Question: Why are organics so ubiquitous?
Answer: We think it may be from plastic hoses. Chemists also say it is commonly found in laboratories; so possibly laboratory contamination.

Question: Why weren't any of the detention basins sampled?
Answer: They don't do anything for water quality because they are only for peak flow control.

NPDES Monitoring - Dallas/FortWorth, Texas Area

Samuel Brush, Marshall Jennings, P. Jonathan Young and Harry McWreath

Values of median and mean constituent concentrations were lower for all constituents than NURP data.

Level 1 priority pollutants monitored: Arsenic Cadmium, Chromium, Copper, Lead, Zinc, Chlordane, Diazinon, FC, FS, TSS.

Recommendations:

- Limit single land use monitoring.
- Locate some monitors on streams.
- Gather some data on undeveloped land for background.
- Limit the number of parameters to be sampled.

Diazinon found mostly on residential areas. Seasonal variations found in Diazinon, dissolved phosphorus, N, FC concentrations.

5-year objectives:

- Develop cost-effective program
- Consider network analysis of current stations
- Add some new stations requested by participating cities

Issues:

- Must all 7 cities start sampling at the same time?
- Can bioassessment substitute for some of the sampling?
- Can regional approach satisfy EPA's desire for equity among cities?
- Can monitoring results be used to measure effectiveness of management programs?
- How much sampling is enough?
- Are in-stream effects being adequately addressed?

Questions/Comments

Comment: Dallas (NCTCOG) has very good BMP manuals available for residential, industrial, commercial areas. These are available from Alan Plummer and Associates (see address for P. Jonathan Young in Proceedings).

Comment: Some WWTPs have problems with pesticides affecting the treatment process - their experience was that high pesticide concentrations were related to background concentrations, and not just to runoff loads.

Question: What is total cost of monitoring program?
Answer: Including USGS contribution ($1.9 million) the total is about $2.9 million.

Stormwater NPDES Monitoring in Santa Clara Valley

Terry Cooke, David Drury, Revital Katznelson, Chow Lee, Peter Mangarella and Keith Whitman

Santa Clara county is semi-arid - total rainfall about 14 in/yr)

Theme - you have to make monitoring work for you; must be mission driven as opposed to task driven.

Toxicity has been added to the monitoring program.

Telecommunications has made a big difference in the measured values of parameters; we cannot compare pre-telecommunication data with post-telecommunications data , because pre-telecommunications we were not able to get to the stations soon enough to set up sample bottles, etc.. Cannot lump data together for analysis because results are from two different data sets.

<u>Land use</u>

- Lead shows land use variability - found in transportation and heavy industry sectors when compared with background.
- Zinc high in heavy industry, but same in other land uses.
- Copper constant at 30 micrograms/l for all land uses except heavy industry (higher) and open areas (lower). Thus, conclude that the effect of land use on water quality is statistically significant only when data are pooled into gross categories.

Defined enrichment ratios as the relative concentrations in streambed locations versus upland soils. From this analysis, determined that the source of copper can be both urban runoff and soils, whereas lead, cadmium, and zinc are found only in urban runoff.

Correlations - can get good correlation of TSS and copper grab samples to flow (Editor's note: One would expect this because TSS is a function of velocity and the copper is attached to flow).

When looking at acute toxicity, only dissolved fractions are available and they are

VOL 12

7532

almost never out of compliance.

Trend analysis is not possible using water quality data because of high variability - because high scatter in data requires large number of samples. May be able to do trend analysis in streambank sediments or bioassays.

Recommendations

- Focus on protection of beneficial uses.
- Initiate integrated watershed management approach e.g. it is more cost effective to control copper in runoff than at the WWTP.
- Shift from a task-driven to a mission-driven approach.
- Vehicles are key sources of stormwater pollution.
- A national strategy is needed to address transportation sources (approximately 50% of the copper in Bay area is from brake pads).
- Need different perspectives for streams in the Bay area vs the Bay.
- Use a multi-media approach (runoff, sediments, fish) in defining the monitoring program.

In the future they will:

- Emphasize source identification and targeted monitoring.
- Public participation is really needed and useful - streamkeepers program.
- Develop multi-media watershed-based monitoring strategy.
- Emphasize missions, goals and priorities.
- Use an integrated watershed management approach.
- Use targeted strategies and actions.
- Increase regional and state coordination and collaboration.

Questions/Comments

Question: Is some copper in streams due to copper treatment in upstream reservoirs?
Answer: Yes - probably as copper sulfate applied to the lake as an algicide.

Question: Were dry-weather flows a problem?
Answer: No, they were not a problem, and amounted to only about 1-2% of annual flows.

Panel Discussion

Question: Is the USGS maintaining a centralized data base for all their data?
Answer: Yes.

VOL 12

7533

Question: Can you say that enrichment is primarily due to channel erosion?
Answer: No - we believe that enrichment is due to urban runoff.

Question: What is the accuracy of the samplers you used?
Answer: About + or - 10%.

Question: Were any samples in the Atlanta study taken both above and below the weir to see if intake location made any difference?
Answer: The USGS did not do this, but the SWFWMD found in their work no difference except in DO and things like that.

Comment: Roesner (supported by Urbonas) thought that correlations of pollutants with flow are probably more related to the sediment (and their relationship to flow and attached pollutants).

Biological and Chemical Testing in Storm Water

William T. Waller[1], Miguel F. Acevedo[1], Eric L. Morgan[2], Kenneth L. Dickson[1], James H. Kennedy[1], Larry P. Ammann[3], H. Joel Allen[1], and Paul R. Keating[1]

Abstract

Watershed management has long been a goal of individuals interested in quality aquatic ecosystems. The implementation of the National Pollutant Discharge Elimination System has gone a long way toward providing the tools necessary to manage point source discharges from waste water treatment plants. Managing episodic toxicity events associated with storm water events has always been problematic. Understanding and controlling episodic toxicity is necessary if watershed management leading to quality aquatic ecosystems is to be realized. This paper provides some examples of the importance of biological and chemical testing in storm water management and provides a developing approach to help achieve management objectives.

Introduction

The 1972 amendments to the Federal Water Pollution Control Act, referred to as the Clean Water Act (CWA), prohibited the discharge of any pollutant to navigable waters from point sources unless the discharge was authorized by a National Pollutant Discharge Elimination System (NPDES) permit. The principal focus of the NPDES program has traditionally been to reduce pollutants in discharges of waste water treatment plants. This program emphasis developed because many industrial and municipal sources were not controlled or poorly controlled at that time and were easily identified as contributing to water quality impairment. Nonetheless, within the framework of the law, channelled storm water was classified as a point source. The passage of the CWA led to a long and intense debate over storm water regulations.

---

[1]Institute of Applied Sciences, Department of Biology, University of North Texas, Denton, TX [2]Tennessee Technological University, Cookeville, TN
[3]University of Texas at Dallas, Richardson, Texas

The Water Quality Act of 1987 added section 402(p) to the Clean Water Act (CWA). Section 5402(p) requires the Environmental Protection Agency (EPA) to establish phased and tiered requirements for storm water discharges under the NPDES program (Federal Register, 1992).

The application for NPDES permits for storm water discharges consists of two parts. Part 1 of the permit application includes a description of legal authority to address separate storm sewer systems; an inventory of outfalls and details about drainage areas; a field screening program to detect illicit discharges; a plan for a representative sampling program to be implemented in Part 2 of the application; and a description of existing storm water controls. Part 2 of the storm water permit application includes a list of industrial dischargers to the municipal separate storm sewer system; quantitative data from the representative sampling program developed in Part 1; and a storm water management plan to be implemented during the term of the permit. An assessment of the effectiveness of the storm water management plan and a fiscal analysis of necessary capital and operations and maintenance expenditures are also included in Part 2 (Oakley and Forrest, 1991).

As part of the response to the Part 2, NPDES storm water permit application requirements, seven major cities in the Dallas-Fort Worth (DFW) metroplex participated in a comprehensive storm water sampling program. Thirty sampling sites representing different land uses (residential, commercial, industrial, and highway) were sampled for seven storm events. Approximately 185 parameters including nutrients, metals, pesticides and organics were analyzed.

Results of the local storm water sampling program are being compared with historical findings of the Nationwide Urban Runoff Program (NURP), as well as historical local data (EPA, 1983). NURP was a five-year program during the period 1978-1983. NURP collected data for ten constituents at 81 sites in 22 cities for over 2300 storm events at acceptable "loading sites" where no devices modifying runoff were upstream. Runoff was characterized by land use and for all urban sites combined. NURP values included biochemical oxygen demand (BOD), chemical oxygen demand (COD), total Kjeldahl nitrogen, nitrite+nitrate, total phosphorus, total suspended solids (TSS), total copper, total lead, and total zinc. In addition to these "standard pollutants", special priority pollutant and metals studies were conducted at many of the sites.

One use of the data collected from the recent Phase 2 sampling program carried out in the Dallas-Fort Worth metroplex is to determine the local event mean concentration (EMC) values for the calculation of the pollutant loads from local watersheds. An EMC value is defined as the flow-weighted mean pollutant concentration for a given or typical storm event. Choosing the correct local EMC value could result in different pollutant loadings than those predicted by the national average NURP EMC values. The regional program is being coordinated by the

VOL 12

7536

North Central Texas Council of Governments (NCTCOG) (Young, *et al.*, 1993) and has as its objectives:

1) **Satisfy the U.S. EPA requirements for Part 2 NPDES storm water permit applications.**

2) **Determine the constituent loads from representative watersheds in the area.**

3) **Characterize the land use impacts on water quality.**

4) **Provide basic information to develop management alternatives for permit compliance.**

Toxicity

Much of the data collected in storm water sampling programs have focused on chemical constituents and loadings because of the emphasis on the reduction of loadings characteristic of most Best Management Practice (BMP) goals, and concerns over the realism of traditional toxicity tests when used to measure episodic toxicity. Nonetheless, concerns exist about the toxicity of storm water, and toxicity tests are the only adequate method of characterization. Poor correlations between conventional contaminant measures and toxicity indicate that toxicity should be measured directly to assess the biological impacts of storm water runoff instead of inferring toxicity from chemical measurements. With chemical specific measurements you only find what you are looking for; what you do find is not always biologically available; the toxicity of all the chemicals that can be measured is not always known; and our understanding of the interaction of toxicants (synergism, antagonism, and/or addition) is poor at best. The need for the use of toxicity tests to determine toxicity has been stated best by Cairns and Mount (1990);

> "No instrument has yet been devised that can measure toxicity! Chemical concentrations can be measured with an instrument but only living material can be used to measure toxicity."

As a supplement to their participation in the Phase 2 storm water study, the City of Fort Worth, Texas applied for and received a 104(b)(3) grant from EPA to test the practical use of biotoxicity tests as screening tools in storm water programs. The City of Fort Worth contracted with the Aquatic Toxicology Laboratory of the University of North Texas (UNT) to perform acute toxicity tests on selected storm water samples collected in the Phase 2 storm water program. Acute toxicity tests using *Ceriodaphnia dubia* and *Pimephales promelas* were performed on these samples according to EPA methods (EPA, 1991a). City of Fort Worth personnel performed Microtox™, test methods on some of the same samples. In addition, UNT tested selected samples for chronic toxicity and some acutely toxic samples were

VOL 12

7537

characterized using Phase I, Toxicity Identification Evaluation methodologies (EPA, 1991b).

Acute toxicity tests were performed on thirty-one storm water samples collected from eighteen storm events. Sixteen stations representing industrial, commercial, residential, and mixed landuses were included in the analysis. Of the thirty-one acute toxicity tests performed on storm water samples from the Phase 2 study there was no significant mortality to *P. promelas* in any of the tests. In 12 of the thirty-one tests the no observable effects level (NOEL) for *C. dubia* was 50% or less. There were 23 tests for which both *C. dubia* and Microtox™ tests were performed. In eight of these tests *C. dubia* showed toxicity when Microtox™ did not, while there were three tests for which a 15 minute EC50 could be calculated for Microtox™ for which there was no measurable *C. dubia* response. In 16 tests neither *C. dubia*, Microtox™, or *P. promelas* showed a significant acute response. In one test both *C. dubia* and Microtox™ showed a significant response. These results suggest that *C. dubia* was the most sensitive indicator of toxicity tested, although strictly speaking comparing Microtox™ EC50's with *C. dubia* NOELs is not a good comparison. A better comparison would have been a comparison between percent light loss for Microtox™ and NOELs for *C. dubia*. Not unexpectedly, the finding that *C. dubia* is more sensitive to a broad range of toxicants is consistent with our findings for effluent tests and ambient toxicity tests.

The data from the Phase 2 study that will be focused on in this analysis involves two different but important toxicants, diazinon and zinc. The chemical specific data from all the samples collected during the Phase 2 study are not as yet available. The results for the chemical specific summaries reported in this paper are based on data from 15 stations represented by eight residential sites, seven industrial sites and four commercial sites. The data are not as yet considered final and are subject to revision. We will focus on diazinon and zinc because they were common to most of the samples collected in the Phase 2 study regardless of land use and they were identified through Phase I, Toxicity Identification Evaluation (TIE) procedures as being the likely causative agents responsible for acute toxicity to *C. dubia*, in some of the samples. Fifty-seven percent of the parameters analyzed for, and reported in the Storm Water Discharge Characterization Final Summary Report--Task 2.0 (NCTCOG, 1993) were not found at the analytical detection limits employed in the Phase 2 study.

Toxicity Reduction Evaluations (TRE), of which Phase I, Toxicity Identification Evaluation (TIE) methods are an integral part, are an important part of the Water Quality Based approach to toxics control (EPA, 1984). Facilities which fail the toxicity portion of their NPDES permits are required to determine the causes of toxicity and develop methods to remove the toxicity. Phase I of the TIE procedures involves the physical and chemical manipulation of a toxic sample. The toxic sample is fractionated by seven manipulations; pH adjustment, filtration, aeration, C_{18} solid phase extraction, oxidation reduction, EDTA chelation and graduated pH. The

VOL 12

7538

R0040846

filtration, aeration, and C_{18} solid phase extraction steps are all performed on the sample at its initial pH and after the pH has been raised to pH 11 and reduced to pH 3. After the sample is fractionated, each fraction is returned to the initial pH, if necessary, and tested for toxicity. Those fractions which remove and/or reduce toxicity are further tested to determine causative toxicants. The process of fractionation and toxicity testing focuses the search for the toxic components by reducing the number and types of chemicals one has to deal with by only concentrating on those fractions which reduce or remove toxicity. Phase II and III of the TIE procedures involve verifying the causes of toxicity.

Diazinon

Diazinon is an important toxicant in the southern part of the United States. Many municipal wastewater treatment plants in the southern part of the country are failing their NPDES permit requirements for toxicity and frequently the indicated toxicant is diazinon. Diazinon is a very popular broad spectrum pesticide and is used extensively in residential settings. Table 1 shows there is a widespread occurrence of diazinon in storm water samples regardless of the landuse from which the samples were collected. The percentage of events and concentrations of diazinon were highest from residential sites and the median concentration in these samples was greater than the 48-hour LC50 for *C. dubia*.

Landuse	Percentage of Sites with Diazinon	Percentage of Events with Diazinon	Median Concentration of Diazinon μg/L
Residential	100	97	0.55
Commercial	100	85	0.20
Industrial	83	39	0.00

Table 1. The relationship between diazinon and its occurrence in samples collected during the Phase 2 study from residential, commercial and industrial sites in the Dallas and Fort Worth metroplex.

Diazinon is also extremely toxic to aquatic organisms. The 48-hour LC50 of diazinon to *C. dubia* is 0.350 μg/L (Norberg-King, *et al.*, 1989). Arthur, *et al.* (1983) recommended that diazinon in aquatic environments not exceed 0.080 μg/L. The 48-hour LC50 for the midge *Chironomus tentans* has been reported as 0.100 μg/L and development of the larvae of this midge have been inhibited by continuous exposure (80 days) to concentrations as low as 0.0006 μg/L (Morgan, 1976). Diazinon is sold in a variety of formulations by numerous companies. One liquid formulation of diazinon sold in quart containers contains 25% diazinon by weight. It would take 247 football field size containers, exclusive of the endzones, three

VOL 12

7539

yards deep to dilute the amount of diazinon in a quart container of 25 Diazinon to the 0.080 μg/L concentration recommended by Arthur, *et al.* (1983).

Figure 1 shows the distribution of diazinon concentrations from the 31 samples from residential sites for which diazinon concentrations were available. While the concentrations found in different rainfall events were highly variable, twenty of the values reported were in excess of the 0.350 μg/L LC50 values for *C. dubia*.

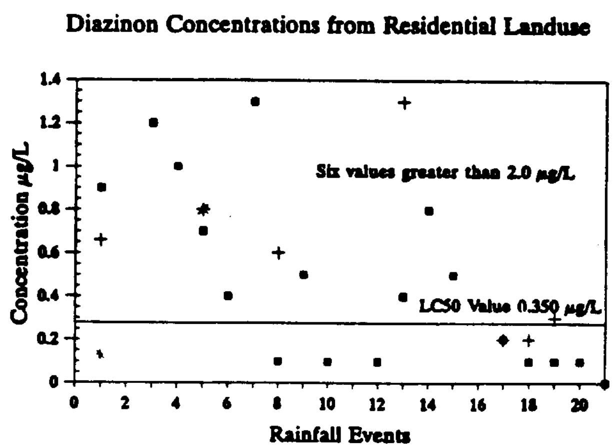

Figure 1. Diazinon concentrations from residential landuse and their relationship to the acute toxicity of diazinon to *Ceriodaphnia dubia*. Different symbols associated with the same rainfall event represent different sites.

The second most frequently measured pesticide was total chlordane which was found at seven sites, five residential and two commercial. A recent California Regional Water Quality Control Board memorandum (March 17, 1994) reported diazinon concentrations found in storm water samples collected in Stockton, California from residential and mixed landuse. Two rainfall events were monitored at thirteen sites.

The diazinon concentrations measured in these samples ranged from 0.160 to 1,050 µg/L. Eleven of the 13 sites had diazinon concentrations greater than the acute LC50 value for *C. dubia* (0.350 µg/L) and 100% *C. dubia* mortality was observed at most of the sites which were sampled.

Clearly, as far as pesticides are concerned, diazinon is a widespread toxicant in storm water runoff and is especially prevalent in samples from residential landuses. Two of the toxicity identification evaluations which were performed on acutely toxic samples from residential sites showed that non-polar organic chemicals were the likely causes of the toxicity and while it was not established without doubt that diazinon was the causative toxicant, all the available information points in that direction.

__Zinc__

Zinc is ubiquitous in its distribution, but was not included in this analysis for that reason. Rather, zinc was included because it helps define the role of toxicity testing in evaluating the impact of storm water events and because zinc is a significant toxicant in aquatic systems. One of the uses of the data collected in the Phase 2 study is to calculate EMC concentrations and to compare these with those observed in the NURP studies as well as other local studies. Therefore, it is important that all data which are collected and represent real values be included in the calculation of the EMC concentrations. The percentage of sites, events and the median concentration of zinc collected during the study showed, as one would expect, that zinc was found at all stations during every event (Table 2).

Landuse	Percentage of Sites with Zinc	Percentage of Events with Zinc	Median Concentration µg/L
Residential	100	100	65
Commercial	100	100	130
Industrial	100	100	110

Table 2. The distribution and median concentration of zinc amongst the landuses studied.

The landuse with the highest median zinc concentration was commercial (130 µg/L) followed by industrial (110 µg/L) and residential (65 µg/L). Thirty-six percent of the samples collected in the study contained zinc concentrations greater than the acute water quality criterion of 112 µg/L calculated based on an average water hardness of 28 mg/L as $CaCO_3$ (Figure 2). The concentrations reported for the same rainfall event were, as was true for diazinon values, highly variable.

VOL 12

R0040849

Zinc Concentrations in Storm Water

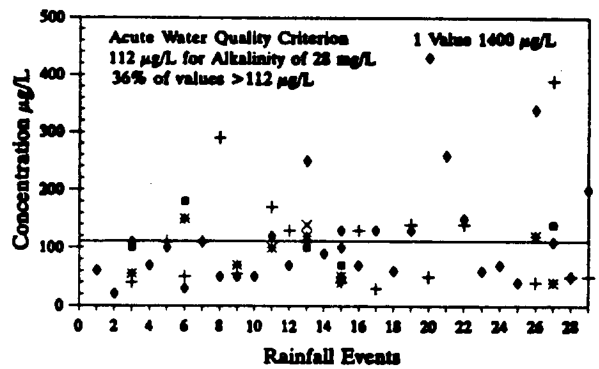

Figure 2. Zinc concentrations from storm water runoff and their relationship to the toxicity of zinc to *Ceriodaphnia dubia*. Symbols from the same rainfall event represent different sites.

In the Storm Water Discharge Characterization Final Summary Report--Task 2.0 (NCTCOG, 1993) from the Phase 2 study, the zinc concentration collected from one of the industrial sites was reported as 1,400 µg/L. In the report, this value was marked as an outlier which was defined as a data value which is obviously out of the expected range of the parameter being evaluated. In addition, in the initial analysis of the data collected in the study the following rule was applied to evaluate outliers. If the value of a parameter falls more than three standard deviations away from the average for that parameter, the value is scrutinized more closely and replaced with a blank if no other measured values are close. Subsequent to the sample for which the 1,400 µg/L zinc value was reported as an outlier another sample was collected from the same industrial site but in this case, acute toxicity tests were performed on the sample. The sample was determined to be acutely toxic to *C. dubia* with an NOEL of <50%. This was the single sample mentioned previously for which both a significant *C. dubia* response and a significant 15 minute EC50 for Microtox™ was calculated. A Phase 1, TIE was performed on the sample. The EDTA chelation

VOL 12

7542

R0040850

fractionation step was the only fraction which removed toxicity. Further independent analysis of the sample showed that the concentration of both zinc and copper were present at acutely toxic levels and lead was present at chronically toxic levels. The zinc concentration was 1,720 μg/L while the copper concentration was 54 μg/L. An examination by City of Fort Worth personnel revealed the presence of a galvanizing company in the area drained by the outfall. Working with the galvanizer the City should be able to remove the toxicity associated with the facility. As mentioned earlier the analysis presented in this paper is based on data included in the Storm Water Discharge Characterization Final Summary Report--Task 2.0. As stated in the report these data are subject to revision. In the final analysis all data, including the outliers, collected during the Phase 2 study were used to calculate event mean concentrations (Young, 1994, personal communication).

These examples show the usefulness of the toxicity and TIE methods in sorting through toxicity. However, the toxicity methods which were employed in this study are not without weaknesses when applied to the analysis of episodic toxicity events. Foremost amongst these weaknesses are concerns about how well, if at all, these methods mimic exposure of aquatic organisms during episodic events. Collins, *et al.* (1992) state that exposure is a function of several factors including discharge volume, duration, frequency and mixing; receiving stream flow; and pollutant concentration. In 1982, EPA recognized that water quality criteria based on continuous exposure of organisms to constant concentrations of toxicants were probably overprotective when applied to episodic storm water samples. EPA (1982) published a procedure to adjust water quality criteria for exposures which were more in line with those observed in storm water runoff events. The Virginia Pollutant Discharge Elimination System permits for storm water discharges contains a toxic management program which integrates acute toxicity testing, chemical specific monitoring and a toxicity reduction evaluation component. Virginia's toxic management plan uses EPA recommended acute toxicity test methods for *C. dubia*, *Daphnia pulex*, and *P. promelas* but recognizes that exposure is a problem with this methodology (Collins, *et al.*, 1992). If traditional toxicity methods do not mimic episodic toxicity exposure, what methods might be used to evaluate episodic toxicity?

Monitoring Episodic Events

Aquatic animals have been shown to induce bioelectric signals into surrounding water which can be recorded as rhythmic analog signals representative of specific movement activities (e.g., gill beats, heart rates, etc.). In addition, gape measurements (the degree to which a bivalve is open or closed) have been successfully used with clams and mussels as a means to determine the status of this organism. Utilizing appropriate statistical techniques and accompanying electronics, changes in bioelectric action responses and gape can be detected, processed, and continuously recorded, and have been used in detecting water quality induced stress in aquatic organisms.

The concept of using bioelectric action potentials to monitor the well being of aquatic organisms is not new. In the early 1970's Cairns, *et al.* (1970, 1972, and 1975) proposed a biological monitoring system for watershed drainage that would provide an early warning of water pollution. In addition to stream surveys, Cairns and his co-workers described a unique system for automatically recording fish breathing and swimming activities in response to developing toxicity in effluents and ambient receiving waters. Since the early 1970's numerous attempts have been made to use remotely sensed bioelectric action potentials to detect adverse conditions (Morgan, *et al.*, 1981, 1986, 1987a, 1987b, 1988a, 1988b, 1989). Morgan, *et al.* (1986) have used signals generated by individually monitored trout to asses environmental conditions. The signals from the trout were accumulated for a 15-minute interval each half-hour. The data were held in memory of a data collection platform and transmitted to the National Oceanographic and Atmospheric Administration, Geostationary Operational Satellite System on six occasions each day. Broadcast data received by satellite were transmitted to a direct-readout ground station at the Tennessee Valley Authority. Ham and Peterson (1994) have evaluated the effect of low level chlorine concentrations on the valve movement of the Asiatic clam (*Corbicula fluminea).*

Europeans have also been involved in the use of remotely sensed bioelectric action potentials as a means of detecting adverse environmental conditions for aquatic organisms (Caspers, 1988; Matthias and Puzicha, 1990; Slooff, *et al.*, 1983). Specific biomonitors evaluated include the rheotaxis of fish (Juhnke and Besch, 1971) the respiration of rainbow trout (Slooff, 1979) and the electric field alteration of the tropical fish *Gnathonemus petersi* among others (Geller, 1984). A more recent European study used the mussel *Dreissena polymorpha* as a biological monitor (Borcherding, 1992).

Managing aquatic ecosystems at the watershed/drainage basin level has long been an objective of environmental managers. Watershed management by its very nature dictates that loadings to an aquatic ecosystem and their sources be understood. The storm water studies which have been and are being undertaken as part of the NPDES permitting process are making significant contributions to our understanding of loading. It is equally important that the impact of these loadings on the system be understood. The rapid evolution of computers, communications links, geographical information systems, remote sensing, and the information highway have, or will contribute toward advancing the tools necessary to achieve this objective.

The biomonitoring system we are developing and testing uses clam gape to continuously monitor, in near real time, the status of clams (*Corbicula fluminea*) at remote sites. Physically, the non-invasive system uses industrial proximity sensors aimed at foil targets located on the clams to record the gape of the animals (Figure 3). The prototype systems we have built, and are testing, monitor the gape of ten clams simultaneously.

VOL 12

7545

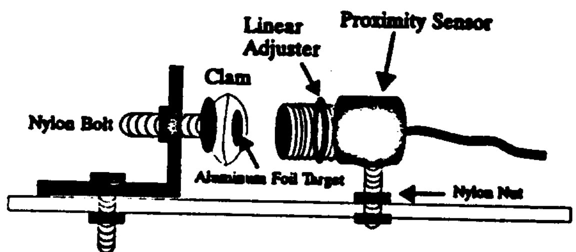

Figure 3. Clam biosensor schematic.

Conceptually (Figure 4) the biosensor system we are developing and testing includes the following components and is part of an overall strategy to manage watersheds:

1. The biomonitoring system consists of the continuous monitoring of clam gape at each site within the drainage basin being monitored.

2. A means to telemeter the data collected on the status of the clams back to a central receiving station.

3. An alarm system which is activated by the behavior of the clams. When the behavior of the clams is determined by a resident computer program to be out of range of normal a series of water samplers will be notified to begin taking samples and an event signal will be sent to the receiving station notifying the operator of an event.

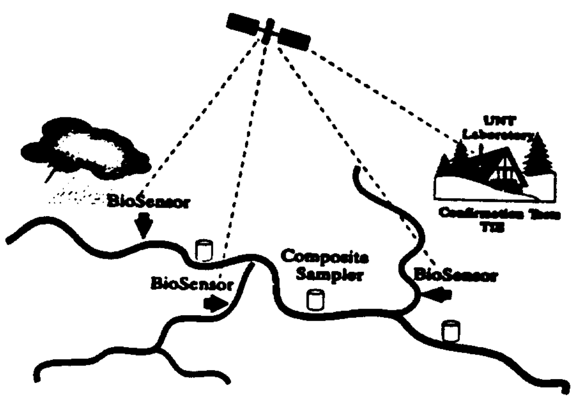

Figure 4. Diagram of the use of biosensors for watershed management.

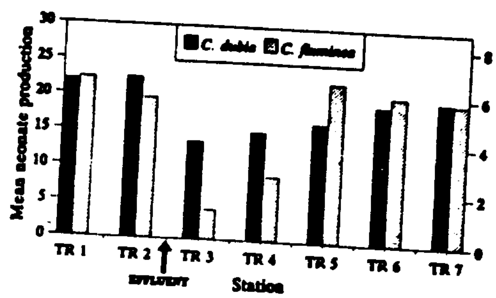
4. The samples are retrieved from the samplers and toxicity is verified using *C. dubia* as the test organism. If the samples are verified as toxic a Phase I, TIE procedure is initiated using *C. dubia* as the test organism. The data from the complete TIE process should be sufficient to identify the causative toxicants. Based on information from the TIE the likely sources of toxicity can be identified and management actions can be undertaken.

Clearly for this monitoring system, or one with similar components, to be effective several important operational conditions must be established. The most important condition is the reliability of the monitor. One consistent problem we have encountered with the monitors we have used in the past is that the volume of information and the complexity of the bioelectric signals being monitored (fish EKG's, breathing, etc.) have been so great as to be nearly overwhelming. This does not mean they have not functioned well for the purposes they were intended, only that it would be advantageous to simplify the signals for this application.

The signals we are monitoring from the clams are greatly simplified. However, we must still establish the frequency of false positives and false negatives before the system can be considered useful. We are in the process of doing this now.

Comparison of *Ceriodaphnia dubia* & *Corbicula fluminea* Dechlorination



Sample period 11/90 to 9/92
C. dubia n=17 monthly grab samples; C. fluminea n=4, in situ 28 day exposure

Figure 5. Relationship between *C. dubia* productivity and *C. fluminea* growth.

The monitoring system must be sensitive to the presence of toxicants but not so sensitive as to falsely indicate damage to the system one is trying to protect. We have been using *C. fluminea* as an *in situ* biomonitor for some time (Figure 5). In this application caged young *C. fluminea* for which initial length and weight measurements had been taken were incubated *in situ* in the system to be monitored. After an incubation time of approximately a month the cages were retrieved and length and weight determinations were made. The relationship between the growth of *C. fluminea* and the productivity of *C. dubia* collected from the Trinity River in the DFW metroplex above and below a municipal WWTP. *C. dubia* productivity is based on grab samples collected from the Trinity River at the same sites the *C.*

fluminea were incubated. In this example the exposure of the organisms were different, but the responses were similar. The suspected toxicant causing depressed *C. dubia* productivity and the reduced *C. fluminea* growth was diazinon.

These data support the use of *C. fluminea* as a reasonably sensitive organism. Additional data collected during this and related studies suggest that the Trinity River was impacted beyond that observed for *C. dubia* and *C. fluminea*. The responses of *C. dubia* have been shown to be predictive of in-stream impact (Dickson, *et al.*, 1992).

The data on clam behavior can be telemetered back to a central receiving station from remote sites. We have done this in the past by collecting and transmitting fish breathing rates to an over-passing N.O.A.A. GOES satellite and then to ground stations. We envision coupling the biological monitors with a network of continuous monitoring gauging stations which record stage height, flow, and selected physical chemical factors which already exist (USGS, ORSANCO, TVA, etc.). While the system we are evaluating does not prevent toxicity from occurring it should distinguish between toxic events and non-toxic events thereby reducing the time and effort spent on non-toxic events (35% of the samples tested for toxicity by UNT for the City of Fort Worth in this study showed no toxicity to any of the test organisms used). Since the organisms are continuously exposed *in situ* the exposure regimes should be more realistic than those based on traditional toxicity methods. The exception to this will be the exposure for those organisms that might be entrained and move with the storm water as it travels down the receiving system. Coupling the biomonitors with TIE methodologies should permit the identification of causative toxics and provide the basis for reductions in those toxics. These methods plus the advances in remote sensing, GIS, computer technology, the information highway, file transfer protocol (FTP) sites and the internet should provide the technical basis for managing watersheds.

Methods and Procedures in Stormwater Data Collection

Thomas Brown, William Burd, James Lewis,
and George Chang, P. E.[1]

Abstract

This paper presents methods and procedures developed to ensure the quality of stormwater monitoring data produced by the City of Austin, Texas, Stormwater Monitoring Program. Since 1975, the City has monitored stormwater runoff to produce data used in many studies, to develop structural-control design criteria, and to develop watershed ordinances. These ordinances have minimized the impact of urban development on water quality and resulted in effluent limitations. Given this high visibility, the City has developed stormwater monitoring techniques and experimental designs to improve the processes of flow measurement, sample collection, data management, and data analysis.

Monitoring Program Goals and Objectives

The goal of the City of Austin's (COA's) Stormwater Monitoring Program (SWMP) is the collection and analysis of water quality data to guide the development of watershed ordinances, manage the City's waterways, and fulfill federal requirements. Stormwater monitoring has been used to comply with U.S. Environmental Protection Agency (EPA) National Pollutant Discharge Elimination System (NPDES) permit application requirements, review and improve the City's watershed ordinances, and evaluate the pollutant removal efficiencies of structural and non-structural Best Management Practices (BMPs). The SWMP has monitored runoff from a spectrum of land uses ranging from pristine, undeveloped watersheds in the Hill Country west of Austin, Texas, to highly-developed urban watersheds in the City's core.

[1]Staff members of the Environmental and Conservation Services Department, The City of Austin, P.O. Box 1088, Austin, Texas, 78767.

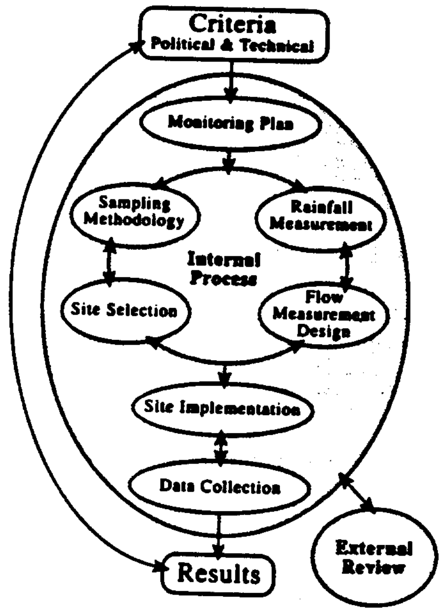

Figure 1. Stormwater Monitoring Process

Stormwater Monitoring as a Process

Stormwater monitoring can be considered as an expanded quality assurance and quality control (QA/QC) process (Figure 1). As in all integrated systems, errors occurring anywhere in the stormwater monitoring process tend to be translated into other components of the process--ultimately affecting the integrity of data. Therefore, careful planning at all stages of the stormwater monitoring process is the key element in the production of quality data (City of Austin, 1993a; City of Austin, 1993b).

a) Monitoring Plan

The monitoring plan defines the quantity and quality of data to be collected, the water quality parameters to be measured, the land use types and BMPs to be monitored, and the cost of data to be collected. The plan also specifies the type of monitoring equipment and software to be installed. The SWMP uses remote-controlled, automatic samplers that are operated from a central office (Figure 2).

VOL 12

7553

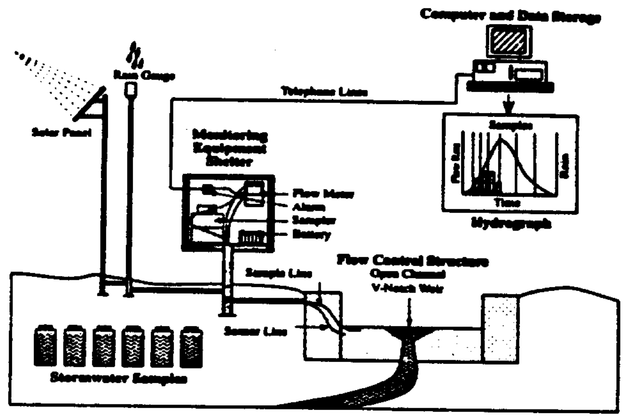

Figure 2. Remote-Controlled Stormwater Monitoring System

The number of storm events to be monitored at each site is determined mainly from the amount of rainfall and the number of dry days before storms. When the frequency distribution of storm sizes (Figure 3) is grouped according to storm-size class, the total average annual rainfall depths contributed by each storm-size class are roughly equal (Figure 4). According to previous data (City of Austin, 1990), the event mean concentrations (EMCs) for all types of watersheds vary by storm size and the number of dry days between storms. In Austin, a range of 18 to 24 storm events should be collected at each monitoring station (Soeur, et al., 1994). The range of storm events to be sampled has been determined by experimental design factoring three or four storm-size classes with two antecedent dry day classes (Figure 5). In order to conduct statistical comparisons, there must be at least three storm events collected for each combination in the experimental design matrix.

The SWMP analyzes 15 standard non-point source water quality parameters representing five categories of pollutants, including total suspended solids (TSS), oxygen-consuming constituents, nutrients, metals, and bacterial constituents. These parameters are commonly used in other studies to characterize point and non-point source pollutants (Environmental Protection Agency, 1983).

b) Rainfall Measurement

Rainfall data are used to relate rainfall amounts to the runoff volumes recorded at a monitoring site. All stormwater monitoring stations use tipping-

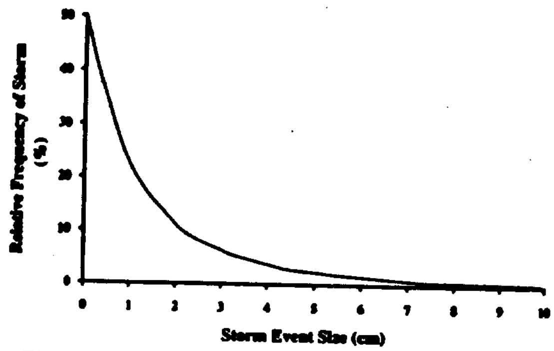

Figure 3. Relative Frequency of Strom Events Versus Storm Event Size Austin, Texas, 1950 to 1992

< 4	3 storms	3 storms	3 storms	3 storms	12 storms
≥ 4	3 storms	3 storms	3 storms	3 storms	12 storms
TOTAL	6 storms	6 storms	6 storms	6 storms	24 storms

Figure 5. Recommended Number of Storms to Monitor by Class

bucket rain gauges, which automatically record both rainfall amounts and rainfall intensities. The SWMP also uses rainfall data collected by the COA's Flood Early Warning System (FEWS) automatic rain gauges to supplement and verify the SWMP rainfall data. The high density of FEWS rain gauges (52 stations in Austin) is especially important during the summer months when highly-localized, tropical thunderstorms are common. Variation in rainfall within large watersheds is common during storm events.

c) Sampling Methodology

The SWMP uses the three standard sampling methods. Grab samples, when chemically analyzed, indicate water quality at a single moment in a hydrograph and are mandatory when manual or sterile sampling techniques are required. Flow-weighted composite samples are composed of a number of equal-volume aliquots collected at equal intervals of runoff volume throughout the hydrograph (Greenberg et al., 1992). When flow-weighted composite samples are chemically analyzed, the data directly yield an EMC for each water quality parameter. Discrete samples are sets of samples taken in some systematic manner throughout the hydrograph. Discrete samples show changes in pollutant concentrations throughout the hydrograph, but can be mathematically combined to yield an EMC for each water quality parameter (City of Austin, 1983).

During runoff events, different watershed types have varying pollutograph characteristics. For example, in small watersheds (< 162 hectares, 400 acres) with medium to high impervious cover, the concentrations of TSS, total phosphorus (TP), total Kjeldahl nitrogen (TKN), and total organic carbon (TOC) are greatest during the first flush of runoff, and then decrease over time (Figure 6)(Soeur, et al., 1994).

In contrast, in large watersheds (> 162 hectares, 400 acres) with a high degree of channel erosion, the concentrations of TSS, TP, TKN, and TOC correlate with flow rate and are greatest at the peak of the hydrograph (Figure 7)(Soeur, et al., 1994). In Austin, this example corresponds to larger urban creeks draining mixed land uses.

A refined method for discrete sampling collects samples more frequently when pollutant concentrations are changing most rapidly. In a small watershed, sampling events should occur during the rising stage of the hydrograph while retaining sample coverage of the tail on the falling stage of the hydrograph. In a large watershed, sampling coverage should be concentrated around the peak of the hydrograph while retaining coverage on the tails of the hydrograph. During flow-weighted composite sampling, EMC's in a small watershed are best represented if many aliquots of small volume are collected during smaller intervals of runoff volume.

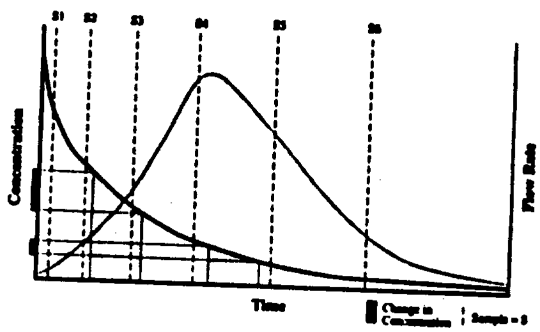

Figure 6. Small Watershed Pollutograph with Hydrograph

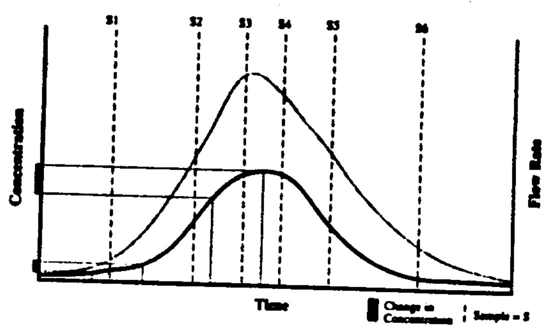

Figure 7. Large Watershed Pollutograph with Hydrograph

Each water quality parameter requires a certain sample volume for analysis (Environmental Protection Agency, 1992). Automatic samplers provide a limited number of sample bottles. The number of water quality samples collected for any monitorable storm event range between three and sixteen samples, depending upon the complexity and size of the hydrograph. To accommodate the need for more sample coverage of both the hydrograph and sample volume for the analysis of 15 water quality parameters, two automatic samplers can be used at each site.

Automatic sampling has certain inherent advantages and drawbacks. An automatic sampling system can be remotely controlled and programmed, reduce human sampling error, and reduce the danger to field personnel during storm conditions. Automatically-taken samples, however, may not be representative because of holding-time limitations of some parameters and sample contamination by the equipment. True duplicate samples cannot be taken with standard automatic sampling equipment. If the sample water is being transported over a relatively long distance (> 15 m. or 50 ft.) or up a steep gradient (approximately > 4.5 m. or 15 ft.), TSS may settle in the line during transit. Automatic sampling may be inappropriate for the collection of volatile organic compounds (VOCs), which require zero head-space sampling, and fecal coliform and fecal streptococci which, have a short holding time and could be cross-contaminated by the Teflon sample line (Environmental Protection Agency, 1992).

In contrast, manual sampling performed by trained staff does not require expensive equipment, always results in representative samples, allows duplicate QA/QC sampling, adjusts sampling for changing conditions, and provides information on flow conditions from field observations. Manual sampling is limited by safety concerns, the ability of personnel to respond in a timely manner, and the number of sites that can be handled in a given storm event (Environmental Protection Agency, 1992).

d) Site Selection and Watershed Documentation

Monitoring site selection requires much planning to achieve characteristic water quality data for a given land use. Ideally, a watershed should be selected that does not have significant point-source discharge (e.g., toxic waste dump, land fill, problematic industrial source, etc.) and is largely covered by the targeted land use or research objective. The selection of a monitoring site is also influenced by the nature of the channel at the proposed monitoring location. To most accurately characterize flow rate and calibrate the rating curve without a flow control structure, a channel should be straight, have uniform cross-sectional shape, and have a milder slope (e.g., slope < 0.02) over a relatively long stretch. The site must be safe for field personnel and secure for monitoring equipment. Ideally, the monitoring station should be accessible for maintenance and sample collection during storms and high water.

Once a prospective monitoring site has been identified, a watershed analysis and documentation process defines hydrographs (or peak flow versus time) for various types of storm events. This watershed information details drainage areas, impervious cover percentages, land-use types, soil characteristics, slope characteristics, flow patterns, detention features, and a computed runoff coefficient. In general, the channel should have enough capacity so that a two-year storm event can be monitored. The peak and average flow conditions help determine which flow control structure and flow monitoring procedure to use. Watershed documentation provides the quantitative information necessary to run computer simulations, such as Stormwater Management Model (SWMM) (University of Florida, 1988) that create synthetic hydrographs and calculate flow rates.

e) Flow Measurement

Determining flow rate through an open channel is the most difficult aspect of stormwater monitoring. The accurate measurement of stormwater discharges at a monitoring station is vital in calculating the EMC's for various water quality parameters. The SWMP uses four basic methods for determining flow: (1) appropriate flow control structures, such as weirs and flumes; (2) cross section area-velocity measurements to generate a flow-rating curve; (3) application of Manning's equation; or (4) using runoff coefficients to estimate runoff (Environmental Protection Agency, 1992). During storm events, field observations and video supply additional information on flow that might not be predicted by preliminary studies.

The SWMP uses flow control structures, such as weirs and flumes to give accurate flow measurement. Flow rating curves are well-established for both weirs and flumes (Bos, 1978; Grant, 1972), and the appropriate flow control structure can be selected according to its sensitivity to a certain range of flow. Flumes allow water to pass freely, limiting sediment and trash (that can accumulate behind weirs), but flumes also tend to be more expensive and difficult to construct than weirs.

The SWMP uses the area-velocity measurement method in larger channels and creeks where no flow-control structures exist. The COA contracts with the United States Geological Survey to generate flow rating curves in these cases (International Organization of Standards, 1983). The average velocity of flow is measured by a hand-held velocity meter.

The Manning's equation can be applied to pipe and channel flow, but accuracy depends on steady flow, straight channels, even and gentle slope, uniform roughness, and uniform channel shape over a long length of channel (Grant, 1992). Satisfaction of these conditions is rare in storm sewers. In a few cases when other methods are not appropriate, the SWMP calculates flow rates using a two-point measurement system based on the theory of gradually-varied flow (Figure 8)(Dalrymple, 1984; Chow, 1959). When using the two-point method to measure discharge in relatively long, straight channels, discharge can be accurately measured by the elevation change in the water's surface profile over distances greater than 20 m. (66.6 ft.). In shorter, straight channels, flow can be approximately measured using the average depth at two points and using that value in the Manning's Equation to calculate a discharge. This method is subject to errors up to +15% due to both the nature of the approximation used and the unsteady flow conditions of stormwater runoff.

VOL 12

7559

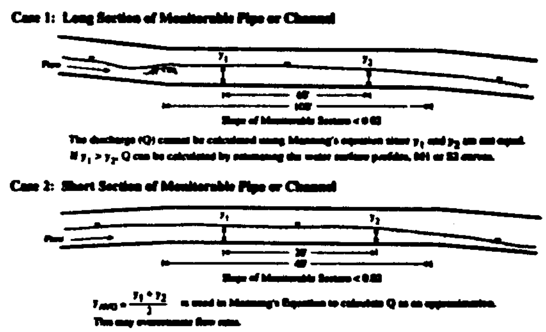

Figure 8. Flow Measurement with Two Points

Runoff coefficients, derived from synthetic hydrographs and the corresponding rainfall data, can be used to estimate flow. This method, used when no other option is available, can also be used as a check against other flow volume calculations.

f) Equipment Testing

The SWMP's flow meters were tested in a hydraulics laboratory flume to investigate equipment performance under a variety of controlled flow conditions. Bubbler, submerged probe, and ultrasonic probe flow meters were tested. Preliminary test results revealed that all flow meters accurately recorded depth at velocities lower than 1.5 m/sec (5 ft/sec). In the 1.5 to 2.1 m/sec (5 to 7 ft/sec) velocity range, 5% errors in depth readings were seen, and in the 2.4 to 3.0 m/sec (8 to 10 ft/sec) range, errors in depth of up to 20% were seen. These systematic errors are most likely produced by flow-induced pressure differentials around the exterior of the submerged sensors. The submerged pressure probes and bubbler lines must be oriented parallel to flow to minimize errors in depth readings at higher velocities. The bubbler sensor orifice must be pointed downstream for best accuracy.

g) Site Implementation

Monitoring site implementation is the culmination of an extensive planning process, which includes a sampling methodology, rainfall and flow measurement techniques, site selection, and watershed documentation. The typical monitoring installation consists of a modular equipment shelter, solar panel, rain gauge, buried conduits for various support systems, flow control structures, a system alarm, batteries, and phone lines or a cellular phone link (for isolated sites). All above-ground structures are modular in design for easy installation and removal, since most monitoring stations have an operational life span of three to five years.

Over the past two years, the SWMP's modular equipment shelters have been redesigned to improve ergonomics and security. The shelters have large interiors so that monitoring equipment is accessible for field operations and site maintenance. A rain guard can be deployed to keep personnel, water quality samples, and monitoring equipment dry when access is necessary during storms.

Modular weir plates have been installed at several monitoring stations and can be inexpensively modified if the actual runoff is found to be different from the calculated runoff values used to size the original weir. Deviations in actual runoff versus calculated runoff may result from watershed mapping errors or from other complex phenomenon in the watershed. For example, a calculated runoff coefficient may not reflect local hydrologic variations caused by a karst terrain. This condition affects all monitoring sites located in the recharge zone of the Edwards Aquifer, which underlies western Austin.

At one location, accurate flow measurement was not possible without channel realignment because the storm sewer channel had a steep slope (slope > 0.043), and was curved. A SWMP field team straightened the pipe's existing alignment, reduced a section of the pipe's slope (reduced slope = 0.004), and installed a rectangular weir near the location of the original outfall (Figure 9).

h) Data Collection

Weather conditions are closely watched by SWMP personnel when rain threatens. The local National Oceanic and Atmospheric Administration (NOAA) weather radar (shown continuously on local cable TV) is used to track storm development and movement. With advanced warning the SWMP field personnel cycle the equipment at the monitoring stations through a set of pre-storm preparations. Typical site maintenance includes checking bottle labels, icing sample bottles, checking system voltages, checking communication lines, cleaning rain gauges, and down-loading data stored in flow meters. Monitoring stations are also maintained on a weekly basis to accommodate surprise storms.

Rain and flow data are recorded at one minute intervals by a data logger inside the flow meter. During a remotely controlled operation, the data are transmitted from the flow meters to the office via telephone. The monitoring equipment can collect data independently. The down-loaded data are checked for errors by a computerized scanning program that detects outliers in rainfall data, and manual scanning of graphical flow and sample event data to verify data integrity. This verification process also identifies maintenance problems and double-checks sample-event data before sample bottles are sent to the laboratory.

When rain threatens, the automatic samplers at each monitoring station are programmed. This feature is useful should a storm hit without warning (e.g. in the hours before dawn). Even then, the monitoring staff can still be mobilized after a storm has begun to collect a balanced sample distribution across the hydrograph. A well-balanced sample distribution throughout any hydrograph is as much art as science, since there is no way to accurately anticipate runoff volume once a storm begins. The best way to achieve good sampling distribution at all monitoring stations is to watch the changing flow and rainfall conditions during a storm event and adjust the sample pacing accordingly.

The SWMP Chain of Custody documentation process has been extensively modified to facilitate sample documentation and communication between the field and laboratory. SWMP staff meet regularly with laboratory staff to coordinate sample collection and analytical QA/QC procedures.

The City's SWMP accumulates large amounts of flow, rainfall, and water quality chemistry data from each monitoring station for each storm event monitored. As additional monitoring stations become operational, the amount of data compiled will grow proportionally. Consequently, the data administration system must not only deal with the current information flow but also be capable of accommodating twice as much information by 1996.

Automated data management and storage save time in processing and reduce human error. Water quality and flow data are stored on disk in an hierarchical file structure such that analogous data classes are stored at the same levels. Data identity labels, such as monitoring site ID codes, facilitate automated data processing. The goal of data management is to file data in a system that is appropriate for the way the data is used during analyses. Qualitative and hard copy data are filed in a restricted central location. Copies for general use are kept in an accessible location, so that if a copy is lost or misplaced the archives are not affected.

i) External Resources

The SWMP utilizes an external, independent group of engineers, that serve as a professional review board to cover all aspects of the SWMP. The COA is also a member of a group of regional water quality agencies called the Joint Water Quality Monitoring Program which is establishing a regional water quality data base.

Conclusions

During the COA's long term Stormwater Monitoring Program (SWMP), the City has refined and standardized stormwater quality monitoring methods and techniques. These practices have improved the accuracy of flow measurements and led to the collection of representative stormwater quality samples. The complexity of natural phenomena remains a large focus with the SWMP despite the fact that emerging monitoring technology and less expensive information systems have improved the ease of the stormwater monitoring process. The collection of comprehensive hydrologic data ensures a more appropriate sample distribution. Design utilizing principles of hydraulics is critical, especially to benefit from the use of automated flow measurement equipment and flow control structures. From careful planning and implementation of a monitoring project to the field calibration of each site, the SWMP endeavors to develop and utilize methods and techniques to achieve data with consistent accuracy and significant statistical validity.

Blackstone River Wet Weather Initiative

Wright, R. M.[1], M. ASCE; Roy Chaudhury, R.[2], A.M., ASCE and Makam, S.[3]

Abstract

A program, initiated by the U.S. EPA, to study the Blackstone River under dry and wet weather conditions was conducted to pinpoint and rank major sources degrading water quality. The river was monitored at 13 locations along 48 miles, in addition to, six tributaries and five point sources. Three storms were monitored for 23 constituents with at least ten samples at each of the stations. Methods of interpreting the water quality data and isolating the sources into dry and wet weather sources are presented. The wet weather component is studied to establish loadings from point sources, new materials (runoff related) and old materials (bottom sediment resuspension). A procedure to estimate annual loading rates is presented.

Introduction

Pollutants enter coastal waters either through direct discharge or via a tributary as an integrated watershed load. Water quality studies are typically done under dry weather, steady state conditions. In general, those types of studies are successful and pollution is readily measured and modeled. On the other hand, wet weather sources are more difficult to characterize and predict. Wet weather sources include storm water runoff, bottom sediment entrainment and combined sewage overflows.

[3] Graduate Assistant, Department of Civil and Environmental Engineering, University of Rhode Island, Kingston, RI 02881

The Narragansett Bay (Bay) is one of the most important natural resources in Rhode Island (Figure 1). As an estuary, the Bay is the spawning grounds for many aquatic species and a major fisheries and recreational water course, and yet, it is continually under pressure to assimilate significant additions of pollutants. In 1989-90, a study was completed which identified and ranked the sources to the Bay (Wright 1991). The study concluded that the Blackstone River watershed was the major source of both nutrients and trace metals.

In 1991, the U.S. Environmental Protection Agency (EPA) reviewed and summarized all water quality data pertaining to the Blackstone River. As a recommendation of this report, a program was proposed to conduct interstate steady state and wet weather water quality monitoring surveys, to identify and characterize the major water quality problems in the watershed and to calibrate and validate steady state water quality models for application in developing waste load allocations.

Following this recommendation EPA, along with the Massachusetts Department of Environmental Protection (MADEP) and the Rhode Island Department of Environmental Management (RIDEM), developed the Blackstone River Initiative (BRI).

<u>Blackstone River Initiative (BRI)</u>

Phase 1 of the BRI was conducted jointly by the EPA, MADEP and RIDEM and included a comprehensive dry weather water quality sampling program on the river, tributaries and discharges. The results of the three surveys are summarized in Hartman (1992).

The water quality data were used by the Civil and Environmental Engineering Department at the University of Rhode Island (URI) (Wright et al. 1993; 1994) to calibrate and validate both QUAL2E (Brown and Barnwell 1985), a dissolved oxygen model, and Pawtoxic (Wright and McCarthy 1985), a trace metals model. These models are being used by both MADEP and RIDEM in their waste load allocations.

Phase 2 was a joint program by the EPA, MADEP, RIDEM, URI and the U.S. Geological Survey (USGS). The summary of the field program is reported in this paper. The program included the monitoring of the river under wet weather conditions for selected parameters including nutrients, trace metals, microbiological indicators and toxicity. The specific objectives of this study include the following:

1. To determine the spatial and temporal changes to water quality due to wet weather

VOL 12

7566

R0040874

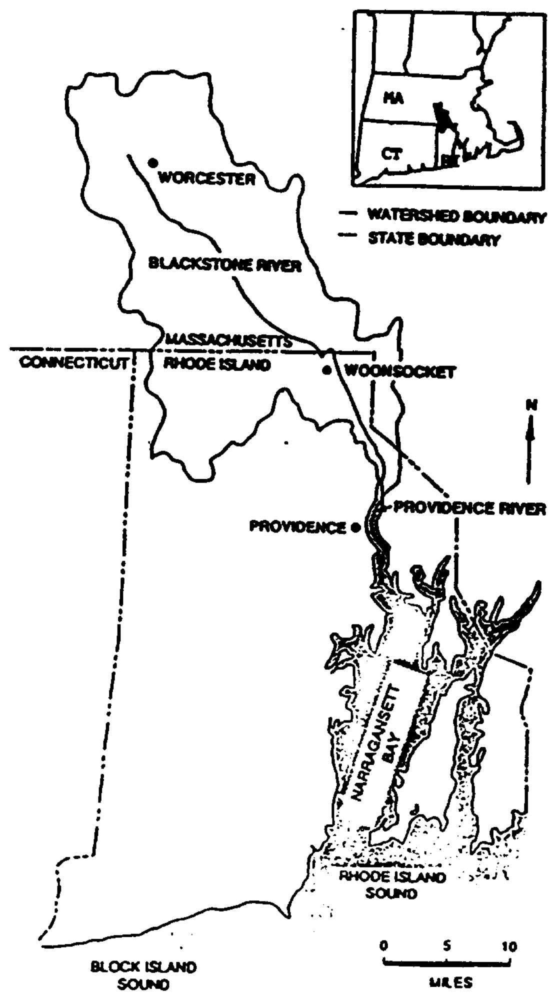

Figure 1: Blackstone River Watershed

VOL 12

7567

2. To identify and rank river reaches relative to wet weather loads and identify major wet weather pollutant sources
3. To determine the relative importance between wet weather and dry weather loadings
4. To forecast annual wet weather loading rates

System Description

The Blackstone River is an interstate waterway with its headwaters in Worcester, MA. It flows south through Pawtucket, RI into the Providence River and finally, Upper Narragansett Bay. The watershed area covers 1230 km^2 (480 mi^2) and its length is approximately 76.8 km (48 mi). The major tributaries to the river are the Quinsigamond, Mumford, West, Branch, Mill and Peter's Rivers.

The sampling stations are indicated on Figure 2 and listed in Table 1 for both Phase 1 and Phase 2 of the BRI. River mile points are listed from the mouth of the river starting with mile point 0. Only minor station modifications occurred between the dry and wet surveys.

Worcester is the second largest city in Massachusetts and historically has been identified as a major pollutant source to the river (Tennant 1973). The city's wastewater is treated at the Upper Blackstone Water Pollution Abatement District's (UBWPAD) wastewater treatment plant which is a secondary facility with average flows of 1.6 m^3/s (36.6 MGD) providing seasonal advanced waste treatment in the form of nitrification. Worcester also has a combined sewage overflow (CSO) facility which provides settling and disinfection. The CSO facility discharges between BWW00 and BWW01 while the UBWPAD discharges between BWW01 and BWW02.

The other significant urban areas along the river are the cities of Woonsocket, Pawtucket and Central Falls in RI. Woonsocket is serviced by a secondary wastewater plant, with a design flow of 0.70 m^3/s (16 MGD), that discharges directly to the Blackstone River between BWW17 and BWW18. Wastewater from the Pawtucket and Central Falls area is transported below BWW21 for treatment and discharge at mile pt. -2. Both Pawtucket and Central Falls have CSO's which discharge into the Blackstone River between BWW18 and BWW20.

The Blackstone River watershed has a significant industrial and manufacturing history. As a result, there are 20 river impoundments initially built for industrial water supply or hydropower. These impoundments are typically 40 - 60 years old, run-of-the-river, and no longer in use. Three of the largest impoundments are at Fisherville Pond above BWW06, Riverdale Dam at BWW07 and the Rice City Pond above BWW08.

Rainfall Criteria

Establishing rainfall criteria was critical to the success of the monitoring program and the interpretation of the data. The goal was to isolate the effect of a discrete event to permit the characterization of runoff and the determination of the impact on receiving water quality. Rainfall criteria were set in advance of the field program, consisting of a minimum duration of six hours, a minimum of 0.5 inches of total rainfall, an antecedent dry period (ADP) of 3 days and a post storm period of three days. The criteria is designed to sample storms associated with frontal systems that provide uniform rainfall over the watershed. Storm development and movement were tracked by meteorologist with the final decision for the call of the storm provided by URI.

A rainfall monitoring network was established to cover the study area, consisting of six gages maintained by the National Weather Service, 4 URI gages and 2 gages maintained by municipal wastewater treatment facilities (Figure 2). Three storms were successfully monitored on 9/22/92, 11/2/92 and 10/14/93, meeting all rainfall criteria with total rainfalls of 14 mm (0.55 inches), 23 mm (0.92 inches) and 20.3 mm (0.8 inches), respectively. The rainfall coverage for storms I and II were relatively uniform. Storm III ranged from 33 mm (1.3 inches) in the north at Worcester, MA to 14 mm (0.55 inches) in the south.

Sampling Protocol and Frequency

A total of thirteen water quality stations were sampled along the Blackstone River, as well as six tributaries and five point sources discharges. Stations were selected to isolate wet weather problem areas such as point sources, impoundments, combined sewer overflows and junk yards and to provide sufficient spatial detail in the system. The stations were compatible with previous water quality studies along the river.

A prestorm sample was collected 3-4 hours in advance of the storm to define the baseline dry weather loads. Initially, sampling was set at a higher frequency to identify the local stormwater and first flush contribution to the receiving water. A total of 15 samples were taken for each location starting at 3 hour intervals from time 0 (observed runoff) and continuing through 12 hours (5 samples), followed every 4 hours for the next 36 hours (9 samples) with one sample on the third day to define the end of storm. Samples were transported to a field lab centrally located in the watershed for processing and distribution. The list of constituents analyzed is given in Table 2.

Flow Measurements

Three permanent USGS gaging stations located at BWW05, BWW14 and BWW17 provided continuous flow information in the watershed (Figure 2). Additional information was derived from two stations maintained by the Army

Table 2: List of Constituents for the Wet Weather Program

Figure 3 illustrates the track of the storm for Storm II starting in Worcester at point A and increasing in magnitude as it progresses south to point D. Major increases in flow associated with tributaries are seen at points B and C.

Spatial and Temporal Changes

The concentration profiles for each event are evaluated by station. Some pollutant concentrations increased indicating significant sources of wet weather loads (ie. TSS, copper and lead) while other pollutants concentrations decreased, a result of dilution (ie. Ca and Mg).

An example case where the combination of the increase and decrease of individual constituents causes a greater environmental impact is seen with respect to the potential toxicity caused by trace metals. The EPA has established acute and chronic concentrations for trace metals using relationships based on hardness. When hardness decreases, the potential toxicity increases. Thus, in the Blackstone River, under wet weather conditions, the decrease of calcium and magnesium, and thus hardness and the increase of trace metal concentrations, results in violations of a greater magnitude (Figure 4).

The evaluation of wet weather concentrations for each event for the entire watershed also enables the identification of the major wet weather sources. For example, copper concentrations in Figure 5 indicate that the major sources occur at the headwaters between BWW00 and BWW04 (Point A). The CSO discharge between BWW00 and BWW01 and the UBWPAD discharge between BWW01 and BWW02 are contributors and were monitored. However, no major source was identified between BWW02 and BWW04, yet sharp increases of trace metals were observed. The land use in to this reach ranges from suburban to rural, without significant sources of runoff related trace metal inputs.

It appears that the wet weather observations are supported by the results of the dry weather surveys. Earlier observations related to the dry weather data (Phase I), indicated significant increases in metal concentrations due to UBWPAD inputs at BWW02. This was followed by a rapid loss of metals between BWW02 and BWW04. The mechanism of removal is not clear but appears to be either a result of settling or biological uptake. The reappearance of metals in this reach under wet weather is most likely a result of either resuspension or sloughing of biological material. The importance of evaluating the system under both dry and wet weather conditions is evident. Clearly, the results of the dry weather survey suggests UBWPAD is the original source.

Additionally, the concentrations decrease at BWW06 and BWW07 (Point B). This is due to the removal of pollutants in the impoundments above these stations. Below BWW07, the river enters Rice City Pond. Sharp increases in copper can be seen at BWW08 (Point C) at the Pond's outlet with concentrations translating further downstream. This source is a result of sediment resuspension. Unlike the

VOL 12

7573

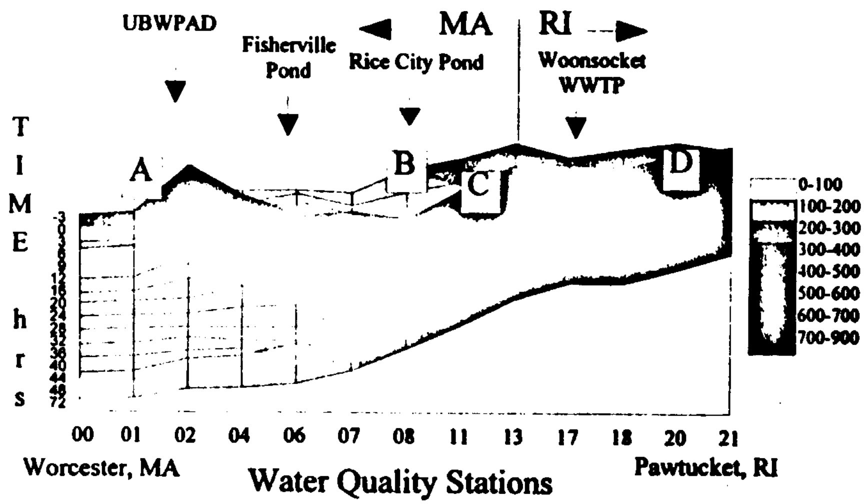

Figure 3:

impoundments upstream, Rice City Pond has seen a lowering of the dam height in recent years exposing historic sediments. As the river carves channels through the soft sediments of the impoundment, even moderate flows cause resuspension.

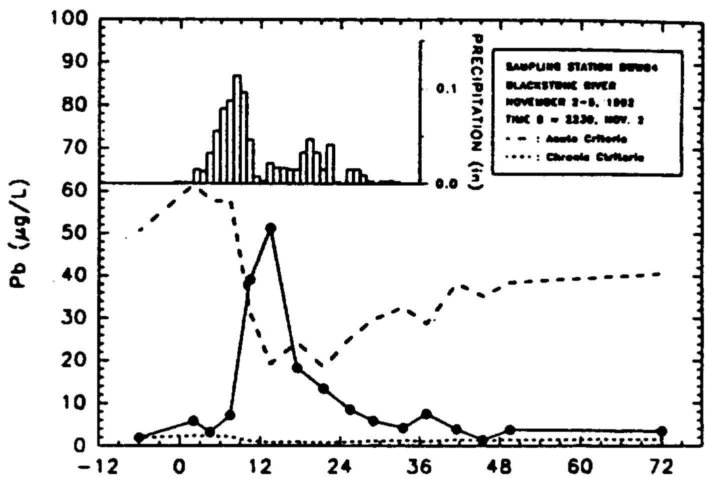

Figure 4: Concentration Profile at BWW04 - Lead

Wet Weather Loadings

The water quality data coupled with stream flows allow for the calculation of mass loading curves. These have been interpreted to define dry weather baseline loads as prestorm conditions and, for comparison, wet weather loads from the integration of the mass curves (Figure 6).

The wet weather mass loads for TSS, lead and copper are presented in Figure 7. The net gain or loss of mass by reach can be observed in Figure 8. These figures provide a spatial view of the river under wet weather conditions. Increases like that occurring between BWW01 and BWW04 are obvious while reductions in wet weather mass loadings are noticed between BWW04 and BWW07.

Pollutants associated with wet weather may come from either new sources (runoff induced) or old sources (river sediments). It is important to note that the former may be easier to control and regulate than the latter. The wet weather

component was separated into its new and old sources by estimating the resuspension component with the trace metal model, Pawtoxic (Roy Chaudhury 1991; Roy Chaudhury et al. 1993). Through application of the model for a range of flows, relationships were developed for each reach between net mass transported and flows. Resuspension is then estimated from these relationships for the observed flows during each of the wet weather sampling runs. The gain in the resuspension load between stations can be deducted from the wet weather load for an estimation of the new source. Figure 9 illustrates this application for the reach between BWW07 and BWW08. The results of this analysis for TSS, copper and lead is summarized in Table 3. With this method, the wet weather loads of Figure 7 may be refined further to provide an estimate of the resuspended and runoff loads as shown in Figure 10. Since the relationships are based on net mass transported, if net settling occurs within a given reach, a similar procedure can be followed to estimate the runoff component.

Figure 11 illustrates the movement of the mass loading of copper as a result of the wet weather event. The sharp increases in the Upper Blackstone at BWW02 and BWW04 (Point A) occur for samples taken between 6 and 36 hours with the peak at hour 6, while at BWW21, the increases are noted between hours 20 and 72, with a peak at hour 32. The progression of the storms impact downstream can be clearly tracked through the hydrograph (Figure 3) and pollutant (Figure 5) and the mass loading (Figure 11) curves.

Figure 11 also supports the partial removal of materials by BWW07 (See also Figure 8) with increases at BWW08 and BWW11. Further downstream it is evident that partial settling occurs by BWW13 and BWW17. The 3-dimensional plots also provided the opportunity to view smaller impacts like localized impacts of the CSOs in Pawtucket (BWW20 and BWW21) seen at hours 3, 6 and 9. Unlike the impacts on system flows, the tributary contribution to the mass loading appears minimum (Figure 7).

<u>Annual Loading Rates</u>

Empirical relationships between the wet weather pollutant mass and rainfall characteristics were evaluated initially by Wright et al. (1991) at BWW21, the mouth of the Blackstone River. These relationships when coupled with the historic rainfall records provided an estimate to annual loading rates. Projections of annual wet weather pollutant loadings at the mouth of the Blackstone River will be important to the restoration of the Blackstone River and to the ongoing Narragansett Bay study. A preliminary assessment of this relationship is presented for BWW21 (Figure 12) that includes the loadings calculated from the BRI.

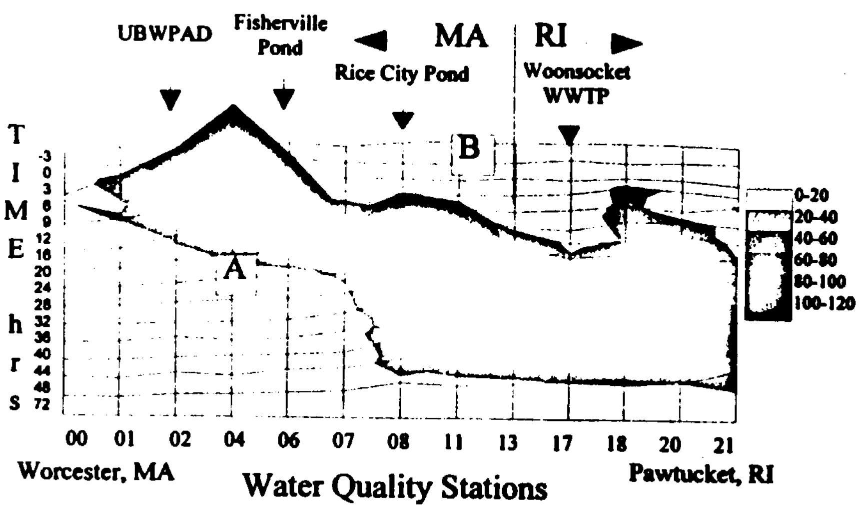
Figure 11:

BLACKSTONE RIVER INITIATIVE

STORM II - Copper (lbs/day)



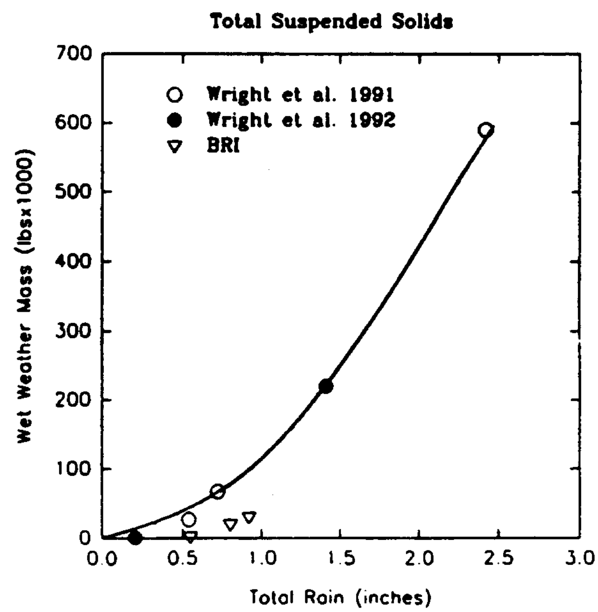


Figure 12: Wet Weather Mass and Total Rainfall Relationship

The dry weather models are utilized to predict annual dry weather loadings which are combined with the annual wet weather loadings to provide the total load by station as well as to the Bay. This enables the permitting process to encompass the impacts of runoff in the river as well as to the Bay.

Conclusion

A comprehensive wet weather monitoring program of an interstate river has been successfully completed. The program consisted of sampling at locations along the river, point sources and tributaries for three storm events to identify and rank sources.

Changes in the river were assessed for impacts from point sources, runoff and resupension of bottom sediments to water quality and water quality based toxic criteria. For initiating and focussing management alternatives, wet weather loadings are determined to identify and rank the various sources. River reaches may also be ranked to isolate locations for optimizing the institution of best management practices for nonpoint sources. Methods of determining annual wet weather loadings using rainfall characteristics are also discussed.

In systems such as the Blackstone River, gains and losses of wet weather materials due to resuspension and settling are a function of the existing physical attributes of the channel, baseflow and rainfall characteristics. Design solutions to remedy adverse wet weather impacts need to account for the conditions that would result in no losses (worst case), also including natural and man-made changes to the channel. Improvements instituted by waste load allocations for dry weather conditions should also be accounted for during the wet weather permitting process.

SESSION IV: NPDES Compliance Monitoring

DISCUSSION

Methods and Procedures in Stormwater Data Collection
Thomas Brown, William Burd, James Lewis and George Chang

The Austin sampling program is not an NPDES required program. All samplers have a telemetry connection so that they can be interrogated before the storm to insure that they are working, to turn them on if necessary, and to change the frequency of sampling during the storm if the hydrograph indicates this is desirable.

Separated storms for sampling into 4 classes, based on total rainfall per storm, so that each class produces approximately the same amount of volume on an annual basis.

The NPDES program should be based on a regionally coordinated program, rather than on individual programs from a number of cities in the region. This will provide better QA/QC and a comparable data base for individual areas (jurisdictions) in the regional area.

Questions/Comments

Question: How do you calibrate pressure flow monitors?
Answer: Hard to calibrate at higher flows, due to unsteady flow, hysteresis loops, etc. A 20% difference was found at high flows (between measured and actual).

Question: What are costs of your monitoring program?
Answer: About $1 million /year (plus a USGS contract for $300,000 with $100,000 matching funds).

Biological and Chemical Testing in Stormwater
William T. Waller, Migulel Acevedo, Eric Morgan, Kenneth Dickson, James Kennedy, Larry Ammann, H. Joel Allen and Paul Keating

Looked at time to death in addition to classic 48- and 96-hour tests. Remember that in toxicological studies organisms respond to extreme events, and not to the means.

In the Fort Worth study we performed a toxicity identification evaluation (TIE).

The TIE found no toxicity for fathead minnows; for ceriodaphnia, there was < 100% survival for 12 out of 24 events. Thus 50% showed a toxic response. Only one event had both ceriodaphnia and Microtox toxicity responses.

Diazinon appears to be a problem in the South across the country (available over the counter), but does not seem to be a problem in the North. There was no analysis for other consumer-applied pesticides, including chlordane, endosulfan, and eldrin, in stormwater samples.

Another way to measure toxicity in-situ - a proposal:

- A biosensor approach using a proximity sensor that tells how far open an Asiatic clam is (the clam is the living material that is open when it is happy and closes during times of toxicity)

This biosensor approach does not deal with bioaccumulation or biomagnification.

Believes that sediment toxicity will be a major problem in the future.

Questions/Comments

Question: Shouldn't the indicator species chosen be specific to the ecosystem being evaluated?

Answer: No. An inference can be made with confidence that the test organism, or biosensor, is responding to stream conditions present, similar to previous studies performed in the laboratory and in the field.

Comment: The clam idea, if it works, could be an excellent way to reduce sampling costs. If the clam or indicator organism is in stress, then start the hunt for the chemical(s) that is(are) causing the stress. Need to develop a protocol that links toxicity testing to the chemical testing that must follow to identify the cause.

Question: Clams also close when the water is clean - how do you sort that out?

Answer: (Herricks) It's related to how often they close and how long they close. Still have a number of things to work out for this test.

Question: How does toxicity testing in samples taken from stormwater and then used to do 48- and 96-hour toxicity tests relate to stormwater toxicity that lasts for much shorter periods of time.

Answer: Need to be reasonable here. Probably should be looking at "time to die" over periods of about 2 hours.

Blackstone River Wet Weather Initiative
R. M. Wright, Roy Chaudhury, S. Makam

The Blackstone River is unique in the Northeast because the city of Worcester is in the headwaters, whereas in most rivers in the NE, the city is at the mouth of the river.

CSO basins in Worcester; 19 small impoundments w/ low head dams; Woonsocket is about 2/3 of the way down the basin; there is a tidal barrier at the bottom.

Minimum rainfall criteria: 0.5 inches, 6-hr duration, 5-day dry period, 3-day post storm dry period (Editor's note: Here, again, is an instance where EPA-specified criteria cannot be used).

Sampling frequency:

- Pre-storm - 3-4 hrs before rainfall
- During Storm - 3-hr increments for the first 12 hrs, 4-hr increments for the next 36 hrs.

This is different from the protocol used for end of pipe monitoring because of the size of the watershed (Base flow is 260 cfs).

Be certain to look at dry and wet weather loads and identify and differentiate water quality problems that are due to dry weather flows from those that are due to storm flows.

Questions/Comments

Comment: You do not have total and dissolved fractions during wet weather because of cost to do this. (Editor's note: This would seem to make it difficult to determine whether toxic concentration exceeds acute level, since dissolved fraction is not known).

Comment: Their problem (in the Northeast) with numerous abandoned small impoundments (at abandoned mills, etc.) is one which will require a much broader (regional) approach.

General Questions

Question: (Austin) Why do you modify sample intervals based on pre-storm radar returns?

VOL 12

7589

Answer: Radar helps the sampling team get ready for the storm by telling them how much time they have to respond, and letting them know when a storm peters out and the sampling event should be aborted.

Comment: (Austin) They have some problems with EMCs, and therefore try to get flow volume-weighted means.

Question: (for Waller-Fort Worth)The toxicity tests use bottled water that has been spiked with a known concentration of pollutant, and an introduced or artificial organism. How can these tests be used to assess the toxicity of a particular stream with its own population of aquatic organisms?

Answer: It is possible to make an inference from the laboratory data previously collected on an organism's response to a pollutant to those conditions found in the field at a particular site. If a toxic response has been observed for a test organism in the laboratory, chances are good that there is some source of toxicity in the water body being tested.

STORMWATER PERMITTING
AN INDUSTRIAL EXPERIENCE

P. Charles Beck[1]

ABSTRACT

The impact of the NPDES stormwater permit program on a water reliant Fortune 500 company located in the semi-arid west is discussed. The results of a stormwater outfall sampling program are presented. Modifications to the facility were made as a result of the sampling and site inspection program. The problems and successes of the stormwater permit program from an industrial environmental manager's perspective are presented. Concerns about the future direction of the program and economic impact on industry are raised. A balanced cost-versus-benefit analysis of the program before the enactment of additional regulatory requirements within the stormwater program is needed. Industry must be an active participant in the development of future regulations.

INTRODUCTION

This paper offers the perspective of a Fortune 500 company located in the semi-arid west. It will address a company's experiences with the stormwater permit program and briefly discuss some positive and negative aspects of the current stormwater program. It will also offer thoughts about the future of the program. The views are those of the author and do not necessarily represent those of Coors Brewing Company.

First some background information for those not familiar with Coors Brewing Company. Coors Brewing Company, America's third largest brewery, is headquartered in Golden, Colorado. Golden is located in the foothills of the Rocky Mountains twelve miles west of Denver, Colorado. The company also has operations in Memphis, Tennessee and Shenandoah Valley, Virginia.

---

[1]Manager, Environmental Engineering, Coors Brewing Company, CE 200, Golden, Colorado 80401

The Golden plant is the largest single-site brewery in the world with a brewing capacity of over 20 million barrels of beer per year. This is the equivalent flow of 2.63 cfs or 1,180 gallons per minute...24 hours per day, 365 days per year.

The physical plant straddles a river known as Clear Creek, a major tributary of the South Platte River. Clear Creek is a heavily allocated river supplying seven major water supply and irrigation conveyances. The Clear Creek headwaters are located within the historic mining districts of Central City and Blackhawk and the Eisenhower Tunnel-Loveland Pass region near I-70. The old mining districts have been identified as CERCLA Superfund sites due to the extensive mineral production and processing activities. The area is dotted with old tailings piles, mine shafts and abandoned processing mills. As a result, water quality in Clear Creek suffers from acid mine drainage and heavy metals pollution from numerous sources plus the effects of rapid urbanization associated with the revitalization of gambling in the Central City and Black Hawk area.

Water flow in the river is highly seasonal and dependent upon winter snowpack and rainfall. During a normal year, flow can range from 22.7 cms to 28.3 cms (800 to 1,000 cfs) to less than 1.42 (50 cfs) in parts of the river. This year the peak flow at the USGS gauging station at the mouth of Clear Creek Canyon was 23.2 cms (820 cfs). The average annual rainfall in the Golden area is approximately 330 to 356 mm (13 to 14 inches).

The brewery has been located in the same area for its entire 120-year existence. Besides the brewing and packaging facilities, Coors operations in the area include three coal-fired power boilers, two waste water treatment plants, a can manufacturing facility (4 billion cans per year), a can lid or end manufacturing facility and a glass bottle plant.

Coors has additional property holdings that include an abandoned landfill and an operating gravel mine and asphalt batch plant. The gravel mine and asphalt plant are operated by others.

CURRENT PERMIT STATUS

The NPDES stormwater permit program is a delegated program administered by the Colorado Department of Health (CDH), Water Quality Control Division. Coors has been issued six general stormwater permits for both Light and Heavy Industry General Stormwater Discharge activities. The permits cover approximately 180 outfalls to either Clear Creek or tributary creeks and irrigation canals. The NPDES discharge permit for the waste water treatment plants is in a renewal process with a final draft expected by mid-September 1994. The new NPDES permit incorporates a complete section on stormwater for the brewing and can manufacturing plant operations. Coors will then operate under four general stormwater permits and the NPDES discharge permit.

SAMPLING PROGRAM

1991 Program

Along with other major industrial concerns Coors was caught up in the initial permitting frenzy in 1991. Coors, by virtue of having one of the largest ammonia based refrigeration systems in the world, was and still is a "313" industry or heavy industry. The decision initially was made to pursue an individual industrial permit using the "Form F" application; however, Coors never submitted the "Form F" because the decision to issue general permits was made just weeks before the individual application due date.

Maps and Surface Areas

Some twenty-five maps have been assembled on CAD using field data that required some 16 person-weeks to gather. The total area surveyed included approximately 300 hectares (742 acres). Two-hundred-and-three (203) hectares (501 acres) are pervious land which includes railroad staging yards and equipment staging areas and undeveloped land. There are 72 impervious hectares (178 acres) that include parking lots, truck aprons and roads. Twenty-five hectares (63 acres) are under roof. At the time of mapping in 1991 the total number of outfalls was 182.

Sampling Data

Form F required sampling all outfalls unless a case could be made to group essentially identical outfalls together under the provision of similar activities and physical characteristics. To reduce the number of samples and control the analytical costs, the 182 outfalls were grouped into five major categories and the number of samples was reduced to twenty-two. The twenty-two outfalls were selected based on access safety and on their being representative of the industrial activity in the area. Both manual sampling and automatic sampling techniques were tried. Manual sampling was the most effective. The automatic samplers did not work satisfactorily particularly in collecting composite samples during storms of short duration.

A team of six people was formed to manually sample assigned outfalls. Sampling protocols were established internally since there were no published sampling requirements available.

Sixteen of the twenty-two outfalls were successfully sampled during the summer and fall of 1991. Both grab and composite samples were obtained and analyzed for up to twenty-seven different parameters.

Rainfall was, and still is, measured using a standard tipping bucket rain gauge connected to a Campbell Scientific datalogger. During the sampling period of June to October the Golden site received 198 mm (7.8 inches) of rain in 50 storms. Of the 50 storms 28 were greater than the 2.54 mm (0.1 inches) required for sampling. The maximum storm occurred in August and produced 41.7 mm (1.64 inches) of rain. The maximum rain rate was in June and was 69.3 mm/hr (2.73 inches/hour).

The parameters measured included nutrients (pH, TSS, Oil & Grease, BOD5, COD, TKN, Total P, etc), metals (Cu, Cd, Pb, Ag, Cr, Zn, Fe) and organics (624, 625 series). Tables 1 and 2 summarize the results for the grab samples for selected nutrients and metals during the 1991 sampling. The results for the composite samples were similar but the values were slightly lower. No significant volatile or semi-volatile compounds were found.

	pH	TSS	BOD_5	COD	O&G	TKN	NH_3	NITRATE
MAXIMUM	8.80	1060	3190	2510	10.8	137.0	36.9	78.1

STD. DEV.	3079	2.7	60	26	11	1667

Table 2. 1991 Stormwater Sampling Results for Metals (Values in ug/l)

Both the nutrients and the metals data show a wide range in variation. The data are skewed by one or two outfalls with very high values. This is noted by the difference between the average and median values. Table 3 compares the metals numbers with some existing water standards to offer some perspective about the significance of the values. The average stormwater values fall within the requirements for both bottled and/or drinking water and RCRA Health Based Standards. The metals values are in some cases above the Warm Class II aquatic life stream standards as established by CDH. Given that the data are for single point samples from different outfalls under different storm conditions it would not be good practice to draw too many conclusions from this data comparison. The data do suggest that additional work would be needed to fully assess the distribution of the data for any given outfall for any given parameter.

METAL	Health Based Std RCRA 40CFR260.2 ug/l	Bottled Water 21CFR103.35 ug/l	STORMWATER MAX ug/l	GRAB SAMPLE AVERAGE ug/l	CDH STREAM STANDARD (Warm II @ 116 ppm Hardness)

* — ALSO A DRINKING WATER STANDARD PER CDH SCCR1002-1.

TABLE 3 -- Stormwater Metals Comparison

Follow-up Actions

The outfalls which had unusually high parameter values were examined and modified to reduce the source or sources of the problem. For example, the outfall with the 3190 mg/l BOD5 was near a spent yeast drying facility and spilled yeast was responsible for the high value. This prompted a review of the storm drains around the yeast drying facility. Modifications were made to reroute the storm drains to a process waste water drain in the high risk areas around the yeast plant.

VOL 12

7595

R0040903

The review of the sampling data resulted in modifications of several other potential problem areas within the plant. Roof drains on fermenting buildings were rerouted from a Clear Creek discharge to the process waste water collection system. Storm drains in high traffic garage areas were modified to collect up to a five year storm event into the sanitary sewer system. Lean-to roof structures have been installed over waste material collection bins and over above ground fuel storage facilities. Manual valves have been installed on outfalls with a high potential for substance spills.

Coors has been under no direct order from a regulatory agency to correct any of the problem outfalls other than the guidance in the general permit. The installation of corrections and modification have been voluntary and done willingly in the spirit of good corporate citizenship. Coors will continue to make minor improvements in the physical plant which will directionally improve the quality of stormwater.

The current sampling program for Coors calls for sampling of ten outfalls a single time for four parameters (pH, Oil and Grease, TOC and BOD5) and for sampling three additional outfalls twice for the four parameters plus selected metals. An estimate of the discharge volume is also requested. The requirements are for 1994 and 1995 only.

The sampling data is to be included in an annual report to the regulatory agency. It has not yet been stated by the regulatory agency how these data will used in the future. It is not clear how this stormwater sampling program will address measurable changes in stream quality. Will the data form a basis for numeric limits or mandatory BMP installation and performance standards? Based on previous experience, industry becomes concerned when reporting numbers to a regulatory agency about how the data will be used and what future requirements may result from the data.

ADDITIONAL COMMENTS

The current stormwater general permit program is, overall, a reasonable program for industry. However, other topics within the stormwater permitting program are of interest to industry.

Regulation Burden

American industry, particularly manufacturers, is surrounded by environmental regulations. The flow of all significant materials into and out of any manufacturing/industrial complex is now controlled in one fashion or another. The stormwater program and its permit requirements are considered to be either redundant or of a relatively minor consequence within the industrial environmental regulation arena. From the regulatory manager's perspective it overlaps the RCRA and Community Right to Know programs and the Spill Prevention and Emergency Response Planning programs. This overlap creates some unnecessary costs for industry. These costs are carried by industry and ultimately by the public through higher product prices.

VOL 12

7596

R0040904

<u>Program Cost</u>

The cost to prepare either the individual permit application or the Stormwater Management Plans was much higher than originally estimated by the EPA. This was aggravated by the switch from the EPA Individual Permit program to the State General Permit Program in 1991. Coors has spent over $250,000 in the mapping, sampling and administration effort over the last three years. The EPA estimated cost of $15,000 to $20,000 to complete the individual industrial permit application was off by a factor of ten. It is not known if the EPA has developed any figures relating to the on-going costs of the program in terms of annual report preparation, sampling and BMP installation. The Coors experience is not unique. In comparing notes with other major industries in the Denver front range area, Coors cost was not unusual or out-of-line. Cities may have experienced similar discrepancies between the EPA cost estimates and the actual cost of the application and plan preparation.

<u>Poorly Defined Program Goals</u>

The understanding of the Stormwater problem and the long-term goals of the program are limited. The specific lasting effects on the river system from non-point source runoff have not been widely discussed in the trade literature. The benefits of the stormwater program have not been effectively communicated to industry and the true costs appear to be much higher than original estimates.

The NURP study demonstrated that levels of contaminants in the stormwater exceeded stream standards. The study did not address, in depth, the acute or chronic effects on the receiving waters from the contaminants originating from the urban and industrial environment versus background levels from non-agricultural land sources.

Because of the lack of a clearly defined problem, the industrial environmental manager tends to be less than enthusiastic about committing resources toward an equally poorly-defined solution. Resources are better utilized addressing the NPDES point source, RCRA waste handling and CAA air emissions programs, which are better defined, more visible and supported with very active regulatory staffs.

<u>Minor Inconsistencies</u>

Lastly the general permits contain inconsistencies in the application of industrial activity restrictions. For example, in the Colorado General Permits irrigation return flows are allowed but air conditioning condensate flows are not. Irrigation flows are often cited as being major sources of suspended solids, pesticides and phosphates. Fire fighting activity water is allowed, but water from the code required hydrant testing is not allowed due to chlorine levels in the testing water. Building foundation dewatering water can be discharged if it is not contaminated, but no standard is cited for defining contamination.

Successes

The NPDES Stormwater Program for industry is successful on several counts. The improvements to water quality resulting from the program will not often be as dramatic as the point source program, they should be positive for receiving water quality. The permit program is raising the awareness of the effects of outdoor industrial activities on water quality within the industrial community.

System Understanding

The preparation of the Stormwater pollution prevention plans required by both the light and heavy industrial permits have caused Coors to closely examine its external work activities and the relationship of those activities with the physical layout of the facility.

The initial mapping and site inspection activities revealed areas where simple, inexpensive changes could be made right away. These areas were prioritized and included in the Pollution Prevention Plan and in the budget planning process for the company. If more complex and costly changes are required in the future then the planning and design process will be facilitated by the mapping program.

Illicit Discharge Elimination

Both the initial and on-going inspection and mapping programs have identified illicit connections and discharges that were previously either undiscovered or forgotten. For the Coors facility, the most common illicit connections were groundwater dewatering collection systems under and around production buildings and HVAC condensate drains. The ground water drains were repiped to the wastewater system. As HVAC condensate drains are identified they are rerouted to the waste water collection system.

Spill Reduction

The three-year spill history review called for in the Pollution Prevention Plan placed emphasis on the correction and modification of areas that had a history of repeated spill events. Coors had experienced repeated discharges from process roof vents in the beer fermenting area and periodic spills from the loadout system for waste beer and related byproducts. In each case the system was modified to reroute the discharges to the waste water collection system.

In other cases, where the spills are more random and much less frequent but the activity concentration was high, the drains were equipped with valving to control the discharges to the local waters.

<u>Improved Storage Practices</u>

Material handling and storage practices have been inexpensively modified to reduce exposure to stormwater. Simple roof structures over material storage areas and material handling areas have reduced stormwater contact with these operations.

Scrap material hoppers used to collect segregated construction debris, such as wood, mild steel, etc., have been either relocated under roof or have had simple covers installed. Outdoor housekeeping practices have received renewed interest from the Environmental Specialists in each operating area in response to the semi-annual inspection program. Housekeeping activities as simple as street sweeping and trash barrel pickup are monitored more closely. The annual inspection program focuses attention on the activities and site conditions which would affect the quality of stormwater leaving the property.

<u>Employee Awareness</u>

The Stormwater program requires employee training. At Coors the stormwater training program has been incorporated into an existing mandatory OSHA program. This is given once a year to all Coors Brewing Company employees and contract employees working on site. The impact for the stormwater program from training program is an increased awareness that spills and careless material handling can affect more than just the immediate area. An unrealized side benefit might be the employee thinking twice before dumping pesticide wastes or radiator fluid on the street at home and finding an alternate means of disposal. This is an area where the local municipalities and industry could work together.

<u>Regulatory Approach</u>

A final success is the approach taken by the regulators within our state. They have recognized the inherent limitations and pitfalls that exist within the regulation. But, more importantly, they have recognized that the intent of the current regulation is pollution prevention. As a result, they have provided a constructive and positive framework for most industry to work in. The enforcement focus has been on the recalcitrant industries which make no positive effort to correct overt problems or industries that could pose a significant risk to the public.

FUTURE DIRECTIONS

What is the future for the Industrial Stormwater Program? The Clean Water Act Reauthorization, which will dictate the future, is stalled for 1994 but the status of the stormwater portion of the Act will likely be addressed in the next congressional session.

Historically, new regulations demand an improvement in the ambient quality of the regulated media, be it air, water or solid waste controls. It is reasonable to expect that the new CWA will require some form of improvements in stormwater quality from both the municipal and industrial sectors of our economy. The timing, nature and level of improvement is still an open question. Will the new stormwater regulations mandate numeric standards or major structural changes to control the quality of stormwater discharges and move away from the current emphasis on pollution prevention?

Congress might be encouraged to adopt numeric standards for stormwater discharges as an expedient measure, particularly if the current round of monitoring data is taken out of context and used without a sound scientific base. Numeric standards and mandated structural controls could prove to be very costly for both industry and municipalities to implement and for the regulatory community to administer. The benefits of numeric standards and structural controls have yet to be adequately identified, much less quantified in receiving waters. It is important to understand at the outset of the program how the dollars spent on stormwater quality improvements will benefit the receiving waters. A recent editorial entitled "Costs of Cleanliness" (6/13/94)in the Washington Post called for "..a careful balancing of costs and benefits.." for environmental programs. The editorial noted that the current cost of environmental programs are "sufficiently large to effect the way the whole economy works".

As pollution prevention practices such as spill control, material handling and housekeeping improvements (non-structural Best Management Practices(BMP's)) are implemented within a facility under the current program, the major pollutant components should, directionally, be reduced and controlled for a relatively small cost. However, there are no provisions to quantify the change in stormwater quality as a result of the same improvements through the current sampling program.

The next increment of control, which include structural BMP's and involve major modifications to the infrastructure of a facility, could be very costly. Yet neither the short term nor the long-term effectiveness of the structural BMP's in controlling specific pollutants has been adequately defined to the point where the BMP's can be implemented with confidence. Therefore the ultimate cost per kilogram of pollutant controlled cannot be well defined and could be quite high.

<u>Basin Paradigm</u>

The air pollution arena provides some insight to a possible future program. The attainment or non-attainment status of a regional air basin is a determining factor in the level of control required for a discharging industry. The RACT (Reasonably Available Control Technology) and LAER (Lowest Achievable Emission Rate) criteria are used for determining a "reasonable" cost per ton of pollutant controlled against the local pollutant reduction requirements for the air basin. Both the RACT and LAER criteria are associated with a set of known control technologies and a related cost-per-ton of emissions controlled.

VOL 12

7600

A similar program could be used for stormwater discharges. The RACT/LAER approach would be used if a receiving water was not achieving a given stream quality criteria within a drainage basin. Based on the quantity and quality on the discharge water certain BMP's could be required if an existing facility is modified or a new facility is built within a given attainment or non-attainment drainage basin.

If a form of the air permit paradigm is used then a valid and enforceable algorithm which balances area of the country, individual stream flow and recovery factors, rain event factors, structural and non-structural control effectiveness factors, discharge flow and pollutant concentrations against a new stormwater stream standard (both chemical and biological standards) would be required. All sources, municipal, industrial and agricultural, contributing to the basin must be included and the control burden could be prorated on a mass/volume basis. This is recognized as being an extremely complex problem with no easy or inexpensive solutions. Creative and innovative solutions will be required. For example, a water pollutant trading program could be established for a basin where the most cost effective means of reducing contaminants is used to improve basin quality. The costs and credit for the reduction would be shared between industry point and non-point dischargers, sanitation district point dischargers and other non-point dischargers.

The cost and time to establish and implement an equitable and enforceable program nationwide will be tremendous. The subsequent monitoring and enforcement costs to both the regulated community and the regulators will also be very high. These costs must be balanced against the economic and quality of life benefits of the program.

Industry, through trade organizations and professional societies, must be an active participant in the development of any future stormwater discharge standards. For industry the costs associated with government regulations and mandated programs are increasing daily.

The current stormwater program, an integral part of a general pollution prevention program, is, in all likelihood, reducing the pollutant loading to the nations rivers and streams. If the United States is to maintain its competitive position in the world market then a very hard look must be given to the cost versus the true economic benefit for all new and reauthorized environmental programs. Industry must work diligently within our political framework toward the establishment of a rational and economically feasible stormwater program for the country in the future.

STRATEGIES FOR USING NPDES STORM WATER DATA

William F. Swietlik and William D. Tate[1], Robert Goo[2], Eric Burneson[3]

ABSTRACT:

This paper discusses monitoring requirements in the National Pollutant Discharge Elimination System (NPDES) storm water permitting program and reflects upon what has been learned since November 16, 1990, when the NPDES storm water program regulations were promulgated.

The monitoring required of regulated municipal separate storm sewer systems (MS4) and of storm water discharges associated with industrial activity are summarized. Examples of municipal separate storm sewer system monitoring are highlighted along with EPA's experience with the storm water monitoring data reported by industries for the group application process. Possible future directions for storm water monitoring for municipal and industrial NPDES storm water discharges are discussed.

INTRODUCTION:

The 1987 amendments to the Clean Water Act added Section 402(p) to the Act which directed EPA to establish and carry out a two-phase National Pollutant Discharge Elimination System (NPDES) storm water point source permitting program. To initiate this permitting effort, EPA published regulations on November 16, 1990 which defined the types of municipal and industrial storm water discharges that would be regulated under the first phase of the program,

[3]Science Applications International Corporation, 7600-A Leesburg Pike, Falls Church, VA 22043

and which laid out specific permit application requirements. Storm water discharge monitoring requirements were an important part of the permit application process and will be an important component of NPDES storm water permits.

During the permit application process, storm water monitoring was required for regulated municipal separate storm sewer systems (MS4s) and storm water discharges associated with industrial activity. In general, the monitoring efforts yielded important information for NPDES storm water permit writers as well as for the permittees. However, a number of important lessons have been learned that should allow permitting authorities and the regulated community to simplify and strengthen storm water monitoring efforts in the future.

BACKGROUND:

The NPDES program provides three major tools for requiring and collecting monitoring data: permit applications; permit requirements; and information requests made pursuant to Section 308 of the Clean Water Act. Permit applications are generally national requirements which can provide a snapshot of the discharger once every five years (NPDES storm water permits are usually issued with a five year term). Monitoring data in permit applications is generally used for the purpose of supporting the issuance of the permit.

Although some monitoring requirements for NPDES permits are established in national regulations, such as the effluent guidelines, most permit monitoring requirements are established by permit writers on a permit-by-permit basis. This provides a great deal of flexibility to tailor monitoring requirements to each individual discharger. In addition, since permits are written for a five-year term, they can be used to require comprehensive monitoring programs that have the potential to evaluate discharge trends.

Requests for information under Section 308 of the CWA are usually done more on an as necessary basis, and can provide a mechanism to fill some of the gaps associated with applications and monitoring requirements in permits or to answer other necessary permitting questions.

The NPDES program takes two very different approaches to controlling pollutants in storm water discharges. Storm water requirements for industrial facilities are established in permits issued by EPA or by an authorized NPDES State. The second approach to storm water controls is through the involvement of municipal governments. Under this second approach, EPA or authorized NPDES States issue permits for discharges from municipal separate storm sewer systems which require the municipal permittee to develop and implement municipal storm water management programs.

One of the major differences between the industrial and municipal approaches is the programmatic flexibility available to develop monitoring programs. As discussed below, the NPDES program relies heavily on the use of general permits to authorize storm water discharges associated with industrial activity. In addition, industrial sites may be one of many sites in a watershed, or within a State, that discharges storm water. These factors tend to limit monitoring efforts to evaluating the nature of storm water discharged from a site and evaluating the effectiveness of the pollution prevention measures implemented at the site.

On the other hand, permits for municipal separate storm sewer systems have a much broader scope which allows consideration of more comprehensive monitoring approaches. As originally intended, storm water monitoring during the term of the NPDES permit for regulated municipal separate storm sewer systems was to be a flexible plan developed by the municipality, and approved by the permitting authority, to meet and support the purposes for the monitoring that the municipality itself identifies as important.

Monitoring for Municipal Separate Storm Sewer Systems (MS4s):

For municipal separate storm sewer systems (MS4) serving a population greater than 100,000, monitoring requirements were established as part of a two-part permit application. For the part 1 permit application, MS4s were required to report the results of field screening efforts to detect the presence of dry-weather discharges, e.g., illicit connections or illegal dumping. Visual observations, including simple colormetric tests, of dry weather flows were used to assist in identifying illicit connections. These were conducted at up to 500 major storm sewer system outfalls, depending on the size of the municipality. The part 2 permit application focused on reporting the results of wet-weather monitoring from representative municipal storm sewer outfalls in a plan approved by the appropriate permitting authority.

Wet-weather monitoring requirements for the part 2 permit application included submittal of quantitative data on physical and chemical characteristics of the discharge taken from at least 5 to 10 representative outfalls during 3 storm events; estimates of the annual pollutant load and event mean concentration of the cumulative discharges from all known municipal outfalls, and proposal of a schedule to provide seasonal loading and event mean concentration estimates for constituents detected during sampling for each major outfall.

Permits for discharges from municipal separate storm sewer systems will require the municipal permittee to develop and implement municipal storm water management programs which focus on implementing non-traditional control measures for priority sites and areas. The nature of these programs presents a number of opportunities that well-designed monitoring programs can support.

Monitoring for Storm Water Discharges Associated with Industrial Activity:

The NPDES regulations provided three different options for industrial facilities with storm water discharges to apply for permit coverage: individual applications; group applications; and submittal of a notice of intent (NOI) to be covered by a storm water general permit. Each option represents a distinct approach to collecting monitoring data.

Individual applications for most types of storm water discharges associated with industrial activity require site-specific narrative information, as well as monitoring data from a representative storm event. Individual industrial permit applications required monitoring for;

- Any pollutant limited in an effluent guideline to which the facility is subject
- Any pollutant listed in the facility's NPDES permit for its process wastewater (if the facility has an existing NPDES permit)
- O&G, pH, BOD_5, COD, TSS, total phosphorus, TKN, and nitrate plus nitrite nitrogen
- Any pollutant known or believed to be present [as required in 40 CFR 122.21(g)(7)]
- Flow measurements or estimates of the flow rate, the total amount of discharge for the storm events sampled, and the method of flow measurement or estimation
- The date and duration (in hours) of the storm events sampled, rainfall measurements or estimates of the storm event (in inches) which generated the sampled runoff, and the time between the storm event sampled and the end of the previous measurable (greater than 0.1 inch rainfall) storm event (in hours). In addition, individual applications must contain a certification that all storm water outfalls have been tested or evaluated for the presence of non-storm water discharges.
- Separate analyses were required for both a grab sample and a flow-weighted composite sample. Grab samples, only, were required for oil and grease and pH.

The Agency developed the group application process to lessen the monitoring burden on industrial facilities and to provide a large, nationally consolidated database of monitoring data from classes of industrial facilities. The

VOL 12

7605

group application process was intended to encourage similar types of industrial facilities to participate in one data collection effort, thereby compiling information on the class of facilities. EPA provided an incentive for industrial facilities to participate in a group application by only requiring a small percentage of the facilities in the group to monitor, provided the facilities were representative of the members in the group. Designated samplers in group applications monitored for the same requirements described for individual applications.

Over 65,000 industrial facilities representing 1250 groups initially participated in the group application process. Approximately 3,500 of these industrial facilities provided storm water monitoring data. This database represents the most comprehensive collection of storm water data from industrial facilities assembled to date.

The Agency is in the process of finalizing an innovative monitoring approach proposed in the multi-sector industrial storm water general permit based on the data received during the group application process. EPA used the data to identify pollutants of concern for each industrial sector, to help identify high priority industries for future monitoring under the permit, and for selecting the most appropriate pollution prevention measures and BMPs. Under the proposed multi-sector industrial permit, monitoring for the high priority sectors is designed as an incentive for industry to implement more effective storm water pollution prevention plans. Under this incentive, if storm water monitoring shows that pollutant concentrations are below specified levels, the industrial facility no longer is required to monitor under the permit.

Most storm water general permits for industry do not require monitoring data to be submitted during application for coverage. General permits for storm water may identify targeted classes of facilities to conduct monitoring as a condition of the permit. Several factors have helped shape the approaches to developing monitoring requirements in permits for storm water discharges associated with industrial activity, including the large number of facilities that need to be covered by permits, difficulties in sample collection, and variability of data.

The NPDES regulations provide that permits for most types of storm water discharges associated with industrial activity must, at a minimum, require dischargers to conduct annual site inspections to identify sources of pollutants to storm water and evaluate pollution prevention measures. This requirement does not preclude the establishment of additional monitoring requirements on a case-by-case basis by the permit writer.

The baseline storm water general permit issued by EPA for industrial activities provides that most types of facilities do not have to conduct monitoring, but must conduct the annual compliance site evaluation. Under this permit, priority facilities that are thought to present higher risks have been required to conduct chemical monitoring of their storm water discharges in addition to conducting the annual inspections.

EPA has initially targeted classes of industrial facilities that need to conduct storm water monitoring on the basis of available information and best professional judgement. Monitoring requirements are intended to help regulators and permittees identify sources of pollution at facilities, evaluate the risk posed by the storm water discharges, evaluate the effectiveness of control measures and establish a database to support more applicable and effective permit requirements in the future.

For any NPDES permittee monitoring their storm water discharge, data collection procedures described in 40 CFR §122.21(g)(7) are required to be followed. Analytical methods are required to be conducted in accordance with 40 CFR Part 136.

Under 40 CFR §122.21(g)(7), specific storm event criteria were defined within which storm water sampling was required to be conducted:

- Rainfall depth must be greater than 0.1 inch.
- The storm must be preceded by at least 72 hours of dry weather
- Where feasible, the depth of rain and duration of the event should not vary by more than 50 percent from the average depth and duration.

These additional technical criteria were established to: (1) ensure that adequate flow would be discharged; (2) allow some build-up of pollutants during the dry weather intervals; and (3) ensure that the storm would be "representative," (i.e., typical for the area in terms of intensity, depth, and duration). Collection of samples during a storm event meeting these criteria also ensures that the resulting data will portray more consistent conditions at each site. However, the permitting authority was authorized to approve modifications of these criteria, especially for applicants in arid areas where there are few representative events.

EPA published a storm water monitoring guidance document that describes in detail the methods used for storm water discharge monitoring (5).

7608

MUNICIPAL STORM WATER MONITORING RESULTS:

To illustrate potential uses of wet-weather monitoring data in support of municipal storm water management programs, highlights from the cities of Austin, TX, and Charlotte, NC and the counties of Santa Clara Valley, CA and Montgomery County, MD are discussed below. In addition, a brief discussion is provided on the use of monitoring data to support watershed planning activities in the State of Wisconsin. These examples illustrate how storm water monitoring has been put into practice at various levels. It should be emphasized that these are not the only approaches that may be adopted. Recent studies using biological and habitat assessments suggest that there are a number of cost-effective techniques to accurately assess the extent of impacts associated with storm water discharges (19, 20, 23, 25, 27, 28).

Storm Water Monitoring in Austin, TX:

Austin, TX has maintained a storm water monitoring program for over 10 years. The purpose of the program is to collect information on the quality of urban runoff, evaluate the performance of structural controls, and to support the development of design guidelines for storm water quality controls (16). The impetus for this program was to support efforts at protecting several environmentally sensitive watersheds. These watersheds serve as a source of groundwater recharge to the Edwards Aquifer which discharges to Barton Springs (an important recreation resource) or to two lakes that serve as the primary drinking water supply for the city. The storm water monitoring program in these watersheds is used to support the implementation of the city's watershed protection ordinances.[5]

In a five year summary of results (1984 to 1988), the city monitored at seven sites corresponding to watersheds or catchments ranging from 3 to 371 acres in size (16)[6]. The percentage of impervious cover at these sites ranged from 3% to 95%. With the exception of the control watershed and a low-density residentially developed site, all other watersheds or catchments had structural controls that provided detention and/or filtration.

---

[5]Austin's storm water monitoring program is also augmented by a cooperative monito..ng program with USGS.

[6]The sites monitored included one undeveloped watershed serving as a control, four catchments coinciding with either low or medium density residential development, one high-developed mix between residential and commercial and one highly developed commercial. Five of the seven sites were substantially below 100 acres in size.

A separate study of sampling data (17) found that:

- First flush concentrations were notably higher compared to average concentrations from a subsequent sampled runoff intervals;

- A majority of pollutants are not washed away from impervious surfaces during the first 1/2 inch of runoff. As the amount of impervious surface increases, there is a generally negative trend in the percent removed in the first 1/2 inch of runoff as the volume of runoff increases. A significant pollutant loading will continue to exist if storm water controls are designed to only treat the first 1/2" of runoff.

In addition, analysis of rainfall and sampling data resulted in the development of percent annual pollutant loading curves expressed on the basis of runoff amount and degree of impervious cover. An additional study of monitoring data (1984 to 1989) yielded estimates of removal efficiencies for various structural controls (18). The study also examined the effects of design and maintenance on removal efficiency. The results are used as a basis of maintaining design guidelines for storm water quality control structures (15).

Charlotte, NC In-Stream Water Quality Problem Rating Scheme:

The City of Charlotte, NC has developed a stream problem rating system which is designed to characterize and prioritize stream segments based on a series of pollutant parameters believed to reflect water quality conditions in the stream segment (14). More specifically, the City has developed limiting concentration ranges for a number of indicator pollutants which are segregated into three action rating levels; No Action, Watch, and Action. In order to develop a reliable rating system, the City consulted numerous information sources currently in existence, e.g., NC Sanitation Foundation Index, NC Water Quality Index, 305(b) reports, and water quality standards for the State of North Carolina. Specific range limits were established for dissolved oxygen, fecal coliform, PO_4-P, NO_3-N, BOD_5, total solids, pH, turbidity, lead, and zinc. An exceedance frequency was then developed for each pollutant which established the number of times a limiting concentration could be exceeded before a stream segment was classified as either in the Watch or Action levels. Using a Geographic Information System (GIS), monitoring data were then sorted in order to establish an action level for each stream segment. Charlotte's Part 2 Permit Application indicates that for 27 individual stream segments, the majority of the monitored stream segments were rated as either Action or Watch for all indicator pollutants except for total solids and pH.

The City also developed an action-level correlation matrix for each indicator pollutant based on typical pollutant sources or activities. These sources or activities include; construction runoff, sanitary sewers, fertilizer application, industrial facilities, transportation, illicit connections, agriculture runoff, wastewater treatment plant discharges, residential runoff, and animal waste. The matrix can be used to investigate the most likely source of a problem based on the action level produced for an individual stream segment.

Santa Clara Valley Non-point Source Pollution Control Program:

Santa Clara Valley Water District (SCVWD) is the lead or managing agency working in cooperation with 14 other California municipalities addressing issues related to non-point source pollution control. The purpose of monitoring to collect data necessary to assess compliance with a copper wasteload allocation established for the San Francisco Bay (a 304(l) listed waterbody), and to monitor for pollutants that have caused frequent exceedances of numeric water quality objectives (WQO) (24).

In their FY92-FY93 Annual Report, Santa Clara Valley reported that acute water quality objectives are frequently exceeded for total copper and total zinc, and sometimes for total lead. Chronic water quality objectives are frequently exceeded for total copper, total zinc, and total lead. The Report further notes that acute exceedances were not observed for the dissolved metal concentrations and infrequent chronic exceedances were observed for dissolved metals. Chemical analyses were performed on flow-weighted composite samples collected from several in-stream monitoring stations. The results of the toxicity testing revealed that collected samples were toxic to *Ceriodaphnia*, however, test results were variable based on the season that samples were collected.

Statistical analysis of the data revealed that long-term trend analysis could be performed for a number of pollutants at two stream stations (one in the Guadalupe River and one in Coyote Creek). Conversely, data variability was observed to be much greater at two other in-stream stations (Calabazas Creek and Sunnyvale East Channel). The Annual Report noted that statistical methods would allow for grouping of the data for long-term trend analysis from Calabazas station with that of Guadalupe River and Coyote Creek stations. Extensive channelization in the Sunnyvale East Channel is believed to be a reason that monitoring data cannot be used with other stations for long-term trend analysis (24).

Santa Clara Valley has also instituted a comprehensive source identification program to identify potential sources and land uses suspected of contributing significant amounts of toxic metals. For example, Santa Clara Valley recently completed a study of the contribution of heavy metals from automotive brake pads (Woodward-Clyde 1994). The results of this study suggest that brake pads

VOL 12

7610

could potentially contribute on average between 53%, 3%, and 6% of the total annual loads for copper, lead, and zinc, respectively[7]. Santa Clara Valley has also instituted a toxicity control program (TCP) in an effort to identify appropriate measures to reduce toxicity.

Montgomery County, MD's Alternative Monitoring Strategy:

Montgomery County, MD is a MS4 regulated under Phase I of the NPDES Storm Water Program. The County is proposing an alternative to the historical emphasis on accumulating chemical and physical water quality data (29). The County has noted that focusing exclusively on traditional monitoring approaches, i.e., chemical-specific monitoring, is not necessarily the most appropriate means for accurately assessing impacts associated with storm water. In particular, the County recognizes that the effects of storm water discharges are cumulative in nature (e.g., anthropogenic enrichment of streambed sediments, degradation of aquatic habitat, and loss of benthos and fish species diversity) and cannot be exclusively attributed to urban runoff quality alone. Consequently, the County is proposing to use bioassessment techniques, complemented with physical and stream habitat assessments.

The County's strategy includes the collection of baseline data necessary for the development of biological water quality criteria and envisions the eventual development of aquatic life use classes that contain biological, chemical, and physical attainment criteria. This approach is expected to provide the basis of conducting long term trend assessments of receiving water quality (29).

For example, the County suggests that the degree of impairment could be plotted along the entire reach of a stream segment, similar to an approach currently in practice by Ohio EPA. Those areas which indicate significant impairment would be specifically targeted for further investigation and would also serve as a basis of documenting management program effectiveness. The County's proposed monitoring program is intended to reflect the movement towards holistic approaches to ecosystem protection.

Wisconsin DNR Priority Watershed Planning:

In recent years, numerous States and municipalities have instituted comprehensive watershed planning processes for storm water management. Wisconsin DNR has established a watershed approach as part of its Priority Watershed Planning Program (21). The program consists of three major components; a priority watershed plan, an engineering feasibility study, and an

[7]Estimates for copper ranged from approximately 19% to 75% of the total annual load to South San Francisco Bay. Similarly, the range for lead and zinc were estimated to be approximately between 1% to 4% and 2% to 9%, respectively.

VOL 12

7/6/1

implementation phase. There are a number of elements contained within the priority watershed plan, they include:

a. **Identification of Current and Desired Beneficial Uses:** This element includes results of fish and benthos surveys that quantify existing levels of use. Other habitat surveys may also be included.

b. **Problem Evaluation:** This element includes evaluation of problems that are contributing to impairment of the water resource and, therefore, preventing the attainment of designated uses. Evaluations have included habitat and streambank inventories to determine the suitability of resources to support different aquatic life beneficial uses. This information in conjunction with fish/benthos surveys can then be used to determine the extent of impairment and to identify possible sources contributing to the impairment[8].

c. **Sources of Problems:** This element addresses specific problem sources that are believed to be contributing to receiving water impairment. A distinct aspect of this element of the program is its extensive use of the Source Loading and Management Model (Pitt 1991). Unlike many other urban runoff models in practice, SLAMM was specifically designed as a planning tool for storm water quality management and did not originate as a flood control planning and design tool.

Since storm water impacts are principally cumulative in nature, SLAMM data inputs focus on watershed and land use development characteristics. Consequently, SLAMM is intended to provide information on the significance of different sources, control measures, and drainage characteristics on urban runoff quality[9].

---

[8]For example, the inability of urban resources to meet their designated uses was frequently attributed to periodic flooding and poor water quality. The results of these evaluations could lead to the adoption of goals to reduce streambank erosion, including establishing flow reductions in order to prevent flushing of spawning areas and protection of fish refuge areas (22).

[9]SLAMM represents a tradeoff between the cost of extensive data collection and providing information to support planning level decision-making. It also provides an opportunity to quickly consider the costs and benefits of many different control strategies. The development of SLAMM's specifically focuses on the hydrological characteristics of frequent small storm events which are critical in storm water quality investigations (21, 22).

d. **Identification and Evaluation of Suitable Source Area, Drainage System, Outfall, and Receiving Water Controls:** Once problem sources (pollutants and flows) have been identified, this element focuses on the selection of different control strategies. In particular, selecting the individual or mix of controls effective in removing the types of pollutants found, e.g., particulate vs. dissolved metals. SLAMM model output includes pollutant concentrations (particulate & dissolved), flow, and estimate control costs on an areal basis.

e. **Selection of Urban Runoff Control and Habitat Improvement Program:** In this element, the most effective control strategy is selected after considering other programmatic factors including cost.

The second major component of the Wisconsin Priority Watershed Planning program is the engineering feasibility analysis which follows the completion of the watershed plan. Since, the watershed plan is structured around general land use categories, the engineering feasibility analysis allows for consideration of site specific conditions within a particular watershed or basin that may limit or prohibit the use of control strategies identified in the watershed plan.

a. **Site Specific Area Availability, and Groundwater and Infiltration Conditions:** This element considers potential options for the siting of controls, including retrofit opportunities. Other considerations include identification of sites to promote infiltration provided infiltration rates and groundwater conditions satisfy established standards.

b. **Flooding and Drainage Benefits of Water Quality Controls:** SLAMM cannot be used to perform hydraulic analyses, therefore drainage or local flooding conditions may be required to determine the potential benefits of siting storm water quality controls.

The final component of the planning process is the implementation phase which entails the development of a cost-sharing agreement. Using information from the previous planning steps, the agreement specifically identifies types of cost-sharable projects that may eligible for matching State funds.

EPA also reviewed available sampling data and information from 23 municipal part 2 permit applications located throughout the U.S. The purpose of this review was to obtain a greater appreciation of the efforts involved in collecting storm water sampling data and to gain some insights on the results. Of these 23 municipalities, at least 14 provided some sampling data which could be used for further analysis. Due to the substantial differences in the amount of sampling data between municipalities and gaps in data, this paper does not attempt to draw conclusions about national trends with respect to the pollutant concentration values. However, sufficient information was available from permit applications, to support some general observations:

- Residential and commercial areas represented an estimated 31% and 27% of sites sampled, respectively[10];
- Approximately 96% of the sampled sites corresponded to a single land use classification;
- The median size of the catchments or watersheds sampled was estimated at 47 acres and ranged in size from 8 to 2,252 acres[11].
- The median value for sampled watershed impervious area was estimated at 47%.
- The average number of sampled sites was estimated to be 6, and ranged from 3 to 10.
- The median and average number of sampled storm events was estimated to be 7 and 12, respectively. An estimated 80% of the municipalities sampled more than the minimum 3 representative events required. Approximately 47% sampled more than 10 storm events.
- Approximately 8 municipalities reported that storm event characteristics were consistent with EPA criteria or satisfied modifications in the criteria by State permitting authorities. Most municipalities reported difficulties with start-stop events, meeting the 72 hours of dry-weather, and/or achieving a total rainfall accumulation greater than 0.1 inch.

[10]Information on land use type was provided for 36 sampling sites.

[11]This does not include several watersheds monitored by USGS which ranged in size from 4,032 acres (6.3 sq. mi) to 74,240 (22.3 sq. mi.).

VOL 12

7614

RESULTS OF GROUP APPLICATION MONITORING:

The discharge data collected under the NPDES Storm Water Group Application process is perhaps the largest and most comprehensive industrial storm water discharge data set compiled to date. The data set includes the monitoring results from approximately 3,500 industrial facilities which were selected as representative of their larger industry groups. The data includes results collected from a wide variety of industrial activities. It includes data submitted by manufacturing facilities with little exposure of activities to storm water such as electronic manufacturing facilities to facilities with high degrees of exposure such as scrap recycling facilities. Table 1 lists the sectors of industrial activities for which data was received and analyzed.

There are, however, a number of limitations to the data set which should be considered when analyzing and reviewing the data. The following paragraphs describe some of these limitations.

Monitoring Facilities Were Not Selected Randomly:

The facilities which were designated as samplers in the group application process were not selected at random. The group application requirements established a number of criteria which the monitoring sub-group was required to satisfy. These criteria, which are described in the previous section, were designed to ensure geographic distribution, and representation of the various significant materials and material management practices. EPA required a group to satisfy these criteria prior to approving Part 1 of the application. EPA did not require the groups to randomly select their facilities, therefore once the application criteria were satisfied, a group organizer had discretion in the selection facilities to be monitored.

Monitoring and Analyses Were Typically Performed for Only One Storm Event:

The regulations require facilities to submit analytical results for samples collected from one representative storm event (see the previous section for a discussion of the representative storm event requirements). A significant majority of the facilities limited their monitoring to one storm event, therefore the data does not reflect any variation in concentration that may occur at a facility from storm event to storm event.

7616

Only Half of the Designated Samplers Are Included in the Data:

There were over 6,800 designated samplers from the approved group applications, however, only about 3,500 of these facilities submitted data by the deadlines for EPA to incorporate their data into the analyses. The remaining facilities were not able to meet the application deadline primarily due to a lack of representative storm events during the time frame in which they intended to sample.

Monitoring and Analyses Were Performed by the Permit Applicants:

All data were submitted to EPA by the permit applicants. None of the monitoring or analyses were performed by the Agency. Applicants were required to collect samples in accordance with the regulations under 40 CFR Part 122.21 and analyses were required to be performed in accordance with approved methods under 40 CFR Part 136.

Permit Applicants Determined if They Were Required to Sample for a Portion of the Pollutants:

Within part VII.C of the Storm Water Permit Application form 2F there are a number of pollutants which an applicant is required to sample if he or she "'knows or has reason to believe'... are present in an effluent based on an evaluation of the expected use, production, or storage of the pollutant or on any previous analyses for the pollutant."

Analyses of the Group Application Monitoring Data:

Group application monitoring data were entered into a data base for analyses. Applicant's monitoring data were categorized into one of 31 industry sectors (See Table 1). Categorization was based upon the Standard Industrial Classification (SIC) code of the facility when provided, or upon the narrative description of the industrial activities at the facility when an SIC code was not included in the application. Data within each sector was analyzed separately.

Prior to analyses, units for each of the pollutant data values were standardized to mg/L (except pH, fecal coliform and several other pollutants not measured in mg/L). Pollutant values reported as below detection limit, or not detected were assigned a concentration of 0.0 mg/L for the statistical analyses.

Analyses of the data were performed using the UNIVARIATE procedure of SAS (SAS is a statistical analyses software package developed by the SAS Institute). For each pollutant sampled at least once within each sector, the following statistics were calculated:

Total Number of Observations,
Total Number of Non-Detects Reported,
Total Number of Detects Reported,
Mean Concentration,
Standard Deviation,
Minimum Concentration,
Maximum Concentration,
Median Concentration (the concentration which was greater than half of the

values reported),
95th Percentile Concentration (the concentration which was greater than 95 percent of the values reported), and
99th Percentile Concentration (the concentration which was greater than 99 percent of the values reported).

Statistics were calculated separately for the grab samples and for the flow proportional samples. Tables 2 and 3 present a portion of the results of the analyses. Table 2 lists median pollutant concentration of the grab samples for select pollutants. Table 3 lists median pollutant concentrations of flow proportional composite samples for select pollutants.

Use of the Group Application Data in Permit Development:

The results of the group application data analyses were utilized by the permit writers to develop targeted pollution prevention plan requirements and to select industries and pollutants for further monitoring.

Permit writers utilized the monitoring data to identify pollutants which are likely to be present in high concentrations for an industry sector. They then identified the potential sources of the pollutants and selected pollution prevention measures or structural controls which could be practicably implemented or installed at an industrial facility.

Development of Permit Monitoring Requirements:

The selection of industry sectors for monitoring under the terms of the permit was based in part upon the results of the group application monitoring data. Discharges from the following industries were identified as requiring analytical monitoring as a result of the prioritization analysis: facilities engaged in wood preserving or wood surface treatment, chemical and allied products manufacturing facilities, concrete and clay products manufacturing facilities, primary metals facilities, ore mining and dressing facilities, landfills and land application sites, scrap and waste material processing and recycling facilities, steam electric generating facilities, ship and boat building and repair yards, waste water treatment works, food and kindred products facilities, leather tanning and finishing facilities, and fabricated metal products facilities.

Observations Derived from the Group Application Data:

Despite the limitations discussed, the data collected through the NPDES storm water group application process contains a great deal of information regarding the quality of storm water discharges associated with industrial activity.

The concentration of pollutants in storm water discharges varies widely among facilities within an industry sector and between the different industry sectors. A number of factors influence the concentration of pollutants in storm water discharges associated with industrial activities, including: the amount and types of materials exposed to storm water; the amount and intensity of rainfall; and the types of best management practices employed at a facility. Given the number of factors influencing pollutant concentrations, and the wide variation in conditions at the facilities conducting sampling, it is not a surprise that discharge concentrations of pollutants vary a great deal. Figures 1 and 2 illustrate this variation for total suspended solids (TSS) concentrations in storm water discharges. Figure 1 is a plot of the cumulative distribution of TSS concentrations in discharges from all industry sectors. Figure 2 is a plot of the cumulative TSS concentration distribution for discharges only from scrap recycling facilities.

The highest pollutant concentrations were generally found at industries with the most industrial activity exposed to storm water. While industrial activity is not the only factor that influences the presence of pollutants in storm water, the data do show that there are generally higher concentrations of pollutants found in storm water discharges from facilities where the majority of activities are performed outdoors as opposed to facilities where activity generally takes place indoors. Figures 3, 4 and 5 compare the levels of pollutants from three high exposure industries (ore mining and dressing, industrial landfills and scrap recycling facilities) to three low exposure industries (furniture and fixture manufacturing, printing and publishing, and electronic equipment and instrument manufacturing). Figure 3 compares median concentrations for three conventional pollutants. Figure 4 compares median concentrations for nutrients and Figure 5 compares median concentrations of metals.

MONITORING NEEDS IN THE FUTURE:

Municipal Storm Water Monitoring:

Revision of Municipal Application Requirements:

The existing NPDES permit application requirements for discharges from municipal separate storm sewer systems serving a population of 100,000 or more were designed to provide information for first round permits. A major goal of these applications was to provide an initial description of the system and its discharges. The application used a number of sources of information to address this goal, including narrative descriptions of land use, rainfall data, site inspections of selected outfalls to screen for problems associated with non-storm water discharges and limited discharge monitoring data. As municipal storm water programs evolve, issues such as program effectiveness and identification of specific water quality problems become more important so that limited resources can be more effectively targeted to address these problems.

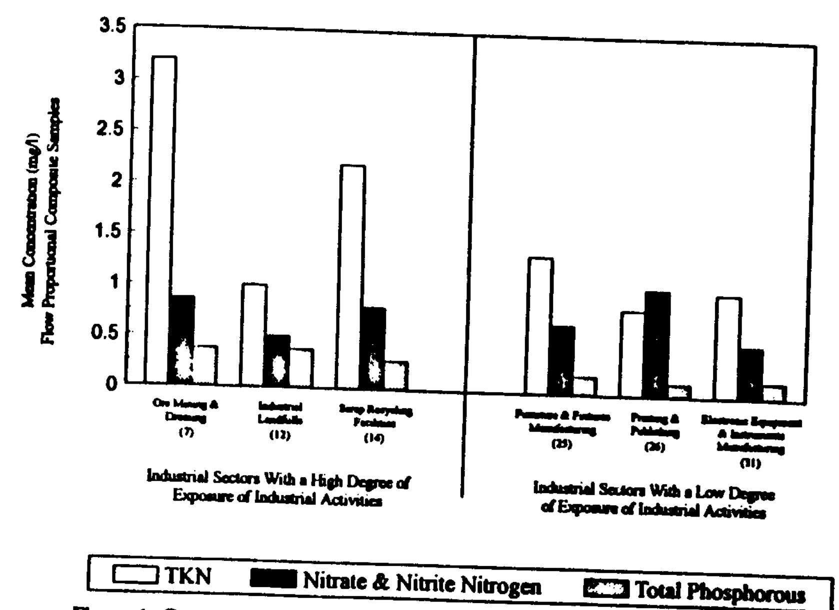

Figure 4. Comparison of Nutrients Concentration In Storm Water Discharges from Industry Sectors With High vs. Low Levels of Exposure

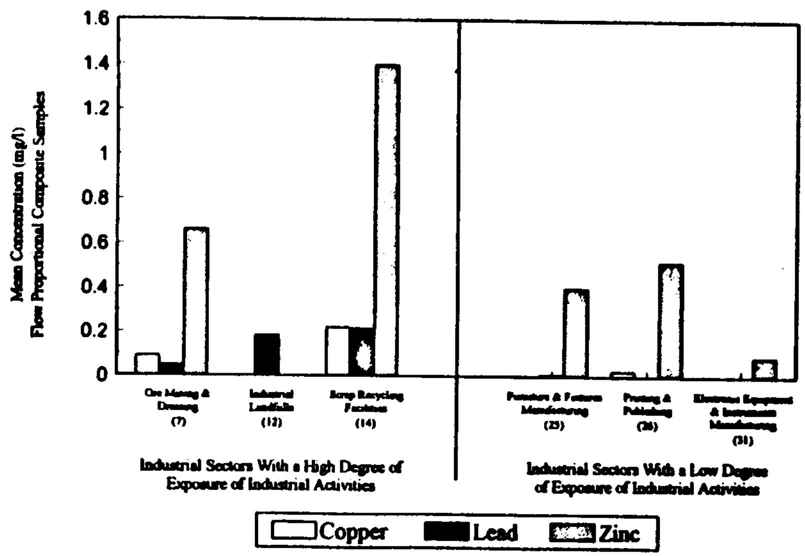

Figure 5. Comparison of Metals Concentration In Storm Water Discharges from Industry Sectors With High vs. Low Levels of Exposure

In addition, site-specific requirements for monitoring programs will give individual municipalities direction to their monitoring efforts. These factors will change the monitoring requirements in future municipal storm water permit applications. This change in emphasis may result in a shift from discharge monitoring to the use of alternative monitoring tools such as environmental indicators.

For many types of municipal storm water controls, municipalities will be required to identify priorities for implementation. Priorities for implementing controls will be based on a number of factors, including the potential for discharges to cause or contribute to water quality impacts, the nature of the discharge, and the effectiveness of potential management measures, the geographic location of the municipality, the size and type of receiving water body and the resources available to the municipality. Providing useful information to evaluate these factors should be a major consideration in the development of monitoring requirements in permits for municipal separate storm sewer systems (MS4s).

In addition, application requirements must be developed for any additional "Phase II" municipal separate storm sewer systems that are brought under the NPDES program in the future. One goal of the NPDES program for municipal separate storm sewer systems will be to strongly encourage municipalities to take regional and watershed approaches that involve interaction and coordination amongst municipalities. One critical programmatic step that can be taken to encourage regional/watershed approaches is to synchronize the resubmittal of applications for municipal separate storm sewer systems currently subject to the program with the first time submittal of applications for surrounding "suburban" Phase II municipalities. Failure to synchronize these submittals will greatly decrease opportunities for municipalities to coordinate storm water monitoring efforts, and may result in independent, uncoordinated efforts by individual municipalities.

Use of Biological Assessment Methods:

Given the complex nature of storm water impacts and attempts to put issues associated with urban runoff quality in the proper context with other runoff related problems (e.g., flooding, aquatic habitat degradation, and sediment enrichment), one prevailing misconception is the need to focus exclusively on urban runoff quality.

Despite the emphasis in the permit application on pollution prevention and identifying potential pollutant sources, it is important to be aware of the significance of other contributing sources. More specifically, practices which produce excessive amounts of runoff, frequently result in substantial alterations to aquatic habitat, e.g., streambank erosion, streambed instability, loss of refuge areas, anthropogenic-enrichment of bed sediments, flushing of juvenile aquatic life forms, and siltation of spawning areas. An example from the State of Ohio illustrates this point.

Lessons from Ohio's Ecological Assessment Program:

Ohio recently adopted numeric biological criteria for its State Water Quality Standards (WQS). A comparison between measured biological impairment and

VOL 12 7627

chemical water quality criteria exceedance frequency revealed that biological impairment was evident in nearly 50% of assessed segments where no ambient chemical water quality criteria exceedances occurred (27). This result could suggest that chemical water quality criteria are not stringent enough, however, Ohio observed that in cases where only biological impairment was observed, the causes of impairment, principally low dissolved oxygen/organic enrichment, habitat alteration, and siltation, are not directly measured by chemical specific monitoring, with the exception of low dissolved oxygen.

Chemical causes of impairment were observed in 30.7% of assessed segments. However, the ability to detect chemical exceedances is heavily dependent on other factors such as adequate sampling frequency and the selection of monitoring parameters. More importantly, however, Ohio's experience underscores that both chemical and non-chemical causes can simultaneously contribute to biological impairment which is only evident using bioassessment techniques (27, 28).

Limitations of Chemical-Specific Monitoring:

As noted above, a prevailing misconception is that monitoring requirements during the permit term must focus exclusively on chemical-specific monitoring. Chemical-specific monitoring does not necessarily result in a good representation of receiving water impacts due to storm water discharges. Furthermore, relying extensively on chemical-specific monitoring data as a basis of prioritizing the investment of resources could lead to inadequate coverage of other areas that are greater sources of receiving water impairments. Numerous papers on this subject have noted the growing trend to use other techniques (e.g., bioassessments, habitat evaluations, and sediment analysis) for assessing receiving water impacts (19, 20, 23, 25, 27, 28).

Monitoring During the Permit Term:

The regulations, as they apply monitoring during the permit term, do not specifically require MS4s to perform chemical-specific monitoring only. The regulations provide flexibility to a MS4 to design a monitoring program to support the objectives of their storm water management program. However, MS4s should take into consideration three significant factors when designing a monitoring program:

1. Complying with the statutory provision that effectively prohibits non-storm water discharges into storm sewers;

2. Information to support a determination that pollutants are being reduced to the maximum extent practicable; and

3. Information to support a determination as to whether discharges from MS4s are or are not attaining applicable State water quality standards.

The implications of each of these points are discussed below.

Non-storm Water Discharges:

The statutory provision regarding the effective prohibition on non-storm water discharges to storm sewers is fairly specific. EPA expects that field screening for illicit connections and illegal dumping will continue during the permit term as a monitoring condition. However, it is also expected that MS4s will use the results of previous screening efforts to establish long term priorities based on some appropriate ranking criteria, e.g., proximity to sensitive receiving waters, extent of directly connected impervious cover, use of raw materials in industrial manufacturing, age of system, potential for inflow from sanitary sewers, and evidence of past problems.

Achieving the Maximum Extent Practicable Standard:

Monitoring programs can provide information to support a determination that the storm water management program is reducing the amount of pollutants to the maximum extent practicable. MS4s may elect to conduct long-term trend analysis as a basis of supporting estimates that pollutant are in fact being reduced. However, methods other than chemical-specific monitoring may be used as a basis of meeting the MEP standard.

MS4s may propose to use other alternative monitoring assessment techniques, e.g., bioassessments, habitat evaluations, sediment quality analysis, etc, to demonstrate long term trends. EPA recognizes that in many instances, MS4s do not possess the in-house expertise to perform such assessments. However, a number of States are already performing such assessments and may be ready source of information.

Some factors that should be considered in advance before adopting an alternative monitoring approach include:

- The type of assessment technique to employ, e.g., narrative bioassessment vs. multi-metric indices such as the Index of Biotic Integrity (IBI) or Invertebrate Community Index (ICI);
- Current State regulations and practices;
- The extent to which basins or watersheds are impacted by other stressors;
- Availability of applicable technical and scientific expertise;
- Limitations of assessment techniques;
- Experience of in-house personnel; and,
- Cost.

From the perspective of a MS4, cost of monitoring will be an important concern. However, experiences from Ohio's ecological assessment program reveal that the cost of using bioassessment techniques is very competitive with chemical-specific monitoring.

VOL 12

7629

Attainment of Water Quality Standards:

The ability of storm water discharges from MS4s to meet applicable State water quality standards remains an important issue but is required under the current statutory framework. Numerous organizations and municipalities have asserted that such a goal is neither realistic or achievable because of the unique aspects of storm water discharges, while others maintain current water quality standards are not applicable to wet weather discharges. This is a complex issue and more complete answers will require further investigation. Given the cumulative effects of storm water discharges on receiving water quality and the significance of other factors such as runoff quantity, habitat alterations, geology, and hydromodifications, future storm water monitoring programs will likely evolve from an emphasis on chemical-specific monitoring alone, to one that more fully integrates other methods such as the use of environmental indicators.

Industrial Storm Water Monitoring:

Evaluating Effectiveness of General Permits for Industrial Facilities:

NPDES permits for storm water discharges associated with industrial activity are unlike NPDES permits for traditional sources such as sewage treatment plants and industrial process wastewaters in that they generally do not rely on the use of numeric effluent limitations. Rather, most NPDES permits for storm water discharges associated with industrial activity have required the implementation of pollution prevention measures and best management practices (BMPs). While the pollution prevention/BMP approach has a number of programmatic advantages, a major disadvantage of this approach is that it becomes more difficult to evaluate the effectiveness of the permit requirements. Ensuring that pollution prevention plans are effective should be a key objective of industrial storm water monitoring.

EPA is currently reviewing a number of methods to evaluate the effectiveness of permit requirements for storm water discharges associated with industrial activity and storm water monitoring results may play an important part in this effort. These include identifying measures, such as the number of industrial facilities that have obtained permit coverage and that have prepared pollution prevention plans to control their storm water, reviewing select pollution prevention plans to extract unique, innovative and creative techniques for storm water control, conducting pollution prevention plan audits of certain high priority facilities, working with industry trade associations and other groups to initiative cooperative efforts to assess the effectiveness of permits for industrial storm water, implementing environmental indicators, and possibly collecting and analyzing trends in storm water monitoring results for industrial dischargers across the country.

As more NPDES permitting is conducted on a watershed basis, monitoring of industrial storm water discharges will be necessary for developing State watershed strategies, identifying high priority sources within watersheds and for calculating wasteload allocations for permitting purposes.

SUMMARY:

Due to the nature of storm water impacts, it is expected that municipal storm water monitoring programs will evolve over time as MS4s gain greater familiarity with site-specific storm water problems. Given that many MS4s are dealing with issues of storm water quality for the first time, monitoring programs can be expected to vary in their complexity and NPDES storm water permitting can allow for this flexibility. EPA also recognizes that cost of monitoring will also be a significant factor, however, EPA encourages MS4s to design monitoring programs that yield useful information to support their storm water management program. Monitoring programs need to be carefully designed to accomplish useful purposes both in the short-term and in the long-term for the regulated municipality, its citizenry, as well as for NPDES the permitting authority.

To accomplish this, municipal storm water monitoring efforts must be carefully designed with a specific programmatic purpose in mind, and then the most appropriate monitoring tools should be selected to meet this purpose. Municipal storm water monitoring programs can be designed to support specific goals, including:

- Identifying/evaluating pollutant levels of discharges from areas and sites;
- Evaluating hydraulic conditions;
- Characterizing the performance of specific controls and providing information to support site-specific BMP designs;
- Evaluating the overall effectiveness of a storm water management program;
- Identifying water quality impacts and/or trends in water quality;
- Estimating/refining estimates of pollutant loadings;
- Supporting watershed protection/planning efforts; and,
- Supporting physical, chemical and biological assessments of receiving waters;
- Supporting national trends monitoring.

With the initial implementation of NPDES requirements for storm water, a number of key questions and issues have arisen in relationship to the purpose and methods for monitoring. Underlying these questions and issues is the central goal of trying to find the appropriate mix of monitoring tools to get information in a cost-effective manner to successfully implement NPDES storm water programs. Monitoring approaches developed under the NPDES storm water program should consider a broad set of monitoring tools, including environmental indicators. This is particularly true due to the intermittent nature of storm water discharges; the significant variability of pollutants in storm water; and the difficulties in correlating end-of-pipe storm water discharge data directly to water quality impacts and benefits.

EPA anticipates that a number of monitoring approaches will play a part in municipal storm water monitoring strategies in the future, including: discharge monitoring for chemical-specific parameters or toxicity, biosurveys, bioassessments, habitat assessments, instream monitoring, and sediment monitoring. Different goals for a municipal storm water management program can be best supported by different monitoring approaches.

VOL 12

7631

In some cases, municipal monitoring efforts conducted during the permit application process did not fully provide the kind of feedback that is necessary to develop the most effective storm water management strategies. EPA is looking at ways to improve municipal storm water monitoring during the permit application process to be more efficient and to derive the greatest benefits from the data collected. Such improvements can be incorporated into the NPDES regulations when the second phase of the NPDES storm water program is implemented and be made applicable to the monitoring that will be necessary when permits are re-issued to phase I municipalities.

For storm water discharges associated with industrial activity, storm water monitoring also plays an important role. As a result of the monitoring efforts during the permit application process, EPA and the NPDES authorized States will be able to write more applicable storm water discharge permits. Such information will also enhance dischargers' ability to identify pollutants of concern at the facility and to target pollutant sources when designing storm water management programs and pollution prevention plans.

Under the terms of an NPDES permit, storm water monitoring should be emphasized as a valuable tool for assessing the effectiveness of an industry's storm water pollution prevention plan and for examining possible receiving water impacts. With reliable storm water data, an industrial operator should be able to determine if current pollution prevention measures are adequate, or if additional measures, and possibly treatment controls, will be necessary. In addition, the ongoing effectiveness of the storm water pollution prevention plan can be assessed by tracking pollutant discharges over time. Finally, and most importantly, where necessary, monitoring of high-risk facilities can be required to ensure compliance with applicable State water quality standards.

STORMWATER MONITORING: LOCAL MUNICIPAL PERSPECTIVES

Doug Harrison[1]

Abstract

This presentation reviews the stormwater program mandate imposed on local agencies, the role of monitoring in the mandate, deficiencies which can be expected in the monitoring results and the impact of these deficiencies on the administration of local stormwater NPDES permit programs.

Introduction

There was a time in the recent past when, as a stormwater agency administrator I was looking forward to the monitoring programs required by the stormwater NPDES permit regulations. Frustrated by the obligation to implement a water quality control program and to comply with pre-existing unrelated standards without benefit of supporting data, the pendency of a structured program of scientific measurement was encouraging.

Implementation of the mandated stormwater monitoring programs through the NPDES permits promised help in defining the physical and chemical character of urban stormwater. In addition, these monitoring efforts promised the ability to identify the long-term changes produced by the stormwater permit programs. Unfortunately, the optimism generated by anticipation of solid stormwater quality data is rapidly deteriorating.

On the basis of an increasing body of work, it seems clear stormwater cannot, within the limits of existing resources, be characterized sufficiently accurately to determine the appropriateness or effectiveness of the stormwater quality controls local agencies are required to implement. Paradoxically, it is likely monitoring activities will divert critical funding away from activities which could actually improve stormwater quality.

---

[1] General Manager/Secretary, Fresno Metropolitan Flood Control District, 5469 E. Olive Avenue, Fresno, California 93726

<u>The Stormwater Quality Mandate</u>

The Congress, in enacting the Water Quality Act of 1987 attempted to clarify the stormwater obligations created by the Clean Water Act. In short, Congress imposed two basic mandates on municipalities that owned and operated stormwater systems.

1. ". . . effectively <u>prohibit</u> non-stormwater discharges into the storm sewers"; and

2. ". . . <u>reduce</u> the discharge of pollutants to the maximum extent practicable . . ." (emphasis added) (WQA, 1987)

To demonstrate "reduction", which is the obvious test of compliance with the Congressional mandate, a local municipality must first establish the current volume of pollutants being discharged. Secondly, the municipality must then determine, with accuracy at least equal to that in the initial determination, how much of the pollutants previously discharged are no longer being discharged. To arrive at this determination, the community must, of course, be able to distinguish between the changes in pollutant discharges caused by factors unrelated to the controls and those produced wholly by the controls.

To insure that these measurements are produced, the stormwater NPDES program regulation promulgated by EPA (November 16, 1990) added certain monitoring requirements to the congressional mandate. The regulation established a two-part application process which leads to an NPDES permit for the stormwater system. Monitoring requirements are contained in each of these three elements.

<u>Part I Application Requires:</u>

". . . quantitative data describing the volume and quality of discharges from the municipal storm sewer . . ."

". . . description of known water quality impacts."

". . . a field screening analysis for illicit connectings and illegal dumping.

<u>Part II Application Requires:</u>

". . . provide information characterizing the quality and quantity of discharges . . . from representative outfalls . . .;"

". . . estimates of the annual pollutant load of cumulative discharges . . . and the event mean concentration of the cumulative discharges . . . from all identified municipal outfalls for [specified constituents]."

VOL 12

7636

Permit Program Requires:

". . . monitoring program for representative data collection for the term of the permit . . ."

". . . monitor and control pollutants in stormwater discharges to municipal systems from . . . industrial facilities . . ."

"Assessment of Controls; estimated reductions in loadings of pollutants from discharges of municipal storm sewer systems . . ."

". . . identification of water quality improvements or degradations . . ." (USEPA, 1990)

In short, the regulation prescribing the elements of the permit program and related application process, outlined five questions local agencies are required to answer:

1. How much pollutant is being discharged?
2. Where is it coming from?
3. What harm has it caused?
4. How do you propose to reduce it?
5. How much did you reduce it?

Given the assumption that it was possible to generate data which would provide answers to these questions, the requirement for local municipalities to produce answers was logical. What is now in doubt however, is the validity of the underlying assumption.

If, in fact, it is not possible to accurately answer these questions the municipality is left in pursuit of a mandate which devours resources without any means of determining results or benefits. Of even more concern, municipalities are left without a defense for allegations of violation of the CWA.

The Critical Role of Monitoring in the Stormwater NPDES Program

Because of the previous conclusion, the justification and the potential for success or failure of the stormwater NPDES permit program is anchored to the monitoring element of the mandate. Only with accurate quantification of the stormwater problem, its sources and the achievable results can the stormwater program maintain its political priority, justify the allocation of resources, and provide the necessary means of enforcement. Clearly, the Congressional mandate for business and local government to spend hundreds of millions of dollars annually on stormwater quality was sold on the basis that preliminary conclusions generated by NURP could be specifically confirmed and quantified by a nation-wide permit driven monitoring program.

The Multiple Objectives of Stormwater Monitoring

Because of the inherent dependency of the stormwater regulatory effort on the program's monitoring component, that component has been assigned a variety of diverse objectives by the many key parties of interest.

- Activists, regulators and legislators must use the monitoring process to demonstrate that stormwater pollution is, in fact, a major controllable source of adverse environmental impacts, warranting the massive expenditures required to achieve "clean-up".
- Enforcement interests must demonstrate that site and use specific sources can be accurately measured to support the civil and criminal actions brought against CWA violators.
- Municipalities and business require data which will support the diversion of financial resources to stormwater quality, and to differentiate between inefficient controls and those which are cost effective.

Many other interests also color the structure of the monitoring program. Some are involved for the pure delight of research; others have an interest shaped by a profit and loss statement.

The impact of such a diversity of interests is compounded by two additional factors which are most significant. The first is the absence of a national strategy for stormwater monitoring and data development. The second is the ad hoc nature of the stormwater permit, with the structure of each of the permit monitoring programs being determined at the discretion of a relatively independent permit writer.

Unlike NURP, which established clear objectives and guidelines toward the goal of a nationally significant data base, the stormwater NPDES permit program has as many different monitoring strategies as it has permits.

The result of this diversified interest in stormwater monitoring has been a predictable disjointedness among the various monitoring programs. Some are conducting research on beneficial use impacts; others are examining sources. Some are examining land use differences while others try to explain hydrologic impacts. Some are still trying to determine how stormwater discharges differ from traditional

VOL 12

7638

point source discharges, and others are evaluating available forms of pollutants in the stormwater. Some may even be trying to do it all. Certainly, because of its complexities, every municipality could conduct focused stormwater quality research unique to their locale, and many permit writers are appearing to require it.

Recognizing that much monitoring and research is now underway, the question that must be asked is whether the results will be sufficiently accurate to justify either the cost of the stormwater quality program — or the cost of the monitoring itself.

Relationship Between Monitoring Costs and Stormwater Program Costs

The matter of stormwater program costs has been hotly debated. Estimates to fully implement the congressional mandate have ranged from the absurdly low levels presented by EPA in its November 1990 regulation ($14.5 million annually) (USEPA, 1990) to the fearfully high levels estimated by the APWA, Southern California Chapter in May 1992 ($542.0 billion annually) (James Montgomery, 1992).

Cost estimates defining stormwater program needs have been as detailed as the use attainability analysis performed by the City and County of Sacramento ($2.0 billion, local need) (Walker, 1993). Others, like EPA's 1992 Needs Survey Report to Congress ($116.5 million, national need) (USEPA, September, 1993) have excluded virtually all implementation costs associated with the stormwater NPDES permit program requirements.

The real issue buried in all of the rhetoric is "what do you get for what you spend?" It is in the satisfaction of this issue that monitoring again assumes the central focus of the entire stormwater quality program. Stormwater managers are being repeatedly asked by policy makers and administrators to demonstrate that the dollars invested will produce a verifiable result.

Unfortunately, a growing body of evidence is suggesting that, as currently structured, our stormwater monitoring program can do neither. More discouraging is that substantial increases in data usefulness cannot be achieved without massive increases in the resources allocated to the monitoring effort.

It has long been recognized that the variables associated with urban runoff, which include the limitless multiplicity of sources, the episodic nature of runoff events, the massive magnitude of source areas and flow volumes, and the unknown assimilative capability of receiving waters, prevented any hope of discreet cause and effect findings from stormwater monitoring. Expectations were high, however, that changes in the long-term stormwater quality trend lines produced by broadly based consistently applied control practices could be observed and measured, providing a form of program assessment and a measure of cost effectiveness.

VOL 12

7639

However, recent work by Woodward-Clyde (reviewed at this conference) has produced conclusions which create reservations about the validity of even this more conservative expectation. Specifically, Woodward-Clyde's work has produced the conclusion that significant increases will be required in monitoring program expenditures if changes in long-term stormwater quality trend lines are to be measured with any significant confidence.

The Woodward-Clyde analysis has determined that, for the Fresno California metropolitan area, 64 composite samples per year will be required over a ten year test period to detect with 80% confidence a 20% change in copper concentrations. This contrasts with the monitoring plan which was to be made a condition of the Fresno NPDES permit, that plan proposing 15 samples per year. However, we now know that at 15 samples, the Fresno program has only a 15% chance of detecting a 20% change over the 10 year test period.

Correspondingly, Woodward-Clyde's work indicates it will be much easier to detect large changes in the long-term stormwater quality trend lines. For example, again in the Fresno California case, the planned 15 sample per year program has a 48% chance of detecting a 30% reduction, and a 79% chance of detecting a 40% reduction.

The obvious caveat for program managers is the imperative of insuring that the control program creates a big change in stormwater quality. If not, your monitoring program is not likely to detect the impact at any significant confidence level.

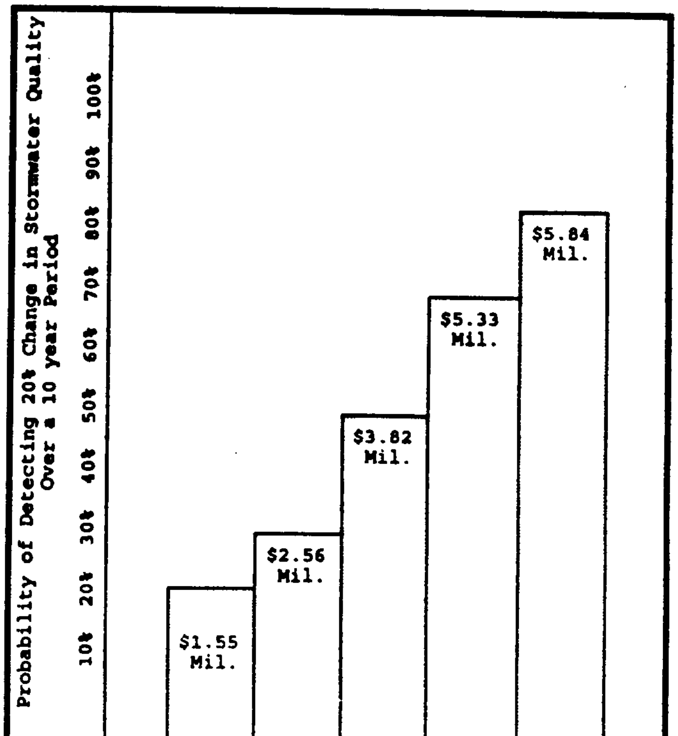
The significance of this information to stormwater program managers can be seen in Table No. 1. The table contrasts the monitoring program costs required under the pending Fresno area NPDES permit with the costs required to increase the confidence level of confirming a 20% change in stormwater quality from 20% to 80%.

As currently structured, the Fresno area NPDES stormwater permit program will expend $1.55 million dollars over the next ten years on monitoring (assumes annual expenditures of 1994 levels), but will achieve only a 20% probability of detecting a 20% change in stormwater quality. Based on the Woodward-Clyde work, to increase the confidence level to 50% the program must increase monitoring expenditures to $5.33 million; and to reach the 80% confidence level it must expend $5.84 million.

VOL 12

TABLE NO. 1

Monitoring Costs To Detect a 20% Change in Stormwater Quality (10 Year Test Period; Fresno CA)



Ten Year Monitoring Program Costs

(Annual costs in 1994 dollars; sampling, laboratory, and analytical costs only, excludes equipment and installation.)

7641

R0040949

Stated another way, the permit program now allocates 21% of the program budget to monitoring. To increase the confidence level of the monitoring results to 50%, the percentage of the permit program resources allocated to monitoring must increase to 27%. To achieve the 80% confidence level, 41% of the program's resources must be directed to monitoring.

Correspondingly of course, increases in the monitoring budget decrease other elements of the stormwater program such as public education, legal enforcement, or — heaven forbid — annual reporting. This places before the local program manager the unique dilemma of maximizing expenditures that are likely to produce a change in stormwater quality, while pursuing a "low confidence" monitoring program; or, increasing the confidence level of the monitoring by reducing the things which are likely to improve stormwater quality. The other option, of course, is simply to divert more money from other municipal needs to invest more in stormwater monitoring.

Arguing strongly for restraint in inflating monitoring budgets, in addition to the resultant reduction in stormwater control practices, is the related difficulty in identifying the cause of an observed change in stormwater quality. Even at the 80% confidence level of detecting a change, it remains doubtful the monitoring program can identify with any confidence, the cause of the change detected. Whether it was the program itself, some specific element of the program, or some other series of events, that produced the observed change is likely to remain an important unknown.

The scope of this issue becomes more visible when statewide and nationwide impacts of raising the monitoring confidence level are considered. While an admittedly primitive approach, the Fresno program can be used to create such an estimate. If it can be assumed Fresno is relatively representative of the stormwater monitoring programs in California, it can be estimated that annual stormwater monitoring activity would have to increase from the $3.7 million actually expended statewide in 1993-94 to $9.1 million in order to achieve the 50% confidence level, and to $13.9 million to reach the 80% confidence level.

Relatedly, if California bears the same permit program monitoring cost relationship to the rest of the nation as it does with respect to the total of all permitted municipalities (35.4% of all permitted communities are in California) (USEPA, October, 1993), it is possible to estimate the confidence level cost impact on a national basis. On this basis, the nationwide cost to achieve the 20% confidence level will total $10.45 million per year. (This represents an estimate of the basic permit monitoring requirement cost which will be incurred by the total of all permitted municipalities assuming no substantive variances from the obligations imposed on California communities). To achieve the 50% confidence level, annual nationwide monitoring costs must increase to an estimated $25.75 million; and to achieve the 80% confidence level, the annual nationwide costs must increase to $39.4 million. (It is noted that monitoring costs, expressed in annual terms, must continue at the same level for ten years to produce the desired confidence level data base.)

VOL 12

7642

Conclusion

The stormwater quality program is the object of intense scrutiny by political, environmental, municipal, and business interests. However, because the program's accountability to all of these interests is so completely dependent on reliable data, the program cannot achieve the objectives ascribed to it without an effective monitoring program producing dependable information.

It is this manager's opinion that the requisite information cannot be developed, and the ascribed objectives cannot be achieved without fundamental changes in the structure of the stormwater quality program.

First, we must change the presumption that stormwater quality problems and solutions can be as easily identified and quantified as other point source problems; and the presumption that given a little time, we can drive stormwater quality into compliance with traditional standards.

It seems a reasonable conclusion that, if we can't clearly measure how much stormwater quality has been changed, it is not likely we can measure how much pollution stormwater carried to begin with. Relatedly, if it is so difficult determining if all of the things we did caused a change, it is even more unlikely we can measure the change caused by any one thing we've done. The same conclusion also applies to accurately identifying the stormwater pollution sources.

Secondly, we must change our approach to defining the problem and testing for solutions. The weak repetitious characterization studies, haphazard source investigations and miscellaneous "nice to know" projects occurring through the permit process must be replaced with a national stormwater quality monitoring and research strategy. Specific goals and objectives must be developed and then implemented through the permit programs by means of specifically focused target/pilot studies. Only that duplication necessary for statistical confidence should be permitted and all efforts should be held accountable to rigid procedural guidelines and QA/QC standards.

The sampling, analysis and development of conclusions should be routinely supervised by a national data coordinating unit, and the data aggregated into a functional data base for use by the political, environmental and municipal interests. From such a data base, appropriate discharge standards for both end-of-pipe and receiving water conditions can then be extracted and useful measurements for assessing effective control practices can be developed.

Unless there is such a change in the structure of the stormwater monitoring program, we are destined to invest a major portion of the stormwater program finances in activity which produces dubious information and no stormwater quality improvement.

VOL 12

7643

Given the magnitude of costs associated with the stormwater quality program, our nation's municipalities simply can not afford to have such a large percentage of its expenditures so unproductively used. Neither can we afford to impose such a devastatingly expensive standards compliance mandate on the basis of irrelevant or inaccurate data. Only with the proper structuring and conduct of a nationwide monitoring strategy can we produce the data necessary to insure successful attainment of the rightful objectives assigned to the stormwater program.

HOW CONGRESS SHOULD ACT ON STORMWATER

Howard Holme[1]

August 10, 1994

ABSTRACT

Cities, industry, and the EPA have resisted, not implemented, stormwater regulation aimed at the near perfection of Water Quality Standards, for over 20 years. The past statutory approach should be repealed and replaced. Congress should rewrite the statute to initiate a flexible, voluntary, cooperative program using a reasonable amount of federal and state or local funding to fix real water quality problems cost-effectively by letting potential and actual polluters bid to reduce pollution.

INTRODUCTION

The author of this paper describes what he thinks should be done with the stormwater subsection of the Clean Water Act (CWA), subsection 402(p). His vision is very different from the way the subsection has been in various forms over the past 22 years, and very different from the proposals Congress is currently contemplating in competing drafts.

The past program is a failure. Can this stormwater program be changed into what the population, the cities, the U.S. Environmental Protection Agency (EPA), and the Congress want? They want a better, more flexible CWA, using partnerships between the federal, state, and local governments, and business, based on good science and realistic risk assessment, designed to reduce damage

[1] Howard Holme, Stanford University A.B., 1967 with distinction, and Honors; Yale Law School, J.D. 1972, is an environmental and water lawyer at Fairfield and Woods, P.C., Suite 2400, 1700 Lincoln St., Denver, Co. 80203-4524. (303) 830-2400, fax (303) 830-1033.

to human health, the economy and the environment from harmful sources of pollution, and to prevent or reduce the worst pollution for the least necessary cost.

The format of the paper is first to state a proposed amendment to Section 402(p), and then to defend it in the form of a proposed Conference Committee report, which repeats and explains the amendment.

PROPOSED AMENDMENT TO SECTION 402(p) CONCERNING STORMWATER.

Section 402(p) of the Federal Water Pollution Control Act (33 U.S.C. 1342(p)) is repealed (along with its supporting regulations, guidelines, and opinions) and reenacted to read as follows:

"(p) MUNICIPAL, INDUSTRIAL, AND OTHER STORMWATER DISCHARGES.--

"(1) GENERAL RULE.--Permits for discharges composed of stormwater are not required under this Act, though they may be subject to Section 319, relating to nonpoint source management programs.

"(2) VOLUNTARY PROGRAM.--The Administrator may establish a voluntary program to reduce the discharge of pollutants from stormwater as follows:

"(A) The Administrator shall consult with persons with expertise in the management of stormwater (including officials of local and state governments, the Soil Conservation Service and scientists), to prepare a request to the National Academy of Sciences to use existing stormwater monitoring and other information and knowledge to report to the Congress by January 31, 1997

"i) compiling a database of stormwater data to be available to the public,

"ii) analyzing stormwater data,

"iii) estimating the present danger or lack of danger of stormwater discharges to human health and the environment, using realistic risk assessment assuming average populations and fully stating uncertainties, "iv) describing programs which the Academy would recommend for entities which want voluntarily to reduce pollution in the most cost-beneficial manner, estimating the economic costs and benefits to the human economy from such programs.

"(B) The Congress authorizes $ _ billion per year from Fiscal Year 1998 to 2002, to be spent for those projects which

"i) are authorized by the local and state governments in the areas directly affected by the projects as well as by the Administrator, and for which local and state governments authorize 50% of the necessary total governmental expenditure,

"ii) prevent or reduce the discharge of particular pollutants in ways that will have the greatest benefit to human health and the economy for the least cost,

"iii) rely on private parties and governments (neither of which shall be preferred over the other) to enter closed bids for the reduction of amounts of the pollutants. Closed bids shall be accepted on the lowest cost per gram of pollutant, either for prevention of otherwise expected discharge of pollutants or reduction of present discharge of pollutants."

PROPOSED CONFERENCE COMMITTEE REPORT ON PROPOSED AMENDMENT TO SECTION 402(p) CONCERNING STORMWATER.

The text of the proposed amendment is repeated in bold, with explanation following.

Section 402(p) of the Federal Water Pollution Control Act (33 U.S.C. 1342(p)) is repealed (along with its supporting regulations, guidelines and opinions)

History of the stormwater effort.

"Storm water means storm water runoff, snow melt runoff, and surface runoff and drainage," 40 CFR § 122.26(b)(13) (1992), but not infiltration. 55 FR at 47,996. Federal law has consistently required National Pollutant Discharge Elimination System (NPDES) compliance for point source discharges of stormwater since 1972. 33 U.S.C. §§ 1311, 1341, 1342 (sections 301, 401, and 402 of the CWA). Various regulatory attempts and lawsuits did not lead to

VOL 12

7647

R0040955

cleanup of stormwater. 1973 EPA regulations and large exemptions; NRDC v. Train, 396 F. Supp. 1393 (D.D.C. 1975), aff'd. NRDC v. Costle, 568 F.2d 1369 (DC Cir. 1977); EPA regulations in March 1976, EPA regulations in 1979; NRDC v. EPA, 673 F.2d 392 (DC Cir. 1980); EPA regulations September 26, 1984, 49 FR 37,998; EPA proposals in March and April 1985, 55 FR 47,991. The Water Quality Act of 1987 attempted to cure the general lack of stormwater permits by suspending the permit requirement and allowing EPA to adopt stormwater permitting regulations in phases.

"Phase I" regulations were adopted by the EPA on November 16, 1990, primarily to regulate discharges from municipal separate storm sewer systems serving populations of at least 100,000. 55 FR 47,990.[1]

Regulations for "Phase II" (all other stormwater discharges) were originally required to be issued by October 1, 1992, and Phase II sources were not required to obtain a stormwater permit until October 1, 1992. EPA missed the original October 1, 1992 deadline, and Congress shortly thereafter extended the Phase II deadlines two years to October 1, 1994. 42 U.S.C. § 1342(p).

EPA solicited public comment on possible approaches for developing the Phase II program, and raised questions of amending the CWA to allow EPA to regulate problem stormwater discharges rather than requiring regulation of all Phase II facilities. 57 FR 41,344, 41,349, (Sept. 9, 1992).[2] Many commenters suggested suspending Phase II.

The program has failed. It costs too much and provides too little benefit.

Through 1994, the stormwater regulatory program has been a failure. Past programs were going to cost too much money for too little benefit.

The costs were too great. Full construction of advanced treatment plants for stormwater from municipalities serving populations of at least 100,000 were estimated (in the most comprehensive study yet done) to have a capital cost of $406 billion and annual costs of $542 billion--about one-tenth of the Gross National Product.[3] Yet even this impossible level of spending probably would not meet Water Quality Standards (WQSs).

Sacramento estimates it would cost $2 billion to try, (valiantly but unsuccessfully) to meet WQSs for 5 metals. Sacramento studied the cost of compliance with only 5 common metals, chromium, copper, lead, and zinc, ignoring organics because "few data exist on the concentrations of organic pollutants."[4]

VOL 12

7648

"Stormwater discharges to the Sacramento River will be unable to achieve the water quality-based effluent limitations for copper and zinc even with the use of a mechanical treatment facility (similar to a water treatment plant) employing lime precipitation, sedimentation and filtration, in combination with discharge through an outfall designed for rapid mixing."

"The estimated present worth cost of such a system, designed to handle flows associated with the *mean annual storm, is on the order of $2 billion.*"

Denver estimates it would cost more than *$1 billion* for structural Best Management Practices (BMPs), a far less expensive treatment alternative. Cities over 100,000 in population have already spent an estimated $130 million to prepare for NPDES permit applications.

No one has demonstrated a problem from stormwater runoff serious enough to justify huge unfunded mandates.[5]

The Nationwide Urban Runoff Program (NURP), designed to find water quality problems caused by urban runoff, found surprisingly few problems. We quote NURP's primary findings, which it underlined:

1. Frequent exceedances of heavy metals ambient water quality criteria for freshwater aquatic life are produced by urban runoff. . . .

2. Although a significant number of problem situations could result from heavy metals in urban runoff, levels of freshwater aquatic life use impairment suggested by the magnitude and frequency of ambient criteria exceedances were not observed. . . .

> However, those NURP project studies which examined this issue did not report significant use impairment problems associated with urban runoff.

3. Copper, lead and zinc appear to pose a significant threat to aquatic life uses in some areas of the country. Copper is suggested to be the most significant of the three. . . .

> [Except in the southeast and southern regions of the country] problems would be expected only in rather unfavorable conditions. . .

4. Organic priority pollutants in urban runoff do not appear to pose a general threat to freshwater aquatic life. . . .

VOL 12

7649

5. The physical aspects of urban runoff, e.g., erosion and scour, can be a significant cause of habitat disruption and can affect the type of fishery present. However, this area was studied only incidentally by several of the projects under the NURP program and more concentrated study is necessary. . . .

6. Several projects identified possible problems in the sediments because of the build-up of priority pollutants contributed wholly or in part by urban runoff. However, the NURP studies in this area were few in number and limited in scope, and the findings must be considered only indicative of the need for further study, particularly as to long-term impacts. . . .

7. Coliform bacteria are present at high levels in urban runoff and can be expected to exceed EPA water quality criteria during and immediately after storm events in most rivers and streams. . . .

8. Domestic water supply systems with intakes located on streams in close proximity to urban runoff discharges are encouraged to check for priority pollutants which have been detected in urban runoff, particularly those in the organic category. . . .[6]

Most of EPA's budget is devoted to avoiding human contact with toxic substances, and avoiding cancer. In 1987, EPA listed its priorities and estimated numbers of cancers in Unfinished Business.[7] *EPA failed to estimate or estimated less than one death per year from point source and nonpoint source discharges to surface water, groundwater contamination other than municipal or hazardous waste sites, and discharges to wetlands, estuaries, coastal waters and oceans.*[8]

The past approach is repealed, in recognition that the premise of compliance with WQSs is impossible and unnecessary to meet.

The core premise underlying stormwater regulation has been that stormwater would meet the near perfection of WQSs, sooner or later. EPA has, several times, interpreted WQSs to apply to stormwater permits for both industrial and municipal discharges. EPA Office of General Counsel opinion on "Compliance with water quality standards in NPDES permits issued to municipal separate storm sewer systems," (E.P.A.G.C., January 9, 1991 from E. Donald Elliott, Assistant Administrator and General Counsel (LE-130), which cites 1991 WL 326640. CWA Sections 402(p)(3)(B)(iii), 301(b)(1)(C), 53 FR 49,457 (Dec. 7, 1988), 40 CFR 122.44(d). These authorities are repealed.

Even the 1994 proposed reauthorizations in both Houses of Congress were based on that premise. S. 2093, Sec. 402 said "during the 10-year period" following enactment municipal storm sewer permits "shall not require compliance

VOL 12

7650

with numeric effluent limitations and water quality standards." (proposed amendment to Section 402(2)(D). Senate Report 103-257, "Water Pollution Prevention and Control Act of 1994, Report of the Committee on Environment and Public Works to accompany S. 2093, May 10, 1994. This report says "When this [10 year] period expires, NPDES permits for stormwater discharges *must include enforceable numeric effluent limitations in the same manner as any other NPDES permit*. The "Substitute House Legislation to Reauthorize the Clean Water Act Introduced April 21, 1994, BNA Daily Environment Report, No. 78, pp. E-1-E--53 (April 25, 1994), amendment to the same section prohibited, with exceptions, permit requirements to comply with numeric effluent limitations or applicable water quality standards before December 31, 2009.

The premise of the last 22 years is impossible and unnecessary to meet. For example, June 23, 1994, the Committee on Ground Water Cleanup Alternatives of the National Research Council said restoring contaminated groundwater to safe drinking standards, as called for in federal laws, is not technologically feasible. The 1972 Clean Water Act which set the idealistic goal "to restore and maintain the *chemical, physical, and biological integrity of the nation's waters*." Section 101(a). "Integrity" could have been interpreted under Webster's Third International Dictionary to mean "complete or undivided," but instead has been interpreted to mean "an uncompromising adherence to a code of moral, artistic, or other values"[9] of fractions of one part per billion, trillion, and even quadrillion. Chemical integrity of water, at least as many would interpret the term now, means H_2O, and nothing but H_2O. The Congress established "the national goal that the discharge of pollutants into the navigable waters be *eliminated*." Section 101(a)(1). Except with a permit, generally "the discharge of *any* pollutant by any person shall be *unlawful*." Section 301.[10] Yet many regulations and programs are justified by reference to, and blind attempts to, achieve this impossible dream.

Combined Sewer Overflows (CSOs), being addressed in new subsections 402(q), are now recognized as not being able to reach WQSs by 2009, but only "reasonable progress toward attainment of applicable water quality standards." The society cannot and should not make all water that clean. WQSs are often hundreds or thousands of times more stringent than drinking water standards, and unnecessarily stringent, especially during short storm events.

The past goals cannot be met even when the nation spends tens of billions of dollars per year for over 3 decades (1972 to 2009). WQSs will not be achievable in 2009, just as they are not achievable in 1994. Further, the problem of stormwater regulation does not justify the attempt.

VOL 12

7651

"(p) MUNICIPAL, INDUSTRIAL, AND OTHER STORMWATER DISCHARGES.–"

Past legislation to clean up stormwater has dealt exclusively with municipal and industrial stormwater from point sources. Stormwater, in the normal sense of water from storms, forms all the fresh water on the earth, both surface and ground water, from both point and nonpoint sources. The distinctions between surface versus ground water, piped versus street flow runoff, and urban versus exurban are increasingly artificial as people clean up even more sources of pollution. As this program moves from a command and control program to a voluntary program, it makes sense to allow pollution prevention and pollution sources such as agriculture to join in the pollution reduction. Thus, "other" stormwater discharges are now included.

"(1) GENERAL RULE.–Permits for discharges composed of stormwater are not required under this Act, though they may be subject to Section 319, relating to nonpoint source management programs."

Because the past program has failed and would not reasonably be expected to succeed in terms of reaching WQSs, this amendment changes the approach of the program and removes it from the water quality permitting program. It does not repeal other programs which also reduce stormwater pollution.

"(2) VOLUNTARY PROGRAM.–The Administrator may establish a voluntary program to reduce the discharge of pollutants from stormwater as follows:

"(A) The Administrator shall consult with persons with expertise in the management of stormwater (including officials of local and state governments, the Soil Conservation Service and scientists, to prepare a request to the National Academy of Sciences to use existing stormwater monitoring and other information and knowledge to report to the Congress by January 31, 1997"

Subsection (p)(2) establishes and describes a voluntary program. One past problem with stormwater regulation is its lack of scientific base. The NURP program found few if any problems from stormwater. The Phase I stormwater program has required the gathering of large amounts of data, which has not been adequately analyzed for the information it can provide as to whether and how stormwater should be regulated. This provision requires greater use of scientific expertise, including that of the National Academy of Sciences, which needs adequate time to analyze the newer data.

VOL 12 7652

By including the Soil Conservation Service, the bill recognizes that agriculture is the leading cause of water quality impairments in rivers, streams and lakes, ahead of urban runoff and storm sewers.[11] The 1985 Farm Bill, and the 1990 Farm Bill, and perhaps future Farm Bills will contribute to reductions of stormwater runoff. The U.S. Department of Agriculture estimates that conservation compliance plans for highly erodible land will have reduced erosion from a national average of 17.5 tons per acre in 1985 to 6 tons per acre by the end of 1994.[12] By including local and state governments, it recognizes them as partners in the planning, as they will be partners in the spending and implementation of projects.

"i) compiling a database of stormwater data to be available to the public,

"ii) analyzing stormwater data,

"iii) estimating the present danger or lack of danger of stormwater discharges to human health and the environment, using realistic risk assessment assuming average populations and fully stating uncertainties,

"iv) describing programs which the Academy would recommend for entities which want voluntarily to reduce pollution in the most cost-beneficial manner, estimating the economic costs and benefits to the human economy from such programs.

Despite 20 years of regulatory effort, insufficient data have been usefully complied into a database and thoughtfully analyzed.[13] With past studies not showing serious actual harm to human health, the economy, and the environment to justify a large regulatory program, the National Academy of Sciences would be delegated to do a thorough and reasonable risk assessment of the danger to actual and average populations. The National Academy of Sciences should do risk assessment and cost-benefit analysis in similar fashion to that contemplated by Senator Bennett Johnston's Amendment No. 1720 to the Senate's Safe Drinking Water Act Reauthorization Act of 1994 (S. 2019).

Because future projects would be voluntary, information must be gathered as to what future efforts would be cost effective, and reasonable for cities and states, as well as the federal government to undertake.[14]

"(B) The Congress authorizes $ _ billion[15] per year from Fiscal Year 1998 to 2002, to be spent for those projects which

VOL 12 7653

R0040961

After the National Academy of Sciences Study, but well before the WQSs deadlines in either S. 2093 or the substitute to H. 3948, money will be authorized, and appropriated, to begin preventing, and cleaning up, stormwater pollution.

"i) are authorized by the local and state governments in the areas directly affected by the projects as well as by the Administrator, and for which local and state governments authorize 50% of the necessary total governmental expenditure,

There is more talk than action on partnership of federal, state, and local governments of flexibility. This program requires approval, and funds from all three levels of government. National, regional, state, and local planning committees would need to operate. If stormwater cleanup is a high priority, then many projects exist for which states and localities want to contribute 50% to the prevention or cleanup. Contribution from all three levels of government will help prevent both "pork barrel" projects viewed as important only by a few members of Congress, and projects not viewed as important at the state and local levels. Flexibility will be returned to this area of the Clean Water Act, because some projects will be extensive, and other geographic areas will not participate, at least for now.

"ii) prevent or reduce the discharge of particular pollutants in ways that will have the greatest benefit to human health and the economy for the least cost,

During a cooperative planning process, parties would study controlling stormwater pollution by prevention or reduction, and by non-structural means, including public education and community participation, as well as by structural means.

For many problem areas, one or a few pollutants or indicators may serve as representative for the cause of the real problem. Some pollutants may be high in volume, but low in toxicity or other characteristics that cause problems. Other pollutants may be low in volume, but cause, for example, serious shellfish kills which hurt the economy. If oil is the problem, oil refineries, city sweepers, and oil recyclers might bid for reduction of oil getting to the streams.

The stormwater program shall concentrate on costs and benefits, and recognize that most real problems, and real benefits, are reflected in human health and the economy. The Administrator may develop guidance or regulations for the implementation of the program which will achieve the greatest benefit to human health and the economy for the least cost, which will encourage at least partial solution of the worst problems first, and obtain the "most bang for the buck."

"iii) rely on private parties and governments (neither of which shall be preferred over the other) to enter closed bids for the reduction of amounts of the pollutants. Closed bids shall be accepted on the lowest cost per gram of pollutant, either for prevention of otherwise expected discharge of pollutants or reduction of present discharge of pollutants."

After local, state and EPA officials have determined there is a serious problem deserving of funding, they may develop a proposal for a project and put it out for bidding. Both private and public entities may bid, and for any reasonable amount of prevention or reduction of pollution. If in one watershed, erosion, stream sedimentation, and salinity are the problems, perhaps cities will bid for reduction of salt and sand use in the winter and more better street sweeping, while some farmers bid to reduce plowing at the edges of the streams, and other farmers on saline land bid to stop farming. If in another watershed copper is killing fish, perhaps mines will bid to cover abandoned mine tailings, and an automotive company will bid to replace copper brake shoes with a more expensive but more benign brake shoe.

A National Academy of Sciences analysis of regulations measuring cost-effectiveness by the cost per kilogram (kg) of PCBs found the cost-effectiveness of the alternatives analyzed varies by a factor of 200,000. 99.9% of the available control would come by certain regulations, while *other regulations, attempting to control the remaining 0.1%, would double the cost of regulation. The government "has declined to incur costs of $731 per kg to reduce risk through the control of PCBs in the diet, while it has incurred costs of over 100 times that amount to prevent the risks associated with releases from contaminated hydraulic fluids.*[16] With a voluntary program of bidding for pollution prevention and reduction, the cost of a given amount of environmental improvement will be much less than with command and control regulations.

The Administrator may develop guidance or regulations on how to evaluate prevention of otherwise expected discharge of pollutants. Some states may decide the voluntary program is insufficient to control, for example, new subdivisions or factories. States, of course, can adopt more stringent standards or requirements than this subsection.

the Conservation Reserve Program for filter strips and to rebuild riparian zones, and improve wetlands.

13. "Historically, the Nation has made a meager commitment to the collection and analysis of toxics data; however, most of these efforts have been poorly designed from an experimental perspective and suffer from inadequate QA/QC and inconsistencies in sampling and analytical methods. The net result is that we have almost no useful instream toxics data upon which to base our decision-making." D. R. Wheeler, "Where is the Pendulum Now? Do We Really Know?," in Howard Holme, Ed., National Water Resources Regulation--Where is the Environmental Pendulum Now?, American Society of Civil Engineers, 1994; Kelly A. Cave, et al "Overview of Stormwater Monitoring Needs, at p. 6, in this volume.

14. National Science Foundation grants and EPA, under the national estuary program, have funded broad-based environmental and water quality studies for several major watersheds, including San Francisco Bay, the Delaware River, and Chesapeake Bay. These studies recommend pollution control programs very different and much less expensive than those under current 402(p). William Whipple, Jr., et al, "Drawing Conclusions as to Environmental Regulation," in Howard Holme, Editor, National Water Resources Regulation--Where is the Environmental Pendulum Now?, American Society of Civil Engineers, 1994.

15. The number of dollars is left blank for this Engineering Foundation paper. The amount to be spent is obviously a policy and political question. Many cities may think other urban needs are more serious than the needs to clean up stormwater, and can say so to their member or members of Congress. Lobbyists for water and environmental interests may support spending tens of billions, or conceivably hundreds of billions of dollars per year to clean up stormwater. Not to vote for a specific amount of money for the problem, but to rely on an unfunded mandate, invites a terrible decision to be made.

SESSION V: Policy & Institutional Issues of NPDES Monitoring

DISCUSSION

Stormwater Permitting - An Industrial Experience
P. Charles Beck

Coors has been in business for 175 years. Built first industrial waste treatment plant in Colorado. Have classified operations for permitting purposes as:

- Heavy industrial permit - brewing, can Manufacturing, abandoned landfill
- Light industrial permits
- Gravel mining

BMPs currently applied:

- Housekeeping processes
- Covered trash bins have been effective
- Covered storage
- Valves on drains to fuelling areas
- Roof drains and drains from some other possible spill areas go directly to the treatment plant

Concerns:

- Regulatory redundancy and bureaucracy
- Cost to implement is $250,000 vs. EPA estimate of $25,000
- Program goals not well defined
- Program support not enthusiastic
- Will numeric standards be mandated?
- Will structural controls be mandated?

Recommendations:

- Air control arena provides insight into improving stormwater regulation program
- Enforceable stormwater quality algorithm is needed

Strategies for Using NPDES Storm Water Data
William Swietlik, William Tate, Robert Goo and Eric Burneson

Municipal Permits

- Current regulations allow a municipality and the permit writer to jointly work out a sampling program for the local area.
- Examples of good monitoring programs: Santa Clara County,CA; Austin, TX; Charlotte, NC; Montgomery County, MD.
- Charlotte, NC, has developed an in-stream rating system based on concentration ranges. Action levels were defined (no action, watch, action). A correlation matrix was developed between pollutants and sources. These suggest the most likely sources of pollution - if they are detected in monitoring program.
- Montgomery County - permit application is focused on bio-assessment and habitat analysis. (Editor's note - Montgomery County is looking at citizen involvement in some of the simpler aspects of the monitoring program). These data will be used in long-term trend analysis (similar to Ohio).

Industrial Permits

Group Applications

- TSS is highest concentration (50% of sites had concentrations greater than the NURP mean).
- High metals concentrations
- Many of the high constituent concentrations come from industries that conduct activities outdoors, or have exposed materials stockpiled outdoors.

Uses of Industrial Data

- Identify pollutants of concern
- Target BMPs
- Identify high risk industrial sectors
- Arrive at permit monitoring provisions - if second year data show a decrease in concentrations, monitoring can be dropped.

Future Direction - Municipal

- Flexibility
- Three regulatory factors - costs, tool availability, purpose

VOL 12

- Watershed planning, long term tracking of results, environmental indicators
- Phase II MS4s and Phase I MS4 reapplication - reflect experience gained from Phase I.

Future Direction - Industrial

- Assess effectiveness of P3 and GPs
- Assess potential for environmental impacts
- Watershed permitting and waste load allocation
- Data for second rounds
- BMP effectiveness evaluation

Questions/Comments

Question: When will EPA come to grips with the definition of "maximum extent practicable (MEP)?

Answer: Agency has tried to provide guidance, but it's a tough problem. Sort of letting municipality and permit writer come to agreement on what constitutes MEP for the particular municipality. Sections 301 and 402 of the Clean Water Act do not allow relief from attaining water quality standards. The reauthorization bills now before Congress may define MEP.

Question: How is the quality of data collected by industry addressed by EPA?

Answer: EPA recognizes that there may be some question about the accuracy of the data, but considers it acceptable for identifying pollutants of concern.

Stormwater Monitoring: Local Municipal Perspectives
Doug Harrison

California municipalities have been under permit for the last three years and are in the process of negotiating Round II. They have been monitoring for the last 3 years and will use this information in renegotiating the monitoring provisions in permit renewals.

Monitoring program results indicate that we are not reducing pollutant loads from urban runoff. Monitoring info is also not telling us what to do. The present NPDES monitoring programs are taking too few samples to be statistically significant in terms of determining differences and/or changes in quality (monitoring does not ensure compliance, yet it has shown that water quality has not been improved).

7560

Identification of performance of control mechanisms, documentation of impacts, documentation of water quality improvements is required by EPA regulations, but monitoring results are indicating that we cannot determine these things.

The EPA mandate used to be to reduce pollution to the MEP. A new aspect to the EPA mandate is that urban runoff must meet WQS in receiving waters.

Unless stormwater programs can demonstrate success (improved environment) to the public, the public will cease to fund it.

We need a national strategy for stormwater management.

Permit writers are too independent in determining content of stormwater permits.

To show with 80% probability a 20% pollutant reduction in storm water will require Fresno to increase present monitoring budget by a factor of 4. Present program provides a 15 percent probability that they can detect a 20% change.

Monitoring costs about $1.5 million/5 years, yet, according to their consultant, this will not provide statistically significant results.

Conclusions

- Must. document uncertainty in the data.
- Agree with Mike's (Cook) prioritization, but emphasis is on his lowest priority, pollutant reduction.
- Our monitoring programs are not supporting management decisions.
- Need Congressional help to set the national management strategy.
- Need to get away from end-of-pipe measurement.
- Need to change the presumption that it is easy to identify stormwater quality problems.

How Congress Should Act on Stormwater
Howard Holme

Congress should rewrite the statute to require a reasonable program, subsidized by the federal government, allowing municipalities to solve real water quality problems.

The requirement of water quality standards (WQS) must be repealed, recognizing that WQS are impossible and unnecessary to meet. Present requirement would require 10% of the national GNP.

VOL 12

7561

R0040969

Human health is the highest priority for WQ management; EPA estimated less than 1 death per year related to point or non-point source discharges. (Editor's note - this is probably not a good statistic).

Stormwater pollution control should be a voluntary program.

Private entrepreneurs should bid to reduce pollution or pollutants.

Congress should recognize the need for cost-effective water quality management.

<u>Questions/Comments</u>

Question: Proposal is interesting, but contrary to current mind of Congress. Also, how will successful bidders be monitored to insure they spend the money and achieve promised results?

Answer: This would need to be worked out, but thinks it would be more cost-effective than command and control.

Comment: (Holme) Now we debate whether there should be federal subsidies; shouldn't we pay to fix our own problems?

Question: How is ecological health included in your proposal?

Answer: If Congress deems it necessary, then just add this provision to the statute.

Question: Ohio data base contradicts the conclusion that stormwater has not affected the environment. Maybe we are not using the right tools to identify the problems.

Answer: A valid criticism, but current WQ act is still chemically oriented in identifying problems and not addressing that problem. Time is needed to develop the appropriate tools.

Question: Given the fact that the present monitoring is not answering the desired questions, does EPA intend to change its rules and regulations regarding monitoring?

Answer: Maybe the wrong type of monitoring was selected. If a municipality thinks its monitoring program is not accomplishing its purpose, then change the program.

Question: Swietlik (EPA) indicated that there is flexibility in the monitoring program. How do we educate permit writers to interpret the regs in a similar fashion?

Answer: This is a problem and requires an education program. There is a gap in the information and guidance that EPA can give them.

VOL 12

7562

VOL 12

Comment: (on Harrison's talk) As a professional engineer, there is a requirement to maintain a standard of practice in technical programs for pollution control, but the public also has a role. It is necessary to have the public involved in monitoring violations and support of stormwater management programs. Mr. Harrison seems to feel that there is not enough money to carry out the program, therefore we need public volunteers to gather WQ samples.

Comment: Much of the country is doing permit application monitoring, not compliance monitoring. Compliance monitoring is a different animal and is oriented at determining progress in meeting requirements of the WQ Act. (Editor's note - inference is that maybe this is where we switch to biological monitoring). Data on the effectiveness of the management program is what is needed.

Comment: New Zealand (Aukland) has determined from bio-assessment that shellfish are affected by urban runoff. The process is then to move toward educating the public (who must approve funding of these programs) on the problem, and then moving initially toward mitigation of these problems by going directly into BMPs to reduce pollution.

7564

PARAMETERS TO REPORT WITH BMP MONITORING DATA

By Ben R. Urbonas, M. ASCE*

ABSTRACT

This paper presents an argument for standardization of the physical, chemical, climatic, geological, biological, and meteorological parameters being reported along with the data acquired by various investigators on the performance of structural stormwater Best Management Practices (BMPs) used to enhance stormwater quality. Also, a standard minimum list of such parameters is suggested. Such a list is needed if we want to have a meaningful exchange of data among the various studies being conducted throughout the world. Transferability of performance results and consistency, or lack of it, in the performance of various BMPs has been an ongoing problem. A mutually agreed upon minimum list of reporting parameters that can be used to relate the performance of BMPs to some, or all, of these parameters could begin to address this problem. Over time such standardization will conserve the resources being expended by various field investigations and may eventually lead to improvements in the selection of, and the design of, various BMPs.

INTRODUCTION

Much data have been collected over the past 10 to 20 years on the performance or "efficiency" of many structural stormwater quality BMPs. Most existing data relate to the performance of detention basins (i.e., detention basins that drain out completely after a storm runoff end, sometimes called "dry pond"), retention ponds (i.e., ponds that have a permanent pool of water and retain at least part of one storm's runoff after its runoff period ends, sometimes called "wet pond") and wetlands. Less data are available on field effectiveness of other types of BMPs. However, this data and/or its reporting lacks consistency. In addition, many of the reported results do not show clear mathematical relationships between the performance of similar BMPs among various sites in which they were investigated. One of the reasons may be that

* Chief, Master Planning & South Platte River Programs, Urban Drainage and Flood Control District, 2480 West 26th Avenue, Suite 156B, Denver, Colorado.

sufficient parametric information about each site has typically not been reported along with the performance data to permit systematic analysis of data collected under a variety of field studies, or to relate these data to a set of physical, climatic, geologic, or hydrologic conditions.

What we have now is a variety of independent interpretations with very little attempt to relate to other investigations that may have occurred in the past or may be occurring concurrently. Some of these interpretations may make a lot of sense while others leave us wondering and questioning what was studied, what was found, and why? More importantly, we cannot answer with any degree of confidence what role various site parameters play in the performance of any particular BMP.

As an example for a retention pond, is it more important to know the *pond size vs. inflow event volume* ratio when designing for the removal of Total Suspended Solids (TSS) or Total Phosphorous (TP), or is it more important to know the *surface area of the pond vs. tributary watershed area* ratio, or is another set of parameters more important? Such questions can only be answered by systematic and consistent BMP monitoring activities, wherever they may take place. Without these we will never be able to develop reliable, field tested, selection and design guidance for structural BMPs, guidance that we need to use these BMPs with confidence.

When we examine what occurs at a retention pond, there are two distinctly separate phases of sedimentation. The first takes place during storm runoff when settling occurs under turbulent conditions. The other takes place during the quiescent conditions between storm runoff periods. In addition, between runoff events biological and chemical processes can remove or remobilize suspended and dissolved constituents in the water column.

In the TSS removal example discussed above, the settling of solids under quiescent conditions is a function of particle density, particle size and the fluid's viscosity, which in turn is a function of temperature. According to Dobbin (1944) and Camp (1946), particle settling under dynamic inflow conditions is dependent on the unit surface hydraulic loading (i.e., Q/A) and the measured distribution of TSS particle settling velocities and critical shear stress, which in turn is a function of flow velocity and depth. There is also evidence (Grizzard et al; 1986) that TSS and other constituent removal efficiencies can be significantly affected by the initial concentration of the constituent. Laboratory and field data using stormwater show that it is easy to remove 80 to 90 percent of TSS from urban runoff when its initial concentration is high (e.g., > 400 mg/l) and difficult to remove even 20 percent when the initial concentrations are low (e.g., < 20 mg/l).

There are a number of key parameters that need to be obtained and reported whenever BMP performance is monitored. Identifying all such parameters at this time is not possible. We can add to the list as we learn more about the passive treatment mechanisms and the performance of structural BMPs. However, an initial list is

VOL 12

7665

suggested for a variety of BMPs that are currently or may be field tested in the future for effectiveness. They need to be reported in all study reports, data transfer reports, and other literature, along with performance data such as the inflow and outflow event mean concentrations (EMCs), the percentages of removal of each constituent, the flow rates and the volumes entering and leaving each structural BMP facility being investigated.

As municipalities and industries in United States of America begin to operate under the federally mandated National Pollutant Elimination Program's separate stormwater discharge permit system, we can expect a profound increase in the amount of stormwater monitoring data being collected and reported. Much of it will be associated with the performance of various BMPs. This data will be collected in a variety of ways, using different monitoring and reporting techniques, manual sampling, automatic sampling, different constituent detection levels, etc. The selection of the techniques used at each site will be determined by local conditions, budgets, expertise of the investigators, and other factors impossible to predict in advance. Some level of consistency in how this data and the type BMP parameters being reported will be needed if we ever hope to make any sense of this data or hope to draw repeatable quantitative conclusions. This will be a particular challenge when trying to draw conclusions relative to how this data relates to various BMP's and tributary watershed design parameters.

It is hoped that the consistent use in the professional literature of a minimum set of standard parameters will result in more reliable tools for the selection of structural BMPs, and in better design tools than we have today. In developing this list, various potential physical, biological and chemical processes were considered for several types of BMPs . Although this list is extensive, every attempt was made to keep it as brief as possible. This does not mean, however, that other site specific parameters should not be measured or reported.

It is also recommend that additional parameters be carefully evaluated before adding them to this list. It is not the intent to limit this initial list or to keep out other potential parameters of merit. It is suggested that before adding to this list consider that the complexity of finding meaningful empirical relationships expands exponentially with each new parameter. Also, we need to be sure that any new parameter is not already on this list, either as part of another parameter or within a grouping of the parameters on the present list. For example, it is not necessary to report the tributary impervious watershed area if the total watershed area and its percent of total imperviousness are reported.

REPORTING CONSTITUENTS AND THEIR REMOVALS

The way that we report data on the constituents in the water column and their removal rates is dictated by whether we have a detailed study report or a paper summarizing the study. The former merits much more detail. Also, should data be reported as event mean concentrations for each storm or should they be reported as a set of discrete sample data obtained at different times during a storm? There is a need to have some level of consistency in how we handle this issue.

Data and Study Reports

Typically, literature reports the constituents being monitored, their removal efficiencies and associated flows. Sometimes the constituents are reported as EMCs entering and leaving the BMP facility, while at other times data are reported for individual discrete samples taken throughout the runoff event, even though discrete samples are often composited into a single EMC. For consistency, it is recommended that stormwater BMP data be reported as paired inflow and outflow EMCs for all the events sampled, along with the event's volume of runoff (inflow and outflow if different) and percent constituent removal rates during each event.

The collection and reporting of discrete sample data taken at various times during runoff events is not discouraged by the above recommendation. It is, however, very expensive to test each discrete sample for a number of constituents, and many stormwater data collection efforts elect to test only the flow weighted composite sample to find the storm's EMC. If budgets permit, however, much understanding can be gained through the collection and analysis of discrete water quality samples throughout the runoff hydrograph. For constancy, the reporting of storm composite EMCs in published literature is recommended. However, discrete sample data should be made available to other investigators upon request as ASCII or data base files, along with the organization and format of these files.

Inconsistencies also occur in the literature in reporting removal efficiencies. To cope with this, it is recommended that the percent removal (*PR*) for any constituent be calculated and reported for each monitored event using the inflow and outflow loads. If the facility records less surface outflow than inflow, as can be the case when infiltration/percolation occurs, the outflow loads should be reported for the surface component based on the measured outflows, and for the subsurface component based on the estimates of the water infiltrated/percolated, into the ground. This should prevent the impression that infiltration/percolation actually eliminates constituents, instead of, as sometimes happens, transferring them to the groundwater flow regime. Equation 1 is suggested as the basic equation for calculating the percent removal rate of any sampled constituent.

$$PR = \frac{V_{in} \cdot EMC_{in} - V_{out} \cdot EMC_{out}}{V_{in} \cdot EMC_{in}} \cdot 100 \qquad (1)$$

in which,
PR = percent constituent load removed,
V_{in} = storm runoff volume inflow into the BMP facility,
EMC_{in} = event mean concentration of inflow volume,

V_{out} = storm runoff volume outflow from a into the BMP,
EMC_{out} = event mean concentration of outflow volume,

Reporting of constituent concentrations in dry weather inflows and outflows, if any, can reveal much about the true performance of a BMP. Many on-site BMPs do not experience dry weather flows and the reporting of the percent constituent removal efficiencies for storm events is sufficient. However, if dry weather flows are present, they sometimes can have a very significant effect on the actual constituent removal rates that take place over an extended period of time (Urbonas et al, 1994). To help us understand how any BMP being studied is affected by dry weather flows, it is recommended that constituent concentrations in dry weather flows be obtained and reported in sufficient numbers to provide averages and their coefficients of variation.

Report Summaries and Published Summary Papers

Summaries of monitoring studies and published papers often cannot include all the data that were collected. As a result, the information has to be reduced to fit the available space. Again there is no consistency in how this is done, and it is suggested that, as a minimum, summary reports and published summary papers report the constituent EMC data as monitoring period (or seasonal) averages for both the inflow and outflow, along with the inflow (and outflow if different) volume averages and numbers of EMC data points (i.e., storm events sampled) for each parameter, along with each average's coefficient of variation (CV). These data need to be accompanied by the long-term average percent removal rates for each constituent reported as the arithmetic mean of individual removal rates. Calculate these using Equation 2. The arithmetic, instead of the flow-weighted, mean is suggested to avoid the problem of a single runoff event, with a very large runoff volume, overwhelming the reported average removal rates. The author has observed that, under typical data sets, the arithmetic and the flow-weighed removal rate averages are similar. On the other hand, a single, very large storm can disproportionately affect the flow-weighted average.

$$PR_{av} = \frac{\sum_{i}^{n} PR_i}{n} \qquad (2)$$

in which, PR_{av} = Average % removed, all monitored events, single constituent,
n = number of events for which percent removals were calculated,
PR_i = % removed for the i_{th} event sampled.

BASIC SEDIMENTATION EQUATIONS

Much of the performance effectiveness attributed to BMPs currently focuses on the removal of TSS from runoff. This is definitely not always the case. Local concerns, such as those in watersheds tributary to Chesapeake Bay and the watersheds in the State of Florida suffering from groundwater depletion, may dictate that the removal of nutrients is of greatest concern, or, as is the case for the watershed

VOL 12

7668

R0040976

draining to San Francisco Bay, the removal of copper, soluble and total, may be of most interest. Nevertheless, the selection of the parameters being suggested is based on the principles for the removal of TSS and other constituents. The reduction in the toxicity of some of the constituents was also considered in developing the recommended list.

The TSS removal process is much more complex than can be explained using simple sedimentation equations. Nevertheless, these equations provide some of the mathematical basis for identifying many of the physical parameters that should be looked at, especially when considering the design of facilities to remove particulates and the constituents that adhere to them.

Newton's Sedimentation Law For Spherical Particles:

Newton proposed the following equation to describe the settling velocity of a particle in a fluid:

$$V_s = \sqrt{\frac{4}{3} \cdot \frac{d_p \cdot g \cdot (r_p - r_v)}{C_D \cdot r_v}} \quad (3)$$

in which,
- V_s = settling velocity of a given particle size in m/s
- d_p = diameter of the particle in m
- r_p = specific gravity of the particle,
- r_v = specific gravity of the fluid,
- g = gravitational acceleration in m/s²
- C_D = drag coefficient, a function of Reynolds Number R_n, which in turn is a function of the fluid's temperature.

Basic Suspended Solid Settling in Turbulent Flow:

Geyer (1954) suggested a relationship to describe the sediment fraction that can be removed in a pool of water under the dynamic conditions that can occur as water enters the pool at one end and overflows through an outlet at the other end. This relationship, Equation 4, relies on the pool's hydraulic surface loading rate, namely the flow-through rate divided by the pool's surface area.

$$R_d = 1.0 - \left[1.0 + \frac{1}{n} \cdot \frac{V_s}{Q/A}\right]^{-n} \quad (4)$$

in which,
- R_d = fraction of the inflow solids removed under dynamic conditions,
- V_s = settling velocity of a given particle size in m/s (ft/sec),
- Q = flow through rate in cubic m³/s (ft³/sec),

A	=	surface area of the permanent water pool in m^2 (ft^2),
n	=	turbulence, or short-circuiting, constant,
	=	1.0 for poor performance, high sort-circuiting potential,
	=	5.0 for very good performance, low short-circuiting potential,
	=	∞ for ideal performance.

As n approaches infinity, Equation 4 reduces to:

$$R_d = 1.0 - e^{-kt} \quad (5)$$

in which,

k	=	V_s/h , sedimentation rate coefficient in /s units,
h	=	average depth of the pond in m (ft),
t	=	V/Q , residence time in the pool in seconds
V	=	volume of the pool in m^3

GENERAL PARAMETERS TO CONSIDER FOR ALL BMPS

There are a number of general parameters that should be recorded and reported, regardless of the type of BMP being tested. Some of these can be used to assess the aquatic environment and the toxicology of the constituents being monitored. Others, such as temperature, give the investigator an idea of the fluid's density and viscosity, both of which influence the settleability of solids. Table 1 lists a number of such general parameters. All of them can be measured in the field and, except for V_{SD}, are relatively inexpensive to obtain.

RUNOFF PARAMETERS

Since storm runoff is a function of the tributary watershed area and its imperviousness, always report the *Tributary Watershed (A_T)*, its *Total Percent Imperviousness (I_{IT})* and the *Percent of the Total Imperviousness that is Hydraulically Connected (I_{IC})* to the storm conveyance system. Often not reported in the literature is information about storm runoff peaks, runoff volumes or storms, and base flows associated with BMP facilities. Figure 1 illustrates storm runoff events as a time series of hydrographs, which information can be summarized using a probability distribution graph shown in Figure 2. To help us find relationships between runoff distribution data at a variety of sites being monitored and the performance of these BMPs, it is recommended that, as a minimum, runoff data (and outflow data if different) be summarized as suggested below for *Runoff Volume*, *Storm Runoff Duration* and *Storm Runoff Inter-Event Time* parameters as follows:

TABLE 1. GENERAL PARAMETERS TO REPORT FOR ALL BMPs

Inlet and Outlet	Plan, profile and details, including dimensions and elevations of the inlet and outlet works. Include inflow baffles and outlet trash racks, if any.
Temp •	Water temperature of influent, effluent and possibly the pond itself. Summarize this data as monitoring season averages, along with their coefficients of variation.
V_{SD}	Settling velocity distribution of the sediments in stormwater determined from a number of settling column tests.
Alkalinity & Hardness	Affect the solubility and the toxicity of metals and of other constituents. To be measured and reported as the Event Mean Concentration (EMC) of the facility influent and effluent.
Conductivity •	Provides a surrogate indicator of ionic activity in the water column, which may indicate the availability of toxic forms of metals to aquatic life. Reporting *dissolved* metals along with *total* metals data provides an indicator of potentially available toxic forms.
pH •	Affects the solubility and toxicity of metals and other constituents.
•	Indicates that these parameters are to be measured in the field and reported as the mean of the measured values.
Solar Radiation	Reported daily from the nearest first-order U.S. Weather station, only for retention ponds, wetlands and other biologically active treatment water quality facilities. Summarize this data as the mean of daily averages for each monitoring season and their coefficients of variation.
Maintenance	Provide type and frequency of maintenance such as dredging of sediments, harvesting, mowing, removing and replacing filter media, etc.
Facility Description	Full description of the BMP, including layout, typical cross-section and profile, inlet and outlet details, vegetative cover, etc.

<u>Runoff Volume Parameters During Monitoring Season:</u>

V_R = Volume of the average runoff event in watershed mm (in)·

V_{R50} = Volume of the 50th percentile runoff event in watershed mm (in)·

CV_{VR} = Coefficient of Variation in the volumes of runoff events ($_{SD-R}/V_R$),

in which V_{SD-R} = Standard deviation of Runoff volumes,

V_B = Volume of the seasonal dry weather base flow in watershed mm (in),

Q_P = Average runoff peak rate in m^3/s (ft^3/sec),

CV_{QP} = Coefficient of Variation of flow peaks.

VOL 12

7571

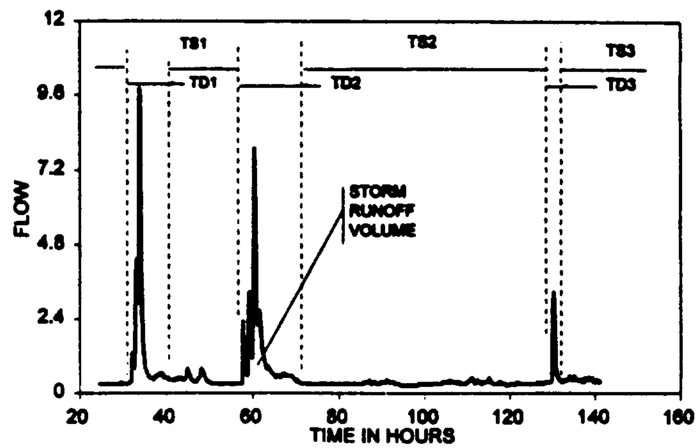

Figure 1. Time series of storm hydrographs, their duration and inter-event times.

Time Variable Parameters of Storms During the Monitoring Season:

Storm Runoff Inter-Event (Separation) Time:

T_S = Average separation period between the end of a storm runoff hydrograph and the beginning of the next one, in hours,

T_{S50} = The 50th percentile of storm runoff event separation periods, in hours,

CV_{TS} = Coefficient of Variation in storm runoff event separation periods (T_{SD-S}/T_S), in which T_{SD-S} = Standard deviation of storm runoff event separation periods.

Storm Runoff Duration:

T_D = Average duration of storm runoff in hours,

T_{D50} = The 50th percentile value of storm runoff duration in hours,

CV_{TD} = Coefficient of Variation in storm runoff duration (T_{SD-D}/T_D), in which T_{SD-D} = Standard deviation of storm runoff duration.

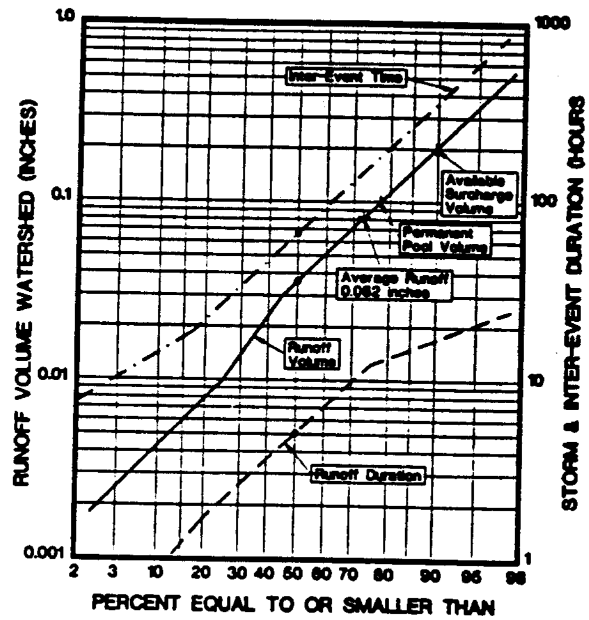

Figure 2. Example of cumulative probability distribution of Surface Runoff, Storm Separation and Inter-Event Time for one BMP site (After Urbonas et al, 1994).

PARAMETERS FOR RETENTION PONDS

Figure 3 is a plan view of an idealized stormwater retention pond used as a structural BMP. Retention ponds such as this always have some surcharge detention storage above the permanent pool water surface.

There are several pollutant removal mechanisms at work within a retention pond. These include sedimentation during runoff events and between runoff events, other physical processes, chemical processes and biological processes. As a result, more information needs to be reported for these types of facilities than for facilities that remove pollutants primarily though physical processes. Also, keeping these points and Equations 3 through 5 in mind, the following set of parameters emerge as needing to be reported with retention pond removal efficiency data.

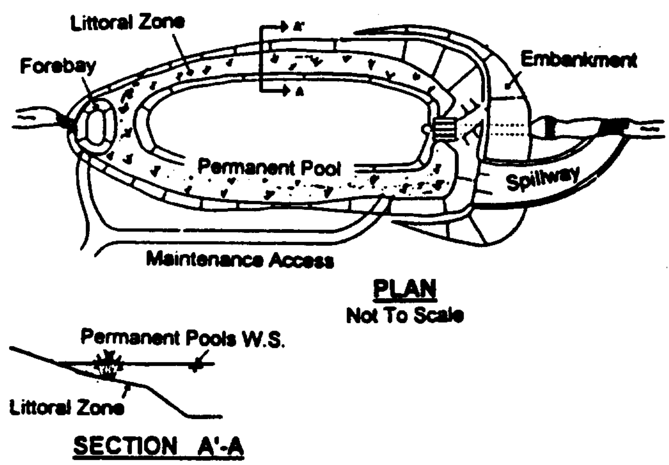

Figure 3. Plan of an Idealized Retention Pond. (After UDFCD, 1992)

Surface Area and Pond Layout Parameters:

A_P = Surface area of the permanent pool in m^2 (ft^2),

A_L = Surface area of the littoral zone (zone ≤ 0.5 m (1.5 ft) deep) in m^2 (ft^2),

A_D = Surface area of the top of the surcharge detention basin in m^2 (ft^2),

L_P = Length of the permanent pool or flow path in m (ft),

L_D = Length of the surcharge detention basin in m (ft),

A_F = Surface area of the forebay in m^2 (ft^2),

L_F = Length of the forebay in m (ft).

VOL 12

7674

Basin Volume Parameters:

V_P = Volume of the permanent pool in m^3 (ft^3),

V_D = Design volume of the surcharge detention basin above the permanent pool's water surface in m^3 (ft^3),

V_F = Volume of the forebay in m^3 (ft^3).

Emptying Time Parameters:

T_E = Time needed to empty 99% of V_D assuming no inflow takes place while the surcharge pool is emptying, in hours, and

$T_{0.5E}$ = Time needed to empty the upper one-half of V_D assuming no inflow takes place while the surcharge pool is emptying, in hours.

PARAMETERS FOR EXTENDED DETENTION BASINS

Figure 4 shows the plan view of an idealized extended detention basin. Such basins employ sedimentation as their primary pollutant removal mechanism. As a result, Equations 3, 4 and 5 apply to extended detention basins, but have to be viewed somewhat differently than for a retention pond. In a retention pond, sediments that settle below the overflow outlet level are essentially trapped within the permanent pool and are less likely to be discharged through the outlet. The trapped sediment continues to settle to the bottom of the pond even after the surcharge volume is drained off. In an extended detention basin stormwater empties through an outlet located on the bottom. As the sediments settle to the bottom they concentrate within the lower levels of the ever shrinking pool and discharge through the outlet. Unless they are scoured out, only the sediments that deposit on the bottom can be trapped within the basin.

The design for extended detention basins thus requires much longer drain times to permit the sediments to settle to the bottom of the basin. Current state-of-practice suggests that the emptying time be set at 24 to 48 hours for a volume equal to the average runoff event expected to occur at the design site. Current practice also suggests that extended detention basins be designed to have two levels. The lower level basin is filled frequently by the predominant numbers of small runoff events, while the upper basin is inundated only few times a year. This two layer design significantly improves the upper basin's usability for other community uses.

The list that follows reflects most of the parameters of importance for an extended detention basin. Many of the same parameters that were recommended for retention ponds are repeated.

VOL 12

7675

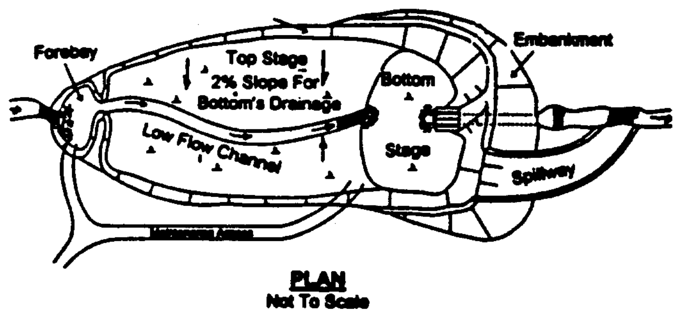

Figure 4. Plan of an Idealized Extended Detention Basin. (After UDFCD, 1992)

Surface Area and Plan Layout Parameters:

A_D = Surface area of the extended detention basin in m^2 (ft^2),

L_D = Length of the extended detention basin in m (ft),

A_B = Surface area of the bottom stage (i.e., lower basin) in m^2 (ft^2),

L_F = Length of the forebay in m (ft).

Basin Volume Parameters:

V_D = Total Volume of the extended detention basin in m^3 (ft^3)

V_B = Volume of the Bottom stage only of the basin in m^3 (ft^3)

V_F = Volume of the Forebay in m^3 (ft^3)

Time Variables:

Use the same *Emptying Time* parameters as defined for the retention pond.

PARAMETERS FOR WETLAND BASINS

Figure 5 depicts an idealized wetland basin. Some wetland basins are similar in their operation to retention ponds while others resemble extended detention basins. The difference between the two is whether or not the wetland basin has standing water or a wetland meadow as its bottom. The pollutant removal mechanisms are probably similar to those found in retention ponds and in detention basins, except that stormwater comes in contact with wetland flora and fauna. This contact and the physical structure of the wetland provide pollutant removals through adsorption and biochemical processes and possibly through reoxygenation of the sediments and detoxification of the water column, processes that may or may not be available in retention ponds, and that are not available in detention basins.

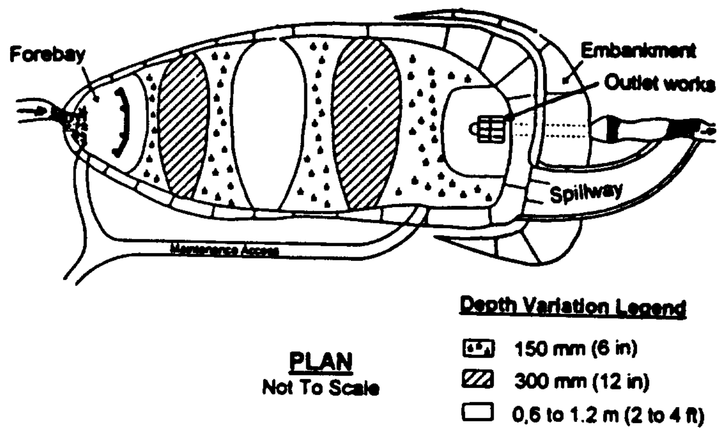

Figure 5. Plan of an Idealized Wetland Basin. (After UDFCD, 1992)

In addition to the parameters of Equations 3, 4 and 5, each performance monitoring program should report parameters that are peculiar to the wetland studied. Most currently available wetland monitoring data rarely contain such information, often not even reporting many of the parameters commonly being reported for other BMPs. Because the quantification of wetland performance as a BMP is relatively new, very little information can be found in the literature and it is difficult to suggest parameters to report when reporting the performance data of wetland basins. Table 2 and the list that follows it suggest the parameters that appear to be most important, many of which are identical to those recommenced for retention ponds.

TABLE 2. ADDITIONAL GENERAL PARAMETERS TO REPORT FOR WETLANDS

Type of Wetland	Cattail marsh, northern peat land, meadow, palustrine, southern marshland, hardwood swampland, brackish marsh, high altitude riverine, freshwater riverine, mixed (include types), constructed or natural, etc.
Rock Filter?	Is there a rock filter media present in the wetland bottom?
Dominant Plant Species	Lists the dominant plant species in the wetland and the age of these plants (i.e., time since their original planting or replanting).

<u>Surface Area and Layout Plan Parameters:</u>

A_P = Surface area of permanent wetland pool, if any, in m^2 (ft^2),

A_M = Surface area of the meadow wetland, if any, in m^2 (ft^2),

$P_{0.30}$ = Percent of permanent pool less than 0.30 m (12 in) in depth,

$P_{0.60}$ - Percent of the permanent pool more than 0.60 m (24 in) in depth,

A_S = Surface area of the surcharge detention basin's top in m^2 (ft^2),

L_S = Length of the wetland surcharge/detention pool or flow path in m (ft),

A_F = Surface area of the forebay in m^2 (ft^2),

L_F = Length of the forebay in m (ft).

<u>Basin Volume Parameters:</u>

V_P = Volume of the permanent pool, if any, in m^3 (ft^3),

V_D = Design volume of the surcharge/detention basin in m^3 (ft^3),

V_F = Volume of the forebay in m^3 (ft^3).

<u>Time Variables:</u>

Use the same *Emptying Time* parameters as defined for the retention pond.

VOL 12

7678

PARAMETERS FOR WETLAND CHANNELS

Channels can be designed to have a wetland bottom which are designed to flow very slowly. Figure 6 shows a profile for such a channel. When properly designed, the channel's bottom is covered by wetlands, with only the sideslopes having terrestrial vegetation. The flow velocity is controlled by transverse berms, by check dams or by an outlet at the downstream end of a given channel's reach. In the last case, the channel is essentially a long and narrow wetland basin.

The pollutant removal mechanisms in wetland bottom channels are similar to those found in wetland basins, except that contact time of stormwater with the wetland vegetation is likely to be less. Because of the flowing channel nature of this BMP, the following parameters, in addition to those in Tables 1 and 2, should provide the information needed to compare the performance of different installations:

V_{2-yr} = Average channel velocity during a 2-year runoff event in m/s (ft/sec).

A_D = Surface area of the wetland bottom in square m^2 (ft^2).

L_D = Length of the wetland channel in m (ft).

Prt = Describe any pretreatment provided ahead of the channel (e.g. detention).

Time Variables.

There are no *Emptying Time* parameters to report for wetland channels.

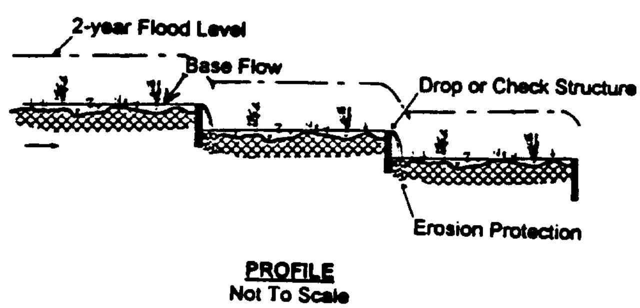

Figure 6. Profile of an Idealized Wetland Bottom Channel. (After UDFCD, 1992)

PARAMETERS FOR SAND FILTERS

Sand filters can be installed as basins or as sand filter inlets. Figure 7 illustrates an idealized filter basin and Figure 8 does the same for a filter inlet. Typically, these installations will have a detention basin or a retention pond (or tank) upstream of the filter to remove the heavier sediment and, if properly designed, some of the oil and grease found in stormwater. However, such a pretreatment basin is not always present. All of the parameters required for a *Retention Pond* or for an *Extended Detention Basin* should also be reported along with the information about the sand filter whenever the filter is preceded by a pre-treatment basin. For example, a filter inlet is often equipped with an underground tank which helps to remove some of the sediment, oil and grease before stormwater is applied to the filter. Such a tank is similar to a retention pond and all of the parameters associated with a retention pond, such as volume, surface area, length, surcharge volume, etc. should be reported.

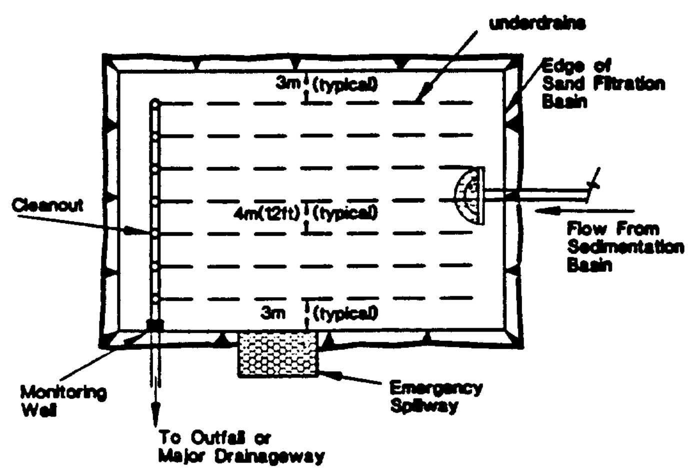

Figure 7. Plan of an Idealized Sand Filter Basin. (After UDFCD, 1986)

VOL 12

7680

R0040988

In addition to the parameters of the pond or basin associated with the filter, provide the following:

- Dimensions of the installation.
- Depth of various filter material layers.
- Type of filter media, its median particle size (i.e., D_{50}) and its Coefficient of Uniformity.
- Maintenance frequency.
- All associated drainage and flooding problems attributed to the installation because of its configuration size, maintenance practices, etc.

Time Variables:

Use the same parameters for *Emptying Time* as defined for the retention pond.

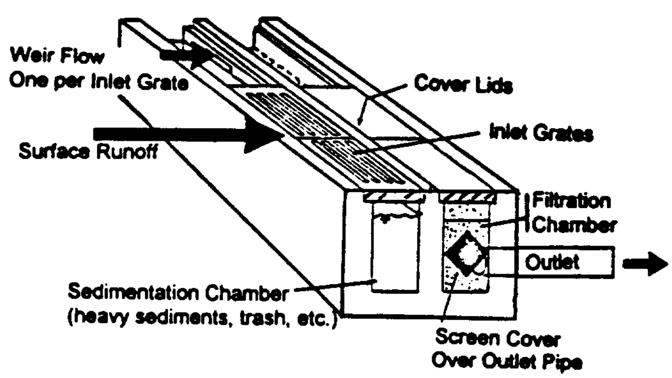

Figure 8. An Idealized Sand Filter Inlet. (After Shaver, 1993)

PARAMETERS FOR OIL, GREASE AND SAND TRAPS

An oil, grease and sand trap is an underground tank, similar to the one illustrated in Figure 9. It is nothing more then a special configuration of a retention pond. As a

VOL 12

7681

R0040989

result, all parameters listed for a *Retention Pond* should be reported for these installations. Typically these installations have a forebay and an outlet basin. In addition to reporting the parameters for a pond, provide the *dimensions of the installation, details of its design (including skimmers, sorbent pillows, lamella plates, baffles, etc.) and the maintenance provided during the testing period.* Because these traps are much smaller than a surface pond, the flow-through velocity is of concern because it can cause trapped oil, grease and sediment to be remobilized and flushed out of the trap. As a result, provide the *average flow velocity that can be expected to occur in this device during a 2-year storm*, which velocity can be used as an index for comparing the performance among a variety of installations.

Time Variables:

Use the same *Emptying Time* parameters as defined for a retention pond.

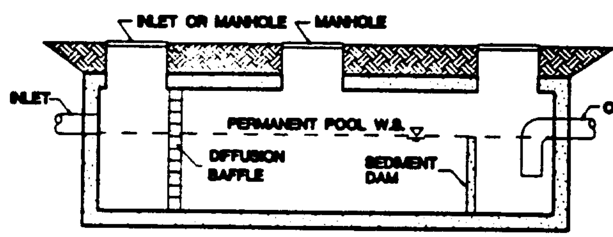

Figure 9. An Idealized Oil, Grease and Sand Trap (After Neufeld, 1994).

PARAMETERS FOR INFILTRATION AND PERCOLATION FACILITIES

An idealized percolation trench is illustrated in Figure 10. For percolation trenches and for infiltration basins report all of the parameters suggested for the *Extended Detention Basin.* In addition, report the following:

- Depth to high groundwater and to impermeable layers below the infiltrating surface of the basin, or below the bottom of the percolation trench.

- The hydraulic conductivity of soils adjacent to percolation trenches and the saturated surface infiltration rates of soils underlying infiltration basins.
- Dimensions of the installation.
- Maintenance needs and associated drainage and flooding problems attributed to the installation.
- Failures to empty out the captured water completely within the design emptying time.

<u>Time Variables:</u>

Use the same *Emptying Time* parameters as defined for a retention pond.

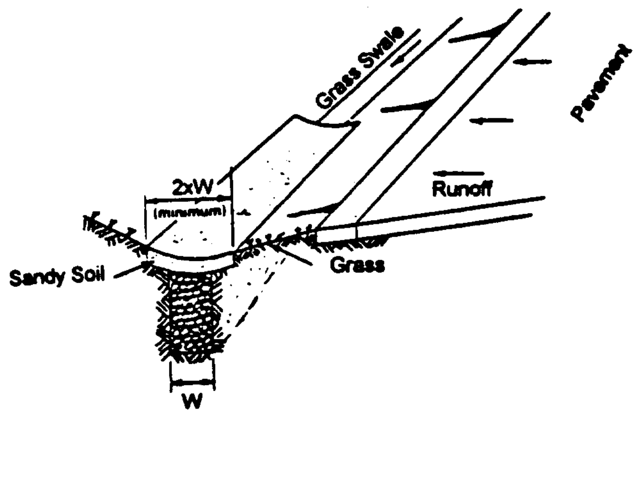

Figure 10. An Idealized Percolation Trench. (After Urbonas & Stahre, 1993)

VOL 12

7683

R0040991

SUMMARY AND RECOMMENDATIONS

In summary, there is a great need for consistent reporting of various BMP parameters along with field testing data on their performance. Table 3 lists these parameters. It is recommended that all agencies and organizations that undertake field studies of BMP performance be encouraged to include in their reports and report summaries the information suggested in this paper. Only through a concerted effort by stormwater professionals to report the suggested minimum list of parameters about each installation, or some other list that the research community deems more appropriate, parametric relationships may be discovered that will allow us to refine and optimize the design tools for structural BMPs.

FURTHER REVIEW COMMENTS TO ASCE

A paper that presented the concepts and recommendations made in this paper is also being published by the American Society of Civil Engineers, Water Resource Planning and Management Division's Journal. Anyone wishing to comment on this topic and these recommendations is invited to write to the ASCE Journal's services. All comments are welcome as this topic deserves wide debate and discussion.

ACKNOWLEDGMENTS

The author acknowledges the many professionals that contributed to the development of this paper. The initial and pre-final drafts were distributed to approximately 40 individuals, many of who have contributed significantly to the field of stormwater management over the last 25 to 30 years. A special thanks goes to all those that responded with their comments and suggestions. As a result, the recommendations being made in this paper reflect the suggestions, opinions and the experience of many individuals and not only those of the author. Special acknowledgment goes to the following for their specific and extensive review comments and suggestions: Eric Strecker, John Warwick, Betty Rushton, Jim Wulliman and Harry Torno.

Constituents and Methods for Assessing BMPs

Eric W. Strecker[1], P.E., A.M. ASCE

Abstract

The purpose of this paper is to recommend the utilization of consistent storm water monitoring techniques so that data collected on the effectiveness of individual best management practices (BMPs) will not only be useful for a particular site, but will also be useful for comparing studies of similar BMPs in other locations and other types of BMPs. The data collected may then be useful for assessing factors (such as settling characteristics of inflow solids and physical features of the BMP) that might have led to the performance levels achieved. This paper presents a list of constituents that are recommended for analysis of samples collected as a part of studies assessing the effectiveness of urban storm water BMPs. It also discusses other considerations that affect data transferability, such as effectiveness estimations, statistical-testing, etc.

Introduction

Many studies have been completed which have assessed the ability of storm water treatment BMPs (e.g., wet ponds, grass swales, storm water wetlands, sand filters, dry detention, etc.) to reduce pollutant concentrations and loadings in storm water. However, in attempting to review and summarize the information gathered from these individual BMP evaluations it is very apparent that inconsistent study methods and reporting make assessment difficult. Often the studies included the analysis of different constituents and utilized different methods for data collection and analysis. These differences alone contribute significantly to the range of BMP effectiveness reported. This makes assessing what other factors may have contributed to the variation in performance almost impossible.

[1]Director, Water Resources Group, Woodward-Clyde Consultants, 111 S.W. Columbia, Suite 990, Portland, Oregon 97201.

As an example, in a review of the use of wetlands for storm water pollution control (Strecker et. al., 1992), a summary of the literature was prepared regarding the performance of wetland systems and the factors that led to pollutant removals. The literature was inconsistent with respect to the constituents analyzed and the methods used to gather and analyze data. There are a number of pieces of information that, if collected and recorded, would have improved the ability to evaluate the effectiveness of storm water wetlands as BMPs and facilitated the transfer of that knowledge into better design practices. Urbonas (1994) summarized the information that should be recorded regarding the physical, climatic, and geological parameters which likely affect the performance of a BMP. This paper presents a suggested list of constituents for analysis along with recommendations for reporting data, methods of reporting pollutant removal efficiencies, a brief discussion of statistical approaches to selecting the number of samples needed, methods for including detection limit data, sample collection considerations, and the need for dry weather assessments.

Constituents for Assessing BMP Performance

The Nationwide Urban Runoff Program (NURP) (EPA, 1983), which included monitoring of land use runoff and BMP performance at over 28 cities nationwide, adopted consistent data collection methods and analytical parameters. Results from the NURP program could then be used to evaluate similarities and differences in pollutant concentrations in urban storm water from different and similar land uses and could be used to explain what might be causing these differences. The following pollutants were adopted by NURP as "standard pollutants characterizing urban runoff:"

TSS	Total suspended solids
BOD	Biochemical oxygen demand
COD	Chemical oxygen demand
TP	Total Phosphorus
SP	Soluble phosphorus
TKN	Total Kjeldahl nitrogen (as N)
$NO_2 + NO_3$	Nitrate + nitrite (as N)
CU	Copper
PB	Lead
ZN	Zinc

Because of the difficulty in obtaining representative samples, oil and grease was not included. On a less consistent basis, NURP also monitored for other pollutants including other metals, dissolved metals, semi-volatile organics, volatile organics, pesticides, and herbicides.

Since NURP, there have been a number of studies which continued to assess pollutant concentrations in storm water runoff. These included the Federal Highway Administration's highway runoff program (Driscoll et al., 1990) and some selected studies done in a few locations. These studies typically were not consistent with the standard NURP protocols. Based upon the 1987 amendments to the Clean Water Act, EPA recently required operators of municipal separate storm drainage systems that served populations of over 100,000 to collect flow-weighted composites at a minimum of five stations to characterize residential, commercial, and industrial runoff quality. Only a few additional parameters have been identified as "problems" in storm water based upon these post-NURP studies (this despite the improved analytical methods that have become available for conducting laboratory analyses). In addition, NURP focused primarily on residential and commercial land uses, while NPDES testing has included industrial land uses which were suspected of having a greater probability of having more pollutants present. However, there has not been a comprehensive review by EPA or others of the newly collected information to assess the results of requiring the analysis of over 130 constituents, including priority pollutants. This type of review is needed. EPA's requirements included monitoring three storms at selected stations. This number of storms is only useful for identifying potential problem pollutants. Statistically, it is not enough data to perform regional or other factors analyses of urban storm water concentrations, but could provide useful information on rates of detection.

The choice of constituents to include as "standard pollutants" is a subjective one. As an example, some would argue that cost should be a primary consideration; others would say that it should not. To include a parameter in the recommended list of monitoring constituents the following factors were considered:

- The pollutant is one that has been identified as prevalent in typical urban storm water at concentrations that could cause water quality impairment.
- The analytical test is one that can be related back to potential water quality impairment.
- Sampling methods for the pollutant are straight forward and reliable for a moderately careful investigator.
- Analysis of the pollutant is economical on a widespread basis.
- The pollutant is one where treatment is a viable option.

Not all of the pollutants recommended fully "meet" all of the factors listed above; however, the factors were considered in the recommendations. When developing a list of pollutant analyses for an individual BMP evaluation, it is important to consider the upstream land use activities. The parameters recommended below are generally present and of concern in "typical" urban storm water.

Table 1 presents a list of suggested standard constituents for assessing the effectiveness of BMPs. The table includes a typical cost (Portland, Oregon) for each of the tests.

Lab Analyses	Cost	Detection Limit
Conventional		
TSS and TDS	$24	1 mg/l
BOD5	$31	3 mg/l
COD	$15	
Total Hardness	$15	
Nutrients		
TKN (as N)	$25	0.3 mg/l
(NH_3 - N)	$15	0.3 mg/l
Total phosphorus (as P)	$20	0.05 mg/l
Ortho-phosphate (as P)	$15	0.05 mg/l
Nitrate + nitrite (NO_3 + NO_2 - N)	$15	0.1 mg/l
Total Metals		
Cd (cadmium)	$20	0.0002 mg/l
Pb (lead)	$20	0.001 mg/l
Cu (copper)	$20	0.001 mg/l
Zn (zinc)	$20	0.001 mg/l
Dissolved Metals		
Cd (cadmium)	$20	0.0002 mg/l
Pb (lead)	$20	0.001 mg/l
Cu (copper)	$20	0.001 mg/l
Zn (zinc)	$20	0.001 mg/l
Total Cost Per Sample	$350	

Table 1. Recommended Standard Analytical Tests for Urban Storm Water BMP Assessments

Presented below is a discussion by group of pollutants that are recommended to be included in a base list.

Total Suspended Solids (TSS). The term "suspended solids" is descriptive of the organic and inorganic particulate matter which is of a size and type that allows the particles to stay suspended in water. The solids load in a water body is influenced by a number of factors including but not limited to: particle sizes, stream flows, climate, geology, and vegetation of each drainage system. The conditions under which suspended solids are considered a pollutant is a matter of definition. In general, suspended solids are considered a pollutant when they significantly exceed natural concentrations and have a detrimental effect on water quality and/or beneficial uses of the water body.

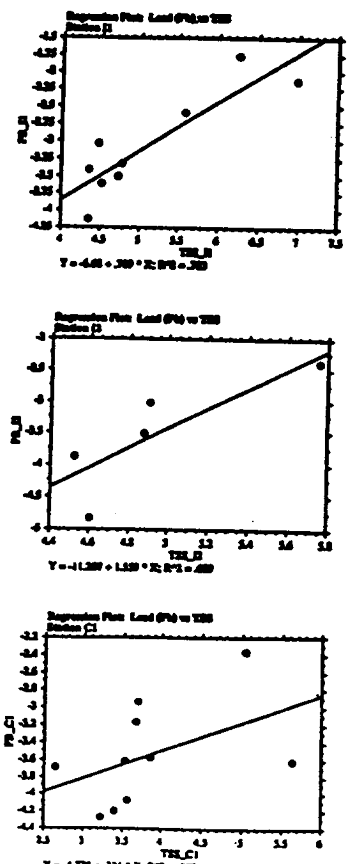

Figure 1. Natural Logarithm Concentration (mg/L) Regression of Total Lead (Pb) vs. Total Suspended Solids (TSS) for Stations I1, I2, and C1 (Portland, Oregon)

Suspended sediments are often used as a surrogate for other contaminants which bind or adsorb easily with fine particulate matter, including heavy metals. Although TSS is often highly correlated with other parameters, it is most often not a strong enough correlation to eliminate the need to address other parameters specifically. Figure 1 is an example of Total lead vs. TSS relationships found in the NPDES monitoring in Portland, Oregon at two industrial stations and a commercial station. The amount of lead that can be explained by the TSS concentration ranges greatly and is only statistically significant for one of the stations. Figure 2 shows pooled data from all ten stations monitored in Portland, Oregon and from the seven stations that were from piped systems. Although the relationship is statistically significant, it does not explain a significant amount of the variability. However, TSS is one good indicator of pollutant removal efficiency and should be included in any evaluation of BMP performance.

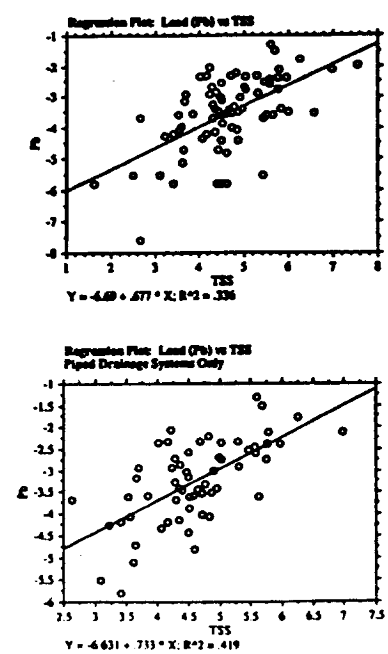

Figure 2. Natural Logarithm Regression Plots of Total Lead (Pb) vs. Total Suspended Solids (TSS) for Pooled Data from Portland, Oregon Monitoring Stations

VOL 12

7692

Many BMPs rely on sedimentation as the primary pollutant removal mechanism. It is recommended that samples also be analyzed for some measure of the expected settling rate of TSS. The performance of a BMP that relies on sedimentation and even filtering can be greatly effected by the particle sizes and densities present in the influent. If the influent TSS is characterized by small particle sizes, and therefore slow settling velocities, it will be much more difficult to treat. The settleability of influent solids has not been adequately addressed in performance comparisons, and may be one of the significant reasons that performance varies so highly from similar BMP to BMP. For consideration, the particle size distribution utilized in Sartor and Boyd (1972), as shown in Table 2, might be an appropriate gage of the "treatability" of storm water. As Table 2 indicates, these distributions vary considerably from City to City and likely from site to site. Another potential measure of the treatability would be settling column tests, as discussed by Urbonas in this session, or those discussed by EPA in their manual on combined sewer overflow control (EPA, 1993a).

Size Ranges	Milwaukee	Bucyrus	Baltimore	Atlanta	Tulsa
>4,800 μ	12.0%	– %	17.4%	– %	– %
2,000–4,800 μ	12.1	10.1	4.6	14.8	37.1
840–2,000 μ	40.8	7.3	6.0	6.6	9.4
246–840 μ	20.4	20.9	22.3	30.9	16.7
104–246 μ	5.5	15.5	20.3	29.5	17.1
43–104 μ	1.3	20.3	11.5	10.1	12.0
30–43 μ	4.2	13.3	10.1	5.1	3.7
14—30 μ	2.0	7.9	4.4	1.8	3.0
4—14 μ	1.2	4.7	2.6	0.9	0.9
>4 μ	0.5	—	0.9	0.3	0.1

Table 2. Particle Size Distribution of Solids
Selected City Composites

The advantage of particle size tests is that they are much more cost-effective. Settling column tests to determine the range of particle settling velocities are labor intensive. Using a settling test with only one settling time may not reveal the true differences with regard to settling characteristics among inflows to different BMPs.

Oxygen Demand. Oxygen demand refers to the amount of oxygen that will be consumed by biological or chemical reactions involving organic compounds. The decomposition of biodegradable materials by natural soil and water bacteria draws upon the dissolved oxygen resources of a water body. This process is countered by natural re-aeration processes that occur in all water bodies to varying degrees. Significant reductions in dissolved oxygen concentrations can result when the demand rate exceeds the rate of replenishment through re-aeration. In general, moderately high dissolved oxygen content is necessary for the maintenance of healthy aquatic ecosystems. The relationship of oxygen-consuming discharges to the amount of dissolved oxygen in a receiving water body, therefore, is fundamental to the maintenance of environmental quality in natural water bodies. However, the tests available for assessing oxygen demand are not straightforward indicators of potential problems.

Biochemical Oxygen Demand (BOD). The 5-day BOD test provides an indirect measure of the quantity of biologically degradable organic matter in water in terms of the amount of oxygen required by microorganisms to oxidize it to carbon dioxide and water. The BOD test is quite variable. A number of factors can affect results, including the quality of the seed culture utilized in the test. The BOD test can also be inhibited by toxicants in the sample, which may react differently once the runoff mixes with the receiving water. The levels of BOD that are normally found in urban storm water are near detection limits for the BOD test. Therefore, they are subject to wide variation.

Chemical Oxygen Demand (COD). The COD test provides a more rapid measure of oxygen demand. The test is used to measure the organic content of the sample. The consumption of oxygen from an introduced strongly oxidizing chemical agent is measured by this test. As a result, it typically measures appreciably higher levels of oxygen demand than will be produced by biological decomposition because it oxidizes some organic compounds that are not biodegradable, and may also react with inorganic compounds as well. In urban storm water, for example, COD levels are typically found to be about 8 to 10 times greater than BOD levels. COD measures a "maximum possible," but not probable, oxygen demand.

COD and BOD have been monitored relatively frequently in urban runoff studies. Both tests are imperfect measures of the potential for urban runoff to cause oxygen depletion of receiving waters. However, both tests are indicators of the potential for oxygen depletion and are recommended for inclusion on the base list. It is also recommended that dissolved oxygen be measured on a "grab sample" basis, to indicate if the BMP may be having an effect on oxygen levels.

Nutrients. Nutrients are necessary for the growth and support of biota in natural water systems. Excessive quantities can result in the over-stimulation of biological growth and the creation of objectionable water quality conditions (eutrophication). Some forms of nutrients can also be toxic (e.g., ammonia). In general, the most important nutrient factors causing an acceleration in algal production are nitrogen compounds and phosphorus.

Nitrogen. Nonpoint sources of nitrogen include lawn fertilizers, leachate from waste disposal in dumps or sanitary landfills, atmospheric fallout, nitrite discharges from automobile exhausts and other combustion processes, natural sources such as mineralization of soil organic matter, and farm-site fertilizers and animal wastes. Many water treatment methods have no significant effect on nitrate removal from water (Dunne and Leopold, 1978).

Three forms of nitrogen have been analyzed extensively in storm water runoff water quality studies. These are nitrite plus nitrate ($NO_2 + NO_3$), ammonia nitrogen (NH_3), and total Kjeldahl nitrogen (TKN). The latter, named after the analytical test procedure, provides a measure of ammonia and organic nitrogen forms that are present. The first ($NO_2 + NO_3$) provides a measure of the inorganic nitrogen. There is usually very little nitrite in storm water. Nitrate (NO_3) is very mobile and is usually difficult to treat utilizing storm water BMPs. Ammonia nitrogen can be toxic to aquatic life. It can be assessed for toxicity to aquatic life with data on pH and temperature. These three forms of nitrogen are those that characterize nitrogen forms that are important to conducting receiving water assessments. Therefore these three forms of nitrogen are recommended for analysis, and it is recommended that they be consistently reported based upon their mass of nitrogen (as N).

Phosphorus. Phosphorus is used by algae and higher aquatic plants and may be stored in excess of use within plant cells. With decomposition of plant cells, some phosphorus may be released immediately through bacterial action for recycling within the biotic community, while the remainder may be deposited with sediments.

Phosphorus enters waterways from many of the same sources as nitrogen. Domestic sewage contains significant concentrations of phosphorus which is contributed by detergents and human wastes. Primary and secondary treatment processes normally remove only about 20 to 30 percent of this element from sewage (Dunne and Leopold, 1978). Fertilizers and the erosion of soils rich in phosphorus can also be a potential source.

Three forms of phosphorus have been somewhat routinely analyzed in storm water runoff water quality studies. These include total phosphorus (TP), soluble phosphorus (SP), and ortho-phosphate (OP). Ortho-phosphate indicates the phosphorus that is most immediately biologically available. Soluble phosphorus includes both the ortho-phosphate and a fraction of the organic phosphorus. Most all of the SP is usually OP, however. Total phosphorus includes phosphorus in the forms that may not be as readily biologically available plus the forms discussed above. TP and OP are recommended for inclusion in a monitoring program, as they characterize both the total and bioavailable forms of phosphorus. All forms should be reported as mass of phosphorus (as P).

Metals. Heavy metals such as copper, lead, and zinc are naturally released in very small quantities by the weathering of exposed soils and mineral deposits, corroding metal surfaces, decomposing paints, and certain corrosion-control compounds. Heavy metals tend to have comparatively low solubilities and are often mobilized by forming soluble complexes with humic materials or by becoming attached to clay particles. Heavy metals have been identified consistently as the most significant toxics found in urban storm water and often exceed water quality criteria for aquatic life.

These metals are present in the biosphere as trace elements and are micronutrients necessary for plant and animal growth. Heavy metals are of concern because elevated concentration levels of soluble forms in natural water bodies can produce toxic effects in biota. Sources include domestic and industrial point-source discharges, urban storm water runoff, and direct atmospheric deposition. In this paper, copper (Cu), lead (Pb), zinc (Zn), and cadmium (Cd) have been recommended for inclusion in a monitoring program because storm water runoff water quality studies conducted at many urban locations have indicated that these metals are almost always present, and are at concentrations which tend to be elevated, relative to other heavy metals. They also can be used as surrogates for other heavy metals, as they tend to display the range of transport characteristics for heavy metals. However, other heavy metals should be analyzed if there are known sources of significant quantities of these metals in influent flows.

It is recommended that both the total and dissolved form of each be analyzed. Based upon EPA's recommendation, it is the dissolved fraction that should be compared to water quality criteria, with modifications to the criteria as noted in EPA (1993). To compare data to criteria, hardness should be measured for each sample. Too often metals data are compared to criteria using some hardness value not directly associated with the monitoring.

Total concentrations are valuable in assessing the overall reduction of the heavy metal in both soluble and particulate forms. There is a concern about the long-term bioavailability of these metals in sediments and sediment standards are beginning to be developed and implemented.

A third test that could be conducted is settleable metals. This test gives an indication of the metals that might be removable through sedimentation. The test merits will be discussed in the work session.

When conducting these tests, it is recommended that low detection limits be achieved. For copper, lead, and zinc, the detection limit should be 1 ug/l and for cadmium 0.2 ug/l. This will minimize problems with analyses that include below detection limit data, which can severely impact performance evaluations. Special "clean" procedures will be necessary to achieve low detection limits, both in the laboratory and in the field.

VOL 12

7696

Too often, BMP effectiveness for metals is estimated base upon data that is very near or below detection. This is troublesome when both the inflow and outflow concentrations are at or near detection, and effectiveness is based upon a storm by storm comparison of loads or concentrations. It is recommended that if both the influent and effluent concentration are within five times the method detection limit, the pollutant data pair not be considered in the effectiveness analysis if a storm by storm effectiveness method is used. If statistical characterizations of the inflow and the outflow concentrations are utilized to assess effectiveness and some of the data are below detection, appropriate techniques should be utilized. Driscoll et al. (1990) describes a method to address detection limit data. The setting of these values to 0 or ½ the detection limit or the detection limit, which is often done, will lead to an underestimation of the mean.

Oil and Grease. Oil and grease is a prevalent constituent in urban runoff and often exceeds discharge limits set by states (such as 10 mg/l in Oregon for industrial storm water permits). In a study of oil and grease concentrations in urban runoff in Richmond, California, Stenstrom et al. (1984) found that oil and grease concentrations in runoff from commercial properties and parking lots are about three times higher than from residential and open areas. The NURP program did not address oil and grease as a standard constituent. Accurately measuring oil and grease is very difficult, especially due to its affinity for coating sampling bottles and sampling tubes, and its highly nonuniform distribution in the water column (except in the most turbulent situations). Other tests include total petroleum hydrocarbons, which measure the petroleum based fraction of oil and grease. Other sources of oil and grease include animal and vegetable. For BMPs which are designed to address oil and grease, it is suggested that some multiple within a storm grab sample analyses would be appropriate. For most BMPs, it is recommended that the parameter be optional. If completed, the TPH evaluation is the most appropriate measure to gage effectiveness of a BMP at reducing man-induced sources of petroleum oil and greases.

Pesticides/Herbicides. Pesticides and herbicides are regularly detected in urban runoff. However, the number of constituents usually detected is low and most often at levels below available criteria. In Portland, Oregon (WCC, 1993a) the frequency of detection of pesticides, herbicides was less than 1 percent of all the pesticides and herbicides tested. However, the city has noted locations where pesticide concentrations in sediments are high. This could indicate that the problem with pesticides and herbicides might be due to misuse or dumping, rather than a general storm water problem. Although it is possible that pesticides accumulate in sediments from low concentrations in storm water, some regional assessments of the effectiveness of source control measures (education, identification and elimination of dumping problems) are needed. The Alameda County, CA monitoring program (Cooke and Lee, 1993) has recently identified that the pesticide Diazinon may be a primary cause of toxicity at very low concentrations (below 8140 method detection limits) of *cerodaphrin dubia* in receiving streams in the south bay area of San Francisco. More research is needed to further define the level of this problem in

VOL 12

7697

R0041005

relation to the instream biota, rather than test organisms. Other regional assessments have identified Diazinon as a pollutant which may be impairing water bodies. At this time, I would not recommend including the pesticide in a standard list, but focused research studies on the magnitude of the problem and the effectiveness of BMPs on these pesticides should be performed. Due to the low values at which these constituents can cause problems, it will be difficult to assess BMP performance on a wide-scale basis. For example, it may be more appropriate to eliminate or control the use of Diazinon rather than research BMP effectiveness.

Volatile and Semi-Volatile Organics. These pollutants have not generally been detected at a high frequency and in quantities that exceed available criteria [with the exception of Polynuclear Aromatic Hydrocarbons (PAHs), which are discussed separately]. In the recent City of Portland and Eugene sampling programs (WCC, 1993a and 1993b) detection rates were less than 2 percent of all the tested constituents and below all available criteria. These parameters are not recommended for general analysis unless the BMP effectiveness study is being considered in an industrial area suspected or known to have elevated levels of organics.

Polynuclear Aromatic Hydrocarbons. The carcinogenic properties of PAHs has generated increased interest in the study of their sources, transport, fate, and aquatic toxicity. Major sources include the combustion of fossil fuels, uncombusted petroleum products (fuels, etc.), and natural and man-caused fires. PAHs have recently been analyzed utilizing detection levels that are significantly below those achieved utilizing the standard semi-volatile organic scans (WCC, 1993a and 1993b; Cooke and Lee, 1993). These tests (GC-MS methods at the nanogram per liter level) have shown that PAHs in storm water are above human consumption criteria by significant amounts (up to over 100 times). This has been documented in a number of studies. However, these tests are specialized (only a few laboratories provide this level of analysis) and expensive (about $500 to $600 per analyses). In addition, there are no criteria for aquatic life and toxicity identification evaluations performed in the San Francisco Bay Area have not identified PAHs as the source of toxicity in either developed land-use runoff or in stream stations. For these reasons, PAHs are not recommended for the standard list of constituents to be monitored. However, because of their carcinogenic nature and their tendency to bioaccumulate, new studies may identify potential long-term aquatic life impacts that may require reevaluation of this recommendation.

Data Reporting

There are some practical and technical considerations regarding data reporting which would facilitate data usefulness, including consistent formatting of data, the clear indication of QA/QC results, standard comparisons to water quality criteria, and utilization of consistent methods for estimation of pollutant removal effectiveness. It is recommended that all constituent concentration data be reported as event mean concentrations (EMCs).

<u>Data Formatting</u>. Table 3 is an example table format for reporting storm event EMCs. It indicates the date of the storm, the EMC value for each sampling point, the data that are estimates based upon QA/QC evaluations, method used for analysis, and detection limit achieved. Also included are summary statistics of the EMCs. These statistics should be based on use of the lognormal distribution. The NURP and FHWA studies (EPA, 1983; Driscoll et al., 1983) identified that the lognormal distribution is suitable for characterizing EMC distributions.

The inclusion of outlet data as a part of any paper or report will allow comparisons of typical outlet concentrations and may allow the determination of the lowest expected concentration from a particular type of BMP. For example, it may be that

Results expressed as mg/L (ppm) unless otherwise noted. COV is the Coefficient of Variation. ** Criteria are hardness dependent.
"nd" means none detected at or above the detection limit listed. If no value is shown, the lab analysis was not performed.
Summary statistics are based upon the assumption that the sample of EMCs is lognormally distributed.
Italicized values are considered estimates due to QA/QC review but are included in the calculations.

Table 3. Example Data Reporting Table from Eugene NPDES Monitoring Summary Report (WCC, 1993b)

wet ponds may only be able to treat to some minimum concentration range at the outlet and the "effectiveness" is greatly impacted by the inlet concentrations.

Quality Assurance/Quality Control (QA/QC). All monitoring studies should include a QA/QC program. The results of the QA/QC program should be reported in monitoring study reports and summarized in papers. It is especially important to discuss when data are characterized as estimates due to QA/QC results and when detection limits were affected. Too often this information is not included.

Comparisons to Water Quality Criteria. Another method to gage effectiveness could be to monitor how the BMP effects the number of times that criteria are exceeded in both the inflow and the outflow, to assess how the BMP reduces (or does not reduce) the number of times water quality criteria are exceeded. For heavy metals analyses, it is recommended that hardness be collected for all storms monitored and that comparisons to criteria be made utilizing the dissolved fraction with the computed aquatic criteria as modified by EPA (1993). Table 4 presents an example presentation of metals exceedances for data collected in Portland, Oregon (WCC 1993a).

Estimation of Pollutant Removal Effectiveness

BMP pollutant removal effectiveness estimations are not straightforward. Martin and Smoot (1986) discussed the following three types of methods to compute efficiencies:

- The first method employs the efficiency ratio (ER), which is defined in terms of the average event mean concentration (EMC) of pollutants from inflows and outflows, thus:

$$ER = 1 - \frac{\text{Average outlet EMC}}{\text{Average inlet EMC}}$$

- The second method is based on the summation of loads (SOL) of pollutants removed during the monitored storms, thus:

$$SOL = 1 - \frac{\text{Sum of outlet loads}}{\text{Sum of inlet loads}}$$

- The third method of determining efficiency was developed by Martin and Smoot (1986). This method defines the ratio as the slope of a simple linear regression of inlet loads and outlet loads of pollutants. The equation for the regression of loads (ROL) efficiency is thus:

$$\text{Loads in} = \beta \cdot \text{Loads out}$$

where β equals the slope of the regression line, with the intercept constrained at zero.

Results expressed as mg/l, unless otherwise noted.
Shaded, bold face type indicate acute criteria exceedances. Acute criteria shown is for Cr (+3). Cr (+6) criteria is 0.016 (mg/l).
The "nd" symbol means none detected at or above the indicated value and represents the method detection limit.

Table 4. Example Comparison to Water Quality Criteria

The ER and SOL methods assume that the monitored storms include samples that are representative of all storms that occur. The SOL method assumes that enough samples were collected such that any significant input loads or output loads were not missed. They are different in that one gages effectiveness in terms of concentration reduction, while the other gages effectiveness in terms of load of pollutant removed. The ROL method assumes that the treatment efficiency is the same for all storms.

Urbonas in this session suggested one should utilize an efficiency measure based upon storm pollutant loads into and out of the BMP on a storm by storm basis. This would weight the effectiveness considering that all storms are "equal" in computing the average removal. Similarly one could utilize concentrations on a storm by storm basis.

One factor that complicates the estimation of the effectiveness is that for wet ponds and wetlands (and other BMPs where there is a permanent pool), comparing effectiveness on a storm by storm basis neglects the fact that the outflow being measured may have no or only a limited relationship to the inflow. In analysis of rain gages utilizing SYNOP (EPA, 1989), if a basin where sized to have a permanent pool equal to the average storm, about 60 to 70 percent of the storms would be less than this volume. Therefore, storm to storm comparisons are probably not valid. In cases like this, it is probably more appropriate to utilize statistical characterizations of the inflow and outflow concentrations to evaluate effectiveness or, if enough samples are collected (i.e., almost all storms monitored), to utilize total loads into and out of the BMP.

Sample Collection Techniques

This topic deserves much more attention than this paper can possibly address. The collection of the sample alone is likely the largest source of variation in reported removal efficiencies. Questions and concerns such as how well mixed are the flows, placement of intake tubes, the effects of peristaltic pumps and pumping of a sample from up to 15 feet or more below the sampler, and how they affect what gets into the sample bottle. Another question is how often are sub-samples collected as a part of the flow-weighted composite? Sartor and Boyd (1972; and Boyd, personal communications) contemplated some post sampling/pre-analysis techniques to address some of these issues. They felt that a more representative sample for comparisons would be 1) to avoid collecting surface scum in the sample and 2) to perform a 20-minute settling to remove the settleable solids that were probably not collected representatively (due to settling that probably occurs in the intake tube). Then effectiveness comparisons could be made on the remaining "more representative" samples. The easily settleable material could still be analyzed separately.

BMP Evaluations – Statistical Considerations

There are several types of BMP evaluations that may be conducted. First, the standard evaluation of a single BMP, testing input and output; second, the evaluation of multiple BMPs within a basin; and third, the evaluation of a BMP with multiple inlets (where it might be impossible to evaluate the BMP utilizing input/output). For the second and third, the only practical method of evaluation may be a downstream analysis of before and after implementation of BMP(s). This will require that a rigorous statistical approach be applied in selecting the number of samples to be collected to assure detection of a given level of change. As an example of the number of samples required to detect a "true" difference, Table 5 presents an analysis of two of the NPDES monitoring stations where 10 flow-weighted composited samples were collected. The Fanno Creek station is a large (about 1,200 acres) residential catchment, while the M1 station is a smaller (about 100 acres) mixed land use station. An analysis of a variance-based test was utilized to determine how many samples would need to be collected to detect a 5%, 20%, and 50% change in the mean concentration at the station. The test was performed considering an 80% probability that the difference will be found to be significant, with a 5% level of significance (Sokal and Rohlf, 1969). The results are shown in Table 5. This analysis does not consider potential seasonal effects on the collection of data as a factor. Even so, quite a large number of samples would be required to detect a 5% to 20% difference in concentrations. There are numerous examples in the literature where differences of these levels are reported based upon much fewer samples than indicated by this analysis. This indicates the need to be more rigorous with regard to statistical testing of reported effectiveness estimates. To detect larger changes, the number of samples becomes reasonable. The mixed land use catchment in Portland is currently being studied for the effectiveness of the implementation of a number of source controls and other controls that do not lend themselves to input/output testing. Examples include maintenance changes (catch basin cleaning, street sweeping), education (business and residences), tree planting, etc. Post-BMP monitoring will be conducted along with qualitative evaluations.

Other Considerations

There is a need to conduct dry weather analyses between storms on BMPs with dry weather flows. It may be that pollutants captured during storms are slowly released during dry weather discharges.

Biological assessments such as those discussed by Eric Livingston in this conference should be explored as an alternative to just utilizing chemical measures of effectiveness. Long-term trends in receiving water quality, coupled with biological assessments, would likely be a much better gage of the success of the implementation of BMPs, especially on an area-wide basis.

Monitoring Site	Parameter	Number of Samples Required to Detect the Indicated % Reduction in Site Mean Concentration* 5%	20%	50%
R1 - Fanno Creek Residential	TSS	202	14	4
	Copper	442	29	6
	Phosphorus	244	16	4
M1 - NE 122nd and Columbia Slough Mixed Use	TSS	61	5	2
	Copper	226	15	4
	Phosphorus	105	8	3

*80% certain of detecting the indicated % reduction in mean of the EMCs.

Table 5. Analysis of Sample Sizes Needed to Statistically Detect Changes in Mean Pollutant Concentrations from 2 Stations in Portland, Oregon

Summary and Recommendations

There is a great need to have consistency with the constituents and methods utilized for assessing BMP effectiveness. This paper has presented only some of the consistency issues. It is recommended that researchers who undertake BMP effectiveness studies consider the recommendations suggested here or some other recommendations developed based upon further analysis of this subject. EPA should require studies receiving federal funding to conduct BMP effectiveness studies which utilize standard methods as suggested here to improve data transferability.

SESSION VI - BMP Monitoring for Data Transferability

DISCUSSION

Parameters to Report with BMP Monitoring Data
Ben Urbonas

Efficiency Calculations - should report long term removal as mass in minus mass out over the season, rather than event by event.

All federally funded BMPs should be required to enter data into a public database like GLIN (Great Lakes Information Network, operates on INFONET) or EPA CIESIN.

- Include estimates of error associated with measurements.
- Include whether the facility is on-line or off-line. Include event size captured by facility if it is designed to bypass larger flows.
- The volumes and EMCs of the by-passes, if monitored or estimated, would allow a better estimate of total annual or seasonal removals attributed to the BMP. Can address this by measuring the composite inflow and the co-mingled outflow of treated and bypassed flows. Thus, each event's effectiveness is reported in total.

Measure rates of sediment accumulation, sediment volume and grain size in detention facilities.

Residuals management should be part of the evaluation. This information is useful for solid waste concerns (nice to have), but is not necessary for BMP assessments.

Water balance must be included in BMP evaluation.

Measure settling velocity of influent using settling column test (nice to have).

Report percentage of flow included in calculation of event EMCs. Report percentage of total storm volume and annual flow included in the EMC calculation.

Include construction cost and O&M cost for the facility (This is nice to have, but not a technical issue.)

VOL 12

Safety should be included in the BMP evaluation; keep a record of accidents, etc. (nice to have).

Keep record of O&M practices on the site (must have).

Questions/Comments

Question: Should standardization take place through ASTM, ASCE or some formal organization?
Answer: We are not ready to propose a mandatory program.

Question: There are a number of other areas where standardization would be useful, such as monitoring. Should the Council (or ASTM, or ASCE, etc.) work on these others?
Answer: Might be useful.

Question: When talking about efficiency you use arithmetic averages. How about long-term efficiencies over several events?
Answer: Good point - I need to look at my equations. (Post-conference response: Suggest using arithmetic averages of removal efficiencies and not flow-weighted ones to avoid being overwhelmed by the effects of one or more very large, atypical, events.)

Question: The parameter list seems quite long. Shouldn't we separate it into must have and nice to have categories?
Answer: Most of the parameters defined in the paper are "must haves" for BMP assessments.

Comment: Class parameters into "must have" and "nice to have." Need to define some criteria for differentiating between: 1) extended detention ponds with a permanent pool; 2) "wet pond", which has a biological component in littoral vegetation and permanent pool; and 3) wetland.

Question: How about including measurement error (error estimates)?
Answer: Very good point.

Question: Shouldn't we also report if a facility is on-line versus off-line?
Answer: Yes.

Comment: We should have a simple procedure for measuring settling velocity distribution. (Editor's note: Hans Brombach, a German consultant, is working on such a device, and the CSO people have been using one for some time).

7708

Comment: The residuals management aspect of a facility, such as the disposition of sediments removed from a pond, should also be reported.

Response: This is nice to have, but not necessary for evaluating the performance effectiveness of a BMP. Residuals management is a problem that must be addressed at all BMP sites.

Comment: We should also report the water-balance aspects of a facility. This may help to interpret the volumes reported and any losses in storage.

Response: Good point - this is suggested indirectly in the paper and should be one of the descriptive parameters.

Question: Shouldn't we be reporting the inflow and outflow hydrographs?

Answer: That is a good idea, however, storm volume is the operative term when we try to come up with a minimum list.

Question: We often sample and report only a portion of the storm event - don't we also need to have some idea of the total event (and total annual) flow?

Answer: This is also a good point. I presume that is the case in such evaluation studies.

Constituents and Methods for Assessing BMPs
Eric Strecker

Recommendations:

- Adopt consistent constituents as a minimum
- Adopt consistent reporting techniques
- Produce a monitoring methods manual

TOC in conjunction with BOD is a good indicator of total organic hydrocarbons. Use as surrogate for individual tests. (Editor's note - another individual believes that TOC is a better way of measuring organic carbon content - if values are high, then one can look at specific organic compounds further. This is one place where it would be good to consult with the analytical chemists).

The low-detection methods recommended for pesticides are not always necessary. Use of a gas chromatograph-mass spectrometer is suitable for most purposes.

Sample some simple conservative parameter to help you do a mass balance and calculate the error in your measurements.

Should list standard methods for each constituent. Also need to get some help from the chemists in setting these parameters. Need to pay particular attention to concentrations at or near the detection limit - likely not accurate.

Provide guidance on how to report data near or below the detection limits.

If BOD is measured, need to do ultimate BOD and K determination.

For ponds with multiple inflows, might use storage equation with stage and outflow volume to compute inflow (but what about computing quality and mass load in?).

Report rainfall intensity of storm events used in BMP assessment.

Use a coulter counter for the determination of solids.

Report age of BMP and maintenance practices to assist with understanding long term behavior.

Lithium chloride can useful as a tracer to verify weir or channel discharge stage curves.

Should not ignore how BMPs affect the quality of the groundwater.

Fecal Coliform or pathogens should be considered as an addition to the parameter list.

Analytical methods that indicate partitioning of metals should be considered.

May need to modify Standard Methods to work better for stormwater.

Transpiration should be part of the water balance in wetlands.

Questions/Comments

Comment: A vital part of your monitoring program is good specifications for your analytical chemistry labs. It is also a good idea to use blanks, spikes, etc. for quality control, and in fact our laboratories welcome this.

Comment: (Post-Conference Comment by Strecker) Recommend that BOD be dropped as a constituent. It is extremely difficult to sample, especially when drain time is measured in periods of days, and of little practical value in stormwater. Surrogates such as TOC or COD can be used.

Time-Scale Toxic Effects in Aquatic Ecosystems

Edwin E. Herricks[1] Member ASCE, Ian Milne and Ian Johnson[2]

Abstract

Although the general effects of stormwater on receiving systems are well described, the relationship between loading/concentration changes during stormwater runoff events and time-scale toxicity, which would support improved modeling and prediction of stormwater effects, is poorly defined. In fact, there are few studies that clearly assess the effects of episodic change in contaminant concentration on individuals, populations, or communities of organisms. To effectively assess these time-scale effects, it is necessary to connect multiple factors, including physical, chemical and biological/ecological characteristics of receiving systems and their watersheds conditions, which affect receiving system biota. The interactions between flow and toxic contaminant concentration in stormwater runoff events, and the measurement of toxic effect is the focus of this paper.

Introduction

When monitoring receiving water trends associated with wet-weather events, including stormwater runoff, there are reasonably predictable changes in water quality but much less predictable changes in receiving water ecosystems produced by toxic contaminants in the stormwater. The changes in water quality are produced by mechanisms that operate on land surfaces as well as in the stream channel affecting both physical (habitat) and chemical (water quality/contaminant concentration) conditions. The result is a powerful mechanism for change in aquatic ecosystems. Although aquatic organisms are adapted to life in a changing environment, stormwater flow events, particularly

[1] Professor of Environmental Biology, Department of Civil Engineering, University of Illinois at Urbana-Champaign, 3215 NCEL, MC-250, 205 N. Mathews, Urbana, IL 61801

[2]Water Research Centre, P.O. Box 16, Marlow, Buckinghamshire SL7 2HD, United Kingdom

in urban areas, are often very different than those found in more natural settings. In addition to increased flow volume, and changes in the unit hydrograph (e.g. higher slope ascending and descending limbs with higher peaks) the presence of toxic contaminants will reduce the capacity of aquatic organisms to function in areas changed from natural conditions. Unfortunately, although the general effects of stormwater on receiving systems are well described, the relationship between contaminant loading and time-scale toxicity, which would support improved modeling and prediction of stormwater effects, is poorly defined. In fact, there are few studies that clearly assess the effects of episodic change in contaminant concentration on individuals, populations, or communities of organisms. To effectively measure these time-scale effects, it is necessary to consider the full range of factors that affect receiving system biota. The interactions between flow and toxic contaminant concentration, and the measurement of toxic effect is the focus of this paper.

Stormwater Characteristics

A key characteristic of stormwater events is rapid change in physical and chemical conditions in the receiving system. Pre-storm conditions usually find the receiving system at a stable flow with low contaminant concentrations, although contaminant presence and concentration may vary based on land use and the presence of industrial, or other effluents. The primary determinant of overall stormwater event characteristics is rainfall. The rainfall required to change receiving system conditions will vary based on land use and watershed conditions. The sequence of events has been well described. Rainfall in excess of interception, infiltration, and storage will run off. Runoff increases the volume of flow in the receiving system, which can be described in terms of a time discharge relationship - the runoff hydrograph. Storm intensity and watershed conditions determine the rising limb slope, the peak, and recession limb characteristics. Contaminant concentrations will vary following a pattern that is hydrograph related. Since contaminant concentrations may be zero, or at very low background concentrations, the transient change may be of several orders of magnitude. Usually, contaminant concentrations will rise and then fall, with the changing concentrations associated with how and when the contaminants are delivered to the receiving system and the dilution produced by increased flow volume. A commonly recognized contaminant maxima is associated with the first flush that carries contaminants stored on land or other surfaces, but other peaks in concentration may occur when critical hydraulic conditions are reached and contaminants in the stream bed are re-suspended. Thus a storm flow may produce one or more high concentration transients during a single event, each transient present for only a short time, potentially a few seconds to several minutes.

Stormwater events also have characteristics common to all discharges of contaminants into receiving waters. These characteristics include source specificity, loading/concentration relationships, and seasonal influences. Source specificity will typically define the contaminant type and the delivery mechanism. Contaminant types are conservative (unchanging) and non-conservative (defined half-life or degradation rate). The addition of both conservative and non-conservative contaminants to the receiving system can create secondary effects such as 1) storage of conservative contaminants increasing potential environmental, and organism, exposure concentration, 2) the breakdown of non-conservative contaminants altering environmental conditions (e.g. dissolved oxygen depletion) or 3) production of new contaminants as parent compounds decompose or are altered (e.g. photolysis). The delivery mechanism will vary based on source (e.g. point or non-point) Point sources of stormwater, such as combined sewer overflows or storm sewer outfalls can be characterized and related to expected receiving system conditions upstream and downstream of the discharge location. Non-point sources of stormwater are by their very nature diffuse and will have characteristics associated with the flow path and associated land use.

Loading/concentration relationships for stormwater runoff deserve some review. The determination of loading begins with an analysis of concentration, then a mass discharge is calculated from analyzed concentrations and measured discharge flow. Loading effects can be related to receiving system dilution capacity. A small load may produce a high concentration in a small stream where dilution capacity is limited. Thus in upper reaches of a watershed the greatest concern for time-related change may be for stormwater related concentration transients with minimal attention paid to loading when loads are small. Because loading may produce biological or ecological consequence while the instream concentration remains low because of receiving stream dilution capacity, there may be more concern in the lower watershed may be for stormwater related contaminant loading. In reality, as suggested by Schlosser and Karr (1981), both loading and concentration are important issues when considering stormwater runoff effect.

Seasonal concerns are associated with both what organisms are present and changing background environmental conditions. The species present during a storm event will determine the general susceptibility of receiving system communities to stormwater. Species presence and abundance is expected to change naturally through the seasons due to normal growth and development, and organism movement. Suscepubility to the changes produced by stormwater will be determined by the presence of sensitive life stages or the presence in migratory species. Seasonal change in environmental conditions will find differences in temperature, base flow (general dilution capacity), and other physical and chemical conditions.

In summary, stormwater event characteristics are reasonably predictable. There will be time-related changes in flow and corresponding time and flow related changes in receiving system water quality. To illustrate these general characteristics an example is provided from the Copper Slough, near Champaign,

VOL 12

7/1/3

Illinois. The Copper Slough receives urban runoff and the discharge from a sewage treatment plant. Figure 1 illustrates the effect of a stormwater event on receiving system water quality, tracking changes in temperature, pH, conductivity, and dissolved oxygen. Although event characteristics alone are important, it is essential to view the stormwater event in the context of the receiving system. Figure 2 provides a summary of receiving system conditions before, during, and after the same stormwater event. Figure 1 clearly shows changes in water quality (pH and DO) and the effects of dilution (specific conductivity). Figure 2 shows storm event effects on the natural diurnal variation in stream conditions, indicating that a single storm event may alter natural conditions for some time after a stormwater runoff event.

Species and Community Adaption to Disturbance

Aquatic organisms are adapted to changing conditions in streams. In fact, disturbance is thought to play a major a role in ecosystem maintenance and controls the character of most (if not all) natural systems (Sprugel, 1985; Gerritsen and Patten, 1985; Harper, 1977; Doyle, 1981). This is particularly true for streams where changes in flow, and related habitat, are common. Disturbance can be defined as a greater than expected magnitude of variance (lower than expected predictability) occurring for a time span related to a specified level of analysis (Gerritsen and Patten, 1985). As watersheds develop the general result is an increase in variance in receiving system conditions. Disturbance classes can be developed based on a series of state variables, and change vectors (Gerritsen and Patten, 1985; Fontaine, 1983; Odum, 1985; Odum, 1979).

Because streams are constantly changing (seasonally as well as with storm events), defining disturbance in stream ecosystems is difficult because there is a constant "expectation" of change. A challenge to ecologists, particularly stream ecologists is the full characterization of disturbance variables and vectors rather than simply identifying system state or condition at some point in time and/or space. Finally, it is important to recognize the full influence of time when considering disturbance in stream ecosystems. Connell and Sousa (1983) have suggested that one must study a biotic system for a length of time equal to the life history of the longest lived organism in the system, in order to understand system dynamics. In fact, that time span may be too short to fully understand factors that contribute to ecosystem dynamics. Gerritsen and Patten (1985) suggest that the Connell and Sousa (1983) concepts can be extended to include one complete turnover of biotic (population numbers, biomass) or abiotic (nutrients) elements. If both organism life history and turnover are considered in analysis, disturbance may be classed as: 1) a change in state caused by a) removal of organisms by an external factor (e.g. toxicity); b) by the addition of organisms that displace indigenous flora and fauna (e.g. the Zebra mussel); or c) by changes in the physical structure of the system; or 2) as a change in inputs (increase or decrease) of biotic or abiotic materials (Sprugel, 1985; Gerritsen and Patten, 1985).

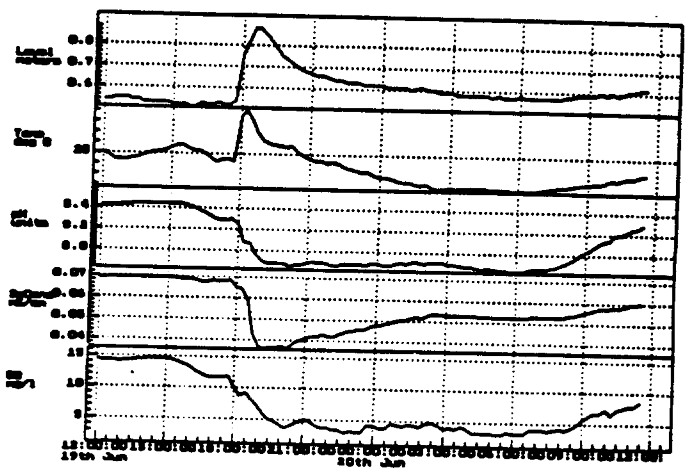

Figure 1. Twelve hour record of a single storm event.

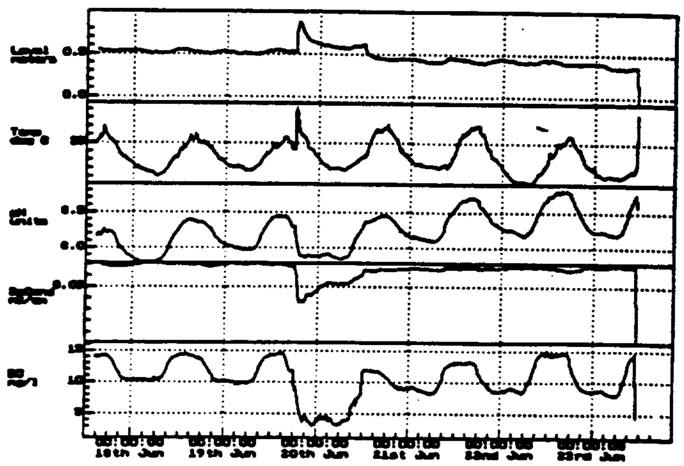

Figure 2. Six day record of stream water quality with storm event on Day 3

What are the implications of these theories on disturbance in streams affected by stormwater. First, a recognition that disturbance plays a role in the natural function of systems receiving stormwater suggests that stormwater, and storm effects, are important to the maintenance of stream ecosystems and regulation should not be developed to "eliminate" stormwater. Next, it is possible to develop a better understanding of variables and vectors that relate storm events to organism and community ecology. Experiments, field manipulations, and assessments involving organisms (including toxicity testing), species life history and interactions, and/or element turnover must go beyond a simple identification of state and condition to address time-related issues in receiving systems. Finally, it will be necessary to fully define disturbance. In a stormwater context that will require identification of what actually constitutes a disturbance in receiving systems affected by stormwater runoff. Further, the definition must consider both physical and chemical factors and develop a solid relationship between those factors and organism presence and receiving system community structure and function.

A Synthesis of Time-Scale Effects

When viewed from an ecological perspective the effects of a single storm may produce: 1) no effect (e.g. if the event produces no change, or changes produced have no consequence to organisms or the receiving system community), 2) short-term effects (e.g. change is disruptive, but disruptions are local and recovery mechanisms exist for rapid restoration of system state or condition), or 3) long-term effects (if change disrupts natural dynamics, producing a new stable state that resists return to pre-storm conditions. In reality, it is seldom that a single storm event produces severe environmental impact. Stormwater runoff effects are usually cumulative, produced over a long time span that includes a combination of storm-related change and large scale alterations of the watershed.

Typically the greatest environmental concern associated with stormwater runoff is toxicity. Toxicity is produced by both contaminant concentration, and the duration of the exposure to a given contaminant concentration. When considering the acute toxicity produced by stormwater runoff, the primary mechanism of effect can be defined by the concentration/time relationships for contaminants, and time related toxicity is typically associated with a single event. When considering chronic toxicity produced by stormwater runoff, the primary mechanism of effect is related to the fate and exposure concentration of contaminants introduced to the receiving system.

We do know that single stormwater events can produce chemical toxicity. Examples of event specific toxicity are given in Figure 3 and 4. In Figure 3, toxicity is determined using a microtox assay of samples collected at different times during a stormwater runoff hydrograph. The results indicate changing toxicity at different stages of the hydrograph. In Figure 4, toxicity is determined using a longer term toxicity test (in this case a 24-hour bioassay using rotifers).

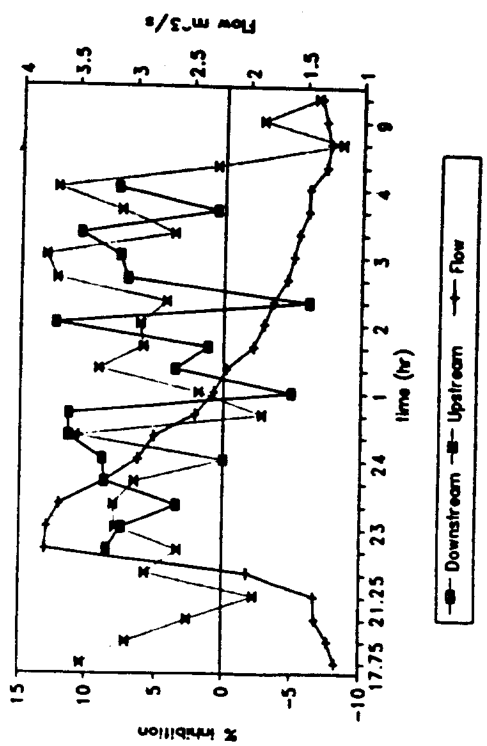

Figure 3. Microtox assay results on samples collected during a storm event.

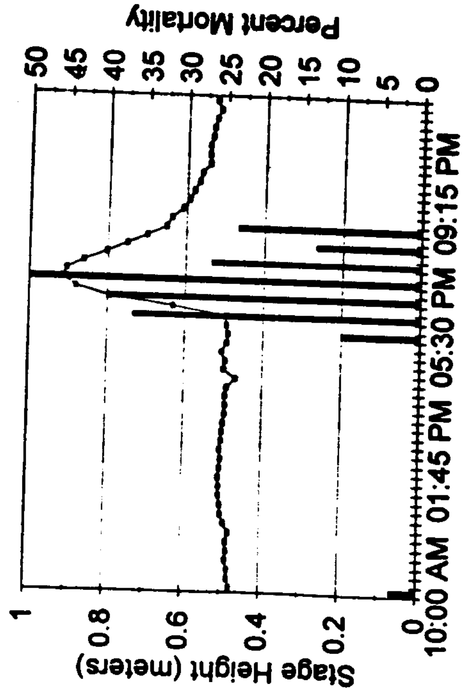

Figure 4. Rotifer 24 hr toxicity measured in samples collected during a storm event.

The results from this testing reveal a slightly different stage-related toxicity. A major cause of this apparent change in toxic effect is that the time of exposure to stormwater related contaminants is near the expected natural exposure time for the microtox assay, and well in excess of natural exposure times for the rotifer assay. A valid question that might be asked is are these toxicity results meaningful? We have measured toxicity, but assigning importance to indications of toxicity is very difficult because the link between acutely toxic events and long-term, or chronic, effect is still uncertain.

To get a handle on potential chronic toxicity we must turn to any of a number of studies have demonstrated "impact" from stormwater, particularly urban runoff (Whiting and Clifford, 1983; Garie and McIntosh, 1986; Willemsen et al., 1990; Bascombe et al., 1990; Milne et al., 1992). In these studies, measurements are usually made of water column, and sometimes sediment, contaminant concentrations along with assessments of receiving system state and condition. A link to chronic toxicity is suggested in many of these studies, and elevated environmental concentrations of contaminants have been related to stormwater loading. The major difficulty in these assessments is that it is difficult to separate stormwater effects from other watershed influences, and, by their nature, these assessments connect multiple events, which may differentially affect receiving system condition. In watersheds changed from their natural state, effects observed may be more from global causes, such as watershed disruption, than from specific factors, such as single or multiple storm event changes to the receiving system, either physical or chemical. Further, we simply do not know enough about the connection between episodic event effects to adequately develop a comprehensive assessment of chronic effects that are specifically stormwater related.

Where are we left in this analysis? A synthesis of time-scale effects produced by stormwater is possible. In a single event, there will most likely be two periods when concentration of contaminants is highest. The first is associated with the first flush, the second associated with the resuspension of previously deposited contaminants. During an event, the concentration and time of exposure of the first flush contaminants may or may not produce measurable toxicity. Nonetheless, the addition of contaminants to the receiving system may have long term consequences. If the contaminant is conservative, it is possible that it will accumulate, and exposure concentrations may reach levels that produce chronic, and possibly even acute, toxicity in target organisms. If a contaminant is non-conservative, its degradation products may extend the effect of a storm event by causing environmental change well beyond the unit hydrograph. It is also possible that degradation byproducts may produce chronic toxicity, or acutely toxic concentrations may be produced some time after the event that added the primary contaminant to the receiving system. In addition, physical disturbances caused by the storm event may increase toxic effects. For example scour or dislocation of organisms may increase their susceptibility to toxic contaminants.

The challenge to developing a reasonable, and scientifically accurate, analysis of time-scale effects will be the development of an effective measurement program that identifies specific stormwater effects, and sorts these effects from the range of other changes that may naturally occur, or be present because of watershed development.

Measurement of Time-Scale Effects

To address the issue of measurement of time-scale effects it is necessary to select actual metrics for measurement. The testing approaches, and test systems, available for these measurements can be selected from a range of physical or chemical measurements, and biological measurements that can be made at the various levels of the biological/ecological hierarchy (Herricks and Schaeffer, 1985; Herricks, 1992). The principal challenge is connecting any measurements made to stormwater runoff. A useful starting point for establishing connections is the identification of both cause and effect through an organized measurement/assessment program. One of the more common cause and effect relationships is that illustrated in the typical dose/concentration response curve commonly developed from toxicity testing, Figure 5. We have identified three regions of response that provide a basis for identifying cause and effect. In the first region no effect is measured, or effects are indeterminant because at this "low" stress/disturbance level although change may be observed in lower levels of the hierarchy (e.g. biochemical responses) change is not disruptive and the capacity of the organism to maintain function produces a flat response at higher levels of the hierarchy. In the second region, the magnitude of the stress increases and a threshold in response is observed. In this region toxicity may be observed as a graded response or a progressive change in community structure and function that can be related to increasing stress dosage. Low doses will be associated with chronic toxicity while high doses will be associated with acute toxicity. If the dose/concentration remains low, organisms can acclimate and the best response measures for community-level assessment will be associated with changes in function. Later in the second region, as dose increases, more profound effects are observed that gradually increase in severity. Dose/concentration levels exceed chronic effect levels leading to acute toxicity while the increased stress/disturbance levels produce responses that are effectively measured using structural metrics (e.g. replacement of sensitive by more tolerant species). At even higher dosages, we find that even tolerant species affected so the response observed is a change in both structure and function. Responses may be magnified because functional redundancy (the capacity of one species to replace the functional role of another species) is lost with progression through the second region. In the final region, measurement of response may be problematic. The high dosage produces such profound effects that responses are limited (e.g. further structural change is minimal and the spectrum of functional responses is reduced to a single response, death.

VOL 12

7721

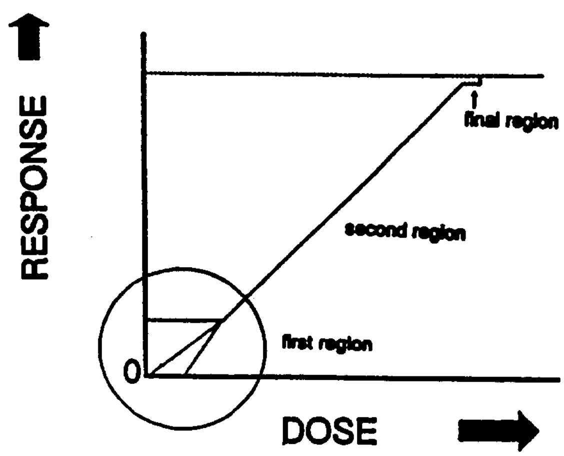

Figure 5. Dose (or Concentration) Response Curve.

VOL 12

7722

The progression of response can also be related to disturbance. The onset of change occurs as the variability of environmental conditions exceed the capacity of the receiving system to adjust to change. With increasing frequency of disturbance, the capacity of the receiving system is further diminished and the ability to cope with additional change is further reduced. Depending on the antecedent state of the receiving system, even a short duration low magnitude disturbance, such as a stormwater runoff event, can lead directly to stages three and four particularly in highly developed watersheds.

Clearly, the effects of stormwater runoff can be complex, ranging from short duration changes in contaminant concentration to long term modification of physical, chemical, and biological habitat conditions. This range of potential effects suggests that the measurement approach, and test systems used, to assess stormwater runoff must have characteristics that allow effect analysis over a range of temporal and spatial scales, which accommodate all levels of the biological/ecological hierarchy. The following characteristics of test systems are needed to effectively and efficiently assess the effects of stormwater runoff.

1. The time scale for the response must match the time scale of the exposure. For stormwater runoff, this means that the ideal test systems must have the capacity to respond to transient changes in contaminant concentration. Continuous monitoring results suggest that the shortest duration for transient concentration change is on the order of seconds with duration measured in minutes.

2. The test system must have response characteristics that track the transient changes in contaminant concentration during a stormwater runoff event. Because each stormwater event can produce a complex set of concentration, duration, and frequency of exposure conditions, an ideal test system must have both rapid response characteristics and some level of independence from exposure history to provide an accurate measure of constantly changing effects.

3. The ideal test system must also have the capacity to measure the effects of a single stressor, as well as integrate the effects of multiple physical, chemical, and/or biological stressors. The nature of stormwater runoff events suggest that it is unlikely that a single stressor will be the primary cause of an observed response during the entirety of a wet weather event although a community response is likely to be the sum of the response of different species to different single stressors. An ideal test system must have the capacity for effective monitoring transients of a single stressor with the ability to exclude other stress types, or the capacity to integrate responses for a range of stressors while maintaining the ability to discriminate between multiple stressor effects on a single, or multiple, response(s).

VOL 12

7723

R0041031

4. The test system must have the capacity to assess an impact, or provide a measure, or measures, that have relevance to an ecological system or at least high hierarchical level effect. The ideal test system will provide measures that correlate highly with observed damage or impact.

In addition to these characteristics specific for stormwater runoff analysis, test systems must also meet other criteria that are applied in either experimental or descriptive analyses that often constitute what is considered Quality Assurance or Quality Control (QA/QC) elements or activities, Table 1. To meet these criteria, it should be evident that more than one test system will be required for stormwater runoff effect analysis. In fact a test battery, concurrent application of multiple test systems, will be required for effective measurement of stormwater runoff effects.

Test Systems

To provide a useful summary for the review of test systems that may be useful in developing a suitable test battery, a table was developed that examined test system types in relation to identified criteria for test system selection (Herricks, et.al. 1994), Appendix A. A critical issue in the selection of test systems, measures, and metrics is the development and implementation of a QA/QC program that meets the stormwater runoff and general testing criteria. Unfortunately, it is not possible to apply QA/QC protocols commonly used in ecotoxicology. For example, where testing is carried out on collected water samples, standard QA/QC procedures can be applied to sample collection and analysis. These procedures can include inclusion of field and analytical blanks, and replicate testing of toxicity. Where *in situ* tests are involved, it is not possible to implement a similar QA/QC program. It is simply not possible to truly replicate field conditions, or provide experimental controls. Further, the evaluation of test systems as a measure of stormwater runoff effect may follow no accepted standard methods because, in fact, the evaluations are a part of the development of new methods. For *in situ* measurements and field assessments it is possible to develop adequate reference samples from unaffected areas, and develop robust experimental designs that incorporate, where possible, standard methods and incorporate effective QA/QC procedures. Addressing the characteristics and criteria in the test system selection process establishes a basic QA/QC program. In addition, reference toxicant testing can be used to assess changes in sensitivity of different batches of organisms used in laboratory studies or field deployments.

Implications for Monitoring and Regulation

Virtually any living system can be used in a bioassay (Schaeffer and Herricks, 1993) but not all test systems are appropriate for the determination of time-scale toxicity. Not all living systems will respond in the same manner to the same contaminant, nor can the response from a single individual necessarily be

VOL 12

7724

Accuracy	Ability to predict actual effects of a contaminant (e.g. minimize false positives and false negatives). In practice, the ability of the test to produce a dose-response curve is evaluated, and to make predictions that are consistent with other measures.
Precision	Ability to produce low variation in the analysis of identical samples.
Sensitivity	Ability to measure low concentrations with acceptable precision.
Variability	Inherent variability of the test system should be known, or easily estimated. Schaeffer and Cox (1986) suggest that variability should be expressed as coefficient of variation that can be classified as low <10%, medium <20%, high <30%, very high >30%
Controls	Test systems must provide adequate opportunity for controlled experimentation or have an adequate reference data base of performance to assist in assessing effect
Specificy	Test system should have a known specificity for contaminants. This specificity can be based on either response or chemicals. Response specificity refers to whether there is a specific uniform response to a dose, or a broad scale, non-uniform response. Chemical specificity refers to whether the test response is limited to a few or to a broad range of chemical types.
Convenience	The test system should have an ease of performance, which includes facilities and equipment requirements as well as procedures.
Cost	Fixed and unit costs associated with the analysis should meet accepted targets developed in the monitoring program.
Technical Requirements	Qualifications and training required for test performance must be specified.
Previous Application	Information on previous test system applications in similar or different systems at other sites by different investigators.

extrapolated to other members of the same species, other communities of organisms, or to the ecosystem (Herricks, 1993). Thus a major requirement for monitoring time-scale toxicity is selection of test systems, and assessment approaches, which 1) respond to a contaminants typical of stormwater runoff, 2) respond in the time/concentration pattern that is appropriate to the event or the condition produced by stormwater discharges, and 3) provide a basis for extrapolating effects to determine the risk of environmental damage.

VOL 12

7725

R0041033

The test systems available can include any biochemical, physiological, or behavioral response that can be measured experimentally, or a range of structural and functional population, community, or ecosystem parameters that can be monitored for change (Appendix). We will argue that any monitoring program for stormwater runoff effects must use a battery of test systems combined with a careful assessment of receiving system physical and chemical conditions. Further, since test system/battery applications to episodic toxicity measurement are limited, we have come to realize that the initial test system selection process should start with the evaluation of test systems that respond effectively to episodic event toxicity. Following the well developed hazard assessment procedures, we suggest that the initial phase of this evaluation should focus on screening tests with future analysis emphasizing predictive and confirmatory level testing. This implies that the program of measurement for time-scale toxicity should be ongoing and iterative, eventually developing a stormwater runoff effect analysis protocols that fully meet the need for realistic testing, follow QA/QC requirements and provide the foundation for regulation.

With regard to regulation, care must be taken when extrapolating existing toxicity testing data, or the use of standard toxicity testing methods, in regulatory programs. In fact, it may be inappropriate to apply existing standard acute or chronic toxicity testing procedures because these procedures inadequately, if not inaccurately, address concentration/time exposure relationships typical of stormwater runoff. The regulation of stormwater runoff should be established on sound scientific principles, meeting criteria for test system selection set out above.

Appendix - Table 3. Integrative responses of impacts produced by toxic substances in ecosystems (after National Research Council, 1991)

1 Elemental Dynamics	inputs, internal transport, and losses of critical plants, animals, and biochemical compounds, including the flux of nutrients essential for primary production and secondary metabolism.
2. Energy Dynamics (physical)	energy exchange at geological and biological surfaces (e.g., radiation, sensible and latent heat fluxes, and evapotranspiration) and mixing processes (e.g. turbulence, convection, and advection).
3 Food Web (trophic dynamics)	the set of trophic relationships among species in a community/ecosystem. In its simplest form, the food web is an energy-flow diagram connecting each consumer to all species that it consumes. However, in its dynamic form, the concept also includes rates of consumption, preference of food items, and prey switching. A given food web may indicate which species are necessary resources for other species (e.g., a particular valued species), the amount of redundancy in community/ecosystem functions, and the degree to which particular consumers, termed "keystone" species may control the competitive processes among the species consumed.
4 Biodiversity	the number of taxa per unit area as represented by populations, guilds, or life forms, as well as the relative abundance of various taxa.
5. Critical Species	keystone, resource, and endangered species: keystone species are those that exert influences over other populations in their ecosystem out of proportion to their abundances; resource species are species that have energetic, economic, or aesthetic importance; endangered species are species in imminent danger of becoming extinct.
6 Genetic Diversity	genetic diversity represents the number and frequency of different genotypes within species.
7 Dispersal and Migration	movements of individuals within and between ecosystems that are crucial to the population's survival and the ecosystem's health, including colonization or dispersal between habitats as well as movements of individuals to different habitats for food, reproduction, overwintering, or protection from predators.
8. Natural disturbance	externally driven disturbances, unrelated to human activities, that have major impacts on ecosystem integrity by altering the species composition, trophic structure, or other important ecosystem developmental processes; these disturbances include wind storms, fires, and floods resulting from weather patterns. these disturbances are often essential to maintenance of certain ecosystems.
9 Ecosystem Development (successional processes)	developmental changes (successional stages) in species composition through time, mediated by biological-physical interrelationships, resulting in a defined ecosystem structure and function.

Use of Sediment and Biological Monitoring

Eric H. Livingston[1], Ellen McCarron[1], Thomas Seal[2] and Gail Sloane[2]

ABSTRACT

Assessing the environmental effects of stormwater discharges presents many new and complex challenges. Unlike traditional point sources of pollution, these discharges are intermittent, creating temporally and spatially variable shock loadings to receiving waters. Consequently, traditional assessment techniques which rely solely upon sampling and characterization of the water column are ineffective in determining the environmental effects of stormwater discharges. This paper will discuss the need and rationale for alternative sampling and assessment procedures that provide a more ecologically-based manner of determining the environmental effects of stormwater discharges. Activities undertaken by the Florida Department of Environmental Protection in the past few years to develop biological community assessment and coastal sediment monitoring tools to evaluate stormwater discharges will be summarized. The development and use of a coastal and estuarine sediment assessment tool, based on the relationship between sediment aluminum and metal concentrations, will be reviewed. Similarly, the steps taken to develop and implement a riverine biological community assessment tool, based on comparisons between impacted sites and ecoregion reference sites, are reviewed.

INTRODUCTION

During the late 1970s, stormwater and other nonpoint sources (NPS) of pollution were identified as major contributors to the degradation of Florida's surface and ground water resources. To minimize stormwater pollutant loadings discharged from new land use activities, the Florida Environmental Regulation Commission adopted a statewide stormwater treatment regulation in February 1982. This rule, implemented cooperatively by the state's Department of Environmental Protection and

1. Stormwater/NPS Management Section, Florida Dept. of Environmental Protection, 2600 Blair Stone Rd, Tallahassee, FL 32399-2400

2. Sediment Research Group, FDEP, 3900 Commonwealth Blvd, Tallahassee, Florida

five regional water management districts, establishes permitting procedures and, for various types of stormwater management practices, design criteria presumed to achieve a specified treatment level. This rule is one of numerous statutes and regulations that have been implemented during the past 20 years to minimize the detrimental environmental effects associated with the state's extremely rapid growth. Collectively, the individual laws and programs enacted during this period can be considered "Florida's Watershed Management Program" (Livingston, 1993).

An essential component of this watershed management program is monitoring, to evaluate environmental conditions and the program's environmental benefits. In the past, water quality management actions focused on traditional point sources of pollution, such as domestic or industrial wastewater discharges, making monitoring and evaluation relatively easy. These point sources typically discharge effluents of uniform, known quality at continuous design flows, making them relatively easy to assess, model and control. Point source assessments generally have relied almost solely upon water column chemistry monitoring. On the other hand, stormwater and other nonpoint sources of pollution, because of their intermittent, diffuse, land use specific nature, are highly variable in effluent quality and environmental effects. Of particular environmental concern is the cumulative impact on a water body from the numerous stormwater/nonpoint sources within a watershed. Traditional water quality monitoring and management efforts generally suffer from several deficiencies in understanding and managing stormwater/NPS pollution. These deficiencies include difficulty in:

1. Assessing intermittent, shock loadings of pollutants.
2. Assessing cumulative impacts of multiple sources.
3. Comparing water bodies and establishing priorities for management actions.
4. Distinguishing actual or potential problems from perceived problems.
5. Discriminating anthropogenic loadings from natural watershed loadings of metals and nutrients.
6. Establishing cost-effective ways to assess pollution trends and understand overall watershed pollution.

Most stormwater pollutants accumulate over time in sediments, not the water column. Therefore, assessment methods to determine the cumulative effects of watershed stormwater/NPS pollution sources on aquatic systems or to evaluate the effectiveness of management programs should include evaluation of sediments and the organisms that reside there and in other aquatic habitats. This paper will review the development and implementation of sediment and biological monitoring protocols in Florida which are being used to improve evaluation and management of stormwater and other intermittent pollution sources, along with traditional point sources.

ASSESSING SEDIMENT CONTAMINATION

Sediment quality is a sensitive indicator of overall environmental quality. Sediments influence the environmental fate of many toxic and bioaccumulative substances in aquatic ecosystems. Sediments tend to integrate contaminant concentrations over time and may represent long-term sources of contamination. Specifically, sediment quality is important because many toxic contaminants found in only trace amounts in water can accumulate to elevated levels in sediments. Sediment-associated contaminants can also directly affect benthic and other sediment-associated organisms since sediments provide benthic and pelagic communities suitable habitats for essential biological processes (e.g. spawning, incubation, rearing, etc.).

Sediments provide an essential link between chemical and biological processes. By understanding this link, environmental scientists can develop assessment tools and conduct monitoring programs to more rapidly and accurately evaluate the health of aquatic systems. Therefore, sediment quality data provide essential information for evaluating ambient environmental quality conditions in water bodies. Additionally, information about the amount and quality of sediments within stormwater systems, stormsewers and other stormwater conveyances can help trace pollution sources, prioritize areas for implementing control measures, and help to assure proper disposal of accumulated sediments.

FLORIDA'S SEDIMENT ASSESSMENT PROJECTS

Florida has an extensive coastline (approximately 11,000 miles) and an unusual diversity of estuarine types. Conditions in its many estuaries range from nearly pristine to localized severe degradation. Metals are of particular concern in terms of protecting and rehabilitating estuaries because of their potential toxic effects and because high metal concentrations can signal the presence of other types of pollution. Natural metal concentrations can vary widely among Florida estuaries presenting special difficulties in comparing estuarine systems statewide and in making consistent, scientifically defensible management decisions.

In the past, determining whether estuarine and coastal sediments were anthropogenically enriched with metals was a difficult process requiring comprehensive site-specific assessments. In 1983, staff from the Department's Office of Coastal Zone Management, in association with Dr. Herb Windom of the Skidaway Institute of Oceanography, began a nearly decade long effort to develop a practical approach for assessing metals contamination in coastal sediments. Projects undertaken include:

1. The Deep Water Ports Project, a survey of sediment quality in eleven major ports around the state, performed in 1983-84.
2. The Statewide Survey of Clean Reference Sites, a survey of sediment quality in many relatively isolated, unimpacted locations around the state, done between 1986 and 1991.
3. Ongoing surveys, some in conjunction with the National Atmospheric and Oceanic Administration, initiated in 1985 to survey sediment quality in estuaries throughout Florida.

From these projects an assessment procedure was developed which relies on normalization of metal concentrations to a reference element. In Florida,

VOL 12

7735

normalization of metal concentrations to aluminum concentrations in estuarine sediments provided the most promising method of comparing metal levels regionally. Other elements such as iron or lithium can also be used as normalizing elements for assessing estuarine and marine sediments. Development of this sediment assessment procedure required three components of monitoring to be addressed:

1. Refinement of sediment sampling protocols and laboratory analytical techniques to assure that sediment data is accurate and comparable.
2. Development of an interpretive technique to determine whether sediment materials are naturally occurring or from anthropogenic sources within a watershed.
3. Development of sediment quality assessment guidelines to help determine whether sediment bound pollutants are harmful to the environment.

Part 1. Collection of Sediment Samples: To ensure that the information used to develop the interpretive tool represented the diverse Florida sediments, uncontaminated sediments from around the state were examined for their metal content and the natural variability of metal/aluminum relationships was statistically assessed (FDER, 1988). Sediment samples from 103 stations in uncontaminated estuarine/coastal areas were collected and analyzed for aluminum and other environmentally and geochemically important metals. The areas sampled encompassed various sediment types ranging from terrigenous, aluminosilicate-rich sediments in northern Florida to biogenic, carbonate-rich sediments in southern Florida. These "clean" sites were selected subjectively, based upon their remoteness from known or suspected anthropogenic metal sources.

The following sampling procedures were developed and refined into a standard protocol:

1. Prior to field sampling, station locations were determined after studying local watershed information (land use, drainage patterns and systems, water depths, potential sediment deposition areas), navigation charts, and meeting with local government staff.
2. Stations were located using LORAN-C by latitude and longitude, compass bearings, and cross referenced to navigational charts. In 1991, the standard field protocol was changed and Global Positioning System (GPS) is now used to locate stations.
3. Upon arrival at the station, the boat was anchored and engines shut off. The location, time, date, weather conditions, and compass bearings (and GPS location) were recorded in a station log notebook along with water column physical parameters taken at the surface, mid-depth, and bottom.
4. Sediments were collected in replicate from the boat using a stainless 9X9" PONAR grab sampler. The grab was suspended from a hoist, acid washed and rinsed with deionized water before use, and rinsed with ambient water between grabs. A 10% HCl solution was used to acid rinse all utensils, the sampling grab, and spatulas used to process samples. Once the sampler was retrieved, it was carefully emptied into a clean, acid washed and rinsed tub. The top two cm of sediment were scooped from the top of the grab. Repeated grabs were made at the same site until enough material was collected for all analyses.

VOL 12

7736

5. Sediments were collected by using sediment coring tubes at stations where the water was too shallow for the boat, or where sensitive habitats (sea grass beds, corals) precluded use of the grab sampler. Acid washed and rinsed clear cellulose-acetate-butyrate core tubes with caps were used for each sample, with three replicate samples collected at each station. Core tubes were plunged into the sediment and the top capped. A diver retrieved the core tube by displacing the sediment around the core, putting on the bottom cap, and lifting the core tube. Cores were taken to the boat where they were transferred into containers using an acid washed extruding tool. The top 3-5 cm of the cores were packed in the collecting jar. Each replicate sample was a composite of the three cores.
6. Samples were transferred to glass jars or whirlpaks which have been precleaned to meet EPA specifications for organic and inorganic materials. Sample containers were labeled, then placed on ice.
7. Since 1991, several changes have been made to the FDEP standard field protocol including:
   a. A 12"X12" Kynar coated stainless steel "Young" grab is used to collect sediment. It is deployed in a similar fashion as the PONAR.
   b. In addition to acid washing, full strength acetone is used to rinse all gear prior to sampling and between all stations. This volatilizes any organic contaminants that might be on the sampler.
   c. The top two centimeters of sediment are scooped from the top of the sampler with an acetone rinsed sterile scoop. The sediment is then transferred to a stainless container, and homogenized using an acid washed, acetone rinsed, long handled stainless scoop.

Part 2. Laboratory Analysis of Sediment Samples: From 1982 to 1990, all FDEP sediment samples were analyzed by Savannah Laboratories and Environmental Services, Inc. (SLES) in Savannah, Georgia. From 1990 to the present, the Skidaway Institute of Oceanography (SIO) in Savannah analyzed sediments. Physical characteristics, such as grain size and percent organic matter, were determined for sediment samples which were then analyzed for nine metals (aluminum, arsenic, cadmium, chromium, copper, mercury, nickel, lead, zinc). Except for mercury, SLES analyzed metals using graphite furnace or flame atomic absorption spectrometer and analyzed organic compounds using gas chromatographic techniques. SIO analyzed metals by ICP (inductively-coupled plasma) mass spectrometry or by atomic absorption spectrometry.

Before analysis for metals, particular care was taken to totally digest the sediment samples using hydrofluoric, nitric, and perchloric acids as required by the project quality assurance plan. Total digestion of the sediment sample is essential when using the sediment assessment tool because of its normalization method to estimate metal contamination. Total digestion is strongly encouraged to produce comparable date for general environmental and trend monitoring of pollutants. FDEP conducted a laboratory intercalibration exercise, in which four laboratories participated, to assess the accuracy and precision of reported metals data from coastal sediments and from sediment reference materials (Schropp, 1992). Results of this exercise and an

VOL 12

7737

international intercalibration exercise (Loring and Rantala, 1988) both showed that sediment trace metal data from different laboratories may not be comparable if different sample digestion techniques are used.

Part 3. Distinguishing Natural vs. Anthropogenically Enriched Sediments: Once methods to reliably and accurately collect and analyze sediment samples were refined, the next step was to develop an interpretive tool to determine whether metals in sediments were natural or from human activities. To understand this assessment tool, one must generally understand the geochemical processes that govern the behavior and fate of metals in estuarine and marine waters. Natural estuarine sediments are predominantly composed of river-transported debris resulting from continental weathering. The solid debris is composed chiefly of chemically resistant minerals, such as quartz and clay minerals, which are the alteration products of other aluminosilicate minerals. The weathering solution also contains dissolved metals leached from the parent rock. Because of their low solubilities, however, the transporting solution (e.g., rivers) carries low amounts of metals. Most metals transported by rivers are tightly bound in the aluminosilicate solid phases. As a consequence, weathering causes little fractionation between the naturally occurring metals and aluminum.

In general, when dissolved metals from natural or anthropogenic sources come in contact with saline water, they quickly adsorb to particulate matter and are removed from the water column to bottom sediments. Thus, metals from both natural and anthropogenic sources ultimately are concentrated in estuarine sediments, not the water column. Since much of the natural component of metals in estuarine sediments is chemically bound in the aluminosilicate structure, the metals generally are immobile. However, the adsorbed anthropogenic or "pollutant" component is more loosely bound and may be more available to estuarine biota and may be released to the water column when sediments are disturbed (e.g., by dredging or storms).

The tool for interpreting metal concentrations in estuarine sediments is based on demonstrated, naturally occurring relationships between metals and aluminum. Specifically, natural metal/aluminum relationships were used to develop guidelines to distinguish natural from contaminated sediments for several metals commonly released to the environment from anthropogenic activities. Aluminum was chosen as a reference element to normalize sediment metals concentrations for several reasons:

1. After silicon, it is the most abundant naturally occurring metal;
2. It is highly refractory;
3. The relative proportions of metals and aluminum in crustal materials are fairly constant;
4. Its concentration is rarely influenced by anthropogenic sources.

Using the data from sediments collected and analyzed as part of the Statewide Survey of Clean Reference Sites, a metal to aluminum normalization method was developed (FDEP, 1988). At these sites, sediment metal concentrations generally are expected to express natural relationships with aluminum. Eight metals (As, Cd, Cr, Cu, Hg, Pb, Ni, and Zn) were tested to determine their relationship to aluminum with a set of graphical tools developed to assess trace metal contamination in a sediment sample. For example, Figure 1 shows that as aluminum concentrations in "clean" sediments increase, metals concentrations, in this case lead, also increase. Least squares regression analysis, using aluminum concentration as the independent variable and the concentration of the other metal as the dependent variable, were performed on log-transformed data and 95% prediction limits were calculated. Significant correlations were obtained for arsenic, cadmium, copper, lead, nickel, and zinc. The plotted regression lines and prediction limits provide the basis for interpreting metal concentrations in sediments.

To determine whether estuarine sediments are enriched with metals, a mean value of each metal (derived from replicate or triplicate samples) is calculated and points representing corresponding metal and aluminum values are plotted (Figure 2). The sediment is judged to be natural or metal enriched depending on where the points lie relative to the regression lines and prediction limits. If a point falls within the prediction limits, then the metal concentration is within the natural range. If a point falls above the upper prediction limit, then the sediment is considered to be metal-enriched. Before concluding sediment "enrichment", the accuracy of the analytical results should be confirmed, since an unusual point can be indicative of procedural errors. Since the results are interpreted with respect to the 95% prediction limit, some points from "clean" stations may plot outside the prediction limit. The greater the distance above the prediction limit, the greater degree of enrichment. An enrichment factor, which is the ratio of the measured metal concentration to its maximum expected concentration in natural sediments, can be calculated using the following equation (FDEP, 1994):

$$\text{Metal Enrichment Factor} = \frac{\text{Observed Metal Concentration } (\mu g/g)}{\text{Max Expected Natural Metal Conc } (\mu g/g)}$$

Applications of the Interpretive Tool: The effectiveness and utility of this sediment assessment tool has been tested in a variety of regional studies (Tampa Bay, Schropp et al., 1989; SE Atlantic and Gulf coasts, Hanson and Evans, 1991; Louisiana, Pardue et al., 1992). The results of these studies indicate that aluminosilicate minerals have a major influence on metal concentrations in natural sediments. The interpretive tool using metal and aluminum relationships allows results of sediment chemical analyses to be used for a variety of environmental information needs:

1. Distinguishing natural versus enriched metals concentrations in coastal sediments.
2. Normalizing metals to a reference element allows comparisons of metal concentrations among sites within a watershed.
3. Comparing investigative results from different watersheds. By normalizing metal concentrations to aluminum, an assessment of relative metal enrichment levels can be made, allowing watersheds to be ranked according to specific metal enrichment problems.
4. Tracking the influence of a pollution source.

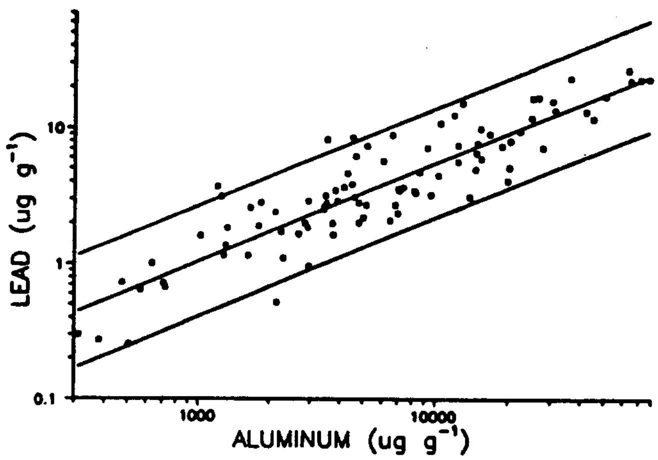

Figure 1. Lead/aluminum relationship from statewide "clean" sediments.

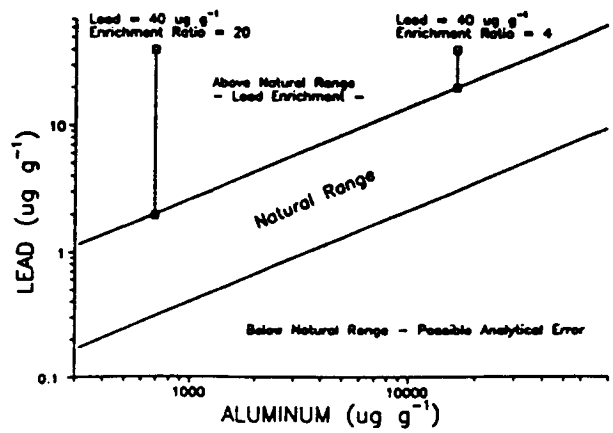

Figure 2. Interpretation of Lead data using lead/aluminum relationship.

5. Monitoring trends in sediment metal concentrations over time.
6. Determining sediment sampling or analysis procedural or laboratory errors.
7. Screening sediment data to promote cost-effective use of elutriate or other sediment quality tests.

Limitations of the Interpretive Tool (FDER, 1988): Funding limitations in Florida have prevented the collection and analysis of sediment samples from freshwater systems to evaluate if the tool can be used in those aquatic systems. However, such sampling is underway in Washington and previously was completed in Illinois. Use of this tool requires knowledge of local conditions and applying professional judgement. Consider the following points when using this interpretive tool:

1. The interpretive tool is useless without reliable data. Results from single, non-replicated samples should not be used. Ideally, sediment samples should be collected in triplicate. If budget constraints dictate analysis of only duplicate samples, the third sample should be archived. In the event of a disparity in the results of replicate analyses, the archived sample should be retrieved and analyzed to resolve the problem.
2. Sediment metals must be analyzed using techniques appropriate for saline conditions and capable of providing adequate detection limits. Because naturally-occurring aluminum and other metals are tightly bound within the crystalline structure of sedimentary minerals, the metal analysis method must include total digestion using HF, HNO_3, and $HClO_4$ acids. If aluminum is not completely released by a thorough digestion, metal to aluminum ratios may appear to be unusually high.
3. Natural concentrations of cadmium and mercury are very low and are near normal analytical detection limits. Because of this, analytical precision and accuracy are reduced and special care must be taken to obtain accurate laboratory results.
4. The data set is, to the extent possible, representative of various types of natural "clean" sediments found in Florida estuaries. Only in a few instances should aluminum concentrations exceed 100,000 ppm (10% aluminum). Any samples containing greater than 100,000 ppm aluminum should be examined carefully for evidence of contamination or analytical error.
5. Interpretation of metal concentrations, using these metal to aluminum relationships, must also consider sediment grain size, mineralogy, coastal hydrography, and proximity to sources of metals.

Part 4. Determining the Ecological Significance of Enriched Sediments: Sediment chemistry data alone do not provide an adequate basis to identify or manage potential sediment quality problems. After determining that sediments are anthropogenically enriched with pollutants, the next assessment step is to determine whether these sediment-bound pollutants are harmful to the environment. Biologically-based numerical sediment quality assessment guidelines (SQAGs) also are required to interpret the ecological significance of sediment chemistry data by providing a basis for assessing the potential effects of sediment-associated contaminants.

VOL 12

7741

MacDonald (1993) reviews the variety of approaches which have been devised to formulate sediment quality guidelines (SQGs). A suitable strategy for deriving SQAGs for Florida must recognize the limitations of the existing database to evaluate the potential biological effects of sediment-associated contaminants. Therefore, the strategy must address both the immediate requirement for defensible SQAGs and the long-term requirement for increased reliability and applicability of these guidelines (i.e., guidelines that account for the environmental characteristics that influence the bioavailability of sediment-associated contaminants).

To develop a tool to assess the potential ecological effects of sediment based contaminants, the FDEP, in association with MacDonald Environmental Sciences, reviewed eight approaches to derive sediment quality assessment guidelines that would be applicable to Florida coastal conditions and appropriate for the state's specific needs. Several criteria were established to objectively evaluate the approaches and select a relevant strategy to derive these guidelines. The primary selection factors were practicality, cost-effectiveness, scientific defensibility, and broad applicability to sediment quality assessment. This review indicated that each of the approaches has deficiencies that limit its direct application in Florida. For this reason, an integrated strategy for deriving numerical SQAGs was recommended for the state of Florida (MacDonald, 1993). This strategy provides relevant near term assessment tools and a basis to refine these guidelines as the necessary data become available.

Using the recommended approach, numerical SQAGs have been developed for 25 priority contaminants in Florida coastal waters (MacDonald, 1993) using a modification of the NOAA's National Status and Trends Program Approach (Long and Morgan, 1990). These guidelines, derived from numerous investigations of sediment quality conducted throughout North America, are based on a weight-of-evidence linking contaminant concentrations and adverse biological effects. In this respect, the guidelines represent a cost-effective response to a practical need for assessment tools. However, these guidelines are preliminary and will likely be refined with results from field validation and other related studies now underway in Florida and elsewhere in North America. The guidelines should be used with other interpretive tools to conduct comprehensive and reliable assessments.

Effects-based SQAGs provide a basis to assess the potential for biological effects associated with various contaminant concentrations. MacDonald (1993) derived no observed effects levels (NOELs) and probable effects levels (PELs) to define three ranges of contaminant concentrations: the probable effects range, the possible effects range, and the no effects range.

The probable effects range is the concentration range of specific sediment contaminants within which biological effects are usually or always observed (probable effects range ≥ PEL). Sediments with contaminant concentrations within the probable effects range *represent significant and immediate hazards to exposed organisms*. Sites with concentrations of one or more contaminants that fall within the

VOL 12

7742

R0041050

probable effects range should be given the highest priority in implementing sediment quality management options. However, direct biological assessment is required at these sites to determine the nature and extent of effects that could be manifested.

The possible effects range is the concentration range of a specific sediment contaminant with uncertain adverse biological effects (NOEL < possible effects range < PEL). This range is likely to be dependent on factors, such as bioavailability, that may influence the toxicity of the substance. Sediment-associated contaminants *represent potential hazards to exposed organisms* when concentrations fall within this range. Sediments with contaminant concentrations within this range require further assessment to determine the biological significance of the contamination. In general, further assessment would be supported by biological tests designed to evaluate the biological significance of sediment-associated contaminants to key species of aquatic biota.

The no effects range of sediment contaminant concentrations where biological effects are rarely or never observed (no effects range ≤ NOEL). Sediments with concentrations of contaminants within the no effects range are *considered to be of acceptable quality* for those contaminants. In general, further investigations of sediment quality conditions within this range are relatively lower priority. However, biological testing may be required to validate the results of the initial assessment of the potential for adverse biological effects, particularly in sediments with low levels of total organic carbon, acid volatile sulfide, and/or other variables that could influence the bioavailability of sediment-associated contaminants.

A Framework For Assessing Site-specific Sediment Quality Conditions in Florida: MacDonald (1993) developed a framework for the Florida Department of Environmental Protection for future use of sediment quality assessment guidelines and related tools. This framework, which identifies essential considerations to address in conducting site-specific sediment quality assessment programs, consists of:

1. Collect Historical Land and Water Use Information
   - Land uses - current and historical; industrial, commercial
   - Infrastructure including stormwater systems
   - Pollution sources - point and nonpoint
   - Hydrology, physiography, ecology

2. Collect and Evaluate Existing Sediment Chemistry Data
   - Sediment deposition location, patterns, transport,
   - Sediment physical and chemical characteristics
   - Temporal and spatial variability, vertically and horizontally
   - Determine data reliability, acceptability, applicability

3. Collect Supplemental Sediment Chemistry Data
   - Determine contaminants, sampling locations
   - Delineate temporal and spatial variability in sediment contamination

VOL 12

7743

- Prepare and follow QA Plan for sampling, handling, and analysis protocols
4. Conduct Preliminary Assessment of the Potential for Biological Effects of Sediment-Associated Contaminants
   - Compare sediment contaminant concentrations to SQAGs
5. Evaluate Natural versus Anthropogenic Sources of Sediment-Associated Contaminants
   - Determine sources using the previously described sediment assessment procedure
6. Conduct Biological Assessment of Sediment Quality
   - Determine whole sediment toxicity
   - Conduct short-term bioassays, long-term microcosm studies, etc.
   - Develop site-specific SQAGs
   - Conduct biological community assessments
7. Implement Management of Sediment Quality
   - Evaluation factors include nature and severity of sediment contamination, potential for exposure of aquatic life, site or regional management goals, availability of remediation technology, costs, and public expectations.
   - Actions may range from none to continued monitoring to remedial actions such as removal and treatment of sediment contaminants or source control implementation.

This framework is designed to provide a consistent approach to assessing sediment quality in marine and estuarine areas. However, the framework is not intended to replace accepted sediment testing protocols such as developed for the ocean disposal of dredged material. Instead, it is intended to provide general guidance to support the sediment quality assessment process.

Applications and Limitations of the Recommended Sediment Assessment Approach: The sediment quality assessment strategy provides a consistent basis to evaluate sediment quality in Florida. While the SQAGs represent an integral element of this strategy, they should be used with other assessment tools to efficiently and cost-effectively evaluate ambient sediment quality conditions. In this context, these SQAGs may be used to:

- Interpret the results of sediment quality monitoring data to assess the potential adverse biological effects associated with concentrations of sediment-associated contaminants.
- Support the design of sediment quality monitoring programs by evaluating existing sediment chemistry data to rank areas and chemicals of concern allowing monitoring priorities to be more clearly and effectively identified.
- Identify the need for site-specific investigations to support regulatory or watershed management decisions, including source controls and the siting of regional stormwater management systems.
- Evaluate the hazards associated with increased levels of contaminants at specific sites.
- Facilitate multijurisdictional agreements on sediment quality issues and concerns by establishing site-specific sediment quality objectives that help define the

responsibilities of various levels of government in preventing and remediating sediment contamination.

These guidelines were established to provide a consistent basis for evaluating estuarine sediment quality in Florida. However, these guidelines are preliminary and, as such, have certain limitations on their application. Therefore, SQAGs:

- Are applicable to marine and estuarine waters only, not to freshwater systems.
- Should not be used in lieu of water quality criteria. However, they may be used to evaluate the effectiveness of regulatory programs and identify the need for more stringent regulations.
- Should not be used to define uniform values for sediment quality on a statewide basis (i.e., they should not be used as sediment quality criteria). Ambient environmental conditions may influence the applicability of these guidelines at specific locations;
- Should not be used as criteria for the disposal of dredged material and should not replace formal assessment protocols established for disposal of dredged material.
- Should not be used directly as numerical clean-up levels at severely contaminated sites (e.g., Superfund sites).
- Are designed to determine the potential for sediment-associated contaminants to induce biological effects. Direct cause and effect relationships should not be inferred when comparing chemical data to the recommended guidelines.
- Have been derived primarily from acute toxicity study results. Few data are available on the chronic responses of aquatic organisms to contaminants associated with sediments.
- Should be used with other assessment tools and protocols, such as the FDEP metals interpretive tool and the Green Book (EPA and ACE, 1991), to provide comprehensive evaluations of sediment quality.
- Were developed using information from various North American locations. These data may not be representative of the wide range of Florida sediment types. For this reason, caution should be exercised in using these guidelines, particularly in carbonate-dominated sediments in southern Florida.

Part 5. Using the Sediment Assessment Tools: MacDonald (1993) stresses the importance of combining the effects-based guidelines and the metals interpretive tool. MacDonald examines data on levels of sediment-associated lead from two geochemically distinct systems, Biscayne Bay and Apalachicola Bay, to illustrate the integrated sediment quality assessment framework. Figure 3 shows a summary of the available data (FDEP, 1994) on the levels of sediment-associated lead in the Miami area. The data, sorted by increasing concentration, were assigned sample numbers of 1 to 108. Evaluation using the SQAGs suggests that approximately 15% of the samples fall within the probable effects concentration range (exceed the PEL of 160 mg/kg). Another 20% of the samples fall within the possible effects range (between the NOEL and the PEL). Therefore, comparing sediment chemistry data with the numerical SQAGs suggests a relatively high probability of observing adverse biological effects. Further examination of these data using the metals interpretive tool (Figure 4) demonstrates that sediments from this area are clearly

7745

anthropogenically-enriched with lead. Roughly 90% of the samples exceed the 95% prediction limits established for clean sites. Concordance between the effects-based tool and the geochemically-based tool suggests that the Miami area should be a priority area for further investigations to evaluate sediment toxicity.

In Apalachicola Bay, roughly 20% of the samples had lead levels that exceeded the NOEL of 21 mg/kg (Figure 5). Comparison of the ambient lead levels in Apalachicola Bay with SQAGs suggests possible adverse biological effects at a significant number of sites. However, further evaluation using the metals interpretive tool indicates that aluminum-normalized lead level in Apalachicola Bay sediments is indicative of those measured in clean sediments in Florida (Figure 6). While the effects-based tool predicts the possibility of adverse effects at some sites, the geochemical tool demonstrates that lead concentration in Apalachicola Bay are naturally-occurring and, as such, should not be considered hazardous to aquatic organisms. This system does not require further investigations to evaluate the extent of sediment toxicity.

In 1994, the Sediment Research Group of FDEP released the *Florida Coastal Sediment Contaminants Atlas*, which describes the spatial extent of sediment contamination in Florida's coastal waterbodies. The *Atlas* presents the results of the previously mentioned FDEP coastal sediment surveys. In addition, the *Atlas* has been strengthened by inclusion of sediment data from the NOAA National Status and Trends Program, as well as sediment data produced by the Mote Marine Laboratory, an independent marine research facility located in Sarasota, Florida. The *Atlas* includes information on the eight metals and five classes of organic compounds - chlorinated hydrocarbons, polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), phenolic hydrocarbons, and aliphatic hydrocarbons. A Technical Volume accompanies this *Atlas* and provides ancillary information for users of this document. Although the Department was not able to fully assess sediment contamination along Florida's extensive coastline, it appears that the highest concentrations of contaminants in sediments are generally near urban centers. However, low to moderate levels of contaminants are common adjacent to many less developed coastal areas. Stormwater runoff appears to be the major cause of contamination of sites identified in the *Atlas*. Regional monitoring of contaminants in living resources and sediments, followed by sediment toxicity studies, is strongly recommended to keep a finger on the pulse of Florida's freshwater and marine ecosystems.

BIOLOGICAL COMMUNITY MONITORING

Since enactment of the Federal Clean Water Act, most efforts to preserve, maintain and restore water quality have relied upon and been directed by chemical and physical measurements of the water column. While this approach may be useful in assessing the effects of continuous point discharges, such as domestic or industrial wastewaters, it cannot accurately determine environmental impairments from intermittent sources such as stormwater or other nonpoint source discharges.

Figure 3. Conc. of Pb in sediments of Biscayne Bay.

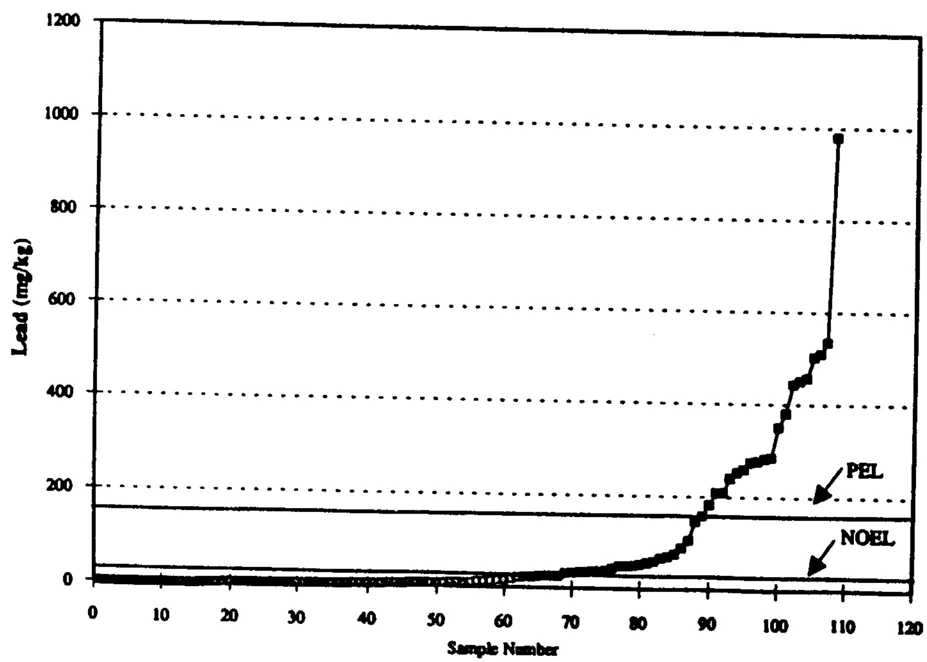

Figure 4. Alum. normalized conc of Pb in Biscayne Bay sediments.

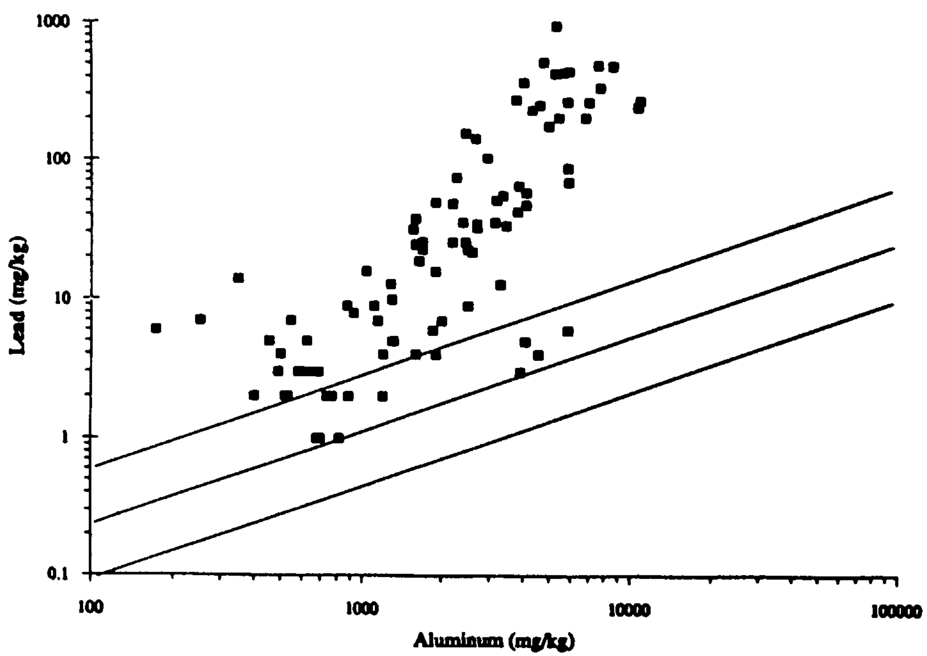

Figure 5. Conc. of Pb. in sediments of Apalachicola Bay.

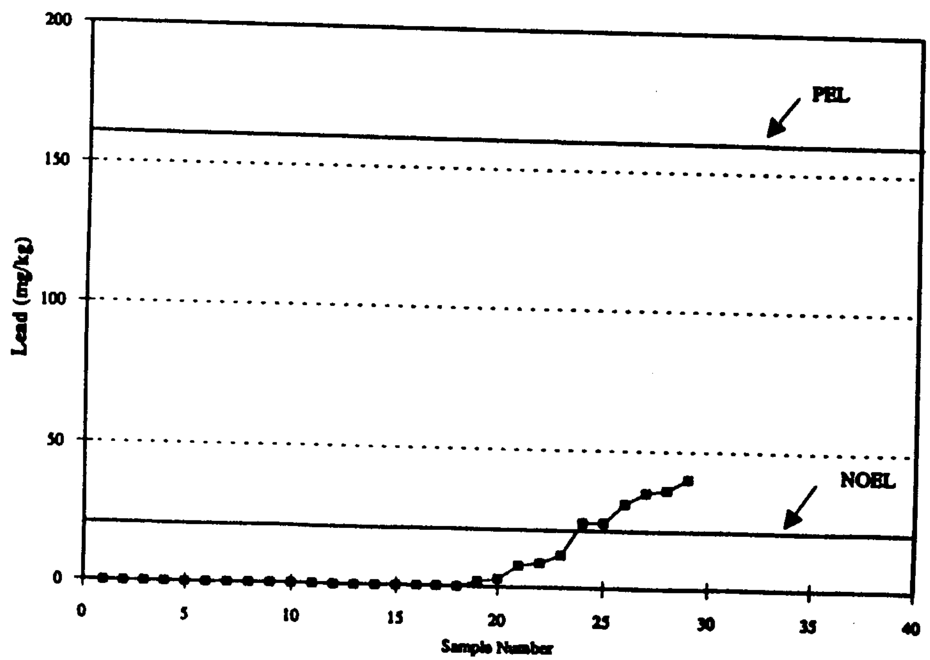

Figure 6. Alum normalized conc of Pb in Apalach Bay sediments.

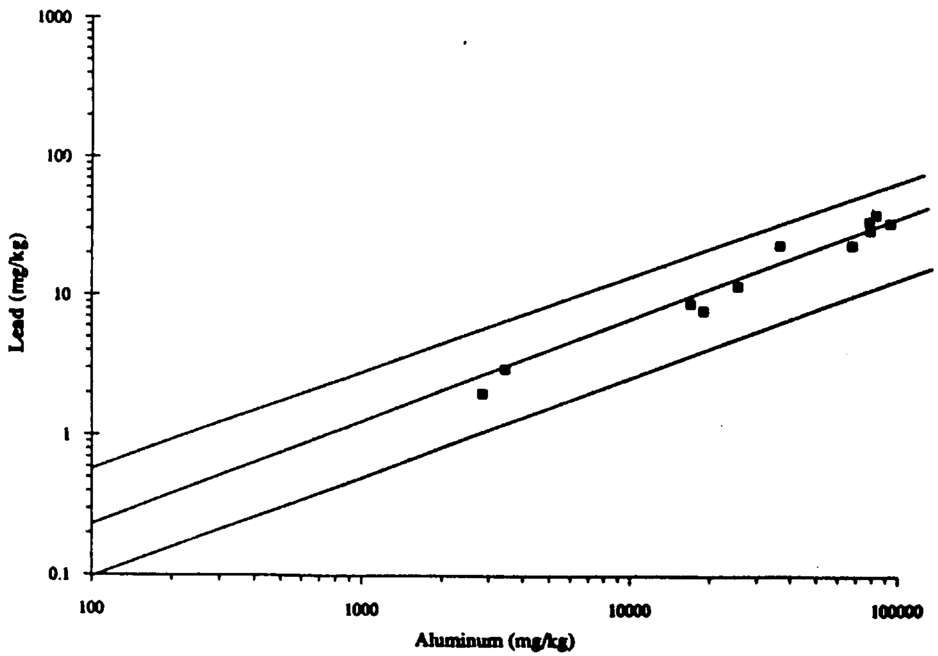

Intermittent discharges create shock loadings to a water body with the ecological effects depending on complex interactions of many variables. Moreover, most stormwater pollutants become attached to sediment particles or settle quickly, exerting detrimental effects over a long period. Furthermore, stormwater discharges degrade habitat (eg, channel and bank erosion) and cause tremendous siltation, neither of which are detected by water chemistry sampling. Karr et. al. (1986) group environmental factors affecting most aquatic ecosystems into five major classes: chemical variables, biotic interactions, flow regime, habitat structure, and energy source. These factors interact to determine the integrity of water resources reflected by the resident aquatic life. Alterations to the physical, chemical, or biological process can adversely affect the aquatic biota and, therefore, the biological integrity of the water body. Monitoring methods integrating all five classes are necessary to accurately assess and manage surface water quality and aquatic life resources.

Inclusion of biological community monitoring allows a more holistic, systems approach that greatly enhances surface water quality assessment and management. While chemical data reflect short-term conditions that exist when a particular sample is collected, biological communities accurately indicate overall environmental health because they continuously inhabit receiving waters where they integrate a variety of environmental influences - chemical, physical and biological.

Biological assessment involves an integrated analysis of functional and structural components of aquatic communities. Bioassessments are best used to detect aquatic life impairments and assess their relative severity. Once an impairment is detected, additional chemical and biological toxicity testing can identify the causative agent and its source. Both biological and chemical methods play critical roles in successful pollution control and environmental management programs. They are complementary, not mutually exclusive, approaches that enhance overall program effectiveness.

Some advantages of bioassessments are:

1. Biological communities reflect overall ecological integrity (chemical, physical and biological).
2. Over time, biological communities integrate the effects of different stressors, providing a measure of fluctuating environmental conditions.
3. By integrating responses to highly variable pollutant inputs, biological communities provide a practical approach for monitoring stormwater/nonpoint source impacts and the effectiveness of best management practices.
4. Routine monitoring of biological communities can be relatively inexpensive, particularly when compared to the cost of assessing toxic substances.
5. The public is very interested in the status of biological communities as a measure of environmental health.
6. Biological communities offer a practical way to evaluate the habitat degradation typically associated with stormwater discharges.

R0041059

Determining Biological Integrity - Rapid Bioassessment Concept: Although the principal goal of the Federal Clean Water Act is to restore and maintain the chemical, physical and biological integrity of the nation's water resources, difficulties in defining an ecological approach to assessing biotic integrity has led regulatory agencies to rely primarily on chemical measurements. However, Karr and Dudley (1981) define biotic integrity as "the ability of an aquatic ecosystem to support and maintain a balanced, integrated, adaptive community of organisms having a species composition, diversity and functional organization comparable to that of the natural habitats within a region". This practical definition is based on measurable characteristics of aquatic communities and comparisons to a regional reference site thus providing a framework for bioassessments.

Recent advances in computer technology and, more importantly, in biological community assessment techniques makes bioassessments more practical. These advances include geographic information systems (GIS) and available digitized data bases, refined laboratory and field methods, development of standard assessment techniques, a practical and useful definition of biological integrity, and the regional reference site concept. These advances provide a framework to incorporate biological community assessments and "biocriteria" into surface water management programs.

In 1985, EPA conducted a survey to identify states that routinely performed biological assessments and to evaluate the field methods being used. A workgroup of state and EPA biologists was formed to review the existing methods and to refine protocols for monitoring benthic macroinvertebrates and fish. In May 1989, EPA published "Rapid Bioassessment Protocols for Use in Streams and Rivers" to which the reader is referred for a more comprehensive discussion of this topic.

The rapid bioassessment protocols (also known as community bioassessment protocols) advocate an integrated assessment, comparing habitat (physical structure and flow regime) and biological measures with empirically defined reference conditions. Reference conditions are established through systematic monitoring of actual sites (ecoregion reference sites) that represent the natural range of variation in "least disturbed" water chemistry, habitat, and biological condition. The concept of ecoregions and ecoregional reference sites is discussed in a July 1989 EPA publication "Regionalization as a Tool for Managing Environmental Resources".

With the publication of these two landmark publications, states began intensive work to refine the ecoregions and protocols to suit local conditions and needs. The state-of-the-art in this rapidly developing field continues to evolve into many more variations. The original authors of the documents strongly advocate customizing both ecoregions and the bioassessment protocols. The most important common element required in these efforts is the use of a scientific approach which can be defended.

Consequently, before this protocol can be used and biological community assessment programs implemented, state specific analyses must be undertaken. This presents many unique challenges, requiring special expertise, adequate funding and several years. For example, state specific subecoregions must be delineated, appropriate ecoregion reference sites selected and sampled, community bioassessment sampling and evaluation methods modified, appropriate biological community metrics selected, and each of these must be verified.

These techniques offer the best means of accurately assessing the impacts of stormwater and other nonpoint sources of pollution. The Florida Bioassessment Project was designed to address many of the above issues to develop a refined bioassessment protocol for use in Florida streams to document impairment from nonpoint sources of pollution and to determine the effectiveness of management programs.

THE FLORIDA STORMWATER/NPS BIOASSESSMENT PROJECTS

In 1990, the Stormwater/Nonpoint Source Management Section of the Florida Department of Environmental Protection began a multi-year effort to refine and enhance current biological community assessment methods. This work consists of four primary components: I. Delineating subecoregions and selecting reference sites; II. Developing standardized biological sampling and habitat assessment methods; III. Evaluating biological data to develop and verify biological metrics and an index of biotic integrity; and, IV. Developing or revising biocriteria. The rest of this paper will discuss program components I through III.

Four contracts, funded by EPA Section 104 (b)(3), 205(j)(1), and 319 grants, are the central focus of this effort:

1. Florida Regionalization Project, contracted to the EPA Environmental Research Lab and to ManTech Environmental Technology, Inc. of Corvallis, Oregon, and led by James Omernik and Glenn Griffith. The two primary tasks included subdividing Florida's three ecoregions into subregions, and selecting and verifying ecoregion reference sites. $160,000. (Component I).
2. Bioassessment for the Nonpoint Source Program, contracted to EA Engineering, Science, and Technology, whose project manager is Mike Bastian, and Tetra Tech, Inc., whose project manager is Mike Barbour. This project's objectives include reviewing and refining DEP's existing biological sampling and analysis procedures; development of standardized stream macroinvertebrate sampling and habitat assessment protocols; testing the protocols by collecting data at candidate reference sites; and, developing candidate biological metrics to quantify the biotic integrity of benthic macroinvertebrates. $236,000. (Components II and III).
3. Development of a Florida Index of Biotic Integrity, contracted to Tetra Tech and Mike Barbour. This project continues the statistical analysis of biomonitoring data being collected from the candidate reference sites and other sites. In particular, the metrics will be refined by further testing and verification of the recommended biological metrics. $122,500. (Component III).

4. Development of a Biological Data Base, contracted to Lori Wolfe Enterprises, a local computer programming firm. $28,500. (Corollary project).

Component I. Delineating Ecoregions and Selecting Reference Sites: Spatial frameworks can profoundly influence the effectiveness of research, assessment, and management of many water resource problems, especially those caused by stormwater and nonpoint sources. Traditionally, we have relied on spatial frameworks based on political boundaries, watersheds, hydrologic units, or physiographic regions. However, these units do not correspond to patterns in vegetation, soils, land surface form, land use, climate, rainfall or other characteristics that control or reflect spatial variations in surface water quality or aquatic organisms.

Effective water quality management programs must recognize the significance of land/water interactions, nonpoint sources, and regional variations in attainable water quality. Water quality assessments need a regional framework to:

1. compare regional land and water patterns;
2. compare ecological and habitat similarities and differences;
3. establish realistic, achievable chemical and biological standards;
4. assess the effects of all pollution sources within a watershed, especially intermittent discharges;
5. predict the effectiveness of management practices;
6. prioritize assessment and management efforts;
7. locate monitoring and special study sites; and
8. extrapolate site-specific information to larger areas.

Omernik (1987) proposed using spatial frameworks based on ecological regions (ecoregions) to assess the health of aquatic systems. Ecoregions are areas of relative homogeneity in ecological systems and relationships between organisms and their environments. Ecoregions usually are defined by patterns of homogeneity in a combination of factors such as climate, physiography, geology, soils, vegetation and dominant land uses. These regions also define areas within which there are different patterns in human stresses on the environment and different patterns in the existing and attainable quality of environmental resources. Ecoregions reflect similarities in the type, quality and quantity of water resources and the factors affecting them. Therefore, regional patterns of environmental factors reflect regional patterns in surface water quality.

Omernik (1987) originally identified 76 ecoregions in the conterminous United States including three in Florida. These ecoregions were useful for stratifying streams in Arkansas, Nebraska, Ohio, Oregon, Washington, and Wisconsin. They were used to set water quality standards in Arkansas, lake management goals in Minnesota, and to develop biocriteria in Ohio. However, in many states, the resolution of the ecoregions was of insufficient detail leading to collaborative projects involving states, EPA regions and the EPA Environmental Research Lab-Corvallis to refine ecoregions and delineate subregions.

Delineating regions or subregions typically involves compiling and reviewing relevant materials, maps and data; outlining the regional characteristics; drafting the regional and subregional boundaries; digitizing the boundary lines, creating digital coverages, and producing maps; and revising after review by state managers and scientists. To delineate subregions in Florida, aerial and satellite images, maps, and other documents were obtained describing environmental characteristics including physiography, geology, soils, climate, land use, vegetation, wetlands, and various biological communities. Analysis of this information led to the definition of the following ecoregions and subregions in Florida (Griffin et. al., 1994):

1. The Southeastern Plains Ecoregion, with three subregions - Southern Pine Plains and Hills, Dougherty/Marianna Plains, and Tifton Upland/Tallahassee Hills
2. The Southern Coastal Plain Ecoregion, with six subregions - Gulf Coast Flatwoods, Southwestern Florida Flatwoods, Central Florida Ridges and Uplands, Eastern Florida Flatwoods, Okefenokee Swamps and Plains, and Sea Island Flatwoods.
3. The Southern Florida Coastal Plain Ecoregion, with four subregions - Everglades, Big Cypress, Miami Ridge and Atlantic Coastal Strip, and Southern Coast and Islands.

Once ecoregions and subregions are delineated and field verified, ecoregion reference sites must be selected. An essential component of the management framework, these sites allow us to evaluate the environmental health of a locale by comparing it to a known reference site - a key concept in Karr and Dudley's definition of biotic integrity, which compares site evaluations to the aquatic community of "natural habitats within a region".

Reference sites must be carefully selected because they will be used for two purposes: (1) Benchmark for establishing regional biocriteria; and, (2) Control sites to which test sites will be compared. The two main criteria for selecting reference sites are that they be minimally impaired and that they represent the region's natural biological community. The ideal reference site will have extensive, natural, riparian vegetation; a diversity of substrate materials; natural physical structures; a natural hydrograph; a representative and diverse abundance of naturally-occurring biological communities; and a minimum of known, human induced disturbances or discharges. General guidelines for selecting reference sites are given in EPA (1989a).

To select stream subecoregion reference sites in Florida, the following steps were taken:

1. Using GIS techniques, information about the general characteristics of each ecoregion and subregion was analyzed to better understand representative conditions. Information reviewed included topographic maps, land use and soil maps, county highway maps, vegetational coverage maps, Landsat imagery, and the 1988 and 1990 Florida Water Quality Assessment 305(b) reports.
2. A set of stream sites with surface watersheds that appear relatively undisturbed and entirely within a subecoregion was chosen in which candidate reference sites were located. The actual number of sites per watershed is a function of the

apparent homogeneity or heterogeneity of the region, the size of the region, hydrologic characteristics, and the number of candidate sites available. Access is a major factor in selection of the final reference sites. The number of candidate sites per subregion varied, ranging from only eight in subregion 75C, the Central Florida Ridges and Uplands where relatively few streams are found, to twenty sites in subregion 75D, the Eastern Florida Flatwoods. A list of the candidate sites was developed that included the subregion, site number, stream name and location, major basin, county, GIS map name, watershed area, and other information.

3. Department and water management district biologists reviewed the information for each candidate site and then conducted site visits. This ground reconnaissance allowed staff to get a sense of the usefulness of the subecoregions, the characteristics that comprise reference sites in each region, the range of characteristics and types of disturbances in each region, and how site characteristics and stream types vary between regions. Using this process, sites were dropped that were found unsuitable because of disturbances not apparent on aerials or maps or because of anomalous situations while additional sites were identified.
4. Aerial reconnaissance was conducted to identify disturbances not observable from the ground, to get a better sense for spatial patterns of disturbances and geographic characteristics in each region, and to photograph typical characteristics, site locations, or disturbances.
5. Over 100 subecoregional candidate reference sites originally were selected by EPA and FDEP biologists. A thorough review process for each site to determine its representativeness and an analysis of available staff hours to conduct bioassessments was performed, reducing the number of sites to 83.

The distribution of reference sites varies among DEP districts as well as among subecoregions. The number of sites in the districts range from three to 30 while the number of subecoregion sites varies from six to 13. This information is summarized below:

Subecoregion	Reference Sites
65F Southern Pine Plains and Hills	8
65G Dougherty/Marianna Plains	6
65H Tifton Upland/Tallahassee Hills	8
75A Gulf Coast Flatwoods	3
75B Southwestern Florida Flatwoods	12
75C Central Fla Ridges & Uplands	8
75D Eastern Fla Flatwoods	10
75E Okefenokee Swamp & Plains	8
75F Sea Island Flatwoods	9

It is important to remember that reference sites represent the least or minimally disturbed ecosystem conditions. All of them have some level of disturbance which is a moving target because of ongoing human activity and natural processes. Since levels of impact are relative on a regional basis, the characteristics of appropriate reference sites will be different in different ecoregions and subregions and for different waterbody and habitat types. It is desirable, therefore, to have a large number of reference sites for each region to help define the different types of streams, to characterize the natural variability within similar stream types, and to clarify the factors that characterize the best sites from factors present in the lower quality sites.

Component II. Developing Standard Biological Assessment Methods: The technical objectives of this component included:

1. Review existing bioassessment protocols used by FDEP's "Point Source Fifth Year Inspection Program" as a template for proposed refinement of protocols for the NPS program.
2. Develop a standardized and cost-effective methodology to (a) collect and process benthic macroinvertebrates collected from Florida streams, and (b) to perform an assessment of habitat conditions.
3. Develop a Standard Operating Procedures Manual (SOP) as a quality assurance/quality control document to provide consistent, standardized methods for sampling freshwater benthic macroinvertebrates and evaluating habitat in rivers and streams.
4. In conjunction with the Ecoregionalization project, design a statewide standardized biological sampling and habitat assessment program to collect data for use in classifying reference streams and in developing the candidate measurements of biotic integrity.
5. Conduct a training program in which FDEP and water management district field biologists discuss and learn the new protocols.

One of the most important aspects of the community bioassessment procedure is the evaluation of stream habitat, which includes physical characteristics and water quality. Since conditions in the watershed determine conditions in the stream, habitat quality is dependent on land use, channel and riparian features as well as instream factors such as substrate types and velocity.

In 1991, the FDEP developed its first habitat evaluation methods (Frydenborg, 1991) based on EPA's Rapid Bioassessment Protocols document. The components of habitat evaluation are: (1) physical/chemical characterization, and, (2) habitat assessment. Physical/chemical characterization includes determining predominant surrounding land uses; identifying local watershed erosion, nonpoint, and point source pollution sources; estimating stream depth, width, high water mark, temperature, and velocity; noting stream alterations such as impoundment or channelization; estimating canopy cover; and evaluating sediment/substrate. Water quality parameters measured include pH, dissolved oxygen, conductivity, and secchi disk depth; and, noting water clarity, color, odors and surface oils.the measurement and observation of land use, riparian zone conditions, channel and substrate features and water quality. Habitat assessment includes evaluating water velocity, substrate

VOL 12

7757

R0041065

and cover, channel conditions, bank stability and riparian zone vegetation based on their capacity to support a stable, well balanced benthic community.

Most of the technical objectives of Component II have been achieved (FDEP, 1994b). However, all SOPs continue to be reviewed. Using DEP training funds, DEP's biologists attend quarterly "Biocriteria Committee Meetings" where they participate in workshops, discussions, and field exercises to learn about the bioassessment protocols. Beginning in the summer of 1992, DEP biologists from the Tallahassee and district offices conducted bioassessments, following the procedures set forth in the SOP, at all of the candidate reference sites. Sampling at these sites, and at additional reference sites, has continued on a summer-winter sampling schedule.

Component III. Data Analysis, Development of Metrics and Index of Biotic Integrity: Framework for Habitat Assessments: An analysis of the reference site habitat data was undertaken to (1) characterize the expected or typical condition for habitat parameters in least-disturbed streams and (2) refine the existing habitat evaluation methods. Sites were classified by (1) the aggregate subecoregions (65, 75a, 75bcd, 75ef) identified with the biometrics; (2) their designation as part of a subset of subecoregional sites versus all sites; and, (3) by flow conditions at the time of sampling. It was determined by analysis of the biological data that the aggregate subecoregions were the most appropriate classification scheme to explain variability in the data. Statistical analysis of the data was used to identify the habitat features that have a limited amount of variability and could be used to define the typical condition. The typical conditions, based on one sampling event and only four sampling sites in two subecoregions (75ef), will be modified when the results of additional sampling events are evaluated.

Framework for Biometrics: Metrics allow the ecologist to use meaningful indicator attributes to assess the status of communities in response to perturbation. The definition of a metric is a characteristic of the biota that changes in some predictable way with increased human influence (Barbour et al., in review). By using multiple metrics to assess biological condition, the information available about the elements and processes of aquatic communities is maximized. The validity of an integrated assessment using multiple metrics is supported by the use of measurements of biological attributes firmly rooted in sound ecological principles (Karr et al. 1986; Fausch et al. 1990; Lyons 1992).

The development of appropriate metrics follows a determination of (1) taxa to be sampled, (2) the biological characteristics of reference conditions, and to a certain extent, (3) the anthropogenic influences being assessed. In many situations, multiple stressors impact ecological resources, and specific "cause-and-effect" assessments may be difficult. However, changes in individual metrics or suites of metrics in response to perturbation by certain stressors (or sets thereof) are important diagnostic assessment indicators. For this reason, use of a multimetric approach for evaluating nonpoint source effects upon the biota is a more powerful tool than traditional approaches to bioassessment.

VOL 12

7758

The basic approach to developing metrics is modeled after EPA's technical guidance for biocriteria (Barbour et al., in review). Candidate metrics are selected based on knowledge of aquatic systems, flora and fauna, literature reviews, and historical data. Candidate metrics are evaluated for efficacy and validity for implementation into the bioassessment program. Less robust metrics, or those not well-founded in ecological principles, are excluded as a result of this research process. Metrics with little or no relationship to stressors are rejected. Core metrics are those remaining that provide useful information in discriminating between good or poor quality ecological conditions. It is important to understand the effects of various stressors on the behavior of specific metrics. Metrics that use the relative sensitivity of the monitored populations to specific pollutants, where these relationships are well-characterized, can be useful as a diagnostic tool. Core metrics should be selected to represent diverse aspects of structure, composition, individual health, or processes of the aquatic biota. Together they form the foundation for a sound, integrated analysis of the biotic condition to judge the attainment of biological criteria. For a metric to be useful, it must have the following attributes: (1) relevant to the biological community under study and to the specified program objectives; (2) sensitive to stressors and provides a response that can be discriminated from natural variation; (3) environmentally-benign to measure in the aquatic environment; and (4) cost-effective to sample and to implement into water resource programs.

To select metrics for Florida streams, a two phase process was used which included an optimization phase, whereby the metrics are evaluated for their relevance and natural variability, and a calibration phase, which is necessary to determine the discriminatory power and sensitivity to perturbation. In the first phase, all potential metrics having relevance to Florida stream macroinvertebrate communities were identified. These metrics were classified into categories roughly corresponding to various elements and processes of the macroinvertebrate assemblage. Categories used for this metric classification corresponded to the following:

A. Richness measures, which signify the relative variety or diversity of the aquatic assemblage.
B. Composition measures, which provide information on the make-up of the assemblage and the relative abundance of particular taxa to the total community.
C. Tolerance measures, which relate to the relative sensitivity or tolerance of the assemblage and component populations to various types of perturbation.
D. Trophic measures, which are surrogates of more complicated processes, such as biotic trophic interaction, production and food source availability. Trophic metrics primarily are related to functional feed group designation and density, both difficult to evaluate. Therefore, these metrics are in an evolutionary status around the country and will continue undergoing refinement.

Selecting Candidate Metrics: From the biological data collected at the candidate reference sites in Summer 1992, a total of 47 metrics were calculated and entered into the data base. These parameters were analyzed using a number of statistical methods including covariate and autocorrelation analysis, analysis of variance, and cluster analysis. Two key graphical displays, scatter plots of physicochemical

VOL 12

7759

variables versus biological metrics and box-and-whisker plots, were relied on for evaluating site classifications and discriminatory power. All of the 47 metrics fit the condition of biological relevance since they represent elements and processes of the macroinvertebrate assemblage and are thought to change in a predictable fashion in response to perturbation. However, by evaluating the inherent variability within the reference site database, 35 candidate metrics were identified. A highly variable metric would not be useful because the discriminatory power would be diminished. Conversely, a metric that has a narrow variance within a maximum or optimal range for reference conditions would be a useful metric. Box-and-whisker plots of the sites classified by subecoregions were used to depict the natural variability of each metric.

Fourteen of the 35 metrics appear to be appropriate as candidate metrics from this initial evaluation (Table 1). These are the metrics that illustrate a relatively tight range of values among the various subecoregions and are at the high end of their range of values for the reference sites. Four of the metrics are from the richness measures and consist of the Number of Total Taxa, EPT Index, the Number ofChironomidae Taxa, and the Number of Crustacean plus Mollusc Taxa. The Shannon-Wiener Index, Percent Diptera, and Percent Crustaceans and Molluscs are from the composition measures. Candidate metrics from the sensitivity measures are the Florida Index, Percent Class 1 and Class 2 Individuals, the HBI, and Percent Dominant Taxon. Percent Collector-Gatherers, Percent Collector-Filterers, and Percent Shredders are representative trophic measures.

These 14 metrics were evaluated by using them as the basic candidate metrics with which to classify the sites, compare the efficiencies of the collecting gear, and test the discriminatory ability of the metrics. Through these additional analyses, some metrics may be eliminated. The resulting core metrics will then be used to develop an aggregation technique to evaluate the biological condition of the sites.

Metric Classification: Once candidate metrics were identified, analyses was performed to develop a classification system for Florida streams that would aggregate the streams into a small number of classes that could be managed and monitored with similar expectations. The classes should account for significant variation in the biological metric data with classes that do not contribute to the variation explained separated from those that do. Classification analysis was done with the dip net data.

Two classification schemes were tested: ecoregional (geographic) and stream type. Nine subecoregions in two ecoregions were in the area sampled in this program, and several stream types were identified that classify the influence of limestone, silica, and organic matter in the streamwater. Four stream types included in this investigation were sand-bottom streams, calcareous-influenced sand streams (with limestone springs or substrates), swamp-influenced streams (draining swamps and bogs), and alluvial streams (large, broad streams with multiple influences). Only the 14 candidate biological metrics (those that showed promise for discriminating reference from impaired conditions) were used to test the alternative classifications.

Metric Category	Rejected Candidate Metrics	Final Core Metrics	Definition Summary	Response to Increasing Biological Condition
Richness Measures	% Ephemeroptera Taxa # Coleoptera Taxa # Orthocladiinae Taxa # Tanytarsini Taxa	% Total Taxa	Measures overall variety of macroinvertebrate assemblage	↑
		EPT Index	Sum of no. taxa in 3 insect orders: Ephemeroptera, Plecoptera, Trichoptera	↑
		# Chironomidae Taxa	Sum of no. larval midge taxa	↑
		# Crustacean/Mollusc Taxa	Sum of no. calcium-dependent tax	↑
Composition Measures	% Oligochaeta, % Odonata, % Ephemeroptera, % Isopoda, % Trichoptera, % Plecoptera, % Coleoptera, % Gastropoda, % Pelecypoda, % Amphipoda, % Orthoclads to Chironomids % Tanytarsini to Chironomids	Shannon-Wiener Index	Measures general diversity using richness and evenness measures	↑
		% Dominant Taxon	Measures dominance of single most abundant taxon	↓
		% Diptera	Relative abundance of dipterans	↓
		% Crustacean/Mollusc	Relative abundance of crustacean/mollusc	↓
Tolerance Measures	# Class 1 and Class 2 Taxa	Florida Index	Uses abundance and pollution tolerance values for some invertebrates, heavily weighted to arthropods	↑
		% Class 1 and Class 2	Total no. Class 1 and Class 2 individuals/total no. individuals	↑
		Hilsenhoff Biotic Index	Uses abundance and pollution tolerance values for all invertebrates	↓
Trophic Measures	% Scraper/Piercer Taxa % Scrapers, % Predators, Density	% Collector-Gatherers	Relative abundance of this functional feeding group	↓
		% Collector-Filterers	Relative abundance of this functional feeding group	↑
		% Shredders	Relative abundance of this functional feeding group	↑

Table 1 Candidate and Selected Core Metrics

The distributions of values of the 14 candidate metrics were plotted as box-and-whisker plots for each of the nine subecoregions investigated. The consistent pattern that emerged from this analysis was that biological metrics of Florida streams tend to aggregate in three groups: the subecoregions of the Florida panhandle (65f, g, h, and 75a), the subecoregions of peninsular Florida (75b, c, and d), and the two subecoregions in the northeast of Florida (75e and f). Metric values of panhandle streams seem to indicate higher stream quality than in the peninsula. The Florida Index, the EPT index and their components were highest in panhandle streams. The Hilsenhoff Biotic Index, an index of tolerant species, was lowest in panhandle streams. Diversity and taxa richness were slightly higher in panhandle streams. Metric values of peninsular streams indicated lower quality than in the panhandle, but slightly higher than the northeast ecoregions. These last two subecoregions, the Okefenokee Swamps and Plains, and the Sea Islands Flatwoods, seemed to have the lowest stream quality of any of the reference sites. However, only four streams were analyzed from this area, and a larger sample would allow comparisons to be made with more confidence.

There were, however, some differences in metric values among the subecoregions within the aggregated groups. In particular, subecoregion 75a, the Gulf Coast Flatwoods, appears intermediate or transitional between region 65, the Southeastern Plains and the other Southern Coastal Plain subecoregions, 75b, c, and d, with several metrics having intermediate values in subecoregion 75a. The Gulf Coast Flatwoods, subecoregion 75a, receives runoff from subecoregions 65f, g, and h, and has lower topographic relief than ecoregion 65.

A similar graphical analysis of metric values plotted by stream type revealed a much weaker influence of stream type, with only four of thirteen metrics having different values in calcareous and alluvial streams than in sand-bottom streams. Two of the metrics are indicators of the variety and abundance of crustaceans and molluscs, which are expected to be more abundant in calcium-rich waters.

Based on the above analysis, the following classification of Florida streams was recommended:

- Streams of the Florida Panhandle, comprising the Southeastern Plains ecoregion (65f, g, h) and the Gulf Coast Flatwoods (75a).
- Streams of peninsular Florida, comprising the Southwestern Florida Flatwoods (75b), the Central Florida Ridges and Uplands (75c), and the Eastern Florida Flatwoods (75d).
- Streams of northeastern Florida, comprising the Okefenokee Swamps and Plains (75e) and the Sea Island Flatwoods (75f).
- Alluvial streams and rivers that receive inflow from several subecoregions. The alluvial rivers are characterized by a predominance of surface run-off, seasonal fluctuations in water quality and flow and a relatively high sediment load.

The above classification must be considered preliminary because of small sample size in several subecoregions and classes. Therefore, the following caveats apply:

- Subecoregion 75a, the Gulf Coast Flatwoods, may be different from the other panhandle subecoregions, but a larger sample (more sites) is needed to verify or refute its affinity to the other panhandle subecoregions.
- Subecoregions 65g, 75c, 75e, and 75f, and the alluvial class, are all under-represented in the data set (N = 2 to 4), and any conclusions regarding these are tentative.

Each of the three major groups is also a contiguous geographic region (panhandle, peninsula, and northeast), with observable physical and chemical differences between the three regions. The observed regional biological differences are partly related to acid-base chemistry of the regions. Peninsula Florida is dominated by limestone bedrock, and surface and ground waters are typically well-buffered. Water in the panhandle and northeastern Florida are more often poorly-buffered or acidic. Relationships between ambient pH and several metric values are seen and can be explained by strong correlations between certain faunal groups and water with a certain pH.

Metric Calibration: The candidate metrics were then calibrated through an evaluation of both reference and impaired sites. The ability of a metric to discriminate between a reference and a known impaired site is essential if the metric is to be useful for monitoring and assessment purposes.

Data from the Florida DEP's Point Source Program were used to evaluate the performance of metrics at impaired sites and to determine their ability to discriminate between "good" and "bad" biological condition. Sites in this point source program were either upstream or downstream of known point source dischargers. Many of the upstream control sites in the point source program were not necessarily good reference sites, because of habitat degradation or some other reason. Two considerations in using the point source data are that although the season of collection was the same as that of the reference sites, some point source data were collected the previous year; and the methods used in the point source program were similar, but not identical in all respects to those employed in the nonpoint source program. However, these considerations did not prevent integration of the data from the two programs to evaluate discriminatory ability.

The evaluation and judgement of the core metrics concluded that five of the metrics, the EPT Index, Number of Total Taxa, Shannon-Wiener Index, Florida Index, and Percent Filterers, were relatively strong in discriminating impairment. Two metrics—the Number of Chironomidae Taxa and Percent Gatherers—were not useful at all in discriminating between reference and impaired sites. It was recommended that these two metrics be removed from the suite of core metrics, pending analysis of additional data.

VOL 12

7763

A corollary study was performed to compare biological sampling methods to determine whether (1) Hester-Dendy artificial substrate samplers provide data representative of stream biological status, and (2) whether dip nets or Hester-Dendy's are more powerful for detecting biological impairment. Results from statistical analysis of metrics suggest that dip net data are as good or somewhat better than Hester-Dendy data in distinguishing biological impairment in Florida streams. These results, together with the fact that use of a Hester-Dendy is more labor intensive and costly, support the use of dip net collections as the primary macroinvertebrate collecting gear for the NPS monitoring program in Florida.

Florida Index Development: The stream invertebrate index for Florida was developed by aggregating the metrics that proved responsive to independent measures of impacts. Aggregation simplifies management and decision-making so that a single index value is used to determine whether action is needed. The exact nature of the action needed (e.g., restoration, mitigation, enforcement) is not determined by the index value, but by analysis of the component metrics. The approach used to define a Florida index was to develop expectations for the values of each of the metrics from the reference data set, and to score metrics according to whether they are within the range of reference expectations. Metrics within the range receive a high score, those outside receive a low score. The index value is then the sum of the metric scores. The index is further normalized to reference condition, such that the distribution of index values in the reference sites forms the expectations for the region.

In an assessment, streams can be judged for impairment based on the summed index value. If the index value is below a criterion, then the stream is judged impaired. The index value criterion is based on the index value distribution in reference streams; for example, the 25th percentile (lower quartile) of reference expectations is commonly used. Reference sites had been carefully selected to be representative of least impacted conditions in each ecoregion, and investigators involved in site selection and sampling were confident that the reference sites represented best available conditions in Florida streams. Therefore, the lower quartile of each metric distribution in reference sites was selected as the criterion for the minimum value of the metric representative of reference conditions. Thus, any metric value above the lower quartile of the reference distribution received the highest possible score. Using this rationale, scoring criteria were developed which are a modification of the methodology of Karr et al.(1986; Karr 1991). Using the scoring criteria, a stream invertebrate index for Florida was calculated in three different ways as alternatives for optimizing the index.

- All metrics summed.
- As above, but with the Shannon-Wiener Index removed since it is strongly correlated with the Percent of Dominant Taxon as well as with Total Number of Taxa and, therefore, may be redundant with these.
- As above, but with all weak metrics removed. Weak metrics are those with limited ability to discriminate between reference and impaired conditions.

VOL 12

7764

R0041072

All three versions of the index were able to discriminate between reference and impaired conditions better than the individual metrics. Removing the Shannon-Wiener Index does not affect discrimination ability, nor does removing the weaker metrics.

The recommended stream invertebrate index for Florida is: (1) to remove the Shannon-Wiener Index because of its redundancy with the Number of Taxa and the Percent of the Dominant Taxon, and its inclusion does not improve the resolution; but (2) to retain the weaker metrics because their correlations with other metrics are not strong (thus they are independent measures), and because they may respond to stressors not represented in the point-source data set. The list of core metrics that compose the stream invertebrate index are: Number of Total Taxa, EPT Index, % Dominant Taxon, % Diptera, Florida Index, % Filterers, and, % Shredders in the Panhandle (Ecoregions 65, 75a) and in the Peninsula (Ecoregions 75b, c, d), with # Crustacean/Mollusc Taxa and % Crustacean/Mollusc added in the Peninsula.

All of these metrics will be re-evaluated with a more complete data set of impaired streams and in different seasons.

DISCUSSION AND CONCLUSIONS

Adding sediment and biological community assessments to traditional water quality monitoring and evaluation approaches greatly enhance the ability of these tools to ascertain the environmental effects of stormwater discharges. The importance of this biological assessment framework in accurately assessing the environmental health of surface waters is seen by comparing Ohio's use attainment conclusions. The Ohio Environmental Protection Agency incorporated biocriteria into its water quality standards regulations in recent years (Yoder, 1989). These biocriteria are based on a system of tiered aquatic life uses representing five classes. These include coldwater habitat, warmwater habitat, exceptional warmwater habitat, modified warmwater habitat and limited resource waters. These designations have been qualitatively defined in ecological terms, and chemical criteria, either quantitative or narrative, have been established for each. Using both the water chemistry and bioassessment data, conclusions about the attainment of beneficial uses in Ohio water bodies include (EPA, 1989a):

- Based on chemical data, 52% of the segments fully attained aquatic life uses;
- Based on biosurvey data, only 23% achieved full attainment;
- The two types of assessment agreed on full attainment in 17% of the cases with overall agreement on 46% of the cases;
- In 35% of the cases, chemical data indicated full attainment but biosurvey data indicated partial or non-attainment. In nearly half of these cases, impairments were due to habitat or flow modifications, or siltation.

Unfortunately, as can be seen from the activities described in this paper, conducting the preliminary technical analyses that are essential to establish the scientific rationale

VOL 12

7765

R0041073

for these assessment tools is not easy, quick, nor inexpensive. Ultimately, the goal of these efforts is to develop quantitative biocriteria which can be used to more effectively assess, manage and evaluate stormwater/NPS pollution sources and management efforts. Metrics reflecting community characteristics may be considered appropriate in biocriteria programs if their relevance can be demonstrated, response range is verified and documented, and the potential for application in water resource programs exists. However, before the FDEP can adopt biocriteria, lots more work must be done to further refine, calibrate and evaluate the biometrics. Frequent evaluation of metrics and indices is an essential feature of the use of biocriteria. However, once established, the multimetric approach for assessing biological condition offers the following attributes: (1) relies on information about several populations or species assemblages, rather than just target species; (2) relates to a community-level potential or expectation based on a reference condition; (3) uses multiple metrics to function as surrogate measures of more complicated elements and processes; and (4) incorporates ecological principles that enable an interpretation of exposure/response relations.

Sediment assessment, together with watershed characterization and mapping of pollution sources, can be used to screen watersheds and sub-basins to determine potential "hot spots". Bioassessment and water chemistry sampling can then be done to assess the actual health of the aquatic system in these locations. The initial focus of a bioassessment should be on habitat quality. Based on a regional reference, the habitat at an impacted site may be equal to or less than the desired quality for that particular system. If the habitat at the impact site and reference are equal, then a direct comparison of biological condition can be made. If the habitat at the impact site is lower in quality than the reference, the habitat potential should be evaluated as a first step. A site-specific control may be more appropriate than a regional reference for an assessment of an impact site. If so, then care must be taken in selecting an appropriate site-specific reference site to assure that its habitat and sediment characteristics are representative for the area. Once a determination of the appropriate reference site type is made, possible outcomes of the bioassessment are: (1) no biological effects; (2) effects due to habitat degradation; (3) effects due to sediment or water quality; or (4) effects due to a combination of sediment, water quality and habitat degradation.

The projects described in this paper greatly contributed to the development, refinement, calibration, and testing of several essential sediment and biological community assessment tools in Florida. The Department is anxious to begin using these tools to better assess the effects of intermittent pollutant sources, evaluate the effectiveness of BMPs and management programs, prioritize watersheds and subbasins for management activities, and, in conjunction with the water management districts, to develop and implement the stormwater pollutant load reduction goals (PLRGs) required by State Water Policy and being established through the state's Surface Water Improvement and Management Program. The sediment and biological community assessment methods, in conjunction with the recently started effort by the

Department to receive delegation of EPA's NPDES permitting program and a future initiative for basin wide monitoring, permitting, and compliance, provide the technical and institutional tools needed to cost-effectively reduce stormwater/NPS pollutant loadings on a watershed basis.

However, before these initiatives can be fully implemented, even more analysis and evaluation needs to be done to refine the assessment methods. For the NPS bioassessment program, issues still to be resolved include (FDEP, 1994b):

1. Test the level of subsampling to improve the integrity of the data. The level of subsampling is presently set at 100 organisms. However, only a small portion of the entire sample is processed to obtain 100 organisms. The subsampling levels of 100-, 200-, and 300-organisms need to be tested for appropriateness with a cost/analysis benefit performed following the power-cost efficiency (PCE) procedure of Ferraro et al. (1989). The PCE should provide the best compromise between the least costly subsampling effort (100-organism) and the most rigorous (300-organism).
2. Evaluate the winter index period to validate both the site classification and suite of metrics for assessment and monitoring during that season. The present analyses are relevant only to the first collection of the summer index period. It is probable that the present site classification and core metrics would not be altered significantly for the winter data set, but this supposition needs to be tested. In addition, subsequent summer and winter datasets collected in 1993 and 1994 should be incorporated into the analysis. The FDEP recently obtained a Section 104(b)(3) grant from EPA that will allow these analyses to be performed by Tetra Tech.
3. Validate the classification of 65g, 75a, 75e, and 75f. These subecoregions are under-represented by reference sites. An evaluation of their classification could be improved with the sampling of additional sites. A collaboration with the neighboring states of Georgia and Alabama may be instrumental in increasing the sample size of the sites. A greater portion of the subecoregions of 65g, 75e, and 75f are in those neighboring states.
4. Evaluate the Hilsenhoff Biotic Index (HBI) as a sensitivity measure. The HBI was evaluated as part of the present data analyses. However, too many assumptions had to be made regarding the tolerance assignment to the various taxa. Logically, the HBI should be more meaningful than similar measures in assessing biological condition, because the index incorporates information from the whole assemblage. The proper assignment of tolerance scores should be addressed and the efficacy of the HBI metric re-evaluated. Similarly, tolerance assignments should address a broader range of pollutants.
5. Conduct habitat evaluations at reference and habitat-limited sites to determine the resolving power of the habitat parameters along a gradient of impact. This kind of analysis has been done for the biometrics using macroinvertebrate data from point source impact studies. Sites with nonpoint source habitat limitations e.g., erosion, deforestation. etc. should be included and the evaluation will require site-

specific chemical analyses to separate chemical and physical limitations to the biota.

6. Develop a software program to handle the storage, sorting, and analysis of the biological and habitat data. For the department to successfully implement the bioassessment program, a "user-friendly" program should be developed. A contractor has been hired to review the current Florida DEP computer programs for handling specific biological data sets and to modify them to include the present suite of metrics and assessment approach.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the creativity, dedication and hard work on these projects by many individuals at the FDEP, especially the biologists and all past and current members of the Sediment Research Group, and by our contractors, especially Mike Barbour, James Omernik, Glenn Griffith, Herb Windom, and Don MacDonald.

Water Quality Trends from Stormwater Controls

Robert Pitt, M.ASCE[1]

__Abstract__

The detection of changes in pollutant levels over time is an important objective of many environmental monitoring programs. This is especially true in stormwater pollution control. In some areas, a great deal of money has been spent to reduce stormwater discharges of pollutants (both urban and rural), and there is much pressure to demonstrate improvements in water quality. Trend analyses can be an important and powerful tool in demonstrating the benefits of stormwater pollution control. Unfortunately, lack of data, or poorly designed data gathering efforts, greatly hinder the use of this technique. This paper will describe several trend analysis tools and the types of data needed for their implementation. It will also present a case study showing water quality benefits in a lake associated with the implementation of an innovative stormwater control program.

__Introduction__

A full-scale plant, using the Karl Dunkers system for treatment of separate stormwater and lake water, has been operating since 1981. The treatment facility is located in the northern part of Lake Rönningesjön, near Stockholm, Sweden. Excess flows are temporarily stored before treatment. Stormwater is pumped to the treatment facility during rains, with excess flows stored inside in-lake flow balancing tanks (the Flow Balancing Method, or FBM). The treatment system consists of a chemical treatment system designed for the removal of phosphorus and uses ferric chloride precipitation and crossflow lamella clarifiers. The stormwater is pumped from the flow balancing storage tanks to the treatment facility. Lake water is also pumped to the treatment facility during dry periods, after any excess stormwater is treated.

[1] Associate Professor, Department of Civil and Environmental Engineering, The University of Alabama at Birmingham, 1150-10th Ave. South, Birmingham, Alabama 35294-4461.

The FBM and the associated treatment system significantly improved lake water quality through direct treatment of stormwater and by pumping lake water through the treatment system during dry weather. The annual average removals of phosphorus from stormwater and lake water by the ferric chloride precipitation and clarification treatment system were 66 percent, while the annual average total lake phosphorus concentration reductions averaged about 36 percent.

Statistically Based Trend Analyses

Several publications have excellent descriptions of statistical trend analyses for water quality data. In addition to containing detailed descriptions and examples of experimental design methods to determine required sampling effort, Gilbert (1987) devotes a large portion of his book to detecting trends in water quality data and includes the code for a comprehensive computer program for trend analysis.

Reckhow and Stow (1990) present a comprehensive assessment of the effectiveness of different water quality monitoring programs in detecting water quality trends using EPA STORET data for several rivers and lakes in North Carolina. They found that most of the data (monthly phosphorus, nitrogen, and specific conductance values were examined) exhibited seasonal trends and inverse relations with flow. Some of the data also exhibited autocorrelation. The remaining random variation (considering the correlations) was then used to determine the number of monthly samples needed for a given power (β) and significance (α). In many cases, large numbers of samples would be needed to detect changes of 25 percent or less (typical for stormwater retro-fitting activities).

Uri (1991) used the Box and Jenkins model to examine trends in sediment loadings to a portion of the Iowa River. The sediment loadings more than doubled in the years from 1948 to 1985. They also presented a method to examine factors causing this trend. They found a strong cause-and-effect relationship between acreage planted in soy beans and corn. For each 1 percent increase in planted area for either of these two crops, a sediment load increase of about 0.4 percent was likely.

Reckhow, *et al.* (1992) prepared a detailed manual presenting nonparametric analysis methods for examining water quality trends in lake waters. The manual presents a brief summary of basic concepts and approaches in applied statistics, followed by discussions of hypothesis testing and common assumptions for statistical tests. The manual contains detailed examples of lake and watershed wide water quality trend analyses. SAS macros are included to efficiently evaluate water quality trends.

Spooner and Line (1993) present recommendations for monitoring requirements in order to detect trends in receiving water quality associated with nonpoint source pollution control programs, based on many years experience with the Rural Clean Water Program. These recommendations, even though derived from rural experience, should also be very applicable for urban receiving water trend analyses. The following is a general list (modified) of their recommended data needs for associating water quality trends with land use/treatment trends:

- Appropriate and sufficient control practices need to be implemented. A high level of participation/control implementation is needed in the watershed to result in a substantial and more easily observed water quality improvement. Controls need to be used in areas of greatest benefit (critical source areas, or in drainages below major sources) and most of the area must be treated.

- Control practice and land use monitoring is needed to separate and quantify the effects of changes in water quality due to the implemented controls by reducing the statistical confusion from other major factors. Monitor changes in land use and other activity on a frequent basis to observe temporal changes in the watershed. Seasonal variations in runoff quality can be great, along with seasonal variations in pollutant sources (monitor during all flow phases, such as during dry weather, wet weather, cold weather, warm weather, for example). Collect monitoring data and implement controls on a watershed basis.

- Monitor the pollutants affecting the beneficial uses of the receiving waters. Conduct the trend analyses for pollutants of concern, not just for easy, or convenient, parameters.

- Monitor for multiple years (at least 2 to 3 years for both pre- and post-control implementation) to account for year-to-year variability. Utilize a good experimental design, with preferable use of parallel watersheds (one must be a control and the other undergoing treatment).

Other water quality trend analysis references contained in Uri (1991) include Box and Jenkins (1970), Hipel and McLeod (1989), Hipel, *et al.* (1988), Hirsch (1988), Hirsch and Slack (1984), and Taylor and Loftis (1989). Reckhow, *et al.* (1992) also listed the following applicable references: Berryman, *et al.* (1988), Hirsch, et al. (1982), Lettenmaier (1976), and Montgomery and Loftis (1987).

Preliminary evaluations before trend analyses are used

Gilbert (1987) illustrates several sequences of water quality data that can confuse trend analyses. It is obviously easiest to detect a trend when the trend is large and the random variation is very small. Cyclic data (such as seasonal changes) often are confused as trends when no trends exist (type 1 error) or mask trends that do exist (type 2 error) (Reckhow and Stow 1990; Reckhow 1992). Three data characteristics need to be addressed before the data can be analyzed for trends because of confusing factors. These include:

VOL 12

VOL 12

• Measure data correlations, as most statistical tests require uncorrelated data. If data are taken close together (in time or in location), they are likely partially correlated. As an example, it is likely that a high value is closely surrounded by other relatively high values. Close data can therefore be influenced by each other and do not provide unique information. This is especially important when determining confidence limits of predicted values or when determining the number of data needed for a trend analyses (Reckhow and Stow 1990). Test statistics developed by Sen can use dependent data, but they may require several hundred data observations to be valid (Gilbert 1987).

• Remove any seasonal (or daily) effects, or select a data analysis procedure that is unaffected by data cycles. The nonparametric Sen test can be used when no cycles are present, or if cyclic effects are removed, while the seasonal Kendall test is not affected by cyclic data (Gilbert 1987).

• Identify any other likely predictable effects on concentrations and remove their influence. Normally occurring large variations in water quality data easily mask commonly occurring subtle trends. Typical relations between water quality and flow rate (for flowing water) can be detected by fitting a regression equation to a concentration vs. flow plot. The residuals from subtracting the regression from the data are then tested for trends using the seasonal Kendall test (Gilbert 1987).

Reckhow (1992) presents a chart listing specific steps that need to be taken to address the above problems. These steps are as follows:

(1) Check the data for deterministic patterns of variability (such as concentration versus flow by using graphical and statistical methods). If deterministic patterns exist, subtract the modeled pattern from the original data, leaving the residuals for subsequent seasonality analyses.

(2) Examine the remaining residuals (or data, if no deterministic patterns exist) for seasonal (can be short period, such as daily) variations. Again use graphical and statistical methods. If "seasonality" exists, subtract the modeled seasonality from the data (residuals from #1 above), leaving the remaining residuals for subsequent trend analyses.

(3) Conduct the trend analysis on the residuals from #2 above, using the standard seasonal Kendall test . If a trend exists, subtract the trend, leaving the remaining residuals for subsequent autocorrelation analyses.

(4) Test the remaining residuals from #3 above (or the raw data, if no deterministic or cyclic patterns or trends were found) for autocorrelation. If the autocorrelation is significant, re-evaluate the trends using an autocorrelated-corrected version of the seasonal Kendall (or regular Kendall) test. If no autocorrelation was found, use the standard seasonal Kendall test if seasonality was identified, or the

7774

standard Kendall test if no seasonality was identified. The final residual variation is then used (after correcting for autocorrelation) in calculating the required number of samples needed to detect trends for similar situations.

Statistical methods available for detecting trends

Graphical methods. Several sophisticated graphical methods are available for trend analyses that use special smoothing routines to reduce short-term variations so the long-term trends can be seen (Gilbert 1987). In all cases, simple plots of concentrations versus time of data collection should be made. This will enable obvious data gaps, potential short-term variations, and distinct long-term trends to be possibly seen.

Regression methods. A time-honored approach in trend analysis is to perform a least-squares linear regression on the quality versus time plot and to conduct a *t* test to determine if the true slope is not different from zero (Gilbert 1987). However, Gilbert (1987) points out that the *t* test can be misleading due to cyclic data, correlated data, and data that are not normally distributed.

Mann-Kendall test. This test is useful when missing data occur (due to gaps in monitoring, such as if frozen waters occur during the winters, equipment failures, or when data are reported as below the limit of detection). Besides missing data, this test can also consider multiple data observations per time period. This test also examines trends at multiple stations (such as surface waters and deep waters, etc.) and enables comparisons of any trends between the stations. This method also is not sensitive to the data distribution type. This test can be considered a nonparametric test for zero slope of water quality versus time of sample collection (Gilbert 1987). Short-term (such as seasonal changes) cycles and other data relationships (such as flow versus concentration) affect this test and must be corrected. If data are highly correlated, then this test can be applied to median values in each discrete time groupings.

Sen's nonparametric estimator of slope. Being a nonparametric test based on ranks, this method is not sensitive to extreme values (or gross data errors) when calculating slope (Gilbert 1987). This test can also be used when missing data occur in the set of observations. It is closely related to the Mann-Kendall test.

Seasonal Kendall test. This method is preferred to most regression methods if the data are skewed, serially correlated, or cyclic (Gilbert 1987). This test can be used for data sets having missing values, tied values, censored values (less than detection limits) or single or multiple data observations in each time period. The testing of homogeneity of trend direction enables one to determine if the slopes at different locations are the same, when seasonality is present. Data correlations (such as flow versus concentration) and dependence also affect this test and must be considered in the analysis.

VOL 12

775

The code for the computer program contained in Gilbert (1987) computes Sen's estimator of slope for each station-season combination, along with the seasonal Kendall test, Sen's aligned test for trends, the seasonal Kendall slope estimator for each station, the equivalent slope estimator for each season, and confidence limits on the slope.

Watershed Characteristics and Treatment System

Lake Rönningesjön is located in Täby, Sweden, near Stockholm. Figure 1 shows the lake location, the watershed, and the surrounding urban areas. The watershed area is 650 ha, including Lake Rönningesjön itself (about 60 ha), and the urban area that has its stormwater drainage bypassing the lake (about 175 ha). The effective total drainage area (including the lake surface) is therefore about 475 ha. Table 1 summarizes the land use of the lake watershed area. About one-half of the drainage area (including the lake itself) is treated by the treatment and storage operation.

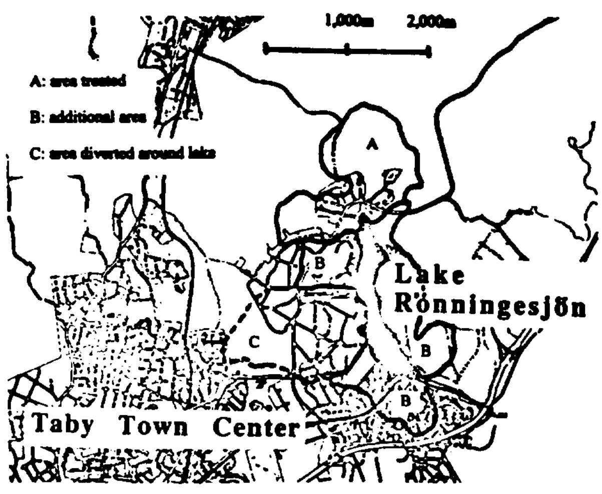

Figure 1. Lake Rönningesjön watershed in Täby, Sweden.

Table 1. Lake Rönningesjön Watershed Characteristics

	Area Treated	Additional Area	Total Area
urban	50 ha	100 ha	150 ha (32%)
forest	75 ha	80 ha	155 ha (32%)
agriculture	65 ha	45 ha	110 ha (23%)
lake surface	60 ha		60 ha (13%)
total drainage	250 ha	225 ha	475 ha (100%)

The lake volume is about 2,000,000 m^3 and has an annual outflow of about 950,000 m^3. The estimated mean lake resident time is therefore slightly more than two years. The average lake depth is 3.3 m. It is estimated that the rain falling directly on the lake surface itself contributes about one-half of the total lake outflow.

The treatment process consists of an in-lake flow balancing storage tank system (the Flow Balancing Method, or FBM) to contain excess stormwater flows which are pumped to a treatment facility during dry weather. The treatment facility uses ferric chloride and polymer precipitation and crossflow lamella clarifiers. Figure 2 illustrates the layout of the FBM, the treatment facility, and the lake discharge in the northern end of Lake Rönningesjön. Figure 3 shows the cross-section of the FBM in the lake. It is make of plastic curtains forming the cell walls, supported by floating pontoons and anchored to the lake bottom with weights.

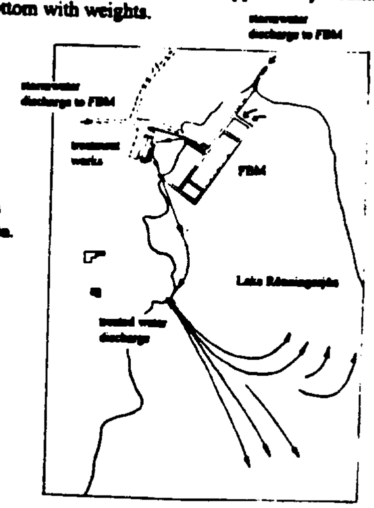

Figure 2. Treatment system layout in Lake Rönningesjön.

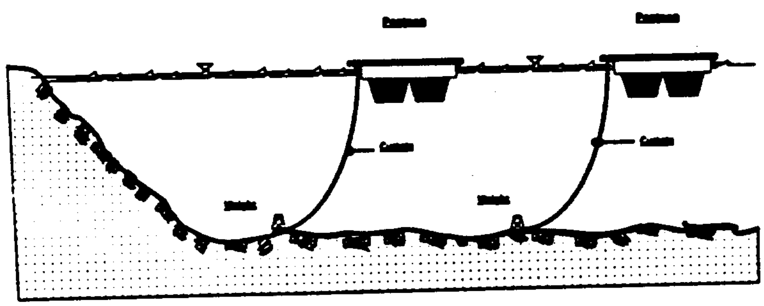

Figure 3. Cross-section of FBM in-lake tanks.

Figure 4 shows that the FBM provides storage of contaminated water by displacing clean lake water that enters the storage facility during dry weather as the FBM water is pumped to the treatment system. All stormwater enters the FBM directly (into cell A). The pump continuously pumps water from cell A to the chemical treatment area. If the stormwater enters cell A faster than the pump can remove it, the stormwater flows through curtain openings (as a slug flow) into cells B, C, D, and finally E, displacing lake water (hence the term flow balancing). As the pump continues to operate, stormwater is drawn back into cell A and then to the treatment facility. The FBM is designed to capture the entire runoff volume of most storms. The Lake Rönningesjön treatment system is designed to treat water at a higher rate than normal to enable lake water to be pumped through the treatment system after all the runoff is treated.

The FBM is mainly intended to be a storage device, but it also operates as a wet detention pond, resulting in sedimentation of particulate pollutants within the storage device. The first two cells of the FBM facility at Lake Rönningesjön were dredged in 1991, after 10 years of operation, to remove about one meter of polluted sediment.

The treatment flow rate is 60 m^3/hr (about 0.4 MGD). The ferric chloride feed rate is about 20 to 35 grams per cubic meter of water. About 30 m^3 of thickened sludge is produced per day for co-disposal with sludge produced at the regional sanitary wastewater treatment facility. The annual operating costs are about $28,000 per year (or about $0.03 per 100 gallons of water treated), divided as shown in Table 2.

From 1981 through 1987, the FBM operated an average of about 5500 hours per year (about 7.6 months per year), treating an average of about 0.33 million m^3 per year. The treatment period ranged from 28 to 36 weeks (generally from April through November). The FBM treatment system treated stormwater about 40% of its operating time and lake water about 60% of its operating time. The FBM treatment system directly treated about one-half of the in-flowing waters to the lake (at a level of about 70% phosphorus removal).

Lake Rönningesjön and Treatment System Phosphorus Budgets

Two tributaries flow directly to the treatment facility. Excess flows (exceeding the treatment plant flow capacity) are directed to the FBM in the lake. As the flows in the tributaries fall below the treatment plant capacity, pumps in the FBM deliver stored stormwater runoff for treatment. When all of the stormwater is pumped from the FBM, the pumps deliver lake water for treatment. Tables 3 and 4 summarize the runoff and lake volumes treated and phosphorus removals during the period of treatment.

1991	7.7	9.8	5.6	23.1	8.9	14.2	61.5

There have been highly variable levels of phosphorus treatment from stormwater during the period of operation. 1988 through 1990 had low phosphorus removals. These years had relatively mild winters with substantial stormwater runoff occurring during the winter months when the treatment system was not operating. Normally, substantial phosphorus removal occurred with spring snowmelt during the early weeks of the treatment plant operation each year. The greatest phosphorus improvements in the lake occurred during the years when the largest amounts of stormwater were treated.

The overall phosphorus removal rate for the 11 years from 1981 through 1991 was about 17 kg/year. About 40% of the phosphorus removal occurred in the FBM from sedimentation processes, while the remaining occurred in the chemical treatment facility. This phosphorus removal would theoretically cause a reduction in phosphorus concentrations of about 10 µg/L per year in the lake, or a total phosphorus reduction of about 100 µg/L during the data period since the treatment system began operation. About 70% of this phosphorus removal was associated with the treatment of stormwater, while about 30% was associated with the treatment of lake water.

Observed Long-Term Lake Rönningesjön Water Quality Trends

Lake Rönningesjön water quality has been monitored since 1967 by the Institute for Water and Air Pollution Research (IVL); the University of Technology, Stockholm; the Limnological Institute at the University of Uppsala; and by Hydroconsult Corp. Surface and subsurface samples were obtained at one or two lake locations about five times per year. In addition, the tributaries being treated, incoming lake water, and discharged water, were all monitored on all weekdays of treatment plant operation. The creek tributary flow rates were also monitored using overflow weirs.

The FBM started operation in 1981. Based on the hydraulic detention time of the lake, several years would be required before a new water quality equilibrium condition would be established. A new water quality equilibrium will eventually be reached after existing pollutants are reduced from the lake water and sediments. The new water quality conditions would be dependent on the lake flushing rate (or detention time, estimated to be about 2.1 years), and the new (reduced) pollutant discharge levels to the lake. Without lake water treatment, the equilibrium water quality would be worse and would take longer to obtain.

Figure 5 is a plot of all chlorophyll *a* data collected at both the south and north sampling stations. Very little trend is obvious, but the wide swings in chlorophyll *a* values appeared to have been reduced after the start of stormwater treatment. Figure 6 is a three-dimensional plot of smoothed chlorophyll *a* data, indicating significant trends by season. The values started out relatively low each early spring and dramatically increased as the summer progressed. This was expected and was a function of algal growth. Homogeneity, seasonal Kendall and Mann-Kendall statistical tests (Gilbert 1987) were conducted using the chlorophyll *a* data. The homogeneity test was used to determine if any trends found at the north and south sampling stations were different. The probabilities that the trends at these two stations were the same were calculated as follows:

	χ^2	Probability
season	14.19	0.223
station	0.00001	1.000
station-season	0.458	1.000
Trend	21.64	0.000

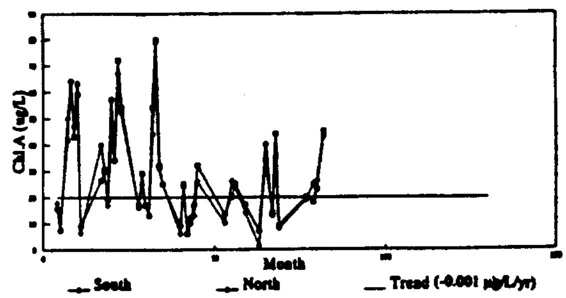

Figure 5. Chlorophyll *a* observations with time (μg/L)

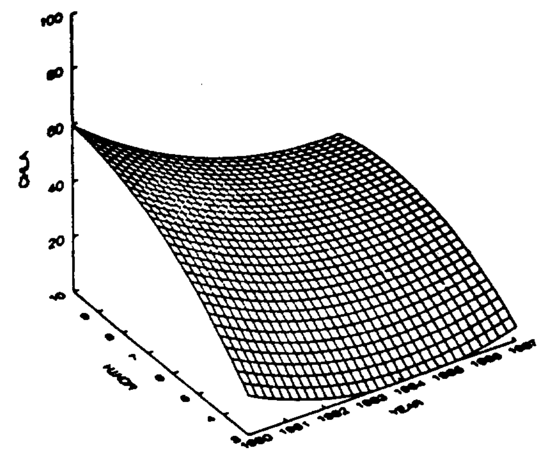

Figure 6. Chlorophyll *a* trends by season and year (μg/L).

This test shows that the trend was very significant (P<0.001) and was the same at both sampling stations (P=1.000). The seasonal trend tests only compared data obtained for each season, such as comparing trends for June observations alone. The station-season interaction term shows that the chlorophyll *a* concentration trends at the two stations were also very similar for all months (P=1.000). Therefore, the sampling data from both stations were combined for further analyses.

VOL 12

7782

The seasonal Kendall test calculated the chlorophyll *a* concentration trends and determined the probabilities that they were not zero, for all months separately. This test and the Mann-Kendall tests found that both the north and south sampling locations had slight decreasing (but very significant) overall trends in concentrations with increasing years ($P \leq 0.001$). However, individual monthly trends were not very significant ($P \geq 0.05$). The trends do show an important decrease in the peak concentrations of chlorophyll *a* that occurred during the fall months during the years of the FBM operation. The 1980 peak values were about 60 µg/L, while the 1987 peak values were lower, at about 40 µg/L.

Swedish engineers (Söderlund 1981; and Lundkvist and Söderlund 1988) summarized major changes in the algal species present and in the algal biomass in Lake Rönningesjön, corroborating the chlorophyll *a* and phosphorus limiting nutrient observations. From 1977 through 1983, the lake was dominated by a stable population of thread-shaped blue-green algaes (especially *Oscillatoria sp. and Aphanizomenon flos aquae f. gracile*). Since 1985, the algae population was unstable, with only a small amount of varying blue green (*Gomphosphaeria*), silicon (*Melosira, Asterionella* and *Synedra*) and gold (*Chrysochromulina*) algae species. They also found a substantial decrease in the algal biomass in the lake. From 1978 through 1981, the biomass concentration was commonly greater than 10 mg/L. The observed maximum was about 20 mg/L, with common annual maximums of 15 mg/L in July and August of each year. From 1982 through 1986, the algal biomass was usually less than 10 mg/L. The observed maximum was 14 mg/L and the typical annual maximum was about 6 mg/L each late summer. The lake showed an improvement in its eutrophication level since the start of the stormwater treatment, going from hypotrophic to eutrophic.

Figure 7 is a plot of all Secchi disk transparency data obtained during the project period. A very large improvement in transparency is apparent from this plot, but large variations were observed in most years. Figure 8 shows these annual variations in grouped box plots. A large improvement may have occurred in the first five years of stormwater treatment and then the trend may have decreased. The smoothed plot in Figure 9 shows significant improvement in Secchi disk transparency since 1980. This three-dimensional plot shows that the early years started off with clearer water (as high as 1 m transparency) in the spring and then degraded as the seasons progressed, with transparency levels falling to less than 0.5 m in the fall months. The later years indicated a significant improvement, especially in the later months of the year.

Homogeneity, seasonal Kendall and Mann-Kendall statistical tests (Gilbert 1987) were conducted using the Secchi disk transparency data. The homogeneity test was used to determine if any trends found at the north and south sampling stations were different. The probabilities that the trends at these two stations were the same were calculated as follows:

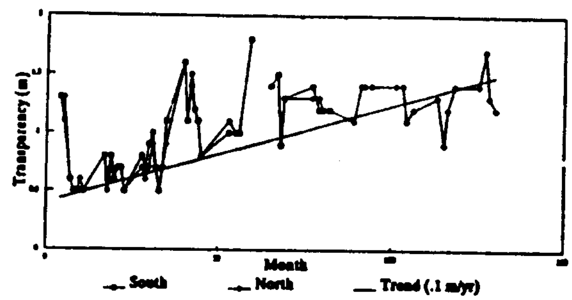

Figure 7. Secchi disk transparency observations with time (m).

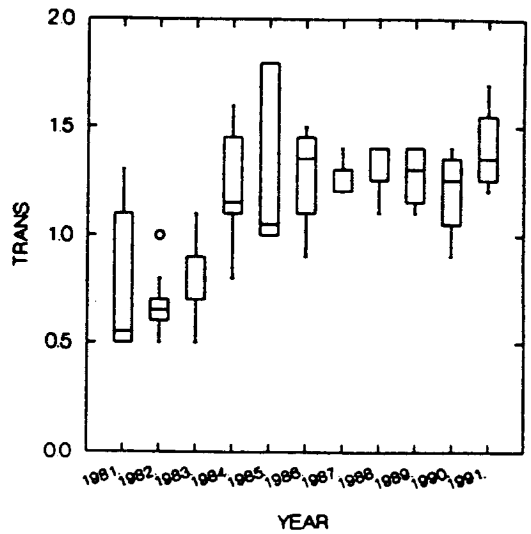

Figure 8. Secchi disk transparencies grouped by year (m).

	χ^2	Probability
season	17.15	0.103
station	0.012	0.913
station-season	3.03	0.990
Trend	29.44	0.000

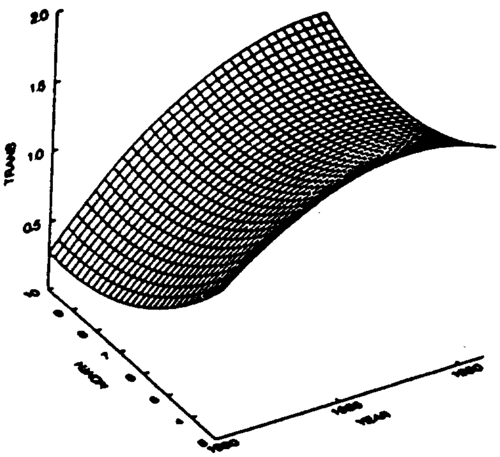

Figure 9. Secchi disk trends by season and year (m).

These statistics show that the observed trend was very significant (P<0.001) and was the same at both stations. The Seasonal Kendall and Mann-Kendall tests found that both the north and south sampling locations had increasing transparency values (the average trend was about 0.11 meter per year) with increasing years (P<0.001). The trend in later years was found to be less than in the early years. The transparency has remained relatively stable since about 1987 (ranging from about 1 to 1.5 m), with less seasonal variations.

Figure 10 plots observed phosphorus concentrations with time, while Figure 11 is a smoothed plot showing seasonal and annual variations together. The initial steep phosphorus concentration decreases in the early years of the FBM operation were followed by a sharp increase during later years. The increase was likely associated with the decreased levels of stormwater treatment during the mild winters of 1988 through 1990 when the treatment system was not operating; large amounts of untreated stormwater were discharged into the lake instead of being tied up as snow to be treated in the spring as snowmelt runoff.

Individual year phosphorus concentrations leveled off in the summer (about July). These seasonal phosphorus trends were found to be very significant ($P \leq 0.002$), but were very small, using the seasonal Kendall test (Gilbert 1987). Homogeneity

VOL 12

7785

tests found no significant differences between lake sample phosphorus concentrations obtained at the different sampling locations, or depths, irrespective of season:

	χ^2	Probability
season	15.38	0.166
station	0.0033	0.954
station-season	1.64	0.999
Trend	12.43	0.000

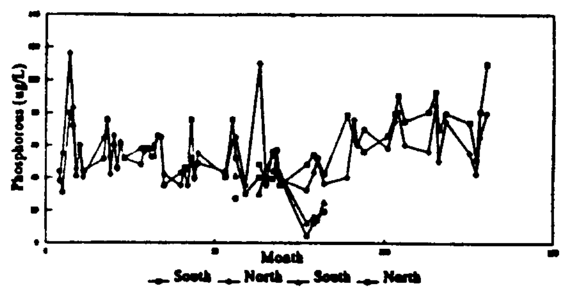

Figure 10. Total phosphorus observations with time (µg/L).

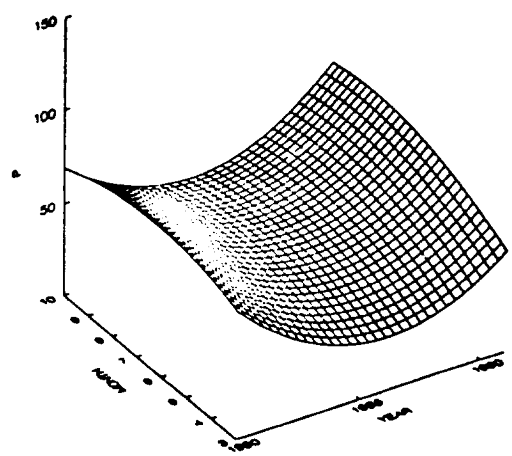

Figure 11. Total phosphorus trends by season and year (µg/L).

The overall lake phosphorus concentrations ranged from about 15 to 130 µg/L, with an average of about 65 µg/L. The monitored stormwater, before treatment, had phosphorus concentrations ranging from 40 to >1,000 µg/L, with an average of about 200 µg/L.

Figure 12 shows all Kjeldahl nitrogen values plotted with time and Figure 13 is a smoothed plot showing seasonal versus annual trends. An increase in nitrogen concentrations is also seen to have occurred from the beginning of each year to the fall months. However, the overall annual trend decreased during the first few years of the FBM operation, but it then subsequently increased. These total nitrogen concentration variations were similar to the total phosphorus concentration variations. However, homogeneity, seasonal Kendall and Mann-Kendall statistical tests (Gilbert 1987) conducted using the nitrogen data found that neither the north or south sampling locations had significant concentration trends with increasing years (P>0.2). However, lake Kjeldahl nitrogen concentration reductions were found to occur during years when the FBM system was treating the largest amounts of stormwater.

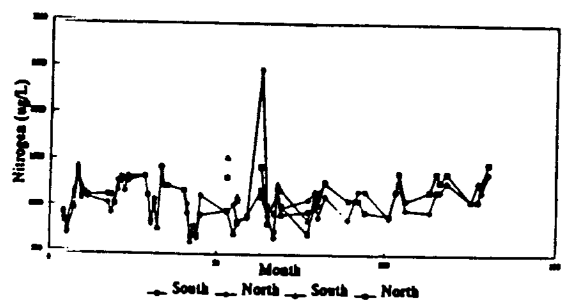

Figure 12. Total Kjeldahl nitrogen observations with time (µg/L).

Lake Water Quality Model

A simple water quality model was used with the Lake Rönningesjön data to determine the total annual net phosphorus discharges into the lake and to estimate the relative magnitude of various in-lake phosphorus controlling processes (associated with algal growth and sediment interactions, for example). These estimated total phosphorus discharges were compared to the phosphorus removed by the treatment system. The benefits of the treatment system on the lake water quality were then estimated by comparing the expected lake phosphorus concentrations as if the treatment system was not operating, to the observed lake phosphorus concentrations.

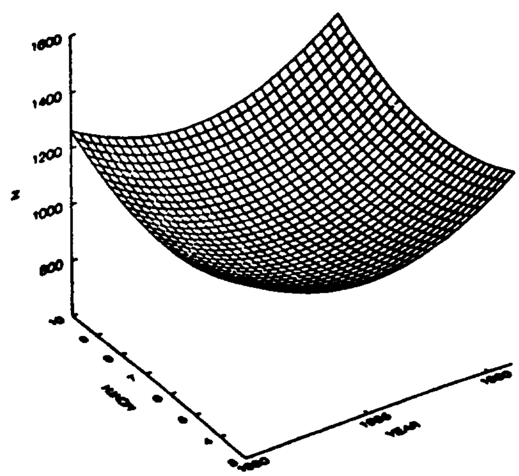

Figure 13. Total Kjeldahl nitrogen trends by season and year (μg/L).

Thomann and Mueller (1987) presented the following equation to estimate the resulting water pollutant concentrations associated with varying input loadings for a well-mixed lake:

$$S_t = (M/V) \exp(-T/Td) \qquad \text{eq. 1}$$

where S_t = concentration associated with a step input at time t,
M = mass discharge per time-step interval (kg),
V = volume of lake (2,000,000 m^3),
T = time since input (years), and
Td = hydraulic residence time, or lake volume/lake outflow (2.1 years).

This equation was used to calculate the yearly total mass discharges of phosphorus to Lake Rönningesjön, based on observed lake concentrations and lake hydraulic flushing rates. It was assumed that the varying concentrations observed were mostly caused by varying mass discharges and much less by variations in the hydraulic flushing rate. The flushing rate was likely to vary, but by relatively small amounts. The lake volume was quite constant and the outflow rate was expected to vary by less than 20 percent because of the relatively constant rainfall that occurred during the years of observation (average rainfall of about 600 mm, with a coefficient of variation of about 0.15).

The total mass of phosphorus discharged into the lake each year from 1972 to 1991 was calculated using the following equation (an expansion of equation 1), solving for the M_{n-x} terms:

$$S_n = M_n\,[\exp(-T_n/Td)/V] + M_{n-1}\,[\exp(-T_{n-1}/Td)/V] + M_{n-2}\,[\exp(-T_{n-2}/Td)/V] + M_{n-3}\,[\exp(-T_{n-3}/Td)/V] + \ldots \quad \text{eq. 2}$$

where S_n is the annual average phosphorus concentration during the current year, M_n is the net phosphorus mass discharged into the lake during the current year, M_{n-1} is the phosphorus mass discharged during the previous year, M_{n-2} is the phosphorus mass that was discharged two years previous, etc.

The effects of discharges into the lake many years previous to a concentration observation have little effect on that year's observations. Similarly, more recent discharges have greater effects on the lake's concentrations. The magnitude of effect that each year's step discharge has on a more recent concentration observation is dependent on the $\exp(-T_n/Td)$ factors shown in equation 2. A current year's discharge affects that year's concentration observations by about 40 percent of the steady-state theoretical value (M/V), and a discharge from five years previous would only affect the current year's concentration observations by less than ten percent of the theoretical value for Lake Rönningesjön. Similarly, a new steady-state discharge would require about 4 years before 90 percent of its equilibrium concentration would be obtained. It would therefore require several years before the effects of a decrease in pollutant discharges would have a major effect on the lake pollutant concentrations.

The annual control of phosphorus ranged from about 10 to 50 percent, with an average lake-wide level of control of about 36 percent, during the years of treatment plant operation. It is estimated that there would have been about a 1.6 times increase in phosphorus discharges into Lake Rönningesjön if the treatment system was not operating. There was a substantial variation in the year to year phosphorus discharges, but several trends were evident. If there was no treatment, the phosphorus discharges would have increased over the 20 year period from about 50 to 75 kg per year. With treatment, the discharges were held relatively constant at about 50 kg per year (as evidenced by the lack of any observed phosphorus concentration trend in the lake). During 1984 through 1987, the phosphorus discharges were quite low compared to other years, but increased substantially in 1988 and 1989 because of the lack of stormwater treatment during the unusually mild winters.

Figure 14 is a plot of the annual average lake phosphorus concentrations with time. If there had been no treatment, the phosphorus concentrations in the lake would

VOL 12 7789

have shown a relatively steady increase from about 50 to about 100 μg/L over the 20 year period. With treatment, the lake phosphorus concentrations were held within a relatively narrower range (from about 50 to 75 μg/L). The lake phosphorus concentration improvements averaged about 50 μg/L over this period of time, compared to an expected theoretical improvement of about 100 μg/L. Therefore, only about one-half of the theoretical improvement occurred, probably because of sediment-water interchange of phosphorus, or other unmeasured phosphorus sources.

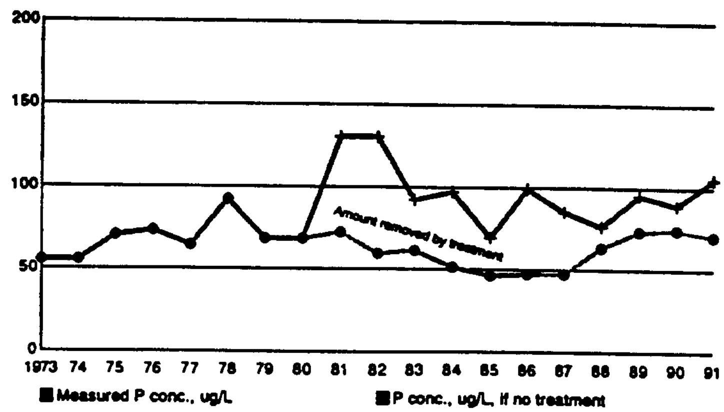

Figure 14. Effects of treatment on Lake Rönningesjön total phosphorus concentrations (μg/L).

Conclusions

The in-lake flow balancing method (FBM) for storage of excess stormwater during periods of high flows allowed for lower treatment flow rates, while still enabling a large fraction of the stormwater to be treated for phosphorus removal. The treatment system also enabled lake water to be treated during periods of low (or no) stormwater flow. The treatment of the stormwater before lake discharge accounted for about 70 percent of the total observed phosphorus discharge reductions, while the lake water treatment was responsible for the remaining 30 percent of the discharge reductions. The lake water was treated during 60 percent of the operating time, but resulted in less phosphorus removal, compared to stormwater treatment. The increased efficiency of phosphorus removal from stormwater compared to lake water was likely due to the more abundant particulate forms of phosphorus that were removed in the FBM by sedimentation and by the stormwater's higher dissolved

VOL 12

7790

phosphorus concentrations that were more efficiently removed during the chemical treatment process.

Lake transparency improved with treatment. Secchi disk transparencies were about 0.5 m before treatment began and improved to about 1 to 1.5 m after treatment. The total phosphorus concentrations ranged from about 65 to 90 μg/L during periods of low levels of stormwater treatment, to about 40 to 60 μg/L during periods of high levels of stormwater treatment.

The annual average removals of phosphorus by the ferric chloride precipitation and clarification treatment system was 66 percent, with a maximum of 87 percent. The observed phosphorus concentration improvements in the lake were strongly dependent on the fraction of the annual stormwater flow that was treated. The annual average total lake phosphorus discharge and concentration reductions averaged about 36 percent, or about one half of the maximum expected benefit.

Watershed Protection Using an Integrated Approach

Earl Shaver[1]
John Maxted[2]
Gray Curtis[3]
David Carter[4]

Abstract

The implementation of stormwater management has historically been accomplished on a piecemeal basis with regulatory requirements being established for new development activities using a standardized approach. Regardless of location, watershed specific problem pollutants, and growth potential, standardized stormwater management requirements tend to be required.

There is general recognition that a watershed approach presents an improved approach for resource protection. This approach considers the cumulative impacts of all sources of stormwater discharges within a watershed including agriculture, urban, and industry. A watershed approach allows for criteria to be developed and implemented which considers an integrated approach to accomplish the various objectives.

The State of Delaware, has embarked on a watershed protection program on a watershed, Silver Lake and its tributaries, which will serve as a prototype for other similar watershed approaches in the State. This watershed, relatively undeveloped, is targeted for high growth over the next 10 years, and a framework must be established if stormwater and resource protection issues are to be addressed.

Hydrologic analyses are provided by the EPA Storm Water Management Model (SWMM). The user friendly characteristics of the geographic information system, ARC/INFO, are utilized to facilitate hydrologic and water quality modeling. Simulations of existing and proposed watershed conditions and inputting industrial discharge moni-

toring information assist in establishing the pollutants of concern in the watershed, and in making land use and permit decisions.

In addition to the traditional water chemistry analysis, information will be developed regarding the biological impacts that urbanization may have on the watershed. More frequent and more severe stormwater flows degrade habitat by scouring banks and smothering habitats with sediment. A survey of the nontidal streams throughout the State was recently completed where various biological and habitat measures were made. The results of the survey will be used to interpret habitat and biological data collected as part of the Silver Lake Watershed project and to make predictions on stream health in various growth scenarios.

Finally, a major impact of the project relates to the resources necessary to accomplish such an effort. A watershed approach is seen as the ideal way to address land use and permit needs, but the allocation of resources and costs can be significant, and other agencies need to be aware of their obligations.

Background

The State of Delaware has had a National Pollutant Discharge Elimination System Program (NPDES) in effect since 1974, when that program was delegated by the Environmental Protection Agency (EPA). That program has provided an effective mechanism of control over industrial discharges since then. In 1991, a statewide sediment control and stormwater management program was also implemented within the Department of Natural Resources and Environmental Control (Department) whose primary purpose was to reduce the water quantity and water quality impacts that new development activities might have on receiving waters.

These two programs have had little coordination over the past several years as permit applications submitted to both programs have been considered on an individual basis with no linkage of these two programs to target efforts on a watershed-wide basis. The implementation of the statewide stormwater management program has functioned as a baseline program for new development activities while local governments, designers, and land developers acquire an understanding of the types of obligations and practices that are necessary for urban land developments.

When legislation for the statewide stormwater management program was being approved, the need for a coordinated watershed approach was recognized. There are many situations where adverse impacts have already occurred from a water quantity or water quality perspective. In those situations, implementation of controls on new development activities is important but there has to be a process where existing problems can be addressed so that an existing situation can be approved. The Sediment and Stormwater Law has a section devoted to those situations where a comprehensive approach to resource protection can be pursued. That section is defined as Criteria for Designated Watersheds.

The Designated Watershed process represents a consensus approach to address existing water quantity or quality problems within a watershed and prevent those problems from becoming worse. An important component of the Designated Watershed process is the necessity of the local government, where the problem exists, to request that the Department formally designate a specific watershed for initiation of study and recommendations for system maintenance and improvement (DNREC, 1993).

Components of the Designated Watershed study effort include:

1. Stormwater quantity or quality problem identification,
2. Impacts of additional development,
3. Alternative approaches to address existing and future problems,
4. A selected approach that includes the overall costs and benefits,
5. Schedule for implementation,
6. Funding sources for implementation of the selected approach, and
7. A public hearing process prior to plan acceptance.

The initiation of a watershed specific study depends on the availability of funding, but once a watershed is designated, the Department must make every effort to secure funding through federal, State, or local means.

When a watershed is designated, the Department is the lead agency for the study effort, but must coordinate the effort with an appointed advisory committee. The advisory committee is composed of individuals from State, Conservation District, and local agencies in addition to representatives of the regulated community and others who may be impacted by the results of the study. Recommendations, based on the results of the study, can only be made with the overall consent of the advisory group. This approach ensures a cooperative effort to incorporate concerns of committee members.

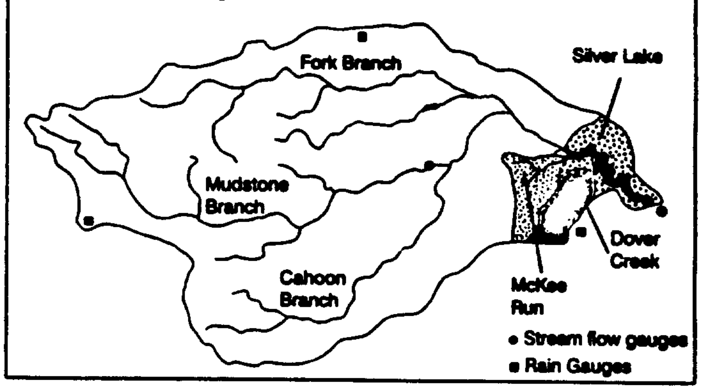
The formal recommendations of the study effort must be approved by the local Conservation District Board of Supervisors, and the local governing body, either county or municipality. Implementation of the study results will also necessitate the development and implementation of a dedicated funding source such as a stormwater utility to ensure design, construction, and maintenance of needed stormwater management structures.

Silver Lake Watershed

The Silver Lake Watershed is approximately 7,695 hectares in contributing drainage area as shown in Figure 1. The predominant land use is agriculture, encompassing 50% of the watershed land use, with forest being approximately 32% and urban development being 18% of the watershed (F. X. Brown Associates, Inc., 1989). The watershed has been experiencing high urban growth with the urban growth increasing by 90% over the last 15 years. The rate of growth is expected to increase in the future.

Soils, for the most part, are deep well-drained soils formed in very old, predominantly sandy sediments, typical of coastal plain soils. Other soils tend to be poorly drained sandy loams. The watershed slopes tend to be gentle with major portions having slopes less than 2%, with only a small portion of the watershed containing slopes greater than 5%. Average rainfall is approximately 1,143 mm/year with rainfall occurring throughout the year.

Figure 1 - Silver Lake Watershed



Silver Lake itself is within the City of Dover while 80% of the watershed is outside of the City in Kent County. The City of Dover has requested the Designated Watershed status for Silver Lake and all of it's tributaries as most of the watershed is out of it's political boundaries. Existing use of the Lake includes swimming, water skiing, recreational boating and fishing. A study of the watershed had previously been done under the EPA Clean Lakes Program so there was good documentation of existing problems in the watershed to justify the Designated Watershed status. The Lake is already highly eutrophic and increasing development in the watershed will increase problems unless an aggressive approach to resource protection is implemented.

There are only two industries in the watershed having industrial discharge permits. Monitoring records from those two industries are available and will be incorporated in the study and implementation phase of the project.

Consensus Approach

It was important that all impacted entities be involved in the planning process as a number of issues are beyond the traditional State role of resource protection. This is a watershed in transition, and land use is a major factor in the ultimate health of the system. In addition to establishing an advisory committee, presentations were made to the local governing bodies of the City and County to acquaint them with the project, as their approval of land use alteration will necessitate their being partners in the project. One means of gaining their assistance was the lure of a Geographic Information System (GIS), that the Department would establish and maintain in the short term. There is general recognition by local jurisdictions that a GIS is an ideal approach to land use planning and the "carrot" provided by the Department to the local jurisdictions was the information contained in the GIS that was to be used for watershed planning.

In addition to involving the local governing bodies, storm drain stenciling is a component to assist in educating the land owners and the general public of the impacts of dumping fluids or chemicals into the storm drain system. Newsletters are delivered on a periodic basis to everyone in the watershed that contain simple facts about the watershed and which strive for feedback on the importance of Silver Lake to the average City or County resident.

Modelling Approach

Computer technology advancement has lead to improved methods for managing and processing (storing, manipulating, displaying and utilizing) data. GIS's are based on a modelling shift to graphical processing made possible by advances in computer hardware capabilities, relational database techniques, and display graphics. GIS functionality makes possible the creation of an environment within a computer in which engineers and planners can readily analyze problems. Such an environment utilizes GIS advances to manipulate data, expert system methods to help the user determine appropriate analyses to be performed, and modern networking to provide access to a number of users to maximize the productive use of data.

ARC/INFO is the GIS that provides data management and user interaction functions. An expert system, which is being created as a component of this project and written in the ARC Macro Language, is referred to as SwmmDuet. Data can be stored, modified and retrieved in a GIS, but, with modern relational database methodologies, they can be related in new ways. Inferences can be drawn and examined visually.

Urban stormwater runoff must be addressed by many jurisdictions throughout the world. Modern concerns about water quality and the severe potential impacts of urban nonpoint source pollution lead to the development of the EPA Storm Water Management Model (SWMM) in 1969-1971. As one of the first computer models to analyze runoff, it suffers from vintage computer technology and would greatly benefit from modern GIS features and data handling methods.

The SWMM model was selected for it's ability to model a wide range of water related parameters, including water quality (Huber, et. al., 1988). That need alone eliminates many existing hydrologic models from consideration. In addition, SWMM has a proven track record of use on many different watersheds, and is in the public domain. One concern with the model is the difficulty and expense of data collection. The approach of linking SWMM to a GIS was to maximize data use for other related purposes.

The flexibility and capabilities of SWMM make it both powerful and difficult to run. SWMM determines the temporal and spatial distribution of runoff generated in a watershed for a given rainfall pattern by deterministic methods. It accounts for the influences of antecedent rainfall, snowmelt, evaporation, stream flow and groundwater seepage. Both the quantity and quality of flow can be evaluated. The myriad influences that characterize hydrologic flows make hydrologic modeling complex. The SWMM user can specify a variety of mechanisms to be modelled and vary the basic model of analysis by choosing different blocks of code and options within each block for processing.

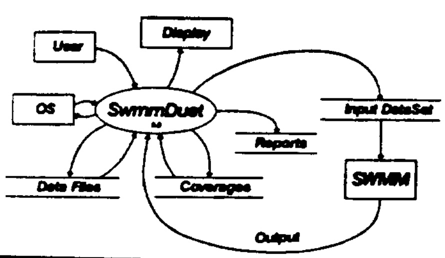
An engineering shell is being created to facilitate the solution of hydrologic modeling problems with SWMM. It is a computing environment created with the GIS, ARC/INFO. With it, hydrologic data can be entered, edited, manipulated, and displayed with ease by the graphical user interface inherent in ARC/INFO. SwmmDuet, written in the associated ARC Macro Language provides:

1. ARC/INFO functionality from a graphical menu-driven user interface;
2. Expert system guidance to lead the SWMM modeler through the block selection and appropriate data entry menus required of selected options;
3. Automatic assembly of the input dataset (transparent to the user); and
4. Post-processing of SWMM output supporting queries for graphical displays of SWMM modeling output (future implementation).

Utilization of data is facilitated in the engineering shell. This makes it more productive and cheaper with reuse. A GIS facilitates use by reducing retrieval time and speeding display in meaningful ways. Expert systems minimize the time needed to reach decisions concerning how data will be used.

SwmmDuet integrates GIS functionality with concepts of expert systems to facilitate stormwater modeling. The program helps the user manage hydrologic data, prepare the input dataset for the SWMM program, and review the results. It enhances the capabilities of the GIS, ARC/INFO, upon which it is built. The enhancement is based on the recognition that a GIS can act as a repository for instructions as well as state variable values. ARC/INFO provides the flexibility and capabilities to integrate the data and enhance task management. SwmmDuet stores hydrologic data as well as the data and instructions for stormwater management. Figure 2 is a context diagram which provides a schematic view of the SwmmDuet interactions with the user, data storage, display, and the SWMM program.

Figure 2 - Context Diagram



Apparently unrelated benefits result from the melding of deterministic analyses and the GIS tools for spatial analysis. There are many obvious applications which should improve accuracies and reduce required computational time. For example, given access to a road coverage within a watershed, the computation of street curb distance can be easily made and used in the specification of street surface buildup.

The coverages needed for the Runoff Block of SWMM are listed in Table 1. A description of the various thematic data stored in datafiles is thereby related.

Table 1
Data Storage
Coverages \& Datafiles

Coverages	Description	Files for thematic data
base_map	map registration data	
basin	subcatchment delineation	basin.data
	erosion data	erosion.data
	groundwater data	seepage.data
	infiltration parameterization	infiltration.data
	subbasin landuse aggregation	landuse.data
	snow data	snow.data
	ground surface	surface.data
	subbasin soil characterization	soil.data
	surface quality data	surface_quality.data
conduits	sewers and natural channels	conduits.data
controls	control structures characteristics	structures.data
gages	rain gages	gages.data
landuse	areal characterization by landuse	
pollutant	point sources & plumes	pollutant.data
process	map of chosen SWMM analysis	process.data
soil	hydrologic soils groups distribution	
topo	physical relief	

Non-spatially referenced data can also be stored, such as characteristics of pollutants and landuse. Time series for hyetographs and hydrographs record values at consistently increasing times in subsequent records. To facilitate access, multiple storm hyetographs are related to the raingage in which they were recorded; the raingages are spatially referenced. The listing of referenced data files are shown in Table 2.

Table 2
Non Spatially Referenced Data

DataFile	Descriptions
air_temp.data	air temperature time series
areal_depletion.data	snow distribution
evaporation.data	monthly average evaporation rate
hyetograph\%i\%.data	precipitation time series
landuses.data	treatment by landuse
pollutants.data	characteristics of treatment
wind_speed.data	monthly average wind speed data

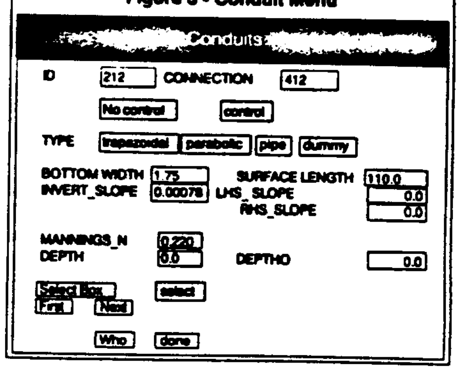
The data for the model are stored in ARC/INFO coverages and files. Accessible to a variety of users, a graphical user interface of ARC/INFO has been modified by customized menus to facilitate access and minimization of data editing and data entry errors. SwmmDuet creates the data set for SWMM from interactive responses entered by the user through this set of menus. Parameter values are requested as needed based on options specified. Unnecessary data need not be entered because only those data required are requested by the software. The graphical paradigm is utilized wherever possible to clarify user understanding. Users can concentrate on the hydrologic aspects of stormwater management.

Form menus enable the user to edit project coverages such as CONDUITS without necessarily having detailed ARC/INFO knowledge. As seen in Figure 3, one need only select the feature, in this case a pipe, and enter the appropriate hydraulic parameters.

The overall SwmmDuet menuing system consists of four main menus. Shown in Figure 4, they help the user:

1. Access help for SWMM modeling and use of SwmmDuet,
2. Enter or edit data which are associated with features, or spatially independent,
3. Choose processing options, and
4. Initiate automatic generation of data or processing.

Figure 3 - Conduit Menu



Calibration and verification of the SWMM model will be accomplished in fall, 1994. SWMM is a source generation model and the goal of the overall effort is protection of Silver Lake. Over the next year, the outputs from SWMM will be linked to the Water Quality Analysis Simulation Program (WASP)(Ambrose, et. al., 1988) to simulate the impact that the loadings will have on the Lake. This is necessary since reductions in pollutant loadings from surface waters after implementing stormwater quality control practices may occur, but there needs to be an assessment of response in the Lake due to lake dynamics such as resuspension of pollutants from sediments. By linking SWMM with WASP, the expected benefits of various watershed development scenarios can be modelled to further justify the implementation of necessary water quality and land use controls.

Stormwater Monitoring

The implementation of the model depends on the quality and amount of data that is inputed. The SWMM model is a data intensive model and the acquisition of data is imperative to overall project success. The general information that is being inputed into the model is contained in Table 1 and Table 2, but the stream flow, chemical sampling, and analysis of sampling results are treated separately in this paper.

There are two permanent stream flow gauges in the watershed, one upstream on Maidstone Branch and the other just below the spillway of the Silver Lake Dam. Both have been established and are read monthly by the United States Geological Survey (USGS). In addition to the two permanent stations, seven temporary stations have been established throughout the watershed where instantaneous flow readings are taken twice a year to give a representation of flow contribution in the major tributaries.

Related to the flow gauges, three rainfall gauges have been placed in the watershed by the USGS. The locations of the rain gauges and the permanent stream flow gauges are shown in Figure 1. It is recognized that additional rain gauges would improve the modelling results, but economics dictated the use of three. Information from the rain and stream flow gauges are digitized by USGS for input into the watershed model.

The chemical analysis includes testing for those parameters listed in Table 3. The intent is to have a broad initial analysis to determine what pollutants are present in the watershed. Based on the results of the initial sampling, parameters which are not detected, or where their level is not considered to be a problem, subsequent sampling may not include testing for that parameter.

Initial monitoring is targeting an urban subcatchment so that data inputs for urban land uses can be fairly well refined. Monitoring of catchments containing other predominant land uses such as agriculture or forest will also be monitored in conjunction with this project. It is intended that monitoring will be accomplished even after a watershed plan has been approved. This would continually refine the model and provide for a barometer of performance in terms of watershed health.

Figure 4 - Menus

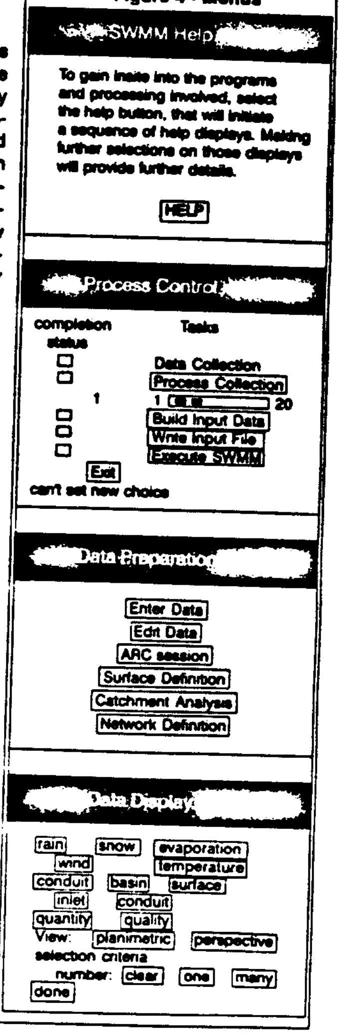


Table 3
Test Parameters

Organics Test		
	TPH	
Metals	Aluminum (100ppb)	Arsenic (5ppb)
	Copper (5ppb)	Iron (100ppb)
	Lead (3ppb)	Zinc (10ppb)

	Residue, Nonfilterable, Total TSS	Specific Conductivity
	Sulfate	Phosphorus, Total (Soluble)
	Phosphorus, Total	o-Phosphorus, Total (Soluble)
	o-Phosphorus, Total	Turbidity
	pH	Temperature

The NPDES permited activities in watershed are subject to permit reissuance every five years. The watershed analysis will allow for a consideration of changes that would be necessary or appropriate for those industries to meet objectives in terms of watershed protection. The use of the SWMM model will give the Department the flexibility to consider the specific pollutants of concern with regard to future permit conditions.

The watershed study in conjunction with a recommended plan of action will have a significant impact on future requirements for new development activities. Existing State regulations have a baseline requirement relating to 80% reduction in suspended solids from a new land use after completion of the construction activity. The study results may determine that nutrients are the critical pollutants of concern. In that situation, criteria for permanent stormwater management practices on new development activities may be required to provide for nutrient reduction in addition to the statewide suspended solids reduction requirement.

Habitat and Biological Monitoring

Habitat quality and biological measures can be cost-effective tools for measuring the effectiveness of stormwater controls. Measures of the condition of the resource are needed to evaluate the effectiveness of controls. In this regard first and second order nontidal streams in the watershed need to be considered for three reasons. First, these resources are directly affected by urban stormwater and are often impacted by few other major pollution sources. Thus, it is relatively easy to relate land use and stormwater to the response of the resource. Secondly; physical habitat and biological measures for streams are well established in the literature. This includes both the

VOL 12

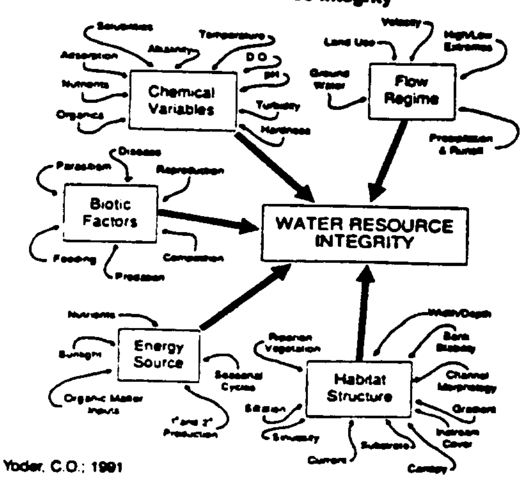
7802

methods of data collection and analysis as well as the establishment of the threshold needed to define conditions; e.g. "good", "fair", and "poor" or "slight", "moderate" or "severe" degradation. While wetlands are often the first aquatic resource to receive stormwater, measurements and threshold are much less developed. And thirdly; the vast majority of nontidal stream resources are first and second order. Delaware has an estimated 3150 miles of nontidal streams; identified as blue lines on USGS 1:24,000 scale maps. Approximately 85 percent are first or second order. It is important that any watershed protection plan protect these headwater streams, and their protection is necessary to protect larger resources downstream.

The focus here is on nontidal perennial streams. It should be recognized that intermittent streams and headwater wetlands also directly receive stormwater and are at even greater risk to the associated impacts. Intermittent streams and wetlands are protected by Delaware Surface Water Quality Standards (DNREC, 1993). Their protection from the impacts of urbanization is necessary to sustain their structure and function and that of larger waters downstream such as streams, ponds, and estuaries.

There are many attributes of water resource integrity, as shown in Figure 5 (Yoder, 1991). We tend to focus on water chemistry and flow because they have been the cornerstone of water pollution control over the years. It is recognized that urban stormwater may require a different approach than the traditional approach used to assess and control point sources. The intermittent nature of stormwater runoff makes the assumption of steady-state used for point sources (e.g., 7Q10) inappropriate. Biologi-

Figure 5
Water Resource Integrity



Yoder, C.O.; 1991

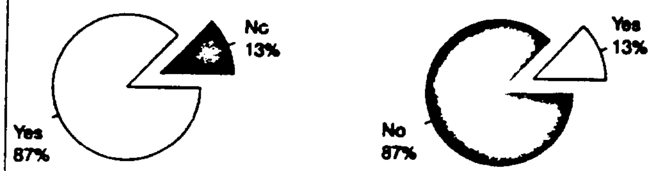
cal and habitat measures may provide a cost-effective way to assess both the direct impacts of urbanization (e.g., channelization, construction in wetlands and in floodplains, etc.) and the indirect impacts caused by changes in hydrology. Both chemical/flow and biological/habitat measures are important and needed. Together, they can provide a strong technical basis for stormwater controls.

Continuous sampling devices make it feasible to take flow and water quality measurements continuously over long time periods. However, even with this more detailed data, we are missing one very important piece of information. There are no criteria for many of the most common stormwater pollutants; e.g., nutrients and suspended solids. We are often still left with the question; Is this level too high? In reality, what we are often forced to conclude is that there is no impact if the existing criteria are not exceeded. And this does not address the impacts to other aspects of stream ecosystem health such as physical habitat and biological quality.

In 1991, DNREC began a project to assess the habitat quality and biological integrity of the State's nontidal stream resources. Streams were randomly sampled in the Fall of 1991 and 1993 for the purpose of producing a Statewide assessment of the condition of nontidal streams for the State's Section 305(b) report. Section 305(b) of the CWA requires the State to report to EPA on the condition of its waters every two years. Figure 6 compares the results of the 1994 assessment using traditional chemical measures, primarily dissolved oxygen, and the approach using habitat and biological measures (Maxted et. al., 1994). As shown, traditional chemical measures vastly underestimated the proportion of the State's stream resources not attaining aquatic life uses.

Figure 6
DNREC Aquatic Life Use Attainment

State of Delaware 1994 305(b) Report
Aquatic Life Use Attainment - All Nontidal Streams



Fixed Stations - Dissolved Oxygen
(no statistical confidence)
(not resource based)

Probabalistic - Habitat/Biology
(95% confidence interval +/- 5-6%)
(resource based)

A similar response was documented by the Ohio EPA when biological monitoring data were added to their 305(b) assessment. Approximately 50% of the stream segments that were determined to be impaired in 1991 were impaired based upon biological measurements alone (Rankin, 1991). In other words, the State would have identified

VOL 12

7804

R0041112

only half of the impairments if only chemical measures had been used. In both of these cases, nonpoint sources were identified as the cause of the much of the impairment reported solely on the basis of biological measures.

Habitat quality and biological measures reflect conditions over long time periods. Such temporal integration is important for intermittent pollution sources such as urban stormwater. Macroinvertebrates have life stages ranging from months to several years, and habitat quality reflects conditions over months and years as well. The lack of vegetation along an eroded stream bank or the accumulation of sediment in the stream channel indicate unstable conditions over periods of several years.

The habitat and biological measures used by DNREC are taken from guidance developed by U.S. EPA (Plafkin, et. al., 1989). The methods developed by EPA have provided a consistent basis for reported data, and have been adopted for use by all of Delaware's neighboring States. The measures vary by physiographic region defined as ecoregions (Omernik, 1987). Almost 95 percent of the State is in the Mid-Atlantic Coastal Plain ecoregion. This region is characterized by flat terrain. Streams have velocities less than 1.0 fps, lack shallow riffles, and are naturally depositional. The Northern 5 percent of the State is in the Northern Piedmont ecoregion. This region is characterized by gently rolling terrain. Streams have velocities greater than 1.0 fps and commonly have riffles. Riffles are shallow areas with fast well aerated water. They contain the greatest diversity of macroinvertebrates in piedmont streams. Under natural conditions they show little evidence of deposition.

The basic measures of the quality of the invertebrate community are taken from a taxonomic list of the organisms found in samples collected using standardized collection methods. Sampling is done in the most stable habitats found in the stream. In the coastal plain ecoregion, collections are made in snags, banks, and aquatic macrophytes using a standard D-frame dip net. In the piedmont ecoregion, collections are made in riffles using a kick-net.

Three types of measurements or biological metrics are taken from a taxonomic list to quantify the condition of the community. The first type of metric are richness or diversity measures. The quality of the community is indicated by the total number of unique taxa. Strength and stability of the community is achieved through redundancy. The second type of metric are tolerance measures. Certain groups of organisms are indicators of pollution while others are indicators of high quality and stable conditions. The third type of metric are composition measures. These reflect the structural make-up of the community and often include the proportion or percentage of the total animals of various groups. A summary of the metrics used by DNREC are listed in Table 4.

The strength of any assessment measure is its ability to distinguish between healthy and degraded conditions. Table 5 is a summary of the mean metric values (genus level taxonomy) calculated from selected macroinvertebrate data collected in the coastal plain and piedmont ecoregions. As shown, sites rated as biologically "poor" had re-

Table 4
DNREC Biological Metrics

Metric Name	Description	Type
taxa richness	total number of unique taxa	richness
EPT* richness	total number of EPT taxa	rich/tolerance
% EPT abundance	% of sample that are EPTs	tolerance/comp
% dominant taxon	largest % of a single taxon	composition
% chironomidae**	% of sample from this group	tolerance
biotic index	composite tolerance by taxon	tolerance

* EPT - the orders ephemeroptera (mayflies), plecoptera (stoneflies), and trichoptera (caddisflies); large diversity or abundance indicates high quality.
** chironomidae - family of midges; large abundance indicates stress.

duced total diversity (TR), reduced diversity and abundance of sensitive organisms (EPT, %EPT), an increase in pollution tolerent organisms (%Midge), and a reduction in community composition (%DT). Similar results are shown for the coastal plain and piedmont ecoregions.

Table 5
Sensitivity of Biological Metrics
by Condition and Ecoregion
(Mean Values at Genus Level)

Ecoregion/ Condition	N	TR	EPT	%EPT	%Midge	%DT
Coastal Plain						
"good"	22	29	8	36.5	24.6	21.9
"fair"	17	25	4	16.1	29.1	25.1
"poor"	3	20	2	3.0	79.9	30.4
Piedmont						
"good"	13	23	10	67.8	9.1	32.2
"fair"	19	21	5	32.2	20.5	24.6
"poor"	6	17	3	15.1	32.8	35.9

taxonomic richness (TR), EPT richness (EPT), percent EPT abundance (%EPT), percent chironomidae (%Midge), and percent dominant taxon (%DT).

Measures of habitat quality used by DNREC are shown below in Table 6. They include four types of measures: general characteristics (degree of channelization), instream measures (variety and abundance of stable habitats submerged in the water such as snags and riffles, evidence of deposition, and the quality of pools), stream bank measures (evidence of erosion and the type of vegetation along banks), and riparian zone measures (shade and width of buffer zone). The measures are shown for the coastal plain and piedmont ecoregions.

VOL 12

7806

R0041114

Table 6
Measures of Habitat Quality

Northern Piedmont Region	Coastal Plain Region
channel modification (g)	channel modification (g)
instream habitat (is)	instream habitat (is)
bank stability (b)	bank stability (b)
bank vegetative type (b)	bank vegetative type (b)
shading (r)	shading (r)
riparian zone width (r)	riparian zone width (r)
velocity/depth ratio (g)	pools (is)
sediment deposition (is)	
embeddedness (is)	
riffle quality (is)	
riffle quantity (is)	

(g) general, (is) instream, (b) stream bank, (r) riparian

The scoring of physical habitat is designed around the premise that, just as with biological quality, ecological functions increase with stability. Thus, "poor" sites in the urbanized piedmont region lack stable submerged habitats (e.g., riffles and woody snags buried by sediment or completely absent), have eroded and unvegetated banks, and show human activities (e.g., mowed yards, parks, structures) within the floodplain or riparian zone.

One of the strengths of the Rapid Bioassessment Approach developed by EPA is its ability to report scientific results in a form understandable to non-scientists. This is done by comparing the values of each individual metric with reference values. Reference values are derived from sites that are least altered by man. The scores of the individual metrics are added together to produce a single score for each site. A simple scaling system is used to produce a single habitat quality score and biological quality score for each site. The scores are reported as "percent of reference".

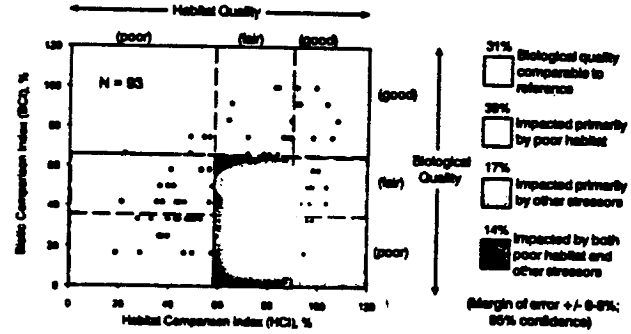
Another strength of this approach is its ability to determine if impairment to the biological community is caused by habitat or water quality stressors. The habitat and biological data are plotted with biology on the y-axis (dependent variable) and habitat on the x-axis (independent variable). Figure 7 illustrates this presentation of data (Maxted et. al., 1992). As shown, the majority of sites (69%) in the coastal plain region of the State had impaired biology, and the majority of the impacts were caused by "poor" physical habitat. 80% of the sites with "poor" biology had "poor" physical habitat.

In the fall of 1993, macroinvertebrate and habitat data were collected at 57 sites in the Northern Piedmont ecoregion. The region is heavily urbanized and provides the basis for evaluating the sensitivity of these measures to urbanization and stormwater. The following are preliminary results. Figure 8 shows a strong relationship between habitat and biological quality. In addition, 100% of the sites with "poor" biology had "fair" or "poor" physical habitat, while 92% of the sites with "good" biology had "good" or "fair"

VOL 12

7807

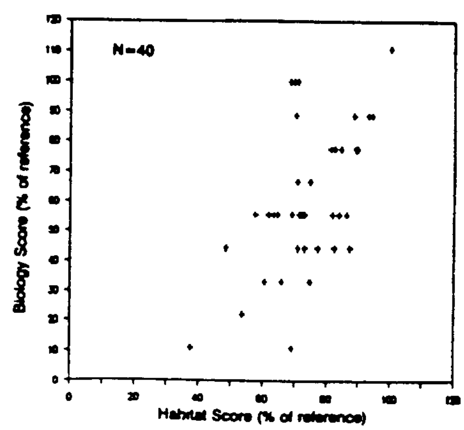
Figure 7
Assessment Summary
Kent and Sussex Counties, Delaware



habitat quality. Overall, the data indicate that (1) the majority of perennial nontidal streams in the piedmont region are degraded biologically, (2) and this condition is the result of urbanization and its effect on physical habitat.

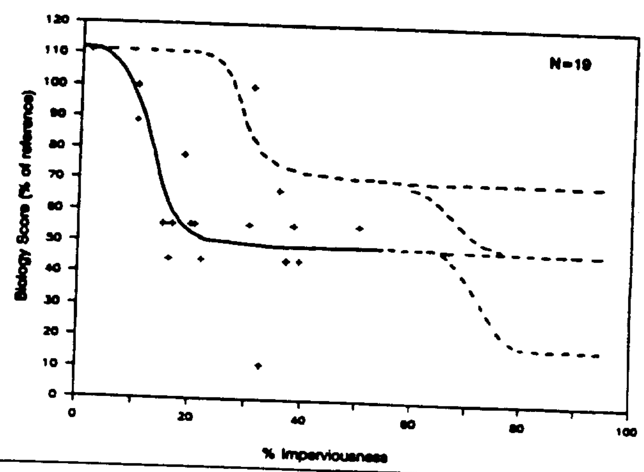
Several investigators have shown, using a variety of biological measures, that the

Figure 8
Relationship Between Habitat and Biological Quality
Piedmont Ecoregion - New Castle County, Delaware



biological community deteriorates dramatically when the percent imperviousness of the watershed exceeds 10-25 percent (Jones and Clark 1987, Klein 1979, Limburg and Schmidt 1990, Pedersen and Perking 1988, and Booth and Jackson 1994). A preliminary analysis of 19 sites sampled in 1993 has been completed. Figure 9 shows that the biological quality drops dramatically when the percent imperviousness in the watershed increased above 8-15 percent. These results are similar to the results reported in the literature. There appears to be a threshold of urbanization beyond which irreversible impacts occur in nontidal streams. Biological and habitat measures provide the basis for evaluating environmental threshholds, such as percent watershed imperviousness, that would not be practical using chemical measures.

Figure 9
Affect of Watershed Imperviousness on Biologic Integrity within the Northern Piedmont Ecoregion of Delaware, 1993
(macroinvertebrates in Riffle Habitats, Genus Level Taxonomy)



The next research question to be answered using these data is whether sites with stormwater controls achieve the physical, chemical, and biological conditions that are comparable to reference sites with healthy aquatic resources. It is assumed that the controls are working to protect aquatic resources. If conditions are comparable, the program is on the right track. If the conditions with controls are no different than conditions without controls, adjustments are needed to achieve the resource-based goals of the stormwater program. This process can only be carried out with resource-based monitoring. Biological and physical habitat measures can be cost-effective measures that will build upon traditional chemical and hydrological measures

7809

Cost Analysis

The initial concept for this project appeared to be straight forward, but the costs have escalated, primarily due to areas where they were not expected. The linkage of ARC/INFO and SWMM requires an enormous amount of computer storage. The data storage alone is in the six to eight gigabyte range. The end result was that the Departmental computer was not adequate to provide for data storage and retrieval. The decision was made to purchase an individual work station for this project rather than to attempt to update the Departmental system. The cost of the work station, which would also act as a server for approximately 18 individuals, was $35,000.

The modelling effort also had numerous areas where existing data turned out to be inadequate or in error. Existing subcatchment boundaries were inaccurate. Existing storm drain systems were not contained in files that were easily extracted. The County didn't have a good listing of existing land uses. Every situation where assumptions were made, turned out to require additional effort to verify or correct. Overall costs for the three year effort are included in the following tables. Table 7 represents costs that were incurred during year 1 (DNREC, 1992).

Table 7
Project Costs for Year 1

Purpose	Cost
Program Manager (includes Other Employee Costs)	$51,923
GIS Contracting	$15,000
Mailings (bulk rate)	$ 6,000
Rain Gauges and flow measurements	$23,000
Printing Newsletter	$ 1,000
SWMM Training	$ 3,000
Other Contracting	$71,000
Total Direct Costs for Year 1	$170,923

These budgeted costs were in addition to the use of existing staff, which significantly exceeded the funded Program Manager Position. Funding sources included State general funds through staff participation, NOAA Section 309 funding, and NOAA Section 306 funds.

The project is in Year 2 at this time and the funding levels are indicated in Table 8. It must be recognized that this project is falling significantly behind the timetable originally outlined prior to project initiation so much of the cost in Year 2 is to provide information that was expected in Year 1.

These costs are in addition to the use of existing staff resources. There are also other unknown costs to Kent County and the City of Dover for their involvement. Federal funding sources include NOAA section 309 funding, NOAA Section 306 funding, and from EPA under Section 319.

Table 8
Project Costs for Year 2

Purpose	Cost
Program Manager Salary (includes other employee costs)	$ 51,923
Travel	$ 3,000
Rain Gauges and Flow Measurements	$ 16,460
Water Quality Sampling	$ 79,846
Public Education	$ 26,000
GIS System Services	$ 10,000
Storm Drain Labeling Program	$ 22,000
Wetland Identification and Orthodigitizing	$ 50,000
Other Contracting	$ 69,912
Direct Costs for Year 2	$329,141

In addition to funding of the watershed project itself, additional funding was obtained from EPA, under Section 319, for the water quality retrofit of an existing urban shopping center by construction of a constructed wetland. In addition to being a water quality retrofit the project is also a demonstration of the types of activities that will be components of a watershed restoration and protection plan. The location of the wetland is highly visible to any individual visiting the shopping center and signs will be strategically placed to detail the retrofit and its benefit to the Silver Lake watershed. The site is approximately 12.1 hectares in size The retrofit cost $40,000 for actual construction with an additional $10,000 for planting with wetland and transition plants.

Funding for Year 3 has only tentatively been assigned. The only clear fact is that the original three year project will result in either a four or five year effort. Funding is only assured through year 3 and as much of the project as possible must be completed in that time frame. The intended funding levels for year 3 are shown in Table 9.

Table 9
Project Costs for Year 3

Purpose	Cost
Program Manager (includes other employee costs)	$ 55,753
Environmental Programs in Schools	$ 12,000
Water Quality Sampling	$ 25,000
Contractual Services	$107,625
GIS needs and Digitizing	$ 15,000
Newsletters	$ 20,000
Public workshops and hearing	$ 1,500
Direct Costs for Year 3	$236,878

The total estimated direct project costs for this watershed project are $736,942, which computes to $95 per hectare ($39/acre) to accomplish the necessary effort. This cost does not include the State or local government costs for State or locally funded staff participation. Also these costs do not include other interests that may exist on another project such as fisheries or wildlife investigations. Additional products or areas of concern would increase the cost per acreage figure.

To look at the overall effort, it would provide a benefit to understand the costs associated with sampling and data analysis. In terms of instrumentation, the Department purchased three ISCO automatic samplers and bubbler flow units at a total cost of $19,500. In addition to the automatic samplers, two YSI data loggers were purchased at a total cost of $12,990 which are programmable to measure temperature, DO, pH, and specific conductivity. These costs are in addition to the laboratory costs related to data analysis. Table 10 presents representative costs for data analysis. The number of samples was arbitrary in order to get representative costs for sample analysis, but the unit costs are accurate if the following constituents are to be sampled. The laboratory costs do not include costs associated with actual collection of samples. Sample collection is being done by available staff having some experience with sample collection.

Biological monitoring to conduct the habitat assessment , flow measurement, basic water quality analyses, and a macroinvertibrate collection costs approximately $1,200 per site. At least 25 sites are necessary in the watershed to project an accurate representation of stream health. Long term trends, in relation to watershed health, would require analysis once every two years. The index period should be accomplished in the fall when vegetation and algae die off makes analysis easier and shows what has happened over the summer, which is considered the critical period in terms of temperature and DO. Ideally, approximately 1/2 of the sites should be checked each year with a total evaluation of all 25 of the sites occurring every two years. The annual cost for this work would be $14,400 compared to the much greater cost associated with chemical monitoring.

<u>Evolution</u>

There are a number of aspects of this project that are expected to provide stepping stones for stormwater management program evolution and for an approach to resource protection on a more comprehensive basis. From a stormwater management program perspective, one product of this effort will be the consideration of SWMM from an individual site design standpoint. Historically, stormwater management design has been based on hydrologic models that have no water quality design components. SWMM, especially from a suspended solids standpoint, can provide information relating to the performance of a stormwater management basin for water quality in addition to water quantity. The intent will be to provide training for local design consultants and regulatory agencies over the next two years so that a change to the regulations specifying stormwater design using the SWMM model could be accomplished.

Table 10. Water Quality Parameters and Laboratory Costs for Initial Model Calibration

Test Category	# of Samples	Unit Cost	Total Cost
Organics Test			
TPH	40	56.00	480.00
Metals			
Filtration (2x)	40	12.00	960.00
Preparation (flame)	80	12.00	960.00
Flame/ICAP			
Aluminum (100ppb)	80	11.20	896.00
Iron (100ppb)	80	11.20	896.00
Zinc (10ppb)	80	11.20	896.00
Preparation (furnace)			
Arsenic (5ppb)	80	24.00	1920.00
Copper (5ppb)	80	24.00	1920.00
Lead (3ppb)	80	24.00	1920.00
General Tests			
Filtration for Dissolved Samples	40	12.00	480.00
Alkalinity	40	13.60	544.00

o-Phosphorus, Total	40	12.15	486.00
Turbidity	40	12.80	512.00
pH	40	0	0
Temperature	40	0	0
Total Cost for staff and resources			$35,372.00

The cost of the project, for the watershed planning and education effort alone, is $95/hectare. Recognizing that some of the expenses are related to development of the SWMM Duet and linking of SWMM to ARC/INFO, future watershed planning efforts are expected to be less than the cost per hectare for this project. In fact, if the one time only expenses are deducted from the total project cost, the cost of the watershed planning is reduced to $63.47 per hectare ($25.70/acre). This is considered a fairly accurate picture of what a similar cost would be for other watershed specific planning efforts. The cost per hectare may be an intimidating factor depending on the size of the watershed and the level of effort needed to justify a watershed specific approach.

This project, and it's associated costs, was deemed necessary as the final product will be the development and implementation of a watershed protection plan linking NPDES permitted activities and traditional nonpoint sources, and the implementation of a funding mechanism such as a stormwater utility. In addition to the project itself, it was considered necessary to attempt such an effort to provide staff with the expertise to conduct watershed studies, especially in light of watershed approaches being considered in the revised Clean Water Act.

The expected results of the study effort will be seen in two areas: political and scientific. From a political perspective, the results of the effort will form the basis where land use and permit decisions are made at the local level. It is critical that the local governments accept the conclusions of the study effort and establish criteria for land use issues in the watershed. In addition, the final product will necessitate a funding mechanism for implementation of study recommendations, and the City and County must have and accept the necessity for a dedicated funding source.

From a scientific basis, there are a number of products from this effort which will facilitate resource protection throughout the State. The development of an engineering shell for the SWMM model will facilitate the use of that model on other watersheds. Experiences learned through this initial effort related to data collection and analysis, modelling, and consideration of alternative approaches to resource protection will be valuable elsewhere. The linkage of chemical and biologic monitoring results will also provide a valuable tool for consideration of overall stream health transferable to other watersheds. The consideration of watershed imperviousness and expectations for maintenance or restoration of stream health also is valuable to recognize.

Conclusions

Watershed analysis, especially from a water quality standpoint, is data intensive and costly to implement in terms of funding, time, and expertise. For these reasons the most accurate models are generally not used on a widespread basis. On this project it was felt that the detail needed must be adequate to "sell" the City and County on the need to take aggressive action if Silver Lake is to be protected. A similar approach in other watersheds will have to be considered very carefully before a similar commitment is made. It is hoped that the conclusions of this study will sell resource protection programs elsewhere in the State.

From a water quantity perspective, the cost of watershed analysis tends to be within reasonable bounds, but the cost of a comprehensive analysis from a water quality standpoint is much more expensive. An alternative approach, when water quality is the primary issue, would be to define existing or proposed land uses in a watershed and conduct a simplified analysis using available loading information from the Silver Lake effort or other projects. The real world impact of the various land use scenarios would be discussed in terms of pollutant loadings and impacts to stream health in terms of biology and habitat.

SWMM is ideally suited for watersheds having a mix of industries in conjunction with traditional nonpoint source loadings. Modelling, in conjunction with data collection, would give a relative view of the impacts that the industrial discharges have with respect to overall watershed loadings. Then a watershed specific strategy can be developed to assess future NPDES permit conditions versus nonpoint source strategies.

It is essential that a dedicated staff and funding mechanism be in place if watershed approaches, including chemical and biologic monitoring, are to be pursued. The rationale that existing staff can assume a greater work load in conjunction with existing responsibilities just won't work. The incorporation of biologic indicators into the traditional chemical sampling process is also critical. Results to date have indicated that, regardless of our best intentions, stream health cannot be maintained or restored if water quality alone is considered. The actual use of the land is so important if resource protection is a program goal, and those decisions are usually made by local government. Education and consensus building at all levels of government and society are necessary if stated goals are to be achieved.

Can stormwater controls protect and maintain the physical, chemical, and biological integrity of our waters? Can we increase the % imperviousness threshold, thus allowing a greater intensity of urban development, with stormwater controls? The answers to these two important questions can only be achieved through resource-based monitoring, and biological and physical habitat measures are well suited to assess urban stormwater impacts. We should not wait 20 years to find out that a multi-billion dollar investment in control has resulted in little improvement in stream condition, or worse that mid-course corrections could have averted widespread and irreversible impacts. Let's not assume that someone else will do this monitoring for our program. The data generated will provide the basis for improving the program and will provide for sound public policy decisions.

These goals can be achieved through the use of existing resources within Federal and State stormwater programs. Funding can also be provided through the support of projects funded through other Federal research programs such as EPA's Environmental Monitoring and Assessment Program (EMAP), USGS's National Water Quality Assessment (NAWQA) program, EPA and State monitoring programs, the Section 319 program, biodiversity programs, and EPA's biocriteria program. And, new funding mechanisms can be established as part of the CWA reauthorization. Most importantly, we need to remember that the goal of the CWA is also the goal of the stormwater control program. To meet this goal, we need to the take ownership of resource-based monitoring by retaining monitoring expertise within the stormwater program. With this expertise, we can keep the lines of communication open between the stormwater program and the variety of resource-based monitoring programs.

SESSION VII: Monitoring Receiving Water Trends

DISCUSSION

Time-Scale Toxic Effects in Aquatic Ecosystems
Edwin E. Herricks

The critical issue

- A single storm event seldom produces severe environmental change
- Stormwater effects are cumulative - produced over a long time span after wide scale changes in the watershed.

Dose-response curve is the proper tool to evaluate time-related toxicity to the ecosystem.

The Microtox test - bacteria have a 5 minute response time; shows good response to storm events; problem is it doesn't give you a clear picture of what happens. Rotifer test kit from Belgium is a better test. It is available on the market.

Herricks notes that WEF will publish a report reviewing test system procedures - should be available in September.

Questions/Comments

Comment: Temperature, pH, conductivity, and dissolved oxygen are good variables to measure since long records, sometimes with continuous recording, often exist.

Question: For TMDL why can't we incorporate test systems and enlarge to bioassimilation capacity?
Answer: Good idea, but a very rigorous protocol must be developed to do this. ASTM is likely to provide one soon.

Question: When the rotifer test was done, wasn't the organism exposed to a discrete concentration for a long time, rather than an actual storm condition?
Answer: That is true and it is why long-term exposure may produce something different. We need to handle these situations according to pollutant loadings, especially with conservative pollutants.

7/8/8

Question: Don't most urban streams fit your class 3, where we do not see fish kills and other Phase 1 and 2 impacts. What about these other effects?

Answer: What you say is true for streams in highly urbanized areas, but streams in areas going through urbanization will go through these other phases. Using caged organisms will integrate and reflect the effects of these phases.

Question: How do you account for avoidance behavior in a toxicity test?

Answer: Must take this into account, but critters that can't move do exhibit a similar response. A test procedure based on sessile organisms could assist in this regard.

Question: Will biomonitor organisms adapt, like insects have to pesticides, to stormwater conditions, and not show effects?

Answer: No, the time period for adaptation is very long, and the exposures we are talking about are too short to change the genome, which is required for this kind of adaptation.

Question: What role has the loss of canopy and greater diurnal temperature variation played in this work?

Answer: This is an agricultural stream with little canopy that has evolved to a new "natural" condition that is stable and has a high fish biotic index.

Use of Sediment and Biological Monitoring
Eric Livingston

Thrust of presentation is on the institutional side of determining the cost- effective sampling of sediment that give useable results.

Simply do not have a handle on the quality of their waters - only have data on 10% of 8000 lakes, for instance. Nor do they have enough data to develop sediment guidelines.

Current environmental standards are not relevant to the actual quality of the environment.

They propose normalizing metals data to aluminum.

Bioassessments have become more practical to do. EPA rapid bioassessment protocols are available, but they must be applied in a way that is comparable to the natural habitats in a region. Even regional specificity may not be enough, may have to adjust to local conditions.

VOL 12

7/8/9

They intend to develop and test biocriteria - expect to take 5 years.

In Ohio, they have found that 52% of their waters meet chemical criteria, but only 25% meet biological criteria.

Conclude that it is possible to meet biomanagement criteria, but it will take a long time, and only happen if continued funding support is available.

<u>Questions/Comments</u>

Question: At what level can we now make an assessment of bioeffects?
Answer: Certainly not at the BMP level.

Question: How do we standardize (depersonalize) bioassessment, i.e. standardize protocols?
Answer: The problem is that, statutorily, we have no targets and there is fragmentation. We need a clear focus. However, there is a lot going on, and we can learn from each other.

Question: How is standardization addressed in your sediment monitoring?
Answer: We have protocols for depth and do cores also.

Comment: Most of the work is being done by a few really dedicated individuals, and not by a range of scientists who are receiving adequate funding.

Question: Is it fair to say that if we identify sediment contamination problems as you have described it is a macroscale phenomenon (e. g., point versus nonpoint sources), rather than at the level of whether or not a BMP works?
Answer: Yes, the focus of this method is at the watershed scale.

Question: Is Ohio classifying discharges that cause problems?
Answer: Ohio is way ahead in applying these methods. There are requirements for states to develop programs but no money. Therefore, people who want to do something just do what they think is best, and sometimes a good program like Ohio's develops. Section 319 is the program that could provide the money, but it is not because of a policy interpretation.

Question: How did you arrive at the metrics you are using in biomonitoring?
Answer: Metrics allow us to quantify using a single number. We listed all the possibilities, sorted them and chose the ones that responded most clearly to conditions, and then aggregated those into an index. They need five years of validation before we finally accept them.

VOL 12

7820

Question: Don't metrics have to be changed regionally?
Answer: Yes.

Comment: I have not seen a single study that states that they were able to use standard metrics - had to make some adjustments.

Question: Have you used fish in your biotic index?
Answer: We have used invertebrates. Fish present special problems, like mobility.

Water Quality Trends from Stormwater Controls
Robert Pitt

Questions/Comments

Question: During this time was watershed stable?
Answer: Yes, but there was some transition of farmland to housing (this may have contributed to poor performance). Stormwater treatment system kept pollutant loading to lake constant, rather than increasing.

Question: How does the Corps of Engineers view putting these in-lake treatment systems in natural waters?
Answer: I would have to look into this.

Question: What about maintenance?
Answer: The facility rides the weather out pretty well, maintenance is minor.

Question: How was internal recycling of phosphorus factored into your trend analysis?
Answer: We got only about half of the potential benefit from treatment, and internal recycling factors into the uncertainty associated with the other half.

Comment: This approach offers an alternative to retrofit of treatment basins into existing areas. Treatment system acts just like a wet pond. (Editor's note - Why not then create a wet pond or wetland treatment system on the shoreline that looks more natural?).

Question: What software do you use for your trend analysis?
Answer: Gilbert's code, with in-house modifications. Reckow also has good SAS macros that can be used. Unfortunately, no standard statistical package can do the job.

Question: What was the cost of treatment?
Answer: The cost was 4 cents/1000 gallons, 20% of which was the cost of monitoring. The overall cost was $40,000 per year, including disposal of residuals.

Question: How do costs compare with other types of BMPs?
Answer: Cheaper, but there can be problems with water quality impacts, or with Corps of Engineers' rules.

Question: What is the cost effectiveness of this treatment relative to alternatives?
Answer: End-of-pipe treatment is sometimes necessary, but there is often a lack of land, making this option less expensive than alternatives that use land.

Question: Can chemical addition be useful on a larger scale?
Answer: This is generally site-specific.

Question: What permitting requirements did you have in your New York City application?
Answer: It was an EPA demonstration project, and I did not get involved in the permitting (ask Rich Field). This method is a good option when you have not land.

Question: What was the effect of ice on the storage tank in Sweden?
Answer: It got 2-3 feet thick and caused some damage to the structure. It was easy to patch the curtain in the spring and reattach any loose wood. We have 10 years of experience in Sweden and 6 in New York, and maintenance is minimal.

Question: Is chemical addition feasible on a large scale?
Answer: Whether or not it is feasible is site-specific. This is really a big wet pond, and chemical addition may not be necessary to achieve what you are trying to do.

Question: What was the rate of sediment accumulation?
Answer: The rate is about 1 inch per year. It needed to be dredged after 10 years.

Comment: You incorporated both monitoring and modeling. We should do more of that.

VOL 12

Watershed Protection Using an Integrated Approach
Earl Shaver, John Maxted, Gray Curtis and Eavid Carter

"Water is not supposed to be brown" is a perception that our people have become accustomed to.

Delaware has adopted a Designated Watershed approach into its law for WQM; Dove/Silver Lake/St. Jones is the first designated watershed. This watershed is in transition from agriculture to urban land use. They are using a systematic approach for the identification of all sources of inflow and quantifying their loads.

Using SWMM to do forecasting - will interface ArcInfo GIS with SWMM.

Biological Assessment - Focusing on 1st and 2nd order streams using established technologies in the literature. Using macroinvertebrate community as a primary indicator of the condition of the aquatic resource.

Habitat Quality - Use four general categories. Assessment is summarized by plotting Habitat Comparison Index (HCI) with Biotic Comparison Index (BCI).

Questions/Comments

Comment: If we don't look at the whole system we can destroy our aquatic ecosystem without ever violating WQ criteria. Also, if we are to have a healthy ecosystem, it must be diverse.

Answer: This approach is expensive. Must build up a public support base for the program. Education of the public and engineers, as well as contractors, is essential for a successful program.

Question: People tend to measure success of public education by the number of talks given and brochures handed out. Brochures, etc. don't change behavior. Voluntary training and mandatory testing work better. What do you think?

Answer: Keep training at the level of the audience. For example, most contractors hunt and fish and can relate to the environment through that. Education programs should have a feedback loop from the audience. In our case contractors said they want more. I want to add that we would not have a program if it were not for NPDES; it can't be voluntary.

Question: About your contractor training program. Is there follow-up? How does Delaware do inspection and enforcement?

Answer: Yes, we have enforcement using law enforcement officers. Local governments refer cases to the state if necessary. State enforcement people go out (with guns) and assess fines. Developers will comply

7823

with regulations if there is a level playing field, and you can't have a level playing field if the program is voluntary.

Question: But state programs do not give a nationwide level playing field, do they?

Answer: That's true. We had a large department store building in Delaware for the first time, and they had never filed a notice of intent before.

Comment: Education must include the practitioner as well as the general public.

Comment: The Environmental Education Network involving 128 nations has water quality test sets that can give a framework for public involvement, including children.

Comment: EPA has an NPS bulletin board which is a good source of information, and a good place to share your information with others.

Monitoring BMP Effectiveness at Industrial Sites

Aicardo Roa-Espinosa[1], Ph.D. and Roger T. Bannerman[2]

ABSTRACT

Storm water runoff sample were collected from five industrial sites. These samples were collected by five monitoring methods. These five methods were: Flow weighted composite, time discrete, time composite, source area and first 30 minutes. Heavy metal, total solids and suspended solids were determined for all the sampling methods for seven storms. Individual samples were collected to illustrate the change of contaminant concentration in runoff versus change in storm water discharge (a pollutograph).

One of the most difficult aspects of the flow based automatic sampling is site selection, due to the difficulty in finding the proper outfall for installation of the flow measuring device and the related cost of installation. The sampling methods that do not utilize flow measuring devices are easier and less costly to install and operate. The consideration of proximity to the source or representativeness of the sample is higher for the source sampler method when compared to the other sampling techniques tested here.

If it is assumed that sampling at the outfall gives the most representative sample, then the time composite is the best method due to low cost and the need for less technical expertise. However, although it was not directly compared to the other methods in the field, it is surmised that the new design of a source sampler discussed in this text will be superior to the other methods for accuracy and reproducibility of results. In addition, if closeness to the source gives the most representative sample, then the new source sampler should be the best method.

INTRODUCTION

In many states industries are currently collecting or preparing to collect and analyze samples of their storm water runoff to fulfill chemical monitoring obligations of their

VOL 12

7825

National Pollutant Discharge Elimination System (NPDES) permit, which regulates the discharge of storm water related to industrial activity. Because pollution prevention is the primary focus of this regulatory program, most state environmental agencies believe that the chemical monitoring of runoff will produce important information to help to focus planning efforts and identify current contaminant movements. As it has in the past, chemical monitoring that relies on the collection of a flow proportional sample will likely be required because it is considered to most accurately represent the actual discharge of contaminants (USEPA, 1992). Unfortunately, this type of runoff sampling technique is often expensive, technically difficult, and very time consuming.

This study was designed as an evaluation of the various storm water runoff sampling techniques available for collecting industrial site runoff. The importance of such a comparison becomes clear as one considers that industries will rely on the results of these analyses to make decisions regarding changes to their storm water pollution prevention plans, an obligation of the industrial storm water permit.

The first step of this study was to establish criteria for comparing the different techniques. The criteria selected were:

How difficult it is to select a site (Site selection)
Sampling costs
How concentrations compare to flow composite (Accuracy)
How concentrations compare among several storms (Reproducibility)
How well concentrations represent the source of pollution (Representativeness)
Technical expertise required to use the method (Technical Difficulty)

Three industrial sites were selected for study based upon site definition, all the runoff being directed to a single outfall, and a desire to cooperate with the project. In addition, the runoff at the outfall had to be related only to the activities of that particular industry.

Initially, no single sampling method was considered as superior based on the previously listed criteria. All of the sampling methods were compared at all three industrial sites. The following sampling techniques were compared: full storm flow composite, full storm time composite, first 30 minute time composite, time discrete, and source area samplers, and the concept of the new source sampler.

VOL 12

7826

R0041134

METHODS

Description of the Sampling Methods

Flow Composite: A composite sample consisting of a mixture of aliquots of constant volume collected proportional to the flow rate;

Source Area: A sample consisting of a mixture of variable volumes collected, and which is proportional to sheet flow runoff volume over time;

Time Composite: A sample prepared by collecting fixed volume aliquots at specified time intervals and combining into a single sample;

Time Discrete: Individual samples of fixed volume aliquots collected at specified time intervals and selected according to the hydrograph for individual analysis;

First 30 Minutes: Individual samples taken during the first 30 minutes of a storm event and combined into a single sample.

Roof Samplers

Roof samplers were installed to divert a small portion of the flow in a roof drain to a gallon bottle. A quarter inch (inside diameter) stainless steel tubing was attached to the inside of the drain, and a vinyl tube directed the water from the stainless steel tubing to the bottle. One of the tubes was positioned where the majority of the water was flowing, and the other allowed air to escape from the bottle or to return the excess water when the bottle was full.

Lawn Samplers

The lawn sampler, first used by Bannerman et al. (1993), consisted of two four foot long PVC pipes (1/2 inch in diameter) placed in a depression on the surface of the soil, with the pipes forming an angle of approximately 150 degrees. The water entered the pipes through three inch slits cut along the entire length of each pipe. Each pipe was wrapped with a fiberglass screen to prevent entry of debris. The pipes were held in place by clothespin anchors. A source sampler was placed between the pipes, flush with the ground to collect water. Silicon tubing delivered the water from the pipes to the source sampler, which was fitted with a special cap to accommodate the two pieces of tubing.

Source Area Samplers

An area sample device, modified in size from the street sampler discussed in Bannerman et al. (1993), was used to sample sheet flow runoff from each type of source area recognized at each of the participating industries. A sampler consisted of a 10 inch inside diameter PVC pipe cut to a length of about 12 inches. A 10 inch inside diameter coupling was cut in half and glued to the top of the pipe. This sleeve

VOL 12

7827

was placed in a hole drilled in the pavement and cemented in place. A cap of one inch thick gray PVC (for the sleeve) with a 5/8" hole at the center was placed at the top of the cemented sleeve. Attached with four aluminum screws to the gray PVC was a bottle cap with a 2.5 liter glass bottle for collecting the storm water sheet flow sample. The final sample collected by the source samplers was a flow composite of discrete samples over time. A clean bottle was installed shortly before each storm event to prevent contamination of the storm water sample by a new storm, traffic or the normal operations of the site. The following number of source area samplers were installed to cover the different source areas at each facility: Warman International, 7 source samplers; AC Rochester and Delco Electronics, 14 source samplers and 13 roof samplers; PPG Industries, 9 source samplers and 7 roof samplers.

New Source Area Samplers

A prototype of a new source sampler has been built. A prototype circuit board would be used to raise and lower a piston in the lid of the sheet flow sampler. At the beginning of the runoff event the sampler would be triggered by a moisture sensor. The piston would go down for a set period of time (approx. 5, 10, 15, 20, 30 seconds). The piston would stay closed for a preset time (approximately 1 minute). The computer board would stop sampling after a preset time or when the level of the sampled sheet flow closed the piston.

LABORATORY PROCEDURES

Cleaning Procedures

The glass bottles used to collect the flow composite samples, roof samples, lawn samples, and source samples were cleaned by washing with double distilled water and phosphorus free soap, rinsed, washed with 20% hydrochloric acid , rinsed again with double distilled water, washed again with acetone and finally rinsed with double distilled water. Sampler caps were cleaned with double distilled water and phosphorus free soap, and rinsed with double distilled water.

Sample Collection

Sample collection and documentation occurred as soon as possible after the end of the runoff event, but in no case more than six hours after the rain event ended. All collected samples were refrigerated until they were combined into a composite sample and split for analysis. Preservation procedures were done immediately upon arrival at the USGS laboratory in Madison. The preserved samples were delivered to the Wisconsin State Laboratory of Hygiene (SLOH) for water quality analysis or to a commercial laboratory for analysis of the organics.

The time composite, time discrete, and source samples were analyzed for the following constituents: Calcium (Ca), Chemical Oxygen Demand (COD), Copper (Cu), Hardness (as $CaCo_3$), Lead (Pb), Magnesium (Mg), Nickel (Ni), Total Solids

(TS), Suspended Solids (SS) and Zinc (Zn). The flow composite samples were analyzed for Antimony (Sb), Arsenic (As), Beryllium (Be), Cadmium (Cd), Calcium (Ca), Chromium (Cr), COD, Cu, Hardness, Pb, Mg, Ammonia-N, Nitrate plus Nitrate-N, Total Kjeldahl Nitrogen, Ni, Total Phosphorus, TS, SS and Zn.

Sample Splitting
Sample mixing and splitting was performed at the USGS Water Resources Laboratory, located on Seybold Road in Madison. The samples coming from the same areas were combined into a composite sample and split, using a Teflon coated churn splitter. After splitting each composite sample, the churn splitter was rinsed three times with double distilled water. Separate sample control forms were used to document which samples were combined, their volumes, and additional comments on the storm water event.

Sample Preservation
The samples collected for metal analysis were preserved with 2.5 ml of 35% nitric acid (HNO_3), and nutrient analysis were preserved with 2.5 ml of 2% sulfuric acid (H_2SO_4). The samples for total and suspended solids and COD had no preservatives added. The samples for the toxicity test were refrigerated at 4^0C.

Water Quality Analysis Data
Water quality data were transferred from the State Laboratory of Hygiene (SLOH) to the USGS's QWDATA data base. ASCII files were created by QWDATA and exported to a PC DOS computer for load computations using EXCEL 5.0 software.

RESULTS AND DISCUSSION

From the standpoint of the number of samples taken during the storm event, the time composite method took more samples than the other methods during the entire storm event, followed by the flow composite, time discrete and the first 30 minutes.

Table 1 details the number of subsamples collected in four different methods for storm water analysis. All but the first 30 minutes had samples representing all of the hydrograph.

Site selection

The first step in the industrial storm water runoff project was to summarize the information from the industrial sites. The information from industry group applications was selected to determine the possible industries to be monitored. Twenty-six SIC codes were selected based on the EPA toxicity code (1 low and 10 high). The descriptions of the raw materials and finished products that possibly were in contact with the storm water was updated from the storm water runoff applications.

VOL 12

7829

The industries in the storm water application have a description of the materials handled and exposed to storm water.

The comparison of the sampling methods called for the selection of sites that fulfill the criteria described in the introduction. The study encountered a significant amount of difficulty in accommodating all the sampling methods at a single outfall. The fact that from 474 industries only 94 presented isolated drainage areas made the site selection difficult. The fact that of the 94 sites, only 14 had a single pipe outfall suitable for accurate flow measurement coupled with a minimal amount of gravel at the site, only compounded site selection difficulty. The sampling methods that take samples at the end of a pipe have a high degree of difficulty in selecting the site.

Cost

Table 2 presents the cost of the equipment for different sampling methods. Table 2 shows that sampling methods that take samples proportional to flow rate discharge are the most expensive due to the equipment utilized to run the samplers, the communication accessories, the data loggers to store the information and the shelters to protect the equipment. The sampling methods that do not utilize flow measurement devices and instrumentation are far less expensive.

For the cost of the laboratory analysis for one storm for full inorganics, full organics, full metals and invertebrate bioassay, once the sample is collected the cost of the analysis of the samples was the same except for the time discrete sample. A minimum of six selected samples according to the hydrograph were analyzed to describe the pollutant concentration during the storm event (pollutograph).

TABLE 2. Summary of the sampling cost including: equipment, installation and lab analysis (1)

Method	Cost Ranking	Total
Flow composite	High	$16,052
Time discrete (2)	High	$22,682
Time composite	Medium	$5,920
Source area fixed	Low	$2,189
Source area variable	Low	$2,889
First 30 minutes	Low	$1,800

(1) Cost of lab analysis for 1 storm event
(2) Approximately six discrete samples

Accuracy

The study used the assumption that the automatic flow weighted sample was the method that most accurately represents the true runoff. Because of these assumptions the composite sample was used as the base to compare the results of the other sampling methods. The advantage of the flow weighted sample is obvious when measurements of the flow are needed to be recorded to evaluate the instantaneous flow load calculations or to associate the concentration of samples taken over time with the flow rate discharge. Figures 1 and 2 give a graphic illustration of the number of the subsamples for a single storm event by the four sampling methods.

The highest number of subsamples corresponded to the time composite. The time composite method reflects the accuracy by the number of subsamples taken. Initially when concentrations are high a large enough number of samples are taken that the over sampling during the last part of the storm is compensated by the initial high concentrations to give fairly accurate results that are the closest to the flow composite method.

VOL 12

7831

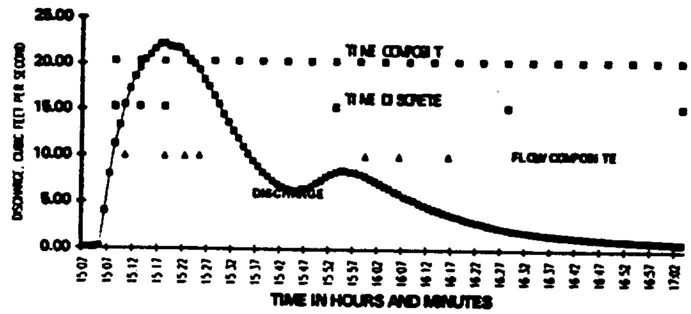

Figure 2. Discharge, flowcomposite, time composite and time discrete samples selected at PPG Industries, September 13, 1993.

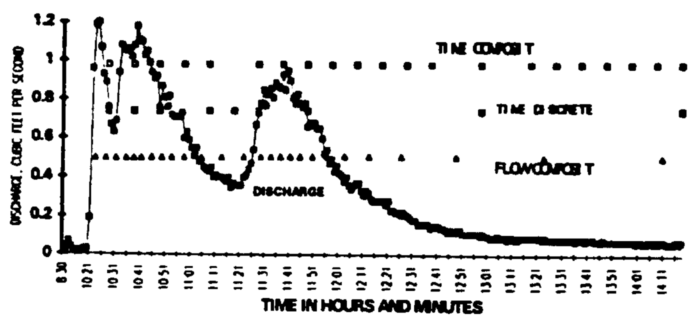

Sampling storm water will generate flow data and chemical characterization of the storm water runoff. Figures 1 and 2 show how the flow data was represented for a storm event runoff and how the monitoring of the storm was done by the different sampling methods. To evaluate accuracy of the characterization of the storm water data it is important that the composite sample be based on a large number of subsamples during the storm event. The composite samples with smaller coefficients of variability are the samples taken with the larger number of samples. The coefficient of variability increases with the decreasing number of samples (Table 3).

Figures 3 and 4 illustrate that three samples during the first 30 minutes are a composite of the highest concentrations during the storm event runoff. The same results were found to be true for all the events at all sites monitored.

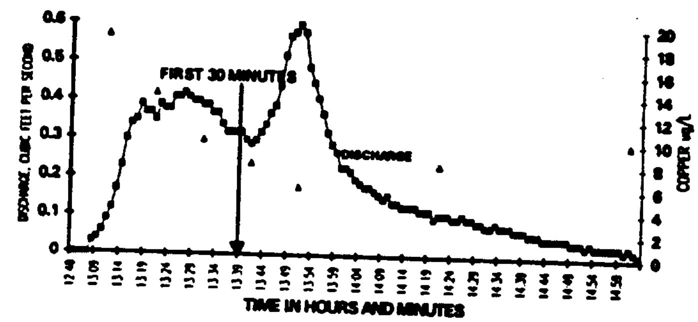

Figure 4. Discharge, concentrations at discrete times selected for suspended solids at Warman International, July 17, 1993.

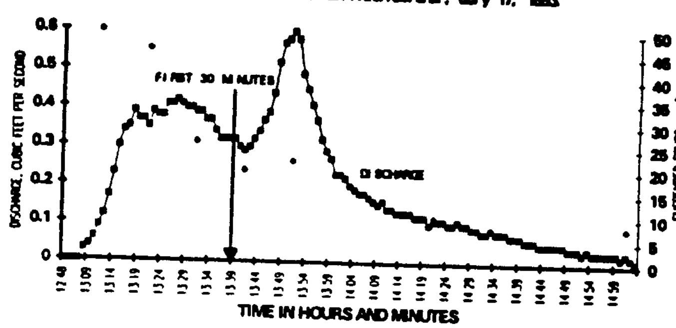

The number of storms are very important in determining the accuracy of the flow composite geometric means at each site. Table 3 presents what could happen when storm water runoff is characterized by infrequent extreme observations. The probability of sampling extreme characterization values is always present. The differences range from minus 78% for suspended solids to 4% for total solids at AC Rochester. For the highest concentration from a single storm event the least

difference for total solids was 24% at AC Rochester and the largest difference was 195% for suspended solids at Warman International (Table 3). The lowest percentage difference of the four constituents compared occurred when 5, 6 and 7 events were compared with a single storm event characterization. Table 3 illustrated that the number of events certainly has an effect on the accuracy of the geometric means. For all the sites when a single storm was characterized, extreme values of the four constituents analyzed were found. These values happened for all the sites monitored. Based on the previous discussion the accuracy of the storm water characterization is

VOL 12

7834

affected by the number of subsamples, the part of the storm sampled, and the sampling method used.

Results from the industrial storm water runoff monitoring done in 1993 suggest that the time settings for the sheet flow sampler must be included in the new design. The new design will have to collect discrete samples from the sheet flow. The first generation of source samplers indicated that it is very important to define the period and the segment of the storm from where the samples have been composited over time. The new source area sampler improves the accuracy because it provides a sample composite over time. Table 4 compares the accuracy of the methods.

Table 4. Ranking of the accuracy for different sampling methods

Method	Accuracy
Flow composite	Good
Time discrete	Good
Time composite	Good
First 30 minutes	Poor
Source area (old) passive	Poor
Source area (new) electronic	Good

Reproducibility

Table 5 compares the flow composite geometric means monitored with the time discrete for the first 30 minutes of individual storms for each site. The characterization of individual storms can give results that can be categorized as extreme infrequent observations, but are nonetheless probable. Table 5 shows that the storm water is more reproducible when larger number of subsamples are taken during the entire storm event. The appropriate reproducible method of sampling storm water to be used to compare with the same site or between individual sites or groups of sites is a method such that the subsamples cover the entire storm event. The reproducibility of a composite sample of many subsamples during the entire storm event is less influenced by the high concentrations at the beginning of the hydrograph and the small concentrations at the receding part of the hydrograph.

VOL 12

7835

Table 5 compares the flow composite geometric means with the time discrete for the 30 minutes for the sites monitored. The geometric means coefficient of variability for the four constituents analyzed was larger for the time discrete first 30 minutes when compared with the flow composite data for the same four constituents. The variability at AC Rochester for copper was slightly higher for the first 30 minutes, and much larger for zinc, total solids, suspended solids. At PPG industries the variability for all the constituents was higher for all the constituents for the first 30 minutes sampling method. At Warman International the variability for all the constituents was similar for both sampling methods.

Figures 5 and 6 represent the monitoring data during storms at different sites. The concentration for copper and suspended solids concentrations are much higher at the beginning of the storm compared with the middle and end of the storm. The flow composite samples represent the entire storm event or a composite of subsamples. Although the flow composite is accurate and reproducible the problem of the flow composite sample is that the flexibility of analyzing multiple samples during the entire storm is no longer possible. To explore the behavior of pollutant concentrations during the individual storm events is no longer a possibility with the flow composite sampling method. The time based sampler has allowed us to analyze the behavior of the pollutants during a storm event. The analysis of the first 30 minutes shows that the concentrations tended to be much higher at the beginning and declining at the receding part of the hydrograph (Figures 5 and 6). The problem of sampling always the first 30 minutes of the storm event is that the variability of the concentration during this part is much higher than the rest of the methods that sample the entire storm event.

To understand storm water runoff contamination we have to look into the contribution of the pollution process from different types of sources. The pollutants present in storm water depend on the industrial yard activity. The pollutants present in the runoff are carried out by a physical process which is the washing off of such contaminants. Many times it is going to be difficult to determine the source unless the industrial yard has source area samplers to determine the areas of concern producing the contamination. Other times it will be very difficult to determine the source at all. The choice of specialized pollution prevention could be very uncertain without the development of better ways to determine the approximate location of the source and the effectiveness of the source area controls or Best Management Practices (BMP's).

The storm water project tested an inexpensive and easy method for industry to monitor industrial runoff. Installation and operation of the sampler had to be simple. The sampler was flexible enough to collect a representative sample of the storm water event.

VOL 12

7838

Self-monitoring will be required as part of the storm water industrial permits for Wisconsin industries. Monitoring would target sources of pollution not adequately controlled by a pollution prevention plan. Source sampling is a method for isolating the level of pollutants washed-off from these sources of pollution. The location and size of these sources varies from industry to industry.

The experience gained in monitoring storm water runoff from industrial sites where samples from a thin layer of water were running across a paved surface during a runoff event allowed us to collect a sample as close as possible to the source of concern and then compare the source area sample with the more technically difficult methods. This demonstrated that the end of the pipe characterizations do not represent the true source of the pollutants present in the storm water runoff.

The source sampling approach for self-monitoring is the easiest to use and always collected a sample with a low degree of difficulty. Not only was the source sampler able to collect samples close to the source, but it was able to collect samples of the part of the storm desired. The source sampler balances the need to have a feasible monitoring method with a method flexible enough to collect a sample for all the industrial sites of the storm water project.

__Technical Difficulties__

The flow proportional methods have a high relative difficulty due to the installation of the flume and the instrumentation at the site to record the rainfall data, flow discharge and the times and flow where the samples were taken. This part of the sampling technique requires knowledge of hydrology, fluid mechanics and the operation of the data logger. The source samplers are less difficult when compared to the automatic sampling techniques because the source sampler does not use a flume and instrumentation, and does not need the command of hydrology and fluid mechanics principles. The ranking of medium difficulty for the first 30 minutes is due to the difficulty of selecting the right outfall to take the grab samples called for by the permit.

The sampling methods that utilize proportional flow rate discharge have the highest degree of technical difficulty which is reflected in the cost (flume, installation, instrumentation and technical skills). The lower cost is reflected in a low technical difficulty for the source samplers because they do not utilize a flume, installation is low technology, and the skills are basic.

Table 7 illustrates the range of skills to take a good sample for the sampling methods. The flow composite samples are initially taken at predetermined flow volume without knowing the characteristics of the rainfall event. This demands continuous attention to change the preset parameters according to the event. The difficulties collecting the

VOL 12

7839

TABLE 7. Ranking of the technical difficulties for different sampling methods

	SAMPLING EFFORT			
METHOD	EQUIPMENT INSTALLATION	FLUID MECHANICS	SAMPLER OPERATION	SAMPLE PROCESSING

ROOF SAMPLER	Low	Low	Low	Low
FIRST 30 MINUTES	Low	Low	Low	Low

flow volume based samples make the relationship between the rainfall physical characteristics and the contaminant concentrations and loads even harder. To compare the sampling methods, excellent communication and knowledge was necessary not only of the sampling equipment but also of the software and communication package with the sampling station.

Table 8 ranks the technical difficulties of the different sampling methods. The flow composite samples demand a range of skills even before the equipment can be operated. Once the samples are taken, understanding the hydrological data, hydraulic data and rainfall data is very important to determine the loads and understand the behavior of the contaminants with the hydrograph. The methods that do not demand the command of such skills make the sampling process simpler (source area samplers).

TABLE 8. Technical difficulties summary of the different sampling methods.

Method	Ranking
Flow composite	High
Time discrete	High
Time composite	Medium
Source sampler	Low
New source sampler	Low
Roof sampler	Low
First 30 minutes	Low

The source sampling approach for self-monitoring is the easiest to use and always collected a sample with a low degree of difficulty. The source area sampler balanced the need to have a feasible monitoring method flexible enough to collect a sample for all the industrial sites of the storm water project.

Representativeness (Proximity to the source)

The main goal of storm water regulation is to prevent the movement of pollutants through storm water to rivers and lakes, affecting the water quality of such receiving waters. The most effective monitoring should be based on the identification of the sources of pollution instead of the end of the pipe monitoring. Storm water monitoring should be implemented to reduce the non point pollution leaving the industries into the receiving waters. The most representative sample, usually related to proximity to the source, is important because this will provide the permit reviewers with information regarding the true sources of pollution and the individual performance of the Best Management Practices (BMP's) and programs to reduce non point pollution. The characterization of samples close to the source are the most fair to the Department of Natural Resources (DNR) as a regulator and to the industry as permittees because this can identify the source of the problem and propose real reduction plans of contaminants. The end of the pipe is the least representative because the outfalls are located far from the potential sources and represent a dilution of the true contamination. Table 9 ranks the best representativeness of the various sampling methods.

TABLE 9. Representativeness of the sampling methods

Method	Ranking
Flow composite	Low
Time discrete	Low
Time composite	Low
Source area	High
First 30 minutes	Low

The current storm water regulations rely on the end of the pipe monitoring discharge characterization data from a given industry to assess the degree of non point pollution to the receiving waters. This approach does not provide the permit reviewers with information on the true sources of contamination. In industrial sites, pollutants from other source areas such as high traffic, storage, auto parking, truck parking, roofs and lawn are significant and should be characterized to support a comprehensive plan to reduce non point pollution loading to the receiving water.

VOL 12

7841

The data from the samples collected by source area samplers in their present design showed that the concentration for the analytes tested was higher than the concentration obtained by the time weighted sampling equipment for that particular time.

The comparison of measured volume with volume estimated by Pitt and Voorhees' 1989 Source Loading and Management Model (SLAMM) at each site is shown in table 10. The runoff values of the volume measured and estimated for AC Rochester varied from minus 3% to 23% for three events compared. The comparison for Warman International varied from minus 14% to 14%. The comparison of the two flow measurements methods is a way to relate the concentrations measured by the four sampling methods. The attempt is to relate the results of the concentration to the hydrological and meteorological data. This is an attempt to answer with a degree of confidence what are the influences that the different source areas play in the concentration at the outfall. When determining if a facility is discharging high levels of contaminants it is more important to know the concentration at the source than the concentration at the outfall and it is more important to know the runoff volume of each source area than the total volume at the out fall. The systematic monitoring of the structural BMP's must be developed and field tested because without a clear hydrological relationship between the sources and the concentration at the outfall it is impossible to determine the effectiveness of such BMP's. The transferability of the results can be used to compare the effectiveness of the BMP's on reducing the contaminants. The model SLAMM to estimate volume runoff (Table 10) is sufficient to permit systematic analysis of the data at a variety of industrial sites. To measure the effectiveness of the BMP's two key parameters must be obtained and reported in all the BMP's installed. These are the concentrations at the source and the volume of runoff. These two parameters need to be reported in every pollution prevention plan to test its effectiveness. The reporting of the concentrations and runoff volume (Table 10) appears to give respectable data to draw conclusions now on how the data is related to the source, and in the future to determine the BMP's at different industrial sites.

Conclusions

Industries and municipalities have already started to monitor and collect storm water data in a variety of ways, using different sampling methods (manual or automatic, flow or time based). Much of the data will be associated with the efficiency of future storm water management practices. It is very important that if a variety of sampling methods are to be used as management assessment tools, they be carefully evaluated to understand if they can adequately fulfill the task.

VOL 12

7842

TABLE 10. Comparison of measured volume with volume estimated by SLAMM at each site.

DATE OF EVENT	MEASURED VOLUME, CUBIC FEET	ESTIMATED VOLUME, CUBIC FEET	PERCENT DIFFERENCE
	AC ROCHESTER		
6/30/93	105,360	122,500	16%
8/5/93	52,500	64,500	23%
8/19/93	149,000	144,300	-3%
	WARMAN INTERNATIONAL		
6/13/93	6,200	6,200	0%
6/17/93	3,000	3,100	3%
6/29/93	4,300	3,700	-14%
7/17/93	1,400	1,600	14%
7/25/93	12,300	12,800	4%

In order to better understand how these methods may fulfill a particular task, Table 11 presents a way to visualize their effectiveness through a ranking of storm water sampling methods according to an evaluation of the various aspects involved in selecting a monitoring method. These aspects of monitoring are: site selection, cost, technical difficulty, most representative, accuracy and reproducibility. In order to select the best sampling method, each method has been ranked numerically according to each aspect.

As was shown in Table 3, one of the most problematic aspects of automatic flow based sampling is site selection, due to the difficulty in finding the proper outfall for installation of the flow measuring device. In Table 11, the sampling equipment and methods that do not utilize flow measuring devices are indicated as easier to install at an outfall, having lower costs associated with their use, and less technical difficulty.

If the consideration of proximity to the source or most representative sample is a higher concern, Table 11 indicates that the source sampler method will be much more useful, when compared to the flow based and time based automatic sampling methods. In addition, it is hoped that the accuracy and reproducibility of the new design of source sampler will be superior to the past designs. If we instead consider that sampling at the outfall gives the most representative sample, then the time composite is the best method.

MONITORING OF WETLANDS, WET PONDS, AND GRASSED SWALES

by

David Green[1], Thomas Grizzard[1,2], M. ASCE; and Clifford Randall[2,3], M. ASCE

Abstract

The use of best management practices (BMPs) to minimize the impact of storm water flow often involves engineered features such as wet and dry ponds, created and natural wetlands, and grass swales. The main purposes of each of these types of BMP are essentially the same: to reduce peak flows; to remove suspended solids; to provide opportunity for natural systems to reduce concentrations of dissolved organic and inorganic pollutants; and to control erosion. Integral to the use of such systems is the need for a monitoring program to assess the effectiveness of these BMPs in reducing pollutant loads in discharged storm water. Federal and State regulations include specific requirements for industrial and municipal storm water monitoring programs that can be, and often are, labor and resource intensive practices. While the storm water regulations have specific requirements for monitoring of discharges for permitting purposes, there remains a need to continue the development of representative and cost-effective monitoring systems that provide data on the efficiency of a variety of structural best management practice (BMP) systems. Data must be usable both for the purpose of demonstrating pollutant removal efficiency, and for the more general purpose of providing process information to facilitate development of design criteria. This paper examines current monitoring requirements, key elements in the design of a monitoring program, and current methods for assessing the effectiveness of runoff controls.

Background

The 1987 amendments to the Clean Water Act (CWA) added section 402(p), which included provisions for the regulation of storm water discharges. Under CWA §402(p), the U.S. Environmental Protection Agency (EPA) was directed to promulgate regulations incorporating discharges of storm water into the National Pollutant Discharge Elimination System (NPDES) permit program.

In November 1990, EPA published regulations governing NPDES permit applications for storm water discharges (43). These regulations included requirements for monitoring both dry weather (i.e., base flow) and storm-related flows to determine the concentration of various contaminants (specified in the regulations) in that discharge. EPA has published several guidance documents on developing and implementing such a monitoring program which provide greater detail on the specific elements required.

Under the Federal program, storm water sampling must begin (a) at a predetermined 0.1 inch of rainfall, and (b) no sooner than 72 hours after the last storm event. Two sampling protocols must be followed for storm water discharges. First, a grab sample of at least 100 mL must be collected during the first 30 minutes of discharge. Second, a flow-weighted composite sample must be taken. The flow-weighted composite sample must either be taken with a continuous sampler that proportions that amount of sample collected with the flow rate or be the combination of at least three sample aliquots, with each aliquot being volumetrically proportional to discharge flow. The collection of samples in this manner is problematic at best, requiring either automated equipment or the ability to have a sampling team in the field on very short notice.

Analysis of organic and inorganic compounds, microbiological species, and water quality parameters is required under the regulations. The specific constituents include the organics listed in 40 CFR Part 124 Appendix D, Table II; the toxic metals, cyanide, and total phenols listed in 40 CFR Part 124 Appendix D, Table III; and additional parameters specified in 40 CFR §122.26(a)-(c). The EPA guidance document *Guidance Manual for the Preparation of Part 1 of the NPDES Permit Applications for Discharges from Municipal Separate Storm Sewer Systems* (40) provides detail as to the parameters that should be addressed in a storm water monitoring program. Table 1 provides a summary of these recommended parameters.

The regulations also require the use of the analytical methods specified in 40 CFR Part 136. If there is no method specified for a particular compound, alternative methods meeting specified criteria can be utilized for the analysis. For the most part, standard laboratory methods exist for the contaminants listed; however, standardized field methods using remote sampling and analytical

systems are not available. Thus, most monitoring programs using field sampling and analysis systems probably will require a method validation element.

The monitoring requirements of regulatory programs should always be considered in the design of a monitoring program for storm water BMPs. Incorporating

7847

these requirements into a study provides data adequate for two purposes: demonstration of compliance plus the data needed to determine how the design and operation of such systems can be improved.

Design of a Monitoring Program

Any program to monitor the effectiveness of storm water BMPs must have clearly defined goals and carefully designed strategies to achieve those goals. In the case of a monitoring program for the types of BMPs discussed in this paper, the goals of the monitoring program should include:

- Estimating storm event flow and loading rates.
- Determining actual flow rates and identification and quantification of the influent and effluent pollutants of concern.
- Assigning the reduction (or increase) in a pollutant of concern to the appropriate physical, chemical, or biological system in a mass balance.
- Assessing possible impacts to other resources, especially groundwater.
- Assessing possible improvements in the design and operation of both the BMP and the monitoring program.

Integral to the design of a monitoring program is the need for a quality assurance (QA) program. Because environmental monitoring data are collected under often less than ideal conditions and a specific sampling event may not be repeated, researchers need to demonstrate that data collection and analysis procedures are based on accepted scientific practices. Typically, QA efforts focus on the laboratory analysis only; however, this is but one small part of the entire investigative process, and it is uncommon to see papers in the literature make specific reference to the entire QA protocol followed. One recommendation for all researchers conducting studies on the effectiveness of storm water BMPs is the use of an accepted protocol for incorporating QA into the monitoring program and to reference the QA program in their discussion. One model for integrating quality assurance into environmental monitoring programs was proposed by Clark and Whitfield (9). Briefly, this model proposes a system with fourteen elements:

(1) A careful study design to delineate the goals of the study and the methods to achieve those goals.
(2) A study plan documenting for all study participants the roles, responsibilities, and authorities of each participant.
(3) Written protocols or standard operating procedures to be followed during the course of the study.
(4) Careful preparation for all field activities before departing on a sample collection expedition.

VOL 12

7848

(5) Field team-headquarters liaison to ensure communication of study activities, problems, and corrective actions taken between "headquarters" and field teams.
(6) Written procedures for sample collection including sampling location selection, sample collection, on-site analysis, and recording of data and observations.
(7) Written procedures for sample handling between the time of collection and receipt at the laboratory where the analysis will be conducted.
(8) Oversight of analytical laboratories in addition to incorporation of the "in-house" QA program of the analytical laboratory into the project QA plan.
(9) Ensuring data are supplied by the analytical laboratory in a usable manner that minimizes the need to reenter data.
(10) Data validation and statistical analysis of the data received to determine the accuracy and precision of the reported results.
(11) Procedures for data approval and the release of the validated data.
(12) Plans for providing the data to the public, regulatory agencies, or others in an established format useful to the recipient.
(13) Procedures for statistical analysis of the data to determine trends or specific relationships between data points or data sets.
(14) Procedures for reporting and interpretation of the data to determine if the goals of the study are fulfilled.

While this appears a cumbersome process and a burden on the investigator, use of a QA program such as is outlined by this model helps ensure that the data collected are of maximum utility, accuracy, and precision. Further, providing a reference in published works to the QA protocols followed may enhance the utility of research efforts that follow.

Estimation of Storm Event Flow Rate and Pollutant Loadings

There are two components to determining storm event flow rates and pollutant loading. First, one must estimate these characteristics in order to plan and implement a monitoring program. This is especially important for monitoring programs that will utilize automatic sampling or analysis devices. Second is the verification of those estimates, and refining of the sampling procedures through analysis of the results of the implemented program.

There are several critical elements to estimating storm event flow rates. First, there is a regulatory definition of a representative storm event, critical to estimating runoff volume for the purpose of determining compliance:

VOL 12

7849

...[A] storm event that is greater than 0.1 inch and at least 72 hours from the previous measurable (greater than 0.1 inch rainfall) storm event. Where feasible, the variance in the duration of the event and total rainfall of the event should not exceed 50 percent from the average or median rainfall event in that area. [40 CFR §122.21(g)(7)].

EPA provided only limited discussion of analytical techniques to use on precipitation data to determine what constituted a representative storm event in the document *Guidance Manual for the Preparation of Part 1 of the NPDES Permit Applications for Discharges from Municipal Separate Storm Sewer Systems* (40). A paper by Hamilton (15) discussed the approach used in conducting an evaluation to determine the criteria for a representative storm event in the Winston-Salem and Greensboro, North Carolina area. For the Winston-Salem area, the National Oceanic and Atmospheric Administration (NOAA) used the following parameters:

1. A storm was defined by a total rainfall accumulation of at least 0.1 inch, with rates averaging at least 0.01 inch per hour.
2. Data were recorded on at least an hourly basis.
3. The start of a rainfall event begins in an hour when at least 0.01 inch of rainfall is recorded.
4. The minimum dry period to signal the end of a rainfall event was 10 hours.
5. At least 10 years of data were required for analysis (data from 1948 to 1986 were actually used).

The City of Greensboro, North Carolina used the same data set, but used two different parameters:

1. The minimum dry period to signal the end of an event was 3 hours.
2. The minimum dry period prior to the start of an event was 72 hours (per the regulatory definition).

Even though the same data set was used for these studies, there was a significant difference in the values for representative storm events, with the NOAA approach yielding consistently higher values for duration, frequency, total precipitation, and average precipitation. This difference led the North Carolina Department of Environmental Management (NCDEM) to define a storm event as a storm having a precipitation depth of 0.2 to 0.8 inch and a duration of 3 to 13 hours. Guidance letters from NCDEM specifically recommended against the use of high-intensity, short-duration storms as a representative storm event.

Other studies used different methods for determining what constituted a representative storm. Thrush and DeLeon (38) recommended using data from

VOL 12

7850

the National Weather Service to determine an average storm by calculating the numeric average of all the storms during the period examined, or by using the frequency of return of a storm of a given intensity which met the regulatory definition. Brown (6) used average data for three years in a study conducted in Minnesota. Chang and Crowley (8) defined a storm event as "any rainfall event with no breaks for more than six consecutive hours in duration." Neither the Brown nor the Chang and Crowley paper explicitly stated that the regulatory definition was reflected in their determination of a storm event. Woftiw (51) developed a computer program to use weather radar by deriving storm intensity-duration curves. This technique is limited to use in areas where there are long-term precipitation data and a weather radar service, but offers promise as system to assess storm events.

Another point to consider is the potential for bias in precipitation data. This will be especially important if a researcher is collecting precipitation data as part of the monitoring program. A study by Legates and DeLiberty (23) suggests the typical gaging system used in the U.S. (i.e., a 324 cm^2 gage, 79 cm above ground level, without a wind shield) introduces a systematic bias into the data record. This bias results from a variety of factors including wind effects (especially on snow), wetting losses to the inner walls of the gage, evaporation, splashing, and other factors dependent of the specific gage being used. According to this study, this bias typically ranges from 10 to 40 percent below actual values, with the worst bias being introduced in the winter months. In the U.S., no correction factors are applied to account for such bias, so, researchers may wish to attempt to correct precipitation data using the methods discussed by Legates and DeLiberty. Poissant and Béron (34) encountered similar problems with the design and operation of an automatic sequential rainfall sampler they designed and tested. The areal distribution of the weather stations is also a potential source of bias. The U.S. Department of Agriculture (UDSA) technique for determining rain gage placement density (39) suggests 4 gages are required for a drainage area of 1 mi^2, 15 for a drainage area of 10 mi^2, and 50 for a drainage area of 100 mi^2. The high costs of such an extensive gaging system would need to be carefully weighed against the benefit derived from the additional accuracy of the data collected.

For characterization purposes, occasions may arise where it is not practical to obtain detailed information on stormwater flows, and discharges must be estimated. This situation may be expected to limit the utility of resulting event mean concentration (EMC) data for pollutants of interest. In addition, the confidence in loading data derived from the product of such EMC's and estimated discharges may be similarly limited. In the absence of flow measurement data, an estimate of the total runoff from a representative storm may be made using the depth of precipitation. The formula for this determination has been adapted from EPA's guidance document *Guidance*

Manual for the Preparation of Part 2 of the NPDES Permit Application for Discharges for Municipal Separate Storm Sewer Systems (41):

$$V_r = P \cdot A \cdot 0.009 \cdot IMP + 0.05$$

Where:
V_r = runoff volume (l^3)
P = rainfall depth (l)
A = drainage basin area (l^2)
IMP = percentage of impervious area in drainage basin

Care must be taken when determining the value for the percentage of impervious area. Even small differences between the estimated impervious area and the actual impervious area can yield significant differences between estimated and actual storm event flow rates.

Once these parameters have been determined, they should be refined by analysis of actual data from the monitoring program. Typically, storm hydrographs are used to analyze the characteristics of a given storm. This analysis allows the researcher to determine the total and the peak flow as a function of time during the storm event. Should the values for the estimated flow and actual flow vary by more than a factor of 2, the estimating procedure should be revisited.

There are a variety of models for estimating storm water pollutant loading rates. Andrews (3) provides analysis of three such models: the model used in EPA's *Guidance Manual for Part 2 Applications for Dischargers from Large and Medium Separate Stormwater Systems* (41); the U.S. Geological Survey (USGS) Nationwide Regression Equation (NRE); and the "P8" computer model developed by W.W. Walker. Andrews suggests that the selection of a model will depend mostly on the user's short- and long-term needs; however, his analysis suggests that although it is more complex, over the long term, the "P8" model will offer the greatest utility. Akan (1) also provides an analysis of several models to estimate pollutant loadings. Marsalek (25) suggests that planning-level evaluation of pollutant loads in storm water should also consider the impact of the environmental pollutants. It will suffice to say that estimates from these models will need to be refined once sampling results are available. Once actual data are available, a variety of models can be used to extrapolate such data to unmonitored areas.

Determining Efficiency of Storm Water BMPs

In order to assess the efficiency of a pond, wetland, or grass swale, it is necessary to accurately characterize the mass of pollutants entering and leaving the system. Although each of these systems has a different design basis, most of the pollutant removal mechanisms are similar. Pollutants entering the system are removed by washout without treatment, settling (especially in conjunction with suspended solids), biological uptake and/or conversion, volatilization, or infiltration. Water entering the system either flows out, infiltrates, or is lost through evapotranspirative processes. Expressed as a mass balance around an external system boundary this relationship takes the form:

$$M_d + C_r \cdot V_r + C_i \cdot V_i = C_o \cdot V_o + C_p \cdot V_p + M_s + M_b + M_v$$

Where:
M_d = mass from direct dry deposition (m)
C_r = concentration in precipitation falling directly into system (m/l^3)
V_r = precipitation volume falling directly into system (l^3)
C_i = influent concentration (m/l^3)
V_i = inflow volume (l^3)
C_o = effluent concentration (m/l^3)
V_o = effluent volume (l^3)
C_p = concentration infiltrating into ground (m/l^3)
V_p = infiltration volume (l^3)
M_s = mass deposited as sediment (m)
M_b = mass taken up by biota (m)
M_v = mass lost by volatilization (m)

BMP removal efficiency would then be described by the equation:

$$E = \frac{C_i \cdot V_i - C_o \cdot V_o}{C_i \cdot V_i} \cdot 100\%$$

E = efficiency of system at pollutant removal, %
C_i = constituent influent concentration (m/l^3)
V_i = inflow volume (l^3)
C_o = constituent effluent concentration (m/l^3)
V_o = effluent volume (l^3)

Assessing Flow and Constituent Concentrations

Obviously, at least two stations are required to assess the effectiveness of a BMP at treating storm runoff: one immediately prior to, and one immediately following the BMP. However, additional sampling stations within the unit are advisable, and may yield valuable information as to the degree of treatment achieved as the flow passes through the system and may also assist in identifying the processes responsible. Establishing such a system is relatively easy; typically inflow to

BMPs is from engineered collection systems serving a larger area that directly impacts the BMP through overland flow. For designs where overland flow is the main source of runoff entering the BMP, a diversion system is needed to channel the flow so it can be monitored and sampled.

There seems to be no standard practice for monitoring storm water flows or the collection of storm water samples. Researchers use weirs, flumes, and other primary devices to measure storm water flow past a given point in order to generate a hydrograph that either will allow manual combining of grab samples into a flow-weighted composite or will be used to trigger automatic sampling devices to directly collect flow-weighted samples. For example, Lynch and Corbett (24) used modified broad-crested Trenton weirs with a sharp-crested, 90-degree, V-notch in the center; McTernan *et al.* (28) used a type-H flume for primary flow control and a pressure transducer flowmeter; Izuno *et al.* (18) used 0.80-, 1.6-, and 2.4-cm diameter PVC pipes that had been calibrated to yield a known relationship between discharge and hydraulic head over the pipe; the Occoquan Watershed Monitoring Laboratory (OWML) (30) used Palmer-Bowlus and type-H flumes; and Higgins *et al.* (16) used 3-ft H flumes, culverts, broad-crested weirs, and 90-degree notch weirs. One study on an experimental plot of fescue with similar conditions to a grass swale conducted by Gross *et al.* (14) used a 0.76 by 1.0-m metal weir with a covered H-flume to measure runoff volumes and to collect samples for analysis.

Each of the types of primary devices has advantages and disadvantages. The advantages of weirs are that they are generally low cost, easily installed, and quite accurate. The disadvantages are that they can cause significant head loss in the flow stream and create a pool that may affect sediment transfer past the device. The advantages of flumes are that they are typically are self-cleaning due to higher flow velocities, there is no "dam" across the channel that will cause pooling, and operate with smaller head loss than weirs. The disadvantages are that they are more costly, more difficult to install, can be submerged by extremely high flows, and are often less accurate. However, the self-cleaning nature of a flume may be an important consideration in measuring storm water flows which are often high is suspended solids and flotsam. This intrinsic feature of flumes may minimize problems from the buildup of settled solids behind the structure or by flotsam occluding orifices. Ultimately, the selection of what type of flow measurement system to use will involve "professional discretion."

A secondary device such as a pressure transducer, flow meter, or other mechanical stage-height detector and stage-height recorder are required to record the flow as a function of time in order to apportion grab samples; however, this sampling technique has several drawbacks. First, it is labor intensive. Personnel will have to be available at very short notice to respond to storm events. In large scale sampling programs, commitment of personnel resources is also a major

VOL 12

7854

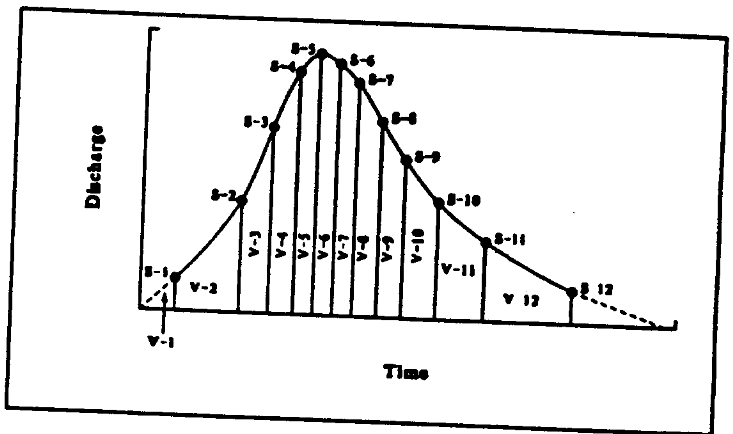

Figure 2. Schematic of Automatically Collected Flow-Weighted Samples.

Notes:
1. With the exception of V_1 (*i.e.*, V-1 above), all V_i (*i.e.*, V-1) are equal.
2. If V_i is very small, the error induced by unequal volume represented by sample 1 and unsampled volume post sample 12, will also be small.
3. If V_i is small, a better representation of flow near peak is also obtained.

contaminant of interest may be found in a higher concentration at the surface or at some other level in the water column. Contamination of groundwater by dense non-aqueous phase liquids (DNAPLs) and the resulting difficulties associated with remediation of this type of contamination is another example. There are a variety of devices that will collect vertically integrated samples. Two passive types of systems are the multi-slot divisor and the Coshocton-type sampler. The disadvantage to using a multi-slot divisor is that a settling tank to remove large sediment particles is usually required to keep the device from becoming clogged. With a Coshocton wheel this typically is not a problem. In a Coshocton wheel water is discharged from a type-H flume onto a rotating water wheel. An elevated sampling slot on the wheel collects an aliquot sample as the wheel traverses the water pouring from the flume. In this way a vertically integrated sample is collected (39). There are also a variety of other more complex devices for collecting vertically integrated samples. Martin *et al.* (26) conducted a study comparing surface grab samples and a cross-sectionally integrated, flow-weighted sampling device. As has been well documented in the literature, there can be considerable cross-sectional variation in suspended sediment concentrations. This becomes important when one considers the pollutants sorbed onto such

VOL 12

7857

sediments. The study concluded that concentrations of suspended sediments and the associated pollutants were routinely lower in manually composited surface grab samples than in cross-sectionally integrated, flow-weighted samples. Generally, the magnitude of the difference increased with flow rate. One other observation was that grab samples consistently contained more fine-grained sediments than the integrated samples.

One report discussing the use of microcomputers for flow measurement warrants additional discussion. OWML (30) uses an inexpensive microcomputer, an analog-to-digital converter, and a 10 psig contact pressure transducer to monitor storm flows. The computer receives a signal from the transducer (via the A/D converter) and calculates the stage using the following equation:

$$HT = \frac{PT}{1000} \cdot 4.614 \frac{ft}{volt}$$

Where: HT = stage in feet
PT = pressure transducer signal in millivolts
The factor of 4.614 is required to convert ft/psi to ft/volt

The stage is compared to a rating table stored in random-access memory. Each minute, the value for the stage is compared to the value for the previous minute. If the stage has risen at least 0.1 foot over each of the last three successive minutes, a storm event is considered to have begun, and the computer starts continuous monitoring and triggering of an automatic sampling device to collect a flow-weighted composite sample. Base flow data are written to disk every hour and storm flow data every 10 minutes. The data record includes: date, time, stage, flow, discharge, incremental discharge, and whether a sample was collected. The data record is downloaded to an IBM-compatible format for analysis.

Using the value for total volume for a storm event, along with values for the number of samples to be collected and a known sample size for composited samples (both set by the investigator), the volume of storm water flow between collection of each sample may be calculated using the following relationship discussed by Thrush and DeLeon (38):

$$\frac{V_r}{FSI} = N = \frac{V_{sc}}{V_{is}}$$

Where: V_r = runoff volume (l^3)
FSI = volume of flow per sampling interval (l^3)
N = number of samples
V_{is}, V_{sc} = Volumes of incremental and composited samples (l^3)

Typically, the volume of the composited sample should reflect the sum of the volumes required for each of the analyses conducted as part of the monitoring program, plus an appropriate safety factor. However, because it is common that storm event flows will often not yield sufficient volume for all analyses, the researcher should be prepared to prioritize the tests to be performed on incomplete samples.

The sampling routine in the computer program used by OWML is controlled by a flow-totalizing subroutine. This routine is based on the following equation:

$$IV = \frac{Q_i + O_{i-1}}{2} \cdot (t_i - t_{i-1})$$

Where:
IV = volume of flow during interval (l^3)
Q_i = discharge at present stage (l^3/t)
Q_{i-1} = discharge at previous stage (l^3/t)
t_i = time at present stage (t)
t_{i-1} = time at previous stage (t)

The values for IV are summed every minute, and when this value exceeds the value for V_{in}, a sample is collected. By analyzing the times when samples where collected against the hydrograph, the researcher can determine if the sample collected is truly representative of the entire storm event. Ideally, the hydrograph will show that sampling was conducted throughout the entire storm event, with the greatest number of samples being collected during the period of peak flow, and with the desired total sample volume being collected.

One issue that needs to be stressed in using remote and automated sensor and sampling systems is the need for quality assurance for these practices. One journal article by Whitfield and Wade (50) discussed the need to develop new QA procedures when using electronic logging devices and made several specific recommendations regarding QA procedures for electronic monitoring. These procedures fall into three areas: (1) sensor validation in the field, (2) time controls for data loggers, and (3) precision and accuracy of sensors over time.

According to this article, little can be done to verify the accuracy of a sensor using field instrumentation. This is because field instruments rarely are as accurate or precise as a laboratory system, while this is the degree of accuracy and precision required. Since field verification is not practical, Whitfield and Wade recommended operating electronic monitoring systems for a fixed number of day duty cycle, with calibration before the system is taken into the field and recalibration when the duty cycle ends. This allows a correction factor to be applied to the data. Unstated in their paper was the need for careful use of such correction factors. Careful analysis of the data collected is necessary to determine if the "drift" was consistent over time, or whether a catastrophic failure occurred. In the latter case, application of the required correction factor to data collected prior to system failure would clearly be inappropriate.

Regarding time controls, Whitfield and Wade discovered that when more than one instrument is used to monitor a given parameter, strict time control (± 5 seconds), with weekly verification, is necessary to prevent generation of time artifacts. Further, a record of all adjustments must be kept to allow for use of correction factors on data collected. While this may not be necessary for systems where sampling is done over longer periods of time, it is critical during high-frequency, short-interval sampling programs, sampling when conditions are changing rapidly, and sampling where temporal correlation of data sets will be performed. For careful tracking of time, microcomputer-controlled systems with the ability to automatically access outside standard reference clocks (e.g., as is available through Loran-C) can be invaluable.

In the last area, precision and accuracy, Whitfield and Wade identified the need to adjust data to account for drift introduced by deterioration related to the age of the sensor. Their study showed that dissolved oxygen sensors were subject to the greatest degradation in performance. Oxidation-reduction potential and pH sensors demonstrated bias over time rather than degradation in sensor performance. As with the first case, knowing the calibration at the time a sensor is placed into service and the calibration at the end of a given service interval, corrections can be made to account for such fluctuations. Additional studies on how age affects other sensors such as pressure transducers, A/D converters, and other features of electronic monitoring systems would prove useful.

Infiltration Measurement and Collection of Samples of Infiltrated Water

Protection of groundwater resources is of such concern that in 1986 Congress amended the Safe Drinking Water Act (SDWA) to include a new program for wellhead protection. This desire to protect groundwater resources is mirrored in a variety of other Federal and State laws severely restricting or prohibiting the land disposal of hazardous waste. Because infiltration of storm water is the major contributor to groundwater recharge, storm water BMPs need to be designed and operated in a manner that will prevent, or at least minimize, contamination of groundwater. Given the high concentrations of some contaminants in storm water, application of design strategies such as are used for hazardous waste surface impoundments (e.g., use of impermeable clay or synthetic liners) may be advisable. Whipple (48) suggests a programmatic control strategy integrating storm water management and infiltration controls. This proposal suggests classifying areas based on the need to protect surface waters and groundwater;

creating a "harmfulness index" for various runoff sources (e.g., industrial/commercial, residential, and undeveloped areas); and requiring specified BMPs depending on the land use and need for protection. Whipple also proposed some special types of BMPs that might be employed for storm water flows known to be contaminated by various classes of pollutants.

The rate of migration of waterborne or liquid pollutants into the ground depends primarily on the hydraulic conductivity of the underlying soil. Higher hydraulic conductivity allows more rapid movement of water into the ground, and allows pollutants to travel farther into the soil column before other processes, for example, adsorption, begin to retard the migration. Determining the rate at which water infiltrates into the ground (i.e., hydraulic conductivity) is accomplished using a permeameter or piezometric wells. The design and operation of these devices are well described in the literature and will not be discussed in detail. For a detailed discussion of the operation of these devices, the reader should refer to a text on hydrogeology, such as by Fetter (13) or Driscoll (11).

Tensiometers are used to determine the negative head exerted by the tendency of water to infiltrate into the ground. An adaptation of a tensiometer can be used to collect samples of infiltrated water. One study by the OWML (30) used a device constructed by attaching a porous cup (similar to those used on tensiometers) to one end of a five-foot-long PVC pipe, and a rubber plug (to create an airtight seal) to the other end. A sample collection tube was passed through the rubber plug and extended to the bottom of the porous cup and a second tube for applying pressure or vacuum to the system was passed through the rubber plug and extended halfway down the pipe. The device was placed into a bored hole approximately three feet deep, and packed into place with excavated soils to prevent surface water from passing down into the soil alongside the PVC pipe. Twenty-four hours prior to sampling, a vacuum was applied to the shorter tube in the system to reverse the negative pressure head and so draw water from the soil into the porous cup. Samples were collected from the device by applying pressure via the shorter tube, thus forcing the water up the longer tube and into the sample container.

There are many methods for estimating infiltration of storm water. The reader is directed to Driscoll (11) for an excellent discussion of these established methods. One new method to determine volume losses due to infiltration not described by Driscoll was developed by Kalita *et al.* (19). They described a mathematical method to model losses from the side walls and bottom of ponded fields under variable water table conditions. The field aspects of their study used an experimental plot are not readily adaptable to the study of systems such as ponds, wetlands, and swales. However, their results do suggest that vertical and lateral infiltration losses from ponded systems can be predicted with a high degree of accuracy, provided adequate hydrologic data are available. The specific factors that would need to be known include: soil-moisture characteristics, hydraulic conductivity, water table depth, evaporation rate, and pond depth.

Assessment of Deposition in Sediments

There are two reasons to monitor the deposition of sediments in storm water BMPs. First, one of the primary reasons for storm water management systems is to control erosive losses of soil into waterways, hence deposition of sediments in storm water BMPs can severely impact storage capacity. Striegl's study (37) of suspended sediments and metals removal by Lake Ellyn, a small lake outside Chicago, showed that in the course of 10 years, the lake accumulated 8,300 m^3 of sediments, a 13 per cent loss of storage capacity. Second, and equally important, is the cumulative effects of pollutants associated with sediments on the benthic community, rooted vegetation, and the land where spoils from dredging the BMP are ultimately disposed of. This last point is worthy of special comment. Studies by a variety of researchers show that toxic metals from urban runoff accumulate in sediments at relatively high concentrations. For example, Striegl's study found mean concentrations of copper, lead, and zinc were 275, 1,750, and 228 mg/kg dry weight, respectively. Nightingale (29) also found concentrations of lead as high as 1,400 mg/kg. These values for lead concentrations are of particular concern in that they exceed the 1,000 mg/kg concentration used by EPA as a guideline for remedial activities under Superfund. No data are available, but an interesting question arises as to how dredged sediment would fare if subjected to the Toxicity Characteristic Leaching Procedure (TCLP) test to determine if it is a characteristic hazardous waste under the Resource Conservation and Recovery Act (RCRA). Under the Federal RCRA program as described in 40 CFR §261.24, a waste demonstrates the characteristic of toxicity for lead if the TCLP extract concentration is greater than 5.0 ppm (mg/kg).

As was stated previously, the rate of migration of liquid or aqueous pollutants into the ground depends primarily on the hydraulic conductivity of the underlying soil. Higher conductivity allows more rapid movement of water into the ground, and consequently less time for degradative, filtering, or adsorptive processes to occur. Other factors, however, do play a major role in the ability of a pollutant to associate with sediment. Oxidation-reduction potential, pH, temperature, and presence of hydrous gels of iron or aluminum all play a role. Adsorption of pollutants onto sediment, however, is of particular concern. Adsorption is greatest when sediment particles have a high surface area/mass ratio; when sediment particles have negatively charged surfaces, as is the case for silts and clays; when the sediment has a high cation-exchange capacity; and when organic carbon fractions in the sediment are high.

VOL 12

7862

As described in the EPA handbook *Remediation of Contaminated Sediments* (42), studies of sediments rely on a variety of sampling and analytical techniques to determine the mass of pollutants in sediments or the overall condition of the benthic community. Almost all involve collection of samples using digging tools such as spoons, scoops, and trowels or coring devices such as split-spoon samplers, piston-tube samplers, or augers. *Standard Methods* (2) provides detailed discussion of various sediment sampling devices, protocols, and analytical techniques. Each has its advantages and disadvantages. For example, the very nature of digging tools makes collection of similar samples from a variety of locations problematic and the disturbance of the sample by the collection method suggests that it may not be representative of actual near-bottom conditions. Coring devices are expensive, bulky, and often difficult to handle. Further, core samplers do not work well in sandy soil or in rock-laden areas. Coring devices can also breach the integrity of a engineered structure, opening a migration pathway for contaminants. Last, attributing pollutants concentrations in sediments to specific storm events can be difficult in any system other than a new construction. For these reasons, sediment sampling as part of an effectiveness study poses some serious challenges.

One method described in the literature that may prove a useful tool in the analysis of sediments is to collect the suspended particles that will become sediment before they settle. Walling and Woodward (45) described the design and use of a simple field-based water elutriation system for monitoring particle size and characteristics. Their system uses four glass sedimentation chambers (25-, 50-, 100-, and 200-mm diameter) linked by glass and flexible PVC tubing. A peristaltic pump provides suction to draw water directly from the channel being monitored into the 25-mm sedimentation chamber via a tube that extends nearly to the bottom of the chamber. Water is drawn off this chamber by means of a second tube positioned at the top of the chamber, and is directed to bottom of the 50-mm chamber. This process is repeated until the water has passed through all the chambers. This technique offers several advantages over traditional sampling techniques in that it provides the researcher the opportunity to assess the characteristics of the suspended sediment based on effective particle size. This does, however, require the assumption that the sediment collected in this manner is representative of the sediment accumulating at the bottom of the BMP. One possible modification to the operation of this system for collecting samples from the bottom would be to apply a microfilter to the collection tube, fill the system with filtered water taken near bottom, remove the filter, manually disturb the sediment, and then collect the sample. Another use would be to monitor the effectiveness of the BMP at removal of particles of various sizes as a function of distance from the inlet into the system.

Physical and chemical analysis of samples

The Federal regulations require the use of the standard analytical procedures described in 40 CFR Part 136 or the use of another accepted standard procedure such as those in the American Public Health Association reference *Standard Methods for the Analysis of Water and Wastewater*. There are, however, drawbacks to the use of these analytical methods.

First, the accepted analytical methods for metals yield total metals concentrations (a conservative approach that may not reflect actual impacts to aquatic organisms) rather than the quantity of metals that are readily bioavailable. Typically, the bioavailable forms are free metal ions or those metals weakly bound in inorganic complexes. Papers by Paulson and Amy (32 and 33) discuss the point that the majority of metals in storm water are found sorbed to particulates or in strongly complexed organic forms that are not readily bioavailable. These studies showed that although storm water quality was quite variable, the relationship between bioavailable and total concentrations was consistent. The factors controlling the speciation between dissolved and bioavailable forms include: (1) suspended solids types, (2) pH of the water, (3) total metals concentration, and (4) dissolved organic carbon concentration and character. Paulson and Amy developed a computer model using the EPA's MINTEQA2 to predict the speciation of copper, zinc, and lead into bioavailable and nonbioavailable forms. The results of the modeling effort suggest that in addition to analysis of total metals, an estimate of the bioavailable concentration would be worthwhile in assessing potential impact to aquatic biota.

The second area of concern is that several of the analyses required under the regulations are nonspecific tests. For example, the test for "oil and grease" is non-specific. *Standard Methods* defines "oil and grease" as any compound recovered as a substance soluble in trichlorotrifluroethane or other solvents. This is not specific for hydrocarbons; chlorophyll, organic dyes, and other compounds will be included in the results from this test. If possible, in addition to these nonspecific analyses, it is recommended that during the first few sampling rounds analysis be conducted for a larger suite of specific constituents (for example, chlorophyll) than is required under the regulations. Once the initial rounds of sampling are completed, the suite of constituents can be winnowed down to a manageable and cost-effective suite by eliminating those compounds that are not detected. This is not to say that the nonspecific tests are not valuable tools; Wass (46) used the oil and grease method with moderate success in evaluating the effectiveness of a submerged-flow vegetated treatment system used to treat runoff from a vehicle maintenance yard. The only problem encountered with using this non-specific method occurred when cold-mix asphalt was used to construct berms to redirect runoff at the study site. An unusually heavy rain leached some of the

VOL 12

7864

constituents from the asphalt, causing a short term increase in the concentrations of oil and grease detected.

Biological Testing

Little definitive work has been published relating efficiency of storm water treatment to the growth of plants or other organisms, nor does there appear to be any definitive standard vegetative analysis for storm water BMPs. Most of the available work discusses either the results of simulated studies or the effects of various agricultural or silvicultural techniques of the quality of storm runoff in streams. For example, Gross *et al.* (14) conducted an interesting study of runoff and sediment losses from tall fescue under simulated rainfall. This study demonstrated that seeding density for turfgrass plays a major role in its ability to act as a sediment trap, and the conclusion was made that well-maintained residential turfgrass stands should contribute to decreasing total runoff volume and sediment loadings. Little other research has been done in recent years on the effectiveness of various grasses as sediment traps or on their ability to assimilate dissolved pollutants. Clearly, this is an area where additional research is needed. The use of reed beds for sludge dewatering was discussed by Kim (20). This study suggests that beds containing the reed *Phragmites* are an effective means of dewatering sludges from 1 to 10 percent solids, suggesting that this species may be a valuable means of promoting evapotranspiration from sediment-laden BMPs operated as dry ponds.

Standard Methods (2) provides an excellent discussion of accepted techniques for sampling macrophyton in method 10400. The reader is directed to this reference for the details of these sampling techniques. It is important to note that these techniques are not specifically developed for storm water BMPs; however, they should certainly be applicable.

Vegetation monitoring was conducted as part of the study by the OWML (30) discussed elsewhere in this paper. The vegetation analysis consisted of identification plant species and a biomass measurement. The biomass measurement was conducted by trimming to ground level the plants in randomly spaced circular plots with an area of 1 m^2. The harvested plants were separated by species, washed with a weak acid solution, and oven dried to constant weight. Below-ground biomass was estimated by excavating a 12 cm by 20 cm soil sample using a piece of PVC pipe. Plant material was manually separated from the soil, washed with a weak acid, and dried. Samples were collected throughout the growing season and the biomass measurement technique repeated to give an indication as to the rate of biomass production. A decomposition study was also conducted by placing a known amount of washed and dried plant litter from known species into 36 porous polyester bags and placing these bags in areas where those plants were dominant. Every month, six bags were removed at

VOL 12

7865

random and weighed to determine the quantity of plant material that had decomposed. The study did not attempt to correlate biomass production with pollutant removal efficiency, but these procedures allowed an analysis of the rate at which organic matter accumulated in the wetland under study.

Recent regulatory initiatives have seen the inclusion of toxicity testing requirements in NPDES permits, including those for storm water discharges. There are problems with toxicity testing for storm water flows. As pointed out by Isom (17), one "glaring deficiency" with toxicity testing is the lack of a national laboratory certification program. Collins *et al.* (10) pointed out that one of the most difficult problems with conducting toxicity testing on storm waters using fathead minnows or *Daphnia* stems from the 36-hour maximum holding time permitted. Because it can be difficult to determine when there will be a storm event (a fact borne out by local television weather forecasts across the U.S.), the laboratory may not have a ready supply of test organisms of the appropriate age. Further, these tests are expensive. Many researchers have examined the potential for microbial toxicity testing as a means of providing a more cost-effective assay; however, none of these tests have proven to be as effective as the standard test using fathead minnows or *Daphnia*. For example, Arbuckle and Alleman (4) assessed the potential for using the commercially available Microtox® test and a procedure using enriched nitrifier cultures. Their study showed that neither test was as sensitive as the *Daphnia* test. *Standard Methods, 18th Edition*, contains two proposed methods for toxicity testing of aquatic plants. One technique is for Duckweed and the other for a variety of vascular plants. These are laboratory techniques and have not yet been approved, nor have these techniques been adapted to field use.

Conclusion and Recommended Directions for Research

There are many areas still to be explored in conducting research on monitoring of storm water BMPs. One of the most important areas where research could be focused is the development of standard methods for conducting studies of storm water BMPs. Currently, there are few standard practices in the field. This makes relating data from one study to another very difficult at best, and impossible at worst. A short list of proposals for research into standardizing protocols for storm water BMP evaluations follows.

1. Development of standard methods for the calibration and operation of remote sensors.

2. Development of standard methods for metering flow (i.e., use of standard designs of weirs, flumes, or other systems).

3. Development of a standard method for sampling infiltrated waters.

4. Development of standard methods for the collection and analysis of suspended sediments and deposited sediments.

5. Development of methods to relate vegetation assessments to treatment efficiency.

6. Development of a recommended list of analyses for bioavailable metals and development of standard analytical methods for those analyses.

Monitoring the Effectiveness of Structural BMPs

George E. Oswald, P.E.[1] and Richard Mattison[2]

Abstract

With the implementation of the NPDES regulations for stormwater discharges there has been a high level of interest in establishing reliable pollution control performance characteristics for structural treatment controls which may be applicable for managing the quality of runoff from urban land uses and industrial facilities.

This paper describes monitoring techniques and data analysis protocols for establishing the pollution control performance of structural treatment controls for stormwater runoff. These techniques are applicable for monitoring oil/grit separators, filtration basins, extended detention basins and wet-detention basins. The following monitoring considerations are addressed:

- General considerations for monitoring instrumentation
- Characterization of contributing drainage area
- Rainfall measurement
- Flow measurement for structure inflow and discharge
- Water quality sampling for analytical characterization of structure inflow and discharge
- Monitoring period of record and storm events rainfall depth distribution
- Structure overflow and bypassing
  - On-line/off-line configurations
  - Storage volume

[2] Kinnetic Laboratories, Inc., 307 Washington Street, Santa Cruz, CA 95060.

- Data analysis
  - Hydrologic mass balance
  - Water quality constituent balance
  - Single event and long-term pollutant control performance

This information is organized to provide guidance for future monitoring activities so that municipalities and industries can implement cost-effective and technically sound BMP performance monitoring programs to support NPDES compliance and BMP specification development for future stormwater management applications.

Introduction

The purpose of this paper is to provide guidance for the development and implementation of effective pollutant control performance monitoring programs for structural stormwater runoff treatment controls.

The monitoring of pollutant reduction performance of structural treatment controls for stormwater runoff presents numerous challenges. Typically, treatment structures such as oil/grit separators, filtration basins, extended dry-detention and wet-detention basins are designed and constructed to meet minimum capture volume/surface area specifications to meet prescribed regulatory requirements and to meet specific site physical constraints such as slope limitations, high ground water elevation, and integration with site plan layout demands. During structure design, little or no consideration is made for siting monitoring stations to characterize inflow and outflow flow rates and water quality improvement performance. Therefore, the usual challenge is to retrofit monitoring equipment to existing structures.

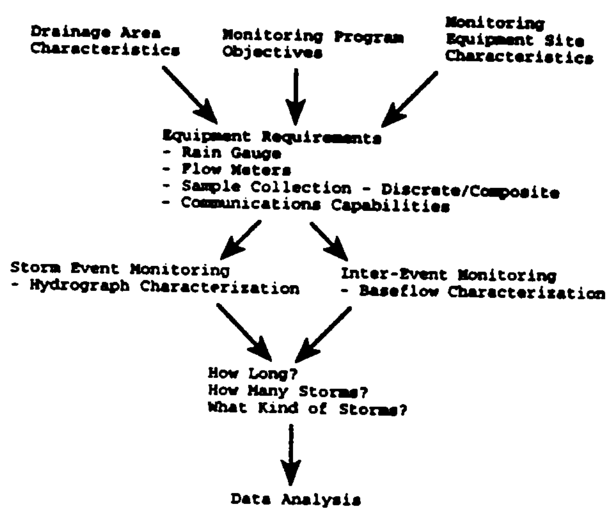
This reality typically dictates that each treatment structure selected for monitoring be evaluated individually to establish feasible methods for reliable flow measurement and water quality sample collection. Also, the basic flow configuration of the structure bears on the extent of monitoring required to characterize structure performance under the range of hydrologic events, both small and large, that occur in the location of the study. On-line structures can be subject to resuspension and washout of accumulated pollutant materials during large storm events and pollutant flux associated with dry weather baseflow can be significant. These occurrences can have a significant effect on long-term pollutant control performance. Properly designed off-line structures are not subject to extreme event

VOL 12

7873

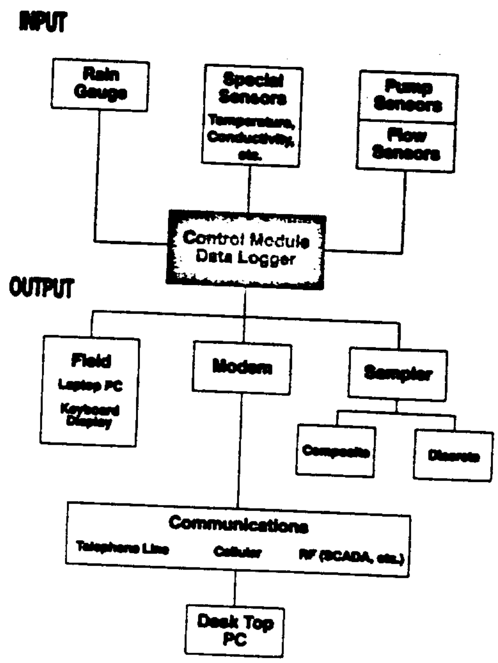
"washout" processes; however, long-term performance monitoring of off-line structures must take into account bypassed volumes that do not receive any treatment. Also, the control performance of wet basins which combine complex physical, chemical and biological pollutant reduction mechanisms is significantly influenced by the variations in hydraulic residence time that occur in response to the normal variation in rainfall/runoff volume and inter-event time periods that are part of the expected "normal" hydrometeorologic cycle. Therefore, accurate characterization of the integrated, long-term pollutant reduction performance of these structures can require intensive sampling programs that address characterization of a wide range of wet weather and dry weather inflows and outflows.

The flow chart below presents the design and implementation steps required for an effective structural treatment control performance monitoring program. The remainder of this paper presents recommendations and guidance on how to address these requirements.



<u>General Considerations for Monitoring Instrumentation</u>

Because of the difficulties associated with timely field personnel mobilization and achieving consistent manual flow measurement and sample collection techniques for extended monitoring program periods, this paper is focused on the application of automated monitoring systems only. Therefore, a limited overview of automated systems is included to highlight the capabilities of these systems. The primary components and configuration relationship of an automated monitoring system are illustrated in the following diagram.



Automated Monitoring Station.

The major component of an automated system is the control module/datalogger microprocessor, which functions to interrogate and record input data from external sensing devices including the flow meter and rain gauge, can perform complex calculations based on these inputs and produce signals to drive ancillary devices, including the automatic sample collection unit and remote communications devices. This flexibility allows for these automated systems to detect storm flow conditions and initiate sampling with no human interaction.

Remote communications capabilities allow for: 1) sample collection rates to be reset to meet variable storm magnitude or baseflow conditions, 2) effective, real-time tracking of storm/hydrograph/sample collection progress, and 3) efficient direction of field crews for sample recovery. Additional equipment considerations for rainfall and flow measurement are included in later sections of this paper.

Characterization of Contributing Drainage Area

It is important to characterize the contributing drainage area tributary to the treatment structure in order to: 1) establish anticipated peak flow rates for the range of storms to be monitored, and 2) identify all significant tributary areas to the structure.

Establishing the anticipated peak flow rate is important for selecting and sizing the inflow primary flow measurement device, such as a weir or flume. Since storms of a depth less than the 2-year return period storm typically account for more than 90% of annual rainfall, designing the flow measurement device to meet the 2-year storm peak flow criteria is a good target. Standard hydrologic methods such as SCS TR-55 can be used to estimate peak flows and total design storm runoff volume based on tributary area, soil type, slope, and land use. It is also recommended that hydrographs be generated for the smaller more frequent storms, such as the 3-month and 6-month events, to establish the nominal flow metering range to allow adequate characterization of these more frequent storms.

A structure may have multiple inflow points, which will require multiple monitoring sites, or may have significant overland sheet flow contributions to the basin between the inlet and outlet. There are additional equipment and operation costs associated with the increase in monitoring sites, and increased pollutant control performance data analysis uncertainty associated

VOL 12

7876

with characterizing inflows associated with unmonitored direct overland flow contributions.

Assuming that performance monitoring of structural treatment controls will be coordinated with other land use related discharge quality monitoring activities, information on land use distribution, percent impervious cover, and age of development should be compiled so that the inflow characterization data is useful for establishing land use related stormwater quality impacts.

Rainfall Measurement

Although rainfall measurement is not specifically required to measure structural control performance, acquisition of incremental rainfall data in the tributary watershed area is strongly recommended because inflow runoff quality may be influenced by rainfall intensity, depth, and duration and, most importantly, rainfall records are necessary to establish the range of storms for which structural control performance has been monitored. It is recommended that rainfall be recorded with a tipping bucket rain gauge with a minimum sensitivity of 0.01 inch with input to a datalogger.

Flow Measurement - Inflow and Outflow

Flow measurement can be accomplished using any of a number of primary measurement devices such as weirs and flumes. A good reference on these devices is the ISCO Open Channel Flow Measurement Handbook (1992). Flumes are recommended over weirs because of their self-cleaning capability, lower head loss, and reduced influence from approach velocity. Weirs must be periodically cleaned to remove deposits of sediment or other solids upstream of the weir or accuracy will be affected. However, weirs are generally recognized as being more accurate than flumes. Properly installed and maintained, most types of weirs and flumes will produce better than ±10 percent accuracy.

The primary factors which affect the selection of type and sizing of the primary flow device are the minimum and maximum range of flow rates to be measured and any limitations associated with the existing site physical configuration. Sizing of the primary flow device for inflow is based on the hydrologic analysis of the inflow monitoring point tributary drainage area discussed previously. Sizing of the primary flow device for outflow should be based on level pool routing of inflow hydrographs for wet-detention basins and design drawdown flow rates for extended detention and filtration

VOL 12 7877

basins. Since oil/grease separators generally have a small storage volume, inflow rate is typically assumed equal to outflow rate and only one flow monitor is installed and is used to provide flow information to drive both the inflow and outflow automatic samplers.

For example, Palmer-Bowlus flumes are recommended for round pipes because of ease of installation. H-flumes have been effectively used at pipe/culvert outfall locations. Weirs typically are best suited for measurement of open-channel flow where low approach velocities can be achieved by increasing weir height and removal of accumulated materials from the upstream face is practicable. Also, compound weirs can be configured to provide very broad flow ranges beyond the capacity of a single flume or simple weir. If a weir is employed under non-"ideal" siting conditions (i.e. inadequate crest height, high velocity of approach), or if better than ±10 percent accuracy is desired for normal installations, it is recommended that a specific rating curve be developed based on independent volumetric flow measurements such as timed gravimetric, tracer dilution, or velocity-area techniques.

In addition to weirs and flumes, several manufacturers offer instrument systems which combine an electromagnetic or sonic-doppler velocity sensor with a flow depth sensor to determine flow rate through a velocity-area continuity computation. These types of systems are costly and it is best to conduct independent flow verification calibration to correlate velocity measurements with actual average flow velocity. Properly installed and calibrated, these devices can produce flow measurements within ±2 percent accuracy for flow velocity up to 20 feet/second.

Flow measurement by weir, flume or velocity sensor requires concurrent depth of flow measurement. Recommended instrumentation includes direct contact electronic pressure transducers, bubbler/isolated pressure transducer combinations, and electronic ultrasonic water surface level sensors. The bubbler and pressure transducer are located in the flow stream, whereas the ultrasonic level sensor is a top-down sensor that measures the distance to the water surface from a mounting location in the airspace above the flow path.

All of these level sensors provide reliable operation and are capable of sensitivities of ±0.1 inch in typical applications.

Water Quality Sampling for Analytical Characterization

Because of the time variation of both flow rate and water quality constituent concentrations that occur in stormwater runoff during storm events and in the outflow from treatment structures, pollutant control performance monitoring requires the collection of flow-weighted composite samples over both the inflow and outflow hydrographs. Additionally, if dry weather inflow is present, inter-event (between storms) flow monitoring and sampling is required for on-line structures such as wet-detention basins in order to quantify water quality constituent flux under dry weather-baseflow conditions.

Storm Event Monitoring. Flow-weighted composite samples should be collected using an automatic sampler driven by time integrated flow measurements (flow paced) to produce either a single collection container direct composite sample or to produce flow-paced discrete samples in separate containers. Both methods have distinct advantages. Direct compositing allows for frequent flow-paced samples to be taken over a storm hydrograph to assure development of an event mean concentration (EMC) composite that is based on many sample aliquots throughout the rising, falling and peak flow periods of the runoff hydrograph or treatment structure discharge hydrograph. Laboratory analytical costs are minimized in comparison to discrete sampling since only a single composite requires analytical characterization.

In comparison, discrete sampling allows the characterization of pollutograph effects during storm events because the individuality of each flow-paced sample aliquot is maintained by separate containers. This permits water quality constituent characterization of each individual sample to identify the time variation of concentration (pollutograph) and/or the mathematical compositing of individual sample aliquot analytical values to produce EMC values. This method also allows for the flexibility to prepare a flow-weighted, manually composited sample from a portion of the individual sample aliquots and reservation of the aliquot remainder for individual analytical characterization. As an example, this approach can be used to produce pollutographs for lower cost indicator parameters such as conventional pollutants and making a manual composite EMC determination for the more costly toxic organic constituents.

A good target for hydrograph water quality constituent characterization is to collect aliquots over at least 80 percent of the total storm hydrograph volume.

VOL 12

7879

R0041185

The initial sample of treatment structure inflow should be collected early in the rising limb of the hydrograph to capture any initial flush effects. Automated sampling systems incorporate the ability to initiate sampling at a predetermined depth level and to convert level into flow rate for flow-paced sampling throughout the inflow or outflow hydrograph. The pacing of sample collection should be based on anticipated storm runoff volume conditions. This can be accomplished by developing a table of flow-pacing rates (i.e. cubic feet of flow/ sample aliquot) as a function of anticipated rainfall amount to produce the desired direct composite volume or number of discrete sample aliquots. It is important that the sample aliquot collection rate not exceed the mechanical capacity of the automatic sampler. Typically, samplers can cycle (system purge and sample collection) as often as once every 60 seconds. It is also recommended that a minimum of eight (8) aliquots be collected of treatment structure storm related inflow and outflow for meaningful EMC or pollutograph characterization. It is best if these samples represent the initial, peak and recession regions of the hydrograph.

Since treatment structure outflow rates are attenuated from inflow rates because of storage volume dampening, outflow hydrographs can be extended over significantly longer time periods than inflow hydrographs, so sample aliquot collection must occur over a longer time period.

It is recommended that minimum analytical characterization include TSS, BOD, COD, nutrients (total phosphorus, dissolved phosphorus, TKN, NO_3+NO_2), and total and dissolved metals (copper, lead, zinc, cadmium).

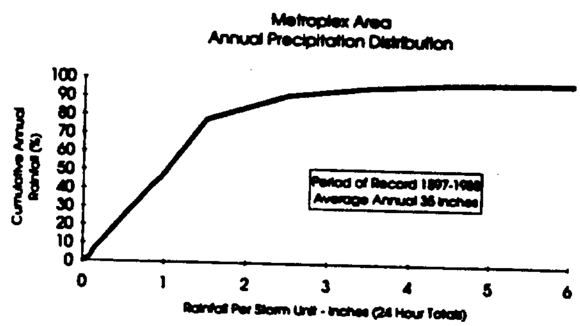
Inter-Event Monitoring. For wet-detention basins, significant outflow flux of algal materials and associated oxygen demand, nitrogen and phosphorus can occur under inter-event baseflow conditions. Therefore, for structural treatment basins which are subject to significant inter-storm event baseflow throughput, it is important to gain an understanding of water quality constituent flux during these low flow periods. This can be accomplished by collecting weekly or daily inflow and outflow flow composite samples during inter-event periods using the same automated monitoring system put in place primarily for storm event monitoring. Sample collection flow-pacing parameters can be reset during inter-event periods to collect adequate characterization samples. These long-term inter-event monitoring activities typically target a limited number of indicator pollutants.

VOL 12

7880

<u>Monitoring Period of Record and Storm Event Distribution</u>

It is desirable that the monitoring program include a distribution of sampled events that is representative of the average annual rainfall event depth distribution. The following figure is an example 24-hour total rainfall event distribution for Dallas, TX which illustrates that 50% and 90% of average annual rainfall occurs for storms of a depth less than 1 inch and 2½ inches, respectively.

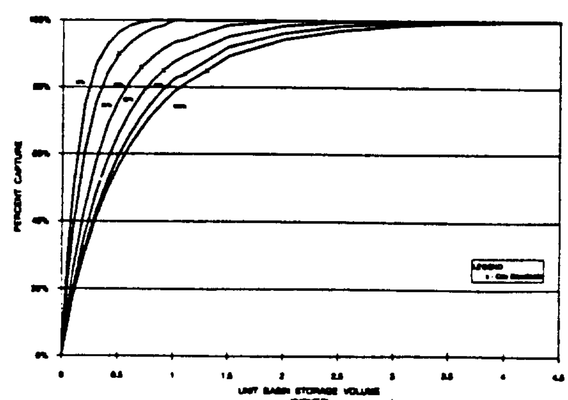


Having actual monitored event-specific rainfall data at hand, the investigator can make astute decisions on future target storms for priority monitoring, or to assess what the previously accumulated control performance data set represents with respect to average annual conditions. Target storm identification should also address identification of seasonal storms (wet/dry, winter/summer) for monitoring through review of long-term monthly average rainfall totals.

Although it is always desirable to acquire as much treatment structure inflow and outflow data as possible, allowable study time and fiscal constraints must be considered in setting realistic data acquisition targets. It is recommended that monitoring programs target acquisition of between 10 and 20 storm event inflow/outflow and baseflow data sets over a two- to three-year period. In the urban land use environment, storm depth must typically exceed 0.2 inch before sufficient runoff/inflow is produced to allow treatment structures inflow/outflow automated sample collection. Of course, this generalization is influenced by site-specific land use/impervious cover conditions. The collected treatment performance data should be reviewed for consistency (i.e. good inflow/outflow water balance, storm volume characterization >80%) and representation of local hydrologic conditions; then, judgements made for future monitoring data needs as necessary.

Effects of Treatment Structure Overflow and Bypassing on Monitoring Requirements

Treatment structure overflow and bypassing impact long-term pollutant control performance. Off-line structures such as extended detention basins and filtration basins are designed to isolate and treat a specific design volume of stormwater runoff. Runoff volumes which exceed the storage volume capacity of the structure are bypassed untreated. In assessing the long-term control performance of off-line structures, bypassing must be taken into consideration. To illustrate this impact, the following figure presents annual capture efficiency curves for off-line basins with 40-hour basin drawdown as a function of storage volume and tributary area percent impervious cover.



These curves were developed for Austin, TX using 50 years of hourly rainfall data and field-verified runoff coefficients. The percent of annual runoff that is not captured is bypassed untreated. This can be addressed in a monitoring program by conducting inflow/outflow water balance calculations to quantify bypasses, or a third flow monitor can be installed downstream of the off-line flow splitter to quantify bypasses directly.

As previously mentioned, wet-detention basins typically function in an on-line configuration and, as such, all surface discharge from the basin is overflow. Since hydraulic residence time affects the dissolved pollutant conversion processes associated with rooted plant and algal biological uptake, water column chemical conversion, and water column/sediment interaction, it is important that performance monitoring programs target a range of storm event and inter-event sample collection activities to address this highly varied range of basin operating conditions. This is important in order to establish the average and expected variation in control performance under the influence of the local hydrologic cycle. For example, extreme events which produce high flow rates can resuspend settled materials and produce "negative" pollutant removal efficiencies, hydraulic short-circuiting of flows can occur if basins are designed without sufficient baffling or length to width ratios and, thus, greatly reduce pollutant control performance. Additionally, inter-event flows can convey significant pollutant mass loads.

Also, dry basins such as extended detention and filtration basins which are configured on-line are also subject to resuspension/washout during extreme storm events and target storms for the monitoring program should attempt to quantify this occurrence. *Therefore, the performance variability associated with on-line treatment structures is much higher than off-line systems and this should be addressed through more extensive monitoring plans.*

Data Analysis

Basic data analysis for each monitored storm event should include: 1) water quality constituents inflow/outflow EMC determination from the analytical laboratory results in combination with the inflow/outflow flow data if time-paced discrete sample collection was employed, and 2) performance of an inflow/outflow water mass balance calculation to assure that inflows and discharges have adequately accounted for any gains or losses and to make any necessary assumptions. All storm data sets are then used together to calculate period of record pollutant removal control efficiency.

VOL 12

7883

EMC Determination. Determination of EMC is a straightforward procedure. Obviously, for direct composite sampling, the analytical laboratory results are the EMCs. For discrete aliquots that are equally flow-paced, EMC is determined by summing the discrete concentration values and dividing by the total number of samples. Time-paced or variable flow-paced discrete aliquots must be mathematically weighted by the percentage of total flow each represents over the hydrograph.

Water Balance. Inflow/outflow water balance calculations allow the investigator to determine if flow monitoring equipment is operating accurately and to account for miscellaneous inflows and losses such as groundwater infiltrative losses or gains, evaporation in wet ponds, and any tributary drainage area between the inflow and outflow monitoring locations. Each of these considerations is site-specific; however, water balance accounting and subsequent follow-up investigation and subsequent assumptions to establish the fate or source of flows and associated water quality constituent loads is important when establishing accurate pollutant load reductions for treatment structures.

Pollutant Control Performance. Ideally, monitoring studies will generate a flow and water quality constituent database consisting only of paired inflow and outflow data resulting from the same storm events or baseflow periods. For characterization of long-term control performance, it is important that evaluation be based on long-term data (multiple years) which quantifies pollutant loadings at the inflow and outflow points over a wide range of hydrologic conditions. Although single event removal efficiencies can be calculated, it is strongly recommended that long-term inflow and outflow records be combined to establish representative long-term performance.

Calculation of Removal Efficiencies. The effectiveness of treatment structures is usually expressed as an efficiency in terms of the relative change between input and output of the structure. As an equation, it takes this form:

$$\text{Efficiency} = \left(1 - \frac{\text{output}}{\text{input}}\right) \times 100$$

There are several methods for developing removal efficiencies. Each method is dependent on the monitoring arrangement for the treatment structure site, as well as the suitability of the data set for analysis.

VOL 12

7884

Where possible, paired inflow and outflow storm data should be used in computing pollutant removal rates for the selected constituents. Before calculating removal efficiencies, it is useful to assess the monitoring data and eliminate storms with anomalous data. Data inspection can be performed graphically (histograms, box plots, scatter plots, etc.) and/or through the use of simple statistics such as mean, median, standard deviation, and coefficient of variance.

Data should be reviewed for any inconsistencies between inflow and outflow volumes and concentrations. A storm may be eliminated if there are documented monitoring problems. Note other outlying data points and eliminate those events from analysis.

Long-Term Removal Efficiency. Of greatest interest to engineers and planners is the typical long-term removal efficiency for a given treatment structure, since the variation in efficiency for individual storm events can often be significant. Mass loadings measured entering and leaving the pond over the entire monitoring interval are summed separately and evaluated using the formula:

$$\text{Efficiency} = \left(1 - \frac{\text{total outflow load}}{\text{total inflow load}}\right) \times 100$$

This method is only appropriate for storm events and baseflow periods with paired inflow and outflow data which exhibit an accurate flow balance. Significant error can be introduced by using unpaired data and/or data records which have significantly different inflow and outflow volumes (poor water balance).

Median Loading Rate Reduction. Past experience has shown that most runoff processes are lognormally distributed and that comparisons of the median values will provide an adequate estimate of the pollutant removal efficiency. An alternative approach for calculating removal efficiencies also uses the entire paired storm data set generated at each monitoring station. In this method, the event mean concentration (EMC) for each storm is multiplied by the total storm flow. Statistically analyze the entire population of inflow and outflow storm loads for all events to determine the median storm event loading at the inlet and outlet of the treatment structure. Removal rates are computed using the following formula:

VOL 12

7885

R0041191

$$\text{Median Efficiency} = \left(1 - \frac{\text{median outflow load}}{\text{median inflow load}}\right) \times 100$$

Accounting for Bypasses. To estimate control performance for off-line treatment structures, the effects of bypassing must be taken into consideration. If the inflow and outflow monitoring data is solely for the treatment structure and does not include quantification of bypass flows, then long-term pollutant control efficiencies should be reduced based on estimates of percent annual runoff bypassed developed from estimates of percent annual capture for treatment as presented previously. Using this technique, measured basin efficiency is reduced by the product of basin average annual runoff volume capture fraction, as follows:

$$\text{Actual Efficiency} = \text{Basin Efficiency} \times \begin{matrix}\text{Annual Runoff}\\ \text{Capture Fraction}\end{matrix}$$

Summary

Monitoring the pollutant control performance of structural treatment controls for stormwater runoff quality management is a complex process which requires simultaneous measurement of flow rates into and out of the structure, with concurrent collection of water quality samples. Typically, monitoring stations must be retrofit to existing inflow and outflow structures and site physical constraints may not allow for "ideal" flow metering conditions to be attained. Under these conditions, development of *in situ* primary flow measurement device rating curves is recommended. Also, if there are significant water gains or losses between the inflow and outflow monitoring locations, flow and quantity estimating techniques should be employed to "close" the water balance for each monitored event or monitoring period if baseflow is included.

In comparison to off-line structures, on-line structures require more extensive monitoring to characterize performance under the normal range of hydraulic residence time variations and both extreme storm high flow and low flow dry weather conditions to which these devices are exposed under local hydrometeorological conditions. Off-line structures, while not subject to the full range of hydrologic variation of an on-line device, do allow bypassing of untreated runoff in excess of basin storage volume. Bypass must be taken into consideration when establishing effective pollutant reduction efficiency for off-line devices.

Establishing long-term pollutant control performance for structural treatment controls requires a long-term paired inflow and outflow database. There are no shortcuts. Monitoring plans should consider the local average annual depth distribution of rainfall events to identify "target" storm magnitudes and wet/dry seasonal differences. Dry weather baseflow, if significant, requires a sampling plan for inter-event periods to quantify pollutant inflow/outflow flux during non-storm periods.

Control performance should be evaluated based on reduction in water quality constituent mass loads from long-term paired inflow and outflow data sets with good water balance data or with water balance resolved through accounting estimates for water quantity and quality.

SESSION VIII: Protocols for Monitoring Non-Structural BMPs

DISCUSSION

Monitoring BMP Effectiveness at Industrial Sites
Roger Bannerman

Site selection required so that each area tested drains to a single inlet.

Testing of sampling methods showed that flow composite, time discrete, and time composite sample gave nearly identical values of geometric means for constituents, but first 30 minutes sample was always higher (first flush).

Reproducibility of first 30 minute samples turned out to be poor.

Conclusions:

- If sampling is close to the source, Source Area Method of sampling is best.
- If sampling is at end-of -pipe, Time Composite Method is best.

Questions/Comments

Question: Did list of industries include industries only or construction also?
Answer: Industries only.

Question: How many samplers are being built and who is going to pay for them?
Answer: Still need to test these and see how many are needed per site for reproducibility. Expect cost to be about $750/sampler. Industry will bear the cost.

Question: Why was H flume selected over others?
Answer: Provided better flow conditions, and cost was not a factor. Flume was calibrated, and they found the manufacturer's curve was wrong. Had to develop our own rating curve.

Question: With source area samplers is plugging a problem?
Answer: Yes that's a problem, but with redundant samplers, not all of them plug.

Question: Do heavy solids go in and light solids not? Is there a size preference?

Answer: We will look at this more carefully, but have assumed that it is not a problem.

Comment: (Bannerman) We were surprised that timed composite samples gave comparable results, at less cost. A practical exercise to find most economical and easiest method which still gives reasonable results.

Monitoring of Wetlands, Wet Ponds, and Grassed Swales
David Green, Thomas Grizzard and Clifford Randall

EPA has not established standard protocols for field methods using remote sampling/analysis. Problem is measuring multiple inflows, identifying a pollutant of concern, and recognizing that pollutants aren't removed from the system, but simply change medium.

There is no QA program for monitoring BMPs. A QA program should be developed in order to lend validity to findings. Need to integrate QA and QC.

Need QA practices for sensor validation and time controls. Account for drift over time to establish precision and accuracy.

Must include short duration, high intensity storms, which carry a lot of TSS and other pollutants.

A long term data record of pollutant flux in and out is necessary to determine BMP efficiency.

Calibration of flow measuring devices is a must using dilution methods like salt or dyes, injection methods, etc..

Flow weighted composite samples are preferred.

Questions/Comments

Comment: One of the most difficult parameters to measure is rainfall. Storms have preferential directions, and rain gauge network must be oriented to allow for this. There are models which can interpret what a storm looks like from a limited set of samples. Radar measurements my be a solution.

Comment: Remember that in assessing BMPs, it is the flow hydrograph, not the rainfall, that drives the system.

Comment: Caution on use of lithium chloride for a tracer. Be certain it gets adequate mixing (this is true of any dye tracer), or it will selectively absorb to solids

Comment: Need to check the equation for mass flux.

Comment: BMPs include structural controls and non-structural controls -- usually thought of as source controls; but some source controls use structures as part of the control, e.g. building covers over chemical storage areas, or spill containment devices, and one always wonders if a swale or buffer strip is a structural or non-structural control. Therefore, it is recommended that we cease to use the terminology "structural" and "non-structural" controls, and instead use the terminology "source" control BMPs and "treatment" control BMPs.

Comment: (Green) Not taking the step of doing toxicity testing - instead are measuring total metals.

Monitoring the Effectiveness of Structural BMPs
George Oswald and Richard Mattison

To adequately monitor these devices, an automated sampling station must be used.

Cannot ignore a water balance around the BMP.

Questions/Comments

Comment: I am glad to see that you recommend use of modeling to evaluate BMP performance.

Comment): (Huber) Using a model to help develop monitoring protocol is a good idea.

Comment: Temperature should be considered - not difficult to collect the data (available from pressure transducers that are temperature compensated!).

Question: Should quality of flows that are bypassed during large storms be monitored?
Answer: No, it is the same as the inflow upstream of the diversion.

Question: What about measurement of temperature?
Answer: Can't recall if temperature is measured.

VOL 12

7890

Comment: There is some disagreement about whether event-by-event measurement is the way to go. Some believe that we should do probability distributions on the inflow and the outflow; the difference is the efficiency. Oswald believes paired data is the proper way to measure efficiency.

Question: What is the accuracy of the electromagnetic flow measurement device?

Answer: They rely on turbidity and bubbles and are good, but require calibration.

7891

VOL 12

7892

SESSION IX: Closing Session

DISCUSSION

There were no formal papers in this session, but the following summarizes closing remarks, as well as questions/comments from the participants.

Mike Cook

Flexibility versus direction - best is probably clear direction combined with flexible implementation:

- Maximum extent practicable - needs definition.
- Water quality standards - depends on CWA, but if no reauthorization, will be considering again, as a matter for EPA policy.
- Monitoring requirements - watershed approach/indicators, are good ideas, but what should be emphasis? In long run shift away from loadings and more toward watersheds and national indicators.

Monitoring - EPA is probably requiring too much, and some monitoring could be redirected to watershed protection. EPA should require less chemical and more biological monitoring. We need to develop measures that give confidence. Expect that this will be an important subject at the next conference.

BMPs - There is, in effect, widespread experimentation. We need much more engineering work on design, performance, and cost-effectiveness.

Illicit connection programs are well developed.

Broader federal action needed on:

- Diazinon

- Copper from brake pads
- Atmospheric deposition - nitrogen in lakes, maybe pesticides; need liaison with air programs.
- Need standardized approach to research and reporting - something like that proposed by Ben Urbonas.

Selling the program:

- Need indicators of progress in short term.
- Clear targets and measures - not sure EPA should set them; initially may be left to state and local permit writers, nationalizing them later.
- Outreach to electorate and elected officials.
- Citizen monitoring could have a place with proper direction, which increases their interest; such monitoring is spreading rapidly with emphasis on a watershed approach.

Future directions - Documenting Performance of BMPs and Monitoring Techniques

- Effective BMPs and monitoring are heart of success
- Funding should come from regulated parties; not more money, just use for more coordinated effort.
- Set priorities for evaluating BMPs and monitoring - by regulated parties.
- Agree who will do what - by regulated parties.
- Agree on format and medium for communicating results - by regulated parties.
- Ensure peer review - by regulated parties.

Future directions for EPA:

- Better training on the flexibility (in monitoring requirements/programs) that exists in current regulations.
- Support studies of BMPs and monitoring - 104b(3) was hard to get through Congress but being well used.
- Identify indicators of progress.

- Integrate stormwater management into watershed approach.

Christine Andersen

The greatest difficulty we face is that we are learning while we are doing.

Issues of monitoring driven by:

- Need for understanding of the system we are trying to regulate.
- Regulatory requirements.

The best solution is for regulators and regulatees to work together, but since we are learning as we go, this has been problematic.

Water quality standards are a red herring - such standards not used in Canada and New Zealand. They are an energy drain, and are not supported by anybody as being cost effective, which harms communication between regulators and the regulated community, and confuses what research should be done.

What we're talking about with BMPs is not the elimination of pollution, but rather changing the disposal means.

BMP monitoring is important. We need a better mechanism to report information (including standardized reporting) so it can be widely used. Would like to see focus of energy, using resources going into municipal permits to generate this information, especially information on how we have improved the environment - relate any performance information back to resource gain. Utilize resources so that required information in permits supports research efforts, and vice versa.

Source control most critical fundamental need. Analogy to what lead-free gas did for us - federal action could help here. Would avoid dilemma about groundwater as we install stormwater retention facilities - need to understand before communities go heavily into this.

VOL 12

7894

Funding constraint at local and state levels is impediment to goal of better environment. Funding situation is often worse than EPA's, but EPA is in the driver's seat with NPDES.

Need flexibility on both sides.

Larry Roesner

Throughout the course of this conference, it has become increasingly apparent to me that the course we are taking with the NPDES stormwater permitting program is going to cost municipalities a lot of money, but is not going to result in any significant improvement in the quality of our urban receiving water systems. This is due principally to the fact that the control strategy singularly targets chemical constituent reduction in urban runoff. It completely neglects the effects of flow on ecosystem integrity, and relies on presumed, rather than documented, cause-effect relationships between chemical concentrations in stormwater and damage to, or degradation of, the receiving water ecosystem.

I strongly believe that reestablishment of urban streams can most cost-effectively be accomplished with the following prioritized approach.

- Reestablish aquatic habitat and implement flow management in urbanized areas. Our urban streams have been decimated by past and present drainage, which is concerned with flow control only of the large storms - those that occur with a recurrence interval of 5 years or more. To re-establish aquatic habitat requires that the pre-development frequency distribution of runoff peaks for small storms must be reestablished in urbanized areas, and preserved in developing areas. This means drainage controls for new development that require control of the runoff from all storms, large and small. In existing areas, some control may be provided by instream flow controls for small storms such as drop structures that retard velocities and provide in-stream storage. Bank stabilization and habitat creation are other practices that should be investigated.

- Apply housekeeping (source) controls on new and existing urban areas and treatment controls on new development. It seems that toxic concentrations do occur in stormwater, but there is a question about the degree of stress they cause because of the short-term exposure of the biota to these toxicant concentrations. Our inability to show cause-effect relationships between urban runoff quality and the health of the biota is for one of two reasons: Either the flow impacts of urbanization are so great that they overshadow the adverse chemical effects, or the adverse chemical effects are, in general, small. Until we know, we should not expend large sums of money controlling the chemical quality of urban runoff. These dollars should go instead toward recreation of habitat in the urban receiving waters. Control of chemical pollutants should be limited to source control through good housekeeping practices, which includes spill management, removal of illicit connections, and control of illegal dumping into drainage systems.

- Establish a public awareness/education/participation program on urban aquatic ecosystem improvement and management. Unless the public supports the protection and enhancement of urban stream environments, it will never happen. The public must police itself with regard to proper chemical handling, litter, and illegal dumping, both at home and at work. Education and awareness are key ingredients to achieving this, and should be a priority program for municipalities.

- Develop baseline sampling programs to document improvement in the ecologic system resulting from the above activities. The NPDES stormwater monitoring requirements need to de-emphasize chemical monitoring and add bioassessment and habitat assessment. We should adopt a chemical parameter list similar to that proposed by Eric Strecker in the Session VI workshop, and turn our attention to bioassessment and habitat assessment. Eric Livingston is developing an excellent protocol; or maybe we can use a simplified procedure, such as the one suggested by Earl Shaver and John Maxted, for use in urbanized areas that will give us direction for short term improvements in urban aquatic systems. Receiving water sampling should emphasize:

- Standard biological surveys on a biannual basis to document improvement or degradation in the aquatic ecosystem.
- Some tissue sample analyses for selected toxic or carcinogenic constituents that bioaccumulate and are known to be present in stormwater.
- Sediment sampling for selected constituents known to be in stormwater to trace illegal connections and/or dumping, and to monitor trends in sediment concentrations of herbicides, pesticides, PAHs, etc.

This information can be used to develop targeted enforcement actions to protect and/or enhance the quality of receiving water ecosystems.

In order for this approach to work, the permitting and enforcement approach of federal and state agencies must change fro a command and control approach, using strict effluent limits and technology-based permit language, to a softer approach where compliance is measured in terms of documented improvement in the aquatic ecosystem. Permit criteria for judging the success or failure in achieving permit goals should be negotiated with the permittee, and should include such things as biodiversity indices, and limiting or reducing chemical concentrations in animal tissues and sediments, as required to protect human health and the ecosystem. To accomplish this, permit writers will need additional training and experience to deal with the technical and administrative complexities that are inherent in such an approach. I see no other affordable way to improve our urban receiving water systems.

<u>Comments/Questions</u>

Comment: It seems that if EPA is to be successful, the key person is the local administrator. These administrators need to be viewed by the public as in charge of a local effort to improve the environment.

EPA needs a complete restructuring - combine various wastewater programs rather than continue the present balkanized system.

EPA should demand and support local water management as a unified effort.

Comment: Oregon has a state committee, like the one in California, which is pro-active and which goes to the state legislators with recommendations on what the state regulations should say.

Comment: Agree with enforcement comment, but how to get the message across to those who do enforcement? They need to be in the loop in a positive, rather than just punitive, way. What is the reality of what is achievable?

Comment: Communication gaps between regulators at different levels a problem. EPA would appreciate advice on how to improve permit writer training.

Comment: Disagrees with statement that EPA should not set standards.

Comment: Agrees with shifting money from monitoring to good housekeeping.

Comment: Our city has <100,000 population, so we are not regulated yet. We do have, however, the same goals as the law - to improve the environment.

It is important to integrate urban watershed managememt into stormwater, rather than vice-versa.

The one place we get a lot of support is with public education. It is more profitable and less costly than BMPs.

Comment: Suggest a national demographic analysis/survey - show who's there and what's exposed (in a chemical or water quality sense). This could be done through EPA.

Note also that we've gotten into some CSO concepts, and we need to look at which, if any, of those concepts are applicable to stormwater. In this light, could include treatability studies - implies stormwater treatment. Should we accept dry weather flow in treatment plants? Should we use pipes for storage? Should we put in flow control devices?

Comment: Treatability analysis of runoff is needed, maybe using innovative settling velocity procedures.

Comment: We should shift more to biological criteria; need to be cautious since big chemical increases could occur without being noticed.

Question: Will flexibility in monitoring requirements filter down to permit writers?

Answer: (Mike Cook) - already exists and will try to emphasize to permit writers, especially biological vs. chemical monitoring.

Question: On the tie between monitoring results and enforcement, can it be written in to avoid use of results in third-party law suits?

Answer: (Mike Cook) - Does not know of any permits being written that will require monitoring results to be used in enforcement.

Comment: EPA should restructure program to integrate all of wastewater management; should require states to develop comprehensive basin management plans; EPA should redirect 319 funds to support this.

Comment: Regulated parties could develop compliance check lists without waiting for regulator.

VOL 12 7899

Comment: Florida has not found any BMP negatively affecting groundwater, but is site-specific and the potential for problems should not be ignored.

Comment: Florida has almost never found hazardous waste problems in residues, but also is site-specific and can't be forgotten.

Comment: We need to get quantitative data on effectiveness of source controls.

Comment: Supports data collection for evaluating source controls, and for setting up pilot areas to apply source controls and monitoring - Portland, OR is planning exactly this.

Comment: EPA should have general monitoring requirements but leave it to local government how to allocate monitoring resources to chemical, physical, biological.

Comment: Should integrate water quality, habitat, and flood control efforts.

Comment: Use education and other source controls, if they will work, rather than building unneeded (and expensive) structural controls.

Comment: Would like coverage of the ad-hoc session on relationships of watershed conditions and aquatic ecosystem response (Editor's note - this has been included in proceedings).

12 programs doing it - should pull together what is in the literature already.

Comment: Residuals are a problem that we need to learn how to manage.

Comment: Pathogens are a big unknown; need to determine the correct indicators and epidemiology; also need to look at viruses in groundwater.

VOL 12

7900

VOL 12

Comment: How do we do drainage design in new areas?

Comment: Water reuse is important and needs to be studied and made more prominent.

Comment: Need better understanding of cause and effect (biological) in order to know what to treat.

Comment: Common pesticides have not been looked at in stormwater. Is diazinon an outlier or the tip of the iceberg? Quality control is very important because pesticide manufacturers will take a lot of interest. Concluded that source control is the only way to go with pesticides.

Comment: We can use event-based monitoring to test BMP effectiveness, but can't use this approach to see trends. Biological monitoring should be regarded as long-term strategy. Questions Cook's recommendation to use in short term, except as political strategy.

Comment: Should consider increased joint use of monitoring and modeling (reinforced by another comment). Can also use modeling to help you determine what to monitor.

Comment: Support for standardizing what we report and how we do it, but not much said about standardizing data bases, which is also necessary.

Comment: Need to learn how to maintain BMPs, especially for mosquito prevention.

Comment: Should standardize statistical approaches.

Comment: Industry can be involved in documenting BMP effectiveness, especially source controls. Industry can also help in standardization. Need to determine standards for selection of outfalls to be monitored when there are multiple discharges. Need to share costs of rain gages

7901

among public and private sources. Industry should work with regulators and public on bioassessments. Industry can also help in education.

Comment: Source control was endorsed over structural BMPs by a large vote.

Comment: Public education should build on existing programs.

Comment: If we standardize reporting procedures for BMP assessments, should this group be a focus for reviewing and disseminating results?

Comment: There is a lot of overlap in studies (some overlap needed because of site-specificity), but should we set priorities and then allow local authorities to could select from these as long as procedures are standardized?

In the San Francisco Bay area, 5 programs now coordinate monitoring and meet with regulators to set priorities and minimize overlap. Parts of the monitoring program are allocated to various participants.

Comment: During the interval between these conferences we could recommend that the UWRRC sponsor sessions (at least annually) at other related conferences (WEF, WRPM Div. of ASCE).

Comment: Issue of fairness in monitoring should be addressed. Measure close to the source or at the outfall? Need to decide the best approach, assuming the goal is to get contaminants out of the receiving waters. Recommend monitoring close to the source (although this may be unfair to industry).

Comment: Enforcement should consider rewards, not only punishment; an example of incentives and punishments exists; regulator could adopt an attitude of helpfulness, as is the case in other countries.

Comment: What we need out of conferences is a synthesis of what we have learned and what we should do next - what is our level of knowledge (and uncertainty), and where are we in various areas. For example, we learned that we don't have to redo NURP.

Comment: Need specific recommendations on water quality standards applied to stormwater. We may be better off with such standards if they can be made appropriate. Also, agreement with earlier comment that existing water quality standards are an impediment.

Comment: Most permit holders will never hear what we have learned, and it is up to EPA to disseminate. NPS News and Notes could be the vehicle.

Comment: Regulators will never solve the problem of "pointless personal pollution." There is an initiative to learn how to change behavior (National Geographic NPS Forum).

Comment: It is disappointing how poorly we have articulated the NPS problem and solutions. Without it we can't achieve our goals.

CHAIRMAN'S CLOSING COMMENTS

How do we communicate what we have discussed this week? The Proceedings will convey the presentations and summaries of the discussions. The challenge to you, the attendees, is to further expand the information learned in a way that goes beyond what is contained in the Proceedings.

Regarding Mike Cook's challenge to the UWRRC to coordinate research activities; not determined how we will do it, especially flow of money. This is a step in right direction. NAFSMA is very interested and represented by managers; they are hopeful that we, the Urban Water Resources Research Council, can join with them and APWA.

Tremendous progress has been made in finding illicit connections thanks to Field's and Pitt's efforts; nevertheless, issues still remain on eliminating these connections.

I believe we have characterized runoff well enough, and don't have to do more in small cities. Any further activity along these liens will not reveal anything new.

Everyone is afraid of compliance monitoring for stormwater discharges - afraid the effort will be concentrated on end-of-pipe monitoring (which would only be a rehash of the current water quality stormwater characterization).

Monitoring of receiving waters is the toughest problem - we've already seen regulatory requirements which do nothing to improve the environment. Need to develop protocols for biological, chemical, and physical monitoring. Protocols should not be specifically dictated but set appropriately for each site. Need multidisciplinary approach.

Reiterated systemization of reporting, but not suggested for compliance monitoring.

Finally, it should be pointed out that the attendees at this conference have training and experience that far exceeds that of the majority of the people in the field. This fact alone makes conferences such as this vital sources of information for practitioners. It is equally important for us to devote some resources to the training of our own professionals.

APPENDIX A

POSTER SESSION

This Appendix includes all papers originally submitted as poster papers, in addition to those papers received too late for incorporation into the main body of the Proceedings. These papers were accepted without review, although they are still eligible for publication in the journals of the American Society of Civil Engineers.

CDOT HIGHWAY STORMWATER RUNOFF MONITORING RESULTS

Philipp Sieber*

Abstract

Extensive stormwater monitoring efforts have been undertaken by municipalities and transportation agencies. The Federal Highway Administration (FHWA) and the Colorado Department of Transportation (CDOT) have been involved in such monitoring.

Findings and conclusions from the FHWA and CDOT monitoring efforts, and comparisons between the two are presented in this document.

Introduction

The National Pollutant Discharge Elimination System (NPDES) stormwater regulations have required municipalities and transportation departments across the country to recently engage in extensive stormwater monitoring efforts.

The intent of the NPDES regulation is to characterize pollutants present in stormwater runoff. For transportation departments, the above translates to pollutants present in highway runoff.

CDOT compiled highway stormwater runoff characterization data collected in the past by FHWA. In addition, CDOT performed highway runoff monitoring during 1993 in Denver, Colorado.

Background data

Most of the existing background data characterizing highway stormwater runoff is from studies performed by FHWA in the mid-seventies and eighties. These

*Sieber, Water Quality Engineer, Staff Design - Hydraulics, Colorado Department of Transportation, 4201 E. Arkansas, Denver, CO 80222.

studies included monitoring data from 993 separate storm events including 16 events in Denver, Colorado. A summary of the FHWA data (shown as median values for highway site median concentrations) is included in Table 1.

Table 1
Highway Site Median Concentration (FHWA[4], 1990)

POLLUTANT (mg/L)	ADT* < 30,000	ADT* > 30,000
Total suspended solids	41	142
Chemical oxygen demand	49	114
Nitrate + Nitrite	0.46	0.76
Total Kjeldahl Nitrogen	0.87	1.83
Total phosphorus	0.16	0.40
Copper	0.022	0.054
Lead	0.080	0.4
Zinc	0.080	0.329

*ADT = Average Daily Traffic

Highway Stormwater Runoff

FHWA defined common sources, and types of pollutants found in highway stormwater runoff, and these are listed in Table 2.

Table 2
Sources of Common Highway Pollutants (FHWA[3], 1984)

POLLUTANT	SOURCE
Particulates	Pavement wear, vehicles, atmosphere, maintenance
Nitrogen, Phosphorus	Atmosphere, roadside fertilizer application
Lead	Leaded gasoline, tire wear, lubricating oil and grease, bearing wear
Zinc	Tire wear, motor oil, grease
Iron	Autobody rust, steel highway structures, moving engine parts
Copper	Plating, bearing/bushing/brake wear, engine parts, insecticides
Cadmium	Tire wear, insecticide application
Chromium	Metal plating, moving engine parts, brake lining wear
Nickel	fuels, oils, metal plating, bushing wear, brake lining wear, asphalt
Manganese	Moving engine parts
Bromide	Exhaust
Cyanide	Anticake compound used to keep deicing salt granular
Sodium, Calcium	Deicing salts, grease
Chloride	Deicing salts
Petroleum	Spills, lubricants, antifreeze and hydraulic fluids, asphalt
P-chlorinated biphenyl	Pesticides, atmospheric deposition, PCB catalyst in synthetic tires
Pathogenic bacteria	Soil, litter, bird droppings, livestock and stockyard waste
Rubber	Tire wear
Asbestos	Clutch and brake lining wear

VOL 12

7907

The concentration of pollutants in highway stormwater runoff is affected by factors such as: precipitation intensity, duration, and volume; temperature; surface wind speed and direction; highway configuration, design, geometrics, and drainage features; pavement composition, condition, and quantity; traffic characteristics (Average Daily Traffic - ADT); vehicular transported, generated, and deposited inputs; maintenance practices; and surrounding land use (urban vs rural). ADT was identified as one variable having a significant impact on pollutant concentrations.

Some overall conclusions reached by FHWA on highway stormwater runoff and its effects on receiving waters were:

- Highway stormwater runoff for highways with ADT < 30,000, with no curb and gutter design, exerts minimal to no impact on the aquatic components of most receiving waters.
- Annual pollutant loads from highways are low relative to loads from entire watersheds.
- Of five species (mayfly, isopod, water flea, gammarid, fathead minnow) used in acute laboratory bioassays, only the gammarid exhibited a toxic response to undiluted highway runoff.

CDOT Monitoring

Location

Initially, CDOT considered using the same site that had been used by FHWA, which was located on interstate I-25, extending from just south of fully directional interchange with interstate I-70 to Fox street. This site had an ADT of 149,000 with a drainage area of 14.29 Ha. The monitoring period was between August 1976 and July 1977 during which data from 16 events was collected. Using this site was, however, not possible due to the I-25 re-construction work currently in progress where the site used to be.

CDOT therefore evaluated several other alternatives, and selected a new site for the monitoring. The site was located on Interstate 225 (I-225) at milepost 2.25. ADT for I-225 is 95,000. Drainage area for this outfall was 7.59 Ha of CDOT's right-of-way (ROW), starting at milepost 2.35 just east of Cherry Creek and ending at milepost 3.07 further east. The drainage area includes paved surfaces (six highway lanes plus shoulder) as well as vegetated surfaces (median and areas between the edge-of-oil and the ROW fence). Stormwater runoff from this area discharges into Cherry Creek through a 60.96 cm outfall.

The following criteria were used to select the monitoring site:

- Location: The site should be located within the cities of Denver, Lakewood, or Aurora.
- Type of runoff: The drainage area had to be exclusively CDOT's ROW with a minimum or no outside contributions. Also, the conveyance for the highway runoff should not have any connections with conveyances draining water from areas outside CDOT's ROW.
- Safety: The site had to have an area to install the monitoring equipment in such a way that no safety hazards were created for the traveling public, nor for personnel operating and servicing the monitoring equipment.
- Accessibility: The area should have easy access to facilitate sample collection.
- Drainage area: The drainage area for the site had to be 4.05 Ha or more.

Equipment

The following equipment was used for the monitoring:

- Automatic sampler with power supply
- Relay to drive autosampler
- Data logger with power supply
- Data storage module
- Pressure transducer
- Con-a-flow bubbler system
- Rain gauge

Description

Surface drainage for the monitored area is collected by inlets located in the median and the roadway ditch, and is conveyed through a storm drain. The storm drain runs in the median on a 3% slope.

Sampling occurred at the last inlet located in the median, just prior to the outfall to Cherry Creek. The inlet is located at milepost 2.25, 30.48 m upstream from the outfall. Because the outfall is actually located outside CDOT's ROW, it was not possible to perform the sampling at the outfall.

A shelter was constructed to house the monitoring equipment which was installed about 4.57 m from the sampling point.

To provide flow measuring ability, a 60.96 cm Palmer-Bowlus flume was constructed just upstream of the outlet of the storm drain into the inlet. Samples were collected just downstream of the flume.

A base flow existed in the storm drain, however its magnitude was so minimal (0.0001 m^3/s) that it was considered negligible. It was assumed that the source of this baseflow is groundwater seepage into the storm drain.

CDOT contracted with the U.S. Geological Survey (USGS), Water Resources Division, Colorado District Office to perform the monitoring. Most samples were analyzed by the USGS National Water Quality Laboratory in Denver; analysis of fecal coliform, fecal streptococcus, and specific conductance was performed by USGS field personnel; analysis for Biochemical Oxygen Demand (BOD) was contracted with the Metro Wastewater Reclamation District laboratory.

Procedure

According to the regulation, samples were to be collected from three storm events occurring at least one month apart and with a preceding 72 hour dry-period. However, due to Colorado's climatic conditions, CDOT used (with previous approval from the Colorado Department of Health) a variance in the sampling requirements according to the following criteria:

- A 7 day separation between storm events.
- A change in the 72 hour dry-period as follows:

Preceding Storm Depth	Dry Period
≤ 5.08 mm	24 hours
≤ 12.70 mm	48 hours
> 12.70 mm	72 hours

Collected samples were analyzed for the constituents listed in the NPDES stormwater regulation [40 CFR 122.26 (d)(2)(iii)(A)].

From the data collected at the I-225 monitoring site, estimates of annual pollutant loads and Event Mean Concentrations (EMCs) were calculated for the following constituents: total suspended solids, total dissolved solids, biochemical oxygen demand, chemical oxygen demand, total nitrogen, total Kjeldahl nitrogen, nitrate plus nitrite, total phosphorus, dissolved phosphorus, cadmium, copper, lead, and zinc.

Individual EMCs were combined and a runoff-volume-weighted average EMC was calculated for each constituent. The calculated EMCs represent Site-average EMCs for the I-225 monitoring site. These EMCs do, however, not account for runoff volumes lost due to storage, infiltration, or evaporation.

Since CDOT has only one land use (highway), in addition to the Site-average EMCs, the calculated EMCs represent the Land-Use average EMC.

Estimated pollutant loads from the state highway system were estimated for the cities of Denver, Lakewood, Aurora, and Colorado Springs. The pollutant loads were calculated as:

Drainage area × Rainfall × Runoff coefficient × EMC

Drainage areas for the state highway system within Denver, Lakewood, Aurora, and Colorado Springs were calculated based on CDOT's highway database. This database contains information on pavement widths and lengths.

Drainage areas were calculated as:

Pavement width × Pavement length

Information regarding median widths, or edge-of-oil-to-ROW-fence widths, is not available, and therefore was not included as part of the drainage area computations. Only pavement area was used for the calculations. However, the pavement is where most of the pollutants are expected from.

Using criteria established by Urban Drainage and Flood Control District for the Denver Metro area, and rainfall data submitted by the city of Colorado Springs, an annual runoff producing precipitation of 327.66 mm was selected for the four cities.

A runoff coefficient of 0.90, which is standard for paved highway surfaces, was selected.

Results

Table 3 includes CDOT's monitoring results for the I-225 site (only for those constituents that were detected). Table 4 includes calculated EMCs for both the FHWA I-25/I-70 site and the CDOT I-225 site. For comparison purposes, the EMCs for the I-25/I-70 site were also calculated as runoff-volume-weighted average EMCs using the same procedure as the one used to calculate the I-225 EMCs.

Comparison

The I-225 data obtained by CDOT, and the I-25/I-70 data obtained by FHWA are graphically compared in Figure 1.

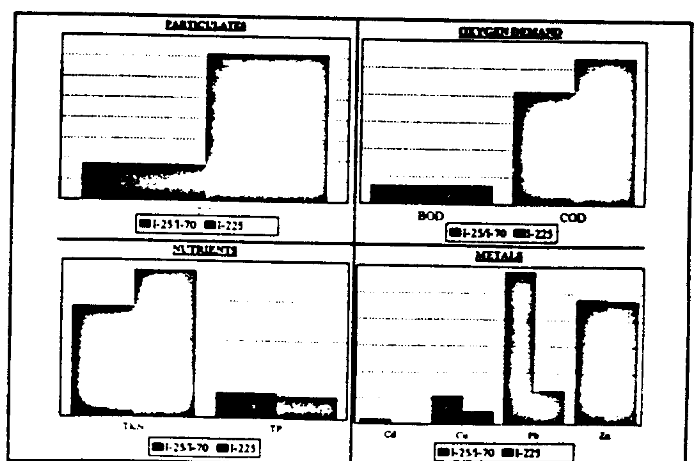

Figure 1: I-225 vs I-25/I-70

VOL 12

7913

By comparing CDOT's data vs FHWA's data it can be concluded that:

- No major differences are observed in oxygen demand or nutrients.

- The most noticeable differences are in Total suspended solids (TSS) and in Lead (Pb).

  The difference in TSS is mostly due to a very high EMC recorded for storm #1 at the I-225 site (2910 mg/L). Values for storm #2 and #3 are much lower (628 mg/L and 114 mg/L) which are more in line with the values recorded at the I-25/I-70 site. The high TSS value recorded at storm #1 could be due to a special condition that day which caused an increase in sediment loads, or it could be also due to a human or mechanical error during the sampling. However, no sufficient data exists which could justify the discarding of this value.

  The difference in Pb is most probably due to the change in gasoline from leaded to unleaded.

- In general, a reduction in metals is observed which could be due to: improvements in refining processes producing cleaner motor oils and greases; reduction in insecticide applications due to environmental concerns; elimination of leaded gasoline; and improvements in tire manufacturing processes.

__Future CDOT Monitoring__

From a regulatory perspective, CDOT does not expect at this time to engage in additional stormwater monitoring efforts for several reasons:

1. Existing data. Much data already exists that characterizes highway stormwater runoff. Additional data will not show different results than those already obtained.

2. Cost/benefit ratio. Benefits of new data will be very low when compared with the high cost of monitoring.

3. Current monitoring efforts by other DOTs. Other transportation departments (i.e. Texas, Washington, Oregon) across the country are still involved in highway runoff monitoring efforts . In the future, CDOT expects to compile this data and compare it versus CDOT's and FHWA's data. After evaluating this data, CDOT will be in a better position to assess any further monitoring needs.

From a research perspective, CDOT expects to engage in monitoring efforts

VOL 12

7/9/14

with specific goals:

1. Goal 1: Monitor three (out of 13) permanent sediment ponds that were constructed as part of CDOT's Straight Creek Water Quality and Erosion Control project. The intent is to assess the efficiency of those ponds in removing sediments in highway and snow-melt runoff, which are caused by sanding from CDOT's winter operations, and by erosion in cut slopes.

2. Goal 2: Monitor highway snow-melt runoff during winter in several locations where various de-icers will have been applied. The intent is to assess impacts to receiving waters from these various de-icers.

Conclusion

CDOT performed monitoring as required by the NPDES stormwater regulation. EMCs and pollutant loads of highway stormwater runoff discharges were estimated.

Data collected during monitoring at I-225 adds more data to that available from FHWA. However, this new data may not be very representative due to the small number of events sampled. According to FHWA: "because of the inherent variability in EMCs, a limited sampling effort consisting of only a few storm events may produce a poor estimate of site characteristics[4]."

Monitoring requirements such as the ones included in the NPDES regulation result in high costs with little benefits due to: the lack of defined and specific goals and guidelines; the existing data; and the high cost of monitoring equipment and sample analyses. It is expected and hoped that in the future, regulatory agencies will assess the above prior to require the regulated community to engage in costly monitoring efforts which will produce little benefits towards the improvement of stormwater quality.

Methods for Assessing Urban Storm Water Pollution

Channy Soeur, P.E., James Hubka, George Chang, P.E[1]., and Steve Stecher, P.E.[2]

Abstract

This paper presents methods for quantifying urban development conditions and characterizing the impact of urbanization on storm water pollution. Based on data collected by the City of Austin (COA), it was found that storm water pollutant mean concentrations can be correlated with development indices and watershed sizes. Use of the arithmetic mean of event mean concentrations (EMCs) to characterize storm water pollution may lead to biased results if the EMC data set is not large enough or not carefully reviewed.

Introduction

The City of Austin (COA) has had several storm water monitoring programs since 1975. The objectives of the programs are to evaluate the impacts of urban development on storm water pollution and to identify Best Management Practices (BMPs) for mitigating these impacts. Based partially on the findings (COA, 1984) of the monitoring programs, the City has implemented a series of watershed ordinances (COA, 1986-92) and protection programs.

Funded by the City's Drainage Utility (COA, 1992), the COA currently has two storm water monitoring programs (COA, 1993). One program is establishing a network of forty-five (45) runoff monitoring stations to test land use and structural BMPs. The other program monitors in-stream storm water quality at eleven (11) creek locations through a COA/USGS (U.S. Geological Survey) cooperative project. Of these fifty-six (56) stations, data for twenty-nine (29) stations were available for this study and are shown in Table 1. This study proposes methods to characterize urban storm water pollution using concentration data and information generated from previous COA studies.

* A normal error regression represents $C = a_1 Q^{a_2}$, where C is instantaneous concentration, Q is the corresponding flow rate, and a_1 and a_2 are regression coefficients.
** R-square is the coefficient of determination. Bold R-square values indicate a significant regression.

Previous Studies

Previous COA studies (COA, 1990) on storm water pollution indicated that for most of the runoff pollutant parameters, there is no significant difference in the average event mean concentrations between residential and adequately-maintained commercial sites. However, some differences exist between undeveloped, residential, and less-maintained commercial sites. The average EMCs for large, mixed land-use, creek basins are generally greater than those of small, single land-use watersheds. Most of the City's creeks are affected primarily by storm water pollution because there are few significant point sources. In order to compute runoff pollutant loads, a relationship between basin runoff coefficient (Rv, the ratio of the average annual runoff to average annual rainfall depth) and percent impervious cover was developed. This relationship can be described by a quadratic polynomial equation (COA, 1992). The equation was substantiated by additional data from this study. In general, a linear approximation of the runoff coefficient versus imperviousness relationship tends to overestimate Rv values, especially for low impervious cover sites. For any low to medium impervious cover site, the single event runoff coefficient generally increases with increasing depth of storm rainfall. The average Rv for this site should not be calculated as the arithmetic mean of all Rv values unless there is a sufficient number (to be described later) of these values. Gilbert (Gilbert, 1987) suggested that the arithmetic mean may be a biased estimation of the population mean if the coefficient of variation of the data is greater than 1.2.

Definitions of Variables

Mean concentration (MC): MC is either the arithmetic mean of event mean concentrations or the flow-weighted mean of instantaneous concentrations for a pollutant parameter for any specific watershed. Flow-weighted mean is the flow-volume weighted average of instantaneous concentrations corresponding to different classes of runoff flow rates (to be further explained).

Percent impervious cover (IC): IC is the ratio of gross impervious area in a watershed to the drainage area of the watershed, expressed as a percentage of the drainage area.

Undeveloped site (UNDS): UNDS is a basin or watershed in which little area has been disturbed by human activity. The ground of the basin is mostly covered by natural vegetation.

Development index (DI): DI is a quantity that represents one or any combination of three variables, including percent impervious cover, land use index, and watershed type index. Land use is classified into five types: undeveloped; single family residential (SF); office or multi-family residential (MF); commercial and industrial (Com/Ind); and roadway. Watershed type means the degree of cleanliness which is determined mainly by the age of roads and structures, and the housekeeping practices in the area. In addition, it may also be identified by the watershed's relative location in the metropolitan area. For the Austin area, the watershed-types are urban, suburban, or rural watershed which correspond to the definitions used in Austin's Comprehensive Watershed Ordinance (COA, 1986).

Mean Concentrations for a Specific Site

The use of the average of event mean concentrations (EMCs) for characterizing storm water pollution for a specific site may lead to biased results if the EMC data are not carefully reviewed and treated. Primarily, it is important to determine whether or not the EMC values represent the average concentrations of the corresponding storm runoff. The majority of the runoff volume (e.g., 80% or more) from a rainfall event should be sampled in order to provide sufficient data for the estimation of an EMC. For any monitored rainfall event, the number of samples should range from three (3) to as many as sixteen (16) depending on the complexity of the hydrograph. An EMC value should not be used if the sampling does not cover the full range of the hydrograph. Secondly, the flow measurement system should be designed carefully and the quality of the data thoroughly reviewed. The measurement of flow in a storm drain system is fairly difficult considering the changing flow conditions during a storm. Inaccurate discharge values can result in erroneous flow volume calculations, which will impact the EMC estimation for the storm. Finally, the flow-weighted mean concentration (FWMC) can be computed as a verification. The FWMC should be approximately the average of EMCs if there is sufficient flow and instantaneous concentration data. In order to calculate the FWMC, the flow rate of runoff should be divided into several classes (e.g., 0.003-0.3, 0.31-1.50, 1.51-3.00, and 3.01-9.00 cubic meter per second). Corresponding to each flow rate class, there is a concentration value and a measurement of percent volume of the average annual flow. The FWMC is the sum of the products of the concentration values and the percent volumes of the average annual flow.

If the average of the EMCs is used to represent watershed mean concentrations, the number of the sampled events should be sufficient to cover the entire range of rainfall classifications. As shown in Figure 1, EMC values decrease with an increase in storm runoff volume. This relationship is not clearly shown unless the number of sampled events are sufficient and the corresponding EMC values are grouped. Also, the EMC values may be dependent on build-up conditions at the onset of rainfall events. Based on the SWMM Manual (U. of Florida, 1988), a COA study (COA, 1994) derived the relationship between load and the number of dry days for specific land uses. As shown in Figure 2, the total suspended solids (TSS) load accumulated at a roadway site is significantly related to the number of dry days before a storm, although there is considerable scatter in the data.

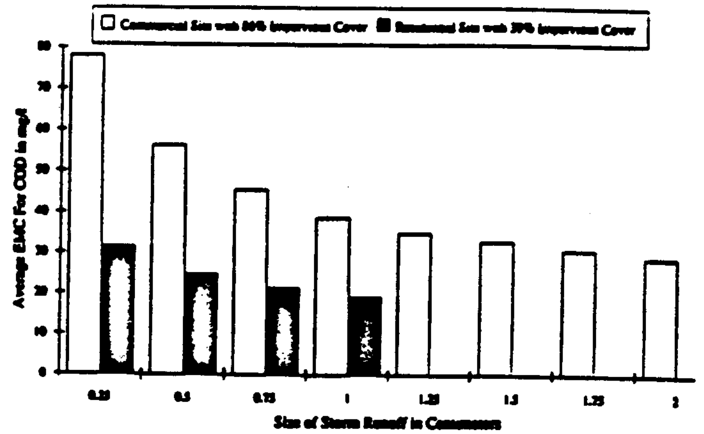

FIGURE 1. RELATIONSHIP BETWEEN AVERAGE EMC AND SIZE OF STORM RUNOFF

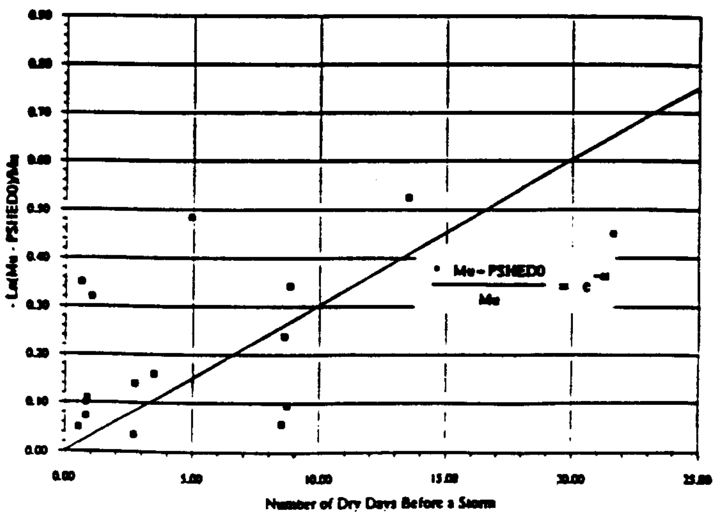

FIGURE 2. AN EXPONENTIAL TYPE BUILD - UP EQUATION DERIVED FOR A ROADWAY LAND USE SITE - FOR TSS

* An exponential type build-up equation (as shown in SWMM manual) was assumed, where Mo is the upper limit of load which can be accumulated on the ground, t is the number of dry days before a storm, PSHED0 is the load on the ground before a storm corresponding to t, and a is regression coefficient.

VOL 12

7920

The EMC values can also vary with the runoff flow rates during rainfall events since the instantaneous concentration for some parameters is related to the flow rate (Table 2). The relationship tends to increase with the increase in of drainage area, and is probably the result of increases in peak flow in relation to both drainage area and growing urbanization. The increases in peak flow typically result in increased channel and bank erosion (COA/ECSD, 1992; Schueler, 1987). If the relationship between instantaneous concentration and flow rate is significant, the mean concentrations of a site should be represented by the flow-weighted mean concentrations. The average EMCs can represent the site mean concentrations only if the EMCs were computed from a sufficient number of storms which cover the full range of flow rates.

For the Austin area, a storm water monitoring period should generally run between two (2) to four (4) years in order to adequately represent the entire range of classifications of rainfall events. Typically this would provide about twenty to thirty (20-30) EMCs. To ensure accurate representation of the different classifications of storm event, the number of dry days before a storm should be divided into a minimum of two (2) classes (e.g., less or equal than two dry days and greater than two dry days) and the size of storm divided into a minimum of three classes (e.g., less or equal than 1.90 cm, 1.91 to 4.50 cm, and greater than 4.5 cm). Therefore the number of combinations of these two factors (the number of dry days and the size of storm) is six (2 x 3). Considering that a minimum of three replicates is needed for each class of events, the number of adequately-sampled events should be at least eighteen (18). For the rainfall conditions in the Austin area, this will require a minimum of two (2) years of monitoring to satisfy. Because of the difficulty of maintaining and operating a large number of monitoring stations, and the potential for drought conditions to occur during the sampling period, this minimum time requirement of two years is typically not sufficient. Therefore it is prudent to plan for storm water monitoring over at least a three (3)-year period.

<u>Derivation of Development Index</u>

The development index (DI) represents watershed development conditions which can be quantified using one or any combination of three variables: percent impervious cover, land-use index (LI), and watershed-type index (WTI). In this study, DI is assumed to be a linear combination of LI and WTI. The following is an example of computation for obtaining DI:

Step one: Develop a matrix of mean concentration (MI) values for the relationship of land-use types to pollutant parameters. Given five (5) pollutant parameters, the matrix is as follows:

VOL 12

7921

Land-use	TSS	TOC	NO_3	TKN	TP
Undeveloped	77	7	0.13	0.32	0.04
SF Residential	151	12	0.70	1.60	0.28
MF Res./Office	97	14	0.63	1.76	0.38
Com./Ind.	216	14	0.61	2.24	0.46
Roadway	320	25	0.40	1.20	0.22

Step two: Standardize all mean concentration values to a dimensionless variable which has a randomly-assigned arithmetic mean and standard deviation (in this example, M = 3, and S = 1.581 for a series of numbers 1, 2, 3, 4, and 5). Using SAS STANDARD procedure (SAS Institute, 1987), the standardized mean concentration is

$$\text{Stan MC} = [(MC - \overline{MC}) / \sigma_{MC}][S] + M \qquad [1]$$

where $\overline{MC}$ is the arithmetic mean of MC values for the five land use types for each of the five pollutant parameters, and σ_{MC} is the standard deviation of these five MC values. Corresponding to the MC matrix above, the standardized MC matrix is:

Land-use	TSS	TOC	NO_3	TKN	TP	Avg.
Undeveloped	1.47	1.23	0.52	0.58	0.68	0.90
SF Residential	2.67	2.42	4.38	3.39	3.06	3.18
MF Res./Office	1.80	2.85	3.95	3.74	3.99	3.27
Com./Ind.	3.70	2.94	3.79	4.79	4.82	4.00
Roadway	5.37	5.55	2.36	2.51	2.44	3.65

The values in the matrix above are the land-use indices for each pollutant parameter. The values in the column labeled "Avg." are the overall land-use indices for each of the land-use types.

Step three: The watershed-type index (WTI) can be derived in the same manner as steps 1-2. In this case the matrix of MC values consists of watershed types (rural, suburban, and Urban) and pollutant parameters.

Step four: Assuming the development index is a linear combination of LI and WTI in the following form:

$$DI = (LI + WTI)/2, \qquad [2]$$

VOL 12

7922

R0041228

then the development index of a watershed can be computed for each of the pollutant parameters in the matrix.

Assessing Storm Water Pollution

The values of mean concentrations and development indices for several pollutant parameters and for all twenty-nine monitoring sites were computed. The pollutant parameters evaluated using local data are total suspended solids (TSS), chemical oxygen demand (COD), 5-day biochemical oxygen demand (BOD5), total organic carbon (TOC), total phosphorus (TP), total nitrogen (TN), nitrite plus nitrate (NO_2+NO_3), total kjeldahl nitrogen (TKN), ammonia (NH_3), total lead (TPb), fecal coliform (Fe. Col.), and fecal streptococci (Fe. Stp.). These are standard parameters considered in assessing non-point source pollution from storm water (EPA, 1983; Shueler, 1987).

Mean concentrations for some parameters such as TP, TKN, TN, COD, and TPb can correlate well with the development indices. As shown in Figure 3, the TP mean concentration for any specific watershed in the area can be reasonably estimated from the development condition of the watershed, i.e., the land-use index and the watershed-type index of TP. Additionally, the percent watershed imperviousness is also an adequate index for estimating mean concentrations for the above mentioned pollutant parameters. On the other hand, regressions of mean concentrations on development indices for other parameters are less significant. As shown in Figure 4, the mean concentration values of nitrite plus nitrate corresponding to the higher values of the development indices vary independently from the development index. There are no significant differences in concentrations among watersheds of all the development conditions except for the undeveloped sites. To further review the data, the NO_2+NO_3 concentrations are generally higher for the SF residential land-use sites, probably because of fertilizer applications.

For the TSS-related parameters such as TSS, TP, TKN, and TOC, the mean concentrations are significantly related to the drainage area of the watershed, as described earlier in this paper. As shown in Figure 3, the relationships between TP concentrations and development indices are represented by two separate regression lines [for watershed size $\leq$ 405 hectares (1000 acres) and $>$ 405 hectares (1000 acres)].

Conclusions

Based on the findings, the following conclusions can be drawn:

1. This study used data collected from the City of Austin's storm water monitoring programs. Although the data is preliminary, its quantity and quality are

VOL 12

7923

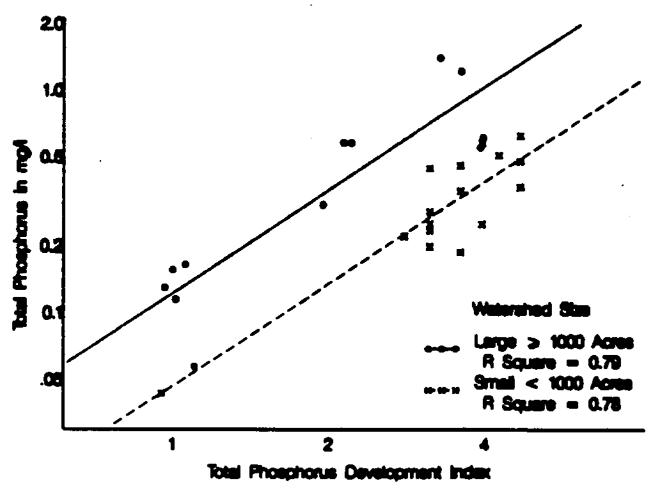

FIGURE 3. RELATIONSHIP OF MEAN CONCENTRATION OF TOTAL PHOSPHORUS TO DEVELOPMENT INDEX

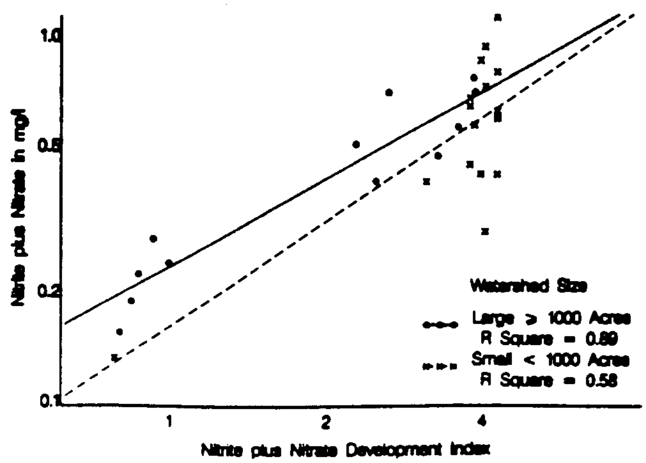

FIGURE 4 RELATIONSHIP OF MEAN CONCENTRATION OF NITRITE PLUS NITRATE TO DEVELOPMENT INDEX

sufficient for the development of a simplified method to characterize urban storm water pollution.

2. The impacts of urban development on storm water quality can be identified by the relationships of watershed mean concentrations to development indices. A development index may be a linear combination of land-use and watershed-type indices which characterize basin development conditions. This index correlates well with the percentage of impervious cover. For some parameters such as TSS, TP, TKN, and TOC, the described relationships also depend on the sizes of watersheds or drainage areas.

3. The use of average EMCs to represent watershed mean concentrations is adequate only if the sizes and antecedent conditions of the sampled events adequately represent the entire range of the rainfall event classifications. It is recommended that the EMC data presented by different organizations not be combined for analysis unless the methods and procedures for obtaining such data are carefully reviewed.

4. The use of arithmetic means to characterize average conditions of EMCs and runoff coefficients may be biased if the size of data sets is insufficient or the coefficients of variation are large (greater than 1.2). This is particularly true in computing the average runoff coefficient for a watershed since the runoff coefficient generally increases with increasing depth of storm rainfall. It is suggested that the population mean of the EMCs or runoff coefficients for any watershed can be best represented by the median, the adjusted geometric mean (Gilbert, 1987), or the flow-weighted mean of the observed EMC or runoff coefficient values.

Practical Experience with Filippi Flow Limiters

Anders Rörholt[1] Dipl. Ing. ETH, WSA, SIA

Abstract

The Filippi stormwater flow limiter belongs to the group of "weirs" of the type "one side overflow weir." The Filippi limiter, due to its specially profiled shape, allows for excellent hydraulic control of flow, but has little effect on solid/particulate separation.

There are many potential applications for the Filippi limiter:

- In combined sewer systems
- Upstream wastewater treatment plants or runoff storage tanks
- Surface water collection (first flushes of concentrated runoff) to be diverted to wastewater treatment facilities.

The excellent hydraulic control is obtained by its unique configuration - venturi channel at the inlet, changes in flow direction, short specially-shaped single-sided overflow edge, and guiding grooves at the outlet to prevent blockage.

The Filippi limiter is patented in most countries, and has successfully been used in various European countries since 1982.

Introduction

Stormwater overflow, overflow weirs, regulators, rainwater overflows, etc. are commonly used technical terms. The most appropriate term to describe the Filippi device is "flow limiter." These flow limiters may not only be used in combined sewers to avoid flooding, but also upstream of wastewater treatment facilities and runoff storage tanks or settling basins. Another potential application for such precise flow limiters would be to divert the first flush of concentrated runoff to a wastewater treatment plant.

[1] General Manager, Tartr-Ex SA, Rte du Châtelard 50 A, CH-1018 Lausanne, Switzerland.

As an active rural engineer, Mr. R. Filippi realized the importance of precise flow limitations at various points in the sewerage systems to improve wastewater treatment, and thus improve water quality. Mr. Filippi began his development work on a flow limiter in 1975, and the Filippi flow limiter was finally patented in most countries in 1982.

The Filippi Storm Water Flow Limiter

Before beginning design, Mr. Filippi defined the following criteria which should be met:

- Flow limiting action with highest possible accuracy.
- Exchangeable - to allow for changes in flow rate over time.
- Shortest possible overall length.
- Blockage- and maintenance-free without moving parts.
- Minimize receiving water pollution.

Mr. Filippi realised early that no theoretical hydraulic calculations would provide a device meeting these criteria, so the development was done on a full-scale outdoor testing apparatus (with all of its inherent shortcomings). The first full-scale testing device was installed alongside a small river near Lausanne, Switzerland. Unfortunately, this device was carried away during a sever storm. The current testing device is installed on the grounds of the University and the École Polytechnique Fédérale de Lausanne. The installation includes a dam with two large manholes for demonstrations and development of additional models.

Testing consisted of a large number of trials and hydraulic testing, which resulted in the development of the first model, designed for a flow through the device of 62 litres per second. Subsequent development resulted in the creation of a total of 15 models, covering a range of flows between 3 and 205 litres/second. Today, there are more than 600 devices, with varying capacities, installed throughout Europe.

The main characteristics which account for the Filippi limiter's excellent hydraulic control are (see Figure 1):

- The venturi channel at the inlet with its two changes in flow direction.
- The specially-shaped "outcaster" which throws out all flow exceeding the design throughput.
- The overflow edge (weir) has a special hydraulic shape which is not horizontal.
- The guiding grooves at the end of the overflow edge (which have no hydraulic function, but which prevent adhesion of debris which could create blockages).

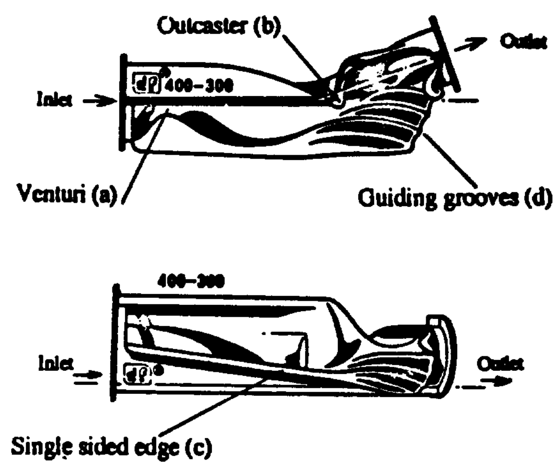

Figure 1: Fillippi Characteristics

Each Filippi model is characterized by two flow rates:

- The flow rate at which the limiter begins to overflow (the first spilling point).
- The guaranteed maximum throughput flow rate.

At flow rates up to the first spilling point, the limiter operates as an open channel. Between this flow rate and the maximum rate, the limiter operates as an overflowing single-sided weir. When flow rates exceed the guaranteed maximum throughput, the outcaster discharges all excess stormwater flow.

It is interesting to note that, within a range of gradients which are appropriate for each model, the first spill point and the maximum throughput do not change. All sizes have the same proportions, and have equal changes in the direction of the overflow.

The creation of additional sizes of Filippi devices can be easily done, and is simply a matter of cost and amortization of the Filippi mold. To date, the existing range has satisfied all requirements.

Hydraulic Flow Graphics of Filippi Flow Limiters

Since the full-scale testing apparatus is installed at the École Polytechnique, specialists on the hydraulic faculty in the Department of Civil Engineering have approved the method of measuring flow rates. Measurement accuracy has been with 1 liter/second.

In addition, hydraulic performance tests have been carried out by other specialists and laboratories, such as:

- The Thames Polytechnic in London in 1984 (model 200/150/200).
- The University of Manchester in 1983 (model 300/250).
- The Centre Technique de Caluire (France) in 1992 (model 300/250).

Test results agreed with those obtained during testing in Lausanne. A suggestion was made to conduct wind tunnel tests to improve device performance, but this was rejected because full-scale test results were satisfactory.

Selection and Design of the Layout for the Filippi Model

Filippi models are designated by their inlet and outlet diameters. Thus the model 300/250 is designed for the first spill at a flow rate of 14 litres/second, and a maximum throughput of 18 liters/second (produced with inlet and outlet diameters of 300 mm and 250 mm, respectively).

The choice of a suitable model is made by establishing the maximum flow rate (as a multiple of dry-weather flow). When receiving water pollution is an important issue, the selection of a suitable limiter should be done by:

- Establishing the first spilling point of the appropriate model.
- By selecting a larger size, the overflow will only occur at higher flow rates, and thus be less frequent.

It is therefore necessary to have good information about the wastewater collection system, and the future population and land use changes.

In the flow graph (Figure 2) each Filippi model is allocated to a range of gradients. For example, for model 300/250, the allowable gradient range is 0.5 - 2.0 percent. The device must be installed within this range if guaranteed flows are to be achieved. It is evident that, as gradient increases, there is less likelihood of having deposits upstream or downstream of the Filippi limiter. The

Overflow-weir and flow limiter **FILIPPI**
Hydraulic flow graphics
of the 14 standard units

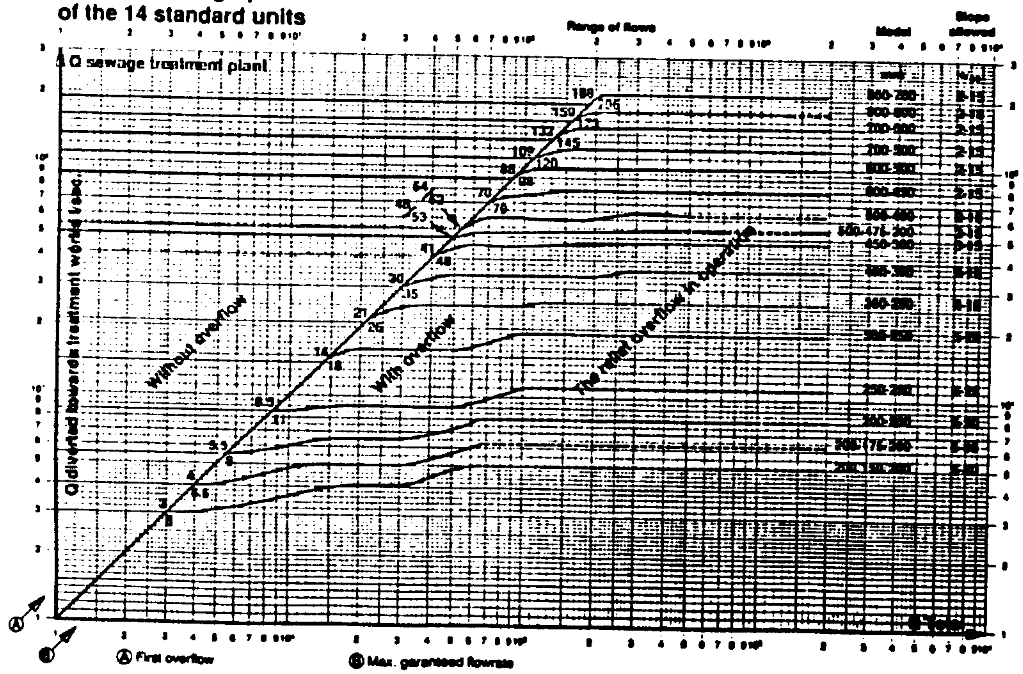

Figure 2: Flow Graph

same is true within the limiter itself, because the venturi effect will increase the flow velocities through the Filippi channel.

If the gradient upstream is higher than that allowed for a given device, it is important to modify the incoming gradient within a distance of not less than 5 meters upstream. The loss in grade is compensated for within the Filippi manhole (see Figure 3). The use of an "energy breaker" upstream is suggested if the gradient of the incoming sewer is very high.

The device can also be used with shallow slopes. When designing for such cases, there is no loss of level in the overflow sewer, and therefore no design problems. The overflow must be allowed to flow out of the Filippi manhole to avoid flow back into the limiter, and to guarantee the maximum throughput. One possible solution (Figure 5) is the use of a larger pipe section, or a rectangular runoff channel (Figure 4).

If overflow must be diverted to the left, it is feasible to allow this flow to pass under the limiter, or alternatively, to use a special overflow chamber, installed at the outlet of the limiter.

The Filippi flow limiter is often installed in combination with a tapered pressure-relief unit, which is installed in the same manhole to avoid any build up of water pressure upstream during heavy storms.

The Filippi limiters are installed in circular or rectangular manholes. For the smaller units, prefabricated GRP (glassfiber reinforced polyester) units are also used. When using the smaller units, it may be advisable to add an automatic rinsing system to avoid blockages. A solenoid-operated valve on a timer (to allow, say, for two rinsings per day), employing two spray nozzles, has been used successfully for this purpose. The valve can be battery-operated, if necessary.

Blockage of the smallest Filippi limiters can occur because gradients are low, or because dry-weather flows are only a few liters/second. No rinsing is required for the larger models.

Typical Applications with the Filippi Flow Limiter

The Filippi flow limiter has been used in the following types of installations:

- As a flow limiter in a combined sewer to avoid both upstream and downstream flooding.
- As a flow diverter or limiter upstream of a stormwater basin where the through flow bypasses the basin.

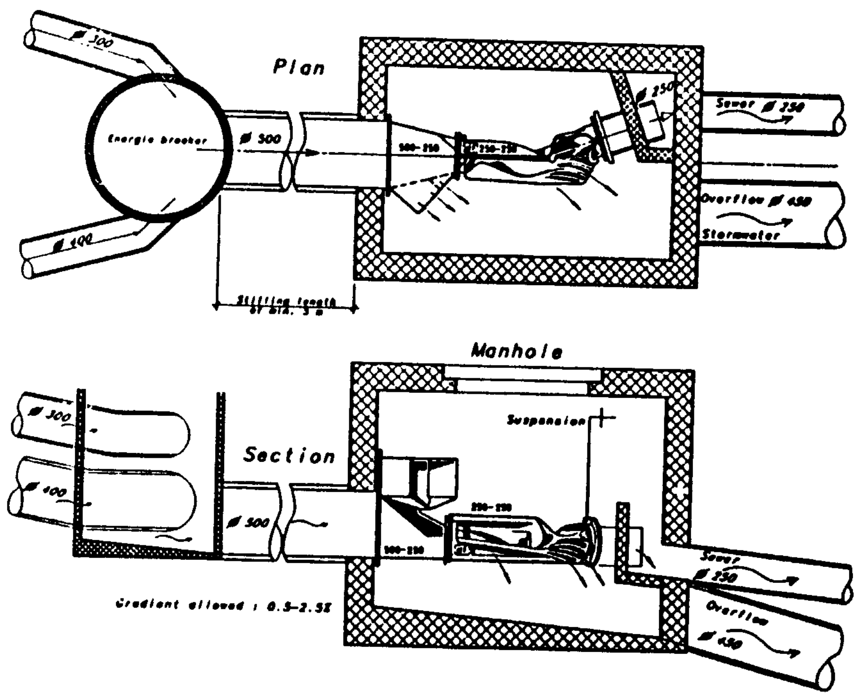

Figure 3: Fillippi Fitted in an Overflowing System with a High Gradient

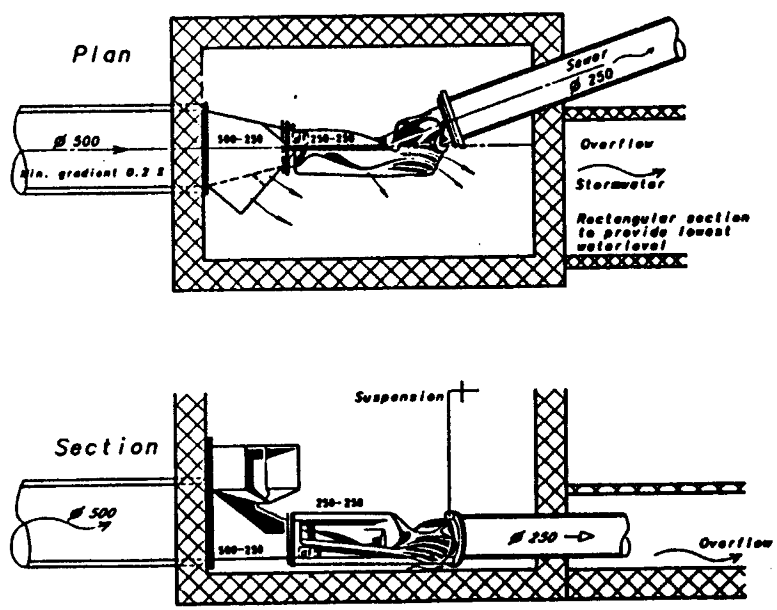

Figure 4: Fillippi Fitted in an Overflowing System with a Shallow Gradient

- As a flow limiter to avoid variations in inflow rates to a wastewater treatment facility.
- As a flow limiter in surface drainage systems, where polluted water ("first flush") is collected as concentrated wastewater, and then passed through the limiter to a downstream treatment facility.

All of these applications have been used in Europe for many years, and they have resulted in:

- Cost reduction - due to smaller spill water pipe downstream.
- Improved efficiency of wastewater treatment works.
- Reduced treatment costs for oil and gas separators.
- Reduced flooding of basements - with consequent savings in cleanup costs and decreased maintenance requirements.
- Reduced receiving water pollution because concentrated first flushes are routed to special treatment (settling basins).

The Filippi Flow Limiter as a Solids and Particle Separator

Due to its hydraulic shape the Filippi limiter also has a positive influence on solids separation. The shape improves the throughput of solids, provided that the inflow does not exceed 15 percent of the maximum throughput. Solids separation efficiency is also dependent on the specific gravity of the solids. "Sinkers" are more easily carried forward than "floaters," which are more likey to follow the overflowing water. If flows exceed 15 percent of maximum throughput, or if upstream turbulence has already suspended the solids, there will be little solids separation.

Limitations on the Use of the Filippi Limiter to Measure Flow Rates

The monitoring of flowrates with the Filippi limiter is possible only when the limiter is overflowing. In these cases a humidity sensor is installed on the overflow edge, and connected to a clock which will allow recording the total time of overflow. Incoming total flow must be measured in the upstream sewer. The overflow itself must be measured in the downstream sewer.

Operational Conditions

Only two operational conditions must be satisfied to ensure functioning of the Filippi limiter:

- The device must be correctly fitted into the manhole, and be rigidly fixed to achieve the proper rotational positioning of the limiter and to ensure the correct gradient.

VOL 12

7935

- Free flow out of the limiter must be assured, so as not to disturb the important venturi effect. No flow restrictions or decreases in gradient are allowed at the outlet (although an increase in the gradient is allowed).

Advantages in Using the Filippi Flow Limiter

The following are the advantages in using the Filippi limiter:

- Absolute guarantee of flow rates - both first spilling point and throughput.
- No additional downstream flows during heavy storms.
- No flooding problems (if an integrated pressure-relief valve is used upstream).
- Extra capacity of the downstream sewer is available.
- Large range of sizes/capacities (15) available.
- Ability to capture highly polluted first flush.
- Can be used on a wide range of gradients.
- Easy installation and fitting - prefabricated components.
- No moving parts or electrical requirements.
- Virtually no maintenance needed - self cleaning.
- No corrosion problems (devices made of stainless steel and GRP).
- Minor engineering of manholes.
- No hydraulic computations required for selection of proper device.
- Easy retrofitting in existing overflow systems.

RCRA IMPLICATIONS FOR SEDIMENTS IN STORMWATER BMPs

Jonathan Jones, P.E.[1]
Scot Anderson, Esq.[2]

ABSTRACT

This paper discusses the circumstances under which sediments that accumulate in municipal and industrial best management practices (BMPs) can be classified as hazardous waste under the Resource Conservation and Recovery Act (RCRA). Under certain circumstances, such sediments, when discarded, can be classified as hazardous waste per the "mixture rule," "derived-from" rule and/or the USEPA's "contained in" policy. Many of the compounds specifically listed as hazardous waste under RCRA have been detected in municipal and industrial stormwater runoff. Simply because a chemical regulated by RCRA is detected in the BMP sediments, the sediments are not necessarily hazardous, as explained herein. Facility designers can call for an array of source control techniques to reduce the probability that RCRA-listed wastes will enter BMPs; however, such pollutants will inevitably find their way into BMPs on occasion. This must be recognized and planned for.

Under what circumstances, if any, can sediments that accumulate in municipal and industrial "best management practices" ("BMPs") be classified as "hazardous waste," as defined by the Resource Conservation and Recovery Act ("RCRA")? Stormwater BMPs include such facilities as retention ("wet") ponds; detention ("dry") ponds; infiltration basins; buried concrete vaults; and created wetlands. This paper provides an overview and recommendations for an issue that will increasingly confront designers and owners of industrial and municipal stormwater management facilities. In brief, key findings are as follows:

1. Under certain circumstances, sediments that accumulate in either municipal or industrial facilities, when discarded, may be classified as hazardous waste.

[1] *Vice President, Wright Water Engineers, Inc., Denver, Colorado*

[2] *Senior Attorney, ARCO Coal Company, Denver, Colorado*

2. Under current RCRA regulations, the "mixture" rule and "derived-from" rule can cause sediments with extremely low concentrations (barely above the detection limit) of one or more listed hazardous wastes to be classified as hazardous waste when those sediments are discarded. Perhaps of greater significance, under Environmental Protection Agency's ("EPA's") "contained-in" policy, environmental media (like water, soil, and sediment) that contain a listed hazardous waste must be handled as if a hazardous waste.

3. Many of the compounds specifically listed as hazardous waste under RCRA have been detected in municipal and industrial stormwater runoff. For example, chemical compounds that are commonly used for automobile maintenance (certain solvents, degreasers, hydraulic fluids, etc.) and yard care (selected herbicides, insecticides, fungicides and other pesticides) have been detected in stormwater runoff samples throughout the United States.

4. The chemicals of concern will mix with total suspended solids ("TSS") in the stormwater and a certain portion of these solids will "settle out" (be deposited) in the BMP. As will be discussed below, it is an open question as to when, if ever, such sediments become solid waste regulated under RCRA.

5. Simply because a chemical regulated by RCRA is detected in BMP sediments, ***the sediments are not necessarily hazardous***. If, for example, a spent halogenated solvent listed as hazardous waste is detected in detention pond sediments, those sediments would be hazardous waste under the mixture rule only if the source of the spent solvent contained more than ten percent of that solvent by volume (40 CFR §261.31 (F001 wastes)). If a potential source is located, there must also be a way for precipitation/runoff to come into contact with the chemical. If no product containing greater than ten percent of the listed solvent is found, or if contact with precipitation/runoff (including via spills) is unlikely, the pond sediments would *not* be classified as hazardous waste per RCRA.

   The distinction between having one or more discernable "point" sources of hazardous waste (with suitable characteristics) versus no clearly defined sources with suitable characteristics is a critical one.

6. Municipal and industrial stormwater designers should specify an array of source control techniques to reduce the probability that RCRA-listed wastes will enter BMPs.

VOL 12

7938

7. Despite aggressive source control efforts, in most municipal and industrial settings, pollutants that are "listed" under RCRA will inevitably find their way into BMPs on occasion. This *must* be recognized and planned for, as should the fact that most BMPs will cause some sediment/pollutant deposition, thereby triggering the potential problem. It is not feasible to design facilities to allow listed hazardous compounds to assuredly pass through, nor would this be desirable from a receiving water impact perspective.

8. There are many ameliorating factors to which regulators may be receptive. For example, appropriate facility analysis may demonstrate that the sediments pose little risk to humans or to aquatic or terrestrial life forms. For BMPs that are "onstream" (in "waters of the state/United States"), it may be feasible to show that the sediment will not cause use impairment or lead to numeric stream standards violations. Lack of clearly defined hazardous waste sources can add considerable uncertainty to this process. (see No. 5, above).

   In short, there are logical arguments that can be offered as to why BMP sediments should not be classified as hazardous waste, even if there are detectable concentrations of hazardous chemicals within the sediments.

9. Ironically, certain federal and state regulations (under the Clean Water Act) call for the implementation of BMPs, which can create regulatory difficulties under RCRA. Stated another way: to comply with one regulation potentially opens the door for violation of another regulation.

10. Pending regulatory modifications and new legislation offer the potential to ameliorate this situation, which could otherwise impose a significant economic burden when viewed from a national perspective.

THE BASIS FOR, NATURE AND IMPORTANCE OF STORMWATER BEST MANAGEMENT PRACTICES (BMPs)

Typical stormwater BMPs include, as examples:

- **"Dry" detention ponds.**
- **"Wet" retention ponds.**
- **Artificial wetlands.**
- **Infiltration practices.**
- **Specially designed stormwater inlets.**
- **Grass-lined swales and other water quality conveyances that promote extended flow time, infiltration, and interaction of pollutants with channel vegetation.**

Facilities of this kind are commonly installed as stormwater quantity and quality mitigation measures. When properly designed and operated, they can reduce peak rates of runoff from developed lands to predevelopment levels and can reduce pollutant loads in stormwater runoff. One common (and desirable) feature of these BMPs is that they promote the sedimentation and deposition of TSS that are commonly found in municipal and industrial stormwater runoff. For example, EPA has determined that the median concentration of TSS in "typical" urban runoff is 100 mg/L (EPA, 1983). Such references as Metropolitan Washington D.C. Council of Governments, 1992; California State Water Resources Control Board, 1993, and Urbonas and Stahre, 1993 indicate that BMPs can attain TSS removal efficiencies of 70 percent or higher.

The important aspect of TSS removal within BMPs (in terms of RCRA regulations) is that many of the chemical compounds regulated by RCRA tend to adsorb onto sediments. As noted by Urbonas and Stahre (1993): "Most pollutants appear to have strong affinity to TSS, and the removal of TSS will often remove many of the other pollutants found in urban stormwater." Therefore, BMPs accumulate in sediments within retention/detention ponds, wetlands, infiltration basins, etc. Proper maintenance practice indicates that sediments should be periodically removed to assure that the facilities properly function, maintain longevity and assure that facilities are attractive.

Historically, and in most instances, the disposal of sediments removed from BMPs has posed no special regulatory or legal difficulty. Instead, industries and municipalities have disposed of such sediments in the same way that they would any uncontaminated soil. Frequently, in fact, upon drying, the sediments have been mixed with other soil and reused as backfill on construction projects, or disposed of in conventional sanitary landfills.

To comply with local, state and federal mandates related to drainage and flood control and stormwater quality management, the past decade (and particularly the past two to three years) has been a period of rapid growth in the numbers and kinds of BMPs used. The 1987 Clean Water Act and the accompanying National Pollutant Discharge Elimination System ("NPDES") stormwater regulations (issued in 1991 and subsequent years) have prompted numerous industries, cities, counties, and businesses to implement BMPs. Those states with authority to administer the Clean Water Act (NPDES permits) have state regulations for runoff quality control. Most local governments have drainage and flood control regulations (which call for BMPs) and many have adopted localized stormwater quality and erosion/sediment control regulations. In short, at multiple levels, there is the necessity to construct BMPs to comply with regulations. In addition, standard civil engineering practice (ASCE and WEF, 1993) mandates the installation of stormwater control measures. Detention ponds, infiltration practices, grass-lined channels, etc., are common elements of nearly every drainage system.

COMPOSITION OF STORMWATER RUNOFF

"Typical" stormwater runoff from urban areas contains a wide array of pollutants. Table 1 summarizes USEPA Priority Pollutants detected in urban runoff samples in the Denver area, according to the Denver Urban Runoff Program (Denver was one of the 26 cities that participated in the National Urban Runoff Program) (DRCOG, 1983).

Many chemicals in urban and industrial stormwater runoff are periodically detected which are RCRA-listed compounds. Excessive herbicide or pesticide use contributes toxic chemicals to the stormwater (California SWRCB, 1993). Household toxics such as oil/grease, paint, antifreeze, cleaner and solvents are widely used and may be improperly used, stored and disposed of which can lend to stormwater pollution (Berman et al., 1991). Atmospheric deposition contains appreciable quantities of pesticides and organic compounds (Novotny and Chesters, 1981). Other toxic pollutants occur through the use of products for de-icing and weed, rodent and insect control (Beaton et al., 1972) Hydrocarbons can come from spills, leaks or blow-off of motor lubrications, antifreeze, hydraulic fluid and asphalt surface leachate (Schueler, 1987). The City of Seattle (1989) found low concentrations of various EPA Priority Pollutants including pesticides, phenols, and polynuclear and polycyclic aromatic hydrocarbons.

In certain municipal and industrial settings, the probability of *detecting* RCRA-listed chemicals in stormwater runoff is significant. We emphasize the word *detect* because the detection limits for many RCRA-listed substances are measured in parts per billion. Practically, this can mean that a few tablespoons of a solvent in the runoff from a large industrial site will be detected by standard gas chromatograph/mass spectrometer ("GC/MS") lab methods. Consider the example of municipal or industrial vehicle equipment maintenance facilities. Even with good housekeeping practices and source controls in place, it is virtually inevitable that certain hydraulic fluids, degreasers, solvents and other RCRA-listed chemicals will sporadically come into contact with stormwater and that they will be detected in sediments in on-site BMPs, assuming that such sediments are monitored.

In larger municipal settings, the probability of RCRA-listed chemicals entering stormwater is high, because it is not practical to implement rigorous source control measures uniformly over vast areas. The benefit of increased dilution flow is not great enough to overcome the problem because detection levels for the relevant constituents are so low. Pesticides, particularly herbicides and insecticides, other chemicals commonly used by homeowners, the wide array of chemicals associated with automobiles and others can enter typical urban drainage systems at innumerable locations and, with appropriate monitoring, they will be detected.

In summary, municipal and industrial stormwater runoff can contain chemicals that are listed under RCRA as hazardous wastes. These chemicals will be found in sediments that accumulate in BMPs.

EFFECTIVENESS OF BMP AT REMOVING SEDIMENTS/PARTICULATE MATTER THAT CONTAIN CHEMICALS OF CONCERN

Typical stormwater BMPs can be quite effective at pollutant removal via sedimentation (the settling out of particulate matter from the water column onto the bottom of the BMP, such that the particulate matter becomes a deposit).

VOL 12

7942

Based upon the work of EPA (1983), Grizzard et al. (1982) and Whipple and Hunter (1982), extended dry detention ponds have been observed to remove 50 to 70 percent of TSS. The EPA (1983) reported that wet retention ponds could remove 60 to 90 percent of TSS. Monitoring of constructed wetlands in Florida (USGS, 1986) indicated a TSS removal efficiency of 41 percent. Modular block porous pavement (Schueler, 1987) can remove 80 to 90 percent of TSS. An excellent summary of TSS removal efficiencies for the most commonly utilized stormwater BMPs is provided on pages 105 through 112 of the Metropolitan Washington D.C. Council of Governments 1992 publication, *The Current Assessment of Urban Best Management Practices - Techniques for Reducing Non-Point Pollution in the Coastal Zone.*

Most of the RCRA-listed chemicals that have been detected in stormwater runoff can be associated with TSS; therefore, they are subject to sedimentation. This is why sediments in BMPs can contain RCRA-listed compounds.

THE KEY RELEVANT ASPECTS OF RCRA

Congress passed the RCRA 42 USC §§6901-6991i to require generators of hazardous waste to manage those wastes from their creation to their ultimate disposal, i.e., "from cradle to grave." RCRA requires every American industry and municipality which generates hazardous wastes to monitor and manage hazardous wastes in accordance with specified procedures.

Wastes can be defined by RCRA as hazardous because they either: (1) have certain *characteristics* (ignitability, corrosivity, explosivity or toxicity) or (2) because they contain constituents specifically *listed* in RCRA regulations. In nearly all cases involving stormwater BMP sediments, the reason that such sediments would be classified as hazardous wastes is because they contain *listed* chemicals rather than because the sediments are hazardous by *characteristic.*

It is not feasible to review RCRA in detail within this paper, but the key aspects of that law and its accompanying regulations for this issue include the following:

- The Mixture Rule (40 CFR § 261.3(a)(2)(iv))

  RCRA regulations include lists of a number of chemicals and their by-products that are considered per se hazardous wastes when used and discarded. Under the mixture rule, a mixture of any solid waste (including such ordinary wastes as dirt, paper, rags or plastics) and the listed waste is considered by regulation to be a hazardous waste. Even small concentrations of a listed waste can render large volumes of material "hazardous waste," as that term is defined under RCRA.

- The Derived-From Rule (40 CFR §§261.3(c)(2)(i) and 261.3(d)(2))

  If solid waste is considered hazardous waste, even if by operation of the mixture rule, then any residue from the treatment, storage or disposal of the hazardous waste is also considered hazardous waste.

- The Contained-in Policy

  Under existing EPA policy, environmental media -- such as soil or debris -- that "contain" a hazardous waste must be handled as if a hazardous waste. It is the contained-in policy, rather than the mixture or derived-from rules, that is most likely to bring BMP sediments within the scope of RCRA regulations. A de minimis exception to the contained-in principle can be made on a site-specific basis (57 FR 37194, August 18, 1992). EPA bears the burden of demonstrating that contaminated media do, in fact, contain hazardous waste before subjecting those media to the panoply of RCRA regulations. See, e.g., Chemical Waste Management v. EPA, 869 F.2d 1526, 1537-40 (D.C. Cir. 1989).

- The Nature of the Source Material

  Simply because a chemical regulated by RCRA is detected in BMP sediments, *the sediments are not necessarily hazardous even after discarded*. If, for example, a spent halogenated solvent listed as hazardous waste is detected in detention pond sediments, those sediments would be hazardous waste under the mixture rule only if the source of the spent solvent contained more than ten percent of that solvent by volume (40 CFR §261.31 (F001 wastes)). If a potential source is located, there must also be a way for precipitation/runoff to come into contact with the chemical. If no product with greater than ten percent of the listed solvent is found, or if contact with precipitation/runoff (including via spills) is unlikely, the pond sediments would *not* be classified hazardous waste.

VOL 12

7944

- <u>Exceptions to the Definition of Hazardous Waste</u>

  There are numerous exceptions to the definition of hazardous waste, and these exceptions must be considered on a site-specific basis. For example, certain mining and mineral processing wastes -- known as Bevill wastes -- are not regulated by RCRA (40 CFR §§ 261.3(a)(2)(i) and 261.4(b)(7)). Also, waste waters containing certain listed wastes are not subject to RCRA regulations if those waste waters are discharged under an NPDES permit or are subject to pretreatment standards.

These examples make it clear that *the distinction between having one or more discernable, "point" sources of a hazardous waste (with suitable characteristics) versus no clearly defined sources with suitable characteristics is a critical one.* Convincing the relevant regulators that there are not definable sources with relevant characteristics is the responsibility of the facility owner.

The mixture and derived-from rules do not apply to BMP sediments until those sediments are removed from the BMP, for it is only then that the sediments are "discarded." See <u>American Mining Congress v. EPA</u>, 824 F.2d 1177, 1192-93 (D.C. Cir. 1987) ("AMC"). The D.C. Circuit's decision in AMC has been limited by later decisions of that same court addressing sludges in sediment ponds that are reprocessed by the metals industry. See <u>American Petroleum Institute v. EPA</u>, 906 F.2d 729 (D.C. Cir. 1990) ("API"); <u>American Mining Congress v. EPA</u>, 907 F.2d 1179 (D.C. Cir. 1990) ("AMC II"). In <u>API</u> and <u>AMC II</u>, the court upheld EPA regulations extending RCRA to sediments in process sediment ponds: No court has yet decided whether a similar extension of RCRA's scope could apply to sediments in ordinary BMPs.

The mixture and derived-from rules do not logically fit with <u>in situ</u> BMP sediments. EPA might, however, apply the contained-in policy to <u>in situ</u> BMP sediments. That policy, as applied to contaminated medium, is not yet a rule. EPA proposed a rule that would codify the contained-in policy (Land Disposal Restrictions ("LDRs") for Newly Identified and Listed Hazardous Wastes and Hazardous Soil, Proposed Rule, 58 FR 48092 (September 14, 1993)). EPA recently gave notice, however, that it intends to tie the codification of the contained-in policy to the promulgation of a hazardous waste identification rule that abandons the strict mixture and derived-from rules for a more flexible approach to identify hazardous wastes (Land Disposal Restrictions ("LDRs") for Newly Identified Hazardous Wastes and Hazardous Soil, Clarification, 59 FR

VOL 12 7945

R0041251

10778 (March 8, 1994)). The contained-in policy, as it now exists, could require that sediments of BMPs be managed as hazardous waste. Given the uncertainties of strict enforcement of a policy (as opposed to a rule) and EPA's intent to revise the regulatory framework in the foreseeable future, EPA may not wish to test the scope of its enforcement powers by seeking to regulate BMP sediments under RCRA.

If *water* stored in the BMP is regulated by an NPDES permit, RCRA may *not* apply to the water. Under all but the most unusual cases, RCRA will not supersede Clean Water Act jurisdiction over waters found in BMPs. Currently, however, sediments in stormwater facilities are a different matter and they may become subject to regulation under RCRA.

Detection limits and the distinction among the terms "practical quantitation limit" ("PQL"), "lower limit of detection" ("LLD"), "method detection limit" ("MDL") and others is critical on many issues involving RCRA. This subject is also beyond the scope of this document. This paper has simplified this subject greatly by indicating that measured concentrations are greater than the "detection limit."

RECOMMENDATIONS TO REDUCE THE POTENTIAL PROBLEM

BMP designers and facility owners are advised to take the following steps to reduce the probability that sediments will be classified as hazardous waste under RCRA:

1. Take all steps reasonable to reduce the likelihood that chemicals listed as hazardous waste under RCRA will come into contact with precipitation or stormwater. These measures are well documented in the contemporary stormwater quality literature and they can include:

   a. Educating workers/public.

   b. Placing hazardous materials indoors or covering them.

   c. Connecting floor drains and sumps to the sanitary sewer rather than the drainage system.

   d. Inventorying hazardous chemicals on a regular basis and keeping track of their usage.

VOL 12

7946

R0041252

e. Discouraging the use of hazardous chemicals and emphasizing replacement compounds that are not listed by RCRA.

f. Formulating, implementing and regularly monitoring an aggressive spill control program.

2. In small drainage areas, the prospects for strictly controlling the kinds of chemicals that enter the drainage system are better than in larger areas with multiple property owners. This states the obvious; however, it is a point that merits emphasis. To provide an example, a vehicle maintenance facility that is three acres in size, and which receives no runoff from adjoining properties, should be able to implement rigorous source controls without difficulty. All work on vehicles can occur indoors. Floor drains and sumps should be connected to pretreatment facilities, which in turn would discharge to the sanitary sewer. Thoughtful drainage design decisions can be made. For example, vehicle parking areas can be separated from stormwater conveyances with vegetated "filter strips" and the conveyances can be lined with vegetation. Both of these practices will promote the interaction of chemicals of concern with vegetation and soils, and will also encourage infiltration.

3. To "localize" the problem, stormwater "pretreatment" facilities should be considered. For example, immediately upstream from a stormwater wetland, it may be feasible to install a sedimentation basin. Even with a retention time of as little as 15 minutes (where soil conditions are favorable), a significant fraction of the total sediment load can be removed from the stormwater prior to discharge into the wetland. This not only localizes sediments and the pollutants that adsorb to them, but also benefits the wetland and results in decreased long-term maintenance costs.

4. Adopt measures to reduce the quantity of sediment that will enter the BMP over time. The smaller the sediment load that accumulates, the less frequently the sediment has to be removed. This is of vital importance because RCRA in most instances becomes relevant *only* when sediments actually need to be removed. Rigorous erosion and sediment control practices, both

VOL 12

7947

during and after construction, are mandatory. Judicious use of sand during the winter months is necessary.

5. Thoughtfully evaluate BMP facility design characteristics and implement techniques that will enhance the likelihood of pollutant "loss" within the BMP. For example, incorporating fountains into retention ponds enhances the volatilization of many volatile and semi-volatile organic compounds that are listed by RCRA. Note, however, that a permit is required to treat a RCRA hazardous waste.

6. Designers are well advised to discuss potential problems with regulators and their clients from the outset of an assignment. By discussing potential problems with the BMP facility owner, professional liability is reduced and the owner and engineer can agree, in advance, on mitigation measures.

   Discussions with regulators are equally important. Generally, the authors recommend that the design engineer: (a) cite regulations that are forcing the implementation of stormwater BMPs in the first place (typically municipal or industrial NPDES regulations); (b) delineate the full range of functions that the BMP will fulfill (flood hazard reduction, stormwater quality management and others specific to the given facility); (c) describe structural and nonstructural measures that will be taken to reduce the probability that hazardous chemicals will enter the BMP; and (d) suggest a regulatory agreement, in advance, that will address the issue in a reasonable, cost-effective manner if and when the sediments do need to be removed, under the assumption that they contain one or more RCRA-listed chemicals.

   The nature of discussions with the BMP owner and regulators are highly specific to the circumstances at hand.

7. Intentionally oversize the sediment storage volume in the BMP. Instead of assuming that the BMP should have its sediments removed once every 5 to 10 years, assume that sediment removal should occur no more frequently than once every 20 to 30 years. This will be impractical and excessively expensive in certain

VOL 12

7948

instances, but in situations where additional sediment storage can be achieved economically, this step should be taken.

It is essential to recognize that in most instances RCRA will not be triggered until sediments need to be removed from the BMP. Therefore, every reasonable step should be taken to avoid the need to remove sediments from stormwater facilities.

8. Where feasible, construct facilities that are "off-line" rather than "on-stream." This is certainly not a panacea, but at least off-line facilities are not subject to the criticism that stormwater facility sediments classified as hazardous waste by RCRA are located in "waters of the state/United States."

It will not always be feasible to avoid RCRA regulations by implementing the measures listed above. Furthermore, existing BMPs may contain sediments that have RCRA-listed chemicals in them *now*. When confronted with the knowledge that BMP sediments do contain RCRA-listed wastes, the facility owner and the designer should consider the following steps:

1. Conduct additional sampling to confirm the presence of the contaminants. Also, sample at multiple locations to assure adequate horizontal and vertical coverage. Critically analyze the data collected and determine if additional actions are required.

2. If the drainage area is small, thoroughly search the area for potential distinct sources of the chemical or chemicals that have been detected in the sediments. If distinct potential sources are noted, their ability to be transported into the stormwater BMP needs to be established.

   Once potential sources are noted, their characteristics should be checked against the RCRA definition of hazardous waste (40 CFR Part 261) to assure that they are, in fact, RCRA-regulated wastes.

   A thorough search of this kind is obviously feasible only in smaller drainage basins.

3. If the search for sources indicates that there are sources regulated by RCRA which have entered the stormwater facility sediments, actions should be immediately taken to assure that the chemical will not continue to be discharged into the stormwater drainage system.

   If no distinct source or sources with the requisite characteristics (as defined by RCRA) are located, this is very important information to be conveyed to the regulators. All other things being equal, RCRA-regulators will be less inclined to rigorously control "contaminated" sediments that have been affected by diffused sources rather than distinct sources with the requisite characteristics.

   The ideal outcome is to identify probable sources that do *not* comply with RCRA requirements. For example, if the trichlorethylene sources in a drainage area that are in contact with precipitation/runoff are less than 10 percent pure, the sediments should not be classified as hazardous wastes.

4. In many cases, a risk assessment will demonstrate that there is no practical risk posed to the public or other life forms by constituent levels within the sediments. This is important information to provide to the regulators because they can exercise a certain amount of judgment when evaluating regulatory options. If volatile or semi-volatile compounds are in the sediments, the risk assessment should account for the sediment dredging and disposal process, because these actions will normally cause substantial volatilization, thereby reducing the risk.

5. Evaluate modifications to the stormwater facility that will avoid the need to excavate the contaminated sediments. For example, it may be reasonable to raise a detention pond outlet structure, thereby increasing sediment storage space. This action could reduce the flood attenuation and water quality enhancement characteristics of the facility, but the reduction, if significant, can be offset with other BMPs in the basin.

6. There is some merit to the argument that the Clean Water Act (NPDES permitting program) forced the construction of stormwater BMPs that would not otherwise have been installed. Consequently, it is unfair to then come back with RCRA requirements for facilities that are functioning in exactly the manner that they were intended.

Irrespective of which of these options (or others) are implemented, the authors suggest that qualified, specialized legal counsel be obtained so that appropriate steps are taken.

UNKNOWNS AND FUTURE CONSIDERATIONS

The subject of potential RCRA regulation of stormwater facility sediments is in its infancy and much is not known. Examples of major unknowns are as follows:

1. The authors are not sure how frequently stormwater BMP sediments actually contain RCRA-listed wastes with requisite characteristics. Common sense tells us that this could be a typical problem, but relevant data are presently lacking. The authors know of three industrial complexes in different states that are currently faced with this situation and that are proceeding under the assumption that the relevant sediments are subject to RCRA regulation.

2. Semantics and design decisions could play a key role in the future. For example, some might argue that "formal," structural BMPs are subject to RCRA regulation while "informal," less significant BMPs are not. Examples of "formal" facilities are wet ponds, dry ponds, artificial wetlands and infiltration basins. Examples of "informal" facilities are small swales and "porous" check dams. In any event, the distinction among different kinds of BMPs, if any, relative to RCRA needs to be defined.

3. Most stormwater conveyance channels, including storm sewers, exhibit sediment deposition -- consequently, can they be regulated under RCRA?

4. The authors have not asked a representative sampling of regulators for their opinion on this issue. We also cannot speculate as to the probable posture of the regulators when it comes to this subject. We suspect that the reaction would be highly dependent upon the person asking the question and the person answering the question.

As of the summer of 1994, there are potential regulatory changes that could be very helpful relative to this situation. Also, RCRA is now in the reauthorization process, and there is the potential for language in the updated law which would specifically exempt stormwater BMPs from RCRA coverage. Important considerations include:

Revisiting the Mixture and Derived-from Rules

In 1991, the United States Court of Appeals for the District of Columbia vacated EPA's mixture and derived-from rules (Shell Oil Company v. EPA, 950 F.2d 741 (D.C. Cir. 1991)). The Court vacated these rules only because EPA failed to follow appropriate notice and comment rulemaking procedures when promulgating the rules; the Court did not reach substantive challenges to these rules. After Shell Oil, EPA repromulgated the mixture and derived-from rules on an interim basis (57 Fed. Reg. 7,628 (March 3, 1992)). Thus, the mixture and derived-from rules are at present the law of the land. In the Bush Administration, EPA proposed a new "Hazardous Waste Identification Rule" ("HWIR") that would have abandoned the mixture rule in favor of concentration-based standards for hazardous wastes (57 FR 21450, May 20, 1992; 57 FR 7636 March 3, 1992). The Bush Administration abandoned this promising approach prior to the 1992 election, but the Clinton Administration has promised to pursue rulemaking that would replace the mixture and derived-from rules with a more reasonable rule defining hazardous waste. (It is also important to note that the DC Circuit's opinion affected only the federal mixture and derived-from rules. Many states have similar or identical rules. A recent court decision, however, invalidated a State's mixture rule based on Shell Oil). The benefits of the revision of these rules are likely to spill over to the contained-in policy and should relax the overly rigid regulation of contaminated environmental media.

VOL 12

7952

- RCRA Reauthorization

RCRA is overdue for reauthorization, and Congress is likely to amend RCRA substantially when that reauthorization finally occurs. Early indications are that most of the action in RCRA reauthorization will be over the regulation of nonhazardous waste. Nonetheless, reauthorization will provide to Congress the opportunity to address the definition of hazardous waste, including the mixture and derived-from rules and the contained-in policy. If EPA promulgates replacement rules before reauthorization, Congress may well stay its hand on these issues.

"Low Cost Automatic Stormwater Sampler"

Lynn A. Dudley[1]

Abstract

The Vortox Co. of Claremont, CA., has developed and applied for patents on a method of sampling stormwater sheetflow, outfalls (from end of the pipe) and "in-the-pipe" during partial or full flow. This unique method is automatic, 100% mechanical and inexpensive when compared to other automatic samplers. The Vortox sampler is finding widespread acceptance among state regulators, environmental consultants, industrial sites, municipalities, as well as military bases.

Introduction

Who is Vortox? How did we become involved in the design and manufacture of a stormwater sampler?

The Vortox Company has been in the business of manufacturing air cleaners for internal combustion engines for 76 years. We held one of the first patents for the oil bath air cleaner. Vortox supplies to OEM's such as Chrysler, Peterbilt, Kenworth as well as some aftermarket applications in alternate fuel conversions. We also lend our expertise in design and sheet metal fabrication to the jobshop market.

Our involvement in stormwater sampling was the result of studying the CWA regulations as it pertained to our industrial site. This led us into an investigation into the accepted methods of sampling stormwater and a

[1]Director of Engineering, Vortox Co., 121 South Indian Hill Blvd., Claremont, CA 91711-4997

determination that no one method of sampling was convenient, simple, safe, obtained a quality sample and was cost effective. At the Vortox plant site we have three (3) points which must be sampled. After determining that we could not sample manually we obtained quotes on electronic samplers which would cost several thousand dollars for three (3) machines. At this point, Vortox was determined to develop a simple sampling concept and gain acceptance from the Los Angeles Regional Board for its use at Vortox. We built a prototype and submitted it to the board with a request to use the method for collecting stormwater samples at the Vortox plant. The regulators at the Los Angeles region not only gave us approval but thought enough of the method to ask us to show the prototype to the other Regional Boards throughout the state. All the Regional Boards in California stated they would accept this method of sampling, including the man credited with writing most of California's stormwater regulations, Tom Mumley from the San Francisco Bay Region. Vortox made the decision to patent the concept and enter into manufacturing and marketing the sampler. We traveled to adjoining states asking regulators, chemists and consultants to critique the approach we had taken.The feedback was always positive and in addition to California's acceptance, we obtained acceptance from Utah, Colorado, Oregon, Wisconsin, Washington and South Carolina. After 2½ years of production, we have over 350 samplers operating in the field which includes military bases (Navy and Air Force), airports (Santa Barbara & Los Angeles County, CA), municipalities (City of San Diego, CA, City of San Francisco, CA, Counties of Orange and San Bernardino CA). The U.S.G.S. has officially recommended the Vortox sampler be used in some of their stormwater responsibilities for the military. Industrial site applications range from the very largest corporations (CocaCola) to the small businessman.

We demonstrated the sampler for Bill Swietlik, Rod Fredrick, Kim Hankins and Nancy Cunningham of U.S.E.P.A. in Washington, DC, with very positive feedback and a request to have an independent laboratory run a test comparing the results of an electronic automatic sampler setting next to a Vortox automatic sampler in a spiked stream of water collecting samples at different flow rates. The results from the two samplers were virtually the same. Copies of the laboratory report is available upon request.

Figure 1, will identify the key components of the samplers as all the samplers work on one basic principle.

How does the Vortox sampler work? The primary design of this product is to capture grab samples and/or composite

(continuous collection) samples. The type 316 & type 304 stainless steel sampler is manufactured in three (3) configurations: Figure 1, The 3 liter (.8 gallon) sampler for surface flow. Figure 2, The 21 liter (5.5 gallon) sampler for surface flow. Figure 3, The 3 liter (.8 gallon) "In-The-Pipe" sampler for end of pipe or underground stormwater systems. The 3 liter (.8 gallon) is sufficient for the standard tests for Ph, TSS, TOC, metals and specific conductivity. The 5.5 gallon sampler is used for applications requiring larger sample volumes (i.e. bio-assay tests) such as stream beds.We have had requests for a more inert surface than stainless steel. To meet this request, we developed an FDA approved Teflon coating which is applied, as an option, to most of the internal parts of the sampler.

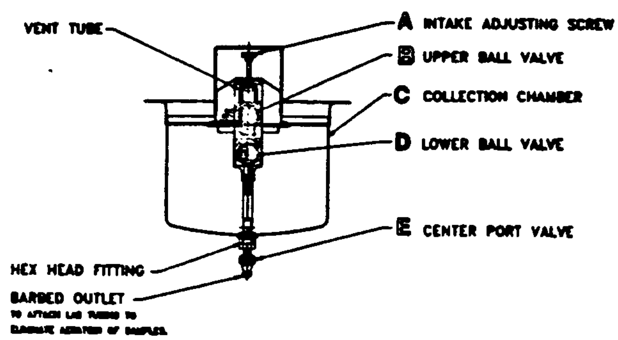

FIGURE 1

FIGURE 2
21 LITER (5.5 GALLON) SAMPLER PLACED INTO SUMP HOUSING

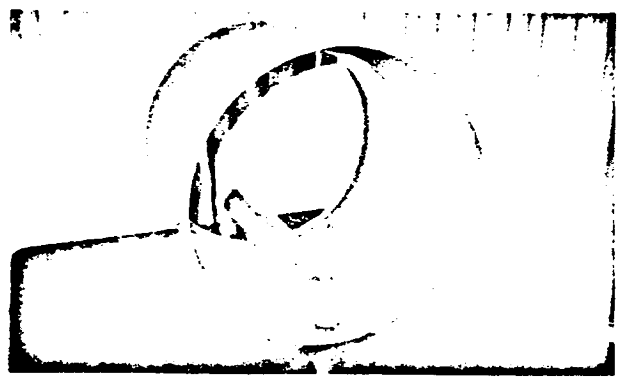

FIGURE 3
"IN-THE-PIPE" 3 LITER (.8 GALLON) SAMPLER
IN 610MM (29 INCH) PIPE

The three (3) configurations are available with a dam around the orifice (Fig. 4) to allow heavy particles in the effluent to settle out in the sediment pan before entering the sampler <u>or</u> without the dam (Fig. 5) so the fluid flows immediately into the sampler.

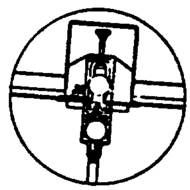

FIGURE 4

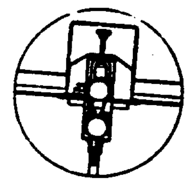

FIGURE 5

Each design has an intake adjusting screw at the top of the ball valve for controlling the rate at which the liquid enters the sampler. As the adjusting screw is turned downward, the ball is restricted in its vertical lift and throttles the orifice opening. When the adjusting screw is adjusted down against the ball, the valve is closed and this is the reference point for all adjustments. When the intake adjusting screw is opened one-half (1/2) turn from the fully closed position it will take <u>clean water</u> approximately 20 minutes to fill the 3 liter (.8 gallon) sampler and shut off the internal ball valve. When the intake adjusting screw is fully open, the 3 liter (.8 gallon) sampler will fill in approximately two (2) minutes. The 21 liter (5.5 gallon) sampler will fill in approximately 10 minutes when the adjusting screw is fully open and well over three and one-half hours (3½ hrs) when throttled down. The adjusting screw is a precision machined screw with slight resistance so as not to slip from its selected position. Because the effluent is site specific, some experimenting might be required to obtain the desired setting.

With the centerport valve closed, top orifice closed by the ball and vent tube open, the sampler is ready to collect samples. The upper ball valve will stay closed (B, Fig.1) keeping contaminants out of the sampler until liquid causes the ball to lift and expose the orifice. This allows liquid to enter the collection chamber (D, Fig.1). As the chamber fills the lower ball valve (C, Fig.1) rises, air is forced from the head space above the liquid and the orifice is closed by the lower ball, preserving the sample. If flow stops and only a partial sample is collected, the upper ball returns to the closed position, preserving the sample.

<u>Transferring the sample</u>

To transfer the sample to laboratory bottles (Fig. 6,7,8) simply attach a flexible tube to the barbed outlet at the end of the center port valve,(E Fig.1) place the opposite end of the tube in the bottom of your laboratory sample bottle and open the valve. The sample will be transferred with very little exposure to the air. Occasionally shake the sampler to keep the heavy particles in suspension and insure equitable transfer of all particulate material.

FIGURE 6

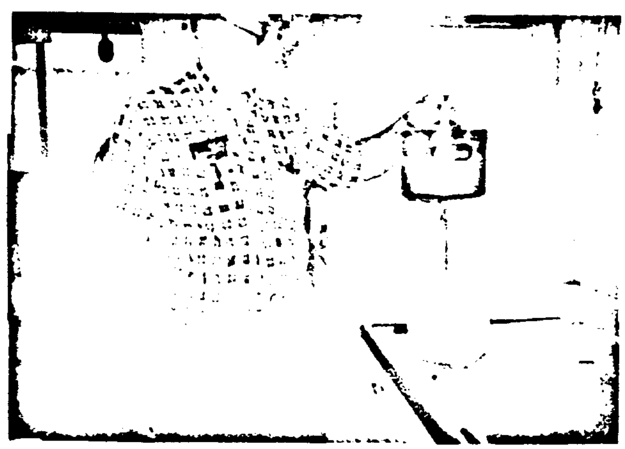

FIGURE 7

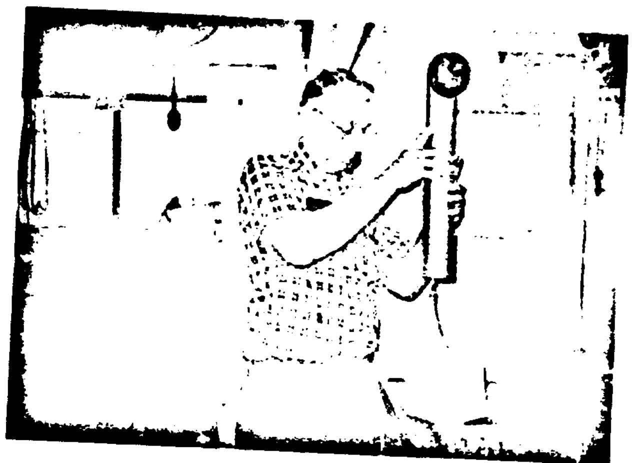

FIGURE 8

Cleaning the sampler

After transferring the sample, the sampler can be disassembled for clean up by turning the hex head of the centerport valve (Fig. 1) clockwise. This disengages the centerport valve from the double ball valve head and separates the sampler into three (3) components; valve, collection chamber and the double ball valve head. These parts can be placed in a container of hot water and non phosphate detergent and scrubbed with a brush to remove any heavy soils. Rinse with deionized water, dry and reassemble. Before placing the sampler into service, blow air through the vent tube to ensure free passage of air, check that the centerport valve is closed and the intake adjusting screw is positioned in the desired position.

Applications

The 3 liter (.8 gallon) sampler can be suspended by stainless steel cable beneath existing grates with a drop box depth of approximately 406 mm (16 in). The cable is laced through the openings in the grate and attached to the eyebolts on the sampler. (The cable and eyebolts are available as an option). As the grate is lowered into place (Fig. 9) the sampler is located at the low point on the grate, when in place. The sample is collected as sheet flow moves across and through the grate into the top of the sampler. Note: The 21 liter (5.5 gal) sampler cannot be suspended due to the weight when full.

VOL 12

7963

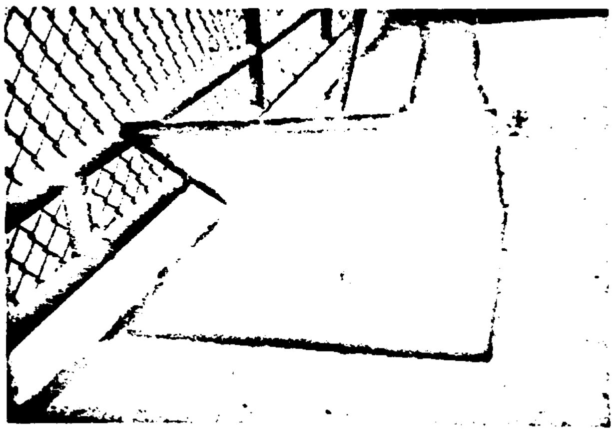

FIGURE 9
SUSPENDED 3 LITER (.8 GALLON) SAMPLER
IN EXISTING DROP BOX WITH GRATE

In situations where there are no existing drop boxes (Fig. 10), we have a kit approach in both the 3 liter (.8 gallon) and 21 liter (5.5 gallon) sampler (Fig. 11) which includes the sampler, sump housing and a traffic rated grate for below grade installation. You simply dig or bore a hole in the ground (508 mm)(20 inches) in diameter and 610 mm (24 inch) deep for the 3 liter (.8 gallon) sampler or 559 mm (22 inch) in diameter and 838 mm (33 inch) deep for the 21 liter (5.5 gallon) sampler to accommodate the sump. The sump is placed in the hole and the grate rests on the top flange of the sump. The top surface of the grate should be at grade level or slightly below. The sump and grate can be a permanent installation by pouring concrete around them or they can be portable, as in stream beds (Fig. 12) by using soil or gravel around the sump. Field experience has shown these installations take a little over one hour.

Once the sump housing and grate rim are in place, the sampler drops inside the sump (Fig. 10) and locks in place by aligning two (2) keyhole slots in the flange of the sampler with welded studs located on the horizonal surface of the sump collar. A slight turn of the sampler will engage the stud and lock the sampler in place. Replace the grate plate in the rim, secure with two (2) Allen screws and you are ready to collect your sample.

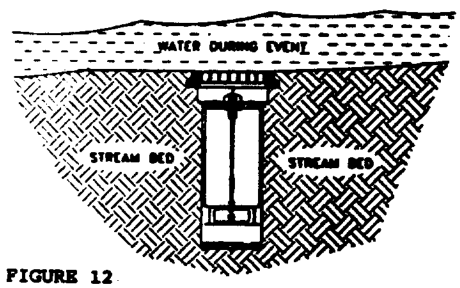

FIGURE 12

The "in-the-pipe" sampler was developed out of requests from California municipalities to be able to bypass a small base flow and catch samples at high or full flow. We were asked to accommodate pipe sizes from 305 mm (12 inches) diameter to 914 mm (36 inches) diameter. The concept we developed uses the same double ball valve, intake adjusting screw and outlet valve (Fig. 8) packaged in a 76 mm (3 inch) diameter stainless steel pipe. The device for anchoring the sampler (in-the-pipe) is an expanding stainless steel band which is locked into place by an inflatable bladder or a mechanical turnbuckle. The expanding band can remain in-the-pipe and the sampler simply disengages by sliding out the open end of the pipe.

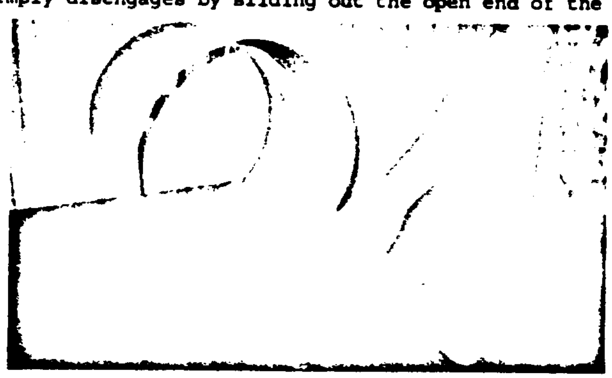

FIGURE 13

What we have presented is a brief description of a family of liquid samplers which offers a variety of methodology for sampling. The equipment is simple, durable, 100% mechanical and user friendly at an affordable cost.

HIGH-ACCURACY CSO AND STORMWATER FLOW MONITORING

Terrance L. Burch[1] and Joanna M. Phillips[1]

Abstract

Growing concern over Combined Sewer Overflow (CSO) discharges has led to the U.S. Environmental Protection Agency's new CSO Overflow Control Policy for incorporation into the National Pollutant Discharge Elimination System (NPDES) permit process. The policy creates a new emphasis on comprehensive CSO system discharge monitoring and documentation programs. Acoustic transit-time flowmeters can be used to meet these monitoring and documentation requirements by providing high-accuracy and continuous flow data during dry- and wet-weather conditions in conduits that flow partially full and/or surcharged. Transit-time flowmeters provide bi-directional flow measurement capability and can be configured for multiple acoustic paths, making them highly accurate over a wide range of changing water level and flow conditions, as well as in locations where other flow measurement methods cannot be used reliably. This paper provides an introduction to the acoustic transit-time technique and its applicability to a wide range of difficult measurement sites and includes descriptions of existing CSO flow monitoring installations.

Introduction

The U.S. Environmental Protection Agency (EPA) is adopting a new Combined Sewer Overflow (CSO) Control Policy for incorporation into the National Pollutant Discharge Elimination System (NPDES) and Municipal Discharge permitting processes. This action is being taken in response to growing public concerns and Clean Water Act requirements for attaining minimum water quality standards in the receiving waters affected by CSO discharges. In many cases, the new CSO Policy and permitting process will require municipalities to develop and implement CSO system monitoring programs for planning, compliance, and reporting purposes.

The new regulatory focus on long-term CSO control programs increases the need for accurate flowrate measurement and monitoring systems that may be deployed at multiple locations within municipal networks. Flow monitoring data collected from key locations over a range of CSO system loadings frequently reveal significant

[1] Accusonic Division, ORE International, Inc.

differences in comparison to flow predictions resulting from computer models such as the Stormwater Management Model (SWMM). Such data is valuable for verification of the overall modeling approach and specific system features to be analyzed, and for calibration of the CSO flow network response to inflow events. However, achieving high accuracy with flow measurements is critical to meaningful system modeling and analysis since the propagation of uncertainties (errors) through flow networks can rapidly grow to unmanageable proportions.

Ultrasonic transit-time flowmeters can be used to meet these CSO monitoring and documentation requirements by providing highly accurate and continuous flowrate measurement during dry- and wet-weather conditions. Transit-time flowmeters include bi-directional (reverse flow) measurement capability and can be configured for multiple acoustic paths, making them highly accurate over a wide range of changing water level and flow conditions, as well as in locations where other measurement methods cannot reliably function.

In addition to providing the data needed for system modeling and evaluation, accurate flow information is valuable for:

- Regulatory reporting and compliance documentation
- Planning and evaluation of CSO control alternatives
- Alerting operators to CSO system malfunctions
- Optimizing operation of treatment facilities
- Allocating user costs and billings
- Pacing chemical treatments for CSO discharges

Requirements for CSO and Stormwater Flowmeter Systems

Flowmeters for CSO monitoring typically are required to operate under both free-flowing (i.e., in partially-filled conduits or open channels) and surcharged (pressurized) conditions. Additional measurement requirements can arise at locations subject to backflow, reverse flow, or tidally governed hydraulics. The need to accurately determine flowrates over such a wide range of conditions places stringent requirements on the methods and technology that can be successfully utilized in CSO applications. Methods that derive flowrate from measurements of water level only (using stage vs. flowrate relationships) are simply not capable of meeting these requirements.

A more suitable approach is developed from consideration of the hydrodynamic continuity equation, with a derived principle that applies to flow through any conduit section; i.e., flowrate is equivalent to multiplication of a true average current profile velocity times the cross-sectional area of the conduit flow. Since flows in conduits range from partially full through surcharged conditions, measurement of water level is used to determine the cross-sectional flow area (based upon the geometry of the conduit), and water velocities are measured to estimate the corresponding true average flow velocity.

VOL 12

7968

Since flow velocity profiles in surcharged conduits are significantly different than under free-flow conditions, a "compound" approach that automatically selects an appropriate integration method for computing representative velocity profiles and resultant averages will provide better flowrate accuracy. Conduit sections that are well-removed from upstream bends, obstructions, or other flow disturbances will exhibit "fully developed" flow velocity profiles; as will be discussed below, the multi-path transit-time method can provide accurate flowrate information even at sites where flow profiles are not well developed.

Ultrasonic Transit-Time Flow Measurement Principles

The Accusonic multi-path transit-time flowmeters discussed in this paper have been installed worldwide for high-accuracy flow measurement in over 1000 large pipes, open channels, and conduits that flow partially full to surcharged. The flowmeters, which operate in clean or "dirty" water environments, have been used in hydroelectric and water system applications since the 1960s. The flowmeters have been installed in numerous large CSOs and wastewater treatment plant influent and effluent channels for high accuracy and reliable flow measurement. Because the flowmeters use relatively low-frequency, high-power ultrasonic pulses for flow measurement, they are capable of operating in water with relatively high concentrations of suspended sediments, as is common in CSO environments.

The transit-time acoustic technique is based on the principle that an acoustic pulse traveling at an angle across a pipe will be accelerated in the downstream direction by the water flowing through the pipe and will arrive at a receiving transducer in less time than an acoustic pulse traveling in the upstream direction, which is decelerated. By mounting transducers to define a path crossing the pipe or channel at an angle to the flow axis (Figure 1) and measuring the difference in acoustic transit times in the upstream and downstream directions, an average flow velocity at the level of the acoustic path is calculated according to the following formula.

$$V = \frac{(T_1 - T_2)}{T_1 T_2} * \frac{L}{2 \cos \theta}$$

where:
- V = average fluid velocity at the level of the path,
- T_1 = acoustic transit time in the upstream direction,
- T_2 = acoustic transit time in the downstream direction,
- L = acoustic path length between transducers, and
- θ = acoustic path angle relative to flow axis.

In the multiple-parallel-path method, average velocity is measured nearly simultaneously at more than one elevation in the flow. These simultaneous velocities define a velocity profile throughout the flow cross-section for use in calculating an integrated flowrate. This should be contrasted with the use of a single-point or single-path velocity to estimate the average velocity throughout the cross-section. The use of multiple simultaneous velocities also makes the method responsive to changing flow profiles associated with quickly changing CSO flow regimes, which can go from completely dry to surcharged within minutes during a rain event.

In addition to the multiple flow velocities, water level within the conduit is measured. With the Accusonic multi-path acoustic technique, as the water level rises above each acoustic path, additional velocity information becomes available. The flowmeter computer changes integration method as appropriate to the number of submerged paths. The highest accuracy is available when the conduit becomes surcharged, and a full-pipe integration technique is applicable. Numerous independent field and laboratory tests have shown that accuracies of ± 0.5 to 1% of actual flowrate can be achieved in surcharged conduits with a 4-path configuration. These accuracies can be maintained even at sites with poor hydraulic conditions by adding a second plane of transducers in a cross-path configuration. The crossed-plane approach compensates for any errors due to cross-flow through the measurement section caused by upstream disturbances.

Under free-flowing (non-surcharged) conditions, flowrate accuracies of ± 2.0 to 3.0% of true flow are typically achieved with a 3-path system. The increased uncertainties are generally associated with determining the flow cross-section area and estimating an average velocity for the region above the highest operating acoustic path. The uncertainty can be minimized by adding acoustic paths (i.e., average velocities) at additional elevations and by averaging redundant level measurements.

For very low flows where the water level is below the lowest acoustic path, the meter can automatically switch to the Manning method (where applicable) to compute flowrate using level data only. Typically, however, an acoustic path is placed very low in the conduit to ensure that velocity data becomes available early in a rain event.

An additional advantage of the acoustic transit-time technique is that the system is "dry calibrated", based on measurement of as-built path lengths and angles at the time of transducer installation. Because the transducers are typically permanently installed, once these path lengths and angles are known and are entered into the flowmeter console as parameters, there is no need to recalibrate the system over time. The multiple-path method also obviates the need for flow profile calibrations that are required for single-point or single-path flowmeters.

Another feature of the multi-path transit-time technique is that it measures bi-directional flow, which can be particularly important in tidally influenced CSOs. For example, at New York City's Fresh Creek CSO, negative velocities occur on the lowest path during the periods of incoming tide while velocities on the higher paths indicate an outward flow. The meter determines the net flow through the CSO even during these periods of bi-directional flow profiles. A single-point, single-path, or acoustic Doppler-type velocity flowmeter cannot resolve true net flowrates under these conditions and can even indicate the wrong direction of flowage! This is of critical concern for control of tide gates or other CSO flow diversion mechanisms.

A general arrangement drawing showing a multiple-path flowmeter configuration installed in the City of Philadelphia's Cottman Avenue CSO is shown in Figure 2.

Transducer Selection for CSO/Stormwater Applications

Important considerations in choosing flowmeter transducers for CSO applications are cost, conduit shape, protrusion into the flow, ease of installation, and whether the transducers need to be certified for use in a hazardous location. Any transducer selected for CSO monitoring use should be constructed of durable, non-corrosible components for trouble-free, long-term operation.

A variety of ultrasonic transit-time transducers have been developed for use in a wide range of measurement applications, including buried and exposed steel pipes, concrete pipes and trapezoidal channels, and open channels. Internal mount transducers are often used in CSO and wastewater applications (Figure 3). Accusonic has developed a dual-element, internal-mount transducer providing a completely redundant back-up capability to the primary sensor. Low-cost, array-mount PVC transducers and explosion-proof transducers are also available. Transducers for mounting on the inside of pipes or channels have generally been designed to minimize protrusion and to direct flow around the transducer. At sites where large items of debris might be expected to damage anything mounted on the channel walls, transducers have been recessed in blockouts in the channels walls, or protective "deflectors" have been mounted upstream of the transducers to prevent damage.

Several different types of water level sensors can be used with the flowmeter--an acoustic "downlooking" transducer, which is mounted above the flow and measures level by the time it takes to receive an acoustic signal bounced off the water surface, an acoustic uplooking transducer (mounted on the channel bottom and reflecting an acoustic pulse off the water surface), or a submerged pressure sensor. Because of the possibility that debris could settle on an acoustic uplooking transducer and obscure the signal, a downlooking sensor is often recommended in CSO applications, with an uplooker or pressure sensor used for redundancy. The downlooking transducer is often recessed in a manhole for continued operation during surcharged conditions.

Recent Flow Monitoring Installations

Massachusetts Water Resources Authority

Accusonic flowmeters are currently operating for the Massachusetts Water Resources Authority (MWRA) in the Somerville, Commercial Point, and Constitution Beach CSOs. All three sites are instrumented with redundant internal mount transducers. The Somerville and Commercial Point sites are large rectangular box conduits (15' x 7' and 15' x 15', respectively) configured with three or four acoustic paths, and both are instrumented with an uplooking transducer for water level measurement. The flowmeter at Constitution Beach CSO is located in a 36-inch-diameter buried concrete pipe. Two acoustic paths and an uplooking level sensor are used here because of space constraints. The flowmeters at all three MWRA sites are used to pace chemical metering pumps for treatment of CSO discharges.

New York City Department of Environmental Protection

An Accusonic flowmeter was installed in one of four 9' x 15' rectangular outfalls at the New York City DEP's Fresh Creek CSO Flow-balanced Storage project as part of a flow study in the early 1990s. The multi-path transit-time method was ideally suited to this site because of the capability to measure simultaneous bidirectional flow at various levels. This site often experiences salt water flowing upstream on the incoming tides near the bottom of the outfalls while fresh runoff flows downstream at

VOL 12

7971

higher elevations. In 1993 the remaining three outfalls were instrumented with 3-path Accusonic flowmeters using low-cost array-mount transducers and an uplooking level sensor.

City of Philadelphia

A 3-path Accusonic flowmeter was installed in the City of Philadelphia's Cottman Avenue CSO in mid-1993 as part of an extensive CSO flowmeter intercomparison study. Low-cost array-mount transducers were installed in this rectangular 9' x 6'9" conduit. Four separate level sensors were included in the flowmeter configuration to measure water level at various locations in the CSO regulator, influent, and interceptor lines. Flow data is logged on a diskette in the flowmeter computer and is downloaded to the City's computers via dial-up modem. Data from several rain events exhibit rapidly changing flow conditions and demonstrate the need for simultaneous multiple-path measurement throughout the channel to provide accurate flow data (Figures 4, 5). Review of the velocity data simultaneously collected at the different levels in the flow during these events has demonstrated the superior flowrate accuracy and resolution provided by the multi-path technique. Flowrates derived from single-path velocity measurements, via use of a "meter factor" to calculate an average velocity representing the flow profile, are found to result in significantly greater uncertainties for flowrates measured over the wide range of conduit flows observed.

Summary and Conclusions

Multiple-path acoustic flowmeters provide capabilities for acquiring high-accuracy flow data in wide-ranging CSO system monitoring applications. New CSO control policies and regulations are increasing the need for flow monitoring by municipalities to meet the new regulatory requirements. Major features and advantages offered by multiple-parallel-path, transit-time flowmeter systems for CSO monitoring applications are summarized below.

- Capability to continuously measure, record, and transmit flow data
- Superior accuracy over complete range of changing flow and water levels
- Compound flow profile integration for free-flow or surcharge conditions
- No required "flow profile" calibration or recalibration over time
- Rugged, streamlined transducer design with minimal flow intrusion
- Multi-level, bi-directional flow measurement capability
- Remote system data access and control via telemodem
- Field-proven, long-term operating performance

STORMWATER INFILTRATION EFFECTS ON GROUNDWATER

Keith Parmer[1], Robert Pitt[2], Richard Field[3], Shirley Clark[4]

ABSTRACT

The research summarized here was conducted during the first year of a 3-yr US Environmental Protection Agency (EPA) cooperative agreement to identify and control stormwater toxicants, especially those adversely affecting groundwater. The purpose of this research effort was to review the groundwater contamination literature as it relates to stormwater. Potential problem pollutants were identified, based on their mobility through the unsaturated soil zone above groundwater, their abundance in stormwater, and their treatability before discharge. This information was used with earlier EPA research results to identify the possible sources of these potential problem pollutants. Recommendations were also made for stormwater infiltration guidelines in different areas and monitoring that should be conducted to evaluate a specific stormwater for its potential to contaminate groundwater.

INTRODUCTION

Prior to urbanization groundwater is recharged by rainfall-runoff and snowmelt infiltrating through pervious surfaces including grasslands and woods. This infiltrating water is relatively uncontaminated. Urbanization, however, reduces the permeable soil surface area through which recharge by infiltration occurs. This results in much less groundwater recharge and greatly increased surface runoff. In addition the waters available for recharge carry increased quantities of pollutants. With urbanization, waters having elevated contaminant concentrations also recharge groundwater including effluent from domestic septic tanks, wastewater from percolation basins and industrial waste injection wells, infiltrating stormwater, and infiltrating water from agricultural irrigation. This paper is a condensation of a detailed report (Pitt, *et al.*, 1993) and addresses potential groundwater problems associated with stormwater toxicants and describes how conventional stormwater control practices can reduce these problems.

METHODOLOGY

An extensive literature review (Pitt, *et al.*, 1993) of stormwater pollutants that have the potential to contaminate groundwater was obtained by searches of prominent databases. Areas of particular concern were sources of pollutants, stormwater constituents having high potential to contaminate groundwater, and treatment of stormwater.

RESULTS

Sources of Pollutants

High bacteria populations have been found in stormwater sheetflow samples from sidewalks, roads, and some bare ground (collected from locations where dogs would most likely be "walked"). Tables 1 and 2 summarize toxicant concentrations and likely sources or locations having some of the highest concentrations found during an earlier phase of this EPA-funded research (Pitt and Field, 1990). The detection frequencies for the heavy metals are close to 100% for all source areas and the detection frequencies for the organics ranged from 10% to 23%. Vehicle service areas had the greatest frequencies and concentrations of observed organics.

TABLE I. Concentrations of Metals in Observed Areas (μg/L)

Toxicant	Highest Median	Source	Highest Observed	Source
Cadmium	8	Vehicle service area runoff	220	Street runoff
Chromium	100	Landscaped area runoff	510	Roof runoff
Copper	160	Urban receiving water	1250	Street runoff
Lead	75	Vehicle service area runoff	330	Storage area runoff
Nickel	40	Parking area runoff	130	Landscaped area runoff
Zinc	100	Roof runoff	1580	Roof runoff

VOL 12

7976

TABLE II. Maximum Concentrations of Toxic Organics from Observed Sources

Toxicant	Maximum µg/L	Detection Frequency,%	Significant Sources
Benzo(a)anthracene	60	12	Gasoline, wood preservative
Benzo(b)fluoranthene	226	17	Gasoline, motor oils
Benzo(k)fluoranthene	221	17	Gasoline, bitumen, oils
Benzo(a)pyrene	300	17	Asphalt, gasoline, oils
Fluoranthene	128	23	Oils, gasoline, wood preservative
Naphthalene	296	13	Coal tar, gasoline, insecticides
Phenanthrene	69	10	Oils, gasoline, coal tar
Pyrene	102	19	Oils, gasoline, bitumen, coal tar, wood preservatives

1,3-Dichlorobenzene	120	23	Pesticide manufacturing

STORMWATER CONSTITUENTS HAVING HIGH POTENTIAL TO CONTAMINATE GROUNDWATER

Nutrients

Nitrates are one of the most frequently encountered contaminants in groundwater (AWWA 1990). Nitrate has leached from fertilizers and affected groundwaters under various turf grasses in urban areas, including golf courses, parks, and home lawns (Petrovic 1990; Ku and Simmons 1986; and Robinson and Synder 1991). Significant leaching of nitrates occurs during the cool, wet seasons. Cool temperatures reduce denitrification and ammonia volatilization and limit microbial nitrogen immobilization and plant uptake.

Residual concentrations of nitrate in soil vary greatly and depend on the soil texture, mineralization, rainfall and irrigation patterns, organic matter content, crop yield, nitrogen fertilizer/sludge application rate, denitrification, and soil compaction. Nitrate is highly soluble (>1 kg/L) and will stay in solution in the percolation water. If it leaves the root zone without being taken-up by plants, it will readily reach the groundwater (AWWA 1990).

Pesticides

Pesticide contamination of urban groundwater can result from municipal and homeowner use for pest control and the subsequent collection of the pesticide in stormwater runoff. Pesticides that have been found in urban groundwaters include: 2,4-D, 2,4,5-T, diazion, ethion, malathion, methyl trithion, silvex (German 1989), atrazine, simazine (Domagalski, *et al.* 1992) and chlordane (Greene 1992). Fungicides and nematocides must be mobile to reach the target pest, and hence, they generally have the highest groundwater contamination potential. Pesticide leaching depends on patterns of use, soil texture, total organic carbon content of the soil,

VOL 12

7977

pesticide persistence, and depth to the water table (Shirmohammadi and Knisel 1989).

The greatest pesticide mobility occurs in areas with coarse-grained or sandy soils without a hardpan layer, and with soils that have low clay and organic matter content and high permeability (Domagalski, *et al.* 1992). Structural voids, generally found in the surface layer of finer-textured soils rich in clay can transmit pesticides rapidly when the voids are filled with water and the adsorbing surfaces of the soil matrix are bypassed. The slower moving pesticides that may better sorb to soils have been recommended for use in areas of groundwater contamination concern.

Literature half-lives for pesticides generally apply to surface soils and do not account for the reduced microbial activity found deep in the vadose zone (Bouwer 1987). Pesticides with a 30-day half life can show considerable leaching. An order-of-magnitude difference in half-life results in a five- to ten-fold difference in percolation loss (Knisel and Leonard 1989). Organophosphate pesticides are less persistent than organochlorine pesticides but they also are not readily adsorbed by the sediment and are likely to leach into the vadose zone and the groundwater (Norberg-King, *et al.* 1991).

Other Organics

Groundwater contamination from organics, like that from other pollutants, occurs more readily in areas with sandy soils and where the water table is near the land surface (Troutman, *et al.*, 1984). Organics can be removed from the soil and recharge water by volatilization, sorption, and degradation (Crites 1985; and Nellor, *et al.*, 1985). Hydrophobic sorption onto soil organic matter limits the mobility of less soluble base/neutral and acid extractable compounds through organic soils and the vadose zone (German 1989). Organic resolubilization can occur during wet periods following dry periods. Temperature, pH, moisture content, ion exchange capacity of the soil, and air availability may limit the microbial degradation potential for even the most degradable organic compound (Crites 1985).

Microorganisms

Viruses have been detected in groundwater where stormwater recharge basins were located short distances above the aquifer (Vaughn, *et al.* 1978). Enteric viruses are more resistant to environmental factors than are enteric bacteria, and they exhibit longer survival times in natural waters. They can occur in potable and marine waters in the absence of fecal coliforms. Enteroviruses are also more resistant to commonly used disinfectants than are indicator bacteria (e.g., fecal coliforms), and they can occur in groundwater in the absence of indicator bacteria (Marzouk, *et al.* 1979).

The factors that affect the survival of enteric bacteria and viruses in the soil include pH, antagonism from soil microflora, moisture content, temperature, sunlight, and organic matter (Jansons, *et al.* 1989; Tim and Mostaghim 1991). The two most important attributes of viruses that permit their long-term survival in the environment are their structure and very small size. These characteristics permit virus occlusion and protection within colloid-size particles. Viral adsorption is promoted by increasing cation concentration, decreasing pH, and decreasing soluble organics (EPA 1992a).

The major bacterial removal mechanisms in soil are straining at the soil surface and at intergrain contacts, sedimentation, sorption by soil particles, and inactivation. Because their size is larger than viruses, most bacteria are retained near the soil surface because of this straining effect. In general, enteric bacteria survive in soil between 2 and 3 months, although survival times up to 5 yr have been documented (Crites 1985).

Metals

From a groundwater pollution standpoint, the metals in stormwater presenting the most concern are aluminum, arsenic, cadmium, chromium, copper, iron, lead, mercury, nickel, and zinc. These metals with the exception of zinc are however, associated with particulate fractions and potentially can be removed by either sedimentation or filtration processes (Armstrong, *et al.*, 1992).

Studies at recharge basins in Fresno California found that lead, zinc, cadmium, and copper accumulated at the soil surface with little downward movement over many years (Nightingale 1987a). At a commercial site, however, nickel, chromium, and zinc concentrations have exceeded regulatory limits in the soils below a recharge area (Wilson, et al. 1990). Allowing percolation ponds to go dry between storms can be counterproductive to the removal of lead from the water during recharge (Hampson 1986).

Similarities in water quality between runoff water and groundwater have shown that there is significant downward movement of copper and iron in sandy and loamy soils. Arsenic, nickel, and lead, however, did not significantly move downward through the soil to the groundwater. The exception to this was some downward movement of lead with the percolation water in sandy soils beneath Fresno stormwater recharge basins (Nightingale 1987b). Zinc which is more soluble than iron, has been found in higher concentrations in groundwater than iron. The order of attenuation in the vadose zone from infiltrating stormwater is: zinc (most mobile) > lead > cadmium > manganese > copper > iron > chromium > nickel > aluminum (least mobile) (Harper 1988).

Salts

Soil is not very effective at removing salts. Salts that are still in the percolation water after it travels through the vadose zone will contaminate the groundwater (Sabol, *et al.* 1987; and Bouwer 1987). Infiltration of stormwater has led to increases in sodium and chloride concentrations above background concentrations. Fertilizer and pesticide salts also accumulate in urban areas and can leach through the soil to the groundwater (Merkel, *et al.*, 1988). Studies of depth of pollutant penetration in soil have shown that sulfate and potassium concentrations decrease with depth, whereas sodium, calcium, bicarbonate, and chloride concentrations increase with depth (Close, 1987; Ku and Simmons, 1986). Once contamination with salts begins, the movement of salts into the groundwater can be rapid. The salt concentration may not lessen until the source of the salts is removed (Higgins, 1984).

TREATMENT OF STORMWATER

Table 3 summarizes the filterable fraction of toxicants found in storm runoff sheetflows from many urban areas found during an earlier phase of this EPA-funded research (Pitt and Field 1990). Pollutants in dry-weather storm drainage flows, however, tend to be associated with filtered sample fractions and would not be readily controlled with the use of sedimentation. (Pitt, et al. 1993)

Sedimentation is the most significant removal mechanism for particulate-related pollutants. Detention ponds are probably the most common management practice for the control of stormwater runoff. If properly designed, constructed, and maintained, wet detention ponds can be very effective in controlling a wide variety of pollutants. The monitored performance of wet detention ponds indicates more than 90% removal for suspended solids, 70% for BOD, and COD, about 60% to 70% for nutrients, and about 60% to 95% for heavy metals (EPA 1983). Catchbasins are very small sedimentation devices. Adequate cleaning can help reduce lead and total solids in urban runoff by between 10% and 25%, and COD, total Kjeldahl nitrogen, total phosphorus, and zinc by between 5% and 10% (Pitt 1984; and Pitt and Shawley 1981).

TABLE III. Reported Filterable (Dissolved Solids) Fractions of Stormwater Toxicants from Source Areas

Constituent	Filterable (Dissolved Solids) Fraction (%)
Cadmium	20 to 50
Chromium	<10
Copper	<20
Iron	Small amount
Lead	<20
Nickel	Small amount
Zinc	>50
Benzo(a)anthracene	None found in filtered fraction
Fluoranthene	65
Naphthalene	25
Phenanthrene	None found in filtered fraction
Pyrene	95
Chlordane	None found in filtered fraction
Butyl benzyl phthalate	Irregular
Bis(2-chloroethyl)ether	Irregular
Bis(2-chloroisopropyl)ether	None found in filtered fraction
1,3-Dichlorobenzene	75

Volatilization and photolysis are other important pollutant removal mechanisms in wet detention ponds. Biodegradation, biotransformation, and bioaccumulation (into plants and animals) may also occur in larger and open ponds.

Upland infiltration devices (e.g., infiltration trenches, porous pavements, percolation ponds, and grass roadside drainage swales) are located at urban source areas. Infiltration (percolation) ponds are usually located at stormwater outfalls or at large paved areas. These basins, along with perforated storm sewers, can infiltrate

VOL 12

7980

flows and pollutants from all upland sources combined. Infiltration devices can safely deliver large fractions of the surface flows to groundwater, if carefully designed and located (EPA 1983). Grass swales allow the recharge of significant amounts of surface flows. Swales can also reduce pollutant concentrations because of filtration. Soluble and particulate heavy metal (copper, lead, zinc, and cadmium) concentrations can be reduced by at least 50%, COD, nitrate nitrogen, and ammonia nitrogen concentrations can be reduced by about 25%, but only inconsistent concentration reductions can be expected for organic nitrogen, phosphorus, and bacteria (EPA 1983).

CONCLUSIONS

This entire research project will provide guidance on critical source area treatment (EPA 1992b), especially for the protection of groundwater quality. Much of the information will also be useful for analyzing stormwater problems and needed controls for surface water discharges. Table 4 is a summary of the pollutants found in stormwater that may cause groundwater contamination problems for various reasons. This table does not consider the risk associated with using groundwater contaminated with these pollutants. This table is appropriate for initial estimates of contamination potential because of the simplifying assumptions made, (e.g., the worst case mobility conditions assumed: sandy soils having low organic content). When the soil is clayey and has a high organic content, then most of the organic compounds would be less mobile than as shown in this table. The abundance and filterable fraction information is generally applicable for warm weather stormwater runoff in residential and commercial areas. The pollutant concentrations and detection frequencies, however, would be greater for critical source areas (especially vehicle service areas) and critical land uses (especially manufacturing industrial areas).

The stormwater pollutants of most concern (those that may have the greatest adverse impacts on groundwaters) include:

- Nutrients
- Pesticides
- Other organics
- Pathogens
- Metals
- Salts

Pollution prevention can also play an important role in minimizing groundwater contamination problems, including reducing the use of galvanized metals, pesticides, and fertilizers in critical areas. The use of specialized treatment devices (e.g., those being developed and tested during this research (EPA 1992b) can also play an important role in treating runoff from critical source areas before these more contaminated flows commingle with less polluted runoff from other areas.

TABLE IV. Potential of Stormwater Pollutants to Contaminate Groundwater

Pollutant	Compound	Mobility	Abundance	Fraction filterable	Potential: surface infiltration	Potential: subsurface disposal
Nutrients	nitrate	mobile	low-moderate	high	low	low
Pesticides	2,4-D	mobile	low	low	low	low
	Lindane	intermediate	moderate	low	moderate	moderate
	malathion	mobile	low	low	low	low
	atrazine	mobile	low	low	low	low
	chlordane	intermediate	moderate	very low	moderate	moderate
	diazinon	mobile	low	low	low	low
Other organics	VOCs	mobile	low	very high	low	low
	1,3-dichloro benzene	low	high	high	low	high
	anthracene	intermediate	low	moderate	low	low
	benzo(a) anthracene	intermediate	moderate	very low	moderate	moderate
	bis(2-ethylhexyl) phthalate	intermediate	moderate	low	moderate	moderate
	butyl benzyl phthalate	low	low-moderate	moderate	low	low-moderate
	fluoranthene	intermediate	high	high	moderate	high
	fluorene	intermediate	low	low	low	low
	naphthalene	low intermediate	low	moderate	low	low
	pentachloro phenol	intermediate	moderate	low	moderate	moderate
	phenanthrene	intermediate	moderate	very low	moderate	moderate
	pyrene	intermediate	high	high	moderate	high
Pathogens	entero viruses	mobile	present	high	high	high
	Shigella	low-intermediate	present	moderate	low-moderate	high
	P. aeruginosa	low-intermediate	very high	moderate	low-moderate	high
	protozoa	low-intermediate	present	moderate	low-moderate	high
Metals	nickel	low	high	low	low	high
	cadmium	low	low	moderate	low	low
	chromium	intermediate-low	moderate	very low	low-moderate	moderate
	lead	very low	moderate	very low	low	high
	zinc	low-very low	high	high	low	high
Salts	chloride	mobile	high	high	high	high

RECOMMENDATIONS

With a reasonable degree of site-specific design considerations to compensate for soil characteristics, infiltration may be very effective in controlling both urban runoff quality and quantity problems (EPA 1983). The following general guidelines for the infiltration of stormwater and other storm drainage effluent are recommended in the absence of comprehensive site-specific evaluations:

- Dry-weather storm drainage effluent should be diverted from infiltration devices because of their probable high concentrations of soluble metals, pesticides, and pathogenic microorganisms.
- Combined sewage overflows should be diverted from infiltration devices because of their poor water quality, especially their high pathogenic concentrations and high clogging potential.
- Snowmelt runoff should be diverted from infiltration devices because of its potential for having high concentrations of soluble salts.
- Runoff from manufacturing industrial areas should be diverted from infiltration devices because of its potential for having high concentrations of soluble toxicants.
- Construction site runoff must be diverted from stormwater infiltration devices (especially subsurface devices) because of its high suspended solids (sediment) concentrations, which would quickly clog infiltration devices.
- Runoff from other critical source areas (e.g., vehicle service facilities and large parking areas) should at least receive adequate pretreatment to eliminate their groundwater contamination potential before infiltration.

Runoff from residential areas (the largest component of urban runoff in most cities) is generally the least polluted urban runoff flow and should be considered for infiltration. Very little treatment of residential area stormwater runoff should be needed before infiltration, especially if surface infiltration is through the use of grass swales.

RECOMMENDED STORMWATER QUALITY MONITORING TO EVALUATE POTENTIAL GROUNDWATER CONTAMINATION

Most past stormwater quality monitoring efforts have not adequately evaluated stormwater's potential for contaminating groundwater. The following list shows the stormwater contaminants that are recommended for monitoring when stormwater contamination potential needs to be considered or when infiltration devices are to be used. Other analyses are appropriate for additional monitoring objectives (e.g., evaluating surface water problems). In addition, all phases of urban runoff should be sampled, including stormwater runoff, dry-weather flows, and snowmelts.

These are the urban runoff contaminates with the potential to adversely affect groundwater:

- Nutrients (especially nitrates)
- Salts (especially chloride)
- VOCs

VOL 12

7983

- Pathogens
- Bromide and total organic carbon
- Pesticides, in both filterable and total sample components
- Other organics, in both filterable and total sample components
- Metals, in both filterable and total sample components

The following urban runoff compounds with the potential to adversely affect infiltration and injection operations:

- Sodium, calcium, and magnesium (to calculate the sodium adsorption ratio to predict clogging of clay soils)
- Suspended solids (to determine the need for sedimentation pretreatment to prevent clogging)

ACKNOWLEDGMENTS

The project was prepared with the assistance of many individuals. Two Coca Cola summer interns, Shirita Scott and Camille Hubbard, assisted in the laboratory and helped prepare the bibliographic information system on groundwater impacts. A number of University of Alabama at Birmingham Civil and Environmental Engineering students also volunteered their time to help with various aspects of this research. Robert Henderson and Ali Ayyoubi helped with the simulated evaluation and design aspects of the critical area treatment device. Thanks are especially extended to Patty Barron, Michael Richards, and Paul Latino, who helped Brian Robertson in the construction of the treatment device that will be tested during the next project phase. Michelle Pickney and Ken Boyer also helped in conducting many of the preliminary treatment column test using soil and other media.

Karen Gordon, Marty Truscott, Keith Henderson, John Hess, Catherine Breen, and other personnel of Henderson, Breen & Hess, Forked River, New Jersey, were instrumental in carrying out the field sampling, coordinating with local agencies, and collecting necessary site data for the Stafford, New Jersey test sites. The City of Stafford and Ocean County, New Jersey, Public Works Departments and the Stafford school board are especially acknowledged for their assistance for access to test sites.

Richard Field, Chief of the Storm and Combined Sewer Pollution Control Program, EPA, was the Project Officer for this project and provided much valued direction during this research. Michael Brown, Tom O'Connor and Bill Vilkelis of his staff also provided important project assistance. Helpful comments from the EPA report reviewers are also gratefully acknowledged.

A MULTI-CHAMBERED STORMWATER TREATMENT TRAIN

Brian Robertson[1], Robert Pitt[2], Ali Ayyoubi[3], and Richard Field[4]

ABSTRACT

The Department of Civil and Environmental Engineering at the University of Alabama at Birmingham is engaged in a three year cooperative agreement with the Storm and Combined Sewer Program of the U.S. EPA. Part of this cooperative agreement includes the testing of a special treatment device (a multi-chambered treatment train, or MCTT) to treat runoff from critical source areas. This paper reviews the design of the MCTT and presents preliminary performance monitoring information. A pilot-scale MCTT has been constructed in Birmingham, AL and a six month monitoring period was started in May 1994. Two additional full-scale MCTT units will be constructed and monitored as part of Wisconsin's 319 grant from the EPA during the coming year. Complete organic and metallic toxicant analyses, in addition to conventional pollutants, are included in the analysis program. It is expected that the MCTT will be capable of cost-effectively removing at least 75% of the most critical toxicants near their source.

INTRODUCTION

Runoff from paved parking and storage areas, and especially gas station areas, has been observed to be heavily contaminated with concentrations of many pollutants being 3 to 600 times greater than typical receiving water criteria. These paved areas are usually found to contribute most of the toxicant pollutant loadings

to the stormwater outfalls in residential and commercial areas. PAHs, the most commonly detected toxic organic compounds found in urban runoff, are mostly from fossil fuel combustion. These compounds are very hard to control by eliminating their use, and, unfortunately, their control by typical stormwater management practices is not well understood. The major benefit of this research project will be to better understand how these toxicants can be controlled at critical source areas, especially automobile service facilities.

METHODOLOGY

Earlier bench scale treatability studies of this U. S. Environmental Protection Agency (EPA) sponsored research found that the most beneficial treatment for the removal of stormwater toxicants (as measured using the Microtox™ test) included column settling for at least 24 hours (generally 40% to 90% reductions), screening through at least 40 micron (μm) screens (20% to 70% reductions), and aeration and/or photo-degradation for at least 24 hours (up to 80% reductions) (Pitt, *et al.* 1994). A pilot-scale MCTT has been constructed and is currently being tested in Birmingham, Alabama. Two full-scale MCTT units are scheduled to be constructed during the summer and fall in Wisconsin as part of their EPA 319 grant. The MCTT contains aeration, sedimentation, sorption, and sand/peat filtration and is expected to result in good toxicant removals. These devices will be suitable for subterranean use at gas stations and other automobile service facilities.

The MCTT includes a special catchbasin followed by a two chambered tank that is intended to reduce a broad range of toxicants (volatile, particulate, and dissolved). The runoff enters the catchbasin chamber by passing over a flash aerator (small column packing balls with counter-current air flow) to remove highly volatile components. This catchbasin also serves as a grit chamber to remove the largest (fastest settling) particles. The second chamber serves as an enhanced settling chamber to remove smaller particles and has inclined tube or plate settlers to enhance sedimentation. This chamber also contains fine bubble diffusers and sorbent pads to further enhance the removal of floatable hydrocarbons and additional volatile compounds. The water is then pumped to the final chamber at a slow rate to maximize pollutant reductions. The final chamber contains a mixed media (sand and peat) slow filter, with a filter fabric layer. The MCTT is typically sized to totally contain all of the runoff from a 12.7 mm (0.5 inch) rain from a typical 0.2 ha (0.5 acre) gas station. If the area is larger, then multiple, or larger, units will be needed. Figure 1 is a diagram of this device. Samples are being collected before and after each chamber of the device.

To better estimate fate and treatability of toxicants, samples are partitioned into filterable ("dissolved") and non-filterable ("particulate") components before being

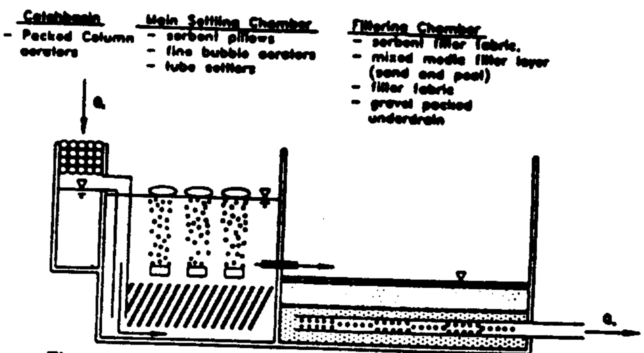

Figure 1. Multi-chambered treatment train (MCTT) schematic.

analyzed for a wide range of toxicants using detection limits from about 1 to 10 μg/L and conventional pollutants. Constituents being analyzed include heavy metals (copper, cadmium, lead, and zinc) and organics (phenols, PAHs, phthalate esters, herbicides, and pesticides). Particle size distributions, using a Coulter Multi-Sizer IIe, are also being made, in addition to conventional analyses for COD, major ions, nutrients, suspended and dissolved solids, turbidity, color, pH, and conductivity. Samples are also screened using the Microtox™ toxicity test to measure relative reductions in toxicity.

DISCUSSION: PRELIMINARY DESIGN OF THE MCTT AND EXPECTED PERFORMANCE

Catchbasin/Grit Chamber

Catchbasins have been found to be effective in removing pollutants associated with coarser runoff solids (Lager and Smith 1976, Pitt and Bissonnette 1985). High reductions in total and suspended solids (SS) (up to 44% reduction, depending on the inflowing water rate) were indicated by a number of prior studies. While relatively few pollutants are associated with these coarser solids, their removal will decrease maintenance of the other chambers.

The size of the MCTT catchbasin sump is controlled by three factors: the runoff flow rate, the suspended solids (SS) concentration in the runoff, and the desired frequency at which the catchbasin will be cleaned so as not to sacrifice efficiency. Figure 2 is a plot of the accumulation of SS versus accumulative rain. This plot provides an approximation for sizing the catchbasin.

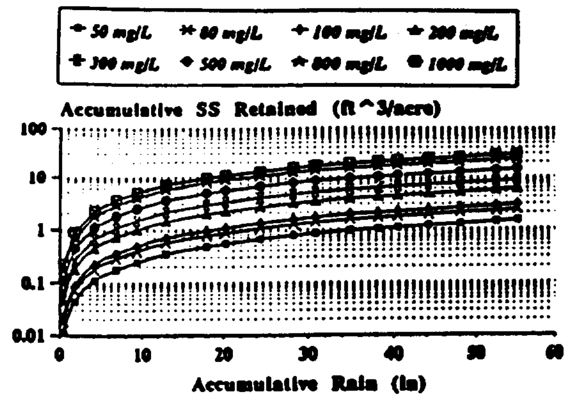

Figure 2. Accumulation of suspended solids in catchbasin sump.

Main Settling and Oil and Grease Trap Chamber

The main settling chamber mimics completely mixed settling column bench-scale tests and uses a treatment ratio of depth to time for removal estimates. In addition to housing plate or tube settlers, the main settling chamber contains floating sorbent "pillows" to trap floating grease and oil and contains a fine bubble diffuser. The settling time in the main settling chamber usually ranges from 20 to 70 hours.

Figure 3 shows the percentage of annual runoff treated, based on specific volumes of treatment provided. If runoff from 25 mm (1 inch) of rain is treated in the main settling chamber, about 70% of the annual Birmingham runoff volume would be directly treated. If this volume was increased to two inches, then about 90% of the annual runoff would be treated.

Figure 4 shows the percent toxicity reductions (compared to the initial toxicity levels) for all samples, plotted against the toxicity removal rate (depth/time), for plain settling alone. Toxicity removal rate is for the batch process which is equivalent to the surface overflow rate for continuous processes. The range of possible toxicant removal is expected to vary greatly, depending on sample characteristics. The settling chamber is supplemented by other processes including flash aeration, extended aeration, sorbent pillows, peat sorption, and sand filtration which will combine to reduce expected variations in treatment performance.

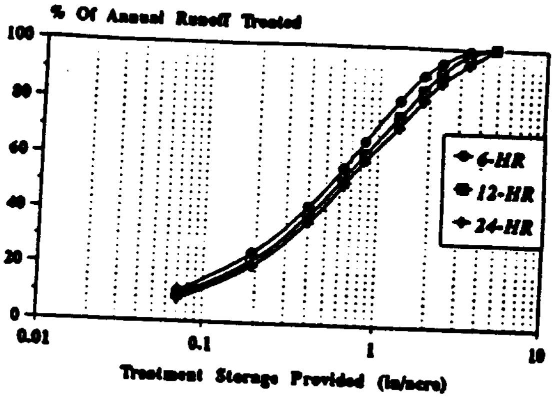

Figure 3. Effects of treatment volume on fraction of annual runoff treated.

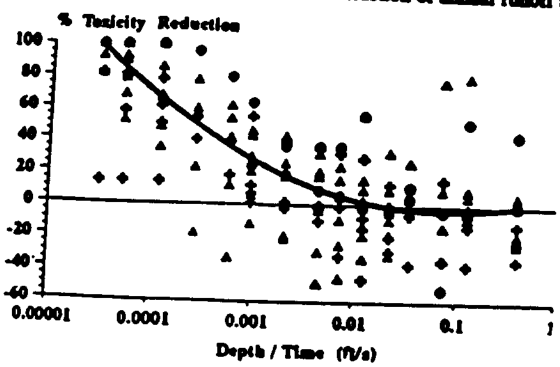

Figure 4. Percent toxicity reduction as a function of treatment rate (ft/s)

EXAMPLE DESIGN

A computer model was developed to determine the amount of annual rainfall treated, the toxicity reduction rate for each individual storm, and the overall toxicity reduction associated with the total annual rainfall for Birmingham, Alabama. Table I shows the treatment rates m/sec and median toxicity reductions for a 2.1m (7 ft) deep main settling chamber with the water held for various times (from Figure 4).

Table I. Median Toxicity Reductions for Different Treatment Holding Times

Holding Period (h)	Treatment Rate (m/s)	Median Toxicity Reduction (%) per Individual Rain
6	9.8×10^{-5}	46
12	4.9×10^{-5}	60
24	2.5×10^{-5}	75
36	1.6×10^{-5}	84
48	1.2×10^{-5}	92
72	8.2×10^{-6}	100

The same treatment rates and toxicity removals would occur if the main settling chamber was half as deep (1.1m or 3.5 ft in this example) and the water was held for half as long. For this shallower example, however, the treatment tank would have to be twice as large in surface area to provide the same volume. The computer simulation shows the significance of having an adequate volume. Table II illustrates the effects of different treatment volumes, expressed as inches of rain and runoff, using small storm hydrology concepts for paved areas (Pitt 1987), on the annual percentage of Birmingham rains captured and treated and on the annual total toxicity reduction. As an example, if the MCTT is full from a previous rain (because of the required holding period), the next storm would bypass the MCTT with no treatment. Birmingham rains occur about every 3 to 5 days, on the average, so it would be desirable to have the holding period significantly less than this value. Similarly, if the storage volume was small, only a fraction of a large rain would be captured and treated, requiring a partial bypass. The annual toxicity reductions are calculated by knowing the individual storm treatment reductions (from Table I) and the annual percentage of runoff treated. As an example, if the holding period was 24 hours for a 2.1 m (7 ft) deep settling chamber, the individual storm treatment would be about 75%. If the MCTT was large enough to contain the runoff from a 38.1 mm (1.5 inch) rain, then about 98% of the annual runoff would be treated, for an annual expected toxicity reduction of 73% (0.75 X 0.98 = 0.73).

Figure 5 is an extension of Table II for additional conditions. It shows plots for Birmingham for different annual control levels associated with holding periods from 6 to 72 hours and storage volumes from 2.5 to 64 mm (0.1 to 2.5 inches) of runoff for a 2.1 m (7 ft) deep MCTT. This figure can be used to determine the size of the main settling chamber and the minimum required detention time to obtain a certain level of control (toxicity reduction). As noted previously, if the tank is shallower than 2.1 m (7 ft), then the holding periods should be similarly decreased. If the tank is only 1 m (3.5 ft) deep, then the required holding periods would only be half as long, but the surface area would have to be twice as large to obtain the same storage volume.

Table II. Effects of Storage Volume and Holding Periods on Annual Runoff Treated and on Total Annual Toxicity Reduction

Holding Period (h)	12.7 mm rain with 10.2 mm runoff (0.50 in. rain with 0.40 in. runoff) % Annual Runoff Treated	% Annual Toxicity Reduction	38.1 mm rain with 33.5 mm runoff (1.50 in. rain with 1.32 in. runoff) % Annual Runoff Treated	% Annual Toxicity Reduction
6	84	39	100	46
12	62	37	100	60
24	52	39	98	73
36	48	41	91	77
48	46	42	88	81
72	44	44	84	84

An example design follows for a 0.2 ha (0.5 acre) paved drainage area and an overall annual toxicity reduction of about 75%. A combination of a 48 h holding time and 27 mm (1.05 in.) runoff storage volume would satisfy this goal. Figure 5 shows that this is the smallest MCTT that could achieve this annual reduction goal, without going to an unusually long treatment period. The marginal reduction in storage volume would be more than offset by problems associated with totally bypassing and not treating many of the storms that would occur with the 72 h treatment time (larger variations in runoff quality would result).

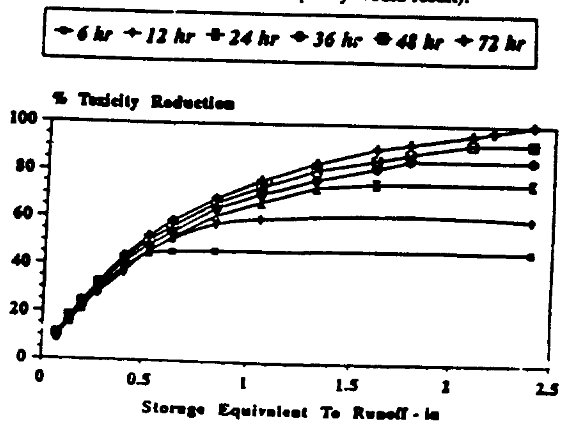

Figure 5. Effects of storage volume and treatment time on annual toxicity reduction

This 27 mm runoff volume corresponds to a rain depth of about 31 mm (1.22 in.). The 27 mm runoff storage volume corresponds to a chamber volume of 54 m^3 (1900 ft^3), a surface area of 25.5 m^2 (273 ft^2), and a depth of 2.1 m (7 ft). The toxicity reductions in the main settling chamber for captured runoff is about 92%. This device would capture and treat about 80% of the annual runoff at this 92% level, resulting in an annual toxicity reduction of about 74% (0.8 X 0.92).

Additional treatment would result from the filter. The pumped effluent from the main settling chamber would be directed towards a mixed peat and sand filter, which must provide a surface hydraulic loading rate of between 1.5 and 6 m per day (5 and 20 ft per day), and have a depth of at least 0.5 m (18 in.). In addition to the pumped effluent, any excess runoff after the main settling chamber is full would also be directed towards the filter.

Each of the treatment chambers would be vented, mosquito proofed, and be easily accessible for maintenance. The device should be inspected, the initial catchbasin should be cleaned, and the sorbent pillows should be exchanged, at least every six months.

PRELIMINARY OBSERVATIONS

A pilot-scale MCTT was set up to capture runoff from a parking and vehicle service area on the campus of the University of Alabama at Birmingham. The catchbasin/grit chamber is a 25 cm vertical PVC pipe containing about 6 L of 3 cm diameter packing column spheres. The main settling chamber is about 1.3 m^2 in area and 1 m deep which with a 48 h settling time should result in a median toxicity reduction of about 90%. The filter chamber is about 1.5 m^2 in area and contains 0.5 m of sand and peat directly on 0.15 m of sand over a fine plastic screen and coarse gravel that covers the underdrain. A Gunderboom™ filter fabric also covers the top of the filter media to distribute the water over the filter surface by reducing the water infiltration rate through the filter and to provide additional pollutant capture.

During a storm event, runoff from the parking lot is pumped into the catchbasin/grit chamber automatically. During filling, an air pump supplies air to aeration stones located in the main settling chamber. When the settling chamber is full, all pumps and samplers cease. After a quiescent settling period of up to 72 hours water is pumped through the filter media and discharged. Monitoring began in late May and five storms (of the 12 proposed) have been evaluated by the end of June 1994. Completion of the monitoring and laboratory analyses is expected by the end of September 1994. The following paragraphs briefly summarize the available data obtained to date.

The reduction in toxicity (as measured using the Microtox© test by Microbics) ranged from 70 to 100%, with a median reduction of 95% (slightly better than the 90% predicted). The toxicity of the filtered samples were also substantially reduced (50 to 100%, median of 76%). Almost all of the total sample toxicity reduction occurred in the sand and peat filter, but large reductions in the filtered sample toxicity (34 to 100%, median of 52%) occurred in the main settling chamber. The results from the specific metal and organic analyses are not yet available, but these toxicity data indicate excellent toxicant removals, as expected based on earlier bench-scale tests (Pitt, *et al.* 1994).

Overall COD reductions ranged from 36 to 100% (median of 64%) with influent concentrations ranging from 2 to 114 mg/L (median of 68 mg/L). Most of these reductions occurred in the filtering unit. Dissolved COD reductions showed substantial variations (0 to 100%, median of 50%), with concentration increases occurring in the filtering unit for some events and most of the dissolved COD reductions occurring in the main settling chamber.

Suspended solids reductions ranged from 25 to 60% overall, including large increases that occurred in the sand and peat filter due to limited media washout. The suspended solids reductions before the filter was much greater, being about 75 to 90%. Turbidity and color also experienced substantial increases during the filtration process (turbidity going from 2 to 16 NTU in the influent to the complete treatment unit to effluent values of 5 to 24 NTU, still relatively low, and color going from 24 to 58 HACH units in the influent to 44 to 100 HACH units in the effluent). The peat also apparently caused a reduction in pH, from 6.95 to 7.27 in the filter influent to 5.93 to 6.37 in the effluent.

CONCLUSIONS

This research examined the design of a multi-chambered tank to collect and treat stormwater runoff from critical urban source areas, including gas stations, oil change facilities, transmission repair shops, and other auto repair facilities. The collected runoff will first be treated in a catchbasin chamber where larger particles will be removed by settling. The water would then flow into a main settling chamber containing oil and grease sorbent material where it will undergo a much longer treatment period (20 to 70 hours) to remove finer particles and to remove oil residues.

These preliminary results show that the treatment unit is providing substantial reductions in stormwater toxicants (both in particulate and filtered phases), organics, and suspended solids. Slight increases in turbidity and color and about a unit in pH reduction also occurred during the filtration step. The filter unit appears to be responsible for most of the toxicity reductions. However, the main settling chamber also resulted in substantial reductions in the dissolved toxicity fraction, total and dissolved COD, suspended solids, turbidity, and color. The catchbasin/grit chamber also showed suspended solids reductions. The use of the MCTT is seen to be capable of reducing a broad range of stormwater pollutants that have been shown to cause substantial receiving water problems (Pitt 1994b).

ACKNOWLEDGMENTS

The Department of Civil and Environmental Engineering at the University of Alabama at Birmingham is engaged in a three year cooperative agreement (CR No. 819573) with the Storm and Combined Sewer Program of the U.S. EPA. This presentation is a preliminary description of one the activities of this agreement. Grateful acknowledgment is extended to the EPA staff for funding and directing this research.

Stormwater Treatment: Inlet Devices and Filtration

Shirley Clark, Robert Pitt[1], and Richard Field[2]

Abstract

The Department of Civil and Environmental Engineering at the University of Alabama at Birmingham is engaged in a three year cooperative agreement (CR No. 819573) with the Storm and Combined Sewer Pollution Control Program of the U.S. EPA to monitor the performance of three stormdrain inlet filters, an optimally designed catchbasin, and several filter fabrics and filtering media. Henderson & Breen Environmental Engineers of Forked River, New Jersey, are overseeing the field installations, sampling, and shipping of the samples to the University of Alabama at Birmingham (UAB) for analyses.

This summary reviews these devices and presents the field verification that has been conducted to date to confirm their performance. The test facilities for the inlet devices are located in a residential area and at the township public works yard in Stafford, NJ. The filter fabrics and filtering media are being evaluated in the laboratory using stormwater runoff from a large parking area on the campus of UAB. The monitoring program began in January 1994 and will include about 12 inlet and effluent samples from these devices over several different storms. Complete organic and metallic toxicant analyses, in addition to conventional pollutants, are included in the analytical program.

Introduction

Stormwater runoff from problem source areas needs to be treated to prevent harm either to the surface waters or the groundwaters. One approach is to treat the

[1] Graduate student and Associate Professor, respectively, Department of Civil and Environmental Engineering, the University of Alabama at Birmingham, Birmingham, Alabama 35294.

[2] Chief, Storm and Combined Sewer Pollution Control Program, Office of Research and Development, U.S. Environmental Protection Agency, 2890 Woodbridge Ave. (MS 106), Edison, New Jersey 08837.

runoff from problem source areas before it mixes with the runoff from less polluted areas. The general features of critical source areas appear to be large paved areas, heavy vehicular traffic and outdoor use or storage of problem pollutants. The control of small critical area contributions to urban runoff may be the most cost-effective approach for treatment/reduction of stormwater toxicants. Single, small point source treatment devices are currently being marketed for runoff treatment. In order for a treatment device to be suitable for an industrial or commercial area, it must be inexpensive both to purchase and maintain. This research is designed to evaluate several commercially-available filtration devices and catchbasin units, as well as the common filtration media that can be incorporated into many stormwater treatment devices.

Monitoring Program

This research program is obtaining paired "before" and "after" samples from each device. About 12 pairs of samples will be obtained for each catchbasin device being tested in the field, creating about 48 samples (including both filtered and unfiltered before and after samples) that will be analyzed for each of the four catchbasin devices. Controlled laboratory tests are also being conducted on the filtration media and filter fabrics.

Samples will be partitioned into filterable and non-filterable components before analysis so that fate and treatability of pollutants may be better estimated. Samples will be analyzed for a wide range of toxicants using very low detection limit (1 to 10 μg/L) methods. The constituents being analyzed include conventional pollutants (COD, major ions, nutrients, suspended and dissolved solids, turbidity, color, pH and conductivity), heavy metals (copper, cadmium, lead, and zinc) and organics (PAHs, phenols, phthalate esters, and herbicides and pesticides). Samples will also be screened for relative reductions in toxicity across the treatment device using the Microtox™ toxicity test and for particle size distributions, using a Coulter Multi-Sizer IIe.

Preliminary Design and Expected Performance of Inlet Devices

Optimal Catchbasin. Catchbasins can be effective in removing the pollutants associated with coarser runoff solids, although relatively few pollutants are associated with these solids. High reductions in total and suspended solids (SS) (up to 45% reduction, depending on the influent flow rate) were indicated by a number of prior studies (Pitt 1979, Pitt 1984). The size of the catchbasin sump is controlled by three factors: the runoff flow rate, the runoff SS concentration, and the desired cleaning frequency (without sacrificing efficiency) for the catchbasin. Based on earlier EPA research, an optimal catchbasin design should have the following dimensions: If the outlet pipe is D inches in diameter, its bottom should be located about 2.5 D below the street level and 4D from the bottom of the catchbasin sump.

The overall height of the catchbasin should therefore be 6.5D, with a diameter of 4D. The optimal catchbasin is located in a residential area in Stafford, New Jersey.

Sages Filter. The Sages catchbasin filter was developed by John VanEgmond of Acton, Ontario. Figure 1 is a cross-section of the unit showing its placement in an existing catchbasin. It consists of subsurface gravel and sand prefilters and an activated carbon filter. After filtration, the stormwater is infiltrated into the local groundwater. The Sages unit is installed on a pole above ground in the Stafford Township public works year in New Jersey. This surface installation enables us to better control the stormwater flow into the unit and to better obtain representative inlet and outlet samples. The unit will be the last inlet device to be evaluated.

EMCON Catchbasin Filter. The EMCON filter unit was developed by Emcon North West in Bothell, Washington for use in existing catchbasins. Figure 2 shows a cross-section of the unit. It is a combination filtration/sedimentation device. When the filter fabric clogs, the stormwater overflows over small rectangular weirs, acting as a small sediment trap. In addition to the field tests, the EMCON filter fabric is also being tested in the laboratory.

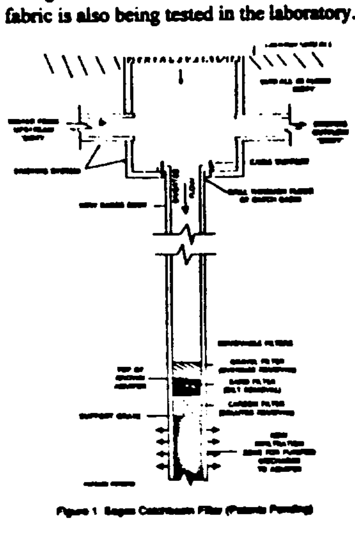

Figure 1 Sages Catchbasin Filter (Patents Pending)

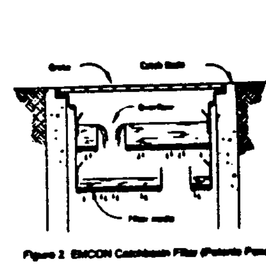

Figure 2 EMCON Catchbasin Filter (Patents Pending)

SoilSave. The SoilSave stormwater filter unit, developed by R.B.S. Enterprises, Paxinos, PA, uses a relatively coarse geofoam filtering media (900 µm cell side diameter) that is sandwiched between two pieces of galvanized screen. The SoilSave unit fits in a catchbasin and is sealed along the bottom and sides of the inlet box, forcing any water through the unit before it is discharged. It is designed to

VOL 12

8001

filter larger debris, including leaves and grass clippings, from the runoff. The SoilSave unit is installed in a residential area of Stafford, New Jersey.

Preliminary Design and Expected Performance of Filtering Media

Sand. Sand filtration for stormwater treatment began in earnest in Austin, Texas. The Austin sand filters are used for single sites and for drainage areas less than 20 ha. They are designed to hold and treat the first 12 mm of runoff with very good pollutant removal ability. If the City's design guidelines are followed, the assumed pollutant removal efficiencies, which are based upon preliminary results of the City of Austin's stormwater monitoring program, are as follows: fecal coliform bacteria (76%), total suspended solids (TSS) (70%), total nitrogen (21%), total Kjeldahl nitrogen (46%), total phosphorus (33%), BOD (70%), total organic carbon (48%), iron (45%), lead (45%), and zinc (45%) (City of Austin 1988).

In Washington, D.C., sand filters are used both to improve water quality and to delay the entrance of large slug inputs of runoff into the combined sewer system. Water quality filters are designed to retain and treat 8 to 12 mm of runoff with the exact design procedure based upon the amount of imperviousness in the watershed.

In the State of Delaware, the sand filter is an acceptable method for achieving the eighty percent reduction requirement of suspended solids, especially for sites with large impervious areas that drain directly to the filter. The purpose of the filter in many areas is to help prevent or postpone clogging of an infiltration device (Shaver). According to Delaware's specifications, the sand filter will adequately remove particulates (TSS removal efficiency 75 - 85%) but not soluble compounds. Studies of a six year old sand filter in Maryland show that the filter is just now becoming clogged after use in a heavily trafficked parking lot. Inspection below the surface of the sand filter shows that oil, grease, and finer sediments have migrated into the filter, but only to a depth of approximately 50 to 75 mm (Shaver).

Activated Carbon. Activated carbon filtration/separation has long been used in hazardous waste cleanup as an effective method for removing trace organics from a liquid. The activation process makes the charred carbon particles porous with a large internal surface area available for pollutant adsorption (Metcalf and Eddy 1991). Examples of compounds adsorbed by activated carbon include *n*-butyl phthalate, chlorobenzene, carbon tetrachloride, phenol, chloroform and nitrobenzene. Compounds that activated carbon does not adsorb include butylamine, cyclohexylamine, ethylenediamine and hexamethylenediamine (Bennett et al. 1982). Activated carbon filtration is limited by the number of adsorption sites in the media. Activated carbon has a very small net surface charge and is ineffective at removing free hydrated metal ions, unless they are complexed with easily-adsorbed organics prior to contact with the activated carbon filter (Rubin and Mercer 1981).

Composted Leaves. Composts made from yard waste, primarily leaves, have been found to have a very high capacity for adsorbing heavy metals, oils, greases, nutrients and organic toxins due to the humic content of the compost. The exact content of the composts and aging process for the composts used by W&H Pacific is not public knowledge. The composted leaf filter was developed by W&H Pacific for Washington County (Washington), the Unified Sewer Agency and the Metropolitan Service District of Washington County (W&H Pacific 1992). The filter consists of a bottom impermeable membrane with a drainage layer above. Above the drainage layer is a geotextile fabric above which is the compost material. The actual removal occurs in the compost layer by filtration, adsorption, ion exchange and/or biodegradation of organics. The composted leaf filter is proposed as an improvement over other stormwater treatment devices, such as detention ponds and grass swales, because of the smaller land area required for the filter. Testing of a prototype has shown the following pollutant removal rates: turbidity (84%), suspended solids (95%), total volatile solids (89%), COD (67%), settleable solids (96%), total phosphorus (40%), total Kjeldahl nitrogen (56%), copper (67%), zinc (88%), aluminum (87%), iron (89%), and petroleum hydrocarbons (87%) (W&H Pacific 1992).

Peat Moss. Peat is a partially decomposed organic material that is formed from dead plant remains in water and in the absence of air. Generally, the more decomposed the peat is, the lower its hydraulic conductivity. Peats are generally light-weight when dry and are highly adsorptive of water. It is highly colloidal and has a high cation-exchange capacity. Peat is also polar and has a high specific adsorption for dissolved solids such as transition metals and polar organic compounds. Peat naturally performs an ion exchange with copper, zinc, lead and mercury, especially at pH levels between 3.0 and 8.5. This capacity to bind and retain cations, though, is finite and reversible and is determined mostly by the pH of the solution. Peat is an excellent substrate for microbial growth and assimilation of nutrients and organic waste materials because of its high C:N:P ratio, which often approaches 100:10:1. Peat's ability to retain phosphorus in the long-term is related to its calcium, aluminum, iron and ash content with the higher the content of each of the above constituents, the higher the retention capability (Galli 1990).

For filtration devices, peat generally has been combined with sand to create a peat-sand filter (PSF). The Peat-Sand Filter System designed by the Metropolitan Washington Council on Governments (Washington, D.C.) has a grass cover on top underlain by twelve to eighteen inches of peat. The peat layer is supported by a four inch mixture of sand and peat which is supported by a twenty to twenty-four inch layer of fine to medium grain sand. Under the sand is gravel and the drainage pipe. The mixture layer is required because it provides the necessary continuous contact between the peat and the sand layers, ensuring a uniform water flow. Because this is a biological filtration system, it works best during the growing season when the grass cover can provide the additional nutrient removal that will not occur in the rest of the system (Galli 1990).

The PSF is usually an aerobic system. However, modifications to the original design by the Metropolitan Washington Council have been made to account for atypical site conditions or removal requirements. The estimated pollutant removal efficiency for the PSF for stormwater is as follows: suspended solids (90%), total phosphorus (70%), total nitrogen (50%), BOD (90%), trace metals (80%), and bacteria (90%) (Galli 1990).

Filter Fabrics. Little information is available in the literature concerning the performance of filter fabrics in removing stormwater pollutants. They have been used for years in controlling construction site runoff, but in filter fence arrangements where they act as small impoundments and not as true filters. This research project will be analyzing samples collected before and after filtering through several representative filter fabrics, including the fabrics used in the catchbasin filters described above.

Preliminary Project Findings

It was expected that the sand filter would retain any particles that it trapped. However, preliminary tests showed that sand by itself did not retain stormwater toxicants (which are mostly associated with very fine particles). This lack of ability to retain stormwater toxicants prompted the investigation of other filtration media during this research. Combinations of filtration media, especially those using organic materials (activated carbon, peat moss, composted leaves and ion exchange resins) along with sand, are currently being investigated for their ability to more permanently retain stormwater pollutants. Sand is mixed with most of these materials in order to maintain adequate hydraulic capacities (especially for peat) or to slow the flow rate of the stormwater passing through the media in order to increase the contact time and potentially improve pollutant sorption (such as for the activated carbon and the zeolite).

The following results are preliminary and are not intended to indicate the final project conclusions. The information does indicate how the performance of these special inlet devices and filtration media vary in their ability to remove common stormwater pollutants and that they have varying hydraulic capacities. Current tests are being conducted to measure their clogging potential and their ability to remove specific stormwater pollutants.

Inlet Performance. Table 1 shows the removal performance of three of the stormdrain inlet devices that were tested. The parameters listed for each inlet device are those where the change in concentration between the influent and effluent of the device was found to be significant ($\alpha < 0.05$) using a paired sample, one-tailed Student's T-test. The following is a complete list of analyses that have been performed to date on the paired samples from the inlet devices:

- Solids (total solids, dissolved solids, suspended solids, volatile total solids, volatile dissolved solids, volatile suspended solids)
- Physical parameters (turbidity, conductivity, pH and color)
- Toxicity (using a Microtox™ unit from Microbics)
- Anions and cations
- Particle Size (using a Coulter Multisizer IIe)

Table 1. Parameters Having Significantly Lower Effluent Concentrations than Influent Concentrations (Removal Percentages).

EMCON Unit.	Nitrate (Average removal efficiency for influents > 0.2 mg/L 6%).
SoilSave Unit.	Conductivity, bicarbonate, total solids, suspended solids, volatile total solids all had negative removals where the effluent > influent concentrations.
Optimum Catchbasin.	Turbidity (0 to 65%, average 38%). Color (0 to 50%, average 15%). Total Solids (0 to 50%, average 22%). Suspended Solids (0 to 55%, average 32%). Conductivity, carbonate, bicarbonate, nitrate, magnesium and calcium all had negative removals.

Those parameters not listed in Table 1 did not show any significant difference in influent and effluent concentrations. Other parameters currently being analyzed include PAHs, phenols, phthalate esters, herbicides and pesticides, and heavy metals. COD, toxicity, and the organic and metallic toxicants are all being analyzed on both filtered and unfiltered sample portions. Only the optimal catchbasin has shown significant (and important) pollutant reductions for major parameters. The SoilSave showed consistent scouring of downstream sediment, while both the SoilSave and the optimal catchbasin showed slight increases for several major ions, most likely associated with contact with concrete and other drainage system materials. The optimal catchbasin performance (32% removal for suspended solids) is within the range reported during earlier studies, as reported above.

Filter Fabric and Filter Media Performance. Initial testing of the filter fabrics was performed using particle size distribution comparisons. The test water was a composite of typical stormwater runoff samples currently being analyzed in our laboratory. The largest particle size found in the analyses was about 90 μm, indicating the typical predominance of smaller particles in runoff. These filter fabrics and media can be divided into four different performance classes, for the particle range 6 to 41 μm, as shown in Table 2. Our current research is testing these materials in much greater detail. The filters and media being selected for further study represent a wide range of performance (both in respect to removing particles and in hydraulic capacity).

Table 2. Filter Performance Classifications with Hydraulic Flow Rate Comments

A: High efficiency for all particles (6 to 41 μm)	Holchst 1125 (fast) Gunderboom (slow, requires several inches of head) Sand (18") (fast) Carbon (18") (very fast) Soil (18") (slow) Soil (9") (slow)
B: High efficiency for larger particles only (> 20 μm)	EMCON filter (fast) Exxon filter (very slow, requires 4" head) Peat (18") (slow) Peat (9") (slow)
C: Moderate efficiency for all particle sizes (6 to 41 μm)	Holchst 1120 filter (fast) Leaves (18") (very fast)
D: Poor efficiency for all particle sizes (6 to 41 μm)	Holchst 1135 filter (fast) ADS 4000 filter (fast) ADS 4420 filter (fast)

Testing newly constructed columns for hydraulic conductivity showed the following ranking of the media from fastest to slowest: sand > zeolite-sand >> composted leaves > carbon-sand > peat-sand. Initial clogging tests have shown that channeling occurred in the zeolite-sand combination media and that the clay solution flowed through these channels and bypassed passage through the areas of the filter where the fine particulates should have been trapped.

Nine filtering fabrics and filtration media are being tested for pollutant removal using stormwater runoff from a parking area on the UAB campus. Initial results from filtration of three (of 12 planned) separate runoff events are shown in Table 4. The activated carbon-sand combination media appears to be an excellent control for toxicity and for most other pollutants. The peat-sand media combination appears to be flushing out part of the media during the tests, resulting in increased sample color and turbidity, but also showed excellent toxicity reductions.

Table 4. Preliminary Results from Filtration of Stormwater Runoff

Toxicity: (two influent samples were "not toxic" and one was "toxic")

Good to excellent toxicity removal efficiency (>70%):	Activated carbon-sand
	Peat-sand
	Composted leaves
No noticeable removal:	EMCON filter fabric
	Gunderboom filter fabric
	ADS 4420 filter fabric
	Zeolite-sand (noticeable channels developed)
	Enretech (increased toxicity during first run; minimal removal in later runs).

Turbidity: (influent turbidity values were low: < 15 NTU)

Activated carbon-sand: initial flushing of fines which decreased in subsequent samples.
No media consistently and significantly reduced turbidity.

Conductivity: (influent conditions were between 50 and 175 µS/cm)

Negative Removal Efficiency (Effluent > Influent):	Activated carbon-sand
	Composted leaves
	Enretech
No noticeable removal:	Peat-sand
	Zeolite-sand
	Sand
	EMCON filter fabric
	Gunderboom filter fabric
	ADS 4420 filter fabric

pH: (influent values were between 6.7 and 7.7)

Peat-sand effluent approximately 0.5 - 1.0 pH units *lower* than influent.
Composted leaves effluent approximately 0.5 pH units *greater* than influent.

Color: (influent color was between 15 and 60 HACH color units)

Fair to good removal efficiency (30 - 80%):	Activated carbon-sand
Negative removal efficiency:	Peat-sand
	Enretech
	Composted leaves

Chemical Oxygen Demand: (influent COD values were between 80 and 100 mg/L)

Good to excellent removal efficiency (>70%):	Activated carbon-sand
Negative removal efficiency:	Peat-sand
	Enretech
	Composted leaves

Particle Size Distribution: (most influent particle sizes were between 1 and 50 µm)

Good removal efficiency:	Activated carbon-sand
	Sand
Fair removal efficiency:	EMCON filter fabric
	Gunderboom filter fabric
Poor (or negative) removal efficiency:	ADS 4420 filter fabric
	Peat-sand
	Zeolite-sand

Deficiencies in Stormwater Quality Monitoring

G. Fred Lee, PhD, PE, DEE, M.ASCE[1] and Anne Jones-Lee, PhD, M.ASCE[2]

Abstract

Typical stormwater "quality" monitoring programs consist of measuring a suite of conventional pollutants in the runoff during selected storms where those concentrations are often compared to numeric water quality criteria and state standards. While such a strategy may conform to current minimum monitoring regulations, it provides essentially no useful data regarding water quality impacts of urban stormwater runoff. Stormwater monitoring programs need to properly evaluate the water quality impacts of the presence of chemical contaminants in concentrations above federal water quality criteria and state water quality standards. Site-specific water quality studies that properly incorporate aquatic chemistry and aquatic toxicology into the study design and data interpretation can provide the needed information to properly evaluate whether elevated concentrations of stormwater-associated contaminants which would lead to violations of water quality standards are, in fact, impairing the designated beneficial uses of the waterbodies receiving the stormwater runoff.

Introduction

A participant in a recent state of California Stormwater Quality Task Force meeting commented that he had been involved in monitoring stormwater runoff for the past few years but could find no useful way to use the data generated from the monitoring program. That finding would be expected based on the nature of typical stormwater runoff monitoring programs; it was predicted more than a decade ago (Lee and Jones, 1981), and key technical issues pointing to it were revisited more recently by Lee and Jones (1991a) and Lee (1992).

1 President, G. Fred Lee & Associates, 27298 E. El Macero Dr., El Macero, CA 95618-1005

2 Vice-President, G. Fred Lee & Associates

R0041315

Typical stormwater "quality" monitoring programs consist of measuring a suite of conventional pollutants in the runoff during selected storms. While such a strategy may conform to current minimum monitoring regulations, it provides essentially no useful data regarding water quality impacts of urban stormwater runoff beyond that which has been well-known since the work of Weibel *et al.* (1964). They found that urban stormwater runoff contains elevated concentrations of a variety of chemical contaminants and sanitary quality indicator organisms. The work of the senior author's graduate students in the 1960's and 1970's confirmed that finding and also showed that substantial portions of the chemical contaminants in urban stormwater runoff are in unavailable, non-toxic forms and thus would not adversely impact water quality as assessed by impairment of designated beneficial uses of the waterbody receiving the runoff.

The function of stormwater quality monitoring programs is to contribute to meeting the goal of urban stormwater quality management programs, which is to protect the quality of the receiving waters from degradation by stormwater-associated contaminants. In order to serve that function, monitoring programs must be designed and executed to provide meaningful information on water quality impacts of contaminants associated with stormwater runoff. It is therefore important to understand the technical deficiencies in the current stormwater quality monitoring approaches and effect appropriate modifications so that technically valid, cost-effective evaluation and management programs can be instituted.

Inadequacies of Current Stormwater Quality Monitoring Programs

Current stormwater quality monitoring programs focus on measuring total concentrations of a selected group of chemical contaminants in stormwater runoff where the concentrations found are often compared to the US EPA numeric water quality criteria and state water quality standards. Not properly considered in this approach are the nature/availability of chemical contaminants in urban stormwater runoff; the environmental chemistry, fate, and toxicity/availability of the chemical contaminants in the receiving water; and the foundations and assumptions of the water quality criteria and standards relative to the characteristics of urban stormwater runoff to receiving waters.

The tone for the current stormwater monitoring and management programs was set by the US EPA National Urban Runoff Program (NURP) conducted in the 1980's. NURP confirmed on a national basis that urban stormwater runoff contains high concentrations of a wide variety of contaminants. Table 1 presents median concentrations of chemical contaminants from the NURP stormwater runoff studies reported by Pitt and Field (1990). It shows that the concentrations of a number of commonly measured constituents in urban stormwater runoff (such as chromium, copper, cyanide, lead, zinc, and chlordane) typically exceed the US EPA freshwater water quality criteria. However, the NURP studies provided no information upon which to evaluate the water quality significance of those elevated

concentrations of contaminants in urban stormwater runoff.

As discussed by Lee and Jones (1991b) and Lee and Jones-Lee (1994b), for numerous reasons, a mechanical comparison of concentrations of chemical contaminants in urban stormwater runoff with US EPA numeric water quality criteria and state standards does not provide a reliable assessment of the impact of stormwater-associated contaminants on water quality/beneficial uses of receiving waters. First, the US EPA criteria and state standards equivalent were generally developed for available forms of contaminants; many contaminants in urban stormwater runoff are present in unavailable/non-toxic forms. Second, it would indeed be rare that fish and aquatic life would be expected to reproduce and live in 100% stormwater runoff. The finding of even toxic levels of available forms of contaminants in urban stormwater runoff does not indicate that there would be toxicity or adverse impacts in the receiving waters. Typically there is appreciable dilution of urban stormwater runoff with the receiving waters at the point of mixing. If adequate dilution were not available, it would be likely that the aquatic life habitat associated with stormwater runoff would be severely limited by other factors, such as available water.

Third, the duration of exposure that aquatic organisms can receive from a runoff event should be considered in the interpretation of stormwater quality data and in the application of existing water quality criteria. The impact of a chemical contaminant on an aquatic organism depends on the duration of the organism's exposure to the given level of available forms of the contaminant. The US EPA water quality criteria were developed for protection of highly sensitive species under worst-case exposure conditions. The aquatic life criteria values listed in Table 1 to which the concentrations of contaminants in urban runoff were compared are what the US EPA considers to be chronic exposure criteria values, specified as 4-day average concentrations. The 4-day average was somewhat arbitrarily selected by the US EPA to represent a worst-case exposure situation so the criteria would be protective under chronic exposure conditions (lifetime or critical lifestage exposure). With few exceptions, many types of aquatic organisms could be exposed to the criterion concentrations of available forms of many types of contaminants for somewhat longer than 4 days without adverse impact. Urban stormwater runoff events are typically short-term and episodic in nature; receiving water organisms would not be expected to be exposed to the available forms of contaminants in urban stormwater runoff for critical chronic exposure durations. Thus, the chronic exposure criteria are over-protective for most urban stormwater runoff situations and for most contaminants.

The US EPA also lists 1-hr criteria values to represent worst-case shorter-term exposure situations and the associated concern for acute toxicity to aquatic life. Application of such criteria values to urban stormwater runoff would also be over-protective for most contaminants in urban stormwater runoff and most aquatic life forms. Many forms of aquatic life can readily survive exposure to available forms of chemical contaminants at the acute criterion concentration for several-day periods without adverse impacts. Generally, the concentration of a toxic contaminant that would kill 50% of test organisms in a 4-day exposure period is 50 to 100 times the chronic safe (no impact) concentration of that contaminant. Even a much larger factor would be expected to apply to typical stormwater runoff situations where the exposure of receiving water organisms would be expected to be on the order of a few hours to a day or so. There are no reliable chemical criteria by which to evaluate the potential adverse impacts on aquatic life-related beneficial uses of receiving waters that could be caused by the short-duration exposures to contaminants in the vicinity of a stormwater runoff discharge.

In addition to the over-protective aspects of the criteria discussed above, the US EPA water quality criteria specify that the 1-hr criteria values not be exceeded more than once in three years, to allow for "recovery" of the perturbed system.

It is well-known that even considering toxic forms of contaminants, exceedance of a 1-hr criterion value more than once in three years does not necessarily adversely affect the aquatic ecosystem - the designated beneficial uses of the waterbodies. To specify that any exceedance, independent of magnitude of the water quality criterion or standard, can occur no more than once in three years is grossly over-protective of the beneficial uses of waterbodies.

The US EPA recognizes the highly over-protective nature of its current water quality criteria and the associated implementation approach; it is, under the current administration, working toward correcting this problem. While the chronic exposure criteria have been in effect for many years, they were not being enforced by many states because of their highly over-protective nature. With its beginning to focus on chronic toxicity to aquatic life, the US EPA is increasing its efforts to require that states enforce chronic exposure aquatic life criteria. This, in turn, necessitates that the Agency adopt more appropriate approaches for development and implementation of its water quality criteria into state standards and NPDES discharge limits. This is especially important for regulating stormwater runoff in order to avoid spending billions of dollars of public funds in the unjustified over-regulation of stormwater-associated contaminants.

The data being generated by current stormwater quality monitoring programs and the approaches used for their interpretation are providing misleading information regarding the impacts of urban stormwater runoff on receiving water quality. These technically unreliable approaches are being used by "environmental" groups and other interest-activists to claim that "the data" show that urban stormwater runoff discharges are having a significant adverse impact on water quality. It is likely that citizens' suits arising out of the implementation of the provisions of the Clean Water Act will become common in the future. In order to defend itself against inappropriate claims, dischargers need reliable data describing the real impacts of urban stormwater runoff based on evaluation of the water quality characteristics of the waters receiving the stormwater discharge. In order to do this and protect the interests of the public, stormwater dischargers will need to do considerably more than the minimum required monitoring of their discharges (e.g., only measuring total concentrations of selected chemical contaminants in stormwater discharges).

Factors to Consider in Establishing a
Stormwater Quality Monitoring Program

A report entitled, "*Guidance for Conducting Water Quality Studies for Developing Control Programs for Toxic Contaminants in Wastewaters and Stormwater Runoff*," was developed by the authors to discuss major issues in the development of technically reliable, cost-effective evaluation and control programs for chemical contaminants in discharges (Lee and Jones-Lee, 1992). Key factors that need to be considered in establishing monitoring programs for urban

VOL 12

8013

R0041319

stormwater runoff-associated contaminants are synopsized below.

- Clearly establish the objectives of the monitoring program.
- Understand the nature and assessment of "water quality," the beneficial uses of the receiving water, and water quality concerns.
- Select the parameters to be measured, justify the selection of each, and understand appropriate approaches for the interpretation of data for each parameter selected.
- Examine the results of previous studies to gain information on the expected concentration ranges and the expected variability (spacial and temporal) of the concentrations of contaminants in stormwater runoff and in the waterbody that is receiving the runoff.
- If no reliable data are available from previous studies, or if existing data are inadequate to define the variability of contaminant concentrations and other characteristics needed to establish a reliable monitoring program, conduct a pilot study for similar types of land use to make these determinations.
- List factors that can influence results of the study and how they may influence the results. For those factors that cannot be controlled, develop a plan to incorporate that information in the interpretation of the study results.
- Determine the statistical level of confidence at which the objective of the monitoring program is to be achieved and understand its relevance to assessing "water quality significance."
- If the purpose of the monitoring program is to determine changes in water quality characteristics that could be influenced by the stormwater runoff, select the magnitude of change that is to be detected and design the monitoring program for the runoff and receiving waters accordingly.
- Determine what factors control or influence the designated beneficial uses of the waterbody of concern, e.g., habitat, hydrodynamics, pollutants, etc.
- For each stormwater discharge point, determine the number and location of discharge/runoff and receiving-water samples to be collected in order to achieve the desired statistical confidence level and to determine water quality significance of the parameters of concern.
- Select sampling techniques and methods of analysis to meet the study objectives and level of confidence desired, being careful to avoid the "standard methods syndrome."
- Verify that sample collection and analytical methods are appropriate for each discharge and for the waterbody receiving the discharge for various seasons of the year.
- Conduct studies to evaluate the precision of sampling and analytical procedures and technique, the reliability of sample preservation, and the spacial and temporal variability of the system under investigation.
- Critically examine the relationship between the results of present and past studies.
- Review data for reliability and sufficiency as they are collected.
- Analyze and interpret data as sufficient information is collected. Consider modifications in the program that may be indicated by the data as they are

VOL 12

8014

collected.

The guidance provided by Lee and Jones-Lee (1992) for establishing a monitoring program for assessing the impacts of stormwater-associated contaminants on receiving water quality is significantly different from the approaches typically followed in establishing stormwater quality monitoring programs. The recommended approach requires a fairly sophisticated understanding of aquatic chemistry and aquatic toxicology as they are pertinent to evaluating impacts on "water quality," i.e., impacts on the designated beneficial uses of a specific waterbody receiving a particular stormwater runoff. For aquatic life-related beneficial uses it is the changes in numbers, types, and characteristics of the desirable aquatic organisms in the waterbody receiving the stormwater discharge of concern to the public that define water quality impact.

Assessing Impacts of Stormwater Runoff on Receiving Waters

Impacts of stormwater runoff-associated contaminants must be assessed on water quality in the vicinity of the discharge (near-field) and in the waterbody overall. For assessing the near-field impacts, the primary points of focus are the concentrations of available forms of contaminants and the duration of exposure that aquatic organisms in the near field can receive during the runoff event, as well as zones of passage by which organisms can traverse the area without exposure. The points of focus are fundamentally the same for assessing the water quality impacts on the waterbody overall, but consider the longer-term dilution and transformations that affect the concentrations and contaminant availability, as well as the aquatic life or other designated beneficial uses of the waterbody overall as they may be impacted by factors other than stormwater discharge.

As discussed above it is technically unreliable to presume that water quality impact is evidenced by the presence of chemical contaminants in runoff or receiving water in total concentrations in excess of US EPA water quality criteria or state water quality standards. The US EPA water quality criteria and state standards equivalent to them were not designed to regulate stormwater-associated contaminants. Because of the episodic nature of stormwater runoff events and the diminished availability/toxicity of many stormwater-associated chemical contaminants, a mechanical comparison between concentrations of total chemical contaminants in stormwater runoff with water quality criteria and standards typically greatly overestimates the potential water quality impacts of the stormwater-associated contaminants.

A reliable stormwater quality monitoring program includes appropriate consideration of the water quality/beneficial-use characteristics of waters receiving the stormwater runoff and how those characteristics may be affected by the discharged contaminants. Water quality impact studies must be highly directed toward addressing the key issues of concern. For example, if the concentration of

VOL 12

8015

R0041321

a contaminant that is regulated because of its potential to bioaccumulate in fish tissue and render the tissue to be judged unsuitable for human consumption (e.g., mercury) exceeds water quality criteria-standards designed to prevent excessive bioaccumulation, the studies of the impacts of that runoff on receiving water quality should include measurement of the mercury concentration in the edible tissue of appropriately selected fish types or other edible aquatic life. If the concentration of mercury in the edible tissue is less than the FDA Action Limit or other appropriate standard, it may be concluded that whatever the past discharges of mercury have been from all sources, and despite the measured concentrations in runoff, those discharges are not resulting in excessive mercury in fish tissue, i.e., are not adversely affecting that aspect of the beneficial use. The finding of what are determined to be "excessive" concentrations of mercury in water without a concomitant finding of "excessive" concentration of mercury in fish tissue (the reason for concern about mercury) is not uncommon. This is because the US EPA criterion for mercury does not consider the fact that mercury exists in a wide variety of chemical forms, only some of which are available to be taken up by fish tissue. If, however, excessive levels of mercury were found in the edible tissue of fish in the waters receiving the stormwater discharge, additional studies would need to be conducted to determine whether the stormwater runoff-associated mercury was the cause or a significant contributor to the excessive mercury in the fish tissue. Such an assessment would require the conduct of specific studies designed to address that issue by qualified individuals.

For many contaminants in stormwater runoff that occur at elevated concentrations, the concern is the potential for toxicity to aquatic life. Since such assessments cannot generally be made on the basis of measured concentrations of contaminants in runoff or receiving water, it is important that the stormwater quality monitoring program include direct assessment of aquatic life toxicity of the discharge at carefully selected locations in the receiving waters. Some urban stormwater discharges will cause toxicity to test organisms in the commonly run standard toxicity tests. However, such toxicity tests tend to greatly overestimate the toxicity that would be expected in the waters receiving the discharges. That is because the duration of exposure and the exposure conditions in the test system are far worse (adverse) than those normally received by aquatic organisms in the receiving waters. Therefore, finding toxicity in toxicity tests of a stormwater runoff sample or of a sample of receiving water containing the discharge should not be interpreted to mean that the stormwater is having a significant adverse impact on the designated beneficial uses of the receiving waters. The toxicity tests conducted should be site-specific studies of the type described by Lee and Jones (1991b) which properly mimic the exposure conditions that organisms would likely encounter in the receiving waters for the stormwater discharge.

Before entering into comprehensive site-specific studies of the impacts of stormwater runoff-associated potentially toxic contaminants in receiving waters, however, it is important to determine whether the receiving waters are, in fact, causing toxicity to sensitive forms of aquatic life in the receiving water. If the receiving water watercolumn waters are not causing toxicity, it is obvious that neither stormwater-associated contaminants nor contaminants contributed from other sources are causing toxicity-related impairment of designated beneficial uses of the waterbody. The importance of making this fundamental assessment, and potential ramifications of overlooking the obvious were illustrated by recent regulatory actions for San Francisco Bay. Studies have shown that even though domestic wastewater discharges and stormwater runoff to San Francisco Bay contain copper and several other contaminants in concentrations above US EPA water quality criteria and state water quality objectives (standards) and the concentrations of copper in the waters of the Bay exceed the US EPA criterion at times by two- to three-fold, the Bay water containing that copper (and for that matter all other contaminants) was non-toxic to several forms of copper-sensitive aquatic organisms. As a result, there is no justification to require that the managers of stormwater discharges to San Francisco Bay spend public funds to treat the stormwater runoff to control contaminants that were of concern because of their potential to cause toxicity to aquatic life in the San Francisco Bay watercolumn.

Another area of expressed concern about the chemical contaminants in stormwater runoff is the potential for particulate contaminant forms in the runoff to accumulate in receiving water sediments where they could cause toxicity to aquatic life living in or on the sediments. While it is conceivable that this might occur, the potential for it to occur cannot be assessed based on the total concentrations of contaminants in the runoff or in the receiving water sediments. Lee and Jones (1992) and Lee and Jones-Lee (1993, 1994a) have reviewed approaches for assessing the significance of chemical contaminants in aquatic sediments that have evolved over the past two decades. As they discussed, biological effects-based evaluations are recommended for that purpose; chemical concentration-based evaluations have proven to be highly unreliable for making such assessments.

It is also important to consider in this regard that many aquatic sediments cause toxicity to aquatic life due to natural or other conditions that have nothing to do with stormwater runoff-associated contaminants. The finding of aquatic life toxicity in tests of sediments from downstream of a stormwater discharge cannot be presumed to indict stormwater runoff even if the runoff contained high concentrations of the same type of total contaminant. Many of the contaminants in stormwater runoff are in particulate forms that do not equilibrate with other forms of the same contaminants in the receiving waters or sediments.

Contrary to the statements made by Paulson and Amy (1993), it is not possible to reliably predict potentially toxic forms of stormwater-associated contaminants that will be present in the receiving waters from equilibrium-based chemical models. The use of those models requires that thermodynamic equilibrium be quickly achieved in the receiving waters. This will rarely be the case. Further, those models require information on complexation and sorption reactions that may occur in receiving waters but for which there are no reliable thermodynamic data available. Chemical measurements, *per se*, of the stormwater runoff or of the receiving waters will not provide reliable information on the potential biological effects of chemical contaminants in the stormwater runoff. Direct measurements of biological effects such as toxicity and bioaccumulation must be made.

Lee and Jones-Lee (1994c) have recently discussed a very significant problem associated with the approach being used by the US EPA in regulating chemical contaminants in aquatic systems that will become of particular significance in regulating stormwater-associated contaminants. This problem evolves out of the Agency's Independent Applicability Policy in which chemical-specific water quality criteria and state standards are presumed to be independently applicable to contaminants in point and non-point source discharge-runoff. This Policy means that in those situations where excessive concentrations of chemical contaminants above the US EPA water quality criteria are found where the exceedance is of concern because of potential aquatic life toxicity, yet measurements of the receiving waters for the discharge show no aquatic life toxicity to several sensitive forms of aquatic life, still requires the control of chemical contaminants causing the exceedance. This is the situation that has developed for copper in San Francisco Bay. The US EPA's Independent Applicability Policy is obviously technically invalid and should be abandoned. Biological effects-based criteria should take precedence over chemical-specific criteria in regulating chemical contaminants.

Monitoring of Performance of BMP's

Jones-Lee and Lee (1994) and Lee and Jones-Lee (1994b) discussed approaches to evaluate the efficacy of structural BMP's for the control of stormwater runoff-associated contaminants. They emphasized the importance of not following the conventional approach of judging the efficacy based on changes in the total concentrations of contaminants across the BMP (upstream vs. downstream). If the purpose of constructing a BMP for an existing discharge is to improve the designated water quality/beneficial uses of waters receiving the stormwater discharge, it is important to select, judge and monitor the performance of the BMP based on changes in the receiving water quality. This will necessitate the conduct of site-specific studies of the receiving water as discussed above.

Conclusions

The stormwater quality monitoring programs typically conducted today are significantly deficient in providing information to properly assess the impact of stormwater runoff-associated chemical contaminants on the designated beneficial uses of the waters receiving the runoff. The data generated by these stormwater monitoring programs provide an exaggerated impression of the potential water quality impacts that can readily be used by environmental activists and others against stormwater dischargers in an attempt to force compliance with measures that have nothing to do with protection of the water quality/designated beneficial uses of waters receiving stormwater runoff. Stormwater dischargers need to expand the scope of their monitoring programs to properly evaluate the water quality impacts of the presence of chemical contaminants in concentrations above federal water quality criteria and state water quality standards. Site-specific water quality studies that properly incorporate aquatic chemistry and aquatic toxicology into the study design and data interpretation can provide the needed information to properly evaluate whether elevated concentrations of stormwater-associated contaminants which lead to violations of water quality standards are, in fact, impairing the designated beneficial uses of the waterbodies receiving the stormwater runoff.

APPENDIX B

OTHER ISSUES

Conference participants were asked, at the beginning of the conference, to write down issues that they considered important. The following are the responses received.

1. Our discussions this week have focused on monitoring related to applications for an NPDES permit, and have emphasized that there is fuzziness in the results, and that to get statistically significant results, you need many samples. The real problem, however, lies in the fact that there are two phases of regulatory activity.

   - Permit Writing - during this phase, the regulatory personnel see things in shades of grey, and one can negotiate with them. These people set the monitoring required for permit compliance.

   - Permit Compliance and Enforcement - These regulatory personnel see things only in black and white. One is either in compliance or not. Furthermore, the performance of these personnel is judged based upon orders and findings, and the dollars assessed in fines.

   We thus need to define monitoring for compliance. Monitoring done for assessment of BMPs or for studies does not work - as evidenced by the discussions this week. Monitoring for compliance must address the black/white mentality.

2. Unrealistic expectations have been placed on our current monitoring. What we really need is classes of monitoring.

   - Event-based chemical monitoring to establish the effectiveness of individual BMPs. This type of monitoring cannot be used to establish aggregated BMP impact on receiving waters.

   - Biological monitoring to establish long-term trends in habitat quality (one must recognize that we will never know the direct impact of BMP implementation on habitat quality).

- Integration of receiving water quality modeling with monitoring to establish probable short-term or projected impacts of BMPs.

3. The municipal permit monitoring requirement should be re-assessed on an annual basis. Changes to the monitoring plan should be negotiated between the permittee and the regulators. Recognize that the monitoring plan needs to evolve over time.

4. We must include the contribution of agricultural activities in an overall monitoring plan, not just the characterization of stormwater from urban areas and industrial sites.

5. The following are two important research needs:

   - Define relationships (descriptively and quantitatively if possible) among watershed conditions, aquatic ecosystem conditions, and biological response. These data should be used to define conditions that need to be maintained for ecosystem stability and productivity, and to determine the effectiveness of various mitigation and management strategies at the biological population, community, and ecosystem levels.

   - Get documentary evidence of the effectiveness of various preventive source controls.

6. As a consultant, in order to give better advice to my firm's clients, I need to be aware of a variety of BMPs, both source and treatment controls, and, most importantly, the effectiveness of these BMPs.

   At this point in time, little is known about the effectiveness of the vast majority of these BMPs. Data are available on some of the more common treatment control (structural) BMPs, such as several types of detention basins and swales. However, these data yield a wide range of BMP effectiveness.

   Thus, a well though out and funded research program is needed to more accurately predict the effectiveness of many BMPs under a wide variety of conditions (climatic, geographic, construction controls, maintenance frequency).

   There was some emphasis on structural (treatment) controls at this conference, however the CWA emphasizes the reduction of pollutants in storm water. This leads us to source controls, and the need for research to define these source controls and their effectiveness. The use of unleaded gasoline is a good example of reduction of a pollutant due to source control.

SUMMARY: AD-HOC SESSION

Stormwater and Aquatic Ecosystem Health

John R. Maxted
(with review by Earl Shaver and Rich Horner)

Attendees:

John Maxted - Delaware Department of Natural Resources
Robert Wilson - Arizona Department of Environmental Quality
Derek Mack-Mumford - City of Scarborough, Canada
Rich Horner - University of Washington
Betty Rushton - SW Florida Water Management District
Bill Snodgrass - Ministry Ontario Transport, Canada
Mike Thomas - Atlanta Regional Commission
Rob McCleary - Delaware Department of Transportation
Ed Herricks - University of Illinois
Randy Greer - Delaware Department of Natural Resources
Earl Shaver - Delaware Department of Natural Resources
Marshall Jennings - USGS
Ron Rossmiller - HDR Engineering
Tom Waller - University of North Texas
Roger Bannerman - Wisconsin Department of Natural Resources
Bill Tate - USEPA; NPDES Stormwater

Introduction:

An ad-hoc session was held during the 1994 Engineering Foundation Conference at Crested Butte, Colorado, on the subject of freshwater aquatic ecosystem health, specifically streams and wetlands. This was a follow-up to the morning session on "Monitoring Receiving Water Trends" in which a holistic approach to stream health was emphasized. This approach involves the assessment of physical habitat and biological integrity (aquatic invertebrates and fish) to complement the more traditional assessments of Stormwater impacts based upon hydrology and water quality. There was general recognition by many Conference Attendees that monitoring programs designed to assess the impacts of Stormwater and the effectiveness of controls should include measures that address all of the primary attributes of stream health including hydrology, water quality, physical structure (habitat) and biological integrity.

It should be made clear that this session on aquatic ecosystem health was focused on ecological health. Therefore, issues related to human health (e.g., bacterial/viral contamination) were not discussed.

Summary:

The discussions can be divided into three areas:

- A review of some of the impediments to expanding monitoring beyond traditional measures (water quality).
- A listing of projects that the group was aware of that focus on physical habitat and biological measures.
- A list of actions that would help to communicate and summarize data and information on the affects of urbanization on aquatic ecosystem health.

The primary impediment to the inclusion of physical habitat and biological measures in stormwater monitoring was identified as the lack of personnel and expertise. Put simply, local governments do not have biologists on staff nor have States directed their biologists to address stormwater impacts or to work with Stormwater regulatory programs. Stormwater regulatory programs are currently an extension of the traditional control philosophy of the NPDES program focused on chemical criteria and water quality. In the area of habitat and biology, methods are available (e.g., EPA, "Rapid Bioassessment Protocols", 1989, EPA444/4-89/001), but have not been widely applied to Stormwater. The lack of public education was also identified as an impediment to incorporating these measures into a Stormwater control program.

The discussion quickly moved on to a review of how biological monitoring was being applied in different parts of the country. In general, it was felt that the tone for focusing more attention on biology in the assessment of aquatic ecosystem health should be set by EPA through the development of biological criteria. While EPA has been successful in promoting a greater awareness of the need to use biological criteria on a national scale, the sense of the group was that the program is not well funded and requirements are lacking that would lead to meaningful progress over the next several years. Accomplishments have been made in selected States where individuals have taken particular interest in biological criteria. A wide variety of activities were presented by the attendees including those of Federal agencies, States, local governments, and academia. No attempt is made here to summarize these activities. The following people may be contacted for information: Jennings, Bannerman, Shaver, Waller, Herricks, Maxted, and Snodgrass.

Action Items:

One of the most interesting and productive discussions focused on the actions that could be taken to summarize data and information on various subjects related to urbanization, stormwater, and aquatic ecosystem health and to consider the need for additional research. The group identified the following three subject areas where information was known to be available but was not summarized or in a form that could effectively be utilized by engineers and scientist in the stormwater field. Summaries of the "State of the Science" in these areas would also help to identify data gaps and promote additional research.

- Effect of Urbanization on Aquatic Ecosystem Hydrology. A report would summarize both empirical studies and modeling estimates of the affect of urbanization on the hydrology of various types of non-tidal streams and freshwater wetlands. The types of systems might be separated by geographic location, gradient, and stream order. Data would be presented on the changes in both the frequency and severity of flooding events after urbanization.

- Factors Affecting the Erosion of Streambanks after Urbanization. A report would present and explain the concept of "shear stress" and the factors that lead to streambank instability due to changes in hydrology after urbanization. The first and second order streams of forested watersheds are often stable and vegetated while the banks of streams in urban watersheds are often unstable and unvegetated. What are the mechanisms that cause defoliation and bank failure and what factors are most important in predicting the affect of urbanization on stream banks; e.g., percent imperviousness, frequency of inundation, velocity, soil type, forest cover, integrity of the riparian zone, etc. Research would also be summarized on the proportion of sediment delivered to stream channels from bank erosion in urbanized and non-urbanized watersheds. Sediment has been identified as one of the primary mechanisms affecting the biological integrity of urban streams.

- Effect of Urbanization on Biological Integrity. Data were presented at the conference on the relationship between percent imperviousness and the macroinvertebrate community of non-tidal streams in Delaware (Shaver and Maxted). Additional work on streams and wetlands was also discussed regarding the effects of various land use changes on the resident biota (Horner). The group was interested in a summary of the literature on these subjects. Biological endpoints might include fish, amphibians, aquatic plants as well as macroinvertebrates.

Marshall Jennings (USGS) indicated some interest in being involved in the first item, while John Maxted (Delaware DNREC) was interested in being involved in the third. The group was very much interested in seeing the topic of aquatic ecosystem health addressed in future Engineering Foundation conferences.

Stormwater NPDES Related Monitoring Needs presents various perspectives and expertise from industry, as well as state and local governments, on the monitoring requirements of the current U.S. Environmental Protection Agency NPDES regulations, and particularly those governing discharges of stormwater to the environment. Twenty-five invited papers review methods of locating inappropriate discharges to storm drains, system runoff characterization, monitoring receiving trends, and policy and institutional issues of NPDES monitoring. BMP monitoring for data transferability, and protocols for monitoring BMP for effectiveness are also addressed.

ABSTRACT

This proceedings contains the papers presented at the Engineering Foundation Conference on "Urban Stormwater Quality Enhancement—Source Control, Retrofitting and Combined Sewer Technology," held October 22-27, 1989, in Davos Platz, Switzerland. Session topics include institutional issues; stormwater regulations and standards; on-site detention, infiltration and percolation; inlet controls; planning; real-time control; in-systems control; treatment; rehabilitation; and research needs. One supplemental paper not presented at the Conference is included.

FOREWORD

The Urban Water Resources Research Council (UWRRC) of the American Society of Civil Engineers has for more than 20 years been a leader in the transfer of urban runoff technology among researchers, practitioners and administrators. A series of Engineering Foundation Conferences, held in the United States and abroad, has been one of the major vehicles for this transfer. This proceedings reports on the latest Conference in the series.

At the preceding such conference on "Current Practice and Design Criteria for Runoff Water Quality Control," held in 1988 in Potosi, Missouri, it was clear that there was a great deal of technology, developed in Europe specifically for first flush control and combined sewers, that would probably be applicable to the solution of storm and combined sewer pollution problems in North America. Of particular interest were presentations on retrofitting of existing urban systems and comprehensive detention facility design. As a result, the UWRRC, together with European colleagues, decided that the best way to exploit the potential of this European technology was to hold an Engineering Foundation Conference in Europe, involving both European and North American engineers.

All papers at the conference were by invitation, and were presented by well-known scientists and engineers. Each was reviewed prior to acceptance by the appropriate session chairman, and by the editor of the proceedings. Each paper was presented by the author, and subjected to discussion and review by the conference participants. The papers are grouped by session, and the session chairman is listed in the table of contents. One supplemental paper, submitted after the conference, has also been included. All papers are eligible for discussion in the appropriate ASCE journal, and all papers are eligible for ASCE awards.

The Conference organizers express their sincere appreciation to the Engineering Foundation for providing financial and administrative support, and particularly to Herman Bieber and Jack Donaldson, for providing outstanding assistance in the day-to-day on-site management of the Conference and related activities. Finally, we would like to thank Mr. James Elder and Mr. Dennis Athayde, of the U. S. Environmental Protection Agency, and Mr. Peter Stahre, Gatukontoret Malmo, for arranging funding support for the conference.

WATER SCIENCE AND TECHNOLOGY: GLOBAL ORIGINS

by Stuart G. Walesh, M. ASCE[1]

Background

This conference was arranged by an international committee. U.S. representatives included members of the Urban Water Resources Research Council (UWRRC) of the American Society of Civil Engineers (ASCE) and staff of the Engineering Foundation (EF), an organization providing support to U.S. engineering societies. Since 1965, the UWRRC and the EF have sponsored 11 EF conferences. All of them, with the exception of this one, were held in the United States.

In spite of the location of the previous UWRRC-EF conferences, at least a small number of water experts from other countries have usually participated. These conferences were characterized by a bond among the water resource engineers and scientists. Regardless of geographic origins, ethnic and cultural backgrounds, and political persuasions, the participants shared a strong interest in their chosen water-related disciplines.

The obvious bond among water engineers and scientists probably reflects the strong and pervasive effect of water on human life. Most communities are concerned with providing drinking water, disposing of wastewater, irrigating crops, and mitigating flooding. Most people appreciate the aesthetic, recreational and other benefits of water -- especially in urban areas.

During the last UWRRC-EF conference, which was held in the State of Missouri in the U.S. during July, 1988, many con-

----

1 Dean, College of Engineering, Valparaiso University, Valparaiso, IN, USA 46383

versations were held between representatives of the UWRRC and conference participants from other countries. As a result of these fruitful discussions, the idea of holding the next EF conference in Europe quickly developed.

The primary purpose for placing the next conference -- this conference -- in Europe was to provide increased opportunities for U.S. participants to hear papers by and learn from water experts who are active in other countries. The international organizing committee for this conference arranged a program in which over two-thirds of the papers are being presented and sessions are being chaired by experts from outside of the U.S.

Purpose

The author is privileged to be invited to address this group as the keynote speaker. Given the international motivation for and international participation in the conference, a global theme seems appropriate. Accordingly, this paper addresses the historic, international basis for the science and technology used in the water resources field.

The preparation of this paper provided an opportunity for some systematic study into the origins of the science and technology used in the water resources field. The author strongly suspected, at the beginning of the project, that modern water resources efforts are built on a foundation of science and technology drawn from around the world and going back to at least the beginning of recorded history. The subsequent study confirmed this initial impression.

Approach and Scope

Presentation of the historic record of the development of the science and technology used in water resources would require volumes of writing or days of speaking. At best, a paper can present only snapshots of the historic and global development of the water resources field. These glimpses will hopefully form a montage of images which, in at least a modest way, enhances understanding of and appreciation for the global origins of our work.

The global origins of science and technology used in the water resources field are presented by selected subject areas drawn from hydrology and hydraulics. Water quality science and technology was excluded in order to provide a manageable scope of coverage. However, analysis and design of water quality systems is highly dependent on hydrology and hydraulics, which are the foundation of the water resources field. Hydrologic-hydraulic subjects were chosen to be of expected broad interest. Topics selected are: the hydrologic cycle, discharge measurement, hydrostatics, dams, collection-transportation-distribution works, the Manning equation, the Lloyd-Davies or rational formula, Darcy's Law, and computer models.

Within each of the selected subject areas, material is presented chronologically and in snapshot fashion. The focus is on the individuals who made scientific discoveries or created new technology. Where feasible, the contemporary environment is framed in terms of existing science and technology and the motivation for discovery and creativity.

The Hydrologic Cycle

Biblical writers referred to and apparently wondered about what is now referred to as the hydrologic cycle. For example, the Old Testament Book of Ecclesiastes says "all streams run to the sea, but the sea is not full; to the place where the streams flow, there they flow again." (Revised Standard Version, Chap. 1, Verse 7).

Curiosity about the hydrologic cycle, particularly the origin of streamflow, can be traced to the earliest of recorded history. In the third century B.C., the Chinese scientist Lu Shihh Chhun Chhiu contributed to the understanding of the evaporation component of the hydrologic cycle by writing (Brutsaert, 1934, p. 19):

> The waters flow eastwards from their sources, resting neither by day nor by night. Down they come inexhaustibly, yet the deeps are never full. The small (streams) become large and heavy (waters in the sea) become light (and mount to the clouds). This is (part of) the Rotation of the Tao.

Thus, the seas never fill because some of the sea becomes "light", that is, evaporates.

One of the Greek philosopher Plato's explanations of the origin of flow in springs, rivers, and lakes, was his concept of a huge subterranean reservoir. The subterranean reservoir, which he called Tartarus, was

VOL 12

8046

located in the center of the earth. The water in Tartarus surged back and forth -- a sort of internal seiche. This reciprocating action pumped water out of Tartarus at high locations on the earth surface, such as hills and mountains, from where the water flowed down slope continuously forming or replenishing springs, rivers, and lakes. The oscillating action of Tartarus also drew inflow from streams, rivers, and lakes at low locations on the earth's surface, thus helping to conserve the amount of water in Tartarus (Biswas, 1970, p. 58).

Aristotle, Plato's student, rejected the Tartarus idea proposed by his teacher. One of Aristotle's arguments against the Tartarus mechanism was that there would be evaporative loss of water during the surface water phase. Plato's theory did not explain how this continuous loss of water from the system would be replenished. Aristotle's critique suggested that he possessed at least a rudimentary understanding of the important roles of evaporation and precipitation in the hydrologic cycle.

Perhaps Aristotle should have stopped with his criticism of Plato's Tartarus. Instead, he went on to theorize a continuous conversion of air into water (condensation) within the earth with water appearing as springs which combined to form rivers and lakes (Biswas, 1970, pp. 66-68).

As inquiring early hydrologists trying to understand the hydrologic cycle, neither Plato nor Aristotle apparently ever made measurements. They knew of length measuring, time measuring (water clock), and weighing (balance) devices. "Why" was their interest, not "how much". Their approach to science, which was casual and undisciplined by modern standards, might be understood by considering the words of Aristotle (Biswas, 1970, p.69):

> Search for truth is one way hard and in other way easy, for it is evident that no one can master it fully nor miss it wholly, but each adds a little to our knowledge of nature, and from all the facts assembled there arises a certain grandeur.

That is, all that really mattered is contributing a little bit of new knowledge, or at least trying.

In contrast with the Greeks, whose hydrologic - hydraulic contributions relied on philosophying and theorizing, other nations focused on observation and measurement. Practical concerns often motivated these efforts. Rain gauges are mentioned in the Mishnah, a book of religious writings which describes four centuries of Jewish religious and cultural activities in Palestine (now Israel and Jordan) from about two centuries B.C. to two centuries A.D. Precipitation was measured because of its importance to agriculture (Biswas, 1970, pp. 99-100).

The writings of the Roman Lucretius, who lived during the last century before Christ, illustrate the Roman's pragmatic, observational approach. In his work, On Nature, he suggests a rudimentary understanding of the evaporation component of the hydrologic cycle -- an understanding apparently based on thoughtful observation of common phenomena. Lucretius writes (Brutsaert, 1934, p.17):

> For certainly we do see that clothes soaking with wet are dried up by the sun with his burning rays. But we see that seas are many and stretching wide beneath; therefore although the sun may sip but a small portion from the surface of any given place, yet over so great an expanse he will take away from the waves in abundance. Then further the winds also can lift a goodly portion of moisture by sweeping the surface, since under the winds we see very often the roads grow dry in one night, and the soft mud massing together in crusts.

In other words, observation of common occurrences reveals the evaporation process -- a process that must be operative in a massive way over the ocean. Lucretius correctly deduced that evaporation was influenced by solar energy and the wind.

Rain gauges were used in China at least as early as 1247 A.D. The conical or barrel-shaped collection containers were systematically placed in every provincial and district capital. The Chinese are thought to be the first to use snow gauges. Placed in mountainous areas, these gauges were in the form of large bamboo cages. One Chinese writer, Chhin Chiu-Shao, described a method for estimating area wide rainfall from point observations

(Biswas, 1970, p. 127).

The Koreans prayed for precipitation from ancient times because of its importance to rice farming and their government began measuring precipitation as early as the fourteenth century A.D. The Korean gauges were cylindrical and apparently made of metal. These gauges were imported from China or copied from the Chinese gauges. They were about 30 cm (12 inches) high and 15 cm (6 inches) in diameter and were mounted on top of a stone block cr pillar. The block or pillar was usually inscribed with the date of installation and with some deferential comment about the king or other high official (Biswas, 1970, pp. 127-132).

In the 17th century, the Frenchman Sedileau was charged with investigating the precipitation that would be available around Versailles to supply artificial fountains and water jets in the Parc of Versailles. He carried out three years of precipitation and evaporation experiments.

Although he obviously judged the experiments to be necessary, he apparently didn't like to do them as suggested by his words (Brutsaert, 1934, p.27):

> There are certain fundamental experiments on which all of physics is based, and which one must necessarily make, however annoying they may be, if one wants to reason correctly in this science: otherwise all the reasonings which are made on natural things are speculations in the air.

Sedileau observed that the annual evaporation rate from a water surface was twice the annual precipitation rate. He correctly explained the watershed implications of this apparent discrepancy by noting that much of the precipitation infiltrates into the ground thus being protected from immediate and rapid evaporation. In other words, regional evaporation would be approximately in balance with regional precipitation (Brutsaert, 1934, p. 28).

Edme Mariotte (1620, approximately, to 1684 A.D.) was one of the first to demonstrate by rainfall-runoff measurements that annual rainfall on a watershed was more than sufficient to account for annual runoff from the

VOL 12

8049

watershed. (Biswas, 1970, pp.213-219) Mariotte's rainfall - runoff studies were carried out on the Seine River watershed which terminated in Paris at the confluence of the Seine and Marne rivers. Interestingly, Mariotte's place of birth, Dijon in east central France, was on the headwater divide of the watershed and the source of the three years of rainfall data used in his rainfall - runoff investigation.

He used the annual precipitation at Dijon to estimate the annual rainfall volume on the Seine River watershed. Streamflow measurements on the Seine at Paris yielded the annual runoff volume for the watershed. Runoff volume was found to be about one-sixth of the rainfall volume clearly indicating the sufficiency of rainfall to account for runoff. Mariotte performed a similar rainfall - discharge study on a large spring.

Edme Mariotte also prepared a manuscript for a book on the motion of water and other fluids (Traite du mouvement des eaux et des autres corps fluides). Apparently knowing that death was imminent, Mariotte gave the manuscript to a friend and scholar who carried the project through to publication in 1686. Titles of the five parts of the book suggest that it was a predecessor of current fluid mechanics textbooks.

As a result of inquiries going back at least 23 centuries, the hydrologic cycle is now understood to be the continuous, unsteady circulation of the water resource from the atmosphere to and under the land surface and, by various processes, back to the atmosphere. The hydrologic cycle is dynamic in that the quantity and quality of water at a particular location may vary greatly with time. Within the hydrologic cycle, water may appear in all three of its states: solid, liquid, and gas. And water engineers and scientists continue to seek further understanding of the hydrologic cycle and of its response to cultural changes.

Discharge Measurement

Measurement or prediction of volumetric discharge in pipes and channels, over dams, through orifices, and at other control structures is basic to water management. From the earliest times, volumetric discharge was thought to be determined solely by cross-sectional area. The Greeks were the first to record the recognition that volumetric discharge of water is a function of cross-sectional area and velocity. The Greek historian, Hero, said (Rouse and Ince, 1963, pp. 21-22):

> It is to be noted that in order to know how much water the spring supplies it does not suffice to find the area of the cross-sectional flow....It is necessary also to find the speed of the flow...

Although the Romans subsequently developed water transportation technologies, such as aqueducts, they apparently did not fully understand or appreciate the discharge principles exposed centuries earlier by the Greeks. A case in point is Sextus Julius Frontinus, water commissioner for the city of Rome. His writings strongly suggest that he understood the dependence of discharge on cross-sectional area but did not comprehend the equally important role of velocity (Rouse and Ince, 1963, p. 25, pp. 30-32).

Leonardo da Vinci (1452-1519 A.D.), the illegitimate child of a Florentine lawyer, was born in Vinci, Italy. Generally considered to have been a genius, his observational and analytic powers contributed to many fields, including hydrology and hydraulics, as documented by Biswas (1970, pp. 136-147).

Leonardo was one of the first to clearly express the continuity principle as it applied to open channel flow. He used the following analogy to explain the principle:

> Let us imagine an avenue formed of three consecutive sections, each of a different width; the first section, the narrowest is four times less wide than the second, and this one (the second) is twice narrower than the third; people, closely pressed against each other, fill these avenues; they must march together in a continuous manner; when the people in the large avenue take one step forward, those in the middle one must make two and those in the smallest, eight; a proportion which you will find in all motions passing through sections of width.

VOL 12

8051

Leonardo contributed to discharge measurement by determining river velocity profiles in vertical and horizontal planes. He used special floats and walked along the river pushing an odometer for distance while he measured time by singing up and down the musical scales.

Incidentally, Leonardo planned to write a book on water and identified 15 chapters. Based on the chapter titles (e.g., rivers, repairing the banks of rivers, conduits, canals, machines turned by water, raising water) his book could have been titled "Water Resources Engineering". Unfortunately, he never had time to complete the project.

Hydrostatics

Hydrostatic principles are frequently and routinely used in urban water management to calculate the pressures and forces exerted by water. For example, hydrostatics enters into the structural design of earthen berms and concrete outlet works and floodwalls. Hydrostatics is also applied in floodproofing of existing and new residential, commercial, and other structures and in calculating the stability of tanks and other vessels totally or partially submerged in saturated soil.

Modern hydrostatic principles were largely developed by Archimedes (287-212 B.C.), the Greek theoretician and mathematician. The son of an astronomer, Archimedes was born in Syracuse, Sicily and devoted his career to advancing mathematics and inventing or refining mechanical devices such as the water screw and war machines or engines. Interestingly, Archimedes died when Syracuse fell to the Romans. The Greeks used some war machines developed by Archimedes in their defense of the city (Rouse and Ince, 1963, pp. 15-19).

According to legend, Archimedes discovered the buoyancy principle while bathing nude in a public bath. A very excited Archimedes is supposed to have left the bath and run through the streets naked shouting "Eureka (I have found it!)" (Rouse and Ince, 1963, p. 16). If he was in fact that exuberant about this discovery of the buoyancy principle, his actions would certainly be excused given the usefulness of his work in modern water management.

Dams

One of the oldest major dams was constructed by King Menes on the Nile River in what was already Egypt in about 3000 B.C. (Biswas, 1970, pp. 2-5). He dammed the Nile just upstream of Memphis, an ancient city and one-time capital of Egypt, about 200 Kilometers (125 miles) from the Mediterranean Sea near what is now Cairo.

King Menes apparently constructed the 450 meter (1470 foot) long, 15 meter (50 foot) high dam on the Nile for two reasons. First, the dam facilitated building Memphis on the fertile, former river bed and floodplain of the Nile. Second, the dam was part of a protective moat around Memphis consisting of the diverted river, a lake, and a canal. The dam functioned for at least 2500 years.

Another of the oldest known dams is the Sadd el Kafara Dam about 18 miles south of Cairo, Egypt. Although the dam was apparently short-lived, according to Biswas (1970, pp. 5-7) the remnants were not discovered until 1855 and remain to this day.

Constructed approximately between 2950 and 2750 B.C., the dam was probably intended to provide drinking water for workers and animals at a nearby quarry. The 106 meter (348 foot) long, 11 meter (37 foot) high dam was constructed of rubble masonry. There was no spillway and mortar was not used in construction. Furthermore, although the dam was to intercept runoff from a 186 square kilometer (72 square mile) tributary area, the resulting reservoir had a capacity of only 568,000 cubic meters (460 acre-feet). This was equivalent to 0.3 centimeters (0.12 inches) of runoff from the watershed.

Because of the absence of a spillway and the very small storage capacity, this first dam was doomed to early failure. Lack of sediment deposits at the site suggest that the dam failed in the first flood season.

The Egyptian engineers probably benefitted from the failed Sadd el Kafara effort. Lessons learned may have included the need for a spillway, a stable and cohesive structure, and a storage capacity commensurate with the tributary watershed. For example, the Egyptians subsequently constructed a 2000 meter (6560 feet) long, 6 meter (20 feet) high, rock-filled dam in Syria in the 14 century B.C. This 34 century old dam is still in use (Biswas, 1970, pp.5-8).

The valley of the Tigris and Euphrates rivers, in what is now called Iraq, is one of the cradles of civilization. According to Biswas (1970, pp. 19-22), the advantages of being in a valley enriched by two rivers was partly offset by the ever-present danger of flooding. Therefore, the careful design and proper maintenance of water control works, such is dams, irrigation channels, levees, and canals, was critical to survival.

King Hammurabi conquered the valley around 1760 B.C. He codified laws into what is now called the Code of Hammurabi (discovered in 1901 and maintained in the Louvre Museum in Paris.) The crucial nature of dams and other water control facilities is clearly evident in the code. Consider, for example, this provision:

> If any one be too lazy to keep his dam in proper condition, and does not keep it so; if then the dam breaks and all the fields are flooded, then shall he whose dam the break occurred be sold for money and the money shall replace the corn which he has caused to be ruined.

A dam owner in the Tigris and Euphrates valley certainly understood the nature of his responsibility. In the area of off-site and downstream responsibility of water managers, the almost 4000 year old Code of Hammurabi is consistent in intent (although not penalties) with modern laws and legal decisions.

Collection - Transportation - Distribution Works

Wherever people have gathered into communities, the provision of water for drinking, bathing, irrigation, and other uses has required the construction of systems to collect, transport, and distribute water. Two of these, the qanat system used in arid areas and the Roman aqueduct systems are of particular interest.

The people of Armenia (now Iran, Turkey, and the Soviet Union) and Persia (now Iran), were among the first to use the ingenious and difficult to construct qanat systems. Qanats existed in Armenia at least as early as the seventh century B.C. They were used extensively in Persia and also later in Egypt, as far west as Spain, and as far east as India. Biswas (1970, pp. 26-29) provides an informative account of the form, function, and historic

VOL 12

8054

development of qanat systems.

A qanat is an excavated, gently sloping tunnel having an egg-shaped cross section and lined with rock if needed. The qanat intercepted ground water and conveyed it to populated areas to meet drinking water, irrigation, and other needs. The vertical or largest dimension of the tunnel cross section was about the height of the workers who excavated the tunnel.

Individual qanats had average lengths of about 40 kilometers (25 miles) with some thought to be over 160 kilometers (100 miles) long. Longitudinal slopes were in the one to three percent range and at some places the qanats were 400 feet below the ground surface.

Vertical shafts positioned every 20 to 140 meters (65 to 460 feet) along the entire length of the qanat supplied air to laborers who dug the tunnel in an upstream direction to permit continuous release of ground water that entered the tunnel. The vertical shafts also provided access for reflected light, which was used to guide the workers, and for removal of excavated material which was placed in goat-skin bags and lifted through the vertical shafts.

Why did the Armenians, Persians, and others develop the elaborate, underground qanat technology as opposed, for example to the seemingly simpler surface and near surface aqueduct used later by the Romans? Several factors apparently lead to the use of qanats.

First, qanats were used in hot and arid areas having limited surface water supplies, which would favor groundwater sources, and having high evaporation rates which would also favor sub-surface or at least covered conveyance works. Second, construction of aqueduct type systems would have required maintaining relatively uniform slopes in hilly country. Although the Romans met this challenge centuries later, they also had to develop the ability to construct massive bridges to convey the aqueducts across river valleys. Finally, the deep, sub-surface route of the qanats would tend to keep the water cool and relatively free of potential pollutants.

In summary, qanat systems were an ingenious solution to a challenging water supply problem--a solution tailored to a particular set of circumstances. Similarly, the Romans subsequently developed aqueduct systems to transport water

VOL 12

8055

in response to their physical and social environment.

Partly because of their extensive public baths, Roman cities required an essentially continuous, large flow of clean water. As the Roman city of Nemausus (now Nimes, in extreme southern France) grew to a population of about 50,000 during the last century B.C., an adequate water supply was required. As researched and described by Hauck (1989), Roman engineers decided to transport water by gravity from springs near the small town of Ucetia (now Uzes), France.

The entire aqueduct system is thought to have been designed by Marcus Agrippa, a friend of Caesar Augustus. Besides being an accomplished military officer, Marcus Agrippa was the chief designer of public works throughout the Roman Empire. He specialized in water supply systems.

Although the springs were located 20 kilometers (12 miles) to the north, the aqueduct which was designed and constructed by the Romans was 50 kilometers (31 miles) long. The much longer route was dictated by the need to maintain gravity flow, the inability to accommodate pressure flow, and the need to minimize crossings of valleys and other low areas.

Because the source spring was only 17 meters (56 feet) higher than the intended distribution point in the Nemausus, the aqueduct had an average slope of only 0.034 percent. The Romans were apparently able to construct the aqueduct within this severe constraint without causing flat or reverse sloped reaches where water stagnated.

Even though the chosen route avoided most obstacles, the aqueduct did have to cross the deep valley of the Gard River (a tributary to what is now called the Rhone River which flows into the Mediterranean Sea on the southern coast of France). This crossing was achieved by designing and constructing in about 19 B.C. the 16 story (49 meter or 160 foot) high, 275 meter (902 feet) long Pont du Gard (Bridge of the Gard). This beautiful, three-tired masonry structure still stands as do some other portions of the 2000 year old aqueduct system. The Pont du Gard is the tallest bridge ever constructed by the Romans.

The two large lower tiers of the bridge are composed of a series of masonry arches -- each 24.5 meters (80 feet) wide. The third tier consists of smaller arches supporting the concrete water channel which conveyed an

VOL 12

8056

average flow of about 350 liters per second (12 cubic feet per second or eight million gallons per day).

To minimize flow resistance, the channel along the entire length of the aqueduct was lined with a pinkish cement composed of lime, pork fat, and the latex-like milk of unripe figs and called maltha. In keeping with Roman custom, most of the channel was constructed just below the ground surface and covered. The typical channel section consisted of a concrete foundation, sidewalls of stone masonry built on the foundation and a semi-circular stone arch over the top. The structure was then back filled. Over the Pont du Gard, the channel was covered by stone plates. Aqueducts were covered to prevent the water from being warmed by the sun and to minimize the entry of dust, dirt, and other materials (Rouse and Ince, 1963, p. 26).

The aqueduct ended at the circular castellum (distribution reservoir). This 6 meter (20 foot) in diameter, 1.4 meters (4.6 feet) deep masonry structure served to distribute flow to lower areas in the city by gravity through ten 0.3 meter (1 foot) diameter pipes. The pressure conduits that distributed the water in Roman cities were usually constructed of lead and clay but sometimes bronze, copper and bored stone were used (Rouse and Ince, 1963, pp. 27-28).

The Uzes-to-Nimes aqueduct conveyed water for about four centuries. The Pont du Gard stands today as a testimony to the creativity and persistence of the Roman engineers.

A system of nine aqueducts, having a total length of 422 kilometers (262 miles) were built to supply water to Rome. Construction dates for these aqueducts, which drew on springs, rivers, and a lake, ranged from 312 B.C. to 52 A.D. The Roman aqueduct system was under the jurisdiction of Sextus Julius Frontinus (35 A.D., approximately, to 104 A.D.). After a military career, he was appointed to serve as commissioner of the Roman waterworks in about 97 A.D., when he was about 62 years old. Frontinus was obviously very proud of his water system as indicated by his statement (Biswas, 1970, p. 89, pp. 92-94):

> Will anybody compare the idle Pyramids, or those other useless though much renowned works of the Greeks, with these aqueducts, with these many indispensable structures?

The Manning Equation

The Chezy formula, experimentally developed about 1770 by the French engineer Antoine Chezy, is the basis for most formulas used for turbulent flow in open channels. Chow (1959, pp. 93-101) and Williams (1970) trace the approximately 120 year evolution of development in open channel flow analysis from the Chezy equation into the now widely-used Manning equation. Chezy verified the formula with measures on the Courpalet Canal and Seine River in late 1969. The Chezy formula is:

$$V = C(RS)^{1/2}$$

Where V = mean velocity with dimensions of length divided by time

C = a flow resistance factor called Chezy's C

R = hydraulic radius of the channel or conduit with dimensions of length

S = dimensionless slope of the hydraulic grade line

Although Antoine Chezy originally developed and verified the formula using experimental data for open channel flow, it may be mathematically derived for both open channel flow and pipe flow.

From the time of its introduction, the principal problem associated with practical application of the Chezy formula was determination of the Chezy flow resistance factor C. As a result, many investigators developed and reported on experimentally-derived formulas including one by Ganguillet and Kutter, two Swiss engineers, which was published in 1869. They expressed Chezy's C as a complicated (i.e., in pre-electronic calculator/computer times) function of S, $R^{1/2}$ and a coefficient of channel roughness called Kutter's n.

Another formula for C was that proposed in 1897 by the French engineer H. Bazin which expressed C as a function of only $R^{1/2}$ and Bazin's m, the latter being a coefficient of channel roughness. In 1867 P. G. Gauckler, a French engineer, proposed an experimentally-derived equation for open channel flow that was equivalent to expressing Chezy's C as being directly proportional to $R^{1/6}$.

Subsequently, many other investigators, including the

VOL 12

8058

R0041364

Irish engineer Robert Manning in 1889, proposed the same dependence of Chezy's C on $R^{1/6}$. The proportionality constant was later determined to be 1/n, in metric units, or 1.49/n, in English units. The coefficient of channel roughness (i.e., n) has been incorrectly attributed to Manning, inasmuch as it is now referred to as Manning's n. Manning's n may be considered numerically identical to Kutter's n.

Thus, based on the work of several investiagators, Chezy's C is expressed as: $C = (1/n)\ R^{1/6}$ in metric units and $C = (1.49/n)\ R^{1/6}$ in English units. This expression, combined with the Chezy formula, yields the familiar open channel formula in, respectively, metric and English units: $V = (1/n)\ AR^{2/3}\ S^{1/2}$ and $V = (1.49/n)\ AR^{2/3}\ S^{1/2}$. This equation was misnamed the Manning Equation--misnamed in the sense that although Manning made a confirming contribution, he was not involved in a major way.

The Ganguillet and Kutter formula, the Bazin formula, and other available formulas were generally not as suitable for practical application as the Manning formula because they are either based on limited experimental data, as is the Bazin formula, or were cumbersome to use without computational aids, as is the Ganguillet-Kutter formula. The Manning formula produced results equal to or better than all other formulas and lent itself to rapid calculation, primarily because of its relatively simple form and the availability of a variety of nomographs and other computational aids prior to the development of electronic calculators and computers.

Because of this combination of accuracy and ease of use, the Manning formula is internationally the most widely used of all open channel flow formulas. It was recommended for international use in 1936 by the Third World Power Conference.

The Lloyd-Davies Formula or Rational Formula

During the period 1842 to 1847, Irish engineers made what is thought to be one of the first attempts to predict flood flows as a function of rainfall. According to Biswas (1970, pp. 301-305), who documents the Irish contributions, their motivation was the design of drainage channels having sufficient capacity to convey the peak discharge generated by the recorded maximum daily rainfall.

The Irish engineers assumed, in essentially correct fashion, that rainfall evaporated, infiltrated, or

VOL 12

8059

appeared as streamflow. Initially, they incorrectly assumed that evaporation and infiltration for a given watershed occurred at a constant rate throughout the year, that is, were independent of factors such as precipitation rates and duration and antecedent moisture conditions. Given their flawed hypothesis, they concluded that annual stream flow volume as a percent of annual rain flow volume could be applied to individual rainfalls, or more precisely, to daily rainfalls. Thus if annual streamflow was X percent of annual rainfall, then X percent of any given daily rainfall would appear as daily streamflow.

The desire to convert rainfall to runoff gave rise to the idea of a runoff factor or coefficient. The Irish engineers soon realized that the factor or coefficient for daily or other rainfall depended on more than the ratio of annual runoff to annual streamflow. More specifically, runoff was gradually seen to be influenced by factors such as watershed slope, soil characteristics, and vegetation.

By 1847, the following flood-flow computation formula was being used in Ireland:

$$Q = 2.52\ CIA$$

Where Q = peak discharge in cubic feet per minute

C = dimensionless runoff coefficient

I = maximum daily rainfall in inches (they used 1.5 to 2.0 inches)

A = tributary area in acres

Irish engineer Thomas J. Mulvaney (1822-1892), in his 1851 paper in the Proceedings of the Institute of Civil Engineers of Ireland, set forth the basic idea of what is now called the Lloyd-Davies method in some countries (e.g., Great Britain) and the rational method in others (e.g., the U.S.). Mulvaney's understanding of the rainfall-runoff process and his influence on the Lloyd-Davies/rational method is suggested by his statement about what is now called the time of concentration (Biswas, 1970, p. 303):

> The first matter of importance to be ascertained in the case of the small or mountain catchment, is the time which a flood requires to attain its maximum height, during the

VOL 12

8060

R0041366

> continuance of a uniform rate of fall of rain. This may be assumed to be the time necessary for the rain which falls on the most remote portion of the catchment, to travel to the outlet, for it appears to me that the discharge must be greatest when the supply from every portion of the catchment arrives simultaneously at the point of discharge, supposing, as above promised, the rate of supply to continue constant, in this length of time being ascertained, we may assume that the discharge will be the greatest possible, under the circumstance of a fall of rain occurring, of the maximum uniform rate of fall for that time...so that, having ascertained the extent, form and average inclination of any catchment, we may be able to determine, in the first place, the duration of constant rain required to produce a maximum discharge, and consequently to fix upon the maximum rate of rainfall applicable to the case.

Mulvaney should probably be honored for his seminal work by having the method named after him. However, the method is called the Lloyd-Davies formula in Great Britain because D. E. Lloyd-Davies published the paper on the subject in the Proceedings of the Institution of Civil Engineers in 1906.

For the origin of the word "rational" in the rational method and for early field measurements on the urban rainfall-runoff process, one must go to the U.S. in the late 19th century. Emil Kuichling, City Engineer of Rochester, New York, carried out some important experiments in the course of his work (Kuichling, 1889; McPherson, 1969). Kuichling was concerned with commonly used methods based on rainfall periods of one hour or more. He hypothesized that shorter periods of more intense rainfall may cause larger flows and, accordingly, perhaps storm sewers were being undersized.

Therefore, Kuichling performed rainfall-runoff measurements on five sub-basins in Rochester, ranging in size from 10 to 145 hectares (25 to 357 acres). Based on his measurements, he concluded the following:

1) Runoff volume is proportional to imperviousness. This effect is accounted for in the Lloyd-Davies/rational method by the runoff coefficient.

2) Maximum discharge occurs when the rainfall lasts long enough for the entire tributary area to contribute flow. This is the basis for defining the time of concentration and is used to determine the average rainfall intensity in the Lloyd-Davies/rational method.

3) Peak discharge is proportional to rainfall intensity. This is the basis for including intensity in the Lloyd-Davies/rational method equation.

4) Antecedent moisture levels are likely to have a significant effect on peak flows. However, Kuichling was not able to provide a means of accounting for antecedent moisture conditions.

Kuichling published the results of his Rochester research to establish a basis for additional investigations that might be done by engineers. He states in his paper (Kuichling, 1889):

> ...and hence is obvious that a more rational method of sewer computation is urgently demanded...it is sincerely hoped that the efforts of the writer will be amply supplemented by many valuable suggestions and experiments each other member of the Society (American Society of Civil Engineers) may generously contribute.

Now known as the rational method in the U.S., apparently because of Kuichling's use of the word "rational", the technique developed by Kuichling is used extensively throughout the U.S. However, in spite of the request for additional investigations as stated in his 1889 paper, few studies have been conducted (e.g., Schaake et al., 1967) and the Lloyd-Davies/rational method has changed little since Kuichling introduced it into U.S. engineering practice a century ago.

The formula is:

$$Q = CIA$$

Where Q = peak discharge for the recurrence interval

VOL 12

8062

VOL 12

T in cubic feet per second

C = dimensionless runoff coefficient

I = average rainfall intensity during a period of time equal to the time of concentration for the selected recurrence interval in inches per hour

A = tributary area in acres

Although the Lloyd-Davies/rational method appears simple, it is apparently often misused. Consider, for example, the results of the survey of 32 U.S. communities (Ardis et al., 1969) in which the staffs were asked to apply the rational method. Only six of the communities used the method correctly, the most common errors being the following:

1) Failing to consider rainfall as being variable, that is, as being dependent on the time of concentration.

2) Calculating flows for individual sub-basins and simply summing them to get total flow for the watershed rather than determining a rainfall intensity and weighted runoff coefficient for each successive downstream point in the drainage system.

3) Failing to account for flow time in storm sewers in computing the time of concentration.

Another widely held misconception about the Lloyd-Davies/rational method is that the time of concentration corresponds to the duration of the storm. The time of concentration is simply the critical time period used to determine average rainfall intensity from intensity-direction-frequency curves. Inasmuch as rainfall is a random event, it is possible that a rainfall event could have a duration equal to the time of concentration of a sub-basin. However, it is much more likely that the total duration of a storm will be longer than the time of concentration used in the rational method. Furthermore, the critical duration of interest could occur anywhere within the storm. Misuse of the rational method in calculating peak discharges and volumes is discussed by Walesh (1989, pp. 100-111).

Darcy's Law

In 1716, the French formed a corps of civilian engineers (Corp des Ingenieurs des Ponts et Chaussees, that is,

8063

corps of engineers for bridges and streets). This civilian corps was formed to distinguish the public works responsibilities of these engineers from the responsibilities of the long standing corps of military engineers (Corps des Ingenieurs du Genie militaire).

The Ecole des Ponts et Chaussees was founded in 1747 to educate the young and growing core of what we would now call civil engineers. As a result, the word ingenieur, which traditionally meant craftsman-builder, now began to take on the meaning of a scientifically-educated professional (Florman, 1987, pp. 48-49).

Henry Philibert Gaspard Darcy (1803-1858) was a member of the French civil engineering corps. Born in Dijon, France, he returned there after his education in Paris and was given responsibility for designing and constructing the municipal water supply system. Because the completed system functioned so well, Darcy was later retained as a consultant on a similar project by the city of Brussels, Belgium.

To gain further insight into the behavior of sand filters, which were one component of the Dijon water supply system, Darcy conducted experiments on flow through porous media. Prior to his research, mechanical energy loss through a porous medium was thought to be proportional to the square root of velocity or the rate of flow. However, his experiments demonstrated that energy loss is proportional to velocity as stated in what is now called Darcy's Law:

$$v = k\ (dh/dl)$$

Where k = coefficient of permeability with dimensions of velocity

h = mechanical energy or total head per unit weight of liquid with dimensions of length

l = distance in the direction of flow with dimensions of length

Darcy published the results of his experiments and the equation he developed as part of his 1856 report (Les fontaines publiques de la ville de Dijon) on the Dijon water supply (Rouse and Ince, 1963, pp. 169-171).

Darcy appears to have been motivated to experiment with flow through porous media--which led to a fundamental discovery--in order to more conscientiously carry out his water filtration responsibilities in Dijon. His results met the needs of that project but also spawned additional significant analytic work in well hydraulics.

Using Darcy's work as a foundation, others developed formulas now commonly used in groundwater work. Examples are Dupuit's and Thiem's analytically-derived equations for axially symmetric, steady flow to well and Theis's methodology for axially symmetric, unsteady flow to a well.

Incidently, Darcy also conducted experiments, with the results published in 1857, on flow of water through conduits of various size and material. He demonstrated that resistance to flow depended, in part, on the type and condition of the inner walls of the conduit. His experiments also suggested that as conduit flow shifted from a laminar condition to a turbulent condition, energy loss changed from being directly proportional to velocity to being proportional to velocity squared. As a result of his work with pipe experiment, Darcy's name is attached, along with that of Julius Weisbach (1806-1871), to what is now known as Darcy-Weisbach pipeflow equation and methodology (Rouse and Ince, 1963, p. 161, pp. 170-171).

Computer Models

Digital computer modeling techniques developed within the water resources field during the last few decades. When used by experienced engineers, these models facilitate greatly improved watershed analysis and design. As stated anonymously:

> The computer is incredibly fast, accurate, and stupid. Man is unbelievably slow, inaccurate, and brilliant. The marriage of the two is a challenge and opportunity beyond imagination.

Computer models enable engineers to answer two fundamental questions typically addressed in all but the most trivial water resource projects. First, how does the existing system function, that is, what are the causes of the water-related problems? Second, how could the watershed system be modified or altered to mitigate existing problems and to prevent similar and new problems from occurring?

Most of the algorithms in watershed models are not new. For example, and as already noted, the basis for the Manning open channel flow equation goes back to at least

VOL 12

8065

1770. Rational method concepts, such as the time of concentration, and similar time parameters used in computer models can be traced at least as far back to the work of Thomas J. Mulvaney in the 1850's. Unit hydrograph theory, which is used in many watershed computer models, was well established as early as 1932 (Sherman, 1932). Therefore, the algorithms used within computer models, and more specifically, the theories and techniques on which they are based, are generally not new. Their origins can typically be traced back decades and even centuries.

The most important feature of the development of watershed digital computer models is that they provided the ability to link the algorithms representing many hydrologic-hydraulic-water quality processes and to make the necessary voluminous computations at a reasonable cost. The practical application of hydrologic and hydraulic knowledge was not fully realized until the development of the digital computer and digital computer models.

One way to classify computer models is event versus continuous. The principal distinction between event and continuous models is the type and amount of meteorologic data used as input and the manner in which the data are processed within the computer program. Event models typically require as input one or a few design storms in the form of a synthetic hyetograph or one or a few historic storm hyetographs. These few hyetographs are entered into the model and output consists of an equal number of hydrographs. If a recurrence interval is attached to an input hyetograph, the usual assumption is that the resulting output hydrograph has the same recurrence interval.

A fundamentally different approach is used with continuous models, as exemplified by the Stanford Watershed model (Crawford and Linsley, 1966), which was apparently the first continuous hydrologic-hydraulic model. The entire meteorologic record, usually consisting of decades of available precipitation, temperature, and other similar data, is used as input. The computer processes all the continuous meteorologic input and produces, as output, a continuous hydrograph. The usual procedure is to statistically analyze the continuous output in the same fashion as one would statistically analyze a long stream-flow record.

Next to the creation of computer models, the subsequent development of continuous simulation was probably the most significant technologic development within modeling. Although the first continuous simulation model was developed in the U.S. by Crawford and Linsley, who were seeking an improved way to more fully incorporate all aspects of the hydrologic cycle, they were influenced by the contributions of the Japanese researcher Sugawara (Crawford, 1989; Sugawara, 1961). Working at the University of Kyoto, he published a paper in 1961 describing the use of idealized storage structures -- conceptualized as containers of various sizes, shapes and configurations -- that he defined and combined to build rainfall-runoff models. Using manual calculations, Sugawara operated the idealized storages on a continuous basis. The computation method was not very sophisticated. However, Sugawara's approach was new in that it included a continuous accounting of various components of the hydrologic cycle -- many factore influencing the overall rainfall - runoff process were included.

Crawford and Linsley were influenced by the work of Sugawara and used some of his concepts in combination with digital computation to produce the Stanford Watershed model in 1966. Other continuous simulation models or models that could be used in a continuous simulation mode were subsequently developed in the U.S. including STORM (Storage, Treatment, Overflow, Runoff Model), HSPF (Hydrocomp or Hydrologic Simulation Program - Fortran), and SWMM (Storm Water Management Model) (Bedient and Huber, 1988), which were developed in the U.S., and a model developed by Dorsch Consult in Germany. The Dorsch model, which was completed in 1972, was developed independent of the Stanford Watershed model (Geiger, 1989).

The principal advantage of the important development of continuous simulation is that it eliminates the design storm dilemma. Instead, continuous simulation produces a result similar to a long-term streamflow record on which a variety of useful statistical analyses may be performed.

Because continuous simulation is such a recent development in the overall chronological history of hydrology and hydraulics, its relative significance is difficult to determine. However, with the passage of time, the development of continuous simulation will probably be increasingly viewed as a very significant milestone in the water resources field.

Concluding Observations

The roots of the science and technology used today in the water resource field encircle the globe and reach back to the beginnings of recorded history. Contributions to water resource engineering science and technology have emerged from all parts of the world. Wherever people have gathered to form a community there has been concern with very basic water-related needs such as providing drinking water, disposing of wastewater, irrigating crops, and mitigating flooding. Paralleling this pragmatic concern, there apparently has been widespread curiosity about water -- rainfall, streamflow, springs, and evaporation. Need and curiosity have been strong motivators in the water resources field.

Many of the scientific discoveries and technologic developments in the water resources field have not been motivated so much by simple desire to better understand the physical world, but rather by a need to "get the job done." Recall, for example, Armenian and Persian developments of qanat systems centuries before Christ to collect and transport water in arid climates; Sedileau's 17th century precipitation and evaporation experiments in support of his assignment to supply water for fountains at Versailles; Kuichling's 19th century rainfall-runoff studies to facilitate improved storm sewer design in Rochester, New York; and Darcy's 19th century porous media and pipe flow experiments which enabled him to design the water supply system for Dijon, France. In their desire to create effective water facilities and systems, engineers from all over the world have contributed much to water resources science and technology.

Acknowledgements

Two books, one by Biswas (1970) and one by Rouse and Ince (1963), were major sources of material used in this paper. The water resources community owes much to these authors for their research and writing. Besides providing enlightenment, perhaps their works will inspire ongoing research into the origins of the water resources science and technology, particularly by non-western nations and cultures.

The engineering profession needs an enlarged understanding of its global roots. By so doing, the profession gives credit where credit is due. Furthermore, knowledge of roots helps in understanding how "small" the world is.

The author gratefully acknowledges the assistance of Dr. Bradford H. Spring, College of Engineering, Valparaiso University who provided some of the source material used in the preparation of this paper and who offered review comments. However, the author is totally responsible for data and information presented, opinions expressed, and conclusions drawn.

STORMWATER QUALITY INSTITUTIONAL CONSIDERATIONS

Jonathan E. Jones, P.E.[1]
D. Earl Jones, Jr., P.E.[2]

ABSTRACT

This paper explores stormwater quality institutional issues and uncertainties in two ways:

1. Characteristics of the four different parties (legislators, regulators, consultants and project proponents) typically involved with the resolution of water quality issues are presented. Understanding the motivating factors behind each of these parties is essential if constructive, cost-effective mitigation strategies are to evolve.

2. For a variety of public and private clients, an eight step evaluation/mitigation strategy has proven effective, assuming that study goals, objectives, principles, and policies are clearly articulated and agreed upon. Despite the effectiveness of the procedure however, important aspects of each of the eight steps will be viewed differently by each of the four parties associated with the process.

The paper concludes with the assertion that our technical capability to mitigate the urban runoff quality problem exceeds our understanding of the problem and current institutional policies that regulate problem responses.

INTRODUCTION

Urban stormwater quality management is presently dominated by institutional considerations. True, a fortune is being poured into assessing impacts on receiving waters; evaluating the effectiveness of artificial wetlands at immobilizing pollutants; establishing the extent to which infiltration practices will contaminate groundwater and other such technical questions; but at the "grass roots" level, institutional questions are the paramount concern.

The four interest groups that interact on this subject are: (1) legislators/politicians, (2) regulators, (3) consultants, and (4) "users" or project advocates (generally private developers). Typical questions that each of these parties asks are as follows.

[1] Member, ASCE; Vice President, Wright Water Engineers, Inc., Denver, Colorado, USA.
[2] Fellow, ASCE; Senior Advisor, Wright Water Engineers, Inc., Denver, Colorado, USA.

Legislators/Politicians

- Is my constituency (the electorate) sincerely interested in controlling pollution from stormwater runoff?
- How much mileage can my political action group get out of attacking some aspect of the stormwater quality management framework?
- Should we have a runoff quality ordinance?

Regulators

- How am I going to regulate urban nonpoint source polluters when I don't even have the budget or staff to regulate point sources?
- From a practical standpoint, how will the U.S. Environmental Protection Agency's (US EPA) NPDES regulations for stormwater discharges affect our regulatory policies?
- How am I going to be able to hold a land developer's feet to the fire to induce him to implement reasonable runoff quality mitigation measures when I don't have the legal authority to do so and when I am not even convinced that the measures will tangibly improve water quality?

Engineering Consultant

- My client has asked me to develop a runoff quality strategy for his proposed development; what am I going to tell him?
- Why can't regulators provide me with good guidance and direction on this subject since they normally have so many specific requirements on water quality issues?
- Where is the reference or manual that tells me how I can solve my client's problem in ten steps and where do I purchase the associated software?

Project Advocates (Usually, Land Developers)

- Tell me, again, how these pollutants that you say are in urban runoff hurt anything or anyone.
- Why can't you tell me, as my consultant, more specifically what I need to do? And why can't you tell me, as the designated regulatory reviewer, what performance standard I need to meet and why I should be expected to accommodate to a rapidly evolving regulatory basis?
- What is the benefit to me? Why must the expense be mine? Is there any way to reduce the cost?

Notwithstanding the fact that there is undeniably linkage between technical and nontechnical considerations in urban stormwater management, the answers to these questions will not come from the technical arena. Yet the importance of these questions is striking. Consequently, we must begin to devote at least as much attention to the institutional elements of the

VOL 12

8072

R0041378

water quality equation as to the technical elements. The question of how an overworked state health department staff member with no budget and no supporting staff and a lifetime of experience with trickling filter design is suddenly going to properly evaluate stormwater management plans for a 500-acre commercial/residential development is just as important as is the question of how complex mixtures typically found in urban runoff affect benthic organisms.

THE FOUR GROUPS INVOLVED WITH THE DECISIONMAKING PROCESS

Institutional problems tend to be "people" problems, problems with differing viewpoints among the various parties involved in the resolution of water quality issues. Consistency among intents of parties involved is elusive. Four principal interest groups are involved routinely in water quality decisionmaking and the scatter among their viewpoints is significant. These interest groups are termed: (1) legislative; (2) regulatory; (4) consulting professionals; and (4) users (developers, clients). Within each group, there are disparate viewpoints, described as follows:

Legislative - This group includes persons with authority to enact statutes and ordinances. They are swayed by various value judgments regarding public and private responsibilities and the significance and reliability of environmental projections. They may be strongly influenced by their constituencies' viewpoints. They may be pro- or anti-development. Most importantly, they often as individuals hold differing views about the intent of enacted statutes and ordinances. Unfortunately, without a clear understanding of legislative intent, regulations and design standards are difficult to formulate.

Regulatory - This group has responsibility for evolving, implementing, applying, interpreting and enforcing statutes and ordinances, which are usually rephrased as regulations in greater detail than the statutes or ordinances themselves. The group includes: (1) zealots, who tend to reflect extreme pro- or anti-development viewpoints; (2) ambitious public employees, who would avoid controversy and generally tend to reflect expediently the viewpoints of their political leadership; (3) objective, practical professionals with centrist viewpoints who seek the most practical technically and economically correct problem solutions and in doing so may alienate those with extreme viewpoints; (4) "enforcers," those who indiscriminately implement the letter of regulations as a matter of worship without regard for specific situation variables; and (5) those who do as they may be instructed without apparent concern, conviction, perception, initiative, eagerness or reluctance. Thus, regulatory policies tend to reflect the personal viewpoints of the persons in charge of the regulatory process.

Consulting Professionals - As individuals they may range in competency from highly developed to incapable. They may have the same individual viewpoints as may regulators, and sometimes appear to lack keen perception of the public interests they are licensed to protect. Some consultants subordinate their own views and respond in accordance with the directions of regulators, to avoid confrontations, delayed acceptance of their client's projects, and the risk of alienating regulators with whom they must interface regularly. Other consultants are easily manipulated by their clients and will doggedly combat regulators if they believe that this will impress their clients. Many consultants are distinctly uneasy without explicit guidance and criteria standards. A final complicating factor is that there

VOL 12

8073

continues to be little interaction among the very disciplines that should work together to maximize benefits, including planners, landscape architects, lawyers, economists, environmental scientists and engineers.

Users - These also should be thought of as individuals rather than institutions. Some are motivated economically and will do only what they are forced to do by regulators. Some perceive good environmental relationships as good business and strive to do what seems best for the public interest, but their perceptions of the latter may vary. They generally seek project approval "yesterday" and will often agree to comply with excessive regulatory demands to avoid project delay. Their consulting professionals often are instructed to do whatever may be necessary to avoid project delays. They may work "behind the scene" to influence project acceptance outcomes.

These are the primary "people variables" which shape and otherwise influence institutional water quality decisionmaking. They explain the diversity or lack of consistency among water quality policies of the many involved institutions. Any of the participants also may jealously seek to preserve authority for unilateral decisionmaking, often causing multijurisdictional decisionmaking or agreement to be impossible or inconsequential.

Interestingly, one technically strong, articulate person in any phase of the procedural hierarchy can have great influence upon institutional policy outcomes. Conversely, one indecisive, technically deficient, inarticulate person in a key decisionmaking position can pose inordinate difficulties for all parties.

The role of the regulatory administrator is viewed as the primary key to the nature of institutional processes. The administrator may have little or no technical ability but he has authority to interpret the intent of statutes or ordinances. These interpretations require rationales that may involve many non-technical considerations, and may be syllogistic rather than logical. With such interpretations, the character of the regulatory process can be distorted to contrast with the intent of the enabling legislation. Consequently, replacing a regulatory administrator may be the quickest and most effective way to influence the functioning of a regulatory institution.

RUNOFF QUALITY EVALUATION/MITIGATION STRATEGY

The authors have found the following runoff quality evaluation/mitigation strategy to be effective, provided that study goals, objectives, policies and principles are clearly articulated and agreed upon:

1. Define pollutant sources,
2. Estimate probable pollutant concentrations based on technical and non-technical factors,
3. Evaluate -- at least qualitatively -- impacts on receiving waters,
4. Establish applicable regulatory requirements and have them confirmed in writing,
5. Examine an array of mitigation measures and select a preferred alternative,
6. Interface water quality management schemes with traditional drainage considerations,
7. Pay special attention to institutional issues such as financing, public safety, maintenance, appearance, etc.

8. Objectively judge the preferred management strategy in the context of goals, objectives; policies and principles defined at the outset of the project.

The four interest groups described above will view each of these eight steps differently and may have widely divergent opinions on the following important kinds of questions:

<u>Define Pollutant Sources</u>

- What "sources" will need to be evaluated for the proposed project?
- Will it be feasible to eliminate certain categories of sources due to land use and/or development requirements? For example, if a privately maintained resort is willing to commit to no use of road salt, should road salt be considered a potential source?
- At what degree of risk do potential sources become consequential?
- How are the source characteristics likely to change over time? This is particularly important in the context of urban runoff because the runoff quantity/quality aspects of a basin vary dramatically as it transitions from undeveloped to active development to early building to maturity.
- What is the behavior/process whereby pollutants may enter or not enter receiving waters through runoff?
- Is pollutant entry into the water environment a function of the rate of runoff, amount of runoff, or time of runoff?
- Is it most appropriate for individual pollutants or classes of pollutants to be regulated by public agencies for the subject setting?

<u>Estimate Probable Pollutant Concentrations</u>

- In the environment or in runoff?
- At what time during runoff; that is, initial runoff, peak runoff, or after discharge into receiving waters?
- Given statistical summaries of the US EPA national urban runoff program (NURP) data, do the unique characteristics of the study area in question argue for projected pollutant concentrations that are low, high or average, and why?
- To what extent do site specific data need to be collected? Phrased in another way, how reliably can data be extrapolated to the specific setting?
- What are the natural "background" levels of pollutants?
- Are "illicit discharges" likely to be a problem?
- What is the pollutant's minimum detection level? What is the practical detection level? If the practical detection level is subject to a 40 percent error under the best of laboratory conditions, what is the significance for regulatory standards?

<u>Evaluate Impacts on Receiving Waters</u>

- Are existing water quality classifications and standards reasonable for the receiving stream? If the receiving stream has not yet been classified, what discharge standards are appropriate?
- Are anticipated impacts actual or hypothetical?
- For the specific setting, can impacts be categorized as: (1) very likely to occur, regardless of site specific considerations, (2) likely to occur given a certain set of site specific conditions,

or (3) nearly impossible to project with any accuracy given our basic lack of understanding of impacts on receiving waters?

- Because the regulating entity will almost certainly have only chronic and acute stream standards, in what context can these standards be utilized? Might other standards be more appropriate?
- Is an occasional "spike" really harmful or will it rapidly disperse without significant lingering affects?
- Do the target pollutants pass through or are they concentrated by each of the various biologic systems?
- One of the great unknowns regarding receiving water impacts is the role that "complex mixtures" play. Is it at all feasible for the subject setting to project the mixture of contaminants likely to be found in the runoff along with the associated implications of such a mixture?

Establish Regulatory Requirements in Writing

- Is the regulator prepared to commit to specific requirements in writing? If not, what will be required to obtain such a commitment?
- Will the regulatory strategy be: (1) technology-based, (2) best management practice-based, (3) receiving stream standard-based, or (4) hydrology-based? What are the implications of each of these regulatory schemes in the context of the US EPA's forthcoming NPDES regulations for stormwater discharges?
- If the regulatory review process requires the consultant to make one conservative assumption after another (such that caution is heaped upon caution), what is the probability of the scenario that is developed? Is this a proper regulatory approach? Is it prudent? Is it equitable?
- Should correction of a problem be the sole responsibility of a project proponent or should the community have concurrent responsibility to manage the introduction of pollutants to minimize the problem? Such as by prohibiting use of certain compounds?
- What actual risks, in terms of probability, are involved with each pollutant? How do such risks compare with other common risks in the human environment? Isn't it incongruous to focus upon elimination of very low risks while routinely accepting much greater risks in our daily lives? Shouldn't we be considering definitions of "acceptable risk" in terms of probable consequences?
- What is a reasonable consensus among regulatory fears, political concerns, arbitrary standards, prudence, potential liability, public health and safety, technical facts, economic soundness and proponents interests? How can unbiased objectivity be achieved?

Examine Mitigation Alternatives and Select Preferred Alternative

- Is the underlying basis (need) for the mitigation measures rational and demonstrable or poorly substantiated? In our view, there should be considerably more latitude in the design process if the underlying need cannot be clearly demonstrated.
- What measures are potentially applicable for the subject setting?
- What are the full array of consequences -- both quantifiable and non-quantifiable -- of a given measure or combination of measures?
- How do various alternatives fare in the context of such considerations as: appearance; safety; maintainability; replacement frequency; groundwater recharge; water rights and other factors?

- How reasonably can design specifications and observed performance be extrapolated from one setting to another? Do pollutant removal efficiencies from an artificial wetland in a hot, humid environment portend removal rates in a cold, high mountain setting?
- What are the comparative risks of the different mitigation strategies being evaluated? Who decides how large these risks can be?
- What constitute significant and insignificant constraints in the subject setting?

Interface Water Quality Management Schemes with Traditional Drainage Considerations

- Are proposed water quality mitigation strategies consistent with existing or proposed drainage and flood control facilities? How can the technologies best be "married"?
- Is one group of regulators involved with drainage and flood control issues while another group is responsible for water quality enhancement? How can the land developer and his consultant best resolve conflicting regulatory desires and requirements?
- Do existing drainage policies focus on getting rid of the water at all costs, or do they look broadly at each of the interfaces between water and all urban activities and interests?
- Do existing drainage policies need reevaluation and modification? Who is to judge? How to influence such change and gain its acceptance?
- Can multiple political subdivisions agree upon and implement a coordinated regional plan and design standards? What value have design standards if there is no coordinated regional drainage master plan?
- Is there a sufficient information/data base available to project comparative benefits and costs of quantity mitigation versus quality mitigation? If, for example, it is clear that flood hazard reduction is far more economically justifiable than water quality enhancement, where does this leave water quality enhancement?

Focus Special Attention on "Institutional" Issues

- Can water quality management be assuredly funded through some mechanism, such as a utility district or other permanent means?
- Can existing inapplicable and burdensome laws or regulations be modified?
- How much special attention should be focused upon: financing; design reviews; multiple interest consensus; performance evaluation; public health and public safety; compliance with drainage master plan objectives; maintenance needs and assurance; public recreation; property value protection and enhancement; short-term versus long-term objectives implementation and comparative benefits of alternative actions?

Judge the Preferred Management Strategy Objectively

- Objectively as viewed by whom?
  - The cautious public servant who feels he must protect himself by being conservative?
  - The more highly placed public servant who is sensitive to the desires of influentials?
  - The public counsel who strives for low liability solutions?

VOL 12

8077

- The consultant who is constantly cognizant of the need to exhibit "standard engineering practice" to reduce liability (this is frequently a real hindrance to innovation)?
- The project proponent who will ultimately pay for the strategy?
- Special interest social (sometimes environmental) groups who may thoughtfully evaluate the available alternatives, but who also may use the proposed project as a smoke screen to further their objectives?

o What criteria should be used to evaluate alternative water quality mitigation strategies?

o How reasonably can dollar benefits be assigned to water quality enhancement of urban streams -- many of which will never be capable of supporting desirable aquatic life forms?

CONCLUSION

A compelling argument can be made that we know more about the technical aspects of urban stormwater management than we do the institutional considerations. Hundreds of millions of dollars have been spent to: (1) collect and analyze urban runoff quality data, (2) assess impacts to receiving streams (although admittedly, much work still needs to be done in this area) and (3) design, install, maintain and monitor mitigation measures. By contrast, relatively little attention to date has been focused upon the legal, social, economic and other institutional factors that have been proven time and time again to be the determining factors in whether or not a stormwater management system will be success or a failure. The probable role that the "people factors" described herein will play in stormwater quality management decisions cries out for greater recognition.

Although many of the institutional questions raised within this paper will only be answered with time, the various parties involved with the stormwater quality decisionmaking process can at least thoughtfully evaluate: (1) perspectives, attitudes and methods of operation commonly associated with legislators, regulators, consultants and project proponents and (2) important provocative and oftentimes unanswerable questions that will be raised during the eight step problem evaluation/mitigation design procedure (or some variation thereof) described herein.

UK URBAN STORMWATER CONTROL - INSTITUTIONAL ISSUES

by David Fiddes[1]

Introduction

Increasingly within the UK sewerage field attention is being focused on performance deficiencies of existing networks and the development of cost effective methodologies for achieving targeted levels of service. The emphasis initially was on structural problems but this broadened to cover flooding and is now embracing also the environmental impact of discharges to receiving waters. This logical progression has allowed much progress to be made but many problems have still to be resolved. Some of these are due to deficiencies in understanding of the underlying processes, others because of deficiencies in available technology. Both are being tackled by research and development, but major impediments to progress are provided by institutional difficulties. The paper concentrates on these institutional issues with the author expressing some highly personal views in the hope of stimulating debate.

Historical background

The UK has probably the oldest and most complete sewerage system in the world. The earliest sewers were built primarily for surface water drainage. Combined sewer building had a great impetus from the death by cholera in 1848 of 53,000 people. The early sewers protected wells and the areas immediately adjacent to the houses but many urban rivers became little better than open sewers. Interceptor sewers and treatment works were installed later in the century. These 19th Century sewers form the backbone of our present system.

As early as the Royal Commission Report of 1865, the benefit of having a single authority responsible for complete drainage systems was recognised but this did not come about for over a century. In 1973 responsibility for the complete water cycle was vested in 10 regional water authorities for England and Wales instead of the previous 1,600 local authorities. This happy situation provided the right climate for very solid advances in sewerage rehabilitation planning during the late 1970s and early 1980s. Unfortunately there has not been the same rationalisation of the wider

-----

[1]Water Research Centre, P O Box 85, Blagrove, Swindon SN5 8YR, UK

planning area and conflicts and impediments to integrated planning are all too frequent as will be discussed later. This frequently results in having to settle for sub-optimal solutions.

Current problems

In the past it was difficult to measure the performance of the sewerage system as it was largely out of sight and out of mind. For several years a national register of sewer collapses was kept but the figures were found to be extremely uncertain and difficult to interpret. Flooding statistics are even more suspect as all surveys have shown that under-reporting is endemic. The reporting of defective storm overflows is also thought to be very much under-estimated. However, on the basis of the best available data, the author made an estimate some years ago of the likely required future expenditure on rehabilitation. This is given in Table 1.

Table 1 - UK sewer future funding - known problems (Fiddes 1986)

PROBLEM	COST (£ million)
Structural backlog	1,000
Short life sewers	1,500
Existing flooding	2,000
Failing overflows	1,500
TOTAL	6,000

These figures justify the high priority put on sewerage rehabilitation activity in the UK.

The performance of the receiving waters is more easy to assess, albeit against some rather arbitrary standards.

Water quality surveys are done at 5 yearly intervals, Table 2 showing the latest results. River and estuary reaches are put into one of four classes - good, fair, poor and bad. From the table it will be seen that 10% of river reaches in England and Wales are in the poor or bad classes. That is, they are not good enough to support reasonably good fisheries or to be economically treatable for drinking water supply. Using a similar classification, 8% of estuary reaches are of poor or bad quality.

Table 2 - Summarised results of 1985 river quality survey (DoE 1986)

WATER AUTHORITY	CLASSIFICATION OF RIVER REACHES			CLASSIFICATION OF ESTUARY REACHES		
	GOOD/ FAIR (%)	POOR/ BAD (%)	TOTAL (km)	GOOD/ FAIR (%)	POOR/ BAD (%)	TOTAL (km)
Anglian	91	9	4328	98	2	547
Northumbrian	97	3	2784	70	30	135
North West	78	22	5323	72	28	451
Severn-Trent	87	14	5150	100	0	61
Southern	97	3	1992	97	3	380
South West	94	6	2941	100	0	355
Thames	93	7	3546	100	0	138
Welsh	94	6	4600	98	2	44
Wessex	95	7	2467	97	3	145
Yorkshire	88	12	5767	74	26	70
England and Wales	90	10	38,896	92	8	2730

Not all rivers, of course, would be expected to support viable fisheries. In 1978 the European Community required all member states to designate waters suitable for fisheries so that a report for the whole community could be produced. The UK's response of over 50,000km, of which 97% were already complying, was far ahead of any other member state.

This relatively good position with respect to other European states is confirmed in Table 3 where results from a number of countries are compared on the same basis. It will be noted in the bottom line that over one quarter of all community river reaches are of poor quality or are grossly polluted.

Table 3 - River quality in Europe

	PERCENTAGE OF RIVER LENGTHS IN UK QUALITY CLASSES			
	UNPOL-LUTED	SATIS-FACTORY	POOR	GROSSLY POLLUTED
UK: England and Wales	67	24	9	2
Scotland	95	4	0.5	0.5
Northern Ireland	84	11	5	0
Belgium	56	17	16	11
West Germany	45	40	14	1
Luxembourg	72	13	11	4
Netherlands	77	18	4	1
EC Overall	39	35	22	5

The UK results give no grounds for being complacent.

In 1985, for the first time since these surveys were undertaken, more river reaches deteriorated than improved. This is thought to be due to non-point pollution but has also been accepted as justification for the need for more money to upgrade sewage treatment works. At present some 22% of major works are failing their discharge consent standards and the Government has agreed to an extra £700 million to ensure compliance within 4 years.

There are a number of further areas of concern. The first is very relevant to this conference - pollutant loadings from storm overflows and surface water outfalls in urban areas. A major research programme, the subject of another paper to this conference (Crabtree and Clifforde 1989), is under way in the UK to collect the data and develop the understanding to be able to set relevant standards and design effective control schemes.

As will be seen in Table 4, there has been a steady increase in pollution incidents over the last few years. These are cases where pollution of rivers has been

VOL 12

8082

reported to the Water Authority and, on investigation, the report was proved.

Table 4 - Water pollution incidents (England and Wales) (WAA 1987)

YEAR	TOTAL INCIDENTS
1980/1981	12,500
1981/1982	12,500
1982/1983	12,300
1983/1984	15,250
1984/1985	18,648
1985/1986	19,892
1986/1987	21,095

The majority of these are industrial spills, washoff from mining areas or failures of the urban drainage system, but a disturbing number are a growing area of concern - agricultural incidents. These are generally failures of the farm internal drainage systems allowing silage liquors or cattle slurry to wash directly, untreated, into a river. Such runoff is far stronger than urban runoff or storm sewage so that when it happens, fish kills are almost inevitable. A recent survey shows that about half of all cattle farms are at risk.

One of the biggest concerns is the quality of bathing waters. The waters around the UK are relatively cold so sea bathing is not as common as, for example, in the Mediterranean. There are, however, 400 Eurobeaches which are required to comply with the Bathing Water Directive. At present only about two-thirds do, but the success rate is steadily improving. The principal remedial measure being adopted is to upgrade the coastal sewers and install long sea outfalls designed with the benefit of comprehensive computer flow and water quality models of the sewer system and coastal waters. All beaches will comply by 1995, but the cost of the outfalls will be £800 million with quite a lot more for the associated sewerage.

VOL 12

UK approach to sewerage rehabilitation

When the Water Authorities were formed in the early 1970s it was possible for the first time to take stock of the inherited problems. The situation regarding sewers looked pretty bleak (NWC/DoE 1977), but following an extensive research effort by the Industry a cost effective strategy emerged which was set out in the Sewerage Rehabilitation Manual (WAA/WRc 1984). The approach advocated was to retain, where practicable, the existing pipework by optimising network performance and hence avoiding wholesale sewer replacement. Detailed investigations would be confined to the core of the system where the consequences of structural failure were most expensive and where the major flooding problems were concentrated. The strategy for the remainder - the bulk of the system - could safely remain one of reaction to failure as in the past. The planning procedure is set out as a flow diagram in Figure 1.

The Manual also brought together advice on the tools and techniques that had been evolving in parallel to the development of the strategic thinking and which formed the building blocks for the implementation of the planning procedures. These included:

- undertaking structural inspections using CCTV (for the smaller sewer systems);
- systematic recording of defects using the Manual of Sewer Condition Classification (WWC/DoE 1980);
- guidance on application of available renovation techniques and lining design to preserve, for the foreseeable future, the structural integrity of unsound sewer lengths;
- building and verifying network analysis models of sewer systems using the Wallingford Procedure simulation program WASSP-SIM and flow surveys;
- optimal use of flow reduction and attenuation techniques to eliminate unacceptable levels of surface and property flooding and discharge of storm sewage to receiving streams;
- integration of all of the above techniques to produce plans for short and medium term implementation of the optimal, cost effective upgrading works.

The approach adopted is to undertake studies of complete sewerage systems (Drainage Area Studies) and to consider concurrently the three aspects of performance: sewer collapse, flooding and environmental impact of discharges. The selection of rehabilitation options is illustrated diagramatically in Figure 2. It should be noted that sewer separation is not considered a viable option and that, because of their high cost, the traditional solutions of replacement and reinforcement are only retained as the final options to be considered when all else fails. This ranking may change in the near future when pipe bursting and other trenchless pipelaying techniques become established.

PERFORMANCE ASPECTS		STRUCTURAL INTEGRITY	SURFACE & PROPERTY FLOODING	POLLUTION OF RECEIVING WATERS
FAILURE DIAGNOSIS		CRITICAL SEWER SURVEY	WASSP-SIM ANALYSIS WITH DESIGN AND TIME SERIES STORMS	
UPGRADING OPTION MATRIX	ASPECT	DEFECTIVE SEWER LENGTHS	FLOOD PRONE AREAS	UNACCEPTABLE STORM SEWAGE OVERFLOWS
OPTION (in order of consideraton)				
FLOW ATTENUATION (M)		x	xxx	xx
REPAIR (L)		xxx	-	-
RENOVATION (M)		xxx	x	x
OVERFLOW RATIONALISATION (L)		-	xx	xxx
FLOW REDUCTION (M)		x	xx	xx
MAINTENANCE (L)		-	x	x
REINFORCEMENT (H)		-	xxx	xx
REPLACEMENT (H)		xxx	xxx	xxx

NOTES: (1) Engineering relevance of option indicated by crosses (xxx = high, x = low).
(2) Relative cost of options indicated by (H) = high, (M) = medium and (L) = low.

Figure 2 - The integrated approach to sewerage rehabilitation (Clegg et al 1989)

Drainage Area Studies are being systematically undertaken by the UK water utilities with two Authorities, North West Water and Severn-Trent Water, having made the greatest progress. By early 1988 each had completed studies for about one-sixth of their drainage areas and reported the results as shown in Table 6.

Table 6 - Comparison of Drainage Area Studies (Clegg et al 1989)

	SEVERN-TRENT WATER	NORTH WEST WATER
Number of study areas	200	91
Population served	8 million	6.9 million
Number of completed and fully reported studies	32	17
Identified required investment	£67 million	£327 million
Estimated overall need	£400 million	£1,320 million
Investigation costs	£2 million/annum	£5 million/annum

The two studies support the following general conclusions:

(1) Investment need varies enormously between study areas and cannot be assessed accurately without a detailed study and good records.

(2) Investment is rarely for a single reason.

(3) System problems can be split into structural, flooding and pollution aspects but solutions are essentially inter-related and any split here is arbitrary, subjective and likely to be misleading.

(4) The Drainage Area Studies identified significantly more problems than had been anticipated. This has the effect of depressing level of service estimates.

Requirement for total catchment planning

The intensive investigation activity related to sewerage networks is providing for the first time the opportunity to undertake comprehensive studies of the impact of drainage discharge on receiving waters. This allows discharge consents to be expressed in terms of permissible pollutant level related to "fitness for use" standards for the receiving water body and the levels of dilution and dispersion of the discharge plumes. The

VOL 12

8087

sewerage authority is then free to consider all of the options open to upgrade the performance of the network and so optimise the capital works involved, minimising the cost without putting the water quality objectives at risk.

The principal drawbacks are greater monitoring and investigative costs and the need for a comprehensive modelling capability within the receiving water networks. If the potential benefits are to be realised, a complementary set of procedures to those for sewerage Drainage Area Studies need to be developed. Such an approach is set out in Figure 3.

Four phases are involved. In the first phase, the region is divided up into catchments and the Uses defined for the individual river reaches and other water bodies. Appropriate standards are defined for these Uses and the current performance monitored against these standards to identify where adequate performance is not being achieved.

In the second phase, flow and water quality computer models are built for the urban drainage, river and marine systems. The urban drainage system will discharge pollutant loads into the river. These will be both continuous, from treatment works, and intermittent discharges of storm sewage. The river model is used to check on the impact of the urban drainage and agricultural discharges and to quantify the pollutant loads passing out to sea. The marine model can then be used to check on the impact for marine Uses (such as bathing and shellfisheries) of the river flows and direct sewage discharges from long sea outfalls, storm overflows and surface water outfalls.

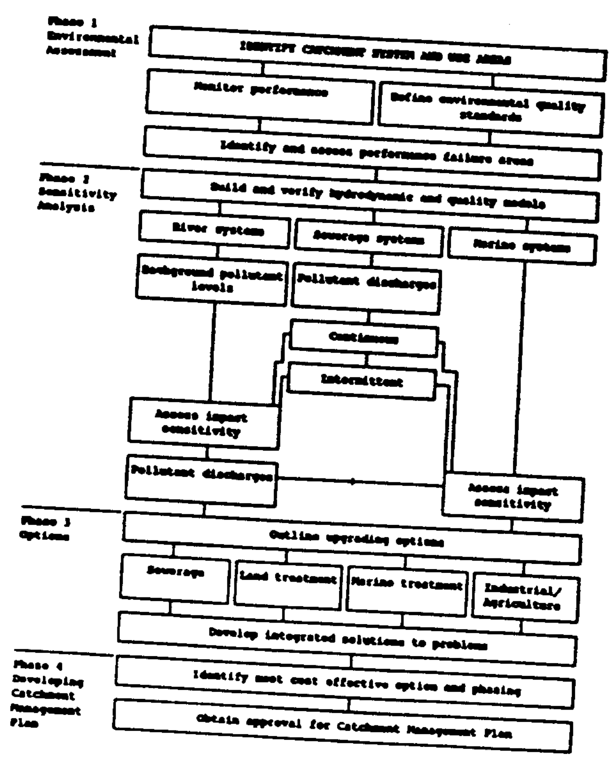
In the third phase, the various options that are open to solve the problems identified can be tested, again using the computer models. These include:

- o improving the sewerage network;
- o upgrading the treatment works;
- o building new long sea outfalls; or
- o requiring on-site pre-treatment by industrialists and farmers.

The important point to note is that we are looking for integrated solutions that will ensure the achievement of the required Environmental Quality Standards for the foreseeable future.

The final phase is producing the plan, including details of how the works will be phased.

Figure 3 - Catchment management plan flow diagram



Move towards integrated planning

Concurrent with the operational side of the Industry developing these new procedures the financial side was also questioning previous practice.

Traditionally the value of assets owned by the Authorities had been assessed either in terms of their historic cost or current replacement value. These asset values were then written off over their assumed effective "life". About 4 years ago, this practice began to be questioned for assets which are long lived and are parts of systems which themselves have virtually infinite life. Sewerage networks certainly qualify. It was argued that these "renewals assets" will be maintained indefinitely and their total replacement value is of little significance. The important cost is the present value of the anticipated maintenance works expected to be needed in the foreseeable future. To make such estimates and audit them it is necessary to undertake Drainage Area Studies as described above to generate what has become known as Asset Management Plans.

The idea of Asset Management Plans was just beginning to catch on when privatisation entered the scene. Information on the outstanding liabilities of an Authority is required to put into the Prospectus to inform potential shareholders. Subsequent to flotation the Government Regulator will also need the same information, regularly updated, in order to be satisfied that sufficient monies are being set aside for long term maintenance and that a national asset is not being allowed to deteriorate.

Institutional impediments

In the paper so far a picture has been painted of an industry which, from knowing virtually nothing about its assets and operating a policy of crisis maintenance, in a matter of 12 years, turned itself round to one committed to a very high level of planned maintenance and performance monitoring.

It might therefore be thought that the UK Water Industry is now able to apply optimally all of the new technology which is being reviewed at this conference. Unfortunately the true picture is very different and the impediments are almost totally institutional.

These institutional impediments can be considered as historical, informational or political, although in practice the boundaries can get a bit blurred.

VOL 12

8090

Historical impediments

Historically, planning responsibility has become very fragmented. To illustrate the problems it is instructive to take the viewpoint of the two bodies with a financial interest in having cost effective solutions to urban drainage problems - the developer and the sewerage authority.

The developer planning a major new housing estate has to get planning permission from the planning authority (the District Council) who, when considering how urban drainage will be handled, will take advice from other authorities likely to be affected. These will be the Highway Authority for road drainage, the Drainage Authority (National Rivers Authority [NRA]) for surface drainage. For both the sewerage authority (Water Services plc) will need to be involved if the new surface water sewers are to be adopted as part of the public network and will have direct involvement for any foul or sanitary sewers. The interests of these bodies may be in conflict.

The Highway Authority will wish to minimise maintenance costs and get surface flows below ground as quickly as possible to avoid hazards to traffic. Thus above ground flow attenuation or flow reduction through infiltration will not appeal. The NRA may wish to favour the opposite approach to reduce flood flows in rivers and streams and maximise groundwater recharge to maintain dry weather flows. The Sewerage Authority will wish to encourage above ground flow control measures as this reduces the storm loading on the existing sewerage system into which the new sewers may be coupled while leaving maintenance responsibility with others. It will however, be less happy to take on responsibility for flow control structures within sewers it is required to adopt. Thus with future financial responsibility split, sub-optimal solutions (from a national point of view) are very likely and the developer frequently gets frustrated.

The Sewerage Authority trying to find cost effective solutions to current system performance deficiencies can get equally frustrated. Here the problem stems from fragmented ownership. Public sewers have linked into them house drains which are owned by the householder and highway drains owned by the Highway Authority. From a hydraulic viewpoint these are a single, integrated system. Many upgrading options are available and some are listed in Table 7.

VOL 12

8091

Table 7 - Methods of hydraulic upgrading

FLOW ATTENUATION	FLOW REDUCTION	INCREASED SYSTEM CAPACITY
Detention tanks Controlled surcharge/flooding Surface detention Storage of road runoff Gully pot storage	Disconnection of roof areas Permeable pavements Infiltration control CSO rationalisation Separation	Replacement Reinforcement Renovation Polymer injection Maintenance operations

It is simple to demonstrate with network analysis models that the most effective methods are the above ground options of disconnection or attenuation of roof runoff, followed by surface detention. However, these are the ones that are institutionally currently impossible to apply.

In March 1986 a Government discussion document introduced the idea of changes to sewerage law which would have made house drains public sewers. Unfortunately it was considered unwise to make this radical change at the same time as privatising the service and the proposal was dropped.

A major study of the scope for control of urban runoff is in progress at the Construction Industry Research and Information Association (CIRIA). This is concentrating mainly on promoting runoff control associated with new development but hopefully it will also provide a strong case to put to Government to re-introduce the changes to the law proposed in 1986.

The fragmentation of responsibility discussed above is about to be made worse. Prior to privatisation the Water Authorities had a large measure of autonomy being controlled only by restrictions on borrowing and charging. They are not going to be privatised in their present form as it was considered unacceptable for a private company, in a monopoly situation, inheriting massive public assets and having such environmental and public health responsibilities, to regulate itself particularly when it would have responsibility for the regulation of others. Two new regulatory bodies have been set up with some responsibility transferred to an existing third.

The NRA will be responsible for setting discharge consents for sewage treatment works, storm overflows, surface water outfalls and sea outfalls. That is unless toxic, persistent (Red List) substances are present when Her Majesty's Inspectorate of Pollution (HMIP) get involved to specify the required treatment process. The logic for HMIP taking an interest is to enable pollution by dangerous substances to be controlled across the three elements of air, land and water. The third regulator is the Director General (DG) of the Office of Water Services who is responsible for ensuring that specified levels of service to the public are being achieved, that the long term assets are being adequately maintained and that any costs being passed through to the consumer for asset maintenance and achievement of environmental standards are fair after making allowance for efficiency improvements to be expected from a well run business. The danger in split responsibility is evident here as in the previous example of housing development. Will the best interests of the community be served when several Government departments have powers to restrict the options of a utility but are not accountable for the consequences?

Information impediments

When crisis maintenance was the only available management option solutions tended to be of high cost and uncertain benefit. This is no longer necessary with the wealth of information on system performance and very much improved appreciation of the true causes of system failure. However, the volume of information required to be collected and interpreted should not be underestimated. It is relatively easy to justify the cost of Drainage Area Studies and Catchment Management Plans when the evidence of flooding and pollution are self-evident. To maintain the models and monitoring systems on a long term basis so as to be able to have regular Plan updates is a very different and more taxing exercise. The challenge of the Information Technology (IT) age is one the Water Industry has started to face up to but history is not too encouraging when, after its first 150 years, the basic information about pipe location is still too frequently lacking.

It will be a tragedy for the Industry, the Government and the country, if the first real opportunity to undertake integrated catchment planning were to be missed and the approach discredited due to the difficulties of collecting, maintaining, updating and auditing basic data which in other process industries is taken for granted.

VOL 12

8093

Political impediments

"Green" issues are no longer the province of only the experts and small pressure groups. All political parties have seen the need to appear to be environmentally concerned and the search is on for "sustainable development". The danger with political enthusiasm is that the accompanying publicity builds up hopes that cannot be fulfilled in politically acceptable timescales. There is a need to be seen to be doing something positive. In the UK, with the advantage of large regional water utilities and a National Rivers Authority, it should be possible to progress steadily, as outlined earlier, towards Catchment Management Planning. Environmental Quality Objectives (EQOs) are set for the component parts of the receiving water system, based on the planned uses. "Fitness for use" standards (EQSs) can then be defined against which discharge consents can be tested by monitoring and modelling. A typical Use Area Chart is shown in Figure 4.

This approach gives the utility a free hand to optimise its engineering solutions while giving the regulatory authority the means of satisfying itself that the proposed solution will not inhibit the achievement of the EQOs.

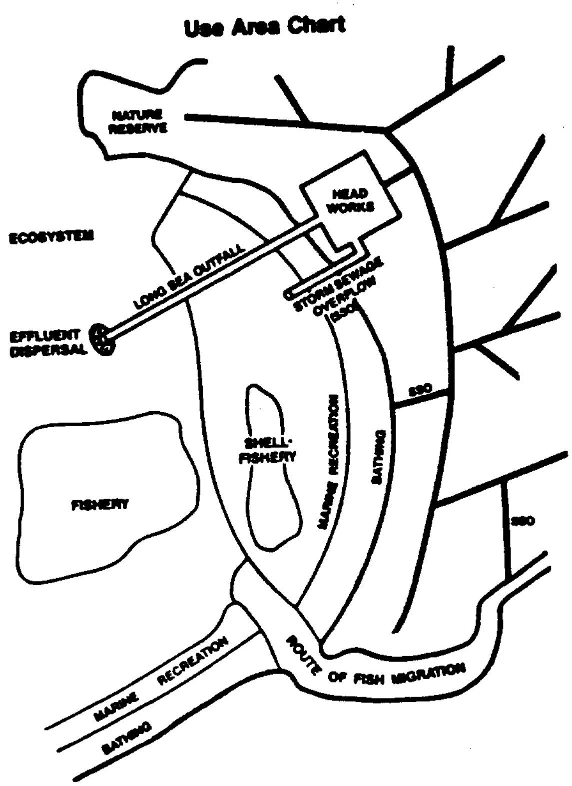
The alternative approach of the regulatory authority specifying the technology to be used is not only sub-optimal from a national viewpoint, as it must be applied conservatively, but it stifles initiative in the utility to look for ways of improving process performance which could have environmental as well as internal efficiency benefits.

An example giving concern is marine treatment. The UK is under pressure from some other European states, who have local eutrophication problems, to install secondary treatment before discharging sewage to sea from long sea outfalls. Apart from the cost - another £2,400 million and no significant environmental benefit - this would result, if implemented, in large additional quantities of sludge, the disposal of which has environmental hazards. Sludge disposal is already a major problem. It is possible to show that the best practicable environmental option for sludge disposal in many cases is disposal at sea. But there is a lot of pressure from other North Sea states to reduce this practice (in the North Sea at least) and the UK has bowed to this pressure and agreed to make 10% cuts for each of the next 5 years.

VOL 12

8094

Figure 4 - Use area chart (Dempsey and Lack 1988)



A political argument sometimes put forward against the EQO/EQS approach is that all dischargers are not equally disadvantaged. It can therefore influence demographic shifts. It is the author's view that such a claim would not bear up under detailed investigation.

Conclusions and general observations

(1) Pressures to improve efficiency and quantify, in an auditable way, future capital funding needs have encouraged and allowed the UK Water Industry to set up the procedures and information systems to be able to undertake comprehensive catchment management planning.

(2) The performance of urban drainage systems still leaves much to be desired, largely due to historic restrictions on capital spending. All current Environmental Quality Objectives are achievable. The timescale by following the EQO/EQS approach will be shorter than by the regulatory authorities specifying Best Available Technology due to the logistics of completing the massive capital programme the latter would require.

(3) The optimal use of evolving stormwater control technology is seriously inhibited by the fragmentation of planning responsibility for new urban development and the split in drain/sewer ownership for the upgrading of existing systems. Better guidance to developers and cooperation between local authority departments will assist the cost effective drainage of new development but a change in sewerage law, as proposed in 1986, will be required before the most effective control technologies can be used for upgrading.

STORMWATER REGULATIONS AND STANDARDS, INTRODUCTION

by Poul Harremoës[1]

Introduction

The pollution derived from rain runoff from urban areas is receiving increasing attention from the public, the press, and politically. That applies in particular to Scandinavia due to increasing demands for better sewage purification. In Denmark, all treatment for towns bigger than 5000 inhabitants must include nutrient removal before the end of 1992. That requirement is based on observations since 1981 of algae and oxygen problems in the coastal waters of Scandinavia. The attention is focused not only on the treatment of the regular daily flow, but also on the diffuse sources of pollution, of which rain runoff is one of the most significant.

The relative contribution of nutrients from rain runoff is not very significant on an integrated scale (Harremoës, 1988c), but may be important in relation to the local recipient. However, the attention has brought to the surface the other problems of urban runoff: bacterial pollution, organic matter and oxygen depletion plus toxicity from ammonia, hydrogen sulfide, metals and specific organic compounds.

The difficulty of the problem is the irregularity of the discharge. It is not possible to apply the well known rules and standards for the discharge from treatment plants. Until today the rules have been crude in relation to the scale and the extent of the problem and in relation to the cost of the engineering structures required for the

[1]Professor of Environmental Engineering, Technical University of Denmark, Building 115, 2800 Lyngby, Denmark. Director of PH-Consult ApS, Kulsviertoften 29, 2800 Lyngby, Denmark.

abatement of the problems. There is a demand for an analysis of principles and for recommendations with respect to the regulation of design and operation of urban runoff.

Upon request from the Danish Environmental Protection Agency an analysis of principles and possibilities was undertaken by PH-Consult ApS. This introduction is essentially an extract of the the report to DEPA (PH-Consult ApS, 1989).

Current practice

Around the turn of the century the sewer system of the city of Copenhagen was changed. Big interceptors were constructed along the harbour. It is interesting to read the reasoning for the rules applied. All reasoning was related to the cost of construction. It was a very costly enterprise for the city. The design criterion was a required dilution of 1:2, corresponding to a frequency of approximately 40 overflows pr. year. That led to reasonable pipe diameters and pump stations. No doubt, it was a significant improvement.

Until recently, the rule was the same, except that the dilution was gradually increased to 1:5, based on daily peak flow.

In recent years we have seen changes: like a maximum overflow frequency of 10 times per year, or a required 95% decrease compared to overflow volume without detention basins. Only seldom have the rules been motivated with a rationale, based on a desired objective for the receiving water.

It is noteworthy that rules in other countries are but variations on the same theme.

Sweden decided to change all combined systems to separate systems. This happened for all but the big cities, where the cost was overwhelming. When the investigations during the 70'es and 80'es revealed the extent of pollution discharged from separate systems, the requirement for change to separate system was abolished.

In Germany they developed rules for the critical flow at which the overflow goes into operation (Abwassertechnische Vereinigung e. V., 1977). They are based on an empirical relationship with the ratio between the flow in the receiving river and the flow in the sewer. The critical flow essentially varies between 7 and 15 l/(s*ha). Detention basins are derived from simple relationships

VOL 12

8099

R0041405

based on the critical flow and the permissible flow to the treatment plant. The rules are under revision (Göttle, 1988).

The rule in England was also based on dilution, essentially 1:6 based on average dry weather flow (Cliffords et. al., 1986). The whole approach is now under revision, but the ultimate approach is still to be seen.

In Switzerland the rules are based on a combination of required dilution and a specific flow, 15 l/(s*ha), above which the overflow can be untreated. The rules are under revision (Krejci, 1987; Gujer and Krejci, 1987).

The Netherlands have very different rules. These are based on the fact that the interceptors are essentially horizontal and act as basins and sedimentation tanks (TNO, 1985 and 1986).

The most comprehensive investigations of the problems associated with urban runoff have been made in USA (Lager et. al. 1974; Field and Turkeltaub, 1981; Field and Weisman, 1982; U.S. Environmental Protection Agency, 1983). The first models were developed in the USA (SWMM) (U.S. Environmental Protection Agency, 1971). However, the ultimate policy is still under revision (U.S. Environmental Protection Agency, 1988).

It is clear from an analysis of the different national rules that they are essentially based on the same tradition and that they are all under revision. It is a good time for international communication on the issue; in order to learn from each other, while the rules are still being shaped and before they harden into fixed approaches, not to be altered for quite some time due to inertia in the legislative and administrative systems.

Fundamental principles

The tradition has been to formulate the rules essentially based on cost of construction. The new wave of concern is based on the demand for pollution abatement. The cost will be significant, but society appears to be willing to pay the cost required to achieve the objective.

Which objective? There is only one rational approach to a solution: That is to reason backwards from a required water quality in the environment to a permissible discharge.

This concept has been the policy in Denmark for two decades. It gave rise to comprehensive receiving water investigations and a lot of planning procedures. There was political division with respect to the merits of the system. Some considered the action to be too slow. The algae and oxygen problems of the Danish waters demanded limits on all discharges with respect to nutrients from treatment plants: 8 mg/l total N and 1.5 mg/l total P. The scheme is being implemented rapidly.

The proposed policy with respect to pollution from runoff is:

(a) The rules should be based on water quality criteria for the local and downstream receiving waters.

(b) The rules should be operationally sound, without giving rise to too many local investigations and possible delaying actions.

It is essential to distinguish between basic features of the pollutants. The most basic categorization is the time scale. It is essential to distinguish between acute and accumalative pollution.

Acute pollution is characterized by a here and now effect. This applies to oxygen depletion and toxicity. These problems have to be judged on the basis of extreme statistics (Harremoës, 1986, 1988a and 1988c).

Accumulative pollution is characterized by the accumulation in the receiving water. The individual discharge is of little concern, apart from its contribution to the accumulation in the water or the sediments. Typically it is important for nutrients, metals and persistent organics.

The real problem is to identify the most basic phenomena and the most essential parameters, that are manageable as a design basis -and forget about all the inferior phenomena. A compromise has to be reached between the oversimplification of the past and the potentially confusing comprehensiveness of computer models. It is a traditional skill of the engineer to make such choices, but it is not an easy task.

The proposal is to standardize the water quality criteria and to standardize the approaches for the calculations to be used for the determination of the permissible discharge to the receiving water. The water quality criteria have to be formulated on a statistical basis. The calculation methods require information about the receiving water, e.g. flow, reaeration, residence time, etc. Where these are not

VOL 12

8/0/1

R0041407

available default values are recommended on the basis of simpler input (slope, depth, etc.).

Approaches to regulation

The rules can be formulated with respect to design at different locations in the system, which is best characterized by following the water flow:

- rain
- surfaces
- gully pot
- wastewater flow
- pipes
- overflows
- basins
- local purification
- sewage treatment
- receiving water

As explained above the rules should always be motivated on the basis of reasoning from water quality objectives to operational rules. In practice such rules cannot be formulated so ideally, but they must nevertheless be precise to be enforcible. One example might be rules forbidding the use of lead in gasoline in order to decrease the lead pollution of surface water due to rain runoff. Another example is to require scumboards as an enforcible rule. It has turned out that it is very diffucult to set standards for floatables and to reason backwards to purification at the individual overflow structure.

Pollution abatement can be achieved through differant approaches:

- affecting the behavior of the public by education
- improving the professional practice in planning, design, construction and maintenance.
- provide guidelines for the profession
- setting norms for the profession
- setting standards for the profession
- making laws through parliament

There has been a tendency in Denmark to pass too many laws. This development has been due to political pressure to achieve abatement fast. This is under revision, because it is being realised that environmental protection is becoming very bureaucratic. "Reading and interpreting laws has become more important than understanding the problem."

VOL 12

8102

Due to the staggering cost of water pollution abatement it is essential to reach solutions which achieve the desired goals under the local circumstances. Such flexible solutions are not reached through the simplicity of the traditional rules. Where possible, the first three items of the list above should be the approach (behavior, professional practice, guidelines). That is possible, because of the very improved and widespread knowledge and skill of the professional today - as compared to two decades ago.

Pollutant runoff

Pollutants are carried with the rain and with the runoff. Numerous investigations have been made of the magnitude, interrelationships, time variation and stochastic properties of the pollutant transport - too numerous to be fully described and evaluated here.

In the literature there are essentially three approaches to the interpretation of the data from such investigations:

- Determination of a characteristic concentration, and its statistical variation.
- Determination of empirical relations between characteristic properties and the concentration in the runoff, and the statistical variation.
- Deterministic description of the runoff processes, involving the important physical, chemical and biological phenomena.

the development of deterministic descriptions of the hydraulic phenomena, e.g. in available computer programmes like SWMM, WASP and MOUSE, has been very successful. They can accurately simulate the runoff processes. Flow and stage can be adequately simulated compared to reality, if the models are adequately calibrated for the systems under investigation.

Typical figures for the uncertainty of simulation are, (Paulsen, 1987):

Runoff volume in mm:

For the calibrated volume runoff data the standard deviation is 4-7% for the mean flow; 20-40% for the individual event. For the non-calibrated events the same figures are: 3-10% and 20-40%.

Pollutant runoff in kg/ha:

> For the calibrated mass transport of pollutant the standard deviation is 10-30% for the mean mass; 50-140% for the individual event. For the non-calibrated events the same figures are: 20-60% and 50-180%.

These data are just examples of the general trend in the literature. It is postulated that it has not been possible to simulate the pollutant runoff without a very significant residual statistical variation. If deterministic description of pollutant transport is to be applied in practice, the significant statistical variation has to be accounted for. The stochastic variation is so big that there is reason to question the need to develop elaborate deterministic simulation tools.

Data from several investigations have been analyzed in order to determine empirical relations between parameters like rain intensity, rain depth, duration, mean and max. flow, etc. Essentially, they have been unsuccessful. An investigation of all available, quality controlled data from Scandinavia did not produce relationships which could stand the test of statistical significance.

One exception is the results from The Netherlands (Uunk, 1985; Onderdelinden and Timmer, 1986). Due to excessive sedimentation in virtually horizontal interceptors the concentration becomes dependent on the flow.

Where such investigations have not revealed empirical relationships the best approach is to use a simple characteristic concentration: the event mean concentration, and to account for its statistical variation (U.S. Environmental Protection Agency, 1983; Harremoës, 1988a).

$$P = Q_w C_w + Q_r(C_r + C_e) = (Q_w + Q_r)C_m$$

P is the total transport
Q_w is the wastewater flow
Q_r is the runoff
C_w is the concentration in the wastewater
C_r is the concentration in the surface runoff
C_e is the concentration from erosion in the pipe
C_m is the mean concentration

Indications are that the statistical variation is log normally distributed, at least good enough for practical application. The standard deviation is in the order of 0.6-0.9 on the natural logarithm, corresponding to a factor of uncertainty of 1.8-2.5.

Water Quality Impact

Overflow from combined systems and outflow from separate systems occur less than 5% of the time and the effect is a statistical phenomenon. The water quality criteria known from continuous loads on receiving waters cannot be applied. The phenomena of transport and conversion of the pollutants in the receiving water are more complicated. There is still a significant lack of knowledge.

The state of the art will be reviewed in brief:

Acute pollution must be evaluated on the basis of the frequency of the rare events with massive loading of the recipient. The accumulative pollution has to be evaluated on the basis of the total discharge over a period. The individual event is important only by its contribution to accumulation, not as an individual event.

Acute pollution:

Bacterial pollution

The bacterial content of outflow from separate sewers is low relative to the well established criteria and is seldom an issue.

The bacterial content in raw sewage is in the order of 10^7 E. Coli/100 ml. That is 10^4 bigger than the traditional criteria, demanding less than 10^3 E. Coli/100 ml., 5% of the time. The effect is reduced by dilution and bacterial disappearance (Harremoës, 1970). One of the difficulties is that overflow occurs less than 5% of the time.

The solution proposed is to expand the established criteria as follows, assuming a log normal distribution:

Probability %	E.Coli conc./ 100 ml.
20	10^2
5	10^3
0.7	10^4

These probabilities are difficult to detect in practice, because they require many samples in the season. However, the criteria for rare events can be used as design criteria.

It is not possible to perform a receiving water investigation in detail for each overflow structure. The idea is to get a general knowledge of the properties of the receiving water and to supplement with default values based on general knowledge as required. Flow data for rivers are mostly available. Currents along coasts can be estimated. However, the rate of bacterial disappearance is like a research project to determine (Harremoës, 1970). In practice, default values have to be made available.

By running historical rain series through a model of the urban runoff system, e.g. the SAMBA model within the MOUSE-package, the statistics for the overflow can be produced. It is the mass of bacteria discharged in each event that counts. The loading series can then be applied to a receiving water model of the transport, dilution and disappearance of the bacteria. At a given point at a beach the statistical distribution of the bacterial contamination can be calculated. The result is evaluated for compliance. Abatement may be achieved by decreasing the overflow frequency by introduction of storage in the runoff system or by relocating the discharge point for the overflow.

Oxygen depletion

Oxygen depletion is seldom a problem for outflows from separate sewer systems due to low BOD in the runoff.

Oxygen depletion from combined sewer overflows can involve three phenomena:

- Immediate depletion due to BOD-degradation in the water phase. The traditional oxygen sag from discharge of dissolved BOD.
- Delayed depletion due to BOD-extraction from the water phase and accumulation in the sediments, from where oxygen demand is exerted on the water phase. This is significant because the extractable part of BOD dominates domestic sewage and because the extraction is very rapid, (Harremoës, 1982).
- Scour of accumulated BOD in the sediments due to increased flow. The BOD may have accumulated in the sediments due to to extraction from a daily discharge if inadequately purified.

These phenomena are well established and can be adequately modelled.

The proposed approach is to run a historical rain series through the runoff system to produce a series of BOD-discharges. An example is given in Figure 1. It is the total mass of BOD per event that counts. That series is then loaded on to a model for oxygen depletion in a river, from which is produced a series of oxygen concentrations to be compared with statistical criteria for oxygen in rivers, (Harremoës, Hvitved-Jacobsen and Johansen, 1986). An example is given in Figure 2.

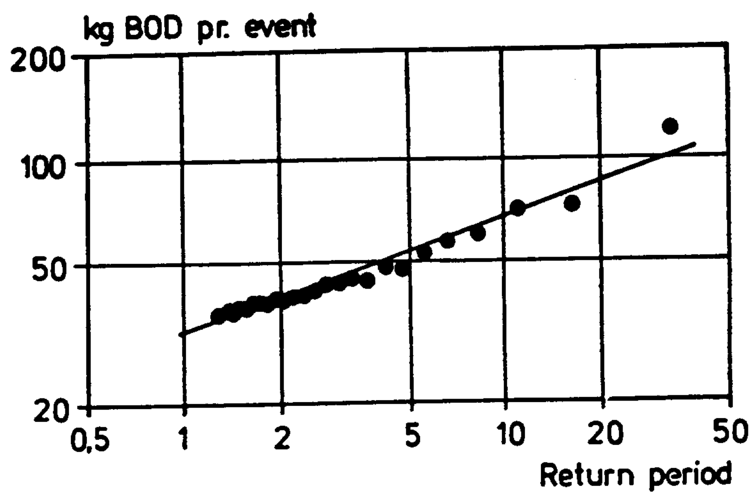

Figure 1: Extreme statistics for the discharge of total BOD from individual overflow events, derived from calculation of overflow from a long historical rain series. Calculation by the SAMBA-model of the MOUSE-program package. The statistical variation between individual overflow events are of significance (Harremoës, 1988a).

VOL 12

8107

R0041413

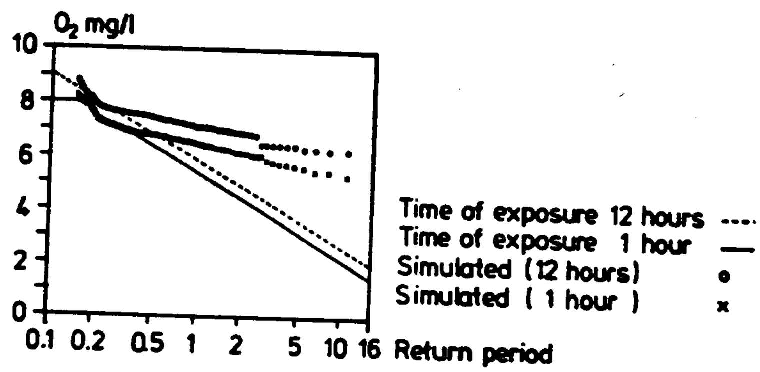

Figure 2: Extreme statistics for the oxygen concentration in a river exposed to combined sewer overflows with extreme loading statistics as shown in Figure 1. The distribution is based on calculation with a simple river model based on immediate and delayed oxygen depletion. The statistics is compared with the distribution of required oxygen in rivers in Denmark.

Overflows are often discharged into small tributaries upstream in the system. These small rivers are sensitive to these shock loads. It is the experience in Denmark, that such overflows will not comply with the criteria unless very costly storage tanks are installed in the system. This is often considered extravagant by practitioners, because the rule is much more stringent compared to the traditional rules. However, there are only three logical reactions to the situation:

- Build the required storage tanks, which may be expensive.
- Relocate the overflow structure, which may be expensive too.
- Declassify the river to a lower standard, which of course is cheap.

Ideally, that choice of pollution abatement versus cost should not be made by the professionals, but by the politicians.

In order to save the investment the river may even be classified as part of the sewer system. The trend in Denmark goes in the opposite direction.

Specific pollutants

There has been concern for the effect of the discharge of potentially toxic substances with the runoff. This is a very complicted issue, but research tends to show that the potential pollutants are toxic only in soluble form. The total concentrations in the runoff tend to be lower than the criteria for acute toxicity. Furthermore the distribution between the soluble form and the adsorbed or complexed form is such that the toxic soluble concentration is but a fraction of the total concentration.

Acute toxicity due to metals and refractory organics is not considered to be a serious problem in connection with rain runoff.

Accumulative pollution:

Nutrients

Nutrients cause eutrophication. It is the accumuleted load on the receiving water that counts, e.g. over the year or the season. It is meaningless to look at the discharge of nutrients from runoff alone. The contribution from urban runoff is just one of many contributions. Frequently, it is a small contribution (Harremoës, 1988c). However, the contribution can be significant when the daily flow of wastewater has been intercepted.

The best approach to the calculation of the load on the lake from combined sewer overflows is to run a historical rain series through a calibrated model of the sewer system. The accumulated discharge can be calculated for each year covered by the series. An example is given in Figure 3. The statistical uncertainty of the concentration of the individual event is damped by the accumulation. It is an interesting fact that the discharge varies significantly from one year to the other due to meteorological variations.

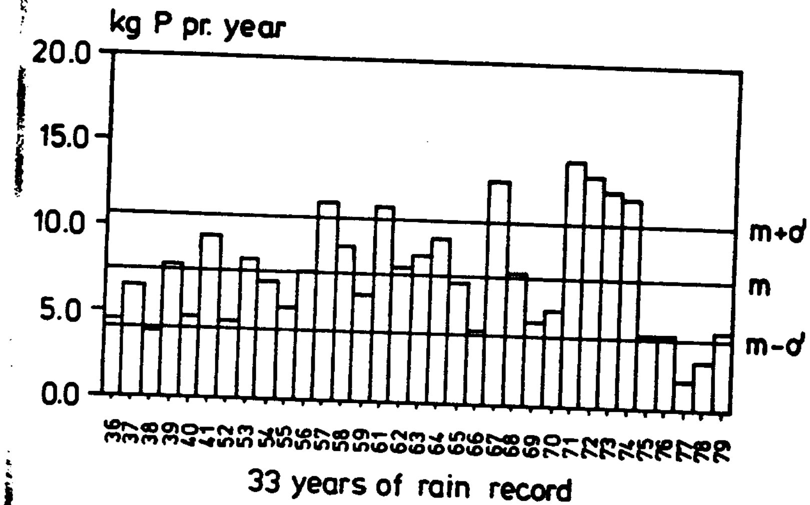

Figure 3: Annual accumulated phosphorus load from a combined sewer overflow to a lake. Calculation by the SAMBA-model of the MOUSE-program package. Notice the significant variation from year to year. The statistical variation between the individual overflow events is without significance.

Priority pollutants

It appears, from U. S. literature in particular, (U.S. Environmental Protection Agency, 1983), that persistent organics in urban runoff do not pose a problem under normal circumstances.

The total annual discharge of metals per unit of paved urban area is not very different for the separate versus the combined sewer system. To many practitioners that fact has come as a surprise.

Indications are that the metals discharged with the urban runoff can accumulate in the sediments downstream from the discharge point to concentrations which may give rise to toxic reactions to the biota living in the sediment or at the surface (Ellis, 1988; Benoist et. al., 1989; Visser and Lijklema, 1989).

This is a very difficult issue. Not only does the scientific evidence for detrimental effects leave much to be desired, but the implications are noteworthy. The separate sewer system was introduced on the assumption, that the discharge from the system was "clean". The separate sewer system is costly by comparison. The cost becomes excessive if the runoff from separate systems has to be purified before discharge to the ocean, estuaries, lakes and rivers.

Treatment plant performance

The traditional focus on pollution during rain runoff is at the overflows. The tradition is to design treatment plants for a fixed maximum permissible flow through the plant. Discharges greater than that are simply diverted to overflows. That is still current practice.

It is the final clarifiers of the treatments plants which are the determining factors for the pollution from the treatment plant during rain. The diffuculty is that the performance of final clarifiers vary from plant to plant, from time to time and during the event. This is a dynamic phenomenon.

It is an essential feature that the clarifier can tolerate high flow for a short time, but only low flows for a long time. The increased storage in the catchment in order to protect the upstream recipients from the pollution from overflows will increase the period of high flow after rain at the treatment plant. The traditional design can no longer be accepted.

The whole systems must be looked at as one entity. The design has to be based on systems analysis in order to reach reasonably optimal design and operation. We are beyond the time when these mattars could be dealt with by simple rules of thumb.

Conclusions

The traditional rules for the regulation of outflow from separate systems and the regulation of overflow from

VOL 12

8/1/1

combined systems no longer serve the needs of the society in the balance between protection of the environment and the cost of achieving that goal. In the past that balance was tilted in favour of the economical aspects.

The demand for improved water quality will be so costly, that traditional rules are too simple. There is need for more differentiated rules, that will justify the high cost where it is needed for water quality abatement, and allow cheaper solutions, where it is not required for achieving water quality standards.

There are available today adequate models, with which to simulate the relation between discharge and resulting water quality for the most essential problems: Bacterial pollution, oxygen depletion and effect of loads of nutrients. There is an inadequate knowledge of the potential for water quality deterioration due to discharge and accumulation of metals. It appears that priority pollutants do not give rise to an acute toxicity problem under normal conditions.

New rules can be formulated on the basis of a combination of limitation of pollution sources (e.g. lead), practical requirement with respect to structure (e.g. scumboards) and guidelines for practical application of models for calculation of permissible discharge quantity per event vs. frequency for acute pollution and quantity per year for accumulative pollutants.

The whole system - the sewer system, the treatment plant and the receiving waters - must be looked upon as a whole. It will not be possible to establish strict rules for design of the individual component in this system in such a way that the result will be even close to an optimal solution for the system under design or operation.

The increased knowledge about the runoff process, the processes in the treatment plant and the processes and effects in receiving waters makes it possible to leave more to be determined through the distributed, professional skills, without simple and strict rules. This is the only way in which local conditions can adequately be taken into account.

It is recommended to establish accepted means for calculation of the permissible discharge based on models for the runoff process, for the treatment plant and for the local properties in the receiving water. The models should be simple, accounting only for the most essential phenomena, not including every conceivable process in the system.

Default values should be available for the many cases where the problem does not justify detailed local investigations. This design procedure should be supplemented with other restrictions of a more practical nature, like scumboards and bar screens.

STORMWATER REGULATIONS FROM LOCAL GOVERNMENTS' VIEW

by L. Scott Tucker[1], ASCE Member

ABSTRACT

Regulations are being prepared by the United States Environmental Protection Agency for permit application requirements for municipal separate stormwater discharges. Local governments in the United States will be required to develop stormwater quality management programs in order to obtain stormwater discharge permits. This paper examines the background, status, and enforcement provisions of the stormwater permit program from the local government perspective. Many metropolitan areas in the United States consist of several independent local governments and the advantages of metropolitan-wide stormwater management approaches are discussed.

INTRODUCTION

Rains finally began to fall on the city. A drought had been in progress and the gentle cooling rains were a welcome relief to the urban residents of Gotham. The rainfall slowly intensified and soon water was making its way from rooftops, yards, parks, and parking lots to the streets and from there to storm sewer inlets in the streets and from there to somewhere else.

The rains also alerted the many government agents who had been standing by the some 896 storm sewer outlets in Gotham for several months. Finally some action. The agents were on the track of one of the biggest busts of this type ever. Gotham had failed to obtain permits for their storm sewer discharges and the agents had suspected that it would eventually rain and illegal discharges would occur. Time was limited for the elected office holders and public works officials of Gotham; they had neglected this problem too long.

[1] Executive Director, Urban Drainage and Flood Control District, 2480 West 26th Avenue, Suite 156B, Denver, Colorado 80211

This scenario may be a little tongue-in-cheek, but one aspect is real - soon permits will be required of local governments in order for them to continue the discharge of stormwaters from their municipal storm sewer systems. The issue of how to regulate and control the quality of urban storm sewer discharges has been brewing in the United States since 1972 when the Federal Water Pollution Control Act (FWPCA) was passed. Regulations have been proposed, promulgated, rescinded, and modified; law suits have been filed by environmental groups to force adoption of urban stormwater regulations; and Congress has deliberated and amended the environmental laws. It is safe to say, however, that municipal storm sewers in the United States will soon be regulated. It is no longer a matter of if, but a matter of when. It is also clear that local government, cities and counties, will be required to bear the burden of the costs associated with the regulatory program.

The "problem" is how to control and reduce the discharge of pollutants contained in urban stormwater. However, data gathered to date indicates that the impacts of stormwater discharges on receiving waters are not consistent from place to place, and in many locations stormwater quality has only been subjectively defined as a problem. Never-the-less, local governments in the United States are beginning to realize that they are going to have to develop programs to reduce pollution in urban stormwater. A few local governments in the United States are aware of the regulation train coming down the tracks, and are beginning to think in terms of how they will respond. Many local governments, however, are unaware or choose to ignore the fact that soon they will need to obtain permits for their storm sewers.

BACKGROUND

The paper by Kevin Weiss gives a good summary of the history and status of the regulation of municipal separate stormwater discharges in the United States. That history will not be repeated, but salient points need to be highlighted to put the issues in perspective from the point of view of a local government.

Congress in 1987 in passing the Clean Water Act (CWA) amended the FWPCA to provide further guidance on the control of urban stormwater. Congress made it clear in the 1987 CWA that permits for discharges from municipal storm sewers will be required. Permits will be required initially for municipal separate storm sewer systems serving populations over 100,000. Permits for smaller systems are to follow at a later date. The scenario is basically playing out as follows. The United States Environmental Protection Agency (USEPA) is in the

VOL 12

8/17

process of writing regulations that set forth minimum application requirements for permits for municipal storm sewer discharges. Final regulations are expected to be promulgated by USEPA in 1990. In about 40 of the 52 American states, authority to administer the permitting program has been delegated to the states through the National Pollutant Discharge Elimination System (NPDES) Program. In the few states without such authority, USEPA will be the regulatory agency. Both the states and USEPA have been issuing NPDES permits for point pollution sources such as publicly owned sewage treatment plant effluent and industrial waste discharges for many years. Both USEPA and the states have virtually no experience, however, in the issuance of permits for municipal stormwater discharges.

The USEPA has published proposed regulations and the period for public comment was open from December 8, 1988 to March 7, 1989. USEPA received comments from over 400 parties and comments totaled over 3,000 pages. This is a high level of response and it indicates the concern over the impact of the proposed regulation. The hierarchy of authority is flowing from the federal level down. USEPA and the states will essentially be the regulators and cities and counties will be the regulatees. The cost of implementing controls will be borne at the local level as there is no indication and little likelihood of federal or state financial support. Local governments will be required to submit applications to the state or USEPA for a NPDES permit for their municipal storm sewer system. The regulations being promulgated by USEPA will establish minimum requirements for the application for permits as well as some requirements for compliance. Permits will be issued within a year after applications are submitted, and the permits will set forth in detail what local governments need to do to meet compliance requirements.

Congress in the 1987 CWA specifically identified requirements for municipal separate storm sewer discharge permits thereby establishing the fact that they are to be addressed differently than permits for other point sources of pollution. The 1987 CWA specifically states that permits for discharges from municipal storm sewers may be issued on a system- or jurisdiction-wide basis. Prior to this clarification the approach being taken was to require a separate permit for each storm sewer discharge point. This would have meant literally the preparation of millions of individual permits for all the urban stormwater outfalls in the United States. This was an absurd proposition and the cost of submitting applications alone was estimated to be $8 billion. This was an important change by Congress.

Congress in the 1987 CWA also defined what municipalities were to be required to do to control storm sewer discharges. The 1987 CWA states that permits for discharges from municipal storm sewers "shall require controls to reduce the discharge of pollutants to the maximum extent practicable, including management practices, control techniques and system, design and engineering methods, and such other provisions as the Administrator or the State determines appropriate for the control of such pollutants." The operative words are "to the maximum extent practicable" (MEP). While there does not exist at this time a precise definition of MEP, it is important to note that it must be different from the operative term "best available demonstrated control technology" which applies to other point sources. The implication of the term MEP is that controls need not be end-of-pipe methods. Congress recognized the impracticality of treating all stormwater discharges, and established the requirement of doing the best job that is reasonable, or in their terms practicable. It would not be practicable, for example, to construct treatment facilities for all storm sewer outfalls even though such treatment may have been demonstrated to be technically feasible. It would simply be unaffordable. The 1987 CWA, on the other hand, specified that permits for stormwater discharges associated with industrial activity must meet all existing applicable requirements including technology and water quality based standards. The new act, however, made significant changes to the permit standards for discharges from municipal separate storm sewers as noted above.

In some areas of the United States it is believed that non-stormwater connections to storm sewers contribute significant pollution. Such non-stormwater connections are termed illicit connections. Congress in the 1987 CWA included the provision that permits for discharges from municipal storm sewers shall include a requirement to effectively prohibit non-stormwater discharges or illicit connections into the storm sewers. There seems to be general support from local governments that illicit connections should be eliminated, and in fact some local governments have been actively pursuing the elimination of illicit connections for sometime.

WHERE ARE WE

The regulation and control of municipal separate storm sewers is in its infancy in the United States. Congress has set forth a basic direction and USEPA now has the opportunity to develop a program that is reasonable and implementable by local governments. USEPA is being pressured and even threatened by the environmental community to show no quarter in their

VOL 12

8/1/9

regulatory requirements. Local governments on the other hand are pleading for reasonable and flexible requirements that can be implemented within an affordable cost framework. The regulations that will be promulgated by USEPA will become the minimum requirements for state administered programs and the requirement for USEPA regulated states. The regulations that have been proposed by USEPA include both good and bad features from a local government perspective.

USEPA has taken the common sense approach that end-of-pipe treatment in most cases is not appropriate for the urban storm sewer problem. Municipal storm sewer permits will not be like industrial discharge permits. One USEPA official explained it this way:

> "These are not permits in the normal sense we expect them to be. These are actual programs. These are permits that go far beyond the normal permits we would issue for an industry because they in effect are programs for stormwater management that we would be writing into these permits" (1988).

USEPA stated in the preamble to the proposed regulations, that the basic approach being recommended is a shift from an end-of-pipe approach towards comprehensive stormwater quality management programs to reduce the discharge of pollutants from municipal separate storm sewer systems. In rationalizing this approach USEPA noted that discharges from municipal storm sewers are highly intermittent, and are usually characterized by very high flow rates occurring over relative short time intervals. This results in a high number of storm sewer outfalls within a given municipality. Traditional end-of-pipe controls are limited by material management problems that arise with high volume, intermittent flows that typically occur.

USEPA also noted in the preamble that the nature and extent of pollutants in discharges from municipal systems depend on the activities occurring on the land which contribute runoff to the system. Municipal storm sewers tend to discharge runoff drained from lands used for a wide variety of activities. Given the material management problems associated with end-of-pipe controls, management programs directed at pollutant sources are often more practicable than relying solely on end-of-pipe controls. Another factor recognized by USEPA is that the water quality impacts from storm sewer discharges depend on a wide range of factors including: the magnitude and duration of rainfall events, the time period between events, soil conditions, the percentage of land that is impervious to rainfall, land use activities, the presence of non-stormwater connections, and the ratio of

VOL 12

8120

stormwater discharge to receiving water flow. USEPA stated that in enacting the 1987 CWA Congress recognized that permit requirements for municipal storm sewers should be developed in a flexible manner to allow site specific conditions to reflect the wide range of impacts that can be associated with these discharges.

Consistent with the intent of Congress, USEPA has stated their goal to develop permit application requirements that are sufficiently flexible to allow the development of site specific permit conditions. This approach is important to local governments in that management programs can be developed that recognize the particular characteristics of each local government and region. USEPA's thrust in their proposed regulations is to force the development of stormwater quality management plans and programs in the urban areas of the United States. The management plans can be tailored according to the conditions of the local situations.

While the basic regulatory approach as discussed above is sound and is consistent with Congressional intent, some of the requirements of USEPA's proposed permit application will be difficult if not impossible to accomplish in the proposed time period of two years. For example, local governments will have about nine months to install a stormwater quality monitoring system, collect the necessary data, evaluate the data, and use it to estimate pollutant loads from the entire municipal stormwater system. Also four management plans will have to be prepared and an assessment of proposed controls made in addition to many other requirements.

Also, some of the proposed application requirements are too specific for nationwide application. This seems inconsistent with USEPA's basic premise that flexibility is needed to tailor permits to local conditions. For example, USEPA proposes to include in the application sampling from representative outfalls in a very specific manner. Samples shall be collected of stormwater discharges from three representative storm events that occur at least one month apart. In some locations in the United States particularly in the arid or semi-arid west rainfall is unpredictable and seasonable and it may not be possible to obtain data from three representative storm events at least one month apart. Quanitative data is required for a specified list of pollutants totalling 126. The cost of this "shot gun" approach is to be borne entirely by local governments. Earlier federal sponsored data collection programs in the United States, such as the Nationwide Urban Runoff Program (NURP) completed in 1983, indicated that most of the 126 parameters being required are not present in the samples. From a local government's perspective, namely the entity that has to

VOL 12

8/2/1

pay for it, it would make better sense if knowledge of local conditions were used in the design of monitoring systems.

Public opinion in the United States at this point in time is supportive of programs to reduce pollution. Local governments are beginning to realize that after many years of confusing regulatory false starts that stormwater quality will have to be managed. The main issue of local governments in the United States now should be to work with USEPA and the states in establishing reasonable regulations.

ENFORCEMENT

The incentive for local governments to obtain a permit for their stormwater discharges and to meet permit requirements is civil action that can be brought against them for violations of provisions of the FWPCA. Civil action may be brought by USEPA or by any citizen. Once the municipal separate stormwater permit regulations are promulgated by USEPA, the clock will start ticking. Municipalities will have two years in the current USEPA proposal, to submit applications for permits. If applications are not submitted by the deadlines, the municipality will be open to civil action for violation of the FWPCA. Eventually, municipalities will be given a permit for their separate stormwater discharges. If they violate, do not meet, or in some way do not comply with the provisions of the permit the municipalities will be similarly open to civil action.

The FWPCA as amended by the 1987 CWA clearly allows civil actions and appropriate relief. Any person who violates provisions of the FWPCA is subject to a civil penalty not to exceed $25,000 per day for each violation. In determining the amount of a civil penalty the court is to consider the seriousness of the violation, the economic benefit resulting from the violation, any history of such violations, any good-faith efforts to comply with applicable requirements, the economic impact of the penalty on the violator, and such other matters as justice may require.

The activity of USEPA in the enforcement of FWPCA previsions seems to be increasing. Headlines such as the following are becoming more and more common: "Judge is Tough on Polluter," Engineering News Record, September 28, 1989; "$1 Million Fine Ok'd Against Sewage District," The Denver Post, August 26, 1989; "Enforcement Program Nets Record EPA Fines," Engineering News Record, August 24, 1989; "Prison Terms for Pollution Giving Corporations the Chills," The Denver Post, August 29, 1989; "Consumers Tune Into Environmental Issues," The Denver Post, August

VOL 12

8/22

14, 1989; "EPA Names Water Polluters," Engineering News Record, June 22, 1989; "Pursuing Environmental Crime New Ground for Prosecutors," Rocky Mountain News, June 19, 1989; "Water Plant in Golden Subject of Probe," Rocky Mountain News, June 17, 1989; "EPA Sues Carbondale Residants Over Dumping in River," Rocky Mountain News, April 1, 1989; "EPA, Stuffed with Steroids, Muscles Out Local Control," Rocky Mountain News, March 30, 1989; "Big Fish in Hot Water," Engineering News Record, January 5, 1989; etc., etc.

The message is clear. Municipalities will not be able to ignore the requirement to obtain stormwater discharge permits. Environmental groups appear quite willing to utilize the provisions of the FWPCA to bring civil action against "polluters." The USEPA also seems to be stepping up enforcement actions. And, public support for such enforcement actions also seems to exist. At this point in time cost is not the major issue, but compliance is.

It can be argued, however, that if compliance with the stormwater regulations is "too ornerous or too expensive" there could be a public backlash and loss of public support. Congress appeared to be sensitive to this potential when they introduced the term "maximum extent practicable." The USEPA also has expressed a sensitivity to reality by de-emphasizing end-of-pipe controls and emphasizing source controls.

The states also have to be concerned about any enforcement actions that may be taken against a municipality. The FWPCA contains a provision that whenever a municipality is a party to a civil action brought by the United States, the state shall be joined as a party. The state is liable for payment of any judgement entered against the municipality to the extent that the laws of the state prevent the municipality from raising revenues needed to comply with the judgement. Potentially, Congress has committed the revenues of entire states to the enforcement of civil actions brought by the United States.

WHAT HAPPENS AT THE BORDER

Typical large metro areas in the United States consist of a core city, several large suburban cities, many small suburban incorporated jurisdictions, and urbanized unincorporated areas. However, the current regulations being proposed by USEPA affect only cities larger than 100,000, or only portions of the larger metro areas. The strategy of USEPA is to limit the initial permitting effort to relatively few permittees and require applications from the smaller communities at a

VOL 12

8/23

later date. According to USEPA (1988) permits will be initially required by 170 cities in the United States. This represents a small percentage of all the cities and counties in the United States, but about 25 percent of the population.

Stormwater systems in metropolitan areas are complex and it is not uncommon for storm sewers to pass from one community into another. Certainly, drainage basin boundaries seldom coincide with jurisdictional boundaries and stormwater typically flows from one community to another. While the proposed USEPA regulations will allow or possibly require permits from entities with systems connected to an entity that has to obtain a permit, this will likely be the exception. So initially at least the interjurisdictional complexity of storm sewer systems will be somewhat ignored. USEPA argues, however, that all communities will eventually be required to obtain permits, so it is only a matter of time before entire metro areas will fall under the permitting program.

USEPA has proposed to initially require permits from large incorporated cities and later from smaller cities and unincorporated urban areas. Permits logically have to be given to the unit of government that controls or owns the storm sewer system, and that has land use control in the area tributary to the storm sewer system. This generally means cities and counties in the United States. However, because of the regional nature of stormwater and receiving water bodies there are advantages to an area-wide or regional approach to stormwater quality management.

Because of the large variety of local political arrangements in metro areas of the United States no one single approach will be uniformly applicable. There are few if any metropolitan areas that are alike. It will, therefore, be up to each metro area to forge regional approaches that fit the situation. A possibility will be the requirement of each city and county (for unincorporated areas) in a metro area to obtain a permit, but for a regional organization to be a copermittee for certain aspects of permit requirements. A logical regional activity would be stormwater quality monitoring. If each local jurisdiction has to pursue a monitoring system on their own, the costs would be greater than if one monitoring system for an entire region could be installed. In the Denver, Colorado metro area there are 31 incorporated cities and towns and five counties that have unincorporated areas with significant urban development. Based on the monitoring requirements in USEPA's proposed regulations, the cost of collecting the required quantitative data from representative outfalls for the permit application was estimated for both conditions. For a region-wide monitoring system the cost was estimated to be $150,000, and for 36 separate monitoring systems the cost was estimated to be $1,440,000. These costs are just for the application phase of the permit process. Monitoring could continue indefinitely as a part of the compliance phase and a similar cost differential could be expected.

Other logical areas of regional involvement include development of region-wide criteria for design, application, and construction of BMP's; coordination of permit applications where storm sewer systems are interconnected; assistance in review of proposals to reduce the discharge of pollutants in stormwater from new developments; assistance with design, construction, and maintenance of stormwater quality facilities that serve more than one unit of local government; development of and assistance with educational programs; and development of area-wide erosion control measures to be required for new construction.

Local governments will generally have to be responsible for all actions that require police powers, i.e., land use authority, and any activities that would be peculiar to an individual entity. For example, local governments would have to adopt ordinances that would require developers to install BMP's such as stormwater quality ponds, adopt ordinances requiring that erosion control measures be implemented during any land disturbing activity, implement programs to eliminate illicit connections to their storm sewers, construct or enforce BMP's as necessary where water quality problems require it, and implement public programs to promote improved public practices such as use oil and antifreeze collection instead of indiscriminate disposal.

The approach being taken by USEPA in the initial round of permitting will tend to encourage balkanization because the smaller entities most likely will not have to obtain permits. The likely decision of a smaller city will be to delay as long as possible the day of reckoning, leaving only the cities over 100,000 going through the initial permitting process. Thus, limited portions of metro areas will be going through the initial permitting process, and there may be little incentive for a smaller community to participate and share in the cost of application requirements. Conversely, when the time comes for the smaller communities to obtain their permits the larger cities will have little incentive to assist the smaller communities unless their costs can be recovered or reduced.

Having said this, however, it simply makes sense to approach many of the stormwater quality issues on a

VOL 12

8 1 2 5

regional basis. In locations with existing regional entities there may be efforts to obtain permits for the entire region. This could be done with both local general purpose governments and a regional entity being copermittees. The responsibilities of each party would have to be clearly stated so one party could not be held responsible if another party is violating a condition of their permit. The argument can be made to the small cities and counties that they will eventually have to get permits anyway, and it would be logical and could reduce long term costs for the whole metro area to be permitted at the same time. As previously noted, however, to expect all communities to volunteer to apply for permits before they are required to do so is being quite optimistic.

SUMMARY

The United States is heading toward a national requirement of regulating the discharge of pollutants from municipal separate storm sewer systems. The USEPA is now preparing regulations pursuant to the 1987 CWA adopted by the United States Congress that will set forth minimum requirements for the application by local governments for permits for their separate storm sewer discharges. The USEPA has published proposed regulations and is now evaluating comments received during the public comment period. USEPA in their proposed regulations targeted cities with 1980 populations exceeding 100,000. Smaller cities and unincorporated urban areas would eventually be required to obtain similar permits. The proposed regulations emphasize the development of stormwater management programs by the nation's urban areas that would reduce the discharge of pollutants in stormwater to the maximum extent practicable. The USEPA is proposing not to emphasize end-of-pipe standards, but instead to rely heavily on best management practices that would reduce stormwater pollutants to the maximum extent practicable.

The burden of implementing and funding the stormwater management programs will fall on local governments, namely cities and counties. There are no indications that federal or state funding support will be available. The permits that will be issued will specify what the local governments will be required to do as well as time frames for compliance. Local governments are concerned whether the regulations as proposed will have enough flexibility to adopt monitoring requirements and management plans to local conditions. The 1987 CWA provides for severe penalties if permit requirements are not met or if a municipality or county fails to apply for a permit within the time allowed.

VOL 12

8/26

The enforcement provisions in the FWPCA will be a motivating factor for local governments to make serious efforts to submit permit applications in a timely manner and to take seriously compliance requirements. Civil actions may be taken by the USEPA or any citizen. Environment groups have been active in suing polluters and even the USEPA when USEPA has not properly implemented environmental laws. The USEPA also has stepped up enforcement of FWPCA provisions and resulting regulations. Consequently, local governments can look forward to active oversight regarding their response to USEPA regulations now being promulgated.

The regulation of stormwater quality will represent a significant effort in the United States. The cost or the effectiveness of the program is not known at this time, but the commitment of the United States to improving water quality expressed through Congress is clear. Clean water is a high priority, and the clean water effort has finally reached separate storm sewers.

THE REGULATION OF CSOs AND STORM WATER IN THE UNITED STATES

by James R. Elder[1]

In 1972, the Federal Water Pollution Control Act (referred to as the Clean Water Act or CWA), was amended to prohibit the discharge of any pollutant to navigable waters from a point source unless the discharge is authorized by a National Pollutant Discharge Elimination Systems (NPDES) permit. However, due to limited resources, efforts to control water pollution have traditionally focused on controlling pollutants in discharges from publicly owned treatment works (POTWs)[2] and industrial process wastewaters. This program emphasis has developed for a number of reasons. At the onset of the program in 1972, many sources of industrial process wastewater and municipal sewage were not adequately controlled, and represented pressing environmental problems. In addition, sewage outfalls and industrial process discharges were easily identified as responsible for poor, often drastically degraded water quality condition.

As discharges from POTWs and industrial process wastewaters have become increasingly under control, it has become evident that more diffuse sources of pollution are also major causes of water quality problems. Some diffuse sources of water pollution, such as agricultural storm water discharges and irrigation return flows, are statutorily exempted form the NPDES program. Controls

[1] Director, Office of Water Enforcement and Permits, U.S. Environmental Protection Agency, Washington, D.C. 20460

[2] In the United States, most sewage treatment plants are owned by local government entities. Sewage treatment plants that are owned by local government entities are called publicly owned treatment works or POTWs.

for other diffuse sources have been slow to develop under the NPDES program.

Although assessments of water quality are extremely difficult to perform and verify, several National assessments of water quality are available. For the purpose of these assessments, urban runoff and other storm water discharges are considered to be a nonpoint source pollution, although legally, most urban runoff is discharged through conveyances such as separate storm sewers or other conveyances which are point sources under the CWA, and are subject to the NPDES program. The "National Water Quality Inventory, 1988 Report to Congress" provides a general assessment of water quality based on biennial reports submitted by the States under Section 305(b) of the CWA.

States are required to submit biennial reports listing water bodies that are not fully supporting designated uses and the pollution sources causing the use impairment. The 1988 Report indicates that a wide range of sources cause water impairment including combined sewer overflows (CSOs), separate storm sewer discharges, agriculture, silviculture, construction, resource extraction, and land disposal as well as POTWs and industrial process discharges. In general, POTWs and industrial process discharges are identified as each contributing to about 10 percent of the water quality impairment problems in lakes and rivers, with diffuse sources of pollution being responsible for most impairment.

As a result of these types of findings, and the 1987 amendments to the CWA requiring the implementation of NPDES requirements for storm water discharges, the Environmental Protection Agency (EPA) has begun to develop and implement National strategies to regulate both CSOs and storm water discharges.

NATIONAL CSO CONTROL STRATEGY

EPA estimates that there are approximately 1,200 communities with combined sewer systems, and these systems operate 15,000 to 20,000 CSOs, many of which are clustered in 'older' developed areas in the Eastern United States.

In a relatively few cities, major effort to control CSOs have already been undertaken. Varied control strategies have emerged, such as: Chicago's underground tunnel system; San Francisco's major interceptor system; a 400 million gallon per day swirl concentrator coupled with other collection system controls in

Washington DC; and the sewer separation projects undertaken by a number of cities.

However, the majority of communities have not adequately addressed CSOs. As a result, EPA issued the "National CSO Control Strategy" on August 10, 1989.

The CSO National Strategy established three objectives:

- To ensure that CSO discharges that do occur are only a result of wet weather; .
- To bring all wet weather CSO discharge points into compliance with the technology-based requirements of the CWA and applicable State water quality standards; and
- To minimize water quality, aquatic biota, and human health impacts from wet weather overflows.

The strategy requires each NPDES approved State with CSOs to develop and submit a state-wide CSO strategy for managing its CSOs to the Region for approval by January 15, 1990. The state-wide strategies consists of three parts:

1) an inventory of all CSO points in the State;

2) the current permit status of each CSO point; and

3) a list of the Stata's CSO priorities.

In addition, the strategy establishes guidance for minimum technology-based limitations, including:

A) proper operation and regular maintenance programs for the sewer system and combined sewer overflow points;

B) maximum use of the collection system for storage;

C) review and modification of pretreatment programs to assure CSO impacts are minimized;

D) maximization of flow to the POTW for treatment;

E) prohibition of dry weather overflows; and

VOL 12

8130

R0041436

F) control of solid and floatable materials in CSO discharges.

Additional control measures may also be required on a case-by-case basis to address the particular circumstances of each combined sewer system and overflow point.

STORM WATER DISCHARGES

Since 1972, EPA has developed technology-based numeric standards or effluent guideline limitations for storm water discharges from ten classes of industries: cement manufacturing; feedlots; fertilizer manufacturing; petroleum refining; phosphate manufacturing; steam electric; coal mining; ore mining and dressing; mineral mining and processing; and asphalt emulsion.

However, most types of storm water discharges, including urban runoff in cities, have not been controlled under the NPDES program to date, even though many storm water discharges (with the exception of agricultural runoff) legally are considered point sources which are subject to the NPDES program under the CWA.

In 1987, Congress amended the CWA to require EPA to develop a phased program for regulated storm water discharges under the NPDES program.

Under the initial phases of the new program, the Agency is to begin to develop requirements for:

- storm water discharges associated with industrial activity;
- discharges from municipal separate storm sewer systems serving a population of 100,000 or more; and
- discharges which are designated by EPA or an NPDES approved State as needing an NPDES permit because the discharge contributes to a violation of a water quality standard or is a significant contributor of pollutants to waters of the United States.

The 1987 amendments to the CWA clarified and amended the requirements for permits for storm water discharges. The amendments clarified that permits for storm water discharges associated with industrial activity must meet all of the applicable technology-based and water quality-based requirements of the CWA. However, the amendments made significant changes to the permit requirements for discharges from municipal separate storm sewers. Section 402(p)(3)(B) provides that NPDES permits for such discharges:

(i) may be issued on a system- or jurisdiction-wide basis;

(ii) shall include a requirement to effectively prohibit non-storm water discharges into the storm sewers; and

(iii) shall require controls to reduce the discharge of pollutants to the maximum extent practicable, including management practices, control techniques and system, design and engineering methods, and such other provisions as the Director determines appropriate for the control of such pollutants.

EPA or NPDES States cannot require a permit for other storm water discharges until October 1, 1992. Prior to that time, EPA, in consultation with the States, is required to conduct two studies on storm water discharges. The first study will identify those storm water discharges or classes of storm water discharges for which permits are not required prior to October 1, 1992 and determine, to the maximum extent practicable, the nature and extent of pollutants in such discharges. The second study is for the purpose of establishing procedures and methods to control storm water discharges to the extent necessary to mitigate impacts on water quality.

Based on the two studies, EPA is required to issue regulations by no later than October 1, 1992 which designate additional storm water discharges to be regulated to protect water quality and establish a comprehensive program to regulate such designated sources. The program must, at a minimum, (A) establish priorities, (B) establish requirements for State storm water management programs, and (C) establish expeditious deadlines. The program may include performance standards, guidelines, guidance, and management practices and treatment requirements, as appropriate.

PROPOSED STORM WATER REGULATIONS

On December 7, 1988, (53 FR 49416), EPA proposed permit application requirements for storm water discharges associated

VOL 12

8132

with industrial activity and discharges from municipal separate storm sewer systems serving a population of 100,000 or more.

These proposed regulations represented a major shift to the NPDES system which has traditionally focussed on end-of-pipe treatment requirements. Instead of emphasizing end-of-pipe treatment for controlling discharges from municipal separate storm sewers, the program emphasizes the development of site specific municipal storm water management programs. The Agency envisions that municipal storm water management programs will generally have four major components:

- control of non-storm water discharges, including illicit connections, spills and improper dumping to municipal separate storm sewer systems;

- control of construction site runoff to the municipal separate storm sewer system;

- control of runoff from residential and commercial sites (this is what the Nationwide Urban Runoff Program or NURP called urban runoff) to municipal separate storm sewer systems; and

- control of industrial site runoff to municipal separate storm sewer systems.

EPA envisions that permit requirements for municipal separate storm sewer systems will be developed in a flexible manner to allow site-specific permit conditions to reflect the wide range of impacts that can be associated with these discharges. Permits for different municipalities will place different emphasis on controlling various components of discharges from municipal storm sewers.

STORM WATER STUDIES

The Agency has begun the development of two studies evaluating other storm water discharges. Two major classes of discharges will be addressed in the studies:

- discharges from municipal separate storm sewer systems; and

- non-municipal storm water discharges from individual facilities.

Municipal Separate Storm Sewer Systems

In the studies, EPA has begun to focus on municipalities that are part of urbanized areas which are defined by the Bureau of Census. These urbanized area are population centers of 50,000 or more people comprised of a central city with surrounding closely settled areas with a population density which is generally greater than 1,000 people.

In 1980, 139 million people, or 61 percent of the total population in the United States lived within 366 urbanized areas. These areas only covered 1.5 percent of the total land are of the United States. Portions of over 3,300 incorporated cities, towns and villages, 601 counties and about 600 unincorporated towns and townships are part of urbanized areas. These local governments account for only 18 percent of the nation's incorporated places, 19 percent of the counties and 4 percent of the unincorporated towns and townships.

EPA estimates that 141 of the 366 urbanized areas are served in part by combined sewer systems. The percentage of area within an urbanized area that is served by combined sewer varies considerably. The Agency estimates that CSOs serve as much as 25% of the population in all urbanized areas, while covering less than 7% of the total area of all urbanized areas. Almost all widespread new development involves separate storm sewers.

The studies will provide a description of a number of pollution sources which affect pollutants in discharges from municipal separate storm sewer system, including non-storm water discharges, construction site runoff, runoff from residential and commercial areas, and industrial site runoff.

Non-Storm Water Discharges

Preliminary information from the studies indicates that non-storm water discharges to municipal separate storm sewers can be caused by one or more of the following:

- illicit connections and cross connections from industrial, commercial and sanitary sewage sources;
- improper disposal of wastes;
- spills;

- leaking sanitary sewage systems; and

- malfunctioning septic tanks.

Most municipalities have not investigated their storm sewer systems for illicit connections or other non-storm water discharge problems. Case studies of cities which have investigated non-storm water discharges indicate that various cities reported different types of non-storm water discharges to their separate storm sewer systems. In some areas of older development, (pre-1972) illicit connections to separate storm sewers were prevalent. Some areas of newer development experienced fish kills caused by spills and improper dumping to the storm sewer system. An investigation of a municipal systems serving industrial land use indicated that concerns from a wide variety of spills, dumping and illicit connections.

Other Pollution Sources

Uncontrolled runoff from construction sites contains high levels of sediment. Pollutants in runoff from industrial land use areas depend on the type of industrial facilities, but in general have a higher potential to contain toxic constituents than other runoff and to be adversely affected by spills and poor material handling practices.

Runoff from Residential and Commercial Areas

Information from the Nationwide Urban Runoff Program (NURP) was used to characterize runoff from residential and commercial areas. In most urbanized areas, the annual discharge volume of runoff from residential and commercial areas is expected to be similar to the annual discharge volume of POTWs. However, the volume of discharges of runoff during most storm events is much greater than the volume of POTW discharges during the same period. Even where separate storm sewer discharges are not affected by either non-storm water discharges or runoff from industrial sources and runoff from construction sites, discharges of runoff from residential and commercial areas have high levels of heavy metals, sediment, bacteria, acidity and floatables relative to discharges from POTWs receiving secondary treatment. Runoff from these areas has concentrations of COD, BOD and oil and grease that are approximately equivalent to POTW secondary treatment discharges. Phosphorus and nitrogen concentrations in runoff from residential and commercials areas tend to be lower than discharges from POTWs, but may cause eutrophication in receiving waters under certain conditions. Discharge locations for POTWs and separate storm sewers also differ. POTWs tend to discharge to larger receiving waters with larger assimilative capacities or, in coastal areas, a significant distance offshore. Separate storm sewers are more diffuse, and discharge at many points within a drainage basin, including for coastal areas, at locations near shorelines.

Non-Municipal Individual Sources

Non-municipal storm water discharges can be classified into eight major classes:

- Mining and Oil and Gas Production Facilities;
- Animal Feedlots;
- Manufacturing Industries;
- Construction Activities;
- Waste Management and Recycling Facilities;
- Automobile Related and Transportation Facilities;
- Electric Power Generation Facilities; and
- Selected Wholesale Facilities

Identifying types of discharges and pollutants associated with the discharges is only an initial step to program development. The Agency must still address the challenge of developing effective regulatory programs for the large number of storm water discharges.

OPTIMIZATION OF STORMWATER QUALITY CAPTURE VOLUME

Ben Urbonas, P.E.[1], James C.Y. Guo, Ph.D., P.E.[2]
and L. Scott Tucker, P.E.[3], all M.ASCE

ABSTRACT

There is a need for rational, scientifically based, methods to size urban stormwater runoff facilities for the purpose of water quality enhancement. This paper describes a procedure that utilizes hydrologic principles for optimizing the capture volume. This procedure takes recorded precipitation data and processes it using a quasi-continuous simulation method to determine the number of storm events and total of storm runoff volume being captured within the period being studied. The application of this procedure is illustrated using a 40 year hourly rainfall record at the Denver Raingauge.

INTRODUCTION

The practice of urban stormwater management has until recently focused primarily on quantity issues such as drainage and flood control. Flooding of streets, streams, and rivers has been the main concern. Local governments have constructed thousands of miles of curb, gutter, road side ditches, and storm sewers to convey stormwaters as quickly and efficiently as possible to the nearest stream. This practice along with the increase in impervious surfaces accompanied by urbanization increases the volume and peak flow of runoff for any given rainfall event.

[1] Chief, Master Planning Program, Urban Drainage and Flood Control District, Denver, Colorado.

[2] Associate Professor, University of Colorado at Denver

[3] Executive Director, Urban Drainage and Flood Control District, Denver, Colorado.

Because development results in greater surface runoff rates when compared with undeveloped land, it is common for local governments to attempt mitigating these runoff increases by requiring developers to construct on-site stormwater detention facilities. The concept is to hold back runoff for a short period from each development in small ponds, on parking lots, or wherever space can be found at the site to temporarily store the water. However, on-site detention criteria varies considerably from community to community, the impact of muliples of on-site facilities is uncertain, and long term maintenance is not a sure thing when it comes to these randomly placed on-site detention facilities.

The alternative to developer constructed on-site detention facilities is regional detention sites. Most people agree that regoinal facilities are more cost efficient and are much more likely to be properly maintained because they would be owned and operated by a public entity. While preferred, it is difficult to fund regional detention. As a result, individual on-site detention requirements are still commonly enforced and the use of on-site detention is the most common approach.

Urban stormwater management, however, is changing quite rapidly from a focus on quantity to a focus on quantity and quality. Two basic issues have and are exerting considerable influence for this change. The first is a fundamental heightening of environmental awareness and concern by the public. There seems to be public support for environmental programs. Stormwater quality in general is probably not a serious problem in relation to concerns such as global warming, Love Canal, sludge disposal, or the Alaska oil spill, and excapt in some specific situations the impact of urban stormwater on receiving water bodies is not documented or understood. Nevertheless, urban stormwater along with non-point runoff from non-urban sources contribute pollutants to the receiving waters and efforts to do something about it are slowly picking up support and momentum.

The second factor causing a shift toward urban stormwater quality is the Water Quality Act of 1987 (WQA), which amended the Federal Water Pollution Control Act. The WQA of 1987 is a reflection of the public's support for pollution control, and such legislation gives focus and direction to general issues. The WQA requires the Environmental Protection Agency (EPA) to develop a National Pollutant Discharge Elimination System (NPDES) permit program for separate urban stormwater discharges. How the 1987 WQA may impact the citizens, communities, local governments, industry, consultants and the water quality across the United States is yet to be seen. Nevertheless, local governments and industries throughout the United States have a mandate from Congress to control pollutants in urban runoff to the "maximum extent practicable" (MEP). This hopefully means that Congress expects solutions to be practical, pragmatic, and economical.

In order to be practical and effective it is important that technologies for dealing with urban stormwater runoff be available that get the job done. Several simple technologies are emerging that willl be able to be used to remove pollutants from urban stormwater (Urbonas and Roesner, 1986), (Roesner, Urbonas and Sonnen, 1989). These include detention and retention basins, infiltration and percolation at the source of runoff, wetlands, sand filters, and combinations of these techniques. It is important to realize that the same design criteria used to design detention ponds to reduce peak flows cannot be used to design detention and retention basins for stormwater quality purposes.

It is clear from reading the 1986 and 1989 references cited above that the size of runoff event to be captured and treated is a critical factor in the design of stormwater quality detention and retention basins. For example, if the design runoff event is too small, the effectiveness will be reduced because too many storms will exceed the capacity of the facility. Or if the design event is too large, the smaller runoff events will tend to empty faster than desired for adequate settling of pollutants. Thus the larger basins may not provide the needed retention time for the predominant number of smaller events.

A balance between the storage size and water quality treatment effectiveness is needed. Grizzard et. al. (1986) reported results from a field study of basins with extended detention times in the Washington, D. C. area. Based on their observations they suggested that these basins provide good levels of treatment when they are sized to have an average drain time of 24 hours, which equates to a 40 hour drain time for a brim-full basin.

EPA (1986) suggested an analytical methodology for estimating the removal efficiencies of sediments in ponds that have surcharge storage above a permanent pool. Subsequently, Schueler (1987) suggested that the surcharge volume be equivalent to the average runoff event volume. Analysis by the authors in Denver using the EPA analysis technique indicates that wet ponds can be very effective in removing settleable pollutants (i.e., annual TSS removal rates in excess of 80 percent). However, this analysis was limited to ponds that have brim-full surcharge volume equal to one-half inch of runoff from the tributary impervious surfaces, with this volume being

VOL 12

8139

drained in 12 hours. Never-the-less, there remains little rationale for the sizing of the capture volume that results in reasonable pollutant load removal while providing reasonably sized cost effective facilities.

Until recently, the primary interest was in drainage and flood control. As a result, the focus was on the larger storm events such as the 2- to 100-year floods. Although drainage and flood control engineers traditionally consider the 2-year event as small, at least in the Denver area it is larger than 95 percent of all the runoff events that typically occur in an urban watershed. Also, through experience we have learned that a detention facility designed to control a 100-year, or even a 2-year flood has little, if any, effect on water quality. Thus, focusing on the traditional drainage design storms is not practical or desirable when considering stormwater quality.

This paper will discuss a method that can be used to find a point of diminishing returns for the sizing of water quality detention facilities. It utilizes rainstorm records as its base instead of synthesized design storms. An example based on tha National Weather Service long term precipitation record in Denver is used to illustrate the suggested methodology.

MAXIMIZATION OF STORMWATER RUNOFF CAPTURE VOLUME

Rain Point Diagram.

In 1976 von den Herik (1976) suggested in Holland a rainfall data-based method for estimating runoff volumes. This method is based on long term record of total rainfall and duration of storms. Subsequently Pecher (1978 & 1979) suggested modifications to von den Herik's work to use in the sizing of detention facilities through the use of a Rain Point Diagram (RPD). The authors modified the original method to transform the RPD to a Runoff Volume Point Diagram (RVPD) by multiplying the individual rainstorm depths on the RPD by the runoff coefficient of the tributary watershed.

The PVPD method approximates continuous modelling without setting up a continuous model. The method requires combining individual recorded hourly or 15 minute rainfall increments in a given period of record into separate storm depth totals. Separate storms are identified by a period of time when no rainfall occurs. Very small storms that are not likely to produce runoff can be then be purged from the record. Rainfall storm totals were then converted to runoff depths (i.e.,

VOL 12

8140

R0041446

volumes) by multiplying the rainfall depth by the watersheds runoff coefficient (C).

Because the RVPD procedure has not taken into account the effects of several successive rainstorms, it would have a tendency to underestimate the capture effectivenes of detention facilites that have very low release rates. This is because the volume captured during one storm may not be fully drained before the next storm occurs. The RVPD assumes an empty basin for each event.

The procedures used to develop the RVPD method and a case study using the Denver rain gage data will be discussed subsequently. However, to illustrata the use of the RVPD a plot of 63 storms is shown in Figure 1, where the individual storm runoff depth in inches is plotted agaist storm duration. A runoff capture envelope is also plotted on this same figure. This captured storage envelope is bases on the "brim-full" volume of the detention facility and its emptying time. In Figure 1 the runoff capture envelope is based on a detention basin that has a brim-full capacity of 0.3 watershed inches which can be emtied throughthe outlet in 12 hours (sometimes called drawdown time).

All the points above the capture volume envelope line represent individual storms that have sufficient runoff to exceed the available storage volume (i.e., brim-full volume) of the detention facility. Obviously, plotting and counting all points for a long record of rainstorms is a very tedious job. As a result, the authors developed a software package to perform this task.

While this procedure is a simplification of a continuous modelling process, the results should be sufficiently accurate for general planning purposes. This conclusion is supported by the fact that the true accuracy of hydrologic calculations is significantly less than the precision implied by stormwater hydrology models (ASCE, 1984) that are commonly used.

To compensate for storms that may be closely spaced, the authors used a storm separation interval equal to one-half of the emptying time of the brim-full volume. In other words, a storm was defined as separate from a previous storm when this separation condition was satisfied between the end of the last recorded rainfall increment and the beginning of the next one.

The sensitivity of the storm separation period was tested using a storm separation period equal to the brim-full volume emptying time. Virtually no difference was found in the capture volume effectiveness between the separation set at brim-full and one-half of the brim-full

VOL 12

8141

emptying time. Such sensitivity tests are suggested whenever other precipitation data are used for this procedure.

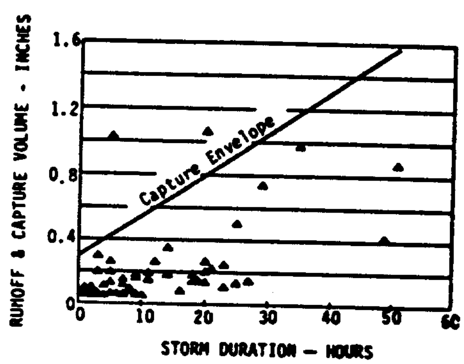

Figure 1. Runoff Volume Point Diagram and Capture Volume Envelope. (1-inch = 24.5 millimeters)

Storage Volume Optimization Procedure

After the total rainfall record is separated into individual storm events, the runoff volume for each storm can be estimated using:

$$V_r = C\ P_t \qquad (1)$$

in which, V_r = total runoff volume for a storm, in watershed inches or meters
C = runoff coefficient
P_t = total precipitation over the watershed for the storm in inches of meters.

For a given detention pond or basin that has a brim-full volume V_p with an emptying time T_e, its average release rate, q, is

$$q = V_p / T_e \qquad (2)$$

The runoff volume capture capacity, V_m, of the detention basin for any storm may be estimated using:

$$V_m = V_p + q\ T_d \qquad (3)$$

VOL 12

8142

in which, T_d = storm duration. The function ($q\ T_d$) represents the storage beyond the brim-full volume that becomes available during the strom as the result of releases from the basin during the storm's duration.

The actual runoff volume captured and processed for quality improvement through the basin for a given storm is equal to V_r, namely storm runoff volume, when V_r is less than V_e; otherwise it is equal to V_m with the excess runoff volume assumed to overflow without any treatment. Adding the volumes captured for all the storms occurring during the record period gives the total volume captured and treated, V_t, within the period. Thus, the volume capture ratio for the period of rainfall record is defined as,

$$R_v = V_t \ / \ V_{tr} \qquad (4)$$

in which, R_v = volume capture ratio for the record period
V_t = total volume captured during the period
V_{tr}= total runoff volume during the same period.

Similarly, the runoff event capture ratio is defined:

$$R_e = N_f \ / \ N \qquad (5)$$

in which, R_e = runoff event capture ratio for the period
N_f = number of runoff events that are less than or equal to V_m in runoff volume
N = total number of runoff events.

For the total set of runoff events in the record there is a detention volume that will capture all of the runoff events of record. For practical reasons this maximum pond volume, P_m, was defined to be equal to the 99.9 percent probability runoff event volume for the record period. For the Denver raingage period of record studied (1944-1984) this is equal to to the runoff from 3.04 inches (77.2 mm) of precipitation, or 6.9 times the precipitation of an average runoff producing storm for this period of record. This 99.9 percentile value, namely P_m, was then used to normalize all pond sizes being tested using the following equation:

$$P_r = P \ / \ P_m \qquad (6)$$

in which, P_r = relative pond size normalized to P_m
P = pond size being tested
P_m = maximum runoff volume (i.e., 99.9% probability).

The maximization procedure incrementally increases the relative (i.e., normalized) pond size and calculates

VOL 12

8143

the runoff volume and event capture ratios (i.e., R_v and R_e) using the RVPD method. Figure 2 illustrates an example of the results of such an analysis using the precipitation record at the Denver gauge between 1944 and 1984. In this example the capture volume was maximized using storms defined by a 6-hour period of separation, 12-hour emptying time for the brim-full basin, and a runoff coefficient C = 0.5 for the watershed.

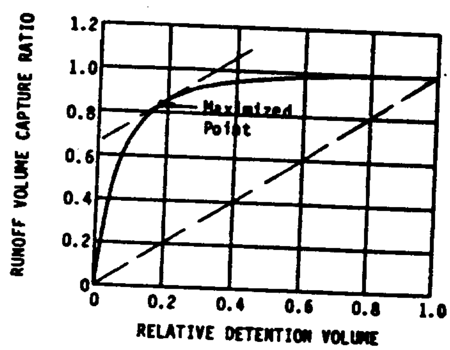

Figure 2. Maximizing Capture Volume.

The maximized pond size occurs where the 1:1 slope is tangent to the runoff capture rate function. Before this point is reached the capture rate increases faster than the relative capure volume size. After this point is reached the increases in the capture rate become less than than corresponding increases in relative capture volume size. In other words, when the point of maximization is passed, diminishing returns are experienced if the capture volume is increased any further. In Figure 2 example, the maximized point occurs when the relative capture volume is equal to 0.18. At this point we capture in total and release slowly approximately 82 percent of the entire runoff depth that has occured during the 40 year study period. This relative capture volume is then converted to actual volume using Equation 6, namely,

$P = P_r\ P_a$
$= (0.18)\ (0.5\ 3.04)$
$= 0.27$ watershed inches (6.86 millimeters)

in which, 0.5 is the watershed's runoff coefficient and P_e = 3.04 inches (77.2 mm), namely the depth of rain during the 99.9 percent probability storm.

CASE STUDY USING DENVER RAIN GAUGE DATA

Developing Regional Detention Sizing Guidelines.

The authors investigated the Denver Gauge precipitation data using several storm separation periods, which has been defined as the time between the end of one storm and the beginning of the next. A statistical summary of rainfall characteristics for all storms that exceeded a total of 0.1 inch (2.54 mm) is given in Table 1. A 0.1 inch (2.54 mm) "filter" was used to eliminate from the record the very small storms, of which most are likely not to produce runoff. The urban rainfall and runoff data in the Denver area indicate that approximately 0.08 to 0.15 inches (2.03 to 3.81 mm) of rainfall depth is the point of incipient runoff.

TABLE 1. DENVER RAIN GAUGE HOURLY DATA SUMMARY 1944-1984 STORMS LARGER THAN 0.1 INCHES (2.54 mm) IN DEPTH

48	876	0.58*	43	310	613	70.0

* Multiply values by 25.4 to convert to millimeters.

A skewed statistical distribution exists with more than two-thirds of the storms having less precipitation than the 40 year average storm depth. Appearently in the Denver area the average runoff producing rain storm depth is a relatively large event.

The distribution of all (i.e., unfiltered) storms vs. total storm precipitation depth when individual storms are defined by a six hours separation period is shown in Figure 3. Note that sixty percent of the precipitation events produced 0.1-inches (2.54 mm) or less of rainfall depth. Over ninety percent of all recorded storms had 0.5-inches or less of rainfall depth. This indicates that the focus, at least in the Denver area should be on the smaller, more frequently occurring storms whenever water quality is being considered.

VOL 12

8145

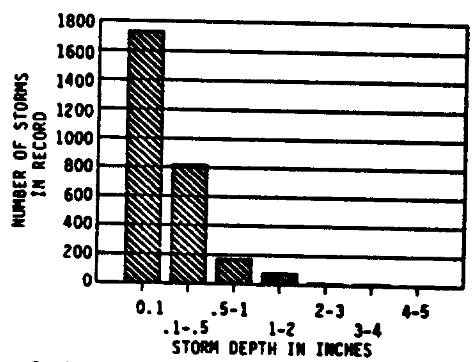

Figure 3. Number of Storms in Denver vs. Storm depth. (One inch = 25.4 millimeters)

Once the precipitation and runoff probabilities were understood, an attempt was made to find a simple yet reasonably accurate relationships for approximating the maximized capture volume of water quality detention basins. As described earlier, the maximized point was defined when additional storage resulted in rapidly diminishing numbers of storms or in the storm runoff volume being totally captured. The final result of this analysis is illustrated in Figure 4, which relates the maximized capture volume to the watershed's runoff coefficient. Separate relationships are shown for the brim-full storage volume emptying time of 12-, 24- and 40-hours.

The captured volume ratio for this relationship exceeds 80 percent and the storm event capture ratio exceeds 86 percent. The storm event capture ratio is of greater importance to the receiving waters because it is the frequency of the shock loads that has the greatest negative effect on the aquatic life in the receiving streams. On the other hand, examination of the precipitation records (i.e., Figure 3) indicates that the volume capture ratio is influenced significantly by the very few very large storms. During these very large runoff events catastrophic flooding is likely to be of primary concern and stromwater quality. It should also be noted that even in these larger events some degree of capture and treatment occurs, although at somewhat reduced efficiency since the detention capacity is exceeded.

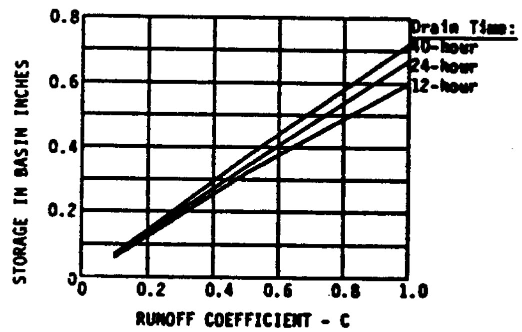

Figure 4. Maximized Capture Volume for Water Quality, Denver Rain Gauge 1944-84 Period. (One inch = 25.4 millimeters)

SENSITIVITY OF PROCEDURE

Capture Volume

Understanding the sensitivity of the event capture ratios to a change in the design capture volume (i.e.. brim-full volume) helps to rationally size water quality facilities. To help define this sensitivity a watershed having a runoff coefficient of C = 1.0 and a storage basin having the maximized volume draining in 12 hours was analyzed. The design capture volume of the basin was increased and decreased in increments and the results were normalized around the maximized volume point. Figure 5 illustrates the findings for this particular case. Although the results varied somewhat between similar tests, the trend was virtually the same for each test that were made using the Denver rain rauge data.

At the ratio of 1.0 on the abcissa, the capture volume has to be almost doubled to capture an additional 10 persent of the runoff events in the fecord. On the other hand, reducing the capture volume by 25 percent results in the reduction of only eight percent in the runoff events that are not captured in total. It needs to be understood that failure to capture a runoff event in total does not mean that the facility will not remove suspended solids. Suspended solids will be removed, but

VOL 12

8147

R0041453

at a somewhat diminished efficiency. The sensitivity of the facility's solids capture efficiency will be discussed next.

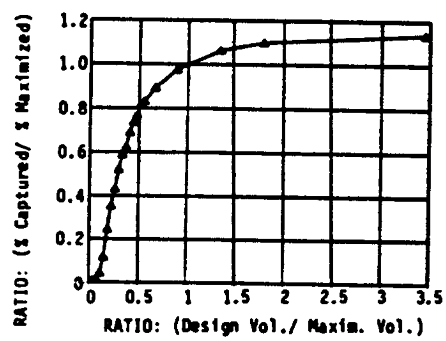

Figure 5. Sensitivity of Capture Volume Size.

__Removal of Suspended Sediments__

An attempt was made to test the sensitivity of the surcharge detention volume above the permanent pool level on the annual removal rates of total suspended solids in stormwater. For lack of local data on sediment settling velocities, the data given by EPA (1986) was use for several capture volume sizes. Estimates were made of the dynamic removals during the runoff events and the quiescent removals in the pond between storms. When using a surcharge capture volume equal to 70 percent of the maximized volume, the annual removal of TSS by the pond is estimated at 86 percent. This compares to an estimated rate of 88 percent annual removal of TSS when using the maximized capture volume, and only a 90 percent removal rate when using twice the maximized volume.

It appears from the preliminary estimates made using the Denver rain gauge records that it is posible to reduce the capture volume for a wet detention pond and see virtually no effect on the annual removal efficiency of the facility. Figure 5 suggests that the the design volume could be set 25 to 35 percent less than the maximized capture volume. Obviously this suggestion needs more testing. If verified, savings in the construction of water quality enhancement facilities should be possible. Continuous modelling and field testing are suggested as posible methods to test this premise.

Extending the Design Procedure

It is clear from the sensitivity analysis that the capture volume may be reduced somewhat from the maximized point without a significant loss in effectiveness. The designer or the water quality administrator may want to target the capture volume size to serve a runoff event of a desired recurrence probability such as the 85%, 80% or lesser runoff event. Figure 6 illustrates the type of relationships that can be developed if such a goal is desired. Obviously economics and practicality of the capture volume size should be considered when selecting the stormwater quality sizing criteria.

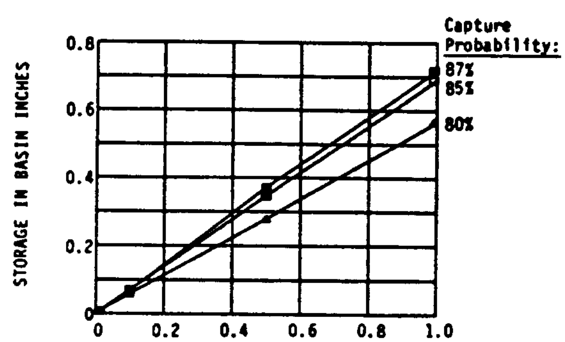

Figure 6. Capture Volumes for a 40-hour Drain Time and Several Runoff Event Capture Probabilities.

From our analysis of the Denver rain gauge data, it looks reasonable, logical and prudent to target the capture of approximately 80th percentile runoff event. This means that the detention facility can be reduced by about 25 to 30 percent in size make it more affordable, while still capturing in total 92 percent of the storm events. When the reduced detention facility is analyzed for impact on the average annual removal in total suspended solids, the difference from the maximized size in water quality being released to the receiving waters is

VOL 12

8149

R0041455

practically not measurable. In other words, the 80 percentile capture volume should provide very good long term TSS removal rates. Also, basins of this size should fit easily within either on-site detention facilities designed for control of runoff peaks or within most landscaping areas of new developments.

At the same time, the removal of dissolved nutrients, such as phosphorous or nitrates, is primarily the function of residence time within the permanent water pool of the "wet pond" between storms. Increasing the capture volume above this pool should have little effect on the removal efficiencies of these compounds. Similarly, "dry ponds" have limited removal efficiencies of dissolved nutrients since their primary removal mechanism is sedimentation (Grizzard, et. al., 1986; Schueler, 1987; Roesner, et. al., 1988; Stahre and Urbonas, 1988).

DETERMINATION OF RUNOFF COEFFICIENT

Using Figure 4 or Figure 6 it is possible to quickly estimate an effective size of a stormwater quality detention basin. Since the engineer has to address smaller runoff events when dealing with stormwater quality, an appropriate runoff coefficient needs to be used. In 1982 EPA published data as part of the NURP study on rainfall depth vs. runoff volume. Although EPA did acknowledge some regional differences, much of the United States was found to be well represented by the data plotted in Figure 7. The curve in this figure is a third order regressed polynomial with the regression coefficient $R^2 = 0.79$. This value of R^2 implies a reasonably strong correlation between the watershed imperviousness, I, in percent and the runoff coefficient, C, for the range of data collected by EPA. Since the NURP study covered two year period, in our opinion this relationship is justified for 2-year recurrence probability and smaller storms.

EXAMPLE OF BASIN SIZING

An example is used next to demonstrate how to determine a "maximized" capture volume for an extended detention basin. A 100 acre (40.5 hectares) multi-family residential tributary watershed that has 60 percent of its area covered by impervious surfaces is used as the example conditions.

VOL 12

8150

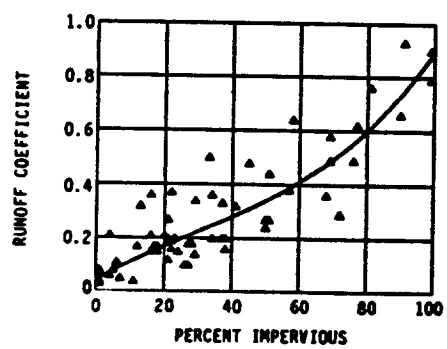

Figure 7. Runoff Coefficient Based on NURP Data for 2-year and Smaller Storms.

Using Figure 7 the runoff coefficient for the watershed, C = 0.4, is estimated. A well performing extended detention basin, according to Grizzard, et. al. (1986), needs to capture approximately the mean seasonal runoff and release it over a 24 hour period, which they suggested could be accomplished if the brim-full volume is drained in 40 to 48 hours. Thus, using the 80 percentile curve on Figure 6 and a brim-full drain time of 40 hours a design volume of 0.22 watershed inches (7.62 mm) is obtained. This is the runoff from a 0.55 inch (14 mm) storm and equates to 1.8 acre feet (2,300 cubic meters) of storage.

CONCLUSIONS

An investigation of sizing stormwater quality facilities for maximized capture of stormwater runoff events and their performance in removing settleable pollutants revealed that simplified design guidelines are possible. These guidelines can be developed using local or regional rain gauge records.

The procedure for the development of these simplified guidelines uses a Runoff Volume Point Diagram method to approximate a continuous simulation process in combination with an optimization routine. This procedure was converted by the authors into computer software.

VOL 12

8/5/1

Using the Denver rain gauge for the testing of this procedure, a figure was prepared that relates a watershed's runoff coefficient, required capture volume and the drain time for this volume. The procedure consists of the following steps:

1. Reduce the recorded rain gauge record (preferably hourly or 15-minute record) to a Rain Point Diagram using several storm separation periods.
2. Transform these Rain Point Diagrams into a Runoff Volume Point Diagrams by multiplying the individual rainfall depths by the watershed's Runoff Coefficient. This can be done for three or more values of C, such as C = 0.1, 0.5 and 1.0 to provide several points on the final design curves.
3. Process the Runoff Volume Point Diagrams through the optimization procedure described earlier using several capture volumes and brim-full storage volume drain times. Suggest using a Runoff Volume Point Diagram that was prepared using a time of storm separation equal to one-half of the desired brim-full drain time.
4. Plot all of the results on a figure similar to Figure 4 for the specific precipitation gauge being used.
5. Perform sensitivity analysis and if appropriate offer options for the sizing of capture volume for several levels of capture probability (eg. Figure 6) and/or TSS removal.

DESIGN CRITERIA FOR DETENTION POND QUALITY

by Thorkild Hvitved-Jacobsen[1]

Introduction

A wet detention pond is a structural measure which might reduce potential pollutant impacts on receiving waters from separate sewered catchments. In this introduction the need for urban stormwater pollutant removal will be discussed.

A distinction between acute and accumulative effects in receiving waters is of major importance with respect to urban runoff pollution from combined sewer overflows (CSO's) as well as stormwater runoff (SWR). Acute effects like dissolved oxygen depletion and bacterial contamination are almost exclusively associated with CSO. Accumulative effects like eutrophication due to nutrient discharges and deterioration of the ecosystems from heavy metals and organic micropollutants may be seen in receiving waters from both CSO and SWR. These accumulative effects are related to yearly - or seasonal - loads of pollutants.

Whether CSO or SWR plays the more important role is not only dependent on the relative size of the effective catchment areas but also on the discharged volumes and the concentrations in the urban runoff. Characteristic values of nutrients and heavy metal concentrations in the runoff water from Danish combined sewered catchments - including contributions from resuspended solids in the sewers but exclusive of sewage contributions - and from separate sewered areas are shown in table 1. Typically, heavy metal concentrations are of similar order of magnitude for these two sources whereas nutrient concentrations are a factor of about 5 lower in SWR. However, on a yearly basis discharged volume per unit area of a

---

[1]Associate Professor, Environmental Engineering Laboratory, Department of Civil Engineering, University of Aalborg, Sohngaardsholmsvej 57, 9000 Aalborg, Denmark.

separate sewered catchment is normally considerably higher than from a combined sewered area depending on the actual sewer design and detention capacity. Therefore, even for the nutrients, it is often seen that the discharged yearly amount per unit effective hectare (total area reduced by runoff coefficient) of a separate sewered area is of similar order as from a combined sewered catchment (Hvitved-Jacobsen and Jensen, 1988). For the heavy metals it can be concluded that the specific load from separate sewered areas normally plays the more important role.

Table 1. Concentrations for calculation of pollutant loads from combined and separate sewered catchments. Values recommended by a sub-committee under the Danish Water Pollution Control Committee (PH-consult, 1989).

	combined sewer system		separate sewer system
pollutant	extreme event median value*	flow proportional mean value	flow proportional mean value
SS (mg/ℓ)	120-240	100-200	30-100
COD (mg/ℓ)	100-150	120	40-60
BI_5 (mg/ℓ)	-	25	irrelevant
tot.N (mg/ℓ)	irrelevant	10	2
tot.P (mg/ℓ)	irrelevant	2.5	0.5
Pb (µg/ℓ)	irrelevant	100-150	50-150
Zn (µg/ℓ)	irrelevant	300-500	300-500
Cd (µg/ℓ)	irrelevant	1-1.5	0.5-3
Cu (µg/ℓ)	irrelevant	30-40	5-40
E.coli (100 ml^{-1})	10^7-10^8	irrelevant	10^3-10^4

* These values should be multiplied by a factor (about 1.5-3) dependent on the return period for the design event.

Apart from source control such as soil infiltration, the possibilities of pollutant reduction from stormwater runoff are limited. Since the 1950's almost all new developed urban areas in Denmark have been separately sewered. The situation today is that about 45% out of a total of about 750 km^2 effective urban areas have separate sewers. The need for control of stormwater runoff pollutants discharged is a question of the absolute as well as the relative amount of pollutants coming from these sources compared with CSO's and dry weather sources like wastewater treatment plants. Furthermore, receiving waters like lakes, and to some extent streams and estuaries, need to have loadings of nutrients and eventually heavy metals from SWR reduced in order to improve water quality. The reduction of nutrients in the daily flow from the wastewater treatment plants to 8 mg total N/ℓ and 1.5 mg total P/ℓ effective from 1993 will increase the need for reduction of the wet weather sources.

Also, it is important to appreciate that most lakes in Denmark are phosphorus and not nitrogen limited and that the urban non-point phosphorus sources play a relatively more important role than nitrogen if compared with rural non-point sources (Hvitved-Jacobsen, 1986). Therefore, it is often seen that if a reduction of phosphorus stormwater loadings especially to urban lakes was possible, the receiving water quality might improve.

It must be emphasized that no single control strategy is the complete answer for improving receiving water quality in terms of nutrient and heavy metal impacts. Removal of these pollutants from SWR in detention ponds is probably one of the few realistic possibilities that simple control devices can achieve. Also it should be mentioned that nutrient reduction from SWR should be decided based on site specific investigations and needs and not required generally.

The concept of wet detention ponds

The concept of detention ponds in separate sewered catchments as a stormwater quality control measure is new in Denmark. As far as the author knows the first detention pond designed for urban runoff pollutant removal is now under construction and will be put into operation in December 1989. Traditionally, these ponds have been employed for flood and flow control only. Although design procedures for detention ponds with the dual purpose of stormwater quality and quantity control have been proposed, the basis for design and operation is still not well known (Ellis, 1985; Urbonas and Ruzzo, 1986).

The purpose of this paper is to highlight pollutant removal in detention ponds and discuss current practice for engineering design and operation procedures for these ponds from a Danish point of view. It is important to stress that the actual design procedure is rather crude. More research is needed - especially concerning physical, chemical and biological processes for pollutant removal and accumulation - in order to obtain the fundamental basis for improved design criteria. Also the hydraulics of these detention ponds determined by the inflow and outflow structures, the pond geometry and operation during wet weather periods must be taken into account in order to simulate long term pollutant removal efficiencies based on a historical rainfall record.

The main characteristics for the detention ponds which will be discussed in this paper is the existence of a permanent water volume during inter-event dry periods between successive storms. Therefore, these detention ponds are referred to as wet. Due to this permanent water volume, pollutants in the stormwater runoff are given a residence time before discharge to receiving waters determined by runoff and pond characteristics. Pollutant removal from the water phase by degradation and accumulation in the sediments and plant biomass may take place and thus reduce pollutant mass loadings to receiving water bodies.

Different systems for wet detention ponds can be proposed. Two types are shown in figure 1 and 2 (Cowiconsult, 1989). In the following, emphasis will be given to design characteristics for the type shown in figure 1.

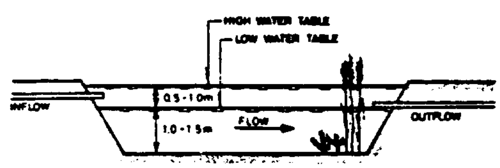

Fig. 1 Principle of a wet detention pond with horizontal flow. Submerged plants as well as marsh plants may be present.

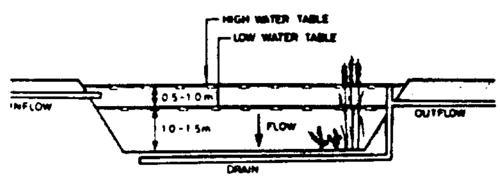

Fig. 2 Principle of a wet detention pond with vertical flow through a stone filter bottom. Rooted plants may be present.

A wet detention pond as a pollutant trap

It is well known that loadings of nutrients, heavy metals and organic micropollutants can accumulate in lakes. The lake sediments particularly act as a pollutant trap and under proper conditions in the water phase and in the sediments an essential part of the loadings may be permanently retained. Furthermore, nitrogen may be partly nitrified and denitrified resulting in a removal from the entire lake system.

It is important to realize that the removal processes taking place in a lake system have also been found to be effective in wet detention ponds (Hvitved-Jacobsen et al., 1984). Therefore, it is obvious to use these pollutant removal processes as a principle of treatment for urban stormwater runoff by the establishment of wet detention ponds. It is a fundamental requirement that these ponds should be considered as treatment facilities and therefore designed and operated based on an optimal function of the removal processes.

In addition it should be mentioned that these wet detention ponds may be effective in case of an accident in the catchment area, e.g. spill of oils and chemicals, which otherwise would result in harmful effects to the receiving water system.

Background for wet detention pond design

The basis for the design procedure which will be discussed in this paper is a result of national investigations as well as experiences from other countries, especially the US. The first Danish investigations in a pond system receiving stormwater runoff were carried out near Copenhagen during the period 1979-80 (Vandkvalitetsinstituttet, 1981). These investigations were oriented towards the loading-effect relationships and not performed as a basis for wet detention pond design. Until now only one Danish investigation include this concept (Hvitved-Jacobsen et al., 1987). From this investigation the general conclusion was as follows:

> For a wet detention pond with a surface area of approximately 1.4% of the effective catchment area the mass removal in the pond for SS, tot.P, Zn, Cd, Pb and Cu varied between 45 and 90%. These findings were based on the study of 10 storm events routed through the pond which - accidentally - through 10 years has been in operation as a stormwater wet detention pond. A study of the upper 12 cm of the

VOL 12

8158

R0041464

sediments and the interstitial water verified that accumulation of phosphorus and heavy metals took place.

Available knowledge from other investigations has also been useful for the development of design principles. Especially the reported studies in USEPA (1983) and USEPA (1986) should be mentioned. These publications summarise several useful investigations.

Design principles

In the following, design principles and criteria for wet detention ponds with horizontal flow will be outlined and discussed. The following details will be emphasized:

- Wet detention pond volume
- Water depth and variations
- Eutrophication and plantation
- Establishment of a catch basin
- Specific pond characteristics

Wet detention pond volume

The fundamental criterion for determination of the pond volume is to achieve sufficient residence time for the pollutants in the pond in order to allow removal processes to take place. These processes include a great number of physical, chemical and biological processes like sedimentation, adsorption, biological uptake and particle exchange processes in the water phase as well as in the sediments. The relative importance of these different processes are not sufficiently known today but will probably play an important role for determination of a sound design principle in the future. Pollutant removal equations have been proposed e.g. the following based on first order kinetics by Goforth et al. (1983):

$$R = R_{max} (1 - \exp(-k \cdot t))$$

where R = pollutant removal efficiency
R_{max} = maximum removal efficiency
k = first order removal rate
t = treatment time in the pond

Due to the lack of available information on process design, rather crude criteria to achieve sufficient residence time in the pond have been proposed. In USEPA (1986) a pond volume of 100-200 m³ per effective hectare of catchment area is recommended in order to obtain an average value of 60% removal for phosphorus.

VOL 12

8159

R0041465

Observed mass removal of total phosphorus and suspended solids in wet detention ponds can be correlated with the ratio of detention pond volume to runoff volume from mean storm events as shown in figure 3 (USEPA, 1986 and Hvitved-Jacobsen et al., 1987). From these investigations it is seen that the residence time for the runoff water - and the associated pollutants - play an important role for the determination of the pond volume.

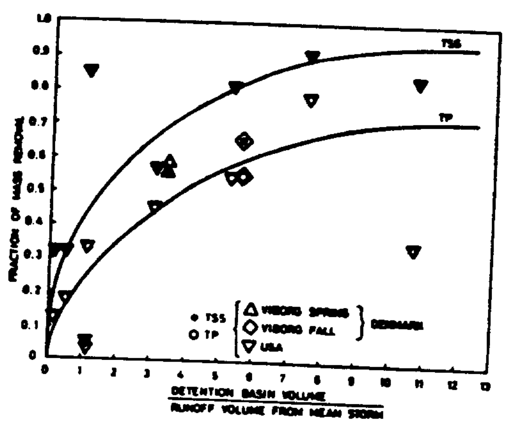

Fig. 3 Mass removal for total phosphorus and suspended solids versus the ratio of detention pond volume to runoff volume from mean storm events. Results from the Danish investigation (the city of Viborg) are compared with the results from 8 different wet detention ponds in the USA.

In order to obtain sufficient residence time for pollutant removal in a wet detention pond it seems important as a basic criterion to ensure sufficient length of an inter-event dry period between successive rainfall events. The rainfall record for the city of Odense, Denmark, was used for this purpose (Johansen and Harremoës, 1979). This series contain complete rainfall data for 33 full years i.e. the total of 1571 storm events with rainfall depths ≥ 3 mm. It is believed that rainfall events < 3 mm will have only a marginal effect on the pollutant removal efficiency. Figure 4 depicts rainfall depths for inter-event dry periods between 2 and

VOL 12

8160

96 h and for low return periods between 3 months and 3.3 years (Hvitved-Jacobsen and Yousef, 1988). Based on observations it seems reasonable to select about 72 h as a minimum inter-event dry period to allow sufficient time for pollutants removal (Hvitved-Jacobsen et al., 1984 and Yousef et al., 1986). If in addition a 4-6 month return period for exceeding the inter-event dry period is accepted for designing detention ponds, 250-300 m^3 per effective hectare should be recommended for a wet detention pond. Based on investigations and model computations this volume is for example expected to result in about 60% removal of phosphorus (Hvitved-Jacobsen et al., 1987 and Toet et al., 1989).

It should be mentioned that the curves shown in figure 4 are sensitive to the choice of the 3 mm rainfall depth limit for the rainfall record. If the hydraulics of the detention pond is known, probably different curves would be obtained if the runoff water was routed through the pond. However, it seems important to obtain inter-event dry periods with minimum disturbance of the water column - except for small runoff events corresponding to < 3 mm of rainfall depth and wind induced mixing - in order to ensure quiescent conditions in the water phase for improved particle sedimentation.

Moreover, it is important to note that the design procedure proposed does not directly allow consideration of physical, chemical and biological reactions or hydraulic factors in the design criterion. These matters will be emphasized in subsequent studies.

<u>Water depth and variations</u>

Because of the required retention of nutrients (phosphorus) and heavy metals in the sediments of a wet detention pond, aerobic conditions in the water phase and in the top layer of the sediments should be predominant. Furthermore, for aesthetic reasons and to maintain an acceptable level of aquatic life, the dissolved oxygen concentration should be recommended > 4 mg O_2/ℓ.

Due to the demands for an acceptable dissolved oxygen level a fairly shallow detention pond should be recommended. Also this corresponds for security reasons with the intention to let these ponds form parts of recreational facilities in city areas. A maximum water depth under steady state dry weather conditions equal to 1.0-1.5 m should be recommended.

During a runoff event this steady state level will increase. The need for detention capacity versus flow from the detention pond is shown in figure 5 for low

VOL 12

8/61

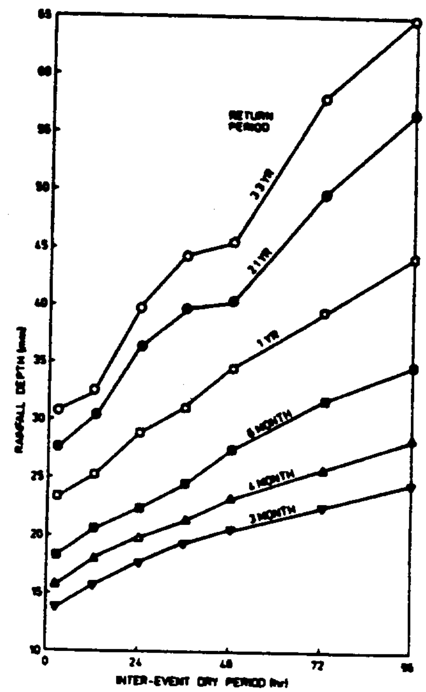

Fig. 4. Rainfall depth - inter-event dry period - frequency curves for low return periods based on the Odense rainfall record.

return periods for exceeding design capacity (Spildevandskomiteen, 1984). As can be seen in figure 5 moderate outflow rates from the pond and return periods about 0.5 year require in addition to the steady state dry weather volume about 100 $m^3 \cdot eff.\ ha^{-1}$. Therefore, during wet weather the total water depth may vary temporarily up to 1.5-2.5 m before overflow from the pond takes place.

What has been mentioned should just be considered as typical levels. For each case specific demands should be taken into account and calculations carried out.

As an example tha dissolved oxygen variations in a wet detention pond should be discussed based on the following conditions:

- Water depth 2 m.
- Reaeration rate from the atmosphere at low wind speed (0-3 $m\cdot s^{-1}$) immediate above the water surface at 20 °C:

  low: $K_L = 0.2\ m\cdot d^{-1}$
  moderate: $K_L = 0.4\ m\cdot d^{-1}$
  high: $K_L = 0.6\ m\cdot d^{-1}$

  These values should under Danish climate conditions be considered as minimum values (Downing and Truesdale, 1955; Thibodeaux, 1979 and Aalderink et al., 1986).
- Sediment oxygen demand, SOD = 2 $gO_2\cdot m^{-2}\cdot d^{-1}$.

  In lakes SOD varies considerably (0.02-2 $gO_2\cdot m^{-2}\cdot d^{-1}$). High values are obtained during summer periods in eutrophic lakes.
- A zero order dissolved oxygen consumption rate for the water phase equal to 0.5 $gO_2\cdot m^{-3}\cdot d^{-1}$. This value should be considered as high.
- Summer conditions; i.e. 20 °C.

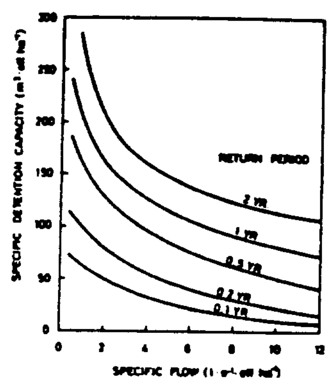

Fig. 5. Required specific detention capacity versus specific flow from detention pond for low return periods based on the Danish rainfall record from the city of Odense. The curves are valid for a full flowing runoff time < 20 min.

Based on a relatively simple dissolved oxygen model for a shallow, fully mixed pond, the following results have been obtained:

Under steady state conditions and based on three levels of reaeration rates (low, moderate and high), dissolved oxygen values of 0, 1.5 and 4 $gO_2 \cdot m^{-3}$ were calculated. For low and moderate reaeration rates a reduction from 7 to 4 $gO_2 \cdot m^{-3}$ should be reached after 2.6 and 3.9 days respectively. The importance of reaeration is therefore quite obvious. The assumption that the water phase is fully mixed need not be correct. Due to a relatively important SOD, the existence of a dissolved oxygen gradient even in a shallow pond might occur.

It is questionable whether wet detention ponds should be exposed to wind. In terms of dissolved oxygen the water quality - and the pollutant removal - should be improved. On the other hand particle settling would be impeded.

The importance of aerobic conditions in the top layer for retention of phosphorus and heavy metals will not be discussed in this paper. However, it should be investigated if low redoxpotential or associated drop in pH is important for sediment release of heavy metals.

<u>Eutrophication and plantation</u>

It should be stressed that a wet detention pond is a treatment facility. In spite of this it is important that eutrophication be suppressed as these ponds should be considered acceptable parts of a recreational area.

Because of heavy loads of nutrients to a wet detention pond eutrophication can cause a potential deteriorating effect. Especially the growth of phytoplankton should be suppressed. The growth pattern of the algae population is very dependent on the residence time in the pond system. Therefore, extended residence time supported by external as well as internal nutrients loads may cause increased concentration of algae biomass and a corresponding high primary production level. Therefore, with respect to the detention pond volume an efficient pollutant removal design criterion may come up against requirements for a low eutrophication level.

In order to evaluate the functioning of these detention ponds with respect to optimal conditions for both efficient pollutant removal and low eutrophication level a simulation model, POND, was developed (Toet et al., 1989). The following goals for the model were set:

- Development of a numerical simulation and eutrophication model for a wet detention pond which includes the removal of suspended solids, phosphorus and heavy metals.

  As for pollutant removal the model was calibrated on data originating from previous investigations (Hvitved-Jacobsen et al., 1987). Parameters and rate constants important for the eutrophication process were selected according to values from eutrophication models for shallow waters (Nyholm, 1978).

- To find design characteristics for a wet detention pond dependent on pollutant removal efficiencies and eutrophication.

From the Odense rainfall record the following three years were selected for the model simulations:

1971: Normal annual total rainfall and wet summer
1976: Dry year and dry summer
1979: Normal annual total rainfall and normal summer

In figure 6 pollutant removal efficiences versus the pond volume per effective hectare are shown. It can be concluded that the pollutant removal obtained from the simulation curves correspond well with previous expectations (Hvitved-Jacobsen and Yousef, 1988). I.e. 250-300 m³ of detention pond volume per effective hectare is still

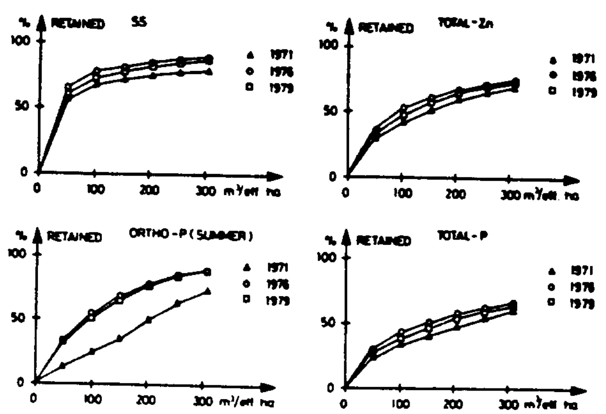

Fig. 6. Mass removal efficiencies for pollutants versus specific pond volume in the model detention pond.

recommended as seen from a pollutant removal point of view.

Results from the simulations of variables and processes related to eutrophication in the model detention pond are shown in figure 7.

The general conclusion is that for detention pond volumes between 100 and 300 m³·eff.ha⁻¹ the main eutrophication variables and processes are almost independant of the pond volume although a minor variation in the yearly mean value may take place due to the rainfall pattern. Therefore, eutrophication caused by phytoplankton should be considered as very likely in wet detention ponds designed for pollutant removal.

On the other hand rooted plants - both submerged plants and marsh plants - may have positive effects on the functioning of a wet detention pond. Especially under Danish climate conditions the risk for excessive growth should be considered as limited.

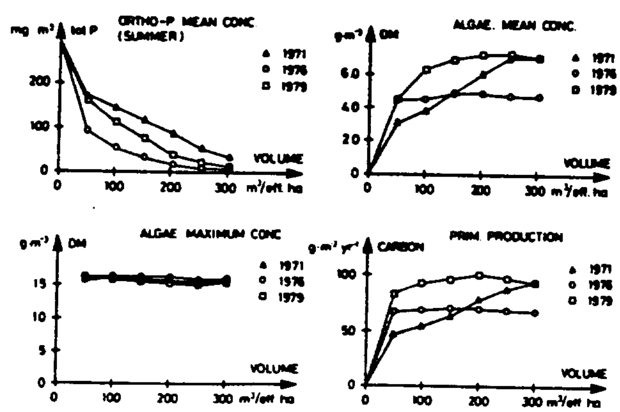

Fig. 7. Variables and processes related to eutrophication versus specific pond volume in the model detention pond.

The following should be taken into account:

- Rooted plants, especially marsh plants in clusters, will add to the recreational value of a wet detention pond.

- Submerged plants will result in dissolved oxygen variations during day and night. Provided that the plant biomass is limited, the dissolved oxygen conditions can be expected to be improved.
- Plants will improve the conditions for sedimentation of particles and reduce the risk of resuspension because of reduced wind exposure. An attendant phenomenon is a reduced reaeration rate.
- Plants will increase the active surface of the water system. Increased physical and chemical adsorption of e.g. colloidal particles and absorption in the biofilms may take place. Also direct plant uptake may be active in the pollutant removal process.
- Observations from Danish lakes have shown that the existence of macrophytes reduce the phytoplankton biomass.

These facts indicate that a limited vegetation of rooted plants is valuable in a wet detention pond. Partial removal of excessive vegetation might take place by hand and by means of special-purpose machines.

Establishment of a catch basin

Suspended solids associated with stormwater runoff roughly consist of large grit particles and small particles made up of organic as well as inorganic constituents. Pollutants are mainly associated with the small particles which might settle far from the inflow structure (Svensson, 1987).

It is observed that grit particles settle near the inflow structure and this part of the detention pond often needs more frequent maintenance than the rest of the pond. For this reason the detention pond should be recommended designed in two compartments. The basin close to the inflow of the stormwater is designed as a simple catch basin (grit chamber) in order to remove inorganic particles > about 0.1 mm. Design of this part should follow common design principles for simple grit chambers, e.g. based on a settling rate of 0.005-0.006 $m \cdot s^{-1}$, a mean storm intensity of 105 $\ell \cdot s^{-1} \cdot eff.ha^{-1}$ and a return period of 0.25 year. A hydraulic surface loading corresponding to 20 $m^3 \cdot eff.ha^{-1}$ for the catch basin should be recommended.

Specific pond characteristics

The following characteristics for a wet detention pond should be mentioned:

- The detention pond should be constructed with sloping banks for security reasons and in order to allow for vegetation along the banks.
- Soil infiltration can be reduced by using a membrane of plastic or clay.

  Investigations have shown that the heavy metals are retained in the upper few cm of the sediments in a detention pond (Yousef et al., 1984 and Hvitved-Jacobsen et al., 1987). Therefore, if a natural steady state dry weather water table can be established there is probably no need for a membrane.
- In order to reduce mixing between incoming stormwater and water in the pond, a length to width ratio of 3-4 should be recommended. Vertical diffusers placed at one of the short sides of the pond is a possible inflow arrangement.
- A sandy bottom layer is appropriate for the macrophytes to take root and to distinguish between original bottom and settled materials.

Maintenance and operation

A wet detention pond should be designed and constructed in a way that maintenance and operation are kept at a minimum level. Although given the present limited experience it is difficult to give recommendations in this respect, the following should be mentioned:

- Grit from the catch basin should be removed at least every second year. Therefore, access with vehicles to this part of the detention pond should be easy.
- Dredging of the sediments in the detention pond once every 10-20 years should be expected. Because of the heavy metal content the sediments should be proper disposed of. The amount to be removed corresponds to an increase in sediment depth of 0.5-1 $cm \cdot yr^{-1}$.

Example of a wet detention pond

The first wet detention pond based on the design principles shown in this paper is now under construction and will be in operation December 1989. The detention pond will be established in the catchment area of the city of Viborg mainly in order to reduce the phosphorus loadings on the urban twin-lakes (Hvitved-Jacobsen and Jensen, 1988).

VOL 12

8168

The detention pond which is shown on figure 8 and 9 is designed based on stormwater runoff from 16 effective hectares. The outflow from the pond will vary between 5 and 10 $l \cdot s^{-1}$.

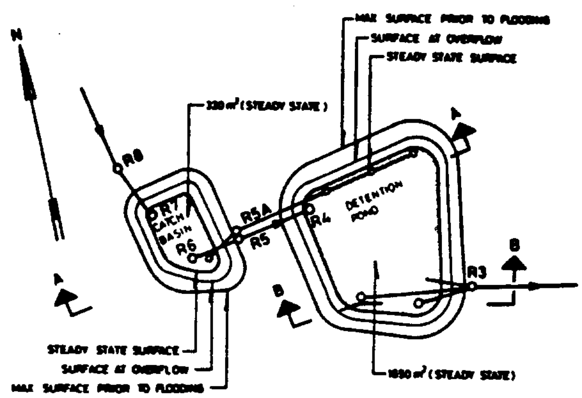

Fig. 8. Wet detention pond under construction in Viborg, Denmark.

Conclusions

Criteria for design and operation of wet detention ponds for pollutant removal from urban stormwater runoff are recommended. The minimum inter-event dry period between successive storms is proposed as a fundamental criterion in order to achieve sufficient residence time for pollutant removal in a pond. Because detailed information on the importance of the removal processes is not available, rather crude design criteria are proposed. Therefore, further investigations directed towards knowledge on the pollutant removal processes and the hydraulic properties should be carried out in order to improve the design principle.

Furthermore, it is important to notice that a wet detention pond is an integrated flood control and quality control structural measure.

The first wet detention pond established in Denmark based on the proposed design principle is under construction and will be effective late 1989.

Permeable Pavements for Stormwater Quality Enhancement

by Dr Christoper J Pratt.

Introduction

Natural, permeable ground surfaces occur in various proportions within urban areas and are usually assumed to contribute little, if any, stormwater runoff to urban drainage systems. In some situations the natural ground surface is graded and shaped to convey stormwater from roof downpipes and paved surfaces to a drainage inlet, situated within the permeable, landscaped area of an urban development, but again little runoff is assumed to be derived from the natural surfaces, except in the case of snowmelt conditions. Rain falling on these natural, permeable surfaces is deemed to infiltrate to groundwater, percolate through the upper soil horizons to a nearby watercourse; or be stored near the surface for subsequent evaporation; or to be taken up and used by plants in evapo-transpiration. In general, permeable surfaces contribute little to the problem of hydraulic overloading of urban drainage systems.

Several studies have shown that natural surfaces and the vegetation upon them may be effective at retaining pollutants as urban stormwater passes over them, and hence the quality of the stormwater discharging to receiving waters has been improved (Yousef et al., (1984, 1987)). The processes of sedimentation and adsorption occurring as stormwater flows over soil particles and plants provide a primary treatment, which may be enhanced over a period of time by natural chemical and biological degradation of the pollutants. Man-made, engineered permeable surfaces provide the opportunity to establish similar processes for urban stormwater.

In situations where the ground conditions permit deep percolation of stormwater, the discharge from such permeable surfaces may be to groundwater. However, even where such methods of disposal are not possible, use may be made of permeable surfaces, with suitable sub-structure, to provide peak flow rate control and

water quality improvements to discharges from the construction to an adjacent sewer or watercourse (Hogland et al., (1987); Pratt et al., (1988)).

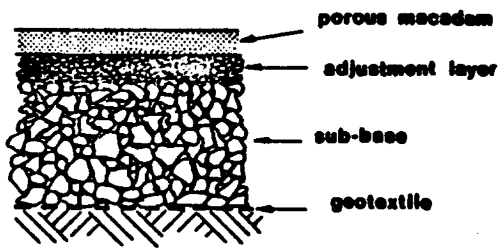

Figure 1 - Permeable pavement with porous macadam surface.

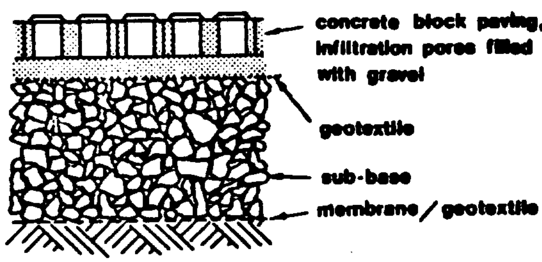

Figure 2 - Permeable pavement with permeable, concrete block surface.

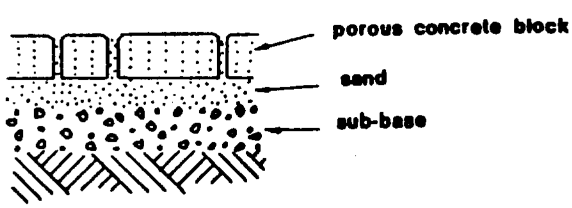

Figure 3 - Permeable paving with porous concrete block surface.

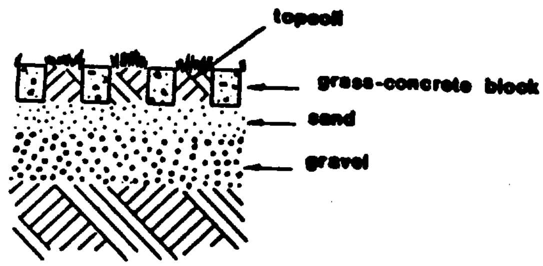

Figure 4 - Permeable pavement with 'grass-concrete' surface.

Engineered Permeable Surfaces

Two general forms of engineered permeable surfacing have been employed in Europe and North America: namely, porous macadam and interlocking concrete blocks, shaped to allow water to flow through spaces between and within the blocks. Both forms of surfacing have been installed over layers of free-draining material, usually clean crushed rock (see Figures 1 - 3). However, it has been more common for concrete block surfaces to be laid on a shallow bed of sand, with soil in the spaces between blocks, to facilitate the growth of grass (Figure 4). This latter form of construction has provided low cost surfacing, frequently for car parking, where problems of surface flooding which might eventually arise with gradual loss of infiltration through the surface could be assumed to be of limited importance. The grass on such surfacing has been seen as advantageous in aesthetic terms; in the context of environmental legislation where such surfaces have allowed the combination of commercial use with the achievement of a 'green' area provision within a development (e.g. requirement on industrial sites in parts of Denmark for 15% area to be 'green' i.e. landscaped with trees, shrubs, grass or grass-concrete); as modifying air temperatures (Smith, (1984)); and in maintenance of infiltration rates into the surface through the action of the grass roots.

The use of grass-concrete surfacing has been limited in the main to locations off the public highway, in situations where landscaping considerations were important and limited heavy commercial vehicle traffic was to be expected, which might destroy the low strength form of construction. Despite this possible limitation, grass-concrete has been shown to provide important water quality improvements to stormwater disposed of to groundwater, and the wider application of such surfacing has been called for in the U.S.A. (Day et al., (1981)).

VOL 12

8176

R0041482

With the exception of traditional stone setts and widely spaced concrete block paving which form a semi-permeable surfacing and one not originally designed for stormwater management (Jacobsen and Harremoes, (1982); van Dam and van de Ven, (1984)), it is believed that only in Japan has permeable or porous concrete, block paving been installed on the public highway for the purpose of stormwater management (see Figure 3: Fujita, (1984); Suda et al., (1988)). Pratt et al. (1988) have reported research, concerning the stormwater quality improvements produced in flow through permeable concrete block paving construction (as Figure 2), but that study had been located only on experimental car parking areas on private property.

Generally in public highway situations, porous macadam has been chosen as the form of engineered surface and experiments have been conducted in North America, Japan and Sweden (e.g. Goforth et al. (1984); Fujita (1984); Hogland et al.(1987), respectively). Stormwater entering through the macadam surface may flow downwards to leave the base of the construction and percolate to groundwater in suitable soil conditions. Where ground conditions do not permit deep percolation, sub-base drains convey the stormwater from the construction to a nearby sewer or watercourse. Field measurements of the quality of the sub-base drain effluent have been made by Hogland et al. (1987) for a site at Lund, Sweden, providing useful information on the water quality parameter changes occurring during through-flow.

Water Quality from Grass-Concrete Construction

Laboratory studies were conducted by Day et al. (1981) on three patterns of grass-concrete blocks, which each formed the surface of water-tight bins containing a typical subsoil and construction layers, totalling some 500mm depth (as Figure 4). The blocks were laid upon 50mm sand, over 150mm gravel, on top of soil. The voids in the concrete blocks were partly filled with topsoil and topped with grass sod.

At least ten rainfall events were simulated on each bin, covering a range of rainfall intensities and durations, and every effort was made to simulate identical events on each bin. Rain infiltrating the voids percolated to the base of the bins from where it was discharged. Artificial, polluted rainfall was applied and samples of water were taken from the outflow at the base of the bins. The approximate concentrations of Pb, Zn and Cr in the rainfall were 0.76, 0.55 and 0.07 mg/l respectively, and the percentage pollutant removals by flow through the grass-concrete construction, on both a concentration and mass basis are shown in Table 1.

The three grass-concrete/soil systems achieved significant removal of the three heavy metals analysed in the effluent, however, the removal of phosphorus forms was very variable and nitrate/nitrite were leached from the soil, hence producing

VOL 12

8177

increased presence in the discharge from the construction. Clearly, the soil characteristics have an important bearing upon the overall performance of these systems. Pb and Cr adsorption tended to increase with depth in the soil, whereas Zn was removed markedly better within the gravel layer above the soil, because of its alkaline nature.

The results of the laboratory study, though limited in duration, indicated the potential for such constructions within a stormwater quality management strategy. Such surfaces tend to concentrate pollutants and limit their rapid transfer to receiving waters. In this case, it was noted that the overland flow, which resulted solely from type B blocks, was only some 0.7% that from an equivalent impermeable concrete pavement under

the same rainfall regime, and hence any rapid tranfer of pollutants was extremely limited. Field measurements reported by Smith (1984) confirmed the very low overland runoff occurring on grass-concrete surfacing. Any long-term transmission of pollutants to groundwater has not been fully assessed, however, in field studies conducted by Malmquist and Hard (1982) no adverse effects were reported as detectable with disposal to ground of stormwater from residential and light commercial areas.

Water Quality from Porous Macadam Construction

An experimental site at Lund, Sweden, comprising a 470m² parking lot having a structure formed of a 50mm layer of porous macadam, over a 50mm adjustment layer of 4 - 25mm diameter crushed granite, itself overlying the sub-base formed of 13 - 80mm diameter crushed granite, was studied by Hogland et al. (1987) (as Figure 1). Overall the layers were some 500mm in total depth and were placed on a geotextile, which separated the construction from the underlying boulder clay, preventing the passage of fine particles into and out of the construction.

Hogland et al. (1987) reported the results of two snowmelt events on the parking lot; the second event being artificially produced by heaping snow on the experimental surface just prior to a thaw. Table 2 shows the results of chemical analyses of the snow and of the sub-base drain effluent. Generally the same trends in the results were seen in both the natural and the artificial events, except in the cases of phosphorous and copper. Concentrations of suspended solids, SS, total dissolved solids, TS, and the majority of the metals showed a reduction in pollutant concentration between the snow on the macadam surface and the drain effluent. However, there were increases in nutrients and chlorides, which it was suggested might be derived from previous agricultural practices on the site, or were due to the release of nutrients from the macadam and crushed granite themselves.

Pollutant Adsorption by Construction Materials

After one year the Lund experimental site was dug up during resurfacing work and samples of the construction materials were analysed for pollutant attachment. The amounts of pollutants (mg/kg dry weight) varied with depth in the construction but, in general, were highest at the level of the geotextile at the base of the construction (see Table 3). This was true for all but phosphorous, total dissolved solids, copper and cadmium. Lowest concentrations were more often observed in samples taken 250mm below the surface, in the crushed granite sub-base.

Comment was made that the observed pollutant concentrations were rather low in all the layers, which was attributed to the fact, that the permeable construction had been in use for only one year, and that a clay layer had accumulated on the surface due to the passage of construction traffic from adjacent areas, which had blocked the pores of the macadam and prevented entry of some stormwater. In practice, it is the question of operating life expectancy of permeable surfaces before blockage that has most concerned engineers. Nevertheless, the results from Lund suggest that the construction may store significant amounts of pollutants, particularly in the region of the geotextile to which level much of the fine particulate matter and associated contaminants were washed. The problems of blockage and the difficulties of cleansing to reinstate infiltration rates to the

surface lead to the assessment by Pratt et al. (1988) of a permeable concrete block paving alternative, which would prove easier, and therefore cheaper, to maintain.

Water Quality from Permeable, Concrete Block Paving

The paving blocks used by Pratt et al. were 200mm long by 100mm wide by 90mm high and were shaped to form a pattern of holes 25mm diameter, when the blocks were laid in the traditional herringbone arrangement. The concrete was formed in hydraulic-

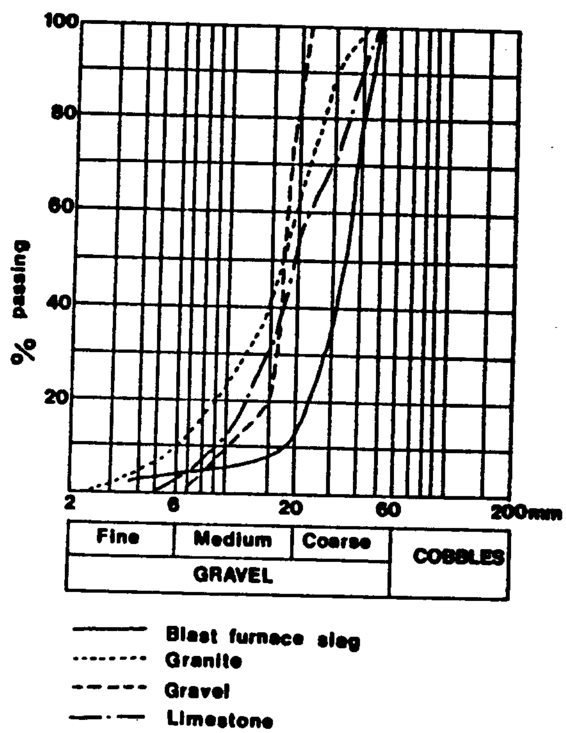

Figure 5 - Grading curves for sub-base stone used in permeable, concrete block paving (After Pratt et al., 1988).

press moulds using a semi-dry mix, which made the blocks themselves have very low water absorption characteristics, and hence low frost susceptability. The upper surface of the blocks had raised discs to carry vehicle tyre loadings preventing the compaction of material in the holes which would decrease infiltration rates. The blocks were laid on a 50mm bedding layer of 5 - 10mm gravel, which also filled the holes between the blocks (see Figure 2). As in the case of porous macadam constructions, the sub-base was constructed of free-draining stone. The gravel bedding layer was separated from the sub-base stone by a geotextile layer to prevent the movement of the gravel into the voids below.

The experimental site at Nottingham studied by Pratt et al. (1988) was similar to the porous macadam site at Lund in being effectively undersealed, preventing any deep percolation of stormwater from the construction. At Lund the boulder clay limited downward movement of water, whereas at Nottingham the construction was entirely sealed by an impermeable plastic membrane. In both cases, discharge from the construction via sub-base drains allowed samples of the effluent to be collected and analysed. Where the two experimental sites differed, apart from in the surfacing and in the construction layers, was that the Nottingham site was sub-divided into four sections, each some 40 m^2 in area, in which a different sub-base stone type was used, instead of the consistent use of granite throughout, as at Lund. The four stone types were gravel, blast furnace slag, granite and carboniferous limestone; grading curves are shown in Figure 5. Each of the stone types was entirely enclosed at its sides and base by an impermeable membrane, and stormwater discharge from the section took place via its own drain which passed through the wall of the membrane at a water-tight flange. The separate drains from the four sections were independently monitored and sampled for both water discharge and quality. Such an experimental set-up allowed assessment to be made of the effects of construction materials upon pollutant discharges, and of the different construction form as compared with that usual with porous macadam.

Short- and Long-term Variations in Pollutant Discharges.

The short-term variation of suspended solids and lead discharge from the permeable concrete block paving construction are illustrated typically in Figure 6 for a storm event on the limestone sub-base section of the car park. In the first months following construction the discharge of suspended solids was higher during an event, but after washout of some of the fine material from the sub-base stone itself, discharges of 40mg/l or less were typical, which was in marked contrast to the very varied concentration profile for impermeable surfacing discharges, illustrated in Figure 7 (Pratt et al., 1986). Similarly, the consistency of the lead concentration at 0.06mg/l, or less for the limestone sub-base, became the norm.

The four different sub-bases produced a range of water quality discharges, which were stone-type dependent. Effluent quality parameters, such as pH and alkalinity, could be reduced by design of the construction with blast furnace slag as opposed to limestone as sub-base. Similarly, reduction of effluent hardness and lead discharge could be achieved through selection of limestone in preference to blast furnace slag. The order of parameter change with stone type was limestone, granite, gravel

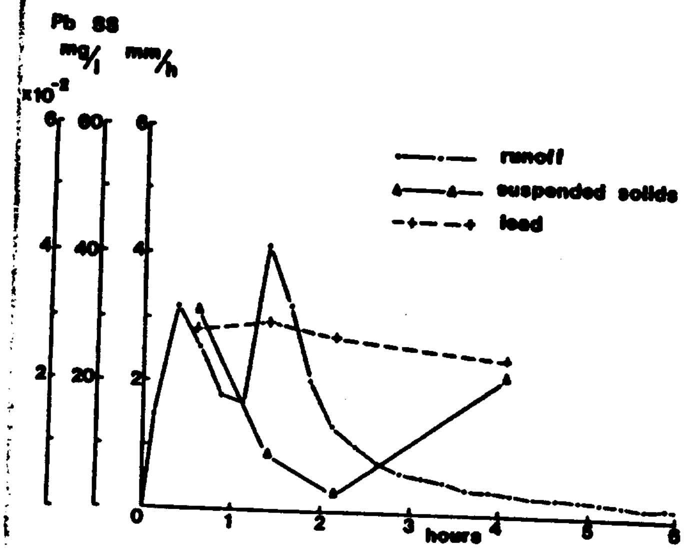

Figure 6 - Hydrograph and pollutographs for sub-base drain effluent from permeable pavement with granite sub-base.

then blast furnace slag. the direction of change depending upon the parameter of interest.

In the long-term. the various sub-base stone constructions showed small. slow variations with time according to stone type. suggesting some limited chemical degradation of the stone. Figure 8 shows the long-term characteristics for effluent from the granite and blast furnace slag sub-base sections. which illustrate the overall range displayed by the four stone types. Blast furnace slag effluent showed a gradual decrease in hardness over an eighteen month period. whilst both granite and blast furnace slag exhibited very slow decrease in conductivity. Suspended solids variation over the same period was limited to a range from near zero to 50mg/l. which was considerably less than is typical for impermeable surfaces with gully pot discharges to a sewer system. From impermeable surfaces. fluctuations in concentration from 30 to 300mg/l occur frequently during storm events: peak concentrations of some 1000s mg/l are not uncommon: and no two events need be similar. since antecedent conditions and the actual storm characteristics determine solids washoff.

Hence, an important feature of permeable pavements is that the effluent discharge quality shows far greater stability in both value and range of pollutant concentrations, in both the short and the long-term.

Laboratory Studies of Long-term Performance

The permeable construction using blast furnace slag, granite and limestone was modelled using a series of interlocking plastic rings, 110mm high by 110mm deep, so that the structure could be dissected and the pollutant deposition at various levels investigated (see Figure 9). The permeable concrete block paving was not included in the models for this study. Urban stormwater runoff from traditional impervious surfacing was collected and used to simulate the equivalent of ten years of rainfall on the permeable surface of each model. The 'rainfall' was applied over several days by pump, drawing from a continuously stirred container of stormwater. No attempt was made to simulate the periods of drying between storms, hence any caking of sediment deposits was not reproduced. The model study aimed to investigate where and in what proportions pollutants were retained by the construction.

The results for total sediment accumulation in the three models are shown in Figure 9. The sediments were washed and filtered from each section following the application of ten year's rainfall. In the case of the blast furnace slag and the limestone a half or more of the total dry weight of sediments was found in the gravel bedding layer, however, for the granite a relatively even distribution of sediments was discovered. The sub-base stone in all cases was not pre-washed before building the models, and the results reflect the initial sediment content of each stone type.

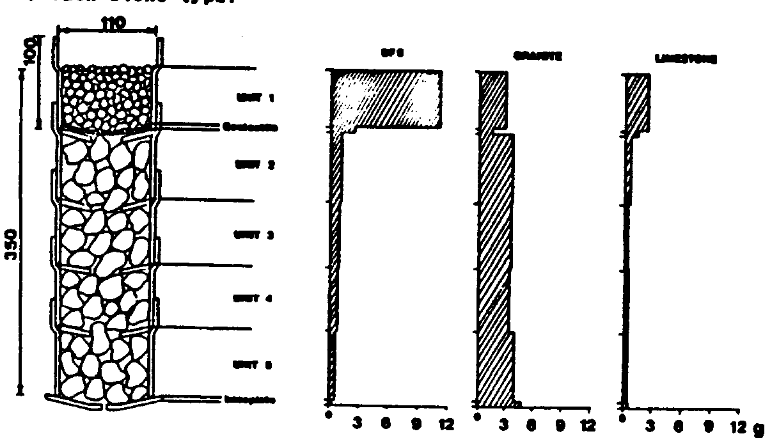

Figure 9 - Weight of fine sediment accumulated on each layer of the section of the model permeable pavements.

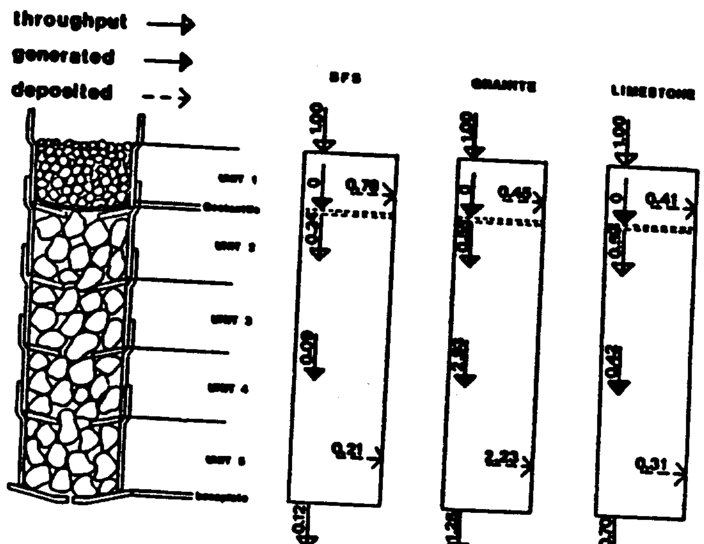

Figure 10 - Sediment balance calculations for model sections of permeable pavement from 10 year's throughflow.

Figure 10 shows the mass balance calculations for sediment in the three models on the basis of unit input of sediment in the rainfall. Again the influence of the initial sediment content of the stone as delivered is evident for the granite, where nearly three times the quantity of sediment was generated from the granite surfaces as was input with the rainfall). However of this internal sediment, most (i.e. 2.23/2.93 = 76%) was retained in the construction, although some did contribute to the increase of sediment discharge over rainfall input by some 25%. This result was not as bad as might appear at first sight, since the nature and pollutant content of the output sediment was different from that input at the pavement surface. The limestone model also demonstrated the internal generation of sediment, where some 13% of the output sediment was derived from the sub-base stone. Only in the case of blast furnace slag, a relatively clean stone with high resistance to abrasion and chemical degradation, was there no contribution to the output sediment from the stone itself i.e. the sub-base was a sink for sediments.

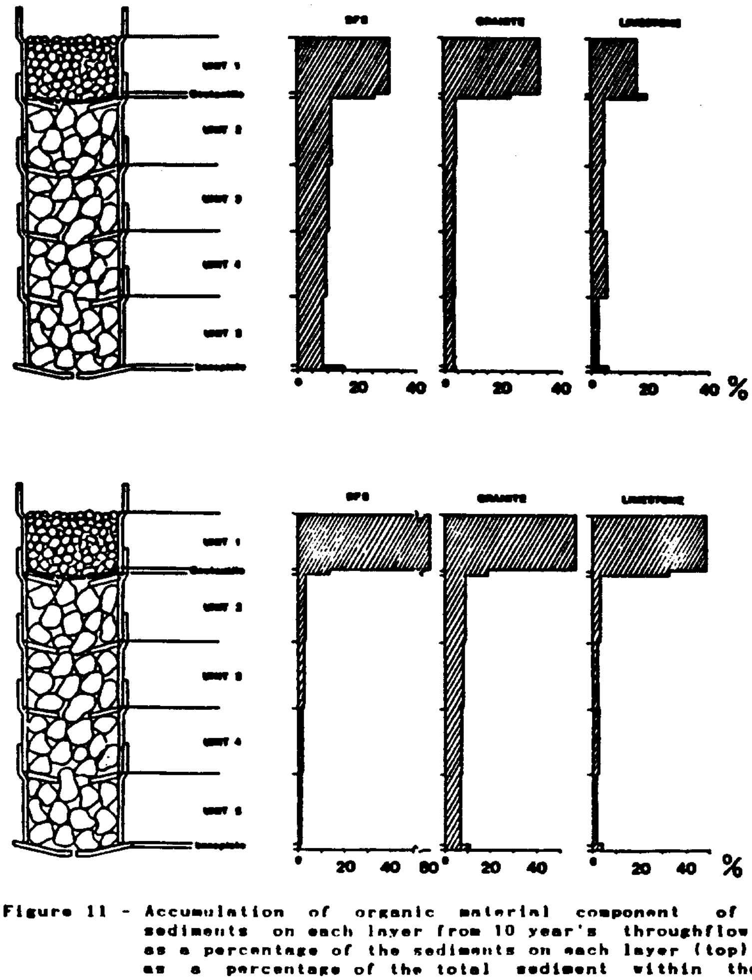

Figure 11 - Accumulation of organic material component of sediments on each layer from 10 year's throughflow: as a percentage of the sediments on each layer (top); as a percentage of the total sediment within the total model section (bottom)

It is unclear why the three gravel layers performed differently in sediment trapping above the geotextile layer. However, the general conclusion that absolute sediment discharge from the construction may be affected adversely by the condition of the sub-base stone at delivery is believed to remain true.

The belief that the output sediments were different from those in the rainfall input is supported by the evidence on Figure 11, where the percentage of organic material in the sediment found on each layer of each model is presented. The organic material is believed to have been solely derived from the applied stormwater and it is clearly illustrated that, below the geotextile layer, the sub-base stones have a relatively constant, low percentage of organic matter throughout the depth of the construction, the percentage being considerably less than that occurring in the gravel layer: unlike the results in Figure 9. Furthermore, if the amount of organic material in each section of each model is displayed as a percentage of the total organic material in a model, the significance of the gravel layer in the accumulation of sediments from stormwater is demonstrated.

The significance of the gravel layer is further illustrated in Figure 12 for the accumulation of lead per gramme of sediment in each layer.

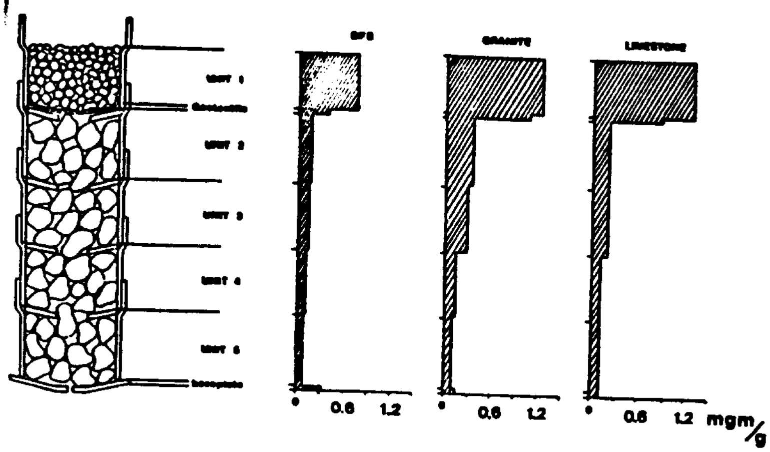

Figure 12 - Accumulation of lead on sediments on each layer from 10 year's throughflow as a proportion of the sediments on each layer.

Permeable Surface Blockage

Both field and laboratory data of inlet blockage have been collected on the Nottingham permeable concrete block paving. The field experimental site was modified in May 1988 and advantage was taken to remove samples of both the gravel bedding layer and the underlying geotextile to assess sediment blockage. Also in February, May, August and November 1988 samples of the gravel in the inlet holes in the block paving were removed and sediment content measured (see Table 4).

Laboratory tests were conducted on samples of the geotextile to determine the sediment content to cause blockage. Blockage was defined to exist when under an initial head of 50mm stormwater, the water had not completely drained through the geotextile in 24 hours. Two sets of stormwater samples were used: gully pot liquor containing both organic and inorganic particles; and liquor from the washing of gravel to remove essentially inorganic silts. The content of sediment in the geotextile specimens to cause blockage was:

for gully pot liquors, 0.060 g/cm^2 organic/inorganic sediment

for gravel washings, 0.094 g/cm^2 inorganic sediment.

The more varied nature and size of particles in the gully liquor presumably produced a more densely packed layer which required less mass of material than in the case of the more uniform inorganic particles to cause blockage. Without the geotextile to retain particles the gravel could not be blocked, as a steady state became established between episodes of deposition and washoff of particles from the gravel layer.

A laboratory model of the complete surface structure, including concrete block, gravel and geotextile, was tested to monitor the deposition of sediments at various levels below the surface. After the equivalent of ten years' rainfall from gully pot liquor applied to one inlet hole, the model was taken apart and the sediment content of the gravel in the inlet hole and in the gravel bedding was measured. Figure 13 shows the results. The upper half of the inlet hole had 0.95% sediment (by weight) as a percentage of the gravel content; the lower half 0.65%; the top half of the bedding layer between 0.5 and 0%, fanning out from immediately below the hole; the bottom half of the gravel bedding layer between 0.6 and 0.2%, similarly fanning out; and the sediment content of the geotextile was 0.007g/cm^2. As the model allowed for inflow through only one inlet, the interaction of adjacent sediment inlets was not reproduced, however, the model did suggest that sediment was transported with stormwater inflow throughout the surface structure, and failure of stormwater to infiltrate the surface could not be assumed to be caused by simple blockage of the inlet holes by sediment. There was the

possibility that the failure was caused by:
a) blockage of the geotextile with sediment content of the order 0.05 to $0.1 g/cm^2$, according to the nature of the sediment;
b) blockage of the entire gravel bedding layer by sediment, thus preventing the movement of additional sediment from the inlet. Further sediment deposition on the surface of the block paving then might not enter the inlet holes and its fate depend upon the use and characteristics of the site e.g. whether wind forces dispersed deposits, or not, in which case they might accumulate to a level at which vehicle tyre loads compacted them, sealing the inlet holes to stormwater.

Overall, it would appear that failure of the permeable concrete block paving to infiltrate stormwater would be the result of general filling of the gravel bedding and inlet holes until sediment was caused to be stored on the surface. From that time, it would require the natural packing of sediment inside the inlet holes to be disturbed by externally applied loads from vehicle tyres to determine eventual failure. Before failure the geotextile and the accumulation of sediments in the gravel layer would generally impede movement of sediments into the sub-base.

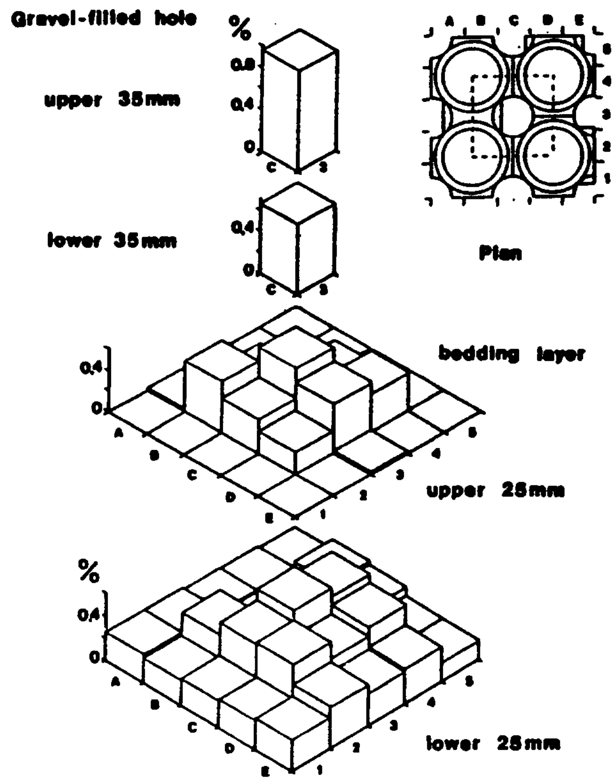

Figure 13 - Sediment accumulation at depths within the gravel-filled hole and bedding gravel as a percentage by weight of the gravel sampled in the surface layers of permeable, concrete block paving.

This action would become more efficient with time, increasing pollutant concentration near the surface.

Remedial Works to Reinstate Surface Infiltration

The field observations (see Table 4) and the latter model suggest that the stormwater movement of sediment through the gravel in the inlet holes would maintain a sediment content of some 1 - 1.5% (by weight) in the gravel. The need for remedial works on the surface structure to avoid problems of poor infiltration might be forewarned by sediment contents increasing markedly above this range.

The remedial works would involve the lifting of the concrete blocks and their stacking for re-use; the removal of the bedding gravel and geotextile layer for safe tipping in view of their pollutant content; and the placement of new geotextile, new gravel and the block paving over the original sub-base structure.

Experience suggests that the work can be quickly and, therefore cheaply, undertaken. The cost of new materials is small relative to labour and machine costs, which are themselves kept to a minimum by the ease of access to the working area.

Unfortunately, the remedial works required on porous macadam constructions to reinstate surface infiltration rates are not so straightforward. The macadam surface requires machine excavation and, because the passage of sediments into the sub-base is unrestricted, the possibility exists that in some cases the sub-base may cease to be free-draining and require replacement. Hence it may be anticipated that there will be higher costs for reinstatement per unit area with porous macadam.

The effective lifespan of either form of surfacing is difficult to assess as external factors dominate performance. Examples of early failure have been reported (e.g. Hogland et al. (1987)), due to high rates of material deposition on the surfaces by natural or human actions. Under the conditions existing at the Nottingham sites of permeable concrete block paving, where no surface sweeping or maintenance was conducted but the general area was well-established with little erodible soil in the vicinity, it was estimated that the lifespan of the surfaces was of the order of 15 years before remedial works.

Hydrograph Attenuation and Discharge Volume

The absolute effects on pollution discharge from permeable pavements have been outlined above, however, these constructions have the additional benefits that they reduce the rates of stormwater discharge and total volume, even when connected via sub-base drains to a storm drainage system. Hence the total mass of pollutants discharged may be reduced.

R0041501

A typical rainfall-runoff plot for the permeable concrete block construction is shown in Figure 14: runoff was monitored at the sub-base drain outfall. In comparison with traditional impermeable surfaces there was an increased 'initial loss' i.e. surface wetting, depression storage, etc. before runoff commenced - some 6.5mm (30% rainfall) as compared with around 1mm, traditionally. Routing of stormwater through the permeable construction attenuated the hydrograph, extending considerably the period of discharge by many hours beyond the end of rainfall. Impermeable surfaces commonly discharge almost all runoff within the storm duration, whereas here only some 42% (9mm) of the 21.6mm rainfall was discharged in this period.

After 9 days without rainfall for a storm over the limestone sub-base pavement, the 'initial loss' before runoff was 9.5mm for the event illustrated in Figure 15. Only 16% (1.8mm) rainfall was discharged within the storm duration, and only a further 27% (3mm) of the total rainfall ever flowed from the construction.

Comparing the total discharge volumes from the permeable construction, using different sub-base stone types with total rainfall in a typical 30-day period, has produced percentage runoffs for the four different sub-base stone types: blast furnace slag 55%; limestone 61%; gravel 63%; and granite 75%. The difference between total rainfall and the total discharges was the water held long-term in the construction, which wholly or in part evaporated before the next storm event. The blast furnace slag had a honeycomb surface texture which could "pool" water, in addition to the water held at points of stone contact and in general surface wetting. The limestone had a rough surface which was slightly porous, hence surface wetting and stone contact storage characteristics dominated discharge response. The gravel had a smooth, non-porous surface which, when wet from a previous event, could transmit flows moderately quickly to the sub-base drain. The grading of gravel employed in the Nottingham study had a relatively large total stone surface area and a large number of stone to stone contacts, hence following a dry period this sub-base was able to retain moderate amounts of rainfall in surface wetting and at stone contact points. The granite sub-base was a coarse grading of impervious, smooth-surfaced, angular stones resulting in the poorest rainfall retention characteristics.

Conclusions

Field and/or laboratory studies of stormwater discharge from the three types of permeable pavement - grass-concrete, porous macadam and permeable concrete block paving, have in each case demonstrated valuable reduction in pollutant discharges. The forms of construction have been found to retain pollutants and, by virtue of the total discharge volume reductions occurring with these structures, the total pollutant mass transfer to downstream receiving waters has been shown to be significantly reduced.

Two principal mechanisms of water quality enhancement exist in permeable pavements: sedimentation/filtration; and chemical adsorption upon materials within the structures. The selection of appropriate materials at the design stage would allow particular attention to be given to specific site stormwater pollutant removal. The accumulation of sediments must be accepted as essential to the overall effectiveness of permeable pavements in stormwater quality management, and designs adopted which facilitate remedial works at suitable intervals.

Permeable pavements are most advantageous when used over large plain areas, intercepting rainfall at source. The elimination of surface streams on permeable pavements minimises flow velocities and flow paths available for the stormwater entrainment of surface pollutants.

The above features of permeable pavements mean that they offer wide scope for a range of strategies in stormwater management.

1) In appropriate ground conditions it may be possible to dispose of stormwater to groundwater on site.

2) Otherwise, with the enhancement of effluent quality, sub-base drains from porous macadam and permeable concrete block paving constructions may be connected directly to an adjacent watercourse.

3) Because discharge rates are reduced and may be further modified by real-time control mechanisms at the outfall from the construction, it is possible to discharge to treatment works at times of low flow for further improvement in quality before final discharge.

4) The large storage capacity in permeable pavements with stone sub-bases having large void space offers the opportunity for water re-use for on-site irrigation and appropriate 'grey' water purposes.

SWEDISH WAY TO STORMWATER ENHANCEMENT BY SOURCE CONTROL

by Janusz Niemczynowicz[1]

Introduction

Stormwater attenuation methods were introduced in Sweden primarily in order to avoid flooding, give relief to overloaded severage systems and to reduce combined sewer overflows. Recognition that source controls enhance stormwater quality has only come recently as a result of increasing environmental awarness.

The costs of wastewater and stormwater management are growing fast in Sweden as well as in many other European countries. The reason for this is that the oldest parts of the sewagerage systems, constructed in the beginning of the nineteenth century, are getting old and urgently need renovation. New suburban areas are connected to already overloaded severage systems. Both reasons result in significant reduction of water treatment efficiency, which contributes to the further environmental degradation of surface waters. The total yearly cost of urban water management in Sweden was calculated to be about nine billion Swedish Crowns for the year 1988 (Falk, 1989).

People in the urban communities are not inclined to accept the tax increases needed for an improvement of water management, nor will they accept further degradation of the environment. Hence, more efficient, powerful and cheap methods of water management in cities must be developed.

The idea of separation of waste- and stormwater systems in cities in Sweden was abandoned during the early 1980's, since it was realized that it is economically unacceptable

---

[1]Professor-in-Charge and the Chief of the Department of Water Resources Engineering, University of Lund, Box 118, S-22100 Lund, Sweden.

and technically insufficient to prevent a further degradation of water quality in receiving waters. The cost of separation of wastewater and stormwater systems in Sweden was estimated to be 100 billion Swedish Crowns in the year 1982 (Darte et. al., 1982). Many examples showed that the separation was wrong from an environmental point of view (Malmquist and Svensson, 1977; Malmquist, 1983; Malmquist and Hård, 1982; Carlson and Falk, 1977; Hogland and Niemczynowicz, 1980; Niemczynowicz, 1989). The only real benefit of such separation is the elimination of combined sewer overflows. However, the total pollution loads from the city would hardly be reduced. The risks of toxic effects on ecologic systems in rivers during heavy rainfalls could be increased.

The local disposal of stormwater before it enters sewage systems seems to many people one of the most reasonable ways to avoid overloading the system.

During the past decades, the use of detention ponds and lakes for stormwater attenuation was popular in Sweden and a number of such facilities exists, mainly in scarcely populated urban areas. However, construction of open detention basins and ponds in densely populated areas is restricted for safety reasons. According to Swedish Construction Regulations (Svensk byggnorm), the open detention ponds must be protected by a 0.9 m high fence if the water depth is more than 0.2 meters (Stahre, 1981). Thus, the number of open detention ponds is not increasing, and the inlet controls consist mainly of various kinds of infiltration and percolation facilities. The method of forced infiltration of storm- and sanitary waters from single homesteads has been used in Sweden for a long time. More systematic use of infiltration and percolation facilities for stormwater disposal on a larger scale began in early 1970's. Several hundred facilities have now been installed.

The utmost extension of the infiltration idea is constructing permeable pavements instead of the traditionally impervious surfaces of streets, parking lots etc. This idea was put into practice in Sweden and a permeable pavement construction, the so-called Unit Superstructure, was developed. During the last ten years, the number of residential areas where pavements have been constructed as permeable Unit Superstructure has grown to about 35, and the number of single surfaces constructed using permeable pavement is now about 300-500. About 100, 000 m^2/year of roads using permeable asphalt types is constructed in Sweden at present. Totally about 7,000,000 m^2 of permeable roads has been already constructed (Hogland, 1989a, b).

Many problems in Swedish cities are created by groundwater depletion caused by fast runoff of rainwater from impermeable surfaces and by groundwater drainage to the conduits. Groundwater depletion in many urban areas in Sweden leads to land subsidence and buildings are damaged due to settling. Repair of buildings damaged by settling costs a considerable amount of money every year in Sweden. All these problems, as well as problems connected to the fast runoff from urban areas would be diminished if traditionally impermeable surfaces could be made pervious.

Infiltration and percolation

The first studies of the effects of stormwater infiltration on groundwater quality were performed in the early 1980's in three locations including the residential, industrial and highway areas in mid-western Sweden (Malmquist and Hård, 1982). The studies showed that there was no significant increase of the nitrogen and phosphorus in groundwater downstream from the infiltration points. The concentrations of heavy metals in groundwater were also, with the sole exception of copper, not influenced. The overall conclusion of the studies was that infiltration of stormwater affects the groundwater quality only to a small extent. This investigation did not claim to give an absolute answer, but nevertheless it gave the "green light" for constructing all kinds of infiltration and percolation facilities, open asphalt pavements etc. Even the infiltration of wastewater is allowed and recommended.

According to the Swedish Environmental Protection Board (SNV, 1985), between 1981 and 1983 more than 14,000 wastewater infiltration facilities have been constructed for single family houses, for settlements with more than 25 persons, have totally 706 larger infiltration facilities been constructed until 1983. Special requirements with respect to design and construction of such facilities have been formulated and published (SNV, 1985 and 1985a). Infiltration facilities must contain construction for sludge separation. For single family houses, the facility must be designed for at least 5 persons or 1,000 liters per person and, depending on soil infiltration capacity, should consist of 3.5 to 7.0 m infiltration conduit per person. For multi-family housing, the recommended load of wastewater is 30-60 l/m' and day.

It was stated (SNV, 1985) that infiltration to the ground gives at least 50 per cent phosphorous reduction. Reduction of coliforms and pathogens in an infiltration bed of 50-80 cm thick is of the same order of magnitude as in active sludge treatment, i.e. ca 99.9 %.

VOL 12

8201

It is worth noticing that design rules for infiltration facilities are mainly based on the soil infiltration capacity and dilution of effluents in groundwater. Long-term effects of pollution migration, propagation of the adsorption front, influence of acid rain on these processes, metal leakage, etc, are not thoroughly considered.

An inventory of stormwater infiltration facilities in nine communities in Sweden and studies of long-term function and maintenance problems in 11 of the oldest facilities in Nordic countries were performed in 1981 (Lindvall and Hogland, 1981). Three main types of stormwater infiltration facilities are in use: surface infiltration, ditch infiltration and percolation basins. The oldest facility in Sweden has been in operation for 22 years, however most of them are not older than 15 years. The area occupied by infiltration surfaces varies between 0.5 and 100 ha with an average of about 20 ha. The study showed that, with an exception of some construction in cold climate where frost damage occurred, most facilities work without operational problems. Some operational and maintenance problems which were locally observed were due to lack of sufficient information exchange between designers and the maintenance personnel. It is worth noting that no serious investigations about the pollution migration from these surfaces were made.

Porous pavement

When the economical and environmental benefits connected to stormwater attenuation in urban areas were recognized by hydrologists, ecologists and city planners, technicians and inventors started to devise sound technical solutions which would also be economically attractive. One such invention is the Unit Superstructure mentioned above. The construction consists of a layer permeable concrete-asphalt DRAINOR, a macadam bed, and a geotextile underneath to prevent fine soil particles from entering the construction. Excess water from the construction may be collected in a perforated plastic pipe which is connected to the stormwater system or put into an infiltration well. The method can be utilized on streets, roads, parking lots, sidewalks, tennis courts, factory yards, etc. During the rain the construction acts as an infiltration surface. If the infiltration capacity of the soil is small, the structure functions as a storage facility with a strong runoff-delaying effect (Hogland and Niemczynowicz, 1986). Because of generally positive view on the question of water infiltration to the ground in Sweden, and the positive economical outcome, the very intensive increase in the number of sites where the Unit Superstruction has been constructed was possible.

The infiltration capacity of newly constructed Unit Superstructure surface is about 500-600 mm/min. The infiltration capacity tests performed on the parking lot in Nödinge, constructed as Unit Superstructure, showed that after about 5 years of intensive use, the average infiltration capacity was 65 mm/min with a maximum 200 mm/min and minimum 1 mm/min. Infiltration tests made on other surfaces gave similar results, showing that even the oldest surfaces have an infiltration capacity which exceeds by several times the rainfall intensity of any design storm (Hogland et. al., 1987a, b).

The effects on the runoff pattern of using Unit Superstructure pavements, compared to the use of traditional pavements, were tested by means of runoff simulations from an 0.2 km catchment in Gothenburg (Niemczynowicz et. al., 1985). Simulation with the Storm Water Management Model (SWMM) has shown a peak-flow reduction of about 80 % when the Unit Superstructure was employed.

Simulations of the hypothetical situation with permeable pavements in the city of Lund were made using the SWMM, which was calibrated on measured rainfall and runoff during another project (for a detailed description of the modeling procedure, see Niemczynowicz, 1984). With regard to the simulation of runoff from the city, it was assumed that the ground under the pavement was totally impermeable. Permeable surfaces are simulated to act as detention basins; the runoff is delayed, but the volume is not reduced. In practice, of course, there would be some infiltration to the ground and the runoff volume would also be reduced. Results of the simulations for one observed rainfall event are shown in Figure 1. Notice that the runoff from both combined sewers and stormwater conduits is strongly attenuated. The peak-flow reduction from the combined system is about 75% and from the stormwater system about 90%. Simulations made for other rainfall events show the same order of magnitude of peak-flow reductions.

The pollution-reducing capacity of permeable pavements was studied in a full-scale field test conducted in Lund (Hogland and Niemczynowicz, 1986; Hogland et. al., 1987). From analyses of several pollution constituents in the drainage water running off from the test areas, and from analyses of pollution in the body of the pavement, it was concluded that about 50% of the total solids, phosphorus and heavy metals contained in stormwater remain in the body of the pavement. In our hypothetical example involving the

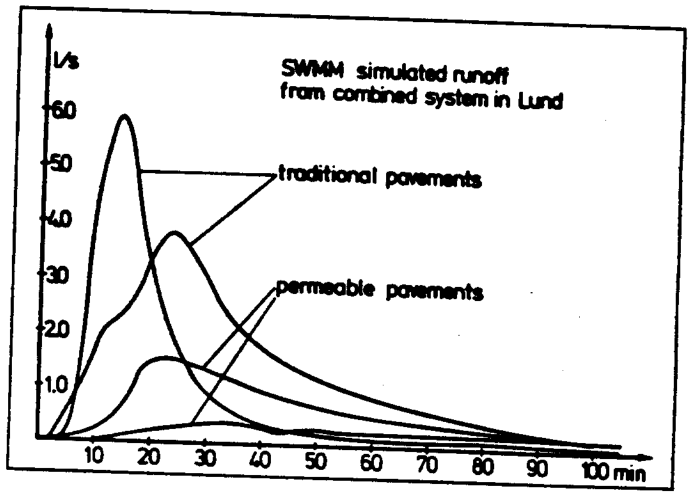

Figure 1. Examples of runoff hydrographs from the city of Lund for the present situation and assuming that permeable pavements were constructed instead of traditional pavements.

use of permeable pavements in Lund, the reduction in the pollution load may be expected to be of the same proportions. The total pollution load reduction would be also combined with a very significant reduction in pollution concentrations in the effluents, due to reduced peak flow and increased time of runoff. Risks of toxic effects on the ecological system during heavy rainstorms and low water flow in the receiving water would be eliminated. Simulated peak-flow reduction is sufficient to stop combined sewer overflows completely in Lund.

Laboratory tests were launched to examine long-term effects of clogging and pollution migration through the structure. The Superstructure surface was constructed in 12 1x1 m boxes in the laboratory. Boxes were exposed to irrigation with original stormwater taken from a conduit beneath. The time was "accelerated" by shortening the dry periods between rainfalls. Irrigation sequences were arranged so that the most important features of rainfall statistical properties were taken into account. Preliminary results of exposure for maximum 30 years of "stormwater rainfall" are very encouraging. Pollution transport through the structure seems to stop on the level of geotextile tissue underlying the construction. There was generally no measurable increase of pollution in the soil beneath the construction observed. Figure 2 schematically shows the distribution of pollution in the construction and in the underlying soil after up to 30 years exposure for "stormwater rain." There were no clogging tendencies observed, and these results have been confirmed by field observations (Hogland and Niemczynowicz, 1986).

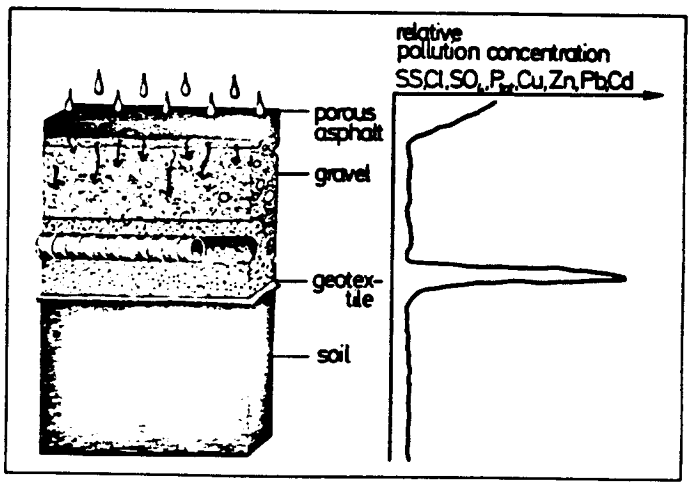

Figure 2. Schematic picture of pollution location in a Unit Superstructure after up to 30 year exposure for stormwater irrigation.

Some maintenance problems may occur if the porous pavement is built before construction in the area is completed. Heavy traffic of lorries and building machinery may damage the pavement construction and result in clogging. The infiltration capacity of the test surface in Lund, which was exposed to extremely heavy traffic of construction machinery during a 9 month period, was reduced to less than 10 mm/min (Hogland et. al., 1987a).

Effective methods of restoring the infiltration capacity of clogged surfaces are under development in Lund. High pressure spray seems to be effective (Hogland, 1989 and Hall et. al., 1988).

Existing permeable pavement surfaces receive the same amount of pollution from fall-out, traffic, corrosion, etc. as any other surface. Additionally, some pollution may be released from the construction itself. The materials of construction may chemically and biologically react with the stormwater remaining in the construction for several days. Most pollution stays in the construction or is accumulated on the textile tissue. Some amount of pollution must migrate to the soil underneath and to groundwater, however this amount is presently not known.

Pollution concentrations in water drained from four existing Unit Superstruction sites were measured and compared with average concentrations in stormwater and with drinking water quality. Table 1 shows the results of these analyses. The following abbreviations are used in Table 1.

Cl	- chloride	P_{tot}	- total phosphorus
PO_4-P	- phosphate phosphorus	Kj-N	- Kjeldal nitrogen
NH_4-N	- ammonium nitrogen	NO_3-N	- nitrate nitrogen
NO_2-N	- nitrite nitrogen	SUSP	- suspended solids
Ts	- dry substance	Ni	- nickel
Cu	- copper	Cr	- cromium
Al	- aluminum	Zn	- zinc
Pb	- lead	Cd	- cadmium
Fe	- iron	Mn	- manganese
K	- potassium		

From Table 1 the conclusion can be drawn that the quality of runoff water from Unit Superstructure surfaces is generally comparable with stormwater quality. The construction has some buffering capacity and the pH of runoff from the construction is usually higher than in stormwater and much higher than in rainwater. The concentration of chlorides is highly reduced by passage through the construction. During a snow-melt period, pollution concentrations are generally much lower in drain water from the construction than from snow melting on impermeable surfaces.

The economic consequences of using permeable pavements on a larger scale were tested by calculating the total costs of two types of pavements: the traditional and the Unit Superstructure. The use of Unit Superstructure results in total costs which are approximately 25 % lower than

TABLE 1. Pollution concentrations in drainwater from permeable pavements at four locations in Sweden. Average concentrations in stormwater and drinking water requirements are also given. Units: mg/liter (after Hall et. al., 1988).

traditional pavements. Most of the cost savings are due to a reduction in the number of necessary inlets and inspection wells, and to reductions in the diameters of stormwater pipes (Niemczynowicz et. al., 1985). Table 2 shows the comparison of total costs for construction of all paved surfaces on a 2 ha housing area in Mölndal in Sweden in two cases: the traditional and permeable pavement construction.

Total	1631	1280

Conclusions

Stormwater enhancement with respect to quantity and quality has became a desirable goal for city planners and practitioners dealing with source control methods in Sweden.

The separation of waste- and stormwater systems in cities in Sweden is economically unacceptable and technically insufficient to prevent a further degradation of water quality in receiving waters. The total pollution loads from the city would not be significantly reduced. The risks of toxic effects on ecologic systems in rivers during heavy rainfalls could be increased.

Since construction of open detention basins and ponds in densely populated areas is restricted for safety reasons, the inlet controls used in Sweden mainly consist of various kinds of infiltration and percolation facilities. Several hundreds of such facilities have been installed.

VOL 12

8209

The idea of constructing porous pavements as so called Unit Superstructure has been put into practice in Sweden, and during the last ten years the number of residential areas where porous pavements has been constructed is growing quickly.

The porous pavement constructions have a great potential when it comes to reducing and attenuating stormwater runoff. It is highly tempting to use this construction on a larger scale. Field and laboratory tests have shown that the porous pavements have the ability to reduce pollution in stormwater on a temporal scale comparable with the length of operation of existing surfaces i.e. ca 20 years. However, the portion of pollution migrating to the soil and groundwater is still not really known.

Now is the time to decide if the general approval of all methods of infiltration of urban waters to the ground can be given. The obvious hydrological, environmental and economical benefits which are certain on a short time scale of some years must be weighted against potential groundwater contamination risks on a longer time scale. It is necessary to be sure that the old philosophy of dilution, which has been proven wrong for receiving waters, will not be repeated in application to groundwater resources. This is important in terms of the possibility of reaching sustainable development.

A REVIEW OF THE PRACTICAL APPLICATION OF DRAINAGE CATCHMENT PLANNING

R P M Smisson
BSc. C Eng. MICE, MIWEM, MSE

INTRODUCTION

Urban growth which has occurred prior to the advent of stormwater regulation has taken a large toll on surface water quality and increased the severity of flood incidence, however, it is only recently that stormwater has been recognised as a major issue of concern for Quality as well as Quantity criteria with an increasing awareness that this is a problem needing to be addressed. Yet the means of doing so are not only complex but sometimes difficult to implement. In response to this need the engineering and scientific community is developing techniques and refining existing methods so as to achieve the desirable objectives of enabling urban growth to continue while avoiding a drop in environmental standards.

Where they have been applied, many of these techniques have been demonstrated to be effective yet their general adoption is often hampered by the legal and procedural machinery under which such work is carried out. To enable systematic adoption of these techniques it is usually necessary to prepare a drainage catchment plan so as to ensure that the definition of objectives and drainage measures is based on the best available information.

The paper highlights some of the constraints and concerns that need to be considered when preparing a catchment plan, illustrated by case study examples of such plans.

CATCHMENT PLANNING FOR LAND DRAINAGE

In its broadest sense a catchment plan should enable an objective view to be taken on all the factors that will be affected by drainage considerations. The future development of our towns and countryside is dependent upon the proper management of water resources and we must never forget that any changes in land use affects hydrology, drainage, and pollution aspects. It should therefore be the objective of an integrated catchment plan to consider the effects of change, determine any adverse effects, set down regulations for development and generally to protect and improve the environment.

HIL Technologies Inc., 70 US Rte 1, PO Box 366, Scarborough, Maine 04074, USA, Tel: 207 883 9100

Hydro Research & Development Ltd, Bank House, Hill Road, Clevedon, Avon BS21 7NE, England Tel: 0272 878371

Adverse effects are well documented [4] and may be summarised that any development will cause an increase in the volume and rate of stormwater runoff, increase the frequency of significant flooding, and increase the mass and concentration of pollutants discharged to the environment.

Any comprehensive catchment plan may also need to consider such other aspects as:-

- land use and zoning
- transport
- recreation
- areas of scientific interest
- tidal reaches
- archaeological sites
- natural wildlife habitats
- farming
- fisheries
- etc.

CONSTRAINTS ON THE DEVELOPMENT OF A CATCHMENT PLAN

Generally catchment plans are not prepared in advance but are only carried out to meet clearly defined objectives. There is, however, a trend for the planning initiative to move from merely reacting to a problem to pro-active planning for the future. Unfortunately, due to the historical development of our drainage systems, there are often a multiplicity of authorities who may need to be involved or have input to such plans depending on the local legal and procedural framework. In the U.K. for example such authorities may include (amongst others) planning authorities at the county or local level, local councils, highway authorities, water authorities, national rivers authority, local drainage boards and riparian owners. In addition the ownership or responsibility for maintenance and improvement, or liability for flood damage, may rest with any of these, jointly or severally depending on the type of watercourse from sewers to local ditches, privately owned rivers, non-main rivers, or main rivers. Thus there are also three main constraints on the development of a catchment plan:-

Who prepares the plan?

Ideally the plan should be prepared by the authority responsible for the watercourse or responsible for approval and enforcement, however it is more usual for the plan to be developed by the party most in need of the answers (e.g. a private developer seeking consent to proceed).

What is the status of the plan?

Ideally this should be mandatory on all involved parties, but again in reality any plan may be viewed as only advisory or be adopted only so far as local legal requirements insist.

VOL 12

8213

Who pays for the plan?

As the cost of a full plan can be considerable, this is a most contentious issue on which at present there is no general agreement. Present opinion ranges from the view that as the 'Private Sector' stands to gain most from development and the release of building land they should pay, to the view that as the main beneficiary will be the general public, and more particularly the local residents, in terms of both increased facilities and local taxes, then the full cost should be met from local taxation. In reality neither argument fully stands up to inspection. A proper catchment plan, taking into account all interests for improvement of an existing situation, or the sensitive development of any area means that there will be benefits both to certain private interests and to the general public.

In consequence, present practice seems to be highly variable and reflects an often confusing situation leading for example, to river flooding, sewage system flooding, development on new sites, or redevelopment are often being considered in isolation and not within the complete framework into which such work should fit.

LAND DRAINAGE AND SEWERAGE

The other main limitation to the present use of integrated drainage plans is the artificial distinction between the land drainage function and the severage function. This has arisen due to the historic development of our drainage systems and been enhanced by the development of different sets of performance objectives and design methodologies to the point where there is a distinct difference between the professions of River Engineer and Sewerage Engineer.

HYDROLOGIC MODELLING FOR CATCHMENT PLANS

The heart of any catchment plan is a hydrologic model or methodology whereby the impact of change on a drainage system can be assessed and where the effectiveness of different strategies can be predicted.

Design Methods:-

Land Drainage Catchment Plans generally need to consider the hydrology of fully developed areas, undeveloped land, rural catchments, and the more difficult problem of urbanising catchments. The objectives and problems to be addressed can also range from a highly localised problem up to more widespread flooding.

In response to this a considerable variety of design methods have been developed. In general, however, these are limited in their application to a specific set of circumstances and reviews of present design methods show that each method is only valid within the bounds set for its use [4].

It is not unreasonable to state that at present there is no single method of analysis and design that can be used to fully model a river catchment from the completely rural situation during progressive development to an urban catchment, or to handle hydraulic modelling from local sewers to main rivers. Different methods are appropriate for different conditions and must be selected for use only within each method's area of validity. In addition the criteria used related to each design application can vary and it is common for different design methods [1] to give wildly differing results if not related to each other.

Design Methods tend to fall into two distinct categories:

- River Design Methods
- Severage Design Methods

These vary both in the basic philosophy of their derivation and theory, and in their definition of objectives, which usually are reflected in the design parameters used.

Alternative Design Strategies:-

For any area the objective of Catchment Planning is to provide a strategic framework within which drainage and other related matters can be controlled, with forward planning for demographic change.

As catchments become urbanised then local flooding becomes more likely due to the increased volumes and reduced times of runoff, which can affect the local severage systems by making them more susceptible to short term high intensity rainfall events. The impact on a river flow may be most critical during longer rainfall events.

Typically several alternative strategies are available to permit urbanization or change without increasing the risk of flooding either on site or elsewhere in the catchment. These can include a combination of:-

- Acceptance of increased volume and rates of flow, with channel improvements as necessary to convey these flows through a system.
- Use of diversion or interceptors to bypass flow restrictions.
- Use of source controls to divert or intercept water at the entrance to the system.
- Use of attenuation storage to limit flows to meet downstream capacity restrictions.

The methodology used within the preparation of a catchment plan must be selected to enable all these strategies to be compared on an equal basis so that the optimum strategy can be identified.

This can be particularly difficult where one strategy can change the design parameters. For example when assessing the use of attenuation storage, whether on a local or a regional basis, the very presence of a storage facility affects the time response of a catchment so that the critical design storm to meet objectives may be changed. In addition the isolation of a small sub-area within a large catchment may result in there being two critical conditions that need consideration, the main catchment critical storm event, and the shorter storm that may affect the sub-area to a greater extent.

Design Parameters

a) **Level of service:**

This term is commonly coming into use to identify the trigger point at which action should be taken to alleviate flooding. This depends upon the system and typically at present such frequencies of flooding as once in ten years is considered as a reasonable level of service so that if flooding or damage occurs more frequently than this then work should be put in hand to alleviate the problem.

b) **Level of Performance:**

Once it has been decided that work should be put in hand, then any such work should be carried out so as to provide a reasonable level of performance into the future.

The level of performance generally depends upon the use to which the land is to be put, both the cost/benefit of carrying out the works (which have been the subject of many studies), [7] and also political considerations. Typical values of these are shown in Table 1.

VOL 12

8216

TABLE 1

Land Use	Level of Performance ie: the system should not overflow more frequently than	Comments
Residential Development	1 in 25 years	
Public Open Space	1 in 1 year - 1 in 10 years	Dependent upon use
Non-Domestic Residential	1 in 25 years	Hotels, hostels etc.
Retail Trading, Offices and Industrial Areas	1 in 25 years	Dependent upon use

The level of performance is one of the main areas of disagreement between the two branches of drainage engineers, mainly due to the differences between Severage and River design methods.

When considering general land drainage and main rivers it is normal to express the level of performance in terms of the actual return period when the banks of a river can be allowed to over-spill. For upper catchments this may be as low as once in twenty five years, however for most main rivers the level of performance is set at a higher level depending on the degree of risk both of damage and to life such an event represents. In many cases these objectives also need to be related to the risk of major disaster where exceedance of the level of performance may require extraordinary precautions to be taken.

When considering local flooding due to the inadequacy of a local severage system the risk to life is normally small and the level of performance is related more to the social effects of flooding where shorter return periods are often considered acceptable. It has been suggested, [8] for example, that it is socially acceptable for domestic housing to flood twice a lifetime or once every 25 to 50 years. To meet this performance, experience backed up by monitoring, has shown that severage design methods provide this level of service if a design rainfall return period of a 1 in 2 or 1 in 5 year frequency is used.

VOL 12

8217

Here is the main problem of calibration between different models, (and I fear the source of a serious communication problem between different sections of the industry).

A design may be based on a 1 in 2 year storm with a sewerage design method, whereas the river design may be for a 1 in 50 year storm using a river design method and each designer may not appreciate that these are describing the same level of protection.

It is for this reason it was decided during the research that resulted in the CONFLO 88 Guidelines (1) that it is necessary to separate the two concepts of "level of performance" and "design return period". The level of performance describes how the system must perform, the design return period used will depend upon the particular design method that is valid and appropriate to use for the condition under investigation, which may or may not be the same as the level of performance. See Tables 2, 3 and 4.

c) **Permissible Outlet Flow:**

Generally the assessment of rates of flow can be based upon a factual knowledge of the physical capacity of the system. This may depend on specific pinch points where such things as a bridge or culvert limits flow although it may be necessary to use a hydraulic model to determine the capacities and effects of different hydrologic solutions.

A less satisfactory but common concept is that of zero increase in runoff, where an assessment is made of the likely rates of flow prior to development which are used as the target rate of discharge to the receiving waters.

CASE STUDIES

To illustrate how these principles can be applied in practice it is worth considering three example case studies of catchment plans, the development of a planning strategy to solve sewerage overloading problems for the city of Modesto in California, the development of a mathematical model for the Aylesbury catchment in England to provide a means of alleviating river flooding and to provide a planning strategy for future development on an urbanising catchment, and the development of a complete catchment plan covering planning, development and pollution control strategies for the complete city of St. Johns, Newfoundland.

The City of Modesto - California:

A catchment plan developed to provide a cost-effective strategy to alleviate an existing stormwater flooding problem on a sewerage system.

The City of Modesto, a market centre for a citrus growing area in the Sacramento Valley in California, grew up along U.S. Route 99 over the last 80-100 years.

The town has a separate drainage system, generally following the streets, however, the stormwater sewers had been allowed to grow "organically" as the town developed. The original storm drain served the original main street through the city only, however, as development continued there has been unregulated connection to this system until by the mid 1980's stormwater flooding had become more than just a nuisance.

The city is bounded on the north by an irrigation ditch (to which no stormwater may discharge to avoid contamination of water supplies), on the West and South West by a main interstate motorway and a railway. The catchment slopes gradually towards the Toulumne river to the south. Recent flooding events show a pattern of flooding being experienced causing not only damage and disruption within the city of Modesto itself but also flooding on both the railway and the highway. It was decided that the situation was not acceptable and the city decided to put work in hand to alleviate the problems.

VOL 12

8221

A detailed survey and analysis of the system had shown that the stormwater drainage system is grossly overloaded. The conventional solution to such problems, involving the reconstruction of the system downstream from locations where flooding is experienced so as to convey stormwater from these areas to the river, was shown to be unaffordable both in capital cost and the disruption that would be caused, as it would be necessary to reconstruct virtually the complete stormwater drainage system to achieve any relief.

This would have required, among other things, constructing two 9 ft. dia. pipes laid parallel right through the city's main street in a fairly narrow and busy highway at up to 8 m. depths, closing the main road during construction.

Alternative solutions were therefore sought for this area, and in 1988 Hydro Research and Development through its associated company, HIL Technology Inc., carried out a detailed survey of the area and proposed a stormwater management catchment plan to the city.

The objective of the study was to consider the use of source control and stormwater attenuation techniques to:-

- Prevent health hazards
- Reduce property damage
- Minimise inconvenience from surface flooding
- Minimise high cost alterations to the existing system
- Minimise downstream flooding
- Minimise the cost of the total system and related works
- Minimise maintenance costs

The analysis of the problem fell into three main sections:-

- Data collection
- Construction of a hydrologic model which could be used to test the effects of different alternative strategies and identify the optimum solution
- A detailed analysis of the optimum strategy

To carry out the analysis, two mathematical models were used:-

- A hydraulic analysis model for the severage system that could be used to determine the existing capacity of the system, and to evaluate the effectiveness of any proposed works.
- A hydrologic model for the catchment, broken down by sub-catchment on the storm drainage system, to provide input data for the hydraulic model and to enable attenuation storage requirements for alternative strategies to be considered.

It became apparent during the analysis that, as is often the case, the optimum scheme would be a compromise incorporating many of the techniques that are now being lumped into the general term "Stormwater Catchment Management".

- Such was the inadequacy of capacity of parts of the existing stormwater drainage system that consideration should be given to reconstruction of some sections of the system.
- The location of road intakes (catch basins) in some areas precludes the use of inlet controls.
- In the commercial districts both roof and hardstanding drains are on private land and not directly controllable by the city.
- Surface storage might be acceptable in the less dense developed areas of the city, subject to political concerns (e.g. they were not keen to flood the town's baseball arena).
- More use could be made of discharges to the subsoil through soakaways, however, their capacity is limited due to the relatively impervious subsoil. Experience has also shown deep bored rockwells have a relatively short life before they silt up.

In consequence the optimum strategy recommended for the city involved making use of all the elements of an inlet control system.

It was concluded that the optimum system would be to adopt a staged implementation for the area comprising:-

(1) Initially to make no modification to the existing sewers

(2) To install flow controls throughout the area to limit discharges into the main stormwater system to the capacity of that system, located so as to mobilise any available storage without the use of surface storage within parking areas and highways in the sub catchments.

(3) To monitor the performance of the system for a period of 12-18 months during which approximately 5-10 significant rainfall events can be expected during the wet season (November - April).

(4) To add storage only where unacceptable surface puddles occur.

(5) Allow a second monitoring period.

(6) Add secondary storage in remaining areas as appropriate.

(7) Establish overland flow routes that will be used during extreme storm incidents to avoid nuisance/damage on any storm event.

(8) To implement a requirement on all new developments or redevelopments within the city to limit discharge flows to the presently identified acceptable rates of flow, and within each development to provide source control measures or attenuation storage facilities to meet the requirements for that development.

VOL 12

8223

These recommendations have been accepted by the city of Modesto and the first stage implementation of the system comprising the installation of flow controls and the establishment of the monitoring programme will have been completed before the end of this year.

The Aylesbury Catchment Model:

A catchment planning model developed to enable comparison of different strategies to be made for the alleviation of existing river flooding and to provide a planning strategy for the future.

Thames Water in conjunction with Aylesbury Vale District Council, initiated a study within Aylesbury (a growing town of population 55,000) with the aim of identifying a cost effective and environmentally sensitive means of reducing the present incidence of flooding and to determine a policy for new development within the town.

The study area comprised the branches to the river Thame that pass through the town of Aylesbury and serve an otherwise largely rural catchment some 5 miles x 2 miles in extent.

Flooding has become an increasingly frequent problem within the lower lying areas of Aylesbury itself, not helped by the complex system of ditches, streams, mill streams, and a canal that has developed over the years. The problem has been highlighted by the recent development of new industrial and commercial parks in areas which in hindsight should, perhaps, have been retained as flood plains to the river.

To determine the optimum strategy to alleviate the present problems and to make provision for future development required the preparation of a catchment plan. The study needed to be able to compare, on an equal and valid basis, the costs and the effectiveness of combinations of six possible alternative strategies.

- A bypass round the town.
- Channel improvements to the various watercourses within the town.
- Use of storage at strategic locations upstream of the town.
- Use of smaller scale attenuation storage schemes within the already developed areas.
- Use of attenuation storage to reduce the impact of new developments.
- Use of storage downstream to reduce the impact of any capacity improvement measures on the main river further downstream.

To enable these alternative strategies to be compared on an equal basis it was necessary to use a modelling technique capable of considering several scenarios. The catchment model falls into three parts.

i) **A hydraulic model of the watercourses through the town:**

The ONDA hydraulic model produced by Sir William Halcrow & Partners, Consulting Engineers, was selected for this purpose as it is capable of simulating open channels; closed pipe systems and culverts, and ancillary structures such as bifurcations, weirs and syphons, that occur on a real system.

The model uses inputs in the form of hydrographs to determine rates of flow and river stage levels at various points through the system.

ii) **A hydrological model of the complete catchment:**

The twin-program UNIHYD (Unit Hydrograph) and FRQSIM (Frequency Simulation) originally developed by the Greater London Council and extended and improved by Thames Water Authority was selected. This model basically adopts the rainfall-runoff approach, using synthetic unit hydrographs and simulated point rainfall.

The model can produce hydrographs and design flows at any chosen point on the channel network, taking into account the catchment shape, distribution of shape within the catchment, soil type, storage within the system and different rainfall profiles.

iii) **A hydrologic model for the Urban area appropriate for use where subcatchments are essentially fully urban:**

The Storm Phase Unit Hydrograph model produced by Hydro Research and Development Ltd was selected for this purpose as it is valid in application to the minor subcatchments defined by the storm sewerage system and has the facility of simulating the use of attenuation storage within urban sub catchments to provide input hydrographs to the hydraulic model.

Development of the Model:-

i) Initially the first two models were used to produce a mathematical model to simulate the hydrologic behaviour of the catchment.

ii) The Second Stage in development was verification and calibration of the model against river gauge data. Rainfall data for observed events was used with the FRQSIM model to produce runoff hydrographs which were input to ONDA and the river stage levels simulated through each storm could be compared to the real observations. The models were then refined so that a realistic correlation between the mathematical model and reality was achieved.

The Storm Phase model for the urban area was also run assuming there to be no storage within the subcatchments and the hydrographs produced compared for the same input data etc. in parallel with FRQSIM so as to establish the calibration on input data between the severage and the catchment model.

iii) Having calibrated the models it is then possible to simulate each alternative strategy, or combinations of these to determine the optimum solution. Bypass options and channel improvements would be simulated in ONDA for the present situation input hydrographs, and during the study the ONDA model was extended to embrace other locations as the design process refined the defined optimum strategy.

iv) Urban Storage on existing developed areas or future development could be simulated using the Storm Phase Unit Hydrograph model to modify the input hydrographs to the ONDA model, and the Unit Hydrograph would also be used to check the critical design storm durations to meet both the watercourse and the local sub-catchment's level of performance.

The appraisal stage using these models has been successful in identifying the most effective strategy to meet the various and sometimes conflicting objectives identified as needing to be addressed by this catchment plan. As anticipated at the start of the development of the model, the optimum cost/effective strategy combined elements of most of the alternatives available and includes carrying out some localised improvement works to watercourses within the urban area to remove the more restricting pinch points, coupled with the use of storage in the rural areas upstream of the town to reduce the incidence of flooding being experienced at present. The addition of storage within the already developed urban area has been concluded to be not necessary, however, all new developments will need to have a controlled discharge to the peak flows identified by the catchment plan with attenuation storage provided on each development to meet its local level of performance. The catchment plan developed for this area will be implemented in order as to overcome the existing problems and enable development of the area to proceed.

<u>Regional Stormwater Management Study for the St. John's Urban Area, Newfoundland</u>:

The development of a catchment plan for the future development planning for the city. [9]

Historically the St. John's area has experienced flooding causing property damage and public inconvenience. With the St. John's area facing pressures to develop the headwater areas of the region's streams and rivers, there was the potential increase in the frequency and magnitude of flooding.

VOL 12

8226

R0041532

Earle & Associates Ltd. and Paul Theil Associates Limited were retained to establish a comprehensive and long-term stormwater management strategy for dealing with existing drainage related problems and for minimizing and/or eliminating potential problems that may result from future development. The study area encompassed four major watersheds which drain into and through the St. John's urban area.

The primary objectives of the study were to:-

1) Establish a comprehensive and long-term Master Drainage Plan that will guide future land development in a manner which will not adversely impact downstream areas.
2) Update policies and standards for stormwater management for new developments and for remedial works within existing developments.
3) Identify existing flooding problems and recommend technical solutions.

Based on existing and anticipated land use patterns it is clear that:-

a) A significant degree of future development will be concentrated in headwater areas of the watersheds;
b) Upon ultimate development there will still remain large tracts of undeveloped land (approximately 44 per cent of the study area); and
c) Based on recent rates of development, it is anticipated that about 20 years would be required to fully develop the area.

To identify existing flood susceptible areas and establish the impact of future development on flow conditions, a hydrologic and hydraulic analysis was needed. The hydrologic design and simulation program MIDUSS was used to estimate return period flowrates and the US Corps of Engineers program HEC-2 to determine water elevations. This analysis provided the framework for the preparation of stormwater management strategies for each watershed by identifying storm drainage deficiencies to be addressed in co-ordination with erosion, sedimentation, and environmental concerns. The broad conclusions of study show that:-

1) The potential for extensive flooding on watersheds in the study area is limited as the floodplains are for the most part confined within relatively narrow valleys and most existing development is generally set back out of the floodplain.

2) Four areas on the Waterford River system and three areas on the Rennies River system have been identified and labelled as flood hazard areas.

3) With future development, an increase in peak flows in the order of 20 to 50 per cent would be expected to occur on the Waterford River and Outer Cove Brook watersheds. For the Waterford River this will result in an increase in flood levels up to 0.5 metres for a given return period event.

VOL 12

8227

4) Due to the topographic features and limited existing development on Outer Cover Brook, the increased peak flows and flood levels will not adversely impact downstream areas.

5) A significant increase in peak flows and flood levels on the Rennies River and Virginia River watersheds will not occur with future development.

6) The major impact of future development will be to increase the frequency and magnitude of existing flooding problems at identified flood hazard areas.

Three stormwater management alternatives were analyzed to develop solutions for existing flooding problems and set forth specific measures to minimize future development impacts. The three alternatives included No Runoff Control (Null or do-nothing option), Post-development to Pre-development Runoff Control, and Runoff Control to a Given Flowrate based on an existing downstream constraint. Stormwater management alternatives were evaluated to establish for each watershed which type of control options would be most environmentally acceptable, cost effective and technically implementable.

The following water management strategies were recommended to achieve a level of runoff control that will minimize the impact of future development on downstream flooding, and address existing flooding, erosion, and fisheries concerns.

1) Control of storm runoff from future developments on the Waterford River system up to the 100-year pre-development level.

2) Storm runoff from future developments on areas tributary to South Brook (Waterford River watershed) can be released uncontrolled.

3) Storm runoff from future developments on the Rennies River, Virginia River, and Outer Cove Brook systems can be released uncontrolled.

4) Implementation of flood protection measures at identified flood hazard areas on the Waterford River and Rennies River systems to provide a 100-year level of protection under ultimate development conditions.

5) To address in-stream erosion concerns, an on-going remedial Erosion Control Plan should be implemented whereby annual walks are made of the watercourses by respective regulatory bodies to identify and prioritize sites of active erosion. A storm drainage levy should be collected to finance existing and future works at erosion sites as identified by the on-going Erosion Control Plan.

6) To reduce the impact of downstream sedimentation from proposed development sites, emphasis should be directed on erosion and settlement control practices during construction.

7) In view of the value of wetlands in the study area from an hydrologic, ecological and water quality perspective, existing wetlands should not be disturbed.

8) To minimize the impact of development on fish habitat, watercourse and floodplain alteration should be restricted, and engineering considerations given to protection of fisheries resources (i.e. provision of oil separators at industrial sites and design of hydraulic structures that do not impede fish passage).

9) Practices that aid in reducing the volume of storm runoff such as discharge of roof leaders onto grassed areas, and use of engineering practices which promote infiltration of water into the ground should be applied.

Remedial works were developed to provide flood relief solutions to a minimum level of protection of up to the 100-year design flood level for areas identified as flood vulnerable.

In addition the following recommendations have been made to provide the respective regulatory bodies with a basis for ensuring that water quantity and quality concerns associated with future development are addressed:

1) Future development within the study area be allowed to proceed subject to meeting the conditions and objectives as described within the Master Drainage Plan.
2) The Master Drainage Plan be used to provide Developers and Consultants with guidelines and criteria as to the works required to meet water management objectives.
3) Functional Stormwater Management Reports be prepared for each drainage area requiring detention storage. The Reports would define, in detail, the characteristics and location of the proposed facilities and provide preliminary engineering specifications. Submission to the regulatory authorities should be made at the Draft Plan stage.

4) To ensure uniformity within the study area, a Storm Drainage Manual be prepared which would apply to all areas of future development. The basic objective of the manual being to provide guidance in design of storm drainage works. The manual to outline design methods, design rainfall hyetographs, runoff coefficients, Major-minor drainage system concepts, options for foundation drain connection, lot grading, and locally implementable techniques for erosion and sediment control, promotion of infiltration, and improving stormwater quality.
5) If the official General Land Use plans are substantially amended, the hydrologic impact of amendments on downstream areas will be addressed by modification of the existing hydrologic model.

NON POINT SOURCES OF POLLUTION

Most of the catchment planning that has been carried out to date has concentrated primarily upon the quantity aspects of stormwater runoff. The pollution problems of urban washoff are, however, becoming of major concern due to long term effects on the receiving waters.

It has now been recognised that, although rainwater may be relatively pure prior to impact on the ground surface (assuming air pollution and acid rain is not a factor) this water will rapidly become contaminated as it runs over the land surface and can have a severe polluting effect on the receiving watercourse.

To illustrate the impact this can have, a monitoring program on a typical urban stream carried out on the Egerton Park Brook in Bexhill-on-Sea by Southern Water [(1)] demonstrates that even the pollutant washoff from the highways of the first few streets in the town has a much greater impact on the stream, particularly with respect to the impact on the number of invertebrate species of fauna, than the impact of combined sewage overflows further down the catchment.

Typical of the problems being experienced is the identification by the State of Maine, USA, that the biggest threat to the Gulf of Maine is storm water, and the Department of Environmental Protection has carried out studies which show that pollution arising from combined sewage overflows and stormwater sewers is causing pollution problems that can affect recreational use of the sea, swimming on coastal beaches, and jeopardise shell fisheries and sea fish. To control this problem a state directed programme is under development and as total elimination of all the combined sewage overflows is economically prohibitive, realistic targets are being defined so as to progressively raise standards.

TAMPA BAY, FLORIDA, SURFACE WATER IMPROVEMENT AND MANAGEMENT

Similarly the Department of Environment Protection in Florida has recognised that stormwater, both urban and agricultural, is a major issue of concern state-wide.

The 2200 square mile watershed of Tampa Bay has been identified by the South West Florida Water Management District as a priority waterbody. Two projects have been identified under the quality initiative which will result in:-

- The establishment of priority criteria for sub-basins for future rehabilitation work
- The immediate identification and implementation of known projects that will result in water quality improvements in the bay.

Through this approach will be laid the groundwork for future stormwater rehabilitation projects to be initiated not only by the District but also by local municipalities.

Improvements to a watershed the size of Tampa Bay will be expensive, hence decisions will be based on the analysis of the cost of works against the expected benefit to the receiving water. This cost/benefit ranking will ensure that funds are applied where they will be most effective within the priority ranking.

A five step approach to the problem has been developed:-

- Initial Data Collection
- Land use/pollutant loading rate formulation
- Calculation of pollutant loads for each sub-basin
- Sub-basin prioritisation
- Detailed planning for selected sub-basins

CITY OF BRADENTON - FLORIDA

Typical of the implementation of this approach is the Wares Creek, Bradenton Study carried out by Smith & Gillespie Consulting Engineers [9].

Water quality in the Manatee River, which is a tributary to Tampa Bay, is being adversely affected by urban and rural stormwater runoff. Large quantities of pollutants consisting of metals, nutrients, pesticides and herbicides are washed into the river and its tributaries during storms. Typically 85% of the pollutant loading in the Manatee River is the result of stormwater runoff, depending on the time of year.

In an effort to reduce pollutant loadings associated with stormwater runoff, a field-model demonstration project was conducted near Wares Creek. The drainage area contributing to Wares Creek was selected as the site for this project because it possessed characteristics typical of urban and residential stormwater runoff as it experiences high nutrient loadings and siltation. This field-model demonstration project consisted of two treatment systems: A Storm King hydrodynamic separator and a grassed swale retention area.

The climate in Manatee Country and in the Wares Creek Study area is subtropical. The relative humidity is high, the winters are mild and short in duration, and the summers are long and hot with abundant rainfall. A typical year is comprised of a summer wet season lasting from June through September and a dry season lasting from October through May. The average total annual rainfall amounts to 54.29 inches. Climate indirectly affects biologic forces and influences the development of inorganic factors such as soil profile formation. In turn, these factors may substantially affect nonpoint source pollution loading rates during different periods of the year. Most environmental damage caused by urban washoff is the result of the mass "wash off" of pollutants rather than the instantaneous quality at a single point in time. The mass pollutant load depends on washoff and the inter-event antecedent dry period (time between storm events) rather than the severity of the storm event. Furthermore, the mass pollutant would generally persist longer into a storm than the "first flush" quality would suggest. Therefore, treatment systems designed for treatment to reduce the overall escape of the greatest mass of pollutants will need to concentrate more on the frequent small storms than on major storm events.

It is expected that nonpoint source pollutant loads would be greatest during the wet season, since this is when the majority of land surface pollutants are scoured and washed off into surface water bodies. Therefore, climatological factors, such as rainfall, runoff, day length, light availability, and increased temperatures may combine to produce profound biological impacts on surface waters during periods of high primary productivity. These impacts include high nutrient and pollutant loading rates which can produce severe productivity stresses leading to low dissolved oxygen levels, problem algal blooms and potential fish kills.

The results of this study indicate that both treatment units are feasible means for treating urban stormwater runoff, however each project must be reviewed on a case by case basis. The disadvantages associated with large grassed swales or retention/detention basins is that they require large land areas. Adequately sized land areas may not be available in the vicinity of tha project construction. Also, this alternative may not be suitable for treating stormwater runoff from existing systems due to land availability. Erosion control and dewatering costs may also render this alternative unfeasible.

The Storm King Separator System has several advantages over the grassed swale. The unit is hydraulically controlled and hence does not require any electricity to operate. It occupies only a fraction of the land area required for grassed swales. The unit can be installed in existing storm sewer systems with minor modifications, provided required hydraulics are available. The report concluded that depending on tha situation, it may be less expensive than construction of grassed swales or retention/detention basins.

CONTROL OF NON-POINT SOURCES OF POLLUTION FROM URBAN AREAS

The realisation that surface washoff from urban areas can result in severe environmental damage calls into question the complete method of conventional drainage practice:-

The Conventional Combined Sewage System may be an effective means of ensuring that all the water draining from the urban environment is taken to a proper treatment facility. Its disadvantages, which include the need to handle vastly varying rates of flow both in the pipes and at the treatment works and the consequent need for combined sewage overflows during extreme storm events has led to the new construction of such systems being effectively abandoned.

The Separate Sewerage System is a logical development, overcoming most of the gross disadvantages of the combined system. Foul sanitary sewers, handling more constant flow rates provide the necessary transport system to enable sewage to be conveyed to a proper treatment facility, and problems with the foul sewers only tend to be experienced on older systems where "illegal" surface water connections and ground water infiltration can result in overloading. Modern techniques of rehabilitation can overcome many of these problems, however some combined sewage overflows to provide a safety valve to the system will probably always be necessary.

The Storm Drainage System is based on the assumption that stormwater is clean and can be discharged to the local land drainage system, however experience shows this often not to be the case.

Pollution control in this case normally is tackled by two main strategies:-

- **Source Control:**

  The reduction and/or interception of pollutants at source before they enter the drainage system. Use of source control and "Best Management Practices" such as reduced use of fertilizers, banning the use of pesticides and weed killers, street cleaning, car parking controls, dog litter control, use of soakaways etc. to intercept surface water, use of storage, reduction of de-icer use, oil interceptors etc. can make a great contribution to the reduction of pollution, however, the cost in capital and social terms may preclude full implementation of these strategies.

- **Treatment of the Stormwater Sewers:**

  This option is being given serious consideration. Systems including the use of storage, facultative ponds, filtration systems, exfiltration ponds, and treatment plants are in use and new approaches are being researched. The main disadvantage is the same problem as experienced with combined sewers - the need for a treatment system capable of handling vastly varying and intermittent rates of flow, with the consequent inevitability of failure during the extreme storm event.

THE SINGLE PIPE SYSTEM FOR STORMWATER MANAGEMENT [illegible]

An alternative strategy that can be adopted is the systematic use of stormwater management, controls and attenuation storage, so as to iron out the vastly varying rates of flow experienced on stormwater drainage systems so that all the contaminated water that enters a drainage system may be conveyed to a proper water treatment facility.

The use of the principles of inlet control [11, 12] where the inlet capacity is limited so that the rates of flow within a drainage system will not exceed the capacity of the pipes and treatment facility coupled with the systematic use of attenuation storage can enable all the drainage for an area to be handled by one single outlet pipe which will transport all water entering the system to the treatment plant.

The advantages of this approach include:-

- Eliminating the need for costly sewer separation on existing drainage systems
- Can provide immediate relief in areas with the most severe flooding problems, leaving areas less prone to flooding until funds are available
- Can provide a higher level of protection than is usually available from conventional methods, usually at a lower cost
- Permits the highly polluted 'first flush' to be treated by existing treatment facilities
- Avoids pollution arising from combined sewer overflows
- Reduces peak rates of flow to receiving waters resulting in reduced flooding and erosion downstream

The systematic use of inlet control avoids the need for separate drainage systems for foul and stormflows. A single pipe sewerage system discharging a controllable peak rate of flow to a treatment facility ensures that all water that enters the piped drainage system is treated before discharge, and that any facilities provided, or already in existence, are used to their optimum.

It is a feature of this approach that, where appropriate, storage on the surface of the ground can be utilised by controlling the rate of discharge to the pipe system. A primary flood is formed adjacent to the intake, holding the water on the surface until there is adequate capacity to drain the store, so these floods would persist for a short time after a storm ceases. The first flush of surface flow, with the more contaminated water usually at lower rates of flow, will be accepted directly into the drainage system so any primary floods so formed will be relatively unpolluted and should cause no nuisance or damage providing they are correctly located. The advantage in terms of pollution control of flood waters can be clearly seen.

It is necessary when designing a single pipe system to carry out an analysis of the major and minor drainage systems. It is also necessary to formulate a functional policy for the area to consider the limitations to discharge, the internal and external drainage patterns, traffic considerations and street patterns, and to define the major flow system.

The minor system will also be under the constraints for providing adequate sanitary sewers to discharge to the treatment facility. Transient storage can be incorporated in recreational water facilities by permitting surcharge during extreme storm incidents and permitting infrequent ponding in areas where flooding will not cause damage or be a serious nuisance. Transient surface storage can be provided in such locations as parks and green belts, sports facilities, on some rooftops, in car parks, adjacent to watercourses by forming artificial flood plains, etc. or in underground stores constructed for the purpose.

When considering providing relief to an already developed area suffering from flooding, the most economical solution is very often found to be a single pipe system making optimum use of any facilities already in existence and limiting inflow to this system to its capacity using storage to hold the excess.

EXAMPLE OF THE ECONOMIC ADVANTAGES OF THE SINGLE PIPE SYSTEM ON A DEVELOPMENT

This example is based on the drainage requirements for the Staplegrove Development in Taunton, England as designed by the Earnest Green Partnership, Cardiff, for Wales Retirement Homes Ltd.

The design of this development, in accordance with the drainage authority's standard requirements required that the present undeveloped peak rate of flow to the watercourse of 28 l/s should not be exceeded with storage being provided to contain any stormwater runoff so that flooding on site would not be experienced more frequently than once every 35 years (as a level of performance). Underground storage being required for the more frequent storms up to a 1 in 10 year storm after which surface storage in about ground swales or car parking areas would be permitted. A detailed hydrologic analysis showed that the requirements for the three alternative sewerage strategies would be as shown on Tables 5, 6 and 7.

Single Pipe System

Subcatchment A			
Storage Volume Required		2 year storm (cu.m.)	34.86
		5 year storm (cu.m.)	53.286
Foul Flow :	0.74		
Storm Flow:	4.65		
Total Flow:	5.59	Pipe 1 - Dia (mm)	150
Subcatchment B			
Storage Volume Required		2 year storm (cu.m.)	21.63
		5 year storm (cu.m.)	33.063
Foul Flow :	1.59		
Storm Flow:	7.53		
Total Flow:	9.13	Pipe 2 - Dia (mm)	150
Subcatchment C			
Storage Volume Required		2 year storm (cu.m.)	51.87
		5 year storm (cu.m.)	79.287
Foul Flow :	3.33		
Storm Flow:	14.45		
Total Flow:	17.78	Pipe 3 - Dia (mm)	225
Subcatchment D			
Storage Volume Required		2 year storm (cu.m.)	101.64
		5 year storm (cu.m.)	155.364
Foul Flow :	6.47		
Storm Flow:	28.00		
Total Flow:	34.47	Pipe 4 - Dia (mm)	300

A cost estimate for the three systems on this site suggests the capital cost for these alternatives to be:

Combined system	£63,558
Separate system	£146,656
Single pipe system	£61,725

VOL 12

8238

The advantage of the latter system being not only the saving in capital cost of 58% over a conventional separate system but also this approach would ensure that all the water entering the drainage system would be conveyed to a proper treatment facility before discharge to the environment.

EXAMPLE OF THE APPLICATION OF THE SINGLE PIPE SYSTEM RETRO FITTED TO AN EXISTING CITY

The Borough of York [7] is a Toronto, Canada suburb with a population of 140,000 and covers about 9 square miles. York is one of six municipalities that make up the Metropolitan Toronto area. York has a combined sewer system and in the past has suffered from severe sewer backup along with combined sewer overflows that pollute the Humber and Don Rivers.

In 1968, following a consultant's recommendations, York embarked on a $50 million program to control flooding and pollution following the traditional philosophy of a structural-intensive solution of sewer separation and storm sewer enlargement to contain a 2 year return period storm. From 1968 through 1976, York spent an average of $646,000 per year, or 22% of its annual budget, on this project.

By 1976 the borough council became quite concerned about the tremendous cost of the project and engaged an engineering firm to find an alternative solution. This firm studied four chronically flooded areas and determined that the conventional method of relief sewers was far too costly. A borough official concluded that for these four areas alone it would cost in the millions to provide relief by conventional means, such as additional sewer capacity and tunnels. As alternatives to the traditional construction, the consultant suggested using regulators in catchbasins, constructing limited-storage underground tanks and either disconnecting downspouts, or installing restrictors in the downspouts.

Under this approach, when sewer system capacity is exceeded, storm water would be temporarily stored in underground tanks or on the surface for slow release into the system. The consulting firm concluded that for $110,000 this approach would provide protection against a 2-year storm. Further, for $830,000 protection could be achieved against a 10-year storm.

York opted for the 10-year storm protection which was completed at a final cost of only $987,633. The alternative approach was completed in October 1978, except for installation of restrictors in the downspouts.

Within the first year after installation York experienced two fairly intensive storms which, according to a York official, represented a good test of the approach. The system has worked effectively and no flooding problems have been reported in the four areas, while numerous complaints have been received from residents in other areas of York.

VOL 12

8239

CONCLUSIONS

The future planning of our drainage systems to meet the increasing demand for good land drainage, pollution control, and enhancement of our environment requires the means of identifying the best strategy for the management of complete catchments from the point of rainfall to the point of outfall so as to meet the environmental quality objectives for the receiving waters.

Techniques for the preparation of catchment management plans are being developed which are beginning to enable alternative strategies to be compared on an equal basis. The use of these techniques can result in the most cost effective and beneficial means of achieving the objectives to be identified and implemented.

The various examples and case studies discussed herein demonstrate that all the principles and methods discussed herein have been applied to projects in both Europe and North America. The benefits of the concepts described are such that consideration is being given to the review of our present standard requirements and conventional methods, so as to provide a better service to the public and protect our environment at an affordable cost.

STUDY ON CATCH BASINS IN SWITZERLAND

by F. Conradin[1]

1. Introduction

In Switzerland, as in many other areas in Europe, it is common practice to feed rainwater falling on roads and in squares via catch basins to the public sewer system. The catch basin acts as a settling device, and has always been constructed to protect the sewer system from deposits.

However, the actual situation is such that catch basins only partially perform this task at best. Deposits in sewers cannot be avoided. Nevertheless at least a proportion of the sand and other contaminants produced are fed into the sewerage system. Dauber and Novak (1982) wrote "that the role of catch basins in the road drainage system is questionable insofar as they retain in their mud catch pits not only sand, but also organic suspended matter, when rainfall is low, but are hardly able to retain such substances and instead discharge them from their mud catch pit at a higher level of heavy rain."

Sand, gravel and other materials introduced into the drainage system with the rainwater via street inlets accumulate at different points, one of these points being the catch basin. During cleaning sand is also conveyed from the sewer. After heavy rain some of these materials are fed into the recipients (combined sewer system) via storm water discharges. Large quantities of sand are retained in the sand catches of the wastewater treatment plants. Extremely fine particles reach the sewage sludge via the pre-clarification and biological purification stage.

VOL 12

8243

2. Changes in the Tasks of the Catch Basins

Today most streets and squares in built-up areas are provided with hard surfaces, with a resultant reduction in the sand and gravel present. But nowadays other fairly fine-grained materials are discharged with the rainwater, such as:

- detritus from highways
- detritus from vehicle tires
- detritus from brake linings
- leakages from vehicles
- residues from fuel combustion
- leaves and other waste materials of an organic or inorganic nature.

Furthermore, the road surface is subjected to polluted precipitation from the atmosphere, due particularly to residues from the combustion of fossil fuels (sulphuric acid, etc.).

However, the mode of operation of today's road catch basin has remained basically the same as it has always been, as these structures can only be used effectively to retain materials of all kinds which can be sedimented relatively easily. Moreover, the catch basin overflow arch (immersion arch) has also been assigned the function of an odor trap to prevent emissions from the sewer system.

3. Questions Raised

3.1. First question

The first question raised is whether catch basins can be improved so that they are much better able to perform their function. "Much better" would have to mean, of course, that deposits of materials are practically eliminated in the sewer system, and that even the extremely fine-grained materials, which appear to be on the increase, could be retained.

3.2. Second question

Since similar materials to those found in the catch basin are also found during sewer cleaning itself, and in the wastewater treatment plant (particularly in the sand catch), the second question would have to be whether the catch basins would have to be dispensed with on economic grounds. One might imagine that it would be cheaper to intensify sewer cleaning slightly, to compensate for the absence of the catch basins, so that an increase in deposits would be prevented.

3.3. **Third question**

The decision to eliminate catch basins should not be based on economic considerations alone. Consideration must also be given to the ecological effects. Will the storm water outlets produce intolerable additional water pollution if they are eliminated? Is the heavy loading of sewage sludge with substances which could be retained in the catchbasins having a negative effect on the use of sludge in agriculture?

4. **The Studies**

In order to answer the questions which have been raised, a working group has been formed by the Swiss Association of Municipal Authorities. The results of the studies conducted are summarised in a report (Swiss Association of Municipal Authorities, 1989).

4.1 **General conditions**

4.11 **Drainage system**

Because the combined sewer system is the principal system used in Switzerland, particularly in the major cities, the studies and following considerations apply mainly to this system. In this country it is common practice to feed the light rainwater runoff to the wastewater treatment plants so that twice the calculated dryweather quantity can be processed. Slightly heavier rain, up to an intensity of 15 l/s ha, is discharged into rain basins and stored, or at least pretreated there in the form of settling. Only very heavy rain is discharged directly into the recipients.

4.12 Street catch basins - Design and arrangement.

Catch basin designs in Switzerland vary from region to region. Catch basin diameters vary from 60 to 80 cm and their water depth, from the bottom to the outlet point, ranges from 60 to 130 cm. The total depth of the catch basin may be up to 2.50 m, depending on the street level, and the useful volume of the street catch basins ranges from 0.25 to 0.45 m3, depending on the type of basin. The type for the city of Zurich is shown in Figure 1.

In the streets the catch basins are installed at average intervals of approximately 30 m, and drain an area of approximately 250 to 450 m^2.

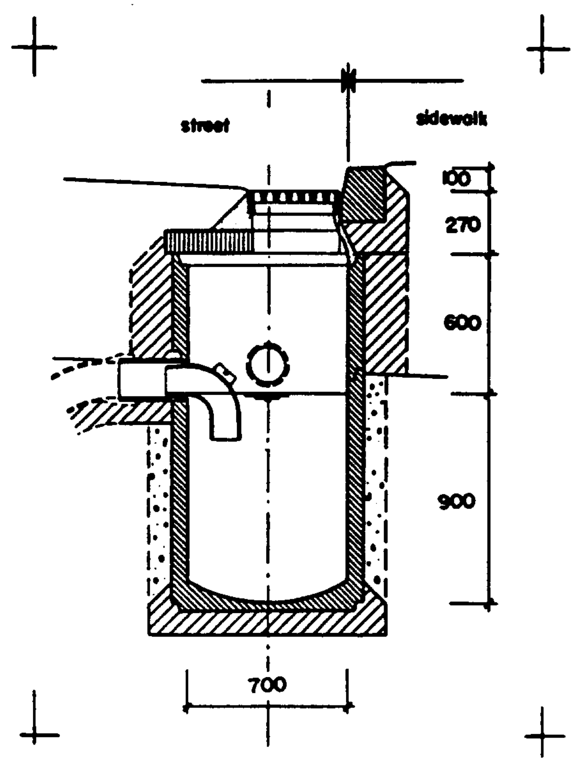

Figure 1. Catch Basin, Zurich Type

4.13 Street Cleaning

Nearly all the streets in the cities considered in the study are cleaned at least weekly by the dry vacuum method.

4.2 Studies and measurements

4.21 Hydraulic tests

Due to the fact that catch basins cannot completely fulfill the task assigned to them, tests were carried out in the laboratory in 1985 (Zurich City Sewer Department, 1985). In particular, the tests were intended to provide information on the possible siphoning off of the basin contents under certain hydraulic conditions. However, no siphoning effect was observed in the Zurich type catch basin, even at a basin supply rate of 25 l/s (equivalent to a rain intensity of approx. 400 l/s ha on a drainage area of approx. 600 m^2), and a 45% bottom gradient of the outlet pipe 150 mm in diameter. On the other hand it was shown that as the water flow rate and level of the sedimented sludge in the catch basin increased, sludge which had already been sedimented was also washed out. Also washout has been observed with medium rain intensities , even if there is little sedimentation in the catch basin. When the sludge level is approximately 10 cm below the immersion arch, practically the same quantity of material is washed out as fed in.

4.22 Theoretical considerations

It can be demonstrated, by calculations, that the Zurich catch basins, or catch basins of a similar design used in the rest of Switzerland, are not capable of retaining fine fractions.

Under the general conditions described in Section 4.12, only sand grains of approximately 1 mm grain diameter and larger can be sedimented in heavy rain, even under optimum hydraulic conditions. At rain intensities as low as 50-100 l/s, all the sand grains from 0.2mm diam. would be washed out. Such rain events occur more than ten times a year.

The effectiveness of the catch basins is also greatly impaired by unfavourable conditions, e.g. by the fact that the material effectively accumulated in the catch basin can be lighter than sand, as a result of which larger grains are also washed out. A high sludge level reduces the settling space, having an unfavourable hydraulic effect. Most importantly, all the water falling down through the inlet gives rise to considerable turbulence in the settling area, thereby greatly reducing the settling effect and swirling up the material already settled.

4.23 Measurements of sludge levels

Since measurement programmes in the laboratory can never accurately record the effective conditions, it was decided to measure the retained quantities of sludge in several Swiss cities on a large number of catch basins. The degrees of filling of catch basins located in a wide variety of zones were measured over a period of about two years (1987/88) with a simple device, consisting of a disk secured to a tube, and a measuring rod running inside the tube (see Figure 2).

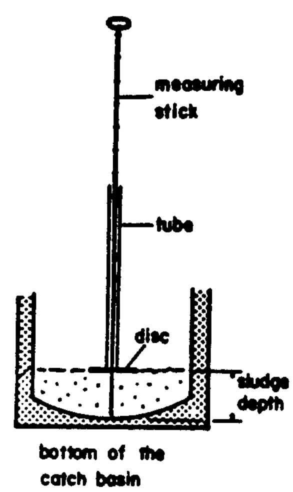

Figure 2. Device for Measuring Catch Basin Sludge Levels

It was supposed that the inlet design, the terrain, the type of developed zones, and the method of street cleaning would have a significant effect on the filling process, and an evaluation of the measured results bore out these assumptions on most points.

(a) Effect of inlet design - Inlet design has no direct detectable effect on the rise in sludge levels, either in flat or in inclined areas.

(b) Effect of terrain (lie of the land) - Catch basins, both in level streets and in streets with a gradient, exhibit sludge level plots which show both low and high rises.

(c) Effect of developed areas - The records do not indicate whether the quantity of sludge accumulated depends on the degree of development in the zone concerned. Taking the figures on the specific sludge inflow, a slightly higher value has been seen for roads carrying through traffic as opposed to residential or business quarters.

(d) Effect of parked cars - It is practically impossible to detect any influence of parked cars on the proportion of sludge on the basis of the data available, although such an effect might be expected from the more difficult street wiping conditions.

(e) Effect of precipitation - In individual cases a rise in sludge level can be associated with simultaneous rainfall, but in other cases the opposite is true, namely a reduction in sludge level at times of precipitation, i.e. the sludge is washed out of the catch basin. However, no correlation is seen between sludge accumulation and the amount of precipitation.

(f) Effect of street cleaning - The evaluation shows that street cleaning is the only factor having a relevant effect on the quantities of sludge reaching the catchbasins. A great deal of granular material and road dust is removed with the mechanical dry cleaning methods practised today, i.e. they are separated from the sewer system. By contrast road dirt is washed into the drainage system and catch basins during wet cleaning on the flushing principle (surface cleaning by flushing). Heavily contaminated streets, e.g. Hagenheimerstrasse in Basel, which is loaded with excavation material and gravel works traffic, must be wet cleaned more frequently, and the amount of sludge accumulating in the catch basins concerned is correspondingly high. The opposite is true in a commercial street such as Rennweg in Zurich, where dry cleaning is often carried out and practically no dirt reaches the catch basins and the sewer system.

VOL 12

These considerations show that the topographical and settlement-specific characteristics may possibly have a certain influence on the volume of sludge stored in the catch basins, but are much less significant in comparison to street cleaning.

It was expected that the use of gravel on the roads in winter would increase the sedimentation in the catch basins; but a few results have shown that this is not the case. This might be due to thorough road cleaning after the snow melts.

An important result was, however, established in the following observations:

(a) Of 63 catch basins observed, around half reached a sludge level of only about 10 cm or less after a year. An example of this is given in Figure 3.

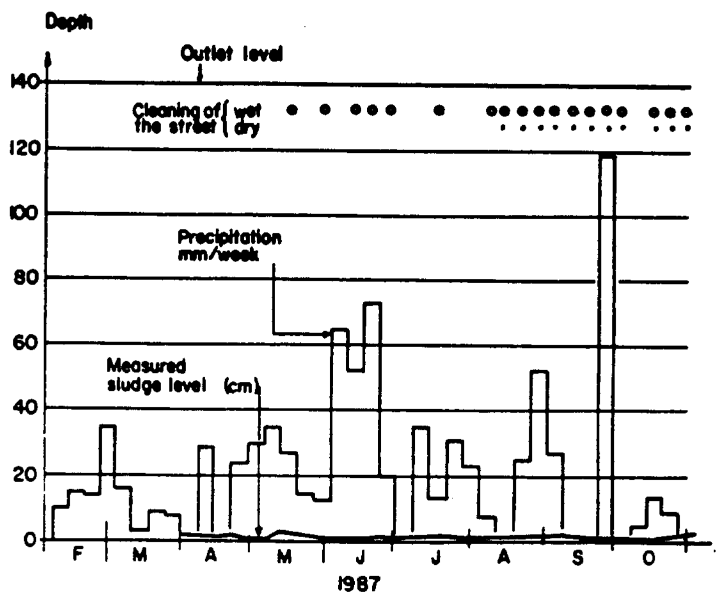

Figure 3. Typical Sludge Levels - Catch Basin with Low Sludge Supply and Insignificant Retention

8249

(b) Only in less than 10% of cases did the sludge attain a substantial level in the basin. Figure 4 shows a typical plot.

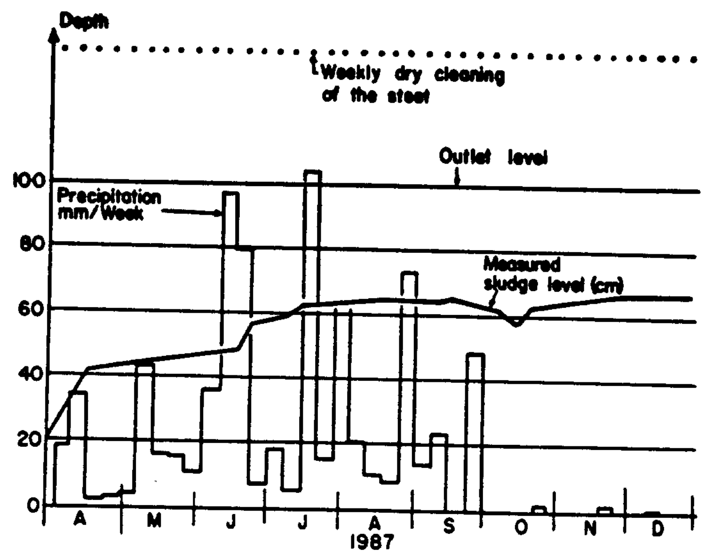

Figure 4. Sludge Level in Catch Basin which Effectively Utilises Settlement Volume

(c) The maximum degree of filling is, in most cases, reached in less than six months, and there is never any continuous increase in the filling depth, extending close to the outlet levels, over a period of time (Figure 5). This means that efficiency is reduced with time.

The following conclusions might be drawn from what has been observed:

(a) Particularly in roads and streets which are dry cleaned, the kind of dirt (sandy material which can be settled) which could be retained in catch basins does not occur.

VOL 12

8250

R0041556

(b) Where such dirt accumulates, a catch basin such as that commonly used in Switzerland can only retain it to a limited degree.

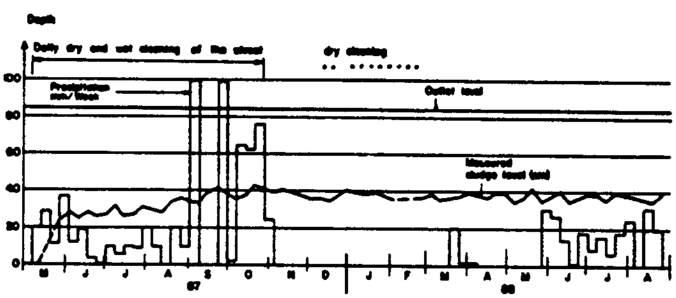

Figure 5. Long-Term Catchbasin Sludge Depths - Retentive Effect Decreases Sharply after 3-6 Months

5. Mass Balance

For a more accurate evaluation of the economic and ecological benefits of catch basins a mass balance was made for the City of Zurich (Figure 6). The quantities of sludge were surveyed by the competent departments, and are represented in Table 1. Certain assumptions had to be made, when converting to dry substance, regarding water content, specific gravity, quality, etc. However, the results obtained lead to some remarkable conclusions:

(a) Over half of the road dirt can be removed by dry cleaning of the road surface (48.6%) and rail cleaning (5.2%). Effective dry cleaning of the traffic areas, by the method commonly used in Swiss cities, can ensure that less than half of road dirt reaches the sewer system.

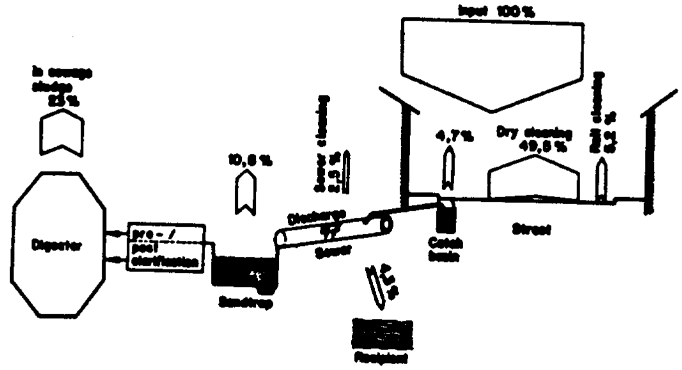

Figure 6. Approximate Catch Basin Mass Balance

Table 1: Annual road sludge volumes in the City of Zurich

Point (1)	Dry Solids (tons) (2)	Dry Solids (tons/ha impervious) (3)	% (4)
Wiped material from dry cleaning	9145	3.9	48.6
VBZ line cleaning	960	0.42	5.2
Catch basin emptying	870	0.38	4.7
Sewer cleaning (direct removal)	455	0.2	2.5
Sand trap (STP's)	2000	0.90	10.8
In digested sludge (STP's)	1250	1.85	23.0
Via discharge works into recipient	800	0.35	4.3
Total	19400	8.00	100.0

(b) Of the road dirt reaching the drainage system:

o approximately half reaches the sewage sludge (fine proportion) in the pre- and post-clarification basins.

o about a fifth can be retained in the sand traps of the wastewater treatment plants

o only about a tenth is retained in the catch basin

o about a further tenth is fed into the recipient stream via discharge structures

o approximately one twentieth is removed from the sewer system by cleaning.

6. **Economy**

Road dirt is removed from many points of accumulation: street cleaning, rail cleaning, catch basin cleaning, sewer cleaning, emptying sand traps, removal of sewage sludge. This raises the specific question of the economy of emptying catch basins, for it appears to be extremely expensive to have to empty around 50,000 catch basins about once a year, when only 5% of the road dirt accumulated is retained, as appears to be the case in Zurich.

For a comparative examination of this economy, the following variants will be compared (Table 2):

Variant A: System with catch basins

Variant B: System with direct inlets (without catch basins) (The associated costs would be incurred, for example, after all the catch basins had been replaced by direct inlets, as part of road reconstruction, etc.).

A consideration of the overall costs of removing road dirt shows very clearly that the construction and operation of catch basins is not economical given the method of dry cleaning the streets, sewer cleaning with high pressure washing practised today, and the efficient sand traps in wastewater treatment plants. The main saving that can be achieved lies in the capital service associated with the catch basins. The savings in operation depend on where the material not retained in a catch basin accumulates, and how it is to be removed. If most of this material is washed into the wastewater treatment plant during the high pressure sewer washing, which takes place regularly, considerable savings may also be expected in both operation and removal.

Table 2: Cost comparison for removal of road dirt from the drainage system, with and without catch basins

Cost item (1)	System with catch basin (2)	Direct inlets (without catch basin) (3)
Sewer cleaning and washing	2,400,000 1)	2,700,000 4)
Catch basin - - Emptying - Removal	1,400,000 1) 100,000 2) up to 300,000	100,000 5) 50,000 5)
Direct inlets, Cleaning	-	250,000 6) up to 700,000
Sand trap, extra costs	-	50,000 7)
Sludge treatment, extra costs	-	200,000 8) up to 600,000
Capital service Catch basin	4,500,000 3)	2,250,000 9)
Total	8,400,000 to 8,600,000 130-135%	5,600,000 to 6,450,000 100%

Notes for Table 2:

1) Data from Zurich City Sewerage Department

2) Removal of material from catch basins, according to measure adopted (e.g. filling or processing), because the material has too high an organic content for filling, according to the Waste Decree).

3) 50,000 catch basins cost SFr. 1,400/- each, return on investment period 50 years, 5.5% interest.

4) Slightly increased expenditure if catch basins were to be removed.

5) Remaining catch basins at a variety of different points.

6) Cleaning every one to two years

7) Removal of additional accumulation of sand in the sand trap in the wastewater treatment plant.

8) Removal of additional accumulation of fine materials in the sludge, according to measure taken (e.g. agriculture, filling or incineration).

9) Assumption: costs of direct inlets approximately half that of catch basins.

7. Ecological and further considerations

The best effect, as far as environmental protection is concerned, is achieved when the roads are dry cleaned. Of the points of accumulation of road dirt in the sewer system, two points are of particular importance from the ecological point of view: stormwater discharges and sewage sludge.

7.1 Storm water discharges

If catch basins were to be dispensed with it could be assumed that some of the quantities of dirt not retained might reach the recipients via storm water discharge works. It is very difficult to quantify this, but logical considerations all point in the opposite direction, namely that catch basins have a detrimental effect from the point of view of water conservation.

When it is considered that most heavy metal pollution, for example, adheres to the finest dirt and sand particles, it should be expected that in light rain the fine dirt from the street is washed into the catch basins and is retained there. But if the rainfall is only slightly more intense, this fraction is washed out of the catch basins in concentrated form, and higher dirt concentrations are found in the overflow water than if the catch basins were not present (Dauber and Novak, 1982).

Measurements of material in catch basins also indicate increases in concentrations of hydrocarbons. The effect during rainfall would probably be the same for the storm water discharge works as in the case of heavy metals. Another point is that the dirt-laden water in the catch basin begins to putrefy. If it is washed into the wastewater treatment plant during rain, this may tend to

VOL 12

8255

cause negative effects on the wastewater treatment operation.

Thus, water conservation can hardly be put forward as a conclusive argument for the installation of catch basins.

7.2 Sewage sludge

It is conceivable that some of the road dirt which reaches the wastewater system in the absence of catch basins will pass through the sand trap and finally reach the digested sludge.

But when it is considered that the catch basins are extremely poor sedimentation basins, it cannot be assumed that they have a notable retaining effect in terms of the retention of the finest heavily contaminant-laden proportions. It is much more likely that the material which could be retained in the catch basin would also be separated without problem in the sand trap. The assumption that the absence of catch basins has a negative effect on sewage sludge quality, and therefore renders its use or removal difficult, could not really be considered valid.

7.3 Odours

In sewer systems, particularly in flat areas, odours may occur as a result of the long flow time and slow flow rates. There is an example, namely Freiburg in Breisgau (Germany), where over two thirds of all the sludge catch basins have been converted to direct inlets, and no odour difficulties are being experienced. There are also direct inlets in various other cities in Germany, but in most cases they are provided with sludge buckets. Paris also has direct inlets.

In this country perforated manhole covers (ventilation covers) are not uncommon. If the stench from the sewer system were a major problem, unpleasant odours from these perforated covers would also be experienced.

In the final analysis it is a question of whether the digesting processes which take place in the catch basin itself are not a greater source of stench than a sewer system with normal flow conditions.

8. Concluding remarks

In the course of the work carried out it was demonstrated that the construction and operation of catch basins is not really feasible from the economic point of view. Nor would catch basins probably have much justification in the

VOL 12

8256

R0041562

combined sewer system, for ecological reasons, when streets are cleaned frequently by the vacuum method. But although catch basins have been used since the beginnings of sewer engineering over 100 years ago, the sceptics have yet to be convinced of their inadequate benefits. Tests in larger areas, extending over several years, in which catch basin emptying will be dispensed with for the time being, are intended to demonstrate the effects on sewer cleaning. In Basel, where such a test has been carried out in a larger area (Bruderholz), hardly any differences relative to the previous condition have been observed.

The dispensing with immersion arches on certain street sections could contribute to obtaining more detailed knowledge of odour emissions.

Scientific tests could contribute towards settling the questions of recipient load and sewage sludge load.

POLLUTANT REMOVAL BY CATCH BASINS IN WEST GERMANY STATE OF THE ART - NEW DESIGN

by Matthias Grottker[1]

INTRODUCTION

The discharge of heavily polluted storm water in terms of accumulated loads of chemicals such as heavy metals are becoming an increasingly dangerous hazard. For efficient environmental protection the processes of storm water pollution need to be investigated in detail. The main objectives of this study are to understand the pollutant accumulation and removal processes through various kinds of catch basins and to improve them. The research work is based upon a half year measurement program in a laboratory. Series of tests with variable rates of flow, pollution loads and test durations were simulated for two basic kinds of catch basins. Further a field measurement program was carried out in different catchment areas to expose the state of the art. Based on these investiga- tions new designs were created to improve the removal efficiency, to reduce the maintenance work or to prevent sewer deposits.

LABORATORY MEASUREMENT PROGRAM

Pilot unit

Figure 1 shows the pilot unit which was used to investigate the different catch basins. A weir, mounted on a scaffold, was charged by the water supply system of the laboratory. The rate of flow was regulated by a wedge gate valve and measured by an electromagnetic flow meter. During each test the water fell into a movable trough where the pollution load was added. The polluted water was then discharged to

[1]Swiss Federal Institute for Water Resources and Water Pollution Control (EAWAG), 8600 Dübendorf, Switzerland.

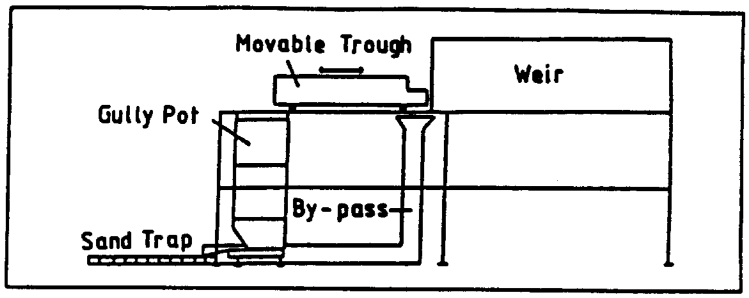

Figure 1 - Pilot Unit

the catch basin. After the water was cleaned in a sand trap it was recycled to the supply system. To finish a test the movable trough was moved away from the weir and the supplied water by-passed the test site.

Test program

The catchment area of a catch basin is normaly limited to 400 m² (1). A discharge of 100 l/s.ha causes a flow rate of about 4 l/s from such a catchment. Under these conditions the flow rates and test duration were chosen, equivalent to the effective depth of precipitation as shown in Table 1.

Test Duration t [min]	Flow Rate Q [l/s]					
	0,50	1,00	2,00	3,00	5,00	10,00
5	0,38	0,75	1,50	2,25	3,75	7,50
15	1,13	2,25	4,50	6,75	11,25	22,50
30	2,25	4,50	9,00	13,50	22,50	45,00

Table 1 - Effective Depth of Precipitation, Flow Rate and Test Duration

The particle sizes and pollution loads to charge the catch basin were chosen based upon earlier research work (2). Table 2 gives an overview about these particle sizes and pollution loads.

Fraction No.	Particle Sizes [mm]	Fraction Load [g]	Fraction No.	Total Load [g]
1	< 0,025	5	2 - 8	35
2	0,025 - 0,08	10	2 - 8	70
3	0,08 - 0,16	15	2 - 8	105
4	0,16 - 0,25	20	3 - 8	120
5	0,25 - 0,50	30	3 - 8	180
6	0,50 - 1,00	40	3 - 8	240
7	1,00 - 1,60	50	3 - 8	300
8	> 1,60			

Table 2 - Particle Sizes, Pollution Loads

The test program concentrated on two kinds of catch basins, shown in Figure 2:

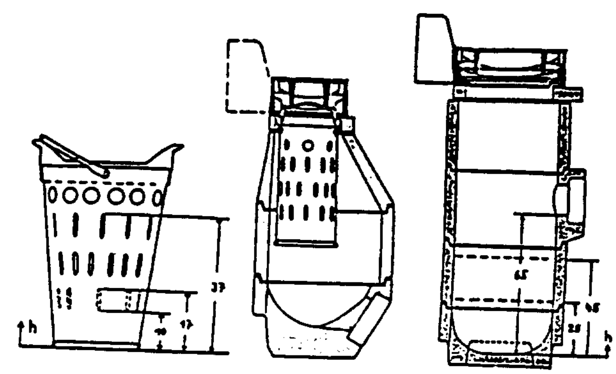

Figure 2 - a) Dry Catch Basin b) Wet Catch Basin

a) Dry Catch Basin (Dry Gully Pct = DGP). The pollution of the surface runoff is reduced by flowing through the slotted bucket. Mainly particles of big size and rubbish

VOL 12

8260

R0041566

like papers, tins, sticks or cigarette stubs are removed. After a storm event, the bucket will be drained by the slots. But the content still keeps wet for a long time, because the ventilation and the temperature within the catch basin is low. b) Wet Catch Basin (Wet Gully Pot = WGP). The surface runoff falls into the small settling pit where pollutants partly accumulate by sedimentation. Also particles of small size are removed beside the big ones and the rubbish. This is caused by the different process of removal (sedimentation). After a storm event the sludge deposits and water will remain within the settling pit.

Most of the other common kinds of catch basins differ only in the volume either of the slotted bucket or the settling pit.

Test procedure

Dry catch basin

Two series of tests were carried out with the dry catch basin.

Test 1 - Simulation of the pollutant removal in an empty slotted bucket. These tests simulate a catch basin just after being cleaned by the sewerage department. In this special case the dependencies between parameters influencing the accumulation and removal processes in the catch basin were found. This was necessary to minimize the number of tests without loss of information. Therefore, all combinations of test duration, flow rate and pollutant load mentioned above were tested.

Test 2 - Simulation of the pollutant removal with different accumulated loads in the slotted bucket. Various stages of accumulated debries were investigated by filling the slotted bucket with wet leaves up to h = 10, 17 and 37 cm (Figure 2a). In this series of tests the discharge parameters "flow rate" and "pollutant load" were kept variable.

Wet Catch Basin

Three series of tests were carried out with the wet catch basin.

Test 1 - Simulation of the pollutant removal with different accumulated loads in the settling pit. Similar to the dry catch basin test 1, all combinations of parameters of the test program were carried out. To replace load levels at h = 25 or 45 cm a metal sheet was fixed at these levels (Figure 2b).

VOL 12

8262

Test 2 - Simulation of the flushing effect from different accumulated loads in the settling pit. Investigations on the flushing effect were carried out with the same load levels in the settling pit as in test 1. The pollutant load was added to the water in the settling pit before the catch basin was charged with water. After ten minutes sedimentation time the test was started. The flow rate was varied from 3, 5 to 10 l/s and the pollutant load was fixed to 100 g of particle size fraction 2-5.

Test 3 - Simulation of the pollutant removal and the flushing effect from different accumulation loads in the settling pit. During the runoff process a superposition of the processes of pollutant removal and flushing takes place. To check this superposition a brief test program was carried out. Hence the pollutant load was added before and during the test comparable to test 1 and 2.

Results

The "passed load" is defined as the part of the pollutant load which cannot be filtered in the catch basin in contrast to the "accumulated load". The description of the passed load as a function of the pollutant load, flow rate, test duration or level of accumulated load is a main objective of the study in laboratory. Therefore coefficients of correlation were computed for all these parameters.

Generally there is no significant correlation between the passed load and the test duration. Furthermore the dependency between the removed load and the pollutant load is linear.

Hence, the generalized function follows as

$L_{pas} = L_{pol} \cdot \mu$	L_{pas} : Passed Load L_{pol} : Pollutant Load μ : Function of flow rate or level of accumulated loads

Function 1 - Pollutant removal

Dry Catch Basin

There is a significant difference between the results of test 1 and 2. An empty slotted bucket (test 1) filters less than half of the pollutant load filtered by partly filled buckets (test 2). The results of the tests with different

R0041568

levels of accumulated load show some scatter. However, no functional dependence between the passed load and these levels could be found. Summarizing these results, μ can be described as a function of the flow rate provided that the slotted bucket is not empty.

Figure 3 and Table 3a illustrate the functional description of μ_{sm} for all particle sizes. It is obvious that the bigger particles were better filtered than the smaller ones. Merely in the range of low flow rates the passed loads of the particle sizes are more random. In this range the passed loads vary between 30 and 50% for the particle sizes and the total load (Σ). The exception is fraction 2 which was passed by about 70% of the pollutant load.

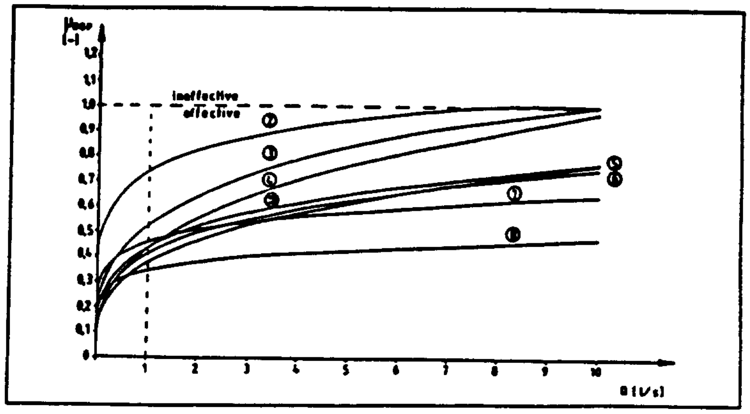

Figure 3 - μ_{sm} - Function

Wet Catch Basin

For all wet catch basin tests no significant correlation between the passed load and the level of accumulated load was found. Except in test 2, the passed load increases from about 10% up to 55% at a flow rate of 10 l/s. Concluding these results μ can be described as a function of the flow rate. Figure 4 and Table 3b illustrate the functional description of μ_{sm} for all particle sizes. Again there is a systematic dependency-among the particle size fractions. The bigger the particles the higher the cleaning efficiency of the catch basin. Merely fraction 7 in the range of low and fraction 2 in the range of high flow rates do not follow this rule. Also the passed loads are limited to 5 to 40% - except fraction 2 with 80% - in the range of low flow rates up to 1 l/s.

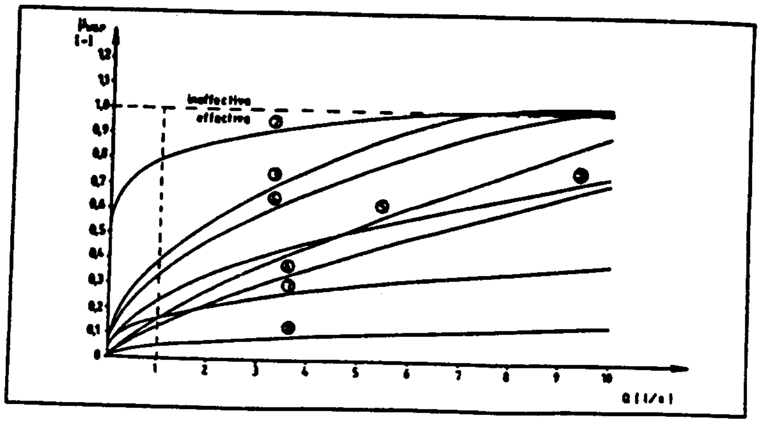

Figure 4 - μ_{sum} - Functions

	a - Dry Gully Pot	b - Wet Gully Pot
Σ	μ = 0,440 $Q^{0,243}$, r = 0,847	μ = 0,236 $Q^{0,496}$, r = 0,846
8	μ = 0,345 $Q^{0,133}$, r = 0,494	μ = 0,046 $Q^{0,492}$, r = 0,639
7	μ = 0,459 $Q^{0,145}$, r = 0,689	μ = 0,166 $Q^{0,372}$, r = 0,777
6	μ = 0,415 $Q^{0,256}$, r = 0,778	μ = 0,132 $Q^{0,734}$, r = 0,783
5	μ = 0,375 $Q^{0,309}$, r = 0,875	μ = 0,165 $Q^{0,737}$, r = 0,766
4	μ = 0,434 $Q^{0,350}$, r = 0,904	μ = 0,335 $Q^{0,497}$, r = 0,858
3	μ = 0,532 $Q^{0,282}$, r = 0,876	μ = 0,391 $Q^{0,481}$, r = 0,828
2	μ = o,739 $Q^{0,151}$, r = 0,935	μ = 0,791 $Q^{0,121}$, r = 0,827

Table 3 - μ-Function a) Dry Gully Pot b) Wet Gully Pot

The flushing effect (test 2) causes passed loads less than 10% of the pollutant load. Merely the passed load of fraction 2 was up to 25% of the initial load. In order to test the results of test 1 and 2 the pollutant removal and the flushing effect was simulated. Generally, the passed load in test 3 was about 10% lower than the separately simulated loads (test 1 and 2). No significant difference between the separate and combined simulation was found among the particle sizes, flow rates and levels of accumulated load.

The acquired results make a continuous simulation of the particle sizes possible. The main uncertainties arise from an empty slotted bucket (DGP) and with the flushing effect at high flow rates (WGP). Therefore, these results have to be verified with data found in real catchments.

Furthermore, a high cleaning efficiency of both dry and wet catch basins were found at flow rates in a range up to 1 l/s. Hence it follows that a revision of the construction of the catch basins could be useful.

FIELD MEASUREMENT PROGRAM

Test procedure

The investigations concentrated mainly on two kinds of catch basins (Figure 5), which are used in the city of Hannover. The dry catch basin differs in the smaller volume of the slotted bucket. The wet catch basin uses a pipe, dipping into the water of the settling pit to hinder smell emissions from the sewer.

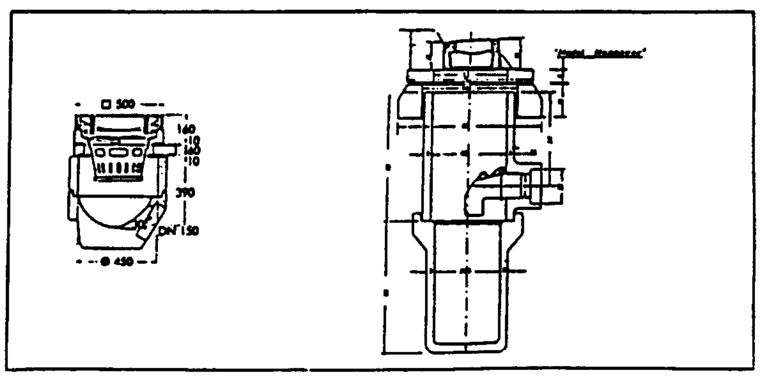

Figure 5 - a) Dry Gully Pot b) Wet Gully Pot

The catch basin maintenance is performed by the municipal cleansing service of the city of Hannover. The dry catch basins shall be cleaned twice or three times a year. A team of 2 or 3 workers empties the slotted bucket into an open trailer. About 70 to 80 catch basins can be cleaned during one day. The annual pollutant removal of each catch basin was measured by weighing the slotted bucket before and after the cleansing procedure. Further on, a sample of the removed matter was taken to analyse some physical and chemical parameters.

The measurement procedure of the wet catch basins was much more difficult. The settling pit is normally emptied by a suction pump lorry. 2 or 3 workers operate the lorry. About 30 to 40 catch basins can be cleaned during one day. The annual pollutant removal of each catch basin was measured by sampling the whole content of the settling pit into suitable sampling bottles. The dry weight was analysed through wet sieving and drying. A part of the removed matter was, further on, analysed like the samples of the dry catch basin.

The investigation was done for both kinds of catch basins in three catchment areas:

1. Residential area, low traffic loading, many trees.
2. Residential area, low traffic loading, few trees.
3. City high traffic loading, no trees.

Later on, a further specification was necessary for each catch basin:

a. The smallest distance of a tree or bush is less than 10 m from the catch basin. b. The smallest distance of a tree or bush is more than 10 m from the catch basin.

Since the characteristics within a catchment area differ very much, we decided to investigate some of the main characteristics of the intake area of each catch basin. The characteristics are:

* intake area (m^2)
* ratio of perviousness of the intake area
* road surface (asphalt, concrete, cobble-stone)
* gutter (width, slope, height)
* slope of road surface (longitudinal, lateral)

The annual pollutant removal of each catch basin was measured and the following parameters have been analysed:

* dry weight
* particle size distribution
* organic matters
* ion exchange capacity
* specific surface
* heavy metal concentrations (few samples of six catch basins)

VOL 12

8266

R0041572

Results

The dependencies between the analysed parameters and the catchment characteristics were checked by a correlation analysis. There is no significant dependency between the catchment characteristics and any other analysed parameter. Consequently the accumulation and removal of surface pollution occurs randomly within the intake area of a catch basin. Further on, there is no significant dependency between the different analysed parameters themselves, with the exception of the small particle sizes and the ion exchange capacity or specific surface. These results confirms the results of the half year measurement program in laboratory. Here we found out, that the pollution removal in a catch basin is mainly depending on the flow rate (3). Of course, there are some other dependencies, which could not be found out by the correlation analysis. These phenomena will be pointed out, by using the mean values of the analysed parameters, shown in Table 4 and 5 - (4).

* The intake area of the dry catch basin is about 125 m² within the residential areas and about 250 m² within thoroughfares. The intake area of the wet catch basin is a little bit less than 250 m². The specific dry weight is situated within the range of 45 g/m² to 68 g/m² for the dry catch basin and within the range of 86 g/m² to 93 g/m² for the wet catch basin. In case trees or bushes are near by, the ratio of organic matters in the catch basin is high. This means, the dry weight is less than in catch basins with only few organic matters. The specific dry weight of the surface pollution load, evaluated by single samples, is about 23 g/m² in Hildesheim (FRG) and about 73 g/m² in Baden-Württemberg (FRG). This is nearly the same amount as the annual removal of the catch basins and makes their small removal efficiency obvious.

* The particle size (PS) distribution shows, that the removal efficiency of fraction PS6 to PS8 is low for the dry catch basin and higher for the wet catch basin. The pollution load on the surface has nearly the same distribution as the one within wet catch basin. Among the PS1, there is a big standard deviation for the dry catch basins, due to tins, sticks or papers. The standard deviation of the other sizes is around 5% as for the wet catch basin.

Table 4 - Physical parameter of the catch basin samples

• The ion exchange capacity and the specific surface characterizes the adsorption potential of a sample. Among the ion exchange capacity, there is no significant dependency between the different samples. This is also caused by the missing results for the wet catch basin. The comparison of the specific surface shows again the small removal efficiency for the dry catch basin, since the specific surface mainly depends on the ratio of small particles.

• The loss of ignition is mainly caused by the PS1 and PS2. In autumn, the loss of ignition is about 6% to 10% greater than in spring, for the dry catch basin. Further on, the mean values of loss of ignition are about 16,7% (residential area) or 11,1% (city) for the dry catch basin and 17,9% (residential area) or 15,4% (city) for the wet catch basin. These values are twice as big as the values of the surface pollution, caused by the higher removal efficiency of the big particle sizes in the catch basins.

Table 5 - Chemical parameter of the catch basin samples

• Investigations about the heavy metal concentrations have only been done for 8 samples out of 207 for the dry and wet catch basins. The investigations about the surface pollution was done more in detail. A comparison has shown, that the concentrations of the seven heavy metals are similar for the dry catch basin and the surface pollution, except for cadmium. The cadmium load of the surface pollution is dissolved by the storm water and can't be removed within the dry catch basin. Differences between the dry catch basins are due to the different land use of the intake areas. This can be proved by the surface pollution concentrations, since the samples in Hildesheim mainly are taken from a thoroughfare, while the Baden-Würtemmberg samples are taken from streets with different traffic loading. The investigations for the wet catch basin have been done more in detail. Each sample was splitted into the fractions < 1,6mm and > 1,6mm. For every heavy metal the small size samples has the higher concentrations. The concentrations in the big size samples are in the same range as the concentrations on the surface. The concentrations in the small size samples are up to ten times higher. This phenomenon might be caused by the good conditions for ion exchanges or adsorption, within the settling pit.

LONG TERM SIMULATION

Simulation model

The removal efficiency of catch basins is characterized in general by physical and chemical parameters. Due to the lack of information about the accumulation and removal on the surface of all the other parameters, the parameter total suspended solids (TSS) shall be used for long term simulation. The simulation model KOSIM is continuously simulating the processes of precipitation losses, runoff concentration, accumulation and removal of surface pollutants and pollution removal by catch basins. With this model, a 11 year long term simulation was carried out. The measured data were used to calibrate and verify the μ_{ww}-function and the μ_{ww}-function within the different catchment areas. The following functions had been fitting best to the measured data (Fig. 6).

Catchment area	Calibration error	Verification error	Number of samples
Dry catch basin Residential road	16,5%	10,5%	154
Dry catch basin Thoroughfare	≈0,0%	23,6%	30
Wet catch basin Residential road	≈0,0%	17,0%	10
Wet catch basin Thoroughfare	≈0,0%	30,0%	5

Table 6 - Calibration and verification errors

Table 6 shows the errors for calibration and verification. They are in a range of 10% to 30%, which can be accepted for the further simulation. The efficiency of the catch basins in the model of the laboratory was much better than under real conditions on the roads. This is caused by the short term measurements in laboratory.

Synthetic catchment area

The efficiency of storm water treatment depends on the rainfall-runoff process and on the surface characteristics. The main sources of surface pollution are the atmospheric deposition and the pollution caused by the traffic. Therefore the surface areas of roofs, resi-

Dry Catch Basin

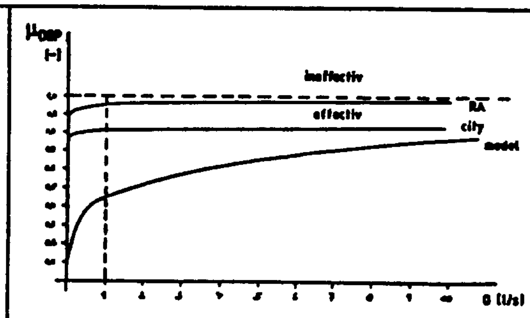
$\mu = 0,810 \cdot Q^{0,080}$



Wet Catch Basin

Model:

$\mu = 0,236 \cdot Q^{0,496}$

Residential area:

$\mu = 0,876 \cdot Q^{0,100}$

Thoroughfare:

$\mu = 0,856 \cdot Q^{0,100}$

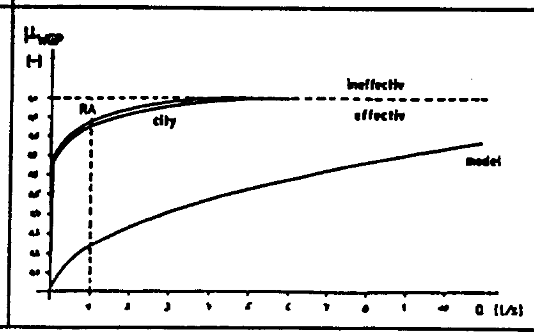


Figure 6: μ-Functions for dry (DGP) and wet (WGP) catch basins

dential roads and thoroughfares are the most significant parameters. These paved areas are defined as follows:

* Roofs include the paved surface within the private property.

* Residential roads include pavements, cycleways and parking lots. The traffic load is less than 6000 cars per day.

* Thoroughfares include pavements, cycleways and parking lots. The traffic load is more than 6000 cars per day.

The roofs are polluted by the atmospheric deposition, the roads are polluted by the atmospheric deposition and the traffic. The average pollution load of the atmospheric deposition (AV 1-4) is in a range of 300 to 900 kg/ha.a. The traffic pollution load is 2000 kg/ha.a in residential roads and 5500 kg/ha.a in thoroughfares. These average values are estimated by data published in the literature. To transfer the results of the simulation to existing catchment areas, a spectrum of synthetic catchment areas is defined like in Table 7:

All together 44 synthetic catchment areas are defined, representing most of the existing catchment areas.

Results

For every synthetic catchment area first a long term simulation was carried out without any treatment of storm water. The discharged annual pollution load of TSS is shown in Table 7. After that the following 12 treatment conditions (Table 8) were simulated:

	Dry catch basin	Wet catch basin
Intake area	50 m^2 100 m^2 200 m^2 300 m^2 400 m^2 500 m^2	50 m^2 100 m^2 200 m^2 300 m^2 400 m^2 500 m^2

Table 8 - Intake areas of the simulated catch basins

Before estimating the removal efficiency of the catch basins the frequence of maintenance was varied for each treatment condition. The necessary frequence is in a range of every 6 to 72 months depending on the kind of catch basin, intake area and land use. Since in the model only particles were simulated, these frequencies are much too great. Mainly sticks, tins, stones or wires may clog the catch basins. To guarantee the hydraulic efficiency the frequency of maintenance should be twice a year for the dry catch basin and once a year for the wet catch basin.

VOL 12

8274

Depending on the land use of the paved surface, the removal efficiency is 2,2% to 8,3% for the dry catch basin and 10,4% to 43% for the wet catch basin (Table 9). The removal efficiency (%) ie better, the more roads are within the catchment. Of course, the amount of discharged pollution load is also greater then. The removal efficiency is less, if the atmospheric deposition is great, since the pollution load of the roof surface can't be treated by catch basins.

In general the dry catch basin is only useful to hinder clogging within the sewer pipe. It is nearly useless to remove TSS out of the storm water. The efficiency of wet catch basins is much better, but still not good enough to protect the receiving waters.

ENVIRONMENTAL AND OPERATIONAL PROBLEMS

Separate severage system (SSS)

In separate severage systems many environmental problems occur due to the great pollutant loads of physical and chemical parameters. Often the concentrations of many parameters are much greater than at the outlet of treatment plants and sometimes greater than at combined severage overflows (6). Since the discharges are polluting the recei-ving water discontinuously and during every storm event the SSS is a serious source of environmental pollution. The storm water needs to be treated in cases of heavy and medium polluted surfaces. Two treatment strategies can be distinguished and qualified like in Table 10:

* Decentralized treatment as
  - Street cleansing
  - Catch basins
  - Infiltration systems
* Centralized treatment as
  - Detention ponds
  - Swirl separators
  - Infiltration systems
  - Vegetative controls

Table 10 - Qualification of storm water treatment systems

In urbanized areas often there is no space to install a central treatment system. In these cases only street cleansing and catch basins can be used to mitigate storm water pollution. Further on, the decentralized systems are cheaper in construction. Since inlets are necessary in any case, their treatment efficiency should be improved and their maintenance costs should be reduced as much as possible.

Combined severage system (CSS)

In flat combined severage systems sewer deposits are causing a lot of maintenance work. These deposits may reduce the hydraulic capacity of the sewer pipes and by this cause a higher frequency of flooding in the streets. Further on, the deposits may be flushed during a heavy storm event and discharged by overflows to the receiving waters.

To guarantee the full hydraulic capacity of the sewer pipes and to mitigate the pollutant discharges to receiving waters the deposits shall be flushed during dry periods and catch besins shall reduce the input of solids from the surface. In sewer pipes with high levels of deposits which

VOL 12

8276

occur within a short period, a new construction of these pipes may be efficient. All these activities cost a lot of work and money. But still the sewer deposits are a serious environmental and operational problem.

Maintenance costs

The maintenance costs for cleansing of catch basins and removal of sewer deposits shall be estimated very rough. The city of BREMEN (500.000 inhabitants) gave us some brief information about their maintenance costs in 1983. This may give an idea of the costs in general. A further investigation shall be done to calculate the maintenance costs in detail.

Removal of sewer deposits

20 special lorries and 40 workers are required to clean all together 1900 km sewer pipes.

Costs:

20 lorries x 500.000,- DM	10.000.000,- DM
Depreciation: 10 years	1.000.000,- DM/a
40 workers x 50.000,- DM/a	2.000.000,- DM/a
Annual costs, whole network:	3.000.000,- DM/a
Annual costs, per meter:	1,58 DM/m

Cleansing of catch basins

About 57.000 dry catch basins (DGP) have to be cleaned twice a year and 19.000 wet catch basins (WGP) have to be cleaned once a year. A team (A) of three workers is cleansing about 100 DGP/day using a small lorry. A team (B) of two workers is cleansing about 40 WGP/day using a special lorry. In average have to be cleaned:

570 DGP/day	6 teams A necessary
95 WGP/day	3 teams B necessary

Costs:

DGP	: 6 small lorries x 50.000,- DM	300.000,- DM
	Depreciation: 10 years	30.000,- DM/a
	6 x 3 Workers x 50.000,- DM/a	900.000,- DM/a
Annual costs, whole city:		930.000,- DM/a
Annual costs, per catch basin:		16,32DM/DGP

VOL 12

8277

R0041583

WGP	: 3 special lorries x 500.000,- DM	1.500.000,- DM
	Depreciation: 10 years	150.000,- DM/a
	3 x 2 workers x 50.000,- DM/a	300.000,- DM/a
Annual costs, whole city:		450.000,- DM/a
Annual costs, per catch basin		23,68DM/WGP
Total maintenance costs:		4.380.000,- DM/a

Requirements on sanitation strategies

The pollutant removal by catch basins in West Germany needs to be improved. Different strategies are practicable to improve the systems. In Table 11 the pros and cons of four different strategies are documented very briefly. The strategies can be described as follows.

	No catch basins	Dry catch basins only	Wet catch basins only	Improved catch basins
Maintenance costs	++	+	-	+
Construction costs	-	0	--	0/-
Storm water pollution	--	-	+	+
Smell emissions	-	0	0	0
Sewer deposits	-	0	+	+
Operation reliability	-	0	0	0

Table 11 - Qualification of sanitation strategies

* Remove all the catch basins and use big inlets which don't remove any pollutants.

Maintenance costs: No maintenance is necessary, no costs will occur.

Construction costs: DGP: Slotted buckets have to be removed. - WGP: Settling pits have to be filled by concrete.

Storm water pollution: High pollution - central treatment is necessary.

Smell emissions: May occur in combined severage systems.

Sewer deposits: In combined systems more deposits may occur.

Operation reliability: Less reliability, since sticks, rubbish and other material may clog the sewer pipes.

* Dry catch basins only.

Maintenance costs: Less costs, since no special lorries are necessary and the cleansing of dry catch basins is much faster.

Construction costs: Step by step slotted buckets shall be installed within the wet catch basins.

Storm water pollution: Increase of pollution - central treatment may be necessary.

Smell emissions: No change.

Sewer deposits: In combined systems more deposits may occur.

Operation reliability: No change.

* Wet catch basins only.

Maintenance costs: Increase of costs, since special lorries can be used only and the cleansing of wet catch basins is much slower.

Construction costs: Very high costs, at every dry catch basin a construction site needs to be installed.

VOL 12

8279

R0041585

Storm water pollution: Decrease of pollution.

Smell emissions: No change.

Sewer deposits: In combined systems less deposits may occur.

Operation reliability: No change.

* Improved catch basins - (A detailed description of the new designs is given in the next chapter).

Maintenance costs: Less costs, since no special lorries are necessary and the cleansing of slotted buckets is much faster.

Construction costs: In separate severage systems the costs of siphon catch basins are very high, since a construction site has to be installed. In all other cases the costs are little.

Storm water pollution: Decrease of pollution.

Smell emissions: No change.

Sewer deposits: In combined and seperate systems less deposits may occur.

Operation reliability: No change.

We decided to improve the catch basins. An inlet construction is necessary in any case, since the reliabilty of operation must be high. In the following chapter different improved catch basins are described, to be used in different drainage conditions.

SANITATION STRATEGY

In general a cheap and an expensive sanitation can be chosen. The way to improve the system depends on the existing catch basin as well as on the drainage system. Table 12 is pointing out the new designs of catch basins with or without construction work.

Sanitation without construction work

In combined severage systems as well as in separate severage systems the dry catch basin can be improved by a new bucket. This new bucket has no slots, but some holes at the bottom to keep the bucket dry (Figure 6a). This design guarantees a better removal also of small particles.

	Combined sewer system		Separate sewer system	
	Dry catch basin	Wet catch basin	Dry catch basin	Wet catch basin
Sanitation without construstion work	modified bucket	siphon catch basin	modified bucket	overflow catch basin
Sanitation with construc-tion work/new construction	siphon catch basin		sewer deposits: siphon catch basin no sewer deposits: overflow catch basin	

Table 12 - Sanitation strategy

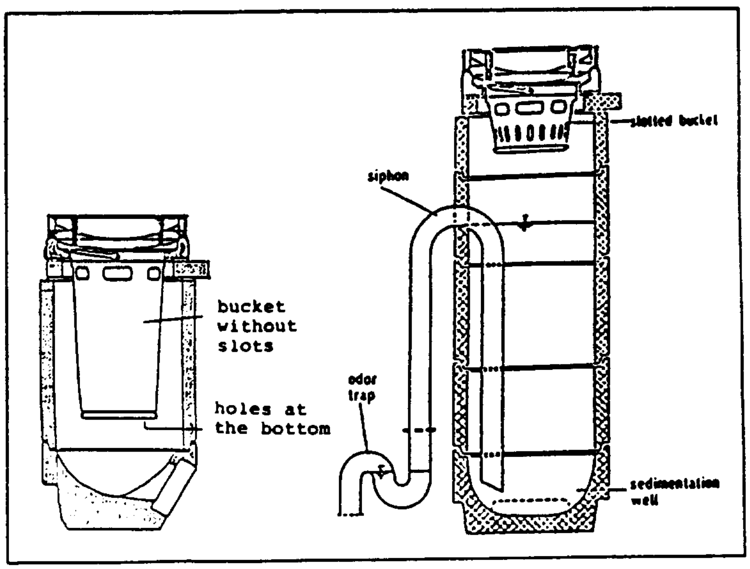

Figure 6 - a: Modified bucket (CSS+SSS) b: Siphon catch basin (CSS)

After the bottom of the bucket is covered with some removed material, the polluted storm water will further be filtered by this material. By this the removal efficiency increases rapidly. If the filtration capacity is less than the inflow rate, the storm water shall be stored within the bucket. In case of very high inflow rates, the big holes at the top of the bucket guarantee the hydraulic capacity of the catch basin. The bucket shall be cleaned as before.

For combined systems with wet catch basins a catch basin is proposed, where the inflow passes a slotted bucket and leaves the catch basin through a siphon (Figure 6b). Thereby, also during moderate storms (inflow > 0,5 l/s) the combined sewer is charged discontinuously with approximately 100-l-flushes, which keep sediments mobil and pipes cleaner. Hydraulic tests proved that the siphon removes all sediments in the sedimentation well. Therefore, expensive suction cleansing of the siphon catch basin is not necessary. Large debris has to be removed from the bucket. The siphon can be installed very easy by inlining the existing outlet with a tube which ends at the bottom of the sedimentation well.

For separate systems with wet catch basins the removal efficiency can be improved by using an throttle/overflow-construction which can be fit into the outlet. The throttle reduces the outflow and by this the turbulences within the sedimentation well (Figure 7b). In case of the inflow rate is greater than the throttle capacity, the storm water shall be stored and later discharged over the overflow. The overflow catch basin has to be suction cleaned, though.

Sanitation with construction work/new construction

In combined systems with or without sewer deposits the siphon catch basin shall be installed. In separate systems without sewer deposits in the sanitary pipe the overflow catch basin shall be used.

In case of sewer deposits in the sanitary pipes of the separate system the siphon catch basin can be adapted to the different conditions (Figure 7a). This catch basin features an additional throttled outlet with overflow as well as a siphon and a slotted bucket. During moderate rainfall the inflow passes the catch basin through the throttle into the storm sewer, while solids settle down in the sedimentation well. In major storms the throttle constrains the regular outlet rate and the catch basin fills up to the siphon crest. The siphon is activated and empties the well including the accumulated sediments into the sanitary sewer. The throttle is sized to have the siphon activated only rarely (e.g. 10 times a year).

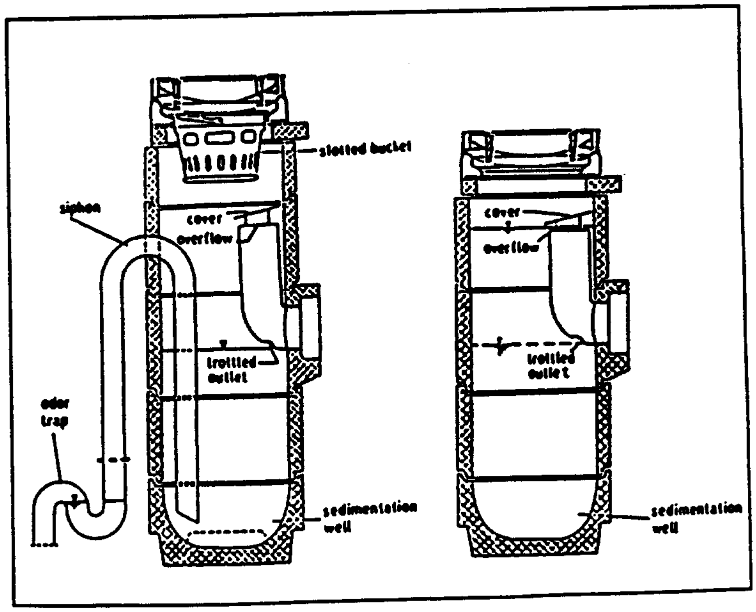

Figure 7 - a: Siphon catch basin b: Overflow catch basin (SSS)

NEW DESIGN OF CATCH BASINS

Laboratory tests

The overflow catch basin and the siphon catch basin have been hydraulically tested in 1:1 scale for a large variety of operating conditions. Thereby details have been optimized to allow for good hydraulic efficiency also at low suction heads of the siphon.

Initial tests showed, that the removal efficiency of both new catch basins is nearly the same as the one of the wet catch basin. Consequently further tests concentrated on different loadings (sand, gravel, leaves, etc.) mainly of the siphon catch basin.

Overflow catch basins: Depending on the diameter of the throttle the overflow was activated at inflow rates between 0,5 and 2,5 l/s. By choosing the diameter the number of overflows can be estimated, taking the intake area of the catch basin into acount. The diameter should be chosen between 2 and 3 centimeters.

Siphon catch basin (SSS): The inflow, outflow and siphon flow during a storm event is illustrated in Figure 8. The process can be divided into four phases. During the first phase the inflow passes through the throttle to the storm sewer, while the water level within the catch basin increases. In the second phase the water level reaches the siphon and flows to the sanitary sewer. During the first seconds there is no suction flow. But soon the siphon starts working and flushing the water of the sedimentation well including most of the sediments to the sanitary sewer. The throttle stops working. In the third phase the well of the catch basin is filled until the throttle starts working again. During the fourth phase there is an outflow to the storm sewer but no more siphon flow. Finally the inflow rate is as big as the outflow rate.

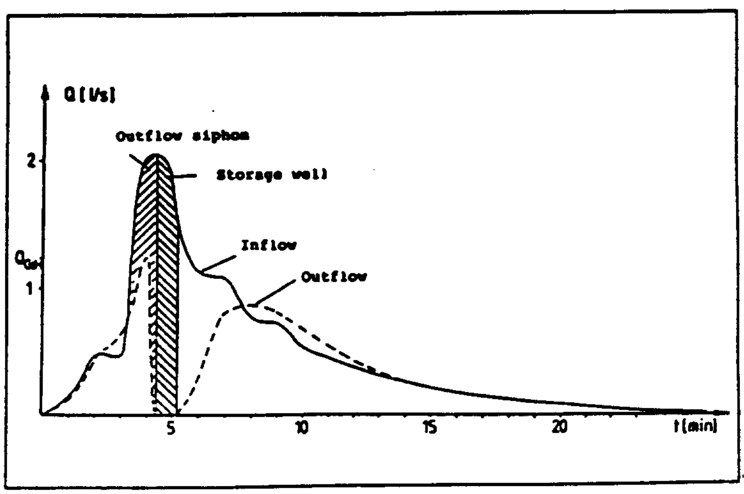

Figure 8 - Hydraulic of siphon catch basin during storm event

VOL 12

8284

Field performance

The hydraulic tests showed that the siphon sucks the sediments in the well. Even stones of a diameter of 4-5 centimeter have been flushed out. Consequently the siphon catch basins have been prepared for field conditions. Main task was the dimensioning of the throttle. The diameter of the siphon was chosen with 7,5 centimeter, since this was a proved dimension.

Analysing a long record of 1-minute rainfall intensities a dimensioning diagram has been set up for North German meteorological and inlet conditions (Figure 9). The throttle diameter is expressed as a function of the inlet catchment area (100-500 m²) and the desired siphon activation frequency.

Two siphon catch basins with a throttle diameter of 2,5 and 3 centimeters have been installed in the separate system of the city of Hildesheim (FRG). Over half a year the catch basins cleaned themselves. During this summer heavy stroms flushed a huge load of sand from the road which is still under construction. Due to this load the end of the siphon was clogged. But the throttle and overflow have been working without any failure. To improve these catch basins, the diameter shall be decreased and further tested over many years. At least after the construction of the brick stone road is finished the siphon shall work without failure.

The flushing effect of the siphon is avaluated with empirical relations found in the literature (7). They indicate, that in smaller pipes the siphon flush is efficient over a diatance that exceeds the average distance between catch basins.

Example:

$$V_s = (13,5 \cdot L^{1,45} \cdot D^{0,23}) / S^{1,40}$$

V_s : Siphon flush volume = 3,531 cf
D : Diameter = 0,82 ft
S : Slope = 5ft/1000ft
L : Distance = 59,0 m (calculated)

R0041591

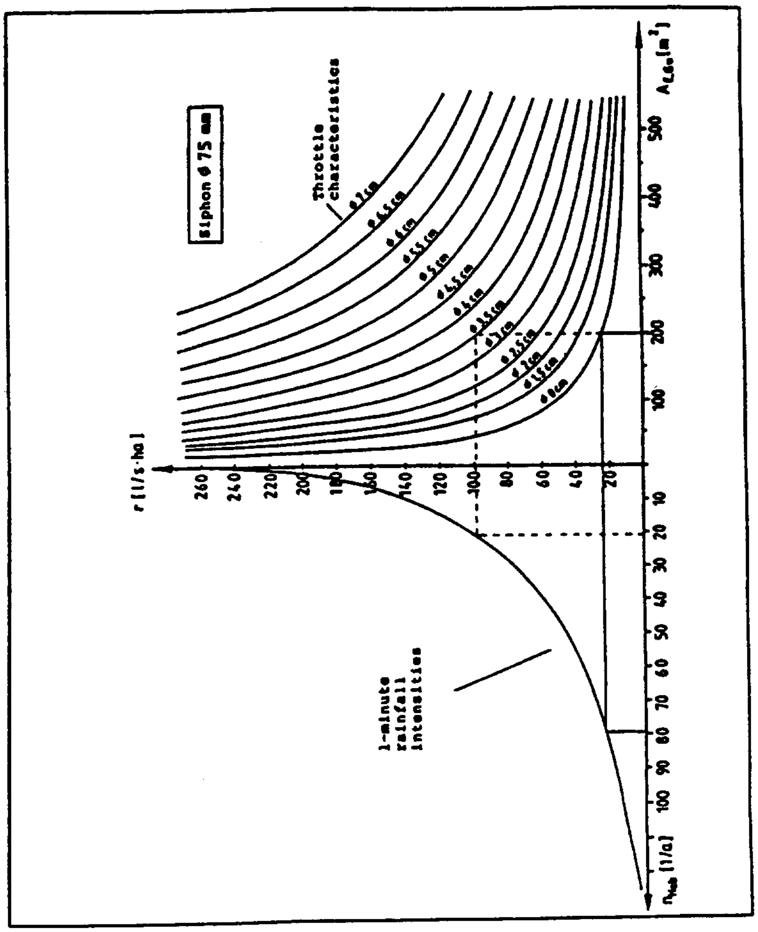

Figure 9 - Dimensioning diagram - siphon catch basin

VOL 12

CONCLUSIONS

The proposed set of redesigned catch basins allows to cut operating costs and reduce receiving water pollution at the same time. Based on the existing type of sewer system (combined or separate), the existing catch basins (dry or wet) and the need for cost reduction (cleansing) and pollution control an individual sanitation concept can be proposed for a drainage area.

POLLUTION ABATEMENT IN TOKYO "ESS"

by Takaaki Koyama[1] and Shoichi Fujita[2]

SUMMARY

The Tokyo Experimental Sewer System (ESS) was developed to study the control of urban storm inundation in a densely populated area. Adopting ESS also reduces both overflow pollution loadings and the volume and peak flow of urban storm runoff.

1. DESCRIPTION OF THE ESS

The ESS was developed to reduce the amount and peak flow of urban storm runoff. It is a system comprised of many facilities to effectively catch pollutants, thereby contributing to the improvement in the quality of public water bodies. The facilities have two primary functions, infiltration and storage. Figure 1 shows the drainage area in which the ESS was installed.

1.1 ESS Facilities

The ESS facilities include:

(a) Infiltration

o Infiltration Inlets - placed every 20 meters along both sides of the roads (see Figure 2)

o Infiltration Trenches - laid along both sides of the roads, and connected with the infiltration inlets, as shown in Figure 3.

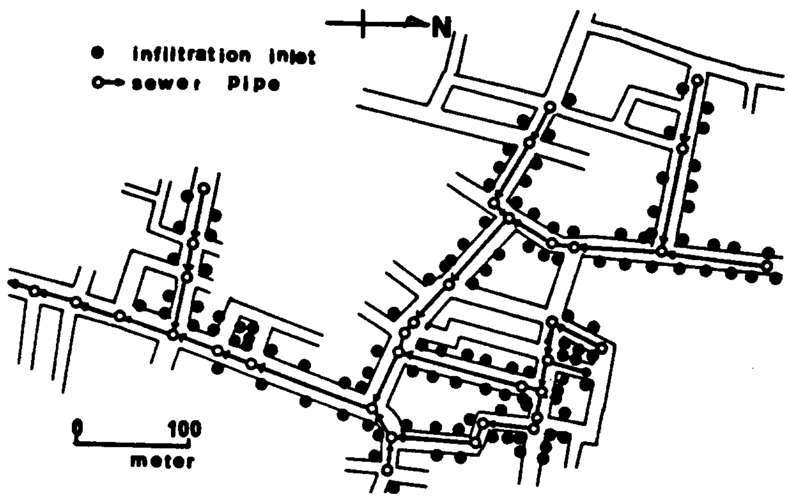

Figure 1. Model Drainage Area (actual installation of ESS)

o Infiltration LU-Curb - used instead of infiltration trenches in narrow roads where trenches are difficult to install (see Figure 4).

o Permeable Pavement - applied to all roads running along sewer mains.

(b) Storage

o Storage inside the infiltration facilities - the entire capacity of the infiltration facilities is used for storage. Storm water is stored in the backfilling materials of the infiltration facilities.

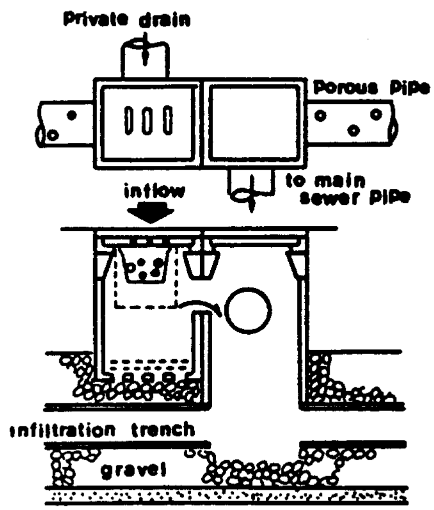

Figure 2. Infiltration inlet

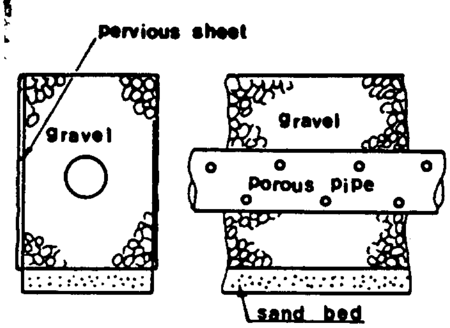

Figure 3. Infiltration trench

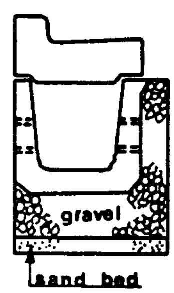

Figure 4. Infiltration LU-curb

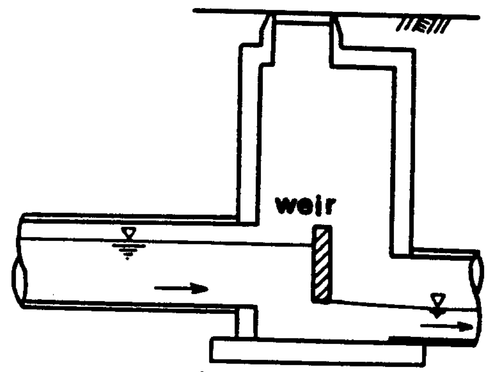

Figure 5. Storage Manhole

o Storage Manhole - a weir is installed inside the manhole (Figure 5) to utilize the storage capacity of the upstream trunk sewer for the attenuation of peak flow.

o Circuitous Routing of Sewer Pipes - sewer pipes are laid in such a way as to prolong the travel time of sewage.

A conceptual layout of the facilities in the ESS is shown in Figure 6, and the arrangement of the ESS in the combined sewer system is illustrated in the flow chart in Figure 7.

Although it is a combined sewer system, wastewater and stormwater should be introduced separately. Stormwater is introduced into the first chamber of the infiltration inlet. Sand and grit are settled in the mudpit. Stormwater which overflows the mudpit proceeds to the second chamber of the infiltration inlet, and flows in

VOL 12

8291

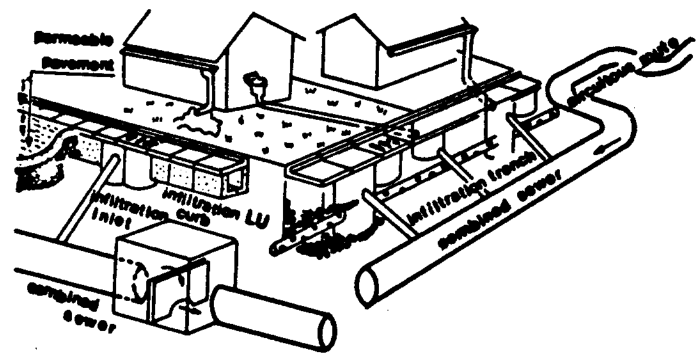

Figure 6. Conceptual Layout of ESS Facilities

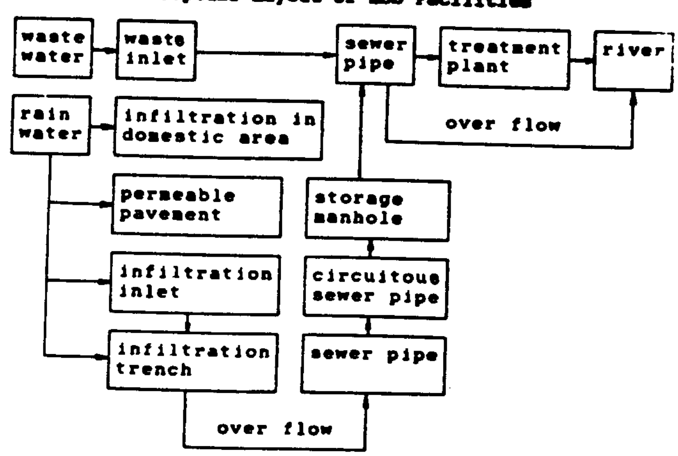

Figure 7. Arrangement of ESS in Sewer System

excess of the infiltration capacity of the inlet are introduced into an infiltration trench or infiltration LU-Curb. Consequently, stormwater does not flow into the combined sewer main until the amount of precipitation exceeds the capacity of these infiltration facilities. Thus, the ESS allows reduction in storm runoff and increased pollution control.

The capacity of the infiltration facilities depends on how effectively they can reduce the incoming clogging materials. Devices to capture such materials are therefore installed in the inlets.

All of the facilities in the ESS are readily-available items in common use, and are thus economical.

1.2 Full-Scale Testing of the ESS

Full-scale ESS testing commenced in April, 1980. on the Shakujii and the Shirako river basins. The kinds and numbers of facilities used in the experimental area are shown in Table 1.

Table 1. Implemented Runoff Control Facilities of the ESS

Facilities (1)	Shakujii River (2)	Shirako River (3)	Total (4)
Infiltration Inlets	4,778	15,218	19,996
Infiltration Trench (km)	43	84	127
Infiltration LU-Curb (km)	22	49	71
Permeable Pavement X 10^3 (m^2)	200	408	608
Construction Cost X 10^6 (yen)	12,588	24,310	36,898
Area (hectares)	305	597	902
Population	39,600	72,100	111,700

The construction costs of the ESS are about 20 percent higher than the cost of conventional sewer systems. The authors believe, however, that the ESS should not be regarded as expensive considering its ability to reduce runoff and pollution loadings.

1.3 Reduction of Stormwater Runoff by the ESS

In combined sewer systems, the amount of stormwater overflows to the public water bodies depends on the total amount of inflow. Therefore, controlling incoming stormwater will also contribute to reduced pollution loadings. In the ESS, facilities typically show high infiltration capacities. In time, however, such capacity may be reduced by the accumulation of clogging materials.

As a result, actual measurements of the accumulation of these materials, and their effects on infiltration capacity, were carried out for the study area. The progression of capacity reduction is shown in Figure 8. For practical design purposes, the infiltration capacity for each type of facility is shown in Table 2.

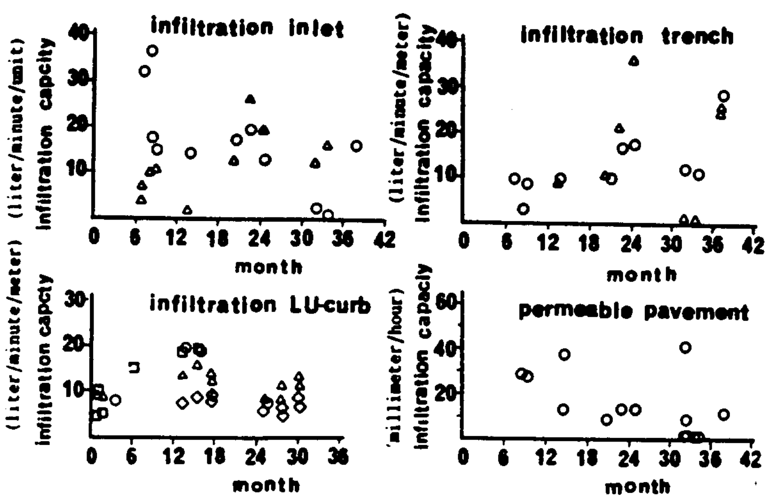

Figure 8. Progression of Capacity Reduction

Table 2. Infiltration/Storage Capacity of ESS Facilities

Facility (1)	Infiltration Capacity (2)	Storage Capacity (3)
Mudpit	0 l/min/unit	0.059 m³/unit
Infiltration Inlet	3 l/min/unit	0.141 m³/unit
Infiltration Trench	8 l/min/meter	0.261 m³/meter
Permeable Pavement	10 mm/hr	0.045 m³/m²

Applying these capacities to the Shirako River basin, it was estimated (see Figure 9) that a 60 percent reduction in stormwater runoff will be obtained at the downstream end of the basin with a rainfall intensity of 50 mm/hr, compared with the conventional combined sewer system.

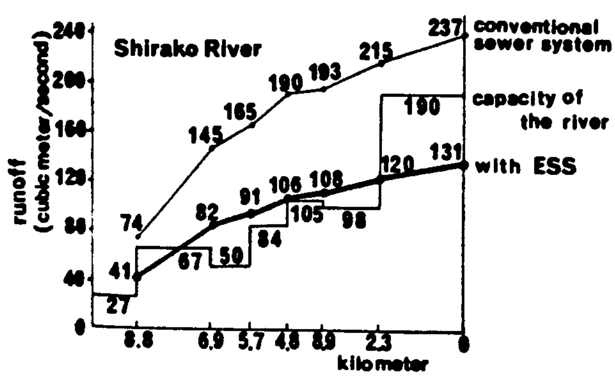

Figure 9. Estimated Effects of the ESS - Shirako River

1.4 Removal of Clogging Materials in the ESS

There are many methods used to maintain the infiltration capacity of ESS facilities. Data on captured materials initially obtained from the study area are shown in Table 3.

Table 3. Weight of Captured Materials (mean value)

2. EVALUATION OF POLLUTION LOAD REDUCTION BY THE ESS

The effects described here focus on the overflow rate and overflow pollution loadings, compared to a conventional sewer system.

The idea of controlling storm runoff using the ESS was introduced at the Fourth International Conference on Urban Storm Drainage held in Lausanne in 1987 (Fujita, 1987). This paper is based on the results of Dr. Fujita's work.

The Tokyo Metropolitan Government started field research in 1971 in the Yabata, Momozono and Tachiai river basins, amongst others. The research accumulated field measurements of flow rate and change in water quality, and was also aimed at establishing model formulas for stormwater overflow and pollution loadings. This section presents the results of a simulation of the Tachiai as a model river basin (see Figure 10) to evaluate the effects for water pollution control.

2.1 Outline of Model River Basin

The Tachiai River basin is located in the southern part of Tokyo and is a residential area. It has an area of 467 hectares, and is serviced by a combined sewer system. Data on the basin are given in Table 4.

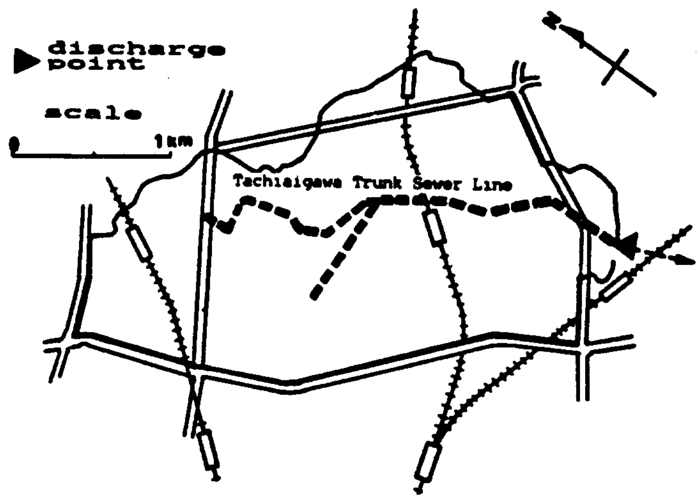

Figure 10. Tachiai Model Drainage Area

2.2 The Calculation Model

(a) Model of Stormwater Runoff - The model is derived from the TRRL method (Ministry of Construction, 1981), which was originally developed by the Transport and Road Research Laboratory in England to estimate the runoff hydrograph in areas where no runoff data exists. The model includes an estimation of the effective amount of precipitation, and a corrected S-Q curve developed by the Public Works Research Institute of the Ministry of Construction in Japan.

The basic formulae used in the calculation are as follows. The modified RRL method is an alternative to storage function methods which estimate stormwater runoff at a

Table 4. Tachiai Model Basin Data

Sewage Treatment District Name:	Morigasaki
Trunk Sewer Line:	Tachiaigawa
Drainage Area:	467.7 hectares
Drainage System:	Combined sewers
Flow System:	Gravity flow
Size of Sewer (Box Culvert)	width = 5900 mm height = 3600 mm
Population:	99,404
Land Use:	
Residential	365.1 hectares (78.0%)
Commercial	72.4 hectares (15.5%)
Industrial	30.2 hectares (6.5%)
Surface Condition	
Impermeable area	57.6%
Permeable area	42.4%

point by making an equal-arrival-time map for the region, with sewer storage capacity as the perameter of interest.

$$I_n = \Sigma(re_{n-i+1} * Ai) / A \quad (1)$$

$$S = K * q^p \quad (2)$$

$$(dS/dT) = I - O \quad (3)$$

Where,

I = rainfall intensity, mm/hr
re = effective rainfall intensity, mm/hr
Ai = equal-arrival-time area, hectares
A = total drainage area, hectares
S = amount stored in sewer, mm
K,p = constants
q = flow rate in sewer, mm/hr
O = rate of runoff, mm/hr

(b) Model of Pollution Loadings Discharges - An accumulative loadings evaluation model developed by the Public Works Research Institute was adopted for the simulation of pollution loadings discharges. The concept of the model is described in Figure 11. The characteristics of the model are:

1. The exponents m and n are employed to express various discharge characteristics of different water quality components.

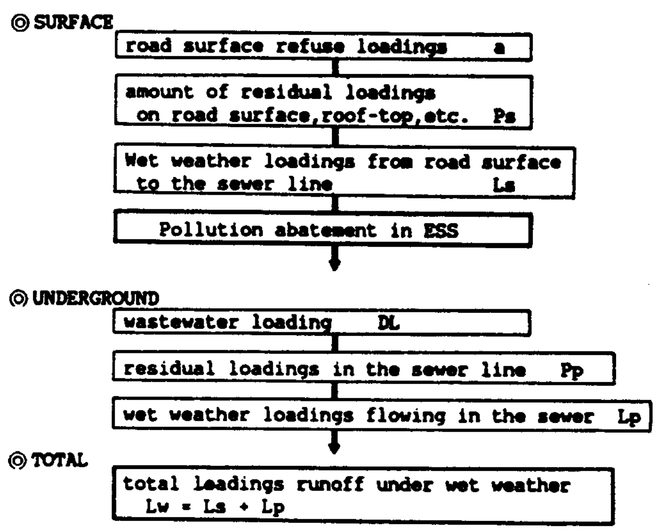

Figure 11. Calculation Procedure

2. It can express total pollution loadings discharge.

3. It can express the "first flush."

4. It can express the re-accumulation after a rainfall event.

The basic formulae for dry-weather pollution loadings discharges are:

$$L_p = C * Pp^{a} * Q^{b} * (Q - Qc) \quad (4)$$

$$(dPp/dt) = D_L - L_p \quad (5)$$

The formulae for wet-weather discharges are:

$$L_w = Lp + Ls \quad (6)$$

$$L_p = C * Pp^m * Q^n * (Q - Qc) \quad (7)$$

$$Ls = (1/3.6) * K * Ps * (re - rc) * A \quad (8)$$

$$(dPp/dt) = D_L - Lp \quad (9)$$

$$(dPs/dt) = a - Ls \quad (10)$$

$$K = CCI * CR * Imp \quad (11)$$

where,

L_p = rate of dry-weather flow loadings in sewer, gm/sec
C = Discharge coefficient of loadings (constant)
Pp = Accumulated residual loadings in sewer line, gm
Q = Flow rate, m^3/sec
Qc = critical flow rate, m^3/sec
D_L = Rate of dry-weather loadings (normal wastewater), gm/sec
m, n = exponent parameters (constant) m=2 and n=0 for BOD and COD, m and n = 1 for SS
Lw = total rate of wet-weather loadings, gm/sec
Lp = Rate of flowing loadings (wet-weather) in sewer line, gm/sec
Ls = Rate of wet-weather loadings from road surface, gm/sec
Ps = amount of residual loadings on road surface, roof tops, etc., kg/hectare
CCI = ratio of loads-generating area to the impermeable area. CCI = 1 for this study.
CR = Coefficient of loadings from road surface, 1/mm
Imp = Percent imperviousness
rc = critical rainfall intensity, mm/hr
a = rate of pollution loadings (road surface refuse loadings), gm/sec

2.3 Calculation Conditions

(a) Precipitation Used for Calculation - The evaluation was conducted on the record of the Tokyo Central Meteorological Observatory for 1975, since 1975 precipitation was found to be closest to the 20-year average value (1962 - 1981). The precipitation data were based on observed precipitation greater than 0.5 mm over a 5-minute interval. A precipitation event was defined as one followed by 3 hours of no precipitation (Tables 5 and 6).

Table 5. Precipitation in Tokyo

Year (1)	Number of Rainfall Events per year (2)	Annual Precipitation (mm) (3)	Total Rainfall (hours) (4)
1962	88	1203	717
1963	87	1550	812[1]
1964	76	1078	718
1965	80	1557	665
1966	65	1495	549[2]
1967	77	1056	615

1976	88	1453	702
1977	66	1449	648
1978	68	995[2]	549
1979	78	1402	714
1980	77	1482	740
1981	65	1422	589
Average	76	1363	680

Note: [1] = Maximum and [2] = Minimum

(b) Ratio of Impermeable Area - The ratio of impermeable area (Imp) was measured on aerial photos using a digitizer. Roofs were generally counted as impermeable in the area served by combined sewers, since roof runoff is introduced through storm water inlets. However, after the survey of this model area, 20 percent of roof runoff was found to flow into permeable areas, such as gardens. As a result, the impermeable area was found to cover 57.2 percent of the total model area.

(c) Calculation conditions for runoff - these conditions are described in Table 7, and one of the results is shown in Figure 12.

Table 6. Precipitation Range in a Year

Loading Supply Rate, a (gm/sec)	0.0022	0.0056	0.116

(e) Overflow Conditions - The total pollution load is the sum of the overflows from storm water outfalls and the wastewater treatment plant effluent. The overflow conditions are based on the case when three times the amount of the maximum hourly dry-weather flow can be intercepted and transported to the treatment plant.

VOL 12

8305

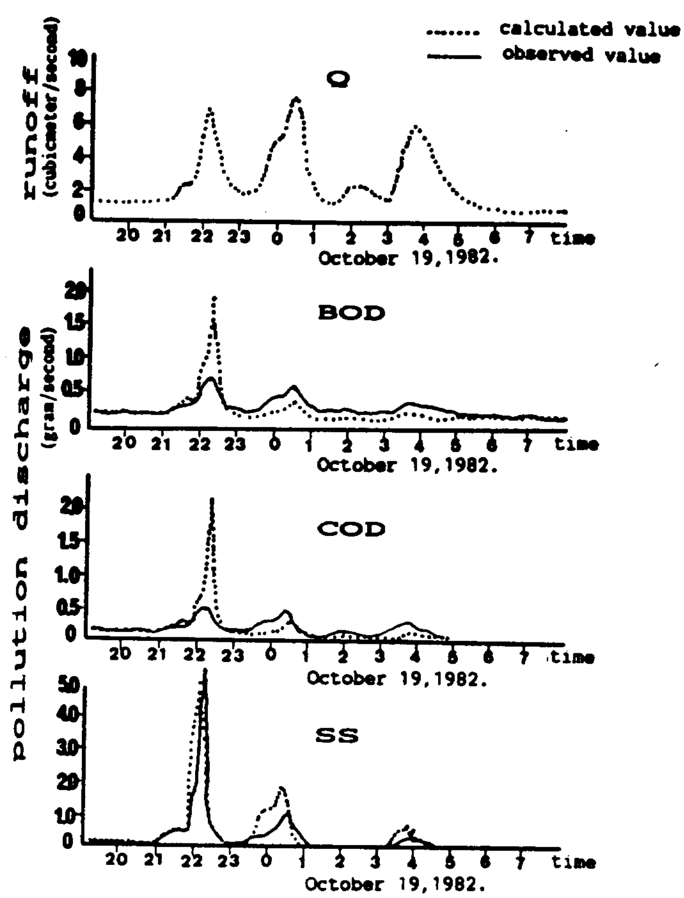

Figure 13. Results of Pollution Loading Discharge Simulation

R0041611

The maximum hourly dry-weather flow was estimated as follows:

Maximum Daily flow = 1.35 x observed average daily flow
= 1.35 x 0.475 = 0.641 m^3/sec

Maximum hourly flow = 1.5 x maximum daily flow
= 1.5 x 0.641 = 0.962 m^3/sec

Maximum interception = 3.0 x maximum hourly flow
= 3.0 x 0.962 = 2.886 m^3/sec

(f) Treatment plant efficiency - treatment plant efficiency was based on the data shown in Table 9:

Table 9. Efficiency of Sewage Treatment

(1)	(2)	BOD (3)	COD (4)	SS (5)
Primary Treatment	Removal Rate (%)	30	20	30
	Effluent Quality (mg/l)	30	30	30
Secondary Treatment	Removal Rate (%)	90	80	90
	Effluent Quality (mg/l)	15	20	15

(g) ESS Facilities - The total area of roads is 64.3 hectares for the model river basin (average road width = 5 meters; road length = 128.6 kilometers). The concentration of infiltration facilities is given in Table 10:

Table 10. Concentration of ESS Facilities

Facilities (1)	Concentration (2)	Total Quantity (3)
Infiltration Inlet	Both Sides of Road unit / 25 meters	4938 units
Infiltration Trench	120% of Road Length	125,456 meters
Permeable Pavement	All Roads in ESS Area	308,640 m^2

VOL 12

8306

R0041612

(h) Infiltration/Storage Capacity of ESS Facilities - Infiltration and storage capacity was estimated assuming a specified progression of clogging, and these values were shown in Table 2.

(i) Amount of Materials Captured by ESS Facilities - Data from Section 1-4 (Table 3) were used in this calculation.

2.4 Overall Estimation of Pollutant Load Reduction

The amount of pollutant load reduction from a combined sewer system depends on the frequency and volume of overflow to public water bodies. With ESS, the overflows are determined by the runoff reduction and interception ratios, taking into account the removal of clogging materials.

The results of calculetions for 1975, based on the conditions outlined above, are shown in Tables 11 and 12, and may be summarized as follows:

(a) Frequency of Overflow - Overflow frequency was reduced to 7/year using ESS (with a total of 71 rainfall events in the year), compared to 36/year without ESS, or a reduction of 81%.

(b) Overflow Loadings - Overflow loadings were reduced to 4.7, 3.4 and 19.2 kg/hectare for BOD, COD and SS, respectively, using ESS. Without ESS the loadings were estimated to be 103.1, 76.1 and 223.3 kg/hectare, respectively. Loadings were thus reduced 95% for BOD, 96% for COD and 81% for SS.

(c) Total Wet-Weather Loadings - Under wet-weather conditions, the total discharged load from ESS was 96.2, 110.0 and 156.4 kg/hectare, respectively, for BOD, COD and SS. From the combined system without ESS these loadings were 326.2, 294.5 and 642.3 kg/hectare, respectively. Thus, total loadings were reduced by ESS by 71% for BOD, 63% for COD and 76% for SS.

(d) Total Annual Loads - Total annual discharges using ESS were 528.9, 686.9 and 589.1 kg/hectare for BOD, COD and SS, respectively, while without ESS these were estimated to be 758.9, 871.4 and 1075.0 kg/hectare, respectively. Thus, total loads were reduced by ESS by 30% for BOD, 21% for COD, and 45% for SS.

(e) Effects Of Infiltration Inlets on Pollutant Load Reduction - devices such as buckets, baskets, screens, etc. are used in the infiltration inlets to prevent clogging, and also to remove pollutants flowing from the road surface to the inlet. The amount of these materials is shown in Table 3.

From Table 3 it can be seen that the annual amount of material removed is 12 kg/unit/yr, which corresponds to a SS load reduction of 3.6 kg/unit/yr (the moisture content is approximately 70%). There are 22 infiltration inlets/ hectare, and the SS removal is therefore 22 x 3.6 = 79.2 kg/hectare.

Meanwhile, as shown in Table 13, the reduction in SS loading using ESS based on runoff attenuation is estimated to be 156.4 kg/hectare. Thus, considering both the effects of runoff control and of pollutant removal, the total SS discharged is 156.4 - 79.2 = 77.2 kg/hectare, a 53% reduction. This explains the high removal efficiency at the infiltration inlets of the ESS. Similar results would be obtained with BOD and COD, and it can thus be seen that ESS has a high potential for reducing wet-weather overflow loadings as well as the total discharges from the sewer system to the receiving waters.

3. CONCLUSIONS

The ESS was originally focused and developed as a means to compensate for delays in urban river improvement, and to promote sewer construction. Since 1980, when full-scale ESS testing was started, the Tokyo Metropolitan Government has installed an area of over 902 hectares in the Shirako and Shakujii river basins, located on the northwest side of Tokyo.

In order to be successful, ESS requires some essential conditions:

(a) Soils should be favorable for infiltration

(b) The ground water level must be low

(c) Conditions must be suitable for the construction of infiltration facilities

In addition, ESS requires the separation of stormwater from the wastewater in combined drainage areas. A good public information program is necessary to provide understanding of the effects of ESS and to encourage cooperation from residents. This has been accomplished with a series of

VOL 12

8309

public meetings held in advance of construction, as well as the use of an easily-recognized symbol for all ESS-related publicity. Finally, good system operation is dependent on a regular maintenance program.

4. ACKNOWLEDGEMENT

The authors wish to thank the Tokyo Metropolitan Government Sewerage Bureau for permission to present this paper, and their gratitude is also expressed to Prof. Arata Ichikawa of Tokyo University for his support in the preparation of the paper.

INLET CONTROL CONCEPTS ON CATCHBASINS
U.S. EXPERIENCE

by William C. Pisano *

This paper summarizes U.S. practice of utilizing inlet control concepts to reduce the impacts of urban runoff flooding and pollution by manipulation of street inflow to catchbasins. Today , there exist over 15,000 such installations in North America. Most installations involve restriction of catchbasin outflow to cause surface inflow to be re-directed by overland routes to more suitable discharge points or to underground storage tanks. A relatively small fraction of these installations are meant to directly induce street ponding. The preponderance of installations involve retro-fitting existing systems to mitigate collection system surcharging , to reduce exfiltration and infiltraton exchange within adjacent sewer systems , and to cause reduction of downstream combined sewer overflows .

The paper first capsulates the general concept of inlet control or stormwater management (SWM) within the urban setting. Descriptions / project concepts , costs , cost savings are presented for implemented,projects in Cleveland, Ohio; Saginaw,Michigan; Montreal,Canada; and Skokie, Illinois. Common types of flow controllers used in the US are described along with operational experience . Several research efforts aimed at defining the cloggability limits of various types of catchbasin controllers are described. Several case studies are presented , including an overview of an ongoing Boston, Ma, CSO Facility Planning investigation which entails catchbasin retrofitting using inlet controls to reduce the cost of combined sewer overflow control in approximately a thousand acres of dense urban area.

1 STORMWATER MANAGEMENT IN URBAN CONTEXT (SWM)

1.1. OVERVIEW

SWM has its historical roots in Scandinavia where the concept has been used throughout Sweden and Denmark for rehabilitating undersized combined sewers to relief basement flooding . The central idea is to control or limit surface stormwater inputs into underlying sewers, and is often referred to as "inlet control" . This practice is widely used for basement flooding and drainage control in Ohio , Maine , Illinois , and Quebec and is widely used as a CSO control throughout Ontario (Canada).

Many sewerage system hydraulic surcharging problems can be mitigated using " inlet control" as a way to lessen the costs of expensive "outlet control" relief sewers. Hybrid solutions employing both concepts generally result , and are cost-effective .

Such solutions were developed for several areas totaling about 1200 acres in Parma, Ohio (Cleveland metropolitan area) . SWM was applied to storm drains ("over/under" systems - see Figure 1) to lessen the "outlet relief" need for surging sanitary lines to mitigate basement flooding (Pisano et al., 1982). For one such area (290 acres) in Parma ,the hybrid approach reduced the cost of new construction by over 100 % and generated a broader range of benefits than anticipated. (See Section 3 - " Ridge Road , Parma Case Study").

In Euclid, Ohio (near Parma and situated on the shoreline of Lake Erie) nearly 2000 catchbasin restrictors (vortex throttles) have been installed to limit storm flow to over/under sewerage systems to relieve basement flooding. Since the land mass in Euclid monotonically slopes to the Lake , released catchbasin flow moves by overland routes to storm drains outletting to the Lake (Smisson, 1981).

A good example showing the Combined Sewer Overflow (CSO) control potential of the catchbasin SWM is depicted in Figure 2. Four vortex controllers are proposed to be placed in catchbasins which are connected to a combined sewer lateral on Westmoreland Street (Boston) to induce surface gutter flow down to an existing separate system on Adams Street (Pisano and Pierstroff, 1988). This micro catchment is in the lower Neponset CSO Facility area in Boston. The action saves $120,000 in new storm drains needed to separate the combined sewer on this street for the purpose of CSO reduction . This scheme was one of six small- scale SWM projects which collectively with other earlier completed (1981) CSO control elements, satisfied regulatory requirements for the sewer shed (750 acres) .

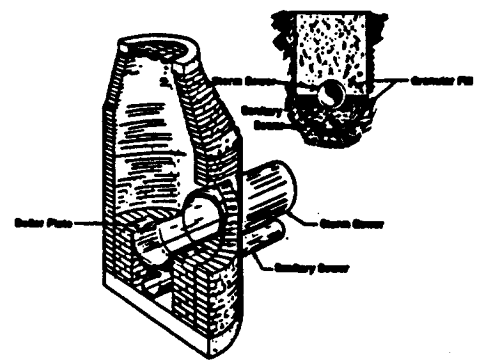

FIGURE 1 - Typical Over / Under Sewer Construction

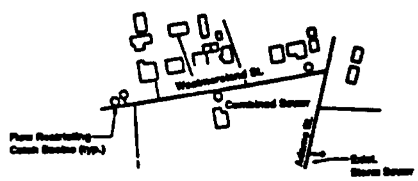

FIGURE 2 - Catchbasin SWM Example for the Lower Neponset Project, Boston.

This new plan was developed as part of a Value Engineering study (Havens and Emerson, 1987) to determine if a new relief trunk sewer, the final element of 1981 CSO program Plan , needed to be constructed . This new relief sewer would require construction along the main egress into the community. Disruption would be significant and the cost of construction was estimated at 1.2 $M . It is estimated that the new SWM program will save an estimated $0.5 million , and will eliminate the need to implement an unpopular project. Boston is presently experimenting with catchbasin flow controllers in one of these micro SWM projects.

An overview is presented in Part 3 of SWM considerations investigated as a part of the ongoing Boston CSO Facility Plan . Roughly a thousand areas of mixed combined and separated (overlayed) systems) were investigated for SWM opportunities similar to the Westmoreland Street solution.

Recently a SWM solution was proposed as part of a scheme for deflecting stormwater " first - flush " from an urbanized area impacting Lake Quinsigamond in Worcester, Mass. The Lake has an enormous recreational usage and preservation of water quality is vital to the community. The program is underway and is reviewed in Section 3- Case Studies.

1-2 SWM CONCEPT

Conceptually, "the stormwater management strategy " in the urbanized context starts at the very top of sewershed and searches for opportunities to control and manage stormwater so that the pipes do not overload as you move downstream (Smisson, 1981; Wisner, 1984). All possible forms of above/underground storage are used to hold the water till the receiving pipe can handle the flow without surcharge, or sometimes to transfer surface flow from combined systems to separated systems (see Figure 3). The analysis begins at the top of the system and progressively moves downstream to the outlet. The idea is either to reduce combined sewer overflow peaks or to reduce combined sewage volumes .

The amount of stormwater that can be feasibly detained by "inlet control" methods is in part a function of the sewer system's capacity to convey flow. "Inlet control" enables the designer to maximize the detention storage potential of any system given its ability to convey flows. Rigorous application of "inlet control" reveals the marginal cost effectiveness of positive relief measures.

Figure 3 pictorially shows some of the SWM methods". For example, a widely employed method in the midwest and Ontario , Canada is to reduce direct uncontrolled flow to the sewer by rerouting roof downspouts to splash pads with drainage to dutch drains/ dry wells / created previous areas/ street catchbasins.

VOL 12

8314

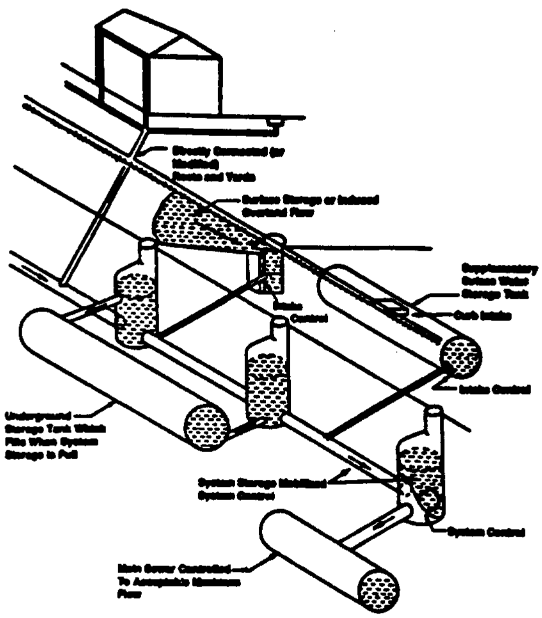

FIGURE 3 - Surface / Subsurface storage Components of Inlet

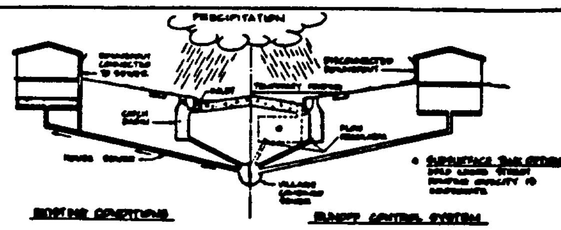

FIGURE 4 - Inlet Controlled System Under Different Conditions

VOL 12

8315

Temporary street ponding is still another method. Flow controllers can be placed in catchbasins to create temporary controlled street ponding. By preventing or slowing the overload, the sewage system is able to cope with the water, thus preventing overflows and basement backups. Figure 4 shows a schematic representation noting dry and wet weather conditions for street ponding considerations (Walesh and Schoeffman, 1985).

Flow restrictors placed within catchbasins are widely used to induce overland flow from sensitive areas to either outlet discharge points or more attractive capture/storage locations (Pisano, 1982, 1987, 1987; Smisson, 1987, 1985). The City of Laval , Canada is the process of "flow-slipping" waters from combined sewer laterals in hundreds of acres within the Marigot area down to the Riviere Des Prairies. These stormwaters would otherwise be captured and drained by existing combined sewers to a newly constructed tunnel with lift and future treatment. (Pisano, 1985)

Speed humps (asphalt) can also be placed to direct overland flow to storage or to maximize street storage potential. Systems of catchbasin flow controllers and speed humps can generate at low cost, controlled street storage. There are in excess of 80 such systems constructed in Parma , Ohio and in Skokie,Illinois (Walesh & Schoeffman, 1985; Pisano, 1982). Speed humps are gently contoured in contrast to speed "bumps". There has been no reporting of snow plow equipment problems.

Placed at specific points within the system, in-line flow controllers can also act as damming devices to utilize storage space that may be available in the existing sewers and/or to direct flow to off-line storage facilities.

Shallow underground off-line storage tanks/basins placed behind curbline/parkways/back alleys or in open park areas are other methods of "urbanized stormwater management ". These detention tanks are meant to temporarily store excess stormwater beyond street storage for controlled bleedback (vortex valves) into sewer system. Shallow new storm drains connected into existing and/or new catchbasins draining to storage tanks are often used to strategically locate underground storage in open areas (Pisano et al., 1982; Wisner, 1984; Walesh and Schoeffman, 1985; Pisano, 1982; Municipal Engineers Association of N.E. Ohio, 1987; Donohue Engineers, 1985; O'Brien & Gere, 1982; Matthews, 1982).

There are over 200 such off-line shallow detention storage installations in the greater Cleveland area (spilt between combined sewer systems and "over/under" sewerage systems). Figure 5 shows a typical installation in City of Parma , Ohio. Catchbasins are inputted into the 42" RCP tank with vortex flow throttle on underflow to relieve surcharge. Up until recently," Wet pit " type throttle chambers have generally been the rule in U.S. practice .

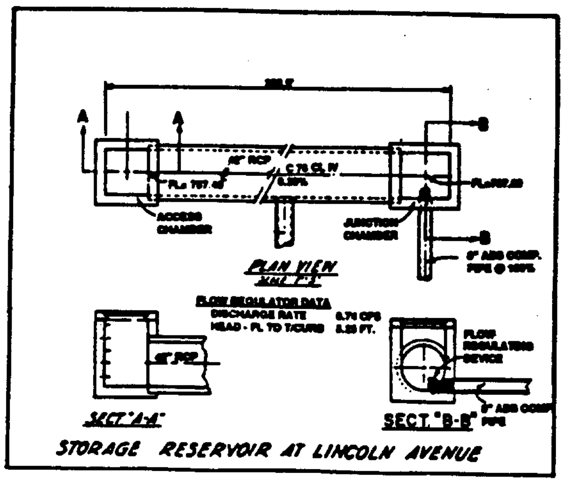

FIGURE 5 - Typical Underground Storage Tank
Parma, Ohio

1-3 BENEFITS AND DISADVANTAGES OF SWM

Benefits of using the "urbanized stormwater management " in local areas with combined sewers can generally be summarized as:

a) minimizes the need and degree for sewer separation and local relief sewers

b) provides immediate relief in areas with most severe basement flooding problems, leaving less critical areas until funds become available

c) lessens CSO and pollution loads since retained transient stormwater (and combined sewer stored in-line) drain back to sewers for treatment

d) provides an adaptive approach for control that can be applied in stages and then as time and funds permit, be integrated with more expensive structural control measures to provide ultimate protection.

SWM has a strong positive benefit for large complicated tunnel/lift station/conveyance/treatment systems. The net effect of applying SWM to a number of catchments tied into a major system is to "base-load" the system output , meaning that flow peaks would be smaller and less frequent , and that a higher system-wide base flow would result.

Disadvantages of SWM are as follows. First, the required degree of engineering support can be enormous for a large area. The analysis proceeds on a street by street basis. Precise topographic surveys are necessary and conditions of minor system piping and appurtenances must be known.

Second, the procedure will invariably release stormwater to the surface overland systems . Visual presence of released stormwater , if in the form of temporary ponding, is viewed as a negative by many inhabitants in urban areas , particularly in middle and high income communities . There seems to be little adverse reaction to overland curb flow.

Third, SWM will invariably require close observation and fine-tuning to ensure all elements are performing correctly. If the controlled areas are large , this task can take a number of years of close observation and attention. Such a long term commitment can be difficult for many communities.

Fourth, SWM may increase street maintenance either to clean up silt and debris from induced curbline flow, or to insure impervious and smooth street surfaces as to minimize subbase damage and micro "pockets" of street ponding.

Fifth, SWM is perceived by many to increase the liability of ice ponding and slippery conditions. In reality, this has not been a problem in the snowbelt areas of Illinois and Ohio, and even in the icebelt areas of Canada . This is probably the result of design flow controller release rates exceeding localized snowmelt conditions. Liability is nevertheless still a major determent of the catchbasin inlet control.

2 METHODS OF CATCHBASIN RESTRICTION

2.1 General Discussion of Methods

There are four different methods to regulate the inflow to piping system from catchbasins. The first entails grate geometry modification. The second consists of restricting the flow at or just below the grate. The third is modification of the outlet pipe (rarely used and not discussed). The fourth involves placement of flow control devices within the leader.

Catchbasin grating restriction has been frequently tried . The grating area may be reduced by mounting plates either on top or below the grating. See Figure 6. This option results in a lower flow capture efficiency. The disadvantage of this method is that the grating capture is reduced over the complete range of flows, meaning that for small events during which the piping system has adequate capacity, some flow reduction occurs. Debris can become packed in the closed grating and can be difficult to remove.

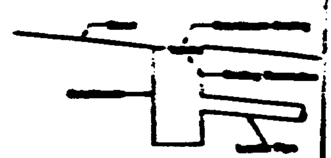

FIGURE 6 - Typical Catchbasin Grating Restriction

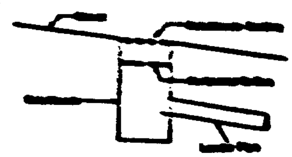

FIGURE 7 - Typical Horizontal Orifice Restriction

Still another type of control is the placement of horizontal orifice plates below the catchbasin grating. (See Figure 7). A variation is to slightly convex the plate to permit solids and leaves to slough toward the orifice . The size of the orifice in the plate restricts the flow to the desired level. Besides being inexpensive to fabricate, the head required for sizing the orifice is simply the expected street ponding depth. A disadvantage of this method is that the horizontal plate restricts access to the basin, as the plate must be removed before the catchbasin or inlet can be cleaned.

This technique is currently used to abate basement flooding in several large combined sewered areas in eastern Michigan. There are roughly 2300 such installations in the Township areas of Saginaw, Michigan (Pisano, 1987). A recent commercial product using this concept called , " "EZ-Flow " controller has emerged in the Canadian market. The device is a one piece molded hopper style plate made from polyethylene foamed plastic. Flow obstruction control is provided by a four "fin" design molded onto the restrictor plate surface about the orifice outlet. No U.S. experience has been noted.

The fourth class of controls for restricting flows are placement of devices in the catchbasin outlet to effectively reduce the leader pipe outlet area. An advantage of this class of controls is that for low flows , they do not interfere with the grating capture. Water is backed up in the catchbasin only during large flows that exceed the capacity top or below the grating. (See Figure 6). This option results in a lower flow capture efficiency . The disadvantage of this method is that the grating capture is reduced over the complete range of flows, meaning that for small events during which the piping system has adequate capacity, some flow reduction occurs. Debris can become packed in the closed grating and can be difficult to remove.

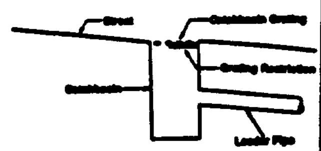

FIGURE 6 - Typical Catchbasin Grating Restriction

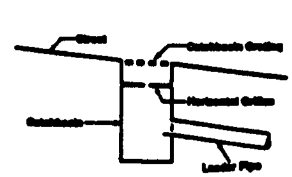

FIGURE 7 - Typical Horizontal Orifice Restrictor

Still another type of control is the placement of horizontal orifice plates below the catchbasin grating. (See Figure 7). A variation is to slightly convex the plate to permit solids and leaves to slough toward the orifice . The size of the orifice in the plate restricts the flow to the desired level. Besides being inexpensive to fabricate, the head required for sizing the orifice is simply the expected street ponding depth. A disadvantage of this method is that the horizontal plate restricts access to the basin, as the plate must be removed before the catchbasin or inlet can be cleaned.

This technique is currently used to abate basement flooding in several large combined sewered areas in eastern Michigan. There are roughly 2300 such installations in the Township areas of Saginaw, Michigan (Pisano, 1987). A recent commercial product using this concept called , " "EZ-Flow " controller has emerged in the Canadian market. The device is a one piece molded hopper style plate made from polyethylene foamed plastic. Flow obstruction control is provided by a four "fin" design molded onto the restrictor plate surface about the orifice outlet. No U.S. experience has been noted.

The fourth class of controls for restricting flows are placement of devices in the catchbasin outlet to effectively reduce the leader pipe outlet area. An advantage of this class of controls is that for low flows , they do not interfere with the grating capture. Water is backed up in the catchbasin only during large flows that exceed the capacity of the restricting unit. It is generally recognized that this class of controls is superior to the other three methods as the restricting orifice can be easily installed ,and with the orifice mounted flush (ideal) to the catchbasin wall, it does not interfere with catchbasin cleaning.

2.2 Discussion of Catchbasin Outlet Controllers

Four different types of restrictors are discussed. The general concept is shown in Figure 8. The first three types have the orifice placed in the outlet leader pipe . The last type has the orifice submerged in the catchbasin. The first two outlet orifice types are called, the "Scepter" and the "Cromac". The third type of orifice placed into the catchbasin leader causes the flow to vortex leaving the leader. The orifice is actually the outlet of a vessel with an intake which causes the flow pattern within the vessel to rotate and cause a vortex to form (creating resistance). The final type discussed is called the "Hanging Trap" in which the orifice is actually submerged within the basin.

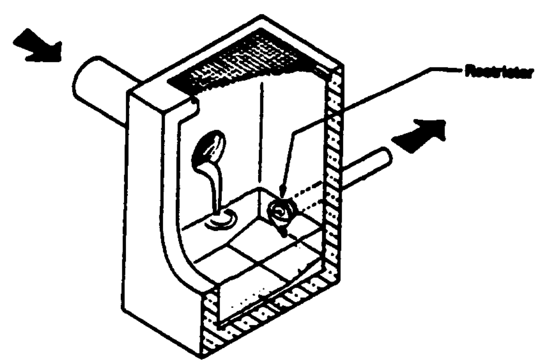

FIGURE 8 - Catchbasin with Restrictor on Leader

A. Scepter

The Scepter flow regulator is a PVC injection molded orifice that can be inserted in catchbasin leader or mounted on the catchbasin wall so as to cover the leader. The orifice has a diamond shape with a keyhole at the bottom. The purpose of the keyhole is to lower the sump level and keep the upper part of the orifice free of floating debris. During significant flow , the water level within the catchbasin rises and passes flow through the upper diamond shape portion of the device.The device was developed in Canada and has been extensively used in new SWM inlet control schemes with a lower flow restricting limit of about 0.5 cfs (Wisner, 1985).

B. Cromac

This orifice device is mounted over the leader pipe inside the catchbasin. It consists of a frame bolted to the catchbasin wall to encircle the leader pipe, and an orifice section which slides into the frame. The orifice section consists of two PVC sheets : one contains a trapezoidal opening 10" at the bottom and 3 1/2" at the top about 10" inches tall; the second plate, called the weir plate, is adjustable and can be fastened to the orifice plate with nylon bolts . The weir plate allows adjustment of the restricted area for flow passage. The orifice section is removeable to permit removal and cleaning(14).

C. Vortex Flow Throttling Devices

a) General Configuration

Figure 9 depicts a standard push-fit "O"-ring type device for catchbasins with suitable sumps. This device was developed in Denmark in the mid 70's. The inlet is the square - shaped hole in the upper foreground, while the discharge occurs through an internal orifice within the vortex drum . This square-shaped intake is well below the normal water level in the sump and is below the general region of floatables.

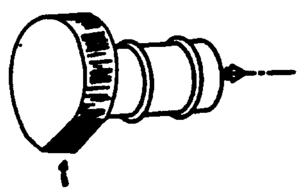

FIGURE 9 - Standard Configuration of Swedish - Type Catchbasin Vortex Valve.

The back portion of the device is simply the connection pipe with stop rings for "O-ring" rubber gaskets. A gas trap results due to the gasket connection and the intake being below the sump water level. Existing leader pipes in catchbasins are often "out-of-round" requiring a small segment of PVC or VCP to be grouted in before inserting the device. Another alternative is to segment the device and grout the device's outlet pipe into the leader, and then connect the "vortex drum" with a mechanical bolted collar connection.

Figure 10-A shows the layout for West German inlet with a "gully" screen for trapping and catching sticks, rocks and floatables . A vortex throttle controls the discharge from the inlet (Pisano, 1988). Shown in Figure 10-B is an advanced form of vortex throttle (German design). The device consists of two dish-heads welded together with a special flared intake and fitted with adjustable orifice inserts to permit changing the stage / discharge flow characteristic.

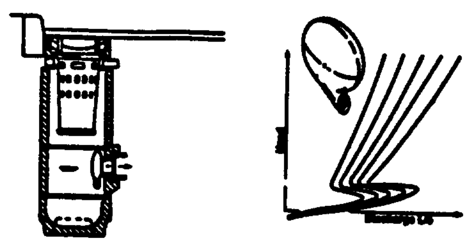

FIGURE 10 - Details for Standard German - Type Catchbasin Vortex Throttle.

b) Number of Vortex Throttle Installations

Several catchbasin type - flow controllers were first installed in the U.S. in 1976 on Puritas Ave. in the City of Euclid, Ohio for the purpose of de-pressurizing hydraulically overloaded storm sewers in "over/under" sewerage systems (over-storm and under-sanitary). As of 1989 there were over 2000 such installations in Euclid.

Overall, about 5000 such devices have been installed in the U.S., mostly in the Greater Metropolitan Cleveland area and in Portland, Maine. During the same time period, roughly 500 such devices have been installed in Canada, mostly in the provinces of Ontario , Quebec and British Columbia. In Europe there are roughly 500 catchbasin and inlet installations mostly in Denmark,England, Sweden, and Norway. Recently, a number have also been installed in West Germany.

c) Sizes and Applications

More than 75% of all U.S. applications have been in storm sewers which are part of "over and under" systems (where the objective is to minimize storm sewer surcharge resulting in less exfiltration and reduced sanitary sewer infiltration), or in strictly separated systems (where the objective is to provide upstream transient stormwater management). The balance of installations have been to limit flow entry into combined sewer systems for a wide variety of applications, ranging from mitigating localized sewer surcharging (basement flooding) to "flow slipping" street load from combined systems to nearby existing storm drain systems .
Generally, the design release rates on storm system applications have been, on the average, larger than those used for combined sewer applications .Almost all of the "over/under" applications have used devices with an orifice

diameter range of 3"-8" (0.25- 1.5 cfs release rate range). Most of the devices used on combined sewer systems have had lesser release rates resulting in orifice sizes of 3"-4".(0.25-0.5 cfs release rate range). For a few projects in Windsor, Ontario during the late 70's , several hundred devices with 2" orifices were used to restrict catchbasins discharging into small-diameter combined sewer pipes.

D. Hanging Traps

The final method discussed is the use of a hanging plastic tee grouted into the catchbasin leader. Tapped plastic insert sections (2- 3 ") create the flow control (Walesh and Schoeffman, 1985). Figure 11 shows the layout. Over 1000 such devices have been installed in Skokie , Illinois. This setup has also been used to control the outflow from shallow underground storage tanks.

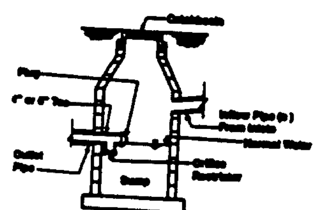

FIGURE 11 - Typical Flow Regulator in Catch Basin Installation Used in Skokie, Illinois

2-5 EXPERIENCE AND CLOGGING EVALUATIONS

The vortex throttle has probably received the greatest attention due to the commercial claim of "non-clogging" vortex flow action, and the high cost of the devices. Since 1976 when the device was first installed in Euclid, there have been a number of reportings of plastic cup and pop bottles lodging themselves in the square - shaped intake (presumably during rising and falling sequences during storm events). There have been few reported instances where the devices have clogged with sand and rocks. This problem has occurred where the devices were installed in catchbasins or in inlets with insufficient sump space.

One notable drawback of this technology is the inability to actually see by inspection whether the device is clogged (since the intake is submerged). In practice, the rate of observed street level drain down (where street ponding in intended) is generally used to detect such problems.

Catchbasin devices were installed and evaluated for the U.S. EPA 108 Program in Rochester, New York as part of a R&D SWM evaluation on a combined sewer system (O'Brien and Gere, 1982). Different tankage applications and catchoasin devices within combined systems were evaluated in Cleveland (Matthews, 1982) . It was concluded that fouling can occur in inlets (where no sumps are provided to catch debris), or where catchbasin sump depth is limited or not maintained. Minimum device size recommended is a unit having a minimum 3" orifice outlet .

It is interesting to note that there have been no reported new combined sewer applications using devices with an outlet orifice less than 3" since the late 70's. German experience with very small (less than 2" orifice units) has not been favorably due to cloggage (Pisano, 1988). From practice it seems that devices having orifice range of 3"-4" are about the practical lower limit.

As part of a SWM technology review and basis of design scheme for the Village of Skokie, Illinois , Donahue Engineers in 1984 conducted a one season (fall) evaluation of cloggage potential for various types of flow restrictors (release rate range of 0.12- 0.78 cfs) within a drainage area having large numbers of deciduous trees (Donahue Engineers, 1985) . Horizontal orifice plates, grating restrictions, Hanging Traps, Sceptors, Cromacs and Danish - type vortex valves were evaluated . This assessment was conducted to select the best flow control device for "inlet control" of the Howard Street District (roughly 800 acres) of combined sewer area impacted by basement flooding problems.

It was concluded that the Hanging Trap, the Scepter, and the vortex throttle were equal in performance . All other devices were adversely impacted by leaf cloggage. The Hanging Trap was chosen to be most cost effective since the first cost of the plastic Hanging Trap is about $25. It is fabricated of readily available materials, and is easily grouted in place (and reportedly easy to snap off and replace) .

In 1985 Hanging Trap flow throttles were installed in approximately 300 catchbasins and as the outlet control in 8 underground concrete tanks within the Howard Street District in Skokie, Illinois. A number of asphalt speed hump systems were also installed to create minor surface ponding areas with drainage back to nearby inlets .A post evaluation phase indicated no substantial problems. Design and implementation for a second area (1200 acres) is in progress . A higher density of underground tanks is envisioned as the area is more commercial in nature.

VOL 12

8326

R0041632

Wisner conducted the most comprehensive set of clogging potential tests to date (Wisner, 1985). In the summer of 1985 he used a test facility consisting of a street section which can be hydraulically grade-adjusted with overhead sprinklers to create runoff to a full -scale plexiglass catchbasin . Solids were manually placed with controlled mixes of leaves, small twigs and sticks, leaf mixes , and paper inputs. The experimental setup also permitted storm inflow to be fed from curb line (creating maximal opportunity for splash turbulence and debris mix), or to be inputted directly into the middle of catchbasin sump, (and thereby creating minimum turbulence within the sump) .

Long-term controlled simulations using different types of catchbasin restrictors were conducted under both types of flow input regimes. It was generally concluded that cloggege potential for all devices was maximal during conditions of high basin turbulence (flow input to basin from curbline) as the likelihood of floatables being mixed within the basin and passing into and through the orifice aperture was greatest.

Wisner concluded that the Hanging Trap flow restrictor was acceptable at release rates down to 0.5 cfs provided the flow input was quiescent and was without turbulence. With normal curb line input, the Hanging Traps continually clogged for all flow release rates considered (0.5-1.3 cfs) . Figure 12 shows the typical catchbasin layout in Skokie . The flow input from inlets (typically 2-3) to the catchbasins were at mid sump level (meaning minimal turbulence) , explaining to a degree why the Hanging Trap flow throttle installations in Skokie performed acceptably.

VOL 12

8327

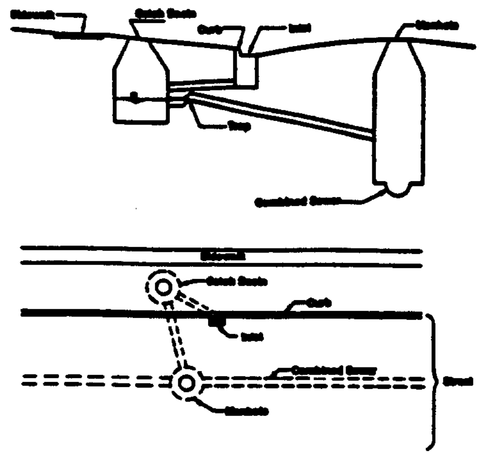

FIGURE 12 - Typical Street Drainage System Configuration for Skokie, IL.

The test results for the Scepter showed that the release rate of 0.5 cfs was the satisfactory lower limit. At lower flow rates it was concluded that the cloggage frequency would be unacceptable . The Cromac constantly clogged and a release rate of 1 cfs was deemed as the lower practical limit .

Wisner found that the vortex valves were nearly clog-free. He found that the German vortex throttle could not be clogged under any conditions . The German device was the only device tested for release rates under 0.2 cfs and was satisfactory for a release rate as low as 0.11 cfs. Wisner found that the intake of the Danish vortex valve could be clogged, but only under extremely adverse conditions such as high rate mixed transport of large twigs and leaves. The lowest release rate used for the Danish device was 0.23 cfs.

3 CASE STUDIES

3.1 Ridge Road Area , Parma Ohio

The "Ridge Road Program " was one of the three projects completed during the period of 1981- 1984 in Parma , Ohio (suburb of Cleveland) . This project best exemplifies inlet control concepts to mitigate difficult surface flooding and stormwater related basement flooding in a dense urban area. The project also reduced spring infiltration contributions to the sanitary sewer system and eventually to the WWTP.

The area known as the "Triangle " in Parma is a topographic "dished" shaped area (30 acres) situated within the lower portion of a 290 acre drainage system . The terrain in the watershed is hilly with deep valleys, and the land generally slopes to the "Triangle" (see Figure 13 for location). The sanitary sewer trunk system passing through the area carries input from 1200 acres upstream. The 290 acre area is highly developed with 1200 homes and many commercial establishments. The area is crossed by two major vehicular arteries and is served by an "over/under" storm/sanitary system (see Figure 1 for typical layout). This method is a common sewerage system configuration throughout the Cleveland area and in other metropolitan areas in the U.S.

Prior to this project, the "Triangle" endured severe basement flooding resulting from surcharging sanitary sewers during heavy rainstorms (at least 3-4 episodes per year) . The cause of surcharge stems from the undersized storm systems which cannot handle storms flows, pressurize, surcharge and leak significant amounts of clear water into the rock filled " french drain" trench section . Since the sewer joints in the sanitary sewer are invariably cracked or broken, the surcharge condition within the rock filled trench adversely affects the sanitary sewer piping, ultimately resulting in basement flooding.

Basement flooding in the "Triangle" is further exacerbated by the poor hydraulic outlet conditions of the local sanitary systems discharging to the trunk sanitary sewer .The trunk sanitary sewer passing through the study area receives significant upstream wet weather related inputs. It then becomes flow-constrained by a sudden flattening of grade just downstream of the study area.

Due to the rolling terrain , there are numerous "low valley pockets" throughout the entire 290 acre area. The storm drains are generally inadequate . Surface water which cannot escape via "major overland routes" at these low lying locations, accumulates and severe street flooding results. Prior to this project, both street and basement flooding frequently and simultaneously occurred in the "Triangle"

during heavy summer thunder storms . Similar problems were experienced throughout the entire 290 acre area but were not as severe as in the" Triangle".

An solution contemplated earlier was to construct a large underground off-line detention basin for relieving the sanitary trunk sewer coming into the study area , and to construct sanitary relief sewers throughout the "Triangle ". Estimated cost of these improvements was $2.2 million. Only basement flooding in the homes within the "Triangle" would be affected . Surface water flooding would not be addressed.

The alternative (implemented) solution involved inlet controls on the storm sewer system within the entire (290 acre) catchment area to minimize sanitary relief sewer improvements. Dual concepts of both "inlet" and "outlet" controls were considered .

Under controlled conditions, experiments were conducted to relate the degree of storm sewer surcharge to sanitary sewer infiltration for different diameter storm pipes . These results were used to relate sanitary sewer infiltration as a function of storm sewer hydraulic control .

A hydrologic model was used (BRRL method), and different stormwater inlet control strategies were investigated for assumed levels of"full pipe or less" flow conditions . The aim was to determine whether sufficient storm sewer exfiltration reduction could either eliminate or minimize the need for sanitary system improvements . Cost effective analyses however indicated that inlet control could not reduce sanitary sewer surcharge to acceptable levels . Several relief sanitary sewer segments improvements were needed. The final solution entailed a "hybrid " of inlet (stormwater management of storm drains) and outlet (sanitary sewer relief) controls.

The following set of inlet controls were implemented as part of the storm sewer system improvement program. A schematic of a portion of the study area controlled is shown in Figure 14.

(a) Storm/sanitary manhole rehabilitation
(b) Re-grouting flow-constrained pipe segments
(c) Overland flow "training" berms
(d) Surface storage berms for surface storage
(e) Re-construction of low curbs to maximize surface storage
(f) Installation of catchbasin vortex throttles to induce street surface storage or overland flow to tanks
(g) New catchbasins to intercept overland flow
(h) New shallow drains to dewater low "trapped" street areas
(i) Underground storage tanks with outlet vortex throttles
(j) Disconnection of residential downspouts (front only).

VOL 12

8331

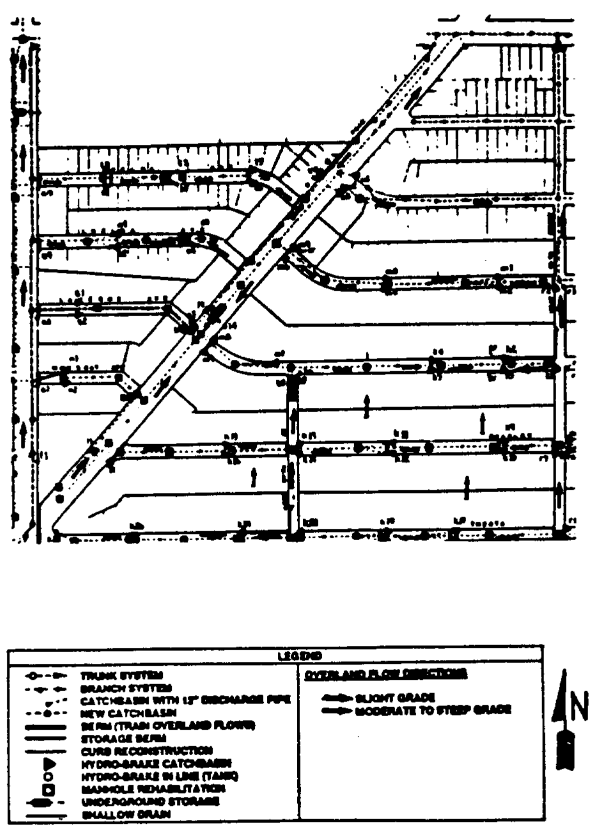

FIGURE 14 - Inlet Control Program Elements on Storm Drainage System

Construction costs in 1984 were $875,000 (SWM inlet controls = $600,000 and sanitary sewer segments = $275,000). Unit cost of underground storage ranged from $6.50 to $9.75/cubic foot (utility re-location, tanks, flow controllers, pavement replacement etc.) Installed catchbasin flow controllers ranged from $700-$900 per basin. (today , stainless steel vortex throttles would cost $500-$700 due to rises in raw material costs). Surface storage generated averaged about $4 per cubic foot. Total savings equalled about $1 million dollars (Pisano, 1982).

The project has mitigated surface water ponding and has provided basement flooding protection throughout the entire 290 acre area including the "Triangle". To date there has been only one reported instance of basement flooding in the "Triangle" (1985 during a 20 year storm) . Although not intended , spring sanitary sewer infiltration has been significantly reduced .

3.2 Lake Quinsigamond, Worcester, Mass.

Summary details of an extremely cost effective solution are presented for decreasing the nutrient loadings from an portion of the urbanized area impacting Lake Quinsigamond in Worchester, Mass. The Lake is a narrow mile-long recreational water body surrounded by dense urban patterns (residential and commercial). It is rapidly becoming eutrophic from stormwater discharges. Sewers within the study area are "over/under" systems .

In the 70's the greater metropolitan area of Worchester (2nd largest City in Mass.) was investigated in a 208 Areawide study, which then led to an intensive National Urban Runoff Program (NURP) program of the Lake Quinsigamond watershed in the early 80's. Extremely high bacterial loadings and high phosphorous emissions were noted from a 320 acre area , the Belmont Street Drain . In 1986, a study was initiated to develcp the "basis of design " details for specific stormwater storage/ treatment controls for this watershed.

The 1987-88 investigation commenced with a thorough physical survey of the sewerage system. Critical observations and measurements during dry and runoff periods indicated that the dominant nutrient source is contaminated storm drain base flow. It is believed that these emissions result from intermixing of contaminants within the "over " (sanitary sewer) with the "under" (storm sewer) during rainfall events (surcharge conditions) . During ensuing dry periods contaminated baseflow emanates from the rock filled trench systems .The service area is extremely steep , and the original storm drains were designed to handle about the 1 year storm . Surcharge levels in portions of the system are significant.

Recent summer dissolved oxygen profiles within the Lake indicated a deterioration since the NURP study in the early 80's . The City believes that immediate action to reduce nutrients to the Lake is needed. Due to extensive rocky soils and "ledge" throughout the area, piping system replacement will be exorbitant and is not feasible . Rehabilitation is probably the best solution, but funding is limited, and implementation is years away.

Instead, a number of system controls were found to immediately eliminate much of the total nutrient loading from this watershed. Construction will commence in 1990 to deflect (using vortex flow throttle) both storm system "first flush " and the highly contaminated baseflow to a nearby combined system (out of watershed and to regional WWTP). SWM concepts will be used in the upper portion of the combined system to delay and flatten street surface peak flows (within the combined sewer area) as to increase the transfer of peak storm system "first flush" flow from the over/under network into the combined sewer system .

Figure 15 highlights the proposed improvements. A new flow deflection chamber on Plantation Street at Tampa Street will permit contaminated upstream stormwater baseflow (about 1 cfs from 90 acres upstream) to be diverted into the combined sewer on Tampa Street. Initially a small vortex throttle valve is to be installed to deflect only dry weather baseflow. The chamber dimensions however will be sized to provide a larger flow deflection capacity.

In another phase of work ,8-9 catchbasin flow controllers and one small stormwater detention tank (with its own discharge flow controller) will be constructed on the combined sewer along backside of Tampa Street and Atlanta Street. The intent is to "free up" flow capacity along the Tampa Street combined sewer so that first flush stormwater flow from the upper Plantation Street catchment can be deflected to the Tampa Street combined sewer. The tank is to capture excess stormwater released from catchbasin restrictors along Tampa Street and Atlanta Street.

When the SWM element is completed on Atlanta Street and Tampa Street, an additional flow controller in the new diversion chamber would be installed . Approximately 12 cfs of stormwater "first flush" runoff (and "base flow") are to be diverted to the combined system . Total construction cost is estimated at $160,000 (Pisano, 1989). It is estimated that about 55% of the total annual nutrient loading to the Lake from this catchment will be eliminated. This "micro-control" , quick -action program is also estimated to reduce the total watershed nutrient loading to the Lake by about 11 % . This reduction in turn ,about equals the estimated nutrient increase basin-wide since 1981 due to rapid urbanization.

TAMPA STREET DIVERSION AND STORMWATER MANAGEMENT PROGRAM

3.3 SWM Considerations -1989 Boston CSO Facility Plan Study

In the late 70's , a CSO facility plan was prepared for the greater Boston area. The new agency created by court decree, the Mass. Water Resources Authority (MWRA), decided to re-investigate the concept of deep tunnels in view of the favorable tunneling costs experienced in Milwaukee. Satellite treatment, sewer separation , surface storage and deep tunnels were considered in the 1989 effort.

In addition, a Best Management Program (BMP) is to be developed for each of the 14 member neighborhoods and communities within the CSO area. Figure 16 shows the MWRA CSO service area. In-system storage , SWM , sewer flushing, street sweeping , and catchbasin cleaning were the major BMP concepts considered.

Production functions (level of scale versus pollutant removal) and cost functions were developed for each of the options considered for each area. These functions were then used in an optimization analysis to determine the best mix of controls for increasing levels of pollutant or overflow volume removal (19).

Three general SWM options were investigated.

(a) Partial Separation ("PS") : direct discoupling of small combined sewer segments directly to nearby separated systems.

(b) Flow Slipping ("FS") : restricting combined sewered catchbasins to move overland (usually not more than a block) street load with connection into existing separate system . Street ponding of released flows was not considered.

(c) Storage ("S"), Detaining combined sewer street load using small tanks with outlet flow throttle.

In order to develop adequate cross-sectional sample data for the production functions ,several large areas representing a broad spectrum of control possibilities were selected . Two major areas chosen are shown in Figure 16.

Area A (about 900 acres) is generally combined and its land mass is interior with few drainage outlets. Area B (about 800 acres) is mostly separated with small combined sewer " pockets". Since this area is situated near a major river and Boston Harbor, there are many drainage outlets. Area B is typical of old combined areas overlayed with relatively new sanitary systems. Land use in both areas is densely residential with mixed hilly and flat terrain. It was believed that these two areas represented a wide mix of

VOL 12

8336

R0041642

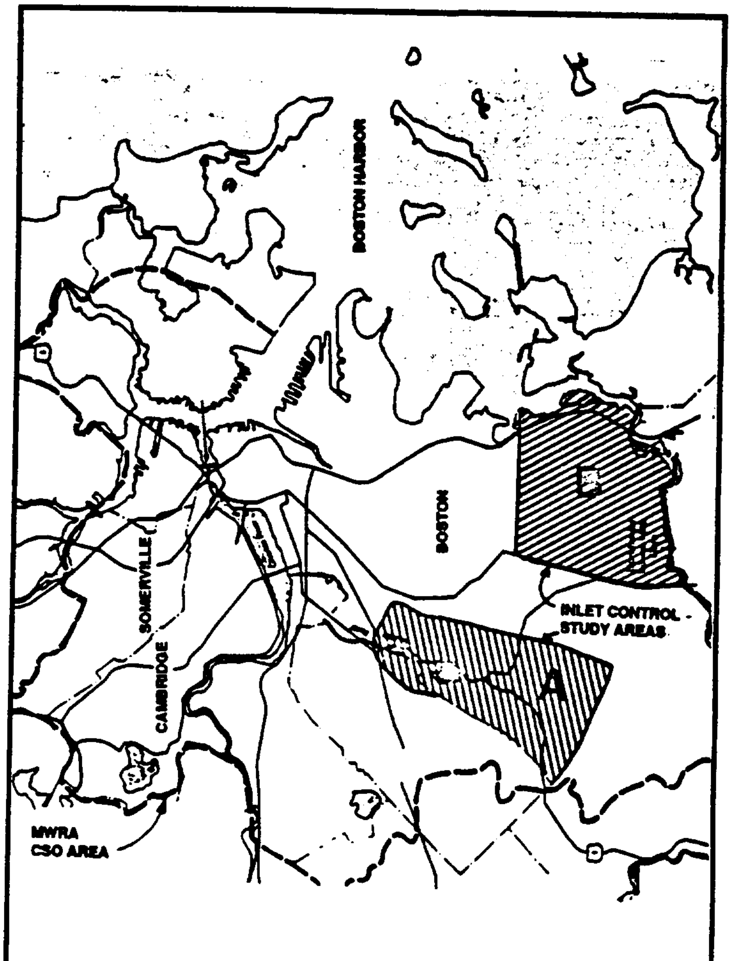

FIGURE 16 - Portion of Mass. Water Resources Authority (MWRA) CSO Service Area Considered for SWM Control

VOL 12

83371

piping systems so that costs and levels of achievable control could be extrapolated to the other subareas.

Maps were reviewed, street by street within the pilot areas to develop a large set of SWM possibilities. For most of the defined "desk-top" projects , the areas were then "windshield" inspected to ascertain general feasibility. Preliminary solutions and costs were developed .

A total of 56 individual small SWM projects were identified and costed for local conditions . Project areas ranged in size from 0.5 to 7 acres. There was about an equal distribution of the three SWM categories ("PS", "FS","S") . Using these projects as the data base , scaling factors (extent of feasibility and costs) were developed for all neighborhoods within the MWRA service area.

Complete separation construction costs (including engineering and contingency) for the two sample areas ranged from $90,000 to $120,00 per acre. Similar costs for the "FS" projects averaged $11,300 per acre . Average costs for the "PS" projects were $33,000. Costs for the "S" type projects were similar to complete separation due to the general lack of street siting opportunities (and achievable scale) to situate small curb-side underground tanks. Parks and green spaces were specifically excluded.

For area B , 57% of the combined sewered area could be impacted by SWM controls , and 48.6% of this area controllable by "PS" projects . The balance is spilt between "FS" and "S" projects .

The optimization procedure generally selected in-system storage as the least cost BMP option, and for some areas street sweeping and catchbasin cleaning were also attractive (CH2MHILL, 1989). SWM options were nevertheless competitive for several areas, particularly within pilot area B.

Since in-line storage was considered difficult to achieve as a BMP (much more study was perceived to be necessary for implementation) ,only a limited area was selected for in-line storage (value was obvious). Street sweeping and catchbasin cleaning at present levels were recommended as BMP controls. These conclusions are presently under review by the regulatory agencies and interested community groups (19).

CONCLUSIONS

The perceived value of SWM for CSO control is still in its infancy in the United States. In Canada , the practice is widespread, particularly in the Ontario provence. The concept is highly opportunistic , but can result in significant cost savings.

VOL 12

8338

VOL 12

8339

A number of implemented case studies have shown that application of inlet control concepts to minimize the extent of outlet control relief systems , i.e. creating hybrid solution strategies, result in substantial cost reductions. Successful examples to date in the U.S. have been primarily for general drainage problems involving basement and street flooding .

Choice of the appropriate catchbasin flow controller for a given design application is difficult . Vortex throttles should be used when the intended release rates are less then 0.2 cfs. Other devices may be suitable for higher flow rates , provided there is minimal presence of deciduous leaves (i.e., large parking malls), and the likelihood of moderate levels of maintenance can be assumed. If these conditions cannot be satisfied , then vortex throttles should be used for design release rates of 0.2-0.5 cfs. Because of increasing size and cost, vortex throttles become less attractive than other options for design release rates exceeding 0.75 cfs.

Besides release rate, the most important determinant in flow control device selection is the presence of deciduous trees within the immediate catchment. Minimum catchbasin sump depths of at least 15 inches are recommended above the invert of the restricting device with catchbasin cleaning at least on an annual basis .

ANALYSIS OF CROSS-CONNECTIONS AND STORM DRAINAGE

Robert Pitt, M. ASCE[1], Richard Field, M. ASCE[2], Melinda Lalor[3] and Gene Driscoll, M. ASCE,[4]

Introduction

This paper is a preliminary summary of the first phase of a current EPA research project to:

- o develop investigative techniques to assist local governments in identifying the magnitude and sources of cross-connections in their storm drainage systems; and
- o present case studies of techniques used by selected municipalities in identifying cross-connections.

Discharges from storm drainage outfalls can be a combination of dry-weather base flows; stormwater runoff; snowmelt water; intermittent discharges of debris, wash-waters, and other waste materials into storm drains; and the relatively continuous discharges

of sanitary and industrial cross-connected wastes. These discharges include stormwater that contains the washoff of pollutants from all land surfaces during rains, including washoff of pollutants from areas such as industrial material and waste storage areas, gas station service areas, parking lots, and other industrial and commercial areas, etc. Therefore, the quality of urban runoff can vary greatly with time (dry versus wet-weather, cold versus warm weather, etc.) and location.

The discharge of sanitary and industrial wastes into storm drainage (cross-connections) can lead to serious water pollution problems. In many cases, storm drain discharges are badly polluted by stormwatar alone, without the additional pollutant loadings associated with sanitary or industrial connections. The addition of sanitary wastes increases the concentrations of oxygen-demanding organic solids and nutrients, and increases the number of pathogenic microorganisms in the storm-induced discharge. Industrial wastes can be highly variable, but can substantially increase the concentrations of many filterable heavy metals in runoff, as an example. In many cases, annual discharge loadings from stormwater outfalls can be greatly affected by dry-weather discharges (Pitt and Shawley 1982; Pitt 1984; and Pitt and McLean 1986, as examples).

Dry-weather and wet-weather urban runoff flows have been monitored during many urban storm runoff studies that have found that discharges observed at outfalls during dry weather were significantly different from wet-weather runoff. Warm and cold weather runoff was also contrasted during some studies and was also found to be quite different. During the Castro Valley, California, Nationwide Urban Runoff Program (NURP) study, Pitt and Shawley (1982) found that the dry-weather flows were very hard and had very few nonfilterable pollutants, while the stormwater runoff was quite soft and had substantial nonfilterable metals. The dry-weather flows were found to contribute substantial quantities of many pollutants, even though the concentrations were not high. The long duration of baseflows in many areas of North America (about 95 percent of the time) off-set their lower concentrations and lower flow rates as compared to wet-weather (stormwater) flows.

The Bellevue, Washington, NURP project (Pitt and Bissonnette 1984) summarized the reported incidents of intermittent discharges and dumpings of pollutants into the local storm drainage system. During a three year period of time, about 50 citizen contacts were made to the Bellevue Storm and Surface Water Utility District concerning water quality problems. About 25 percent of the complaints concerned oil being discharged into storm drain inlets. Another important category of complaints was for aesthetic problems, such as turbid or colored water in the creeks. Various industrial and commercial discharges into the storm drainage system were detected. Concrete wastes flushed from concrete trucks at urban job sites were a frequently occurring problem. Cleaning establishment discharges into creeks were also a common problem. Vehicle accidents also resulted in discharges of gasoline, diesel fuel, hydraulic fluids, and lawn care chemicals into the storm drain inlets. Pitt (1984) also monitored both dry- and wet-weather discharges from stormwater outfalls in Bellevue and found significant pollutant yield contributions associated with dry-weather discharges from residential areas.

Dry-weather flows in a monitored Toronto residential area were found to have high pesticide concentrations, while a monitored industrial area had dry-weather flows that had high concentrations of organic and metallic toxicants (Pitt and McLean 1986). More than 50 percent of the annual discharges of water volume, total residue, chlorides, and bacteria, from the monitored industrial, residential, and commercial areas, were associated with dry-weather discharges. Substantial metal discharges, especially from the industrial area, were also found to be associated with dry-weather discharges.

Gartner Lee and Associates, Ltd. (GLA 1983) conducted an extensive survey of dry-weather flows in storm drainage systems in the Humber River watershed (Toronto) in an attempt to identify the most significant urban runoff pollutant sources. About 625 outfalls were sampled two times during dry-weather, with analyses conducted for many pollutants, including organics, solids, nutrients, metals, phenols, and bacteria. About 1/3 of the outfalls were discharging at rates greater than 1 L/sec. The dry-weather flows were found to contribute significant loadings of nutrients, phenols, and metals, compared to upstream conditions. About 10 percent of the outfalls were considered significant pollutant sources. Further investigations identified many industrial and sanitary sewage cross-connections into the storm drainage. An apartment building with the sanitary drains from eight units illegally connected to the storm drainage system was typical of the problems found. Other problem areas were found in industrial areas, including yard storage of animal hides and yard runoff from meat packing plants.

Methodology

A specific objective of this project is to identify the most promising techniques to identify, quantify, and

VOL 12

8343

locate cross-connections of sanitary and industrial wastes entering storm drainage systems.

As noted above, cross-connections can take multiple forms. Many cross-connection problems are associated with intermittent discharges. These intermittent discharges occur during wet-weather as runoff from storage areas, or as illegal dumping or washing operations that occur during dry or wet weather. Other cross-connection problems are caused by continuous connections that can occur during both wet and dry weather. These can be associated with "non-contact" cooling water discharges (which frequently contain a variety of chemicals, including algicides and corrosion inhibitors), other industrial wastewater connections, and sanitary sewage waste connections, for example.

This project is identifying procedures that can be used to identify the significance and type of either intermittent or continuous discharges occurring during dry weather. The pollutant contributions associated with cross-connections can be distinguished by unique characteristics based on water types and typical pollutants. As an example, the major water types (major ions) of the flow components could vary substantially: the water supply source could be either groundwater or surface water (this water type would represent many of the wastewater types), while an uncontaminated baseflow source could be from local springs, groundwater, or from regional surface flows. Knowing the specific water source for each flow component could enable the relative mixture of uncontaminated baseflow and the wastewater cross-connections to be calculated.

<u>Potential Dry-weather Discharge Sources</u>

The following list summarizes the potential contaminated residential area cross-connection sources being evaluated:

Sewage sources:
- raw sanitary sewage from leaky and directly connected sewerage
- septage from improperly operating septic tank systems

Household automobile maintenance:
- car washing runoff
- radiator flushing
- engine de-greasing
- improper oil disposal

Residential irrigation sources:

VOL 12

8344

- over-watering runoff
- direct spraying of impervious surfaces

Roadway and other accidents:
- fuel spills
- spills of truck contents
- pipeline spills

Other:
- washing of ready-mix trucks
- laundry wastes
- improper disposal of other household toxic substances
- dewatering of construction sites
- sump pump discharges
- contaminated surface and groundwaters

Commercial and industrial dry-weather discharges are being considered in a separate study conducted by Triad Engineering of Milwaukee. The results of the Triad study are being incorporated into the complete EPA manual. The commercial and industrial approach is stressing differentiating industrial categories used in the industrial discharge permit program.

The natural baseflow raw water source flows, along with the sewage related sources and many industrial sources, would be relatively continuous in flow duration. The other sources would be intermittent. As a drainage area increases in size, however, the probability also increases that dry-weather discharges associated with individual intermittent activities would appear continuous at the outfall. Most of the studies referenced previously found flows at the monitored outfalls most of the time during dry weather, even though the flows were very low at times. The quality of the flows also changed dramatically at different times of the day for the monitored Toronto industrial outfall (Pitt and McLean 1986). Some trends were also noted for dry-weather outfall flows for different times of the year (especially in the colder areas).

This study is identifying unique physical, biological, or chemical characteristics that would distinguish the different flow sources. After the potential source categories are identified, additional investigations would proceed upstream in the sewerage to identify the specific sources.

<u>Monitoring Approach</u>

The purpose of the monitoring procedures is to separate the outfalls into three general categories (with a known level of confidence) to identify which outfalls need further analyses and investigations. These categories are: (1) pathogenic or toxic pollutant sources, (2) nuisance and aquatic life threatening pollutant sources, and (3) unpolluted water sources. The pathogenic and toxic pollutant source category would be considered the most severe and could cause disease upon water contact or consumption and significant impacts on receiving water organisms. They may also cause significant water treatment problems for downstream consumers, especially for soluble metal and organic toxicants. These pollutants may originate from sanitary, commercial, and industrial wastewater cross-connections. Other residential area sources (besides sanitary wastewater), such as inappropriate household toxicant disposal, automobile engine de-greasing, vehicle accident clean-up, and irrigation runoff from landscaped areas excessively treated with chemicals (fertilizers and pesticides) may also be considered in this most critical category.

Nuisance and aquatic life threatening pollutant sources can originate from residential areas and may include laundry wastes, landscaping irrigation runoff, automobile washing, construction site dewatering, and washing of ready-mix trucks. These pollutants can cause excessive algal growths, tastes and odors in downstream water supplies, offensive coarse solids and floatables, and highly colored, turbid or odorous waters.

Clean water discharged through stormwater outfalls can originate from natural springs feeding urban creeks that have been converted to storm drains, infiltrating groundwater, infiltrating domestic water from water line leaks, etc.

The proposed monitoring approach is separated into three phases:

- initial mapping effort
- initial field surveys
- confirmatory chemical analyses.

These three initial phases will be followed by detailed storm drainage and site investigations to identify specific pollutant contributors and control options, as appropriate.

An important requirement of the methodology is that an initial field screening effort would require minimal effort and would have little chance of missing a seriously contaminated outfall. This screening program would then be followed by a more in-depth analysis to more accurately determine the significance and source of the dry-weather pollutent discharges.

Mapping. The most important step in a cross-connection investigation is in preparing and studying drainage and land use maps. In addition to mapping, aerial photographs and general site investigations may be very useful. An important objective of the mapping activities would be to identify the locations of all of the stormwater outfalls. Finding the outfalls is not trivial. In the case studies examined, repeated trips typically uncovered additional outfalls that could not be located during earlier excursions. In Toronto (GLA 1983), for example, most outfalls were located during the first field trip, but two more trips were needed before all of the outfalls were located. Similarly, additional outfalls were periodically found that were not identified on the city storm drainage maps. It is very difficult for communities to maintain up-to-date mapping of drainage facilities.

Another important objective of the initial mapping activities is to outline the drainage areas discharging to the outfalls. These drainage maps should identify the predevelopment streams that may have been converted to storm drains (indicating the likelihood of natural uncontaminated baseflows) and the current and past land uses. Specific land use categories to be indicated should include commercial and industrial land uses (identified by Standard Industrial Categories, SIC), plus other activities that may contribute runoff problems (such as land fills). Any industrial activities having significant potential of contributing flows to the storm drainage system, as indicated by Triad's analyses, need to be specifically identified and located.

Initial field surveys. The initial field surveys are to be used as a screening effort: to identify the outfalls needing more detailed investigations which would identify pollutant sources and control options. These initial surveys would include physical and limited chemical evaluations of outfall conditions and would be conducted to minimize "false negatives" (outfalls actually having important discharges, but falsely classified as not needing further investigation).

Different flow and pollutant characteristics of the potential discharge sources can be used to identify and quantify cross-connection problems. The initial surveys to obtain this key information should be repeated at all outfalls over several seasons. Many of the dry-weather discharges are intermittent and may not be noted during any one investigation. Various physical characteristics

VOL 12

8347

near the outfall can provide evidence that inappropriate discharges periodically occur. However, repeated trips to the outfalls significantly increase the probability of identifying problem outfalls. It is also important to time outfall investigations during the times of day when possible activities may be contributing cross-connection discharges.

It is difficult to develop a procedure that will separate the outfalls into clear "problem" and "no problem" categories. In some of the case studies investigated, only correcting problems at the most critical outfalls resulted in insufficient receiving water quality improvements. It may be important to eventually correct all cross-connection problems throughout a city, not just the most severe problems. This screening procedure should therefore be considered as just an initial effort that needs to be followed-up with more detailed confirmatory investigations at the outfalls and receiving water monitoring to document improvements after different stages of the control program.

Candidate parameters. Many different analytical methods are being evaluated as part of this project. The initial screening effort should include the following:

- placement of outfall identification number;
- outfall discharge flow estimate;
- floatables, coarse solids, color, oil sheen, and odor characteristics of water;
- other outfall area characteristics, such as stains, debris, damage to concrete, corrosion, unusual plant growth, or absence of plants;
- water temperature;
- conductivity;
- fluoride concentration;
- ammonia and/or potassium concentrations; and
- surfactant concentration.

These characteristics can be relatively easy to obtain at the outfall location, depending on the needed detection limits for the chemical analyses and potential interferences. The selection of the procedures to use to obtain the tracer concentrations will depend on many conditions, most notably the expected tracer concentrations in the uncontaminated base flows and in the potential cross-connection source flows, along with the needed probabilities of detection at the minimum contamination level. A description of the techniques being developed as part of this study to help in the selection of the analytical procedures is given later in this paper. Other factors affecting procedure selection include ease of use, analytical interferences, cost of

VOL 12

8348

equipment, training requirements, and time requirements to conduct the analyses.

Simple outfall estimates of discharge, and noting the presence of oil sheens, floatables, coarse solids, color, odors, etc. will probably be the most useful indicators of outfall problems. These observations will need to be repeated several times, especially if non-continuous discharges are likely. The presence of stains and structural damage will greatly assist in identifying significant non-continuous discharges, in addition to continuous discharges.

Notably absent from the above list are pH and dissolved oxygen. These have been included in several previous cross-connection studies, but with limited value. These two parameters have not been found to be extremely useful in identifying or categorizing cross-connection sources. However, in areas having known industrial sources, pH may be an important parameter that would have to be added to this list.

Specific conductance and temperature can be quickly and easily measured using a dual dedicated meter. Water color can be quantified using a comparative colorimetric meter or spectrophotometer in the field.

Fluorides can be detected using a variety of methods in the field, including field colorimetric kits having detection limits of less than 0.15 mg/L. This detection limit may not be sufficient to detect low dilutions of contaminants with adequate precision. Dedicated specific ion meters for fluorides are available having very low detection limits (2 ug/L) that would be quite capable of detecting very small dilutions. Neither of these methods are "direct reading" and require some time at the site to conduct the analysis and/or calibrate the meter.

Ammonium forms of nitrogen can be measured in the field using indicator paper, with detection limits of about 10 mg/L. Field colorimetric kits having detection limits of about 0.1 mg/L are available for total ammonia. Ion selective electrodes can be used in the field, with detection limits of about 0.01 mg/L for ammonia. Only the indicator paper method is a direct measurement procedure, but it probably does not have a low enough detection limit to permit the detect of low dilutions of cross-connection contaminants. The other methods require some sample preparation, but would be much more useful.

Potassium can be measured in the field using ion selective electrodes having detection limits as low as 0.01 mg/L. Portable spectrophotometers can also be used,

VOL 12

8349

with detection limits of about 0.1 mg/L. Either of these methods can be useful in a cross-connection study.

Detergents (or surfactants) can be detected in the field using a comparative colorimetric method (having a detection limit of 50 ug/L) or with a recently developed auto titration method having very few interferences and much lower detection limits.

In addition, the following optional characteristics may also be obtained at each outfall, depending on probable pollutant sources:

- o hardness;
- o toxicity screening; and
- o specific metals.

Hardness can be easily determined in the field using field titrimetric kits or even indicator papers, with varying sensitivities and interferences. Toxicity screening tests require laboratory analyses and some can be conducted in several hours. The toxicity tests would be useful in areas known to have commercial or industrial activities. Some individual metals (especially copper and chromium) could also be used in areas having these land uses. In most cases, it will probably be necessary to conduct a variety of carefully selected tests because of the large number of potential pollutant sources that probably occur in most drainage areas.

This scheme should allow an efficient determination of the general category (toxic/pathogenic, nuisance, or uncontaminated) of the water being discharged. In many cases, fluorides can be used to separate untreated water from treated water sources. Untreated water sources may include discharges from natural waters or untreated industrial waters. If the treated water has no fluoride added, or if the natural water has fluoride concentrations close to treated water fluoride concentrations, then fluoride may not be an appropriate indicator. Hardness can be used as an indicator if the clean water source is likely groundwater, while the treated water source is from surface supplies. Specific major ions could also be used to separate groundwater and surface water sources. Specific conductance may also serve as a rough indicator of major water source.

Water from treated water supplies (that test positive for fluorides, or other suitable tracer) can be relatively uncontaminated (domestic water line leakage or irrigation runoff), or it may be heavily contaminated. In areas having no industrial or commercial sources, sanitary wastewater is probably the

VOL 12

8350

most important cross-connection source. Surfactants may be useful in determining the presence of sanitary wastewaters. However, surfactants in water from treated water sources could indicate sanitary wastewaters, laundry wastes, car washing water, or other waters having detergents. Fabric whiteners (as measured by fluorescence using a fluorimeter in the laboratory or in the field) may also be a useful test for laundry and sanitary wastes.

If the surfactants were not present, then the treated water could be relatively uncontaminated (such as from domestic water line leaks or irrigation runoff), or it may be from rinsing ready-mix trucks or other rinsing activities (such as accident scenes). Sanitary wastewater would have the most consistent characteristics (volume and characteristic) compared to most of the other potential sources. Ammonia (or ammonium) nitrogen and potassium have been studied in several previous studies as an indicator of sanitery wastewaters. If the surfactant concentrations were high, but the ammonia and potassium concentrations were low, then the cross-connection contamination is likely laundry water. If they were all high, then sanitary wastewater is the likely source. Obviously, odor and other physical appearances (such as turbidity, foaming, color, and temperature) would also be very useful in separating major sanitary wastewater flows from rinse water or laundry water sources.

Toxicity screening methods would be very useful in areas known to have commercial or industrial activity, or to check for intermittent residential area discharges of toxicants.

Several confirmatory outfall analyses could be conducted to verify the more significant sources of cross-connection waters. These analyses require highly trained personnel and specialized equipment that would not be available in most laboratories. It may not be feasible to analyze samples from each of several hundreds of outfalls several times a year for these materials. These analyses can be very useful to check for false negatives and for more specific results on a random basis. These confirmatory analyses may include:

- o trihalomethanes
- o specific bacteria
- o coprostanol

Trihalomethanes (THMs) are formed when chlorine reacts with certain natural organics present in waters. The detection of these compounds in groundwaters has been used as a positive indication of treated city water

VOL 12

8351

leakage (Hargesheimer 1985). Chloroform and dichlorobromethane are the THMs most frequently used because of their very low detection limits and specific indicators of treated domestic water.

Bacteria are usually poor indicators of the source of cross-connection water. Past use of fecal strep. to fecal coliform ratios to indicate human versus nonhuman bacteria sources in mixed and old wastewaters (such as most nonpoint waters) has not been very successful. There may be some value in investigating specific bacteria types, such as fecal strep. biotypes, but much care needs to be taken in the analysis and interpretation of the results. A more certain indicator of human wastes may be the use of certain human-specific molecular markers, specifically the linear alkylbenzenes and fecal sterols, such as coprostanol and epicoprostanol (Eganhouse, et al. 1988).

Detailed outfall analyses. After the initial outfall surveys indicate the presence of serious contamination, additional pollutants associated with local commercial and industrial activities need to be monitored. This monitoring will assist in identifying the classes of commercial or industrial activities responsible for the contamination.

Watershed analyses to locate specific sources. In order to identify the specific contaminant sources in the drainage system, further detailed analyses are needed. These may include:

- drainage system surveys (tests for specific pollutants, visual inspections, and smoke and dye tests)
- in-depth watershed evaluation (including aerial photographs)
- industrial and commercial site studies

Follow-up Site Investigations. Further drainage area investigations upstream of the outfall would be conducted after the outfall studies have indicated dry-weather discharge problems. These would include drainage system and industrial and commercial site studies (such as dye and smoke studies) to locate specific cross-connections. Additionally, aerial photography can be very useful during later phases of cross-connection control projects. As an example, aerial photography can be very useful in identifying areas having failing septic systems located in residential areas served by storm drainage systems. Aerial photography can also be used to identify continuous discharges to surface drainages, such as sump discharges, and to identify

VOL 12

8352

storage areas that may be contributing significant amounts of pollutants during rains.

<u>Additional Project Activities</u>

In order to identify potential cross-connection sources, it is necessary to have a certain knowledge about each potential source flow component. Specifically, the probable range of concentrations of the alternative tracers in each flow component (including the "clean" background) is needed. As noted above, the watershed survey to identify the presence of specific industrial and commercial activities is crucial.

This project is therefore collecting typical quality data for different cross-connection sources as a guide in helping to design the initial field investigations. Obviously, local information for potential flow sources will be needed. The variations of the characteristics is especially needed in order to select the field procedures needed. Statistical tests are being used in conjunction with the potential cross-connection source concentration information and the capabilities of existing relatively simple tests to help in the selection of the appropriate field and laboratory tests.

Monte Carlo tests (using the microcomputer program PRISM, version 2.01, from Palisade Corporation, Newfield, NY) are being used to examine the sensitivity of different analyses in identifying and quantifying different mixtures of cross-connections. Typical situations representing a broad range of potential runoff mixtures are being examined to identify the most robust analytical methodology. As an example, the concentration variations of individual components can be used to select the required minimum detection limit of the analytical method in order to determine the mixing portion of two sources.

In Figure 1, it is assumed that an uncontaminated component has a 10 to 90 percentile concentration range of 1 to 50 ug/L for a specific tracer and a contaminating component has a comparable concentration range of 10 to 500 ug/L for the same tracer. If a detection probability of at least 90 percent was needed for a contamination percentage of 10 percent, the Monte Carlo tests indicate that a methodology detection limit of at least 5 ug/L would be needed. If the detection limit was only 25 ug/L, the probability of detection of this mixture would be only about 55 percent. Many additional figures are currently being prepared to assist in the selection of detection limits, for a wide variety of concentration ranges and mixing ratios.

VOL 12

8353

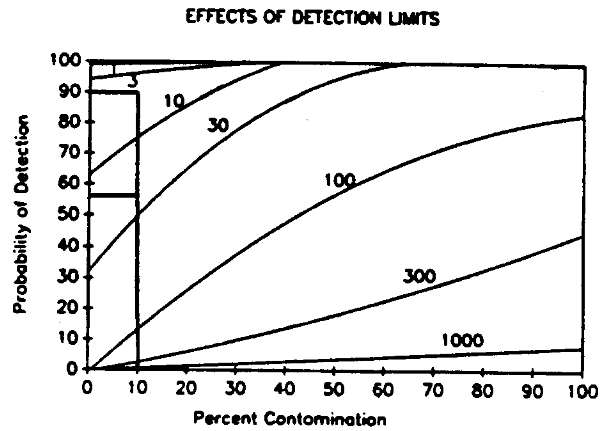

Figure 1. Effects of Detection Limits on Probability of Detection

The continuation of this project will involve field investigations to test the procedures and candidate equipment, and revisions to the draft manual.

Conclusions

Many urban runoff projects have found that dry-weather discharges from stormwater outfalls can contribute significant pollutant loadings. Ignoring these loadings can lead to improper conclusions concerning stormwater control requirements.

Municipalities that have recognized the importance of dry-weather flows have investigated their sources using various methods. Unfortunately, most municipalities have very large numbers of outfalls and an efficient method is needed to separate the outfalls creating the most severe problems. This project is examining three categories of outfalls: pathogenic/toxicant, nuisance and aquatic life threatening, and clean water. The most important category is for outfalls contributing pathogens or toxicants. These are most likely originating from sanitary wastewater or industrial cross-connections. An initial screening analysis at all outfalls should have a high probability of identifying all outfalls in this category.

The first step of this procedure is an extensive mapping effort to identify the locations of all outfalls for sampling and to outline the drainage areas contributing to each outfall. The screening analyses at the outfalls include several visual measures (color, turbidity, oil sheens, floatables, coarse solids, etc.) along with measurements for fluorides and surfactants. Fluorides can be used to indicate if the water originated as treated domestic water (instead of infiltrating untreated groundwater). This may indicate sanitary sewage cross-connections or other waste waters. Surfactants can help in identifying sanitary sewage connections, in contrast to landscaping irrigation runoff or rinse waters, or industrial waters. The drainage area maps need to be studied to determine the presence of potential industrial or commercial cross-connection sources.

More sophisticated analyses are available to confirm the potential sources, but they most likely cannot be employed for all outfall samples because of the required highly skilled analysts and expensive equipment.

Future project phases will evaluate these outfall procedures in test conditions and will result in manual refinements. Procedures to identify and correct specific cross-connections will also be summarized in these future project phases.

A "LIVING MASTER PLAN" FOR COMBINED SEWER SYSTEMS

by Larry A. Roesner, F. ASCE[1], John A. Aldrich, A.M. ASCE[2], and Edward H. Burgess, M. ASCE[3]

INTRODUCTION

Cincinnati, Ohio, celebrated its bicentennial in 1988. Like many of the nation's older and well-established cities, Cincinnati is coping with problems of infrastructure stressed beyond capacity. Chronic flooding occurs in some areas where trunk sewers have insufficient capacity or adequate drainage facilities are not provided. Deteriorated sanitary sewers are overloaded by infiltration and inflow. The combined sewer system that serves much of Cincinnati often overflows during storms, washing pollutants into local waterways.

To solve these wastewater and drainage problems, the City of Cincinnati StormWater Management Utility and the Metropolitan Sewer District of Greater Cincinnati have joined forces to develop a Stormwater Wastewater Integrated Management (SWIM) Master Plan with a 100-year planning horizon. The major objectives of the master plan are:

- To eliminate flooding caused by backups from sewers
- To eliminate all discharges of untreated wastewater into waters of the State
- To develop an operations and construction coordination program
- To eliminate building moratoriums due to sewer problems
- To develop a comprehensive drainage and flood-control system for the City of Cincinnati
- To develop a 100-year stormwater and wastewater master plan to protect and enhance the quality of life in Cincinnati and Hamilton County

Based upon these objectives, the SWIM Master Plan Program is designed to accomplish three primary goals:

[1]Senior Vice President, Camp Dresser & McKee, Inc., 555 Winderly Place, Suite 200, Maitland, Florida 32794-5375.

[2]Associate, Camp Dresser & McKee, Inc., 7535 Little River Turnpike, Suite 200, Annandale, Virginia 22003.

[3]Senior Engineer, Camp Dresser & McKee, 1811 Losantiville Road, Suite 350, Cincinnati, Ohio 45237-3989.

- A Wastewater Master Plan, which will provide adequate conveyance and treatment facilities for projected future wastewater flows and/or reduce or convey excessive infiltration/inflow (I/I) which enters the sewerage system;
- A Stormwater Master Plan, which will safely manage flooding caused by backups of the storm drainage system within the City of Cincinnati; and
- A Combined Sewer Overflow Master Plan, which will adequately control combined sewer overflows (CSOs) during high-river stages and rainfall events.

It is unclear at the present time what level of control will ultimately be required for CSOs. For this reason, a key element of the CSO-control plan is to develop a "building block" approach, which will allow sequential construction of facilities to achieve increasingly higher levels of control as the need for these facilities is demonstrated based upon monitoring and analysis of receiving water. Thus, the plan is a "living plan," providing a road map that identifies the location and type of facilities that are to be constructed but not specifying the ultimate size of those facilities. However, space is reserved to build facilities that will control the one-year storm in case that level of control is finally required in any given area.

For the purposes of the SWIM Program, the study area, which comprises the 414-square-mile area of Hamilton County, Ohio, was divided into nine major drainage areas. This paper describes how this approach to master-planning is being applied in one of these, the Duck Creek Drainage Area (3).

PHYSICAL SETTING

The Duck Creek Drainage Area is located in the southeast quadrant of Hamilton County in southwestern Ohio adjacent to the Ohio River and immediately west of the Little Miami River (Figure 1). The Ohio River is a large, muddy, fast-flowing tributary to the Mississippi River. The drainage area of the Ohio River at Cincinnati is 76,580 square miles (198,257 square kilometers). The Little Miami River, to the east of the drainage area, has a watershed of 1,757 square miles (4,549 square kilometers) and has been classified as a Scenic River over much of its length, including the portions adjacent to the Duck Creek Drainage Area. About 5,100 acres (2,070 hectares) of the total of 17,581 acres (7,115 hectares) in the drainage area drain to these two major rivers, while the remaining 70 percent is drained by Duck Creek and its tributaries.

Over 80 percent of the drainage area is sewered, with combined sewers comprising 60 percent of the sewered area and separate sewers comprising 40 percent of the sewered area. More than half of the sewers were built before 1940, and both structural and hydraulic deficiencies have been reported. Figure 2 show the areas served by combined sewers and by separate sewers. It also shows the eighteen watersheds into which the drainage area was divided for the purposes of this study.

The interceptor sewer system, which is shown on **Figure 3**, diverts dry-weather sanitary flows and a portion of the wet-weather flow to the Little Miami WWTP. Wastewater flows from the remainder of the drainage area are intercepted by the Delta Avenue Pump Station, located along the Ohio River. The existing capacity of this pump station, which pumps flows into the Little Miami WWTP, is 9,000 gallons per minute (570 liters per second).

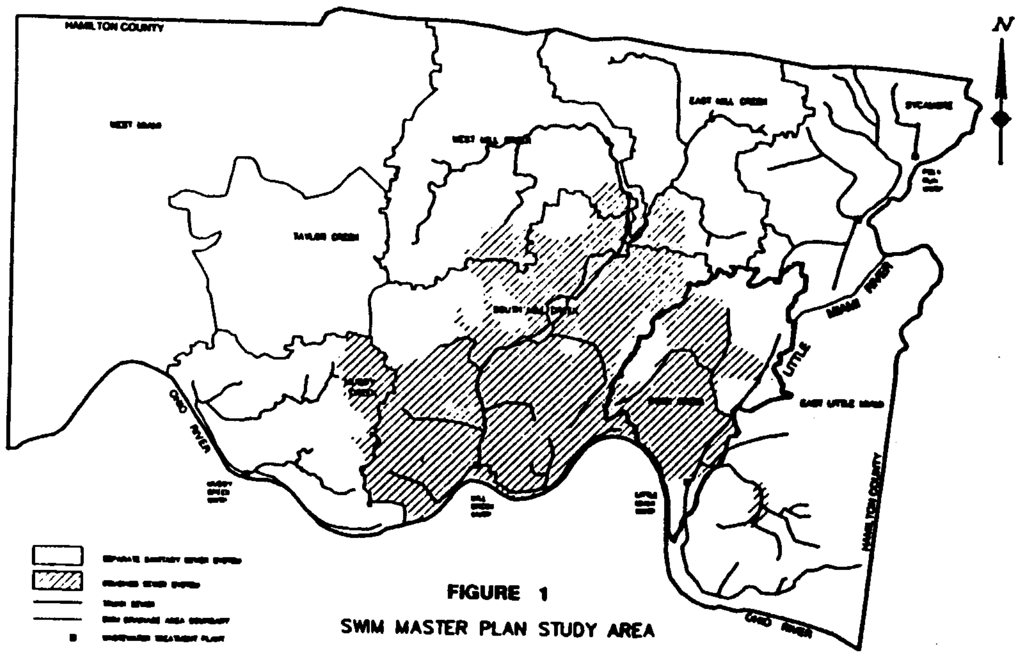

FIGURE 1
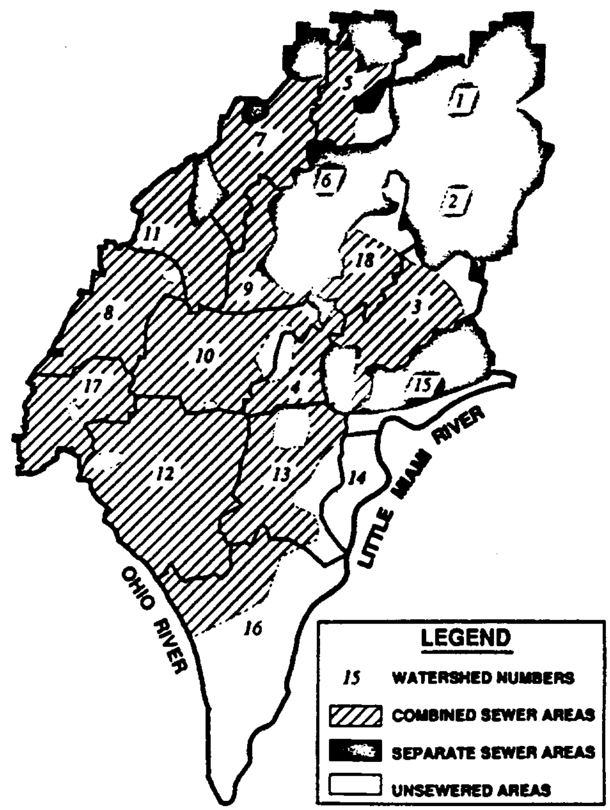
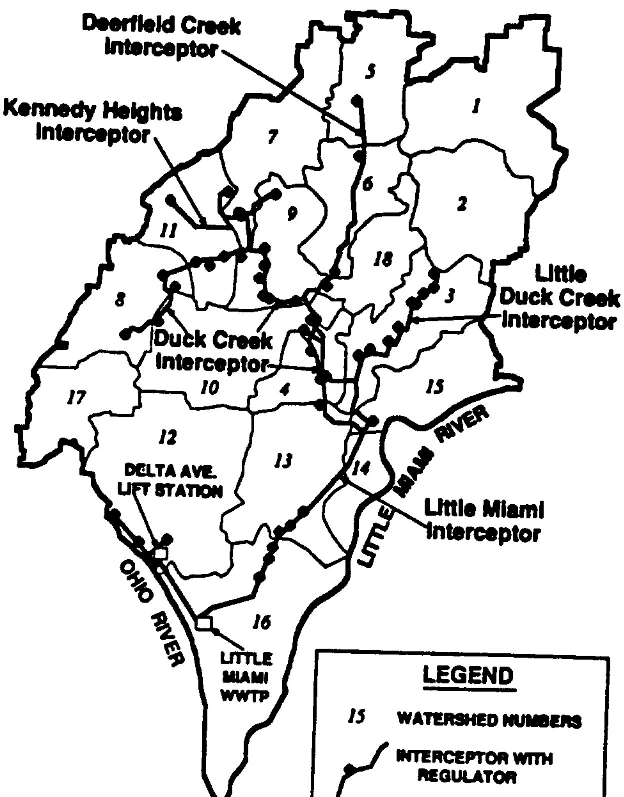
SWIM MASTER PLAN STUDY AREA



WATERSHEDS AND SEWERED AREAS IN DUCK CREEK DRAINAGE AREA | FIGURE 2



COMBINED SEWER INTERCEPTOR SYSTEM IN DUCK CREEK DRAINAGE AREA	FIGURE 3

VOL 12

8361

R0041667

The combined sewer interceptor system in the Duck Creek Drainage Area contains 52 regulators. A regulator is defined as any structure which diverts dry-weather wastewater flows from combined sewers into interceptor sewers. Virtually all of these regulators are static regulators, typically consisting of a grate with a drop inlet (with or without a diversion dam) and containing no moving parts. Figure 3 also shows the location of the regulators in the Duck Creek Drainage Area.

The Duck Creek Drainage Area comprises about 20 percent of the City of Cincinnati, plus all or part of seven other communities. The drainage area is about two-thirds residential, one-fourth open (parks, public land, and steeply sloped areas), and less than 10 percent commercial/industrial. Less than 5 percent of the drainage area is available for new development, and population/employment/dwelling unit projections call for negligible growth over the 100-year planning horizon (2).

RECOMMENDED STORMWATER CONVEYANCE IMPROVEMENTS

Analysis of the storm drainage system consisted of applying the RUNOFF module of the USEPA StormWater Management Model (SWMM) (5) to all storm drainage pipes and channels greater than or equal to 36-inch (0.91 meters) equivalent diameter. This included separate storm drains as well as combined sewer trunks. The objectives of this analysis were:

- Ensure that the trunk sewer can convey runoff from the 2-year storm; where possible, develop facility plans to provide 10-year protection.
- For all new development (or re-development), require runoff controls so that post-development runoff peaks do not exceed pre-development peaks for the 1-, 2-, 5-, and 10-year storms.
- For stormwater quality management, use CSO-control facilities in combined sewer areas and regional facilities in separate sewered areas.

Improvements to stormwater management facilities were proposed to provide adequate drainage for nearly 100 locations. These improvements address both local drainage problems identified by the SWIM team and conveyance problems discovered during simulation of 10-year design storms.

Near-surface storage facilities were generally determined to be more cost-effective for controling severe instances of flooding than replacing existing pipes with larger pipes. Nineteen near-surface storage facilities of various sizes were recommended to detain peak flows during 10-year flooding events. Where adequate sites for near-surface storage facilities were not available, replacement or relief sewers were recommended. The analysis showed that about 4.5 miles (7.2 kilometers) of storm/combined sewer needed to be either replaced or relieved depending on the structural integrity of the existing sewer and constructability problems along the alignment of the existing sewer.

Many of the problems identified by the SWIM team involved surface flooding in areas which are not currently served by storm sewers. Control measures were designed to resolve each of these problems; most of these measures can be implemented immediately (within the available funding levels of the City), while a few measures will significantly increase the volume of CSOs and should not be implemented until CSO control measures adequate to prevent increases in CSOs are in place.

ANALYSIS OF THE LITTLE MIAMI WASTEWATER TREATMENT PLANT

The Little Miami Wastewater Treatment Plant (WWTP) has an average daily secondary treatment capacity of about 36 million gallons per day (mgd, or 1.6 cubic meters per second, m^3/s) and a hydraulic capacity of 96 mgd (4.2 m^3/s). About 66 percent of its average dry-weather flow comes from the Duck Creek Drainage Area, which is predominantly served by combined sewers. The remainder of the flow is generated within the East Little Miami Drainage Area, to the east, which is predominantly served by separate sewers. The WWTP receives an existing average daily dry-weather flow of 25 mgd (1.1 m^3/s), which represents 70 percent of secondary capacity, and an existing dry-weather peak flow of 40 mgd (1.8 m^3/s), which exceeds the plant's secondary capacity by 11 percent. Flow projections for the year 2010 indicate that the average daily dry-weather flow will reach 35 mgd (1.5 m^3/s), representing 97 percent of the plant's secondary capacity. The estimated peak dry-weather flow in 2010, is 56 mgd (2.5 m^3/s), 155 percent of secondary treatment capacity. Therefore, about 20 mgd (0.9 m^3/s) of additional treatment capacity will be required at the Little Miami WWTP by 2010 to enable it to handle projected peak daily dry-weather flows.

Additional treatment capacity is required at the Little Miami WWTP to handle wet-weather flows. Currently, there is only about 11 mgd (0.5 m^3/s) of wet-weather capacity at the plant, which is well below the capacity of the interceptor to convey wet-weather flows to the plant; thus, CSOs are expected to occur at the plant virtually every time it rains. There is no projected wet-weather capacity at the plant by 2010.

ESTIMATE OF COMBINED SEWER OVERFLOWS

Estimates of combined sewer overflow frequency, volume, and pollutant loads were performed with the Storage, Treatment, Overflow, Runoff Model (STORM) (6), based on the hydraulic performance of the combined sewer interceptor and regulator system. STORM continuously simulates overflow quantity and quality, using surface runoff and land-use/pollutant relationships. About forty years of hourly rainfall data from the Greater Cincinnati International Airport were continuously simulated with STORM to determine average annual CSO statistics.

Overflow quantities are calculated from the interaction between the in-system storage capacity, the interceptor transport capacities of the sewer network, and the volume of runoff entering the system. Interceptor capacities were determined from simulations of the hydraulic performance of the combined sewer interceptor system using the EXTRAN model of SWMM (7), as discussed below.

A lumped rational formula coefficient of 0.5 was applied for each watershed; average evaporation of 0.1 inches (2.5 milimeters) per day was used, and surface depression storage was set at 0.06 inches(1.5 mm). A volume of 0.04 inches (1.0 mm) represents the approximate existing capacity available for storage of wet-weather flows in the combined sewer system.

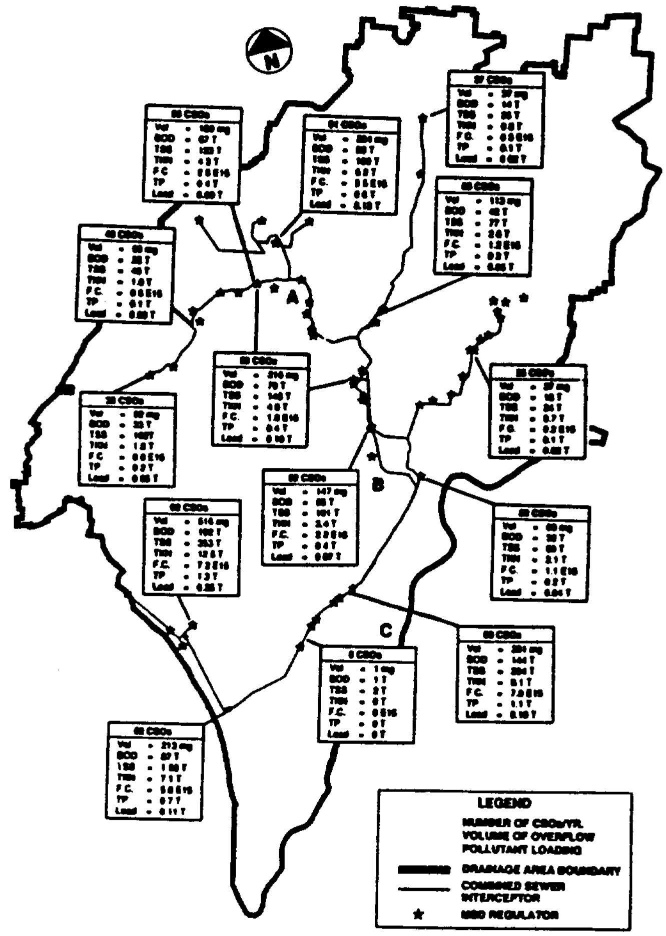
Existing overflow volumes can be projected based on unit treatment rates (expressed in cfs per acre or inches per hour) determined from hydraulic simulations with the SWMM-EXTRAN model. The hydraulic simulation defines the interceptor capacity, indicates the locations of CSOs where interceptor capacity is less than regulator capacity, and locates portions of the interceptor where additional capacity is available. Therefore, this procedure pinpoints wet-weather hydraulic deficiencies--those points where an interceptor is incapable of conveying flows contributed by regulators, thus causing an overflow.

In general, the capacity of the combined sewer interceptor system is significantly less than the total capacity of the regulators. The combined sewer interceptor system has sufficient capacity for existing and projected future dry-weather flows. However, during wet-weather conditions, the interceptor can only capture the runoff from rainfalls of between 0.02 and 0.05 in/hr (0.5 to 1.3 mm/hr). For larger rainfall events, interceptor surcharging prevents flow captured by the regulators from entering the interceptor. CSOs resulting from insufficient interceptor capacity occur throughout the system but are most pronounced along the lower reaches of the interceptor, where the capacity decreases as the interceptor slope flattens along the Little Miami River floodplain. These CSOs are particularly serious since they flow into the Little Miami, which has been designed a Scenic River by the State of Ohio and is therefore subject to stricter water-quality standards.

The CSO frequency and annual overflow volume projections developed with STORM can be applied to determine the severity of CSOs resulting from surcharging and flooding of the interceptor. Dry-weather flows in the interceptor are subtracted from the maximum hydraulic capacity of the interceptor segment which flows out of each watershed to determine the wet-weather capacity of the interceptor and/or the regulators. Figure 4 indicates the average annual overflow frequency, volume, and pollutant loads at key locations along the interceptor system. Based on interceptor capacity, an average of about 50 to 60 overflows per year occur in the Duck Creek Drainage Area. Insufficient interceptor capacity results in approximately twice the number of overflows as are caused by insufficient regulator capacity.

CSOs cause the greatest impacts where high pollutant loads enter into small streams. This is most pronounced at the outlets of the combined sewers draining Watersheds 7, 8, and 17, (shown as the area upstream of A on Figure 4) where about 25% of the total CSO pollution from the Duck Creek drainage area enters the most upstream portion of the free-flowing Duck Creek. In addition, almost all the CSO pollution in lower Duck Creek enters upstream of B on Figure 4; this location is near a residential area which includes parks where water contact occurs. CSO loadings to other tributary streams are not as high but are still of concern due to the close proximity of these CSOs to residential neighborhoods.

Other CSOs enter larger streams but are of equal concern. For example, about a 1-3/4-mile (2.8 km) stretch of the Little Miami River near the confluence with Duck Creek (shown as C on Figure 4) is contaminated by the CSOs which occur at the diversion structure located at the junction of the Duck Creek and Little Duck Creek interceptors. Water-quality impacts from CSOs into the Ohio River at the Delta Avenue Pump Station and the Little Miami WWTP (both located in the southern portion of the drainage area, constitute about 30% of the total CSO pollution load generated in the Duck Creek Drainage Area but are somewhat less serious than those in the rest of the drainage area because of the higher assimilative capacity of the Ohio River. In the Ohio, the most serious water-quality problem is coliform pollution due to potential public health impacts on near-shore recreation and water contact while boating.



Annual Overflow Frequency, Volume, and Pollutant Loads at Key Locations | Figure 4

VOL 12

83655

DETAILED EVALUATION OF CSO CONTROL ALTERNATIVES

A detailed evaluation of alternatives for abatement of CSOs in the Duck Creek Drainage Area was performed. Wastewater facility improvements as described below focused on expansion of the Little Miami WWTP to handle projected increases in dry-weather flows and to provide treatment for wet-weather flows captured by various CSO control alternatives. Several CSO abatement alternatives were then sized to provide various levels of control based on the recommended WWTP expansion. The alternatives are listed below; the following sections discuss first the WWTP expansion and then each of the alternatives in turn.

A. **Combined Interceptor System Optimization** — Limited adjustments and/or replacements of regulators, overflows, manholes, and sewer segments, yielding relatively inexpensive methods to significantly reduce CSOs;

B. **Distributed Storage/Treatment Within Sub-Areas** — Storage/treatment facilities (in-line or off-line) sited within most sub-areas of the combined sewer system;

C. **Regional Storage/Treatment Facilities** — Larger storage/treatment facilities serving one or more watersheds in conjunction with regulator improvements and/or consolidation sewers upstream of the regional facility;

D. **Deep Tunnel** — Storage provided by a hard-rock tunnel about 200 to 300 feet underground, which is emptied after the storm by pumping into the interceptor system; and

E. **Sanitary/Storm Sewer Separation** — Installation of separate sewer systems to reduce the contributions of stormwater to the combined sewer system.

REQUIRED IMPROVEMENTS AT THE LITTLE MIAMI WWTP

Peak dry-weather flows at the Little Miami WWTP are expected to exceed plant capacity by 20 mgd (0.9 m^3/s) by 2010, as discussed above. In addition, treatment capacity is required for wet-weather flows captured by all CSO control methods other than sewer separation. The STORM model was used to explore trade-offs between treatment and storage requirements. In general, secondary treatment costs (both capital and operations/maintenance) are significantly higher than storage costs, and thus maximizing storage is preferable. Storage must be supplemented with enough treatment capacity to ensure that space will be made available to store flows from subsequent rain events.

Based on rainfall statistics and STORM simulations, storage facilities designed to capture the one-year storm (*i.e.*, a CSO frequency of one per year) must be completely drained within four days to provide sufficient storage for subsequent events and to prevent anaerobic conditions within the storage facility. STORM simulations showed that a wet-weather treatment rate of about 0.01 in/hr (0.25 mm/hr) coupled with a total of about 0.96 inches (24.4 mm) of storage would capture the one-year storm and be emptied in the recommended four days. For the Little Miami WWTP, this translates to a wet-weather treatment rate of 54 mgd (2.4 m^3/s) coupled with a total storage volume within the Duck Creek Drainage Area of 210 million gallons (800,000 m^3). An additional 35 mgd (1.5 m^3/s) is required to treat the average dry-weather flow predicted for 2010, bringing total required expansion to 89 mgd (3.9 m^3/s).

VOL 12

8366

Expansion of the Little Miami WWTP is included as an integral part of all other CSO control alternatives discussed in the following sections.

SMALL SCALE CSO CONTROL MEASURES

Combined sewers are less extensive in areas of Watersheds 8 and 11. In Watershed 11, stormwater runoff from over half the watershed is contaminated by CSOs which are produced within a combined sewer area of less than 50 acres (20 hectares). Separation of a few combined sewers and construction of a small storage facility in Watershed 11 will eliminate CSO contamination of stormwater runoff which otherwise must be treated with regional CSO control measures.

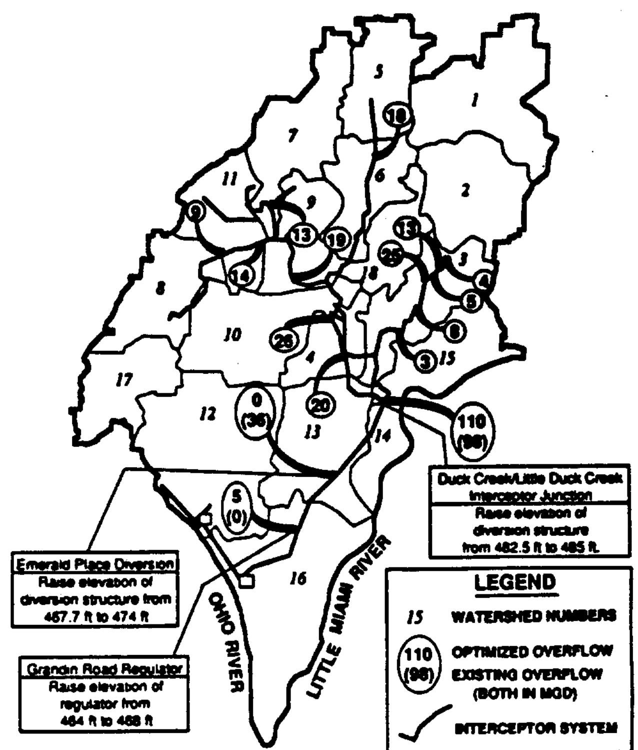
In Watershed 8, numerous connections of sanitary sewers to storm sewers exist. The Master Plan recommends that dry-weather flows from these sanitary connections be intercepted and CSO control facilities be provided for the wet-weather flows. CSO control in this watershed is provided partially by converting a large box-culvert system into a CSO consolidation sewer. This culvert system can be used as an in-line storage device to provide control in the short term and can be integrated into a long-term CSO control plan.

Alternative A: Combined Sewer Interceptor/Regulator Optimization to Reduce Wet-Weather CSOs

As described earlier, the overall performance of the existing combined sewer interceptor system in the Duck Creek Drainage Area is limited during wet-weather conditions by low overflow elevations at key regulators. Alternative A provides for raising of overflow elevations of regulators which obviously limit interceptor system performance to increase the driving head through the system. Figure 5 shows sites where reductions in interceptor overflow rates would be achieved if the following system optimization measures are implemented (shown in boxes on Figure 5):

- Junction of Duck Creek/Little Duck Creek interceptors: The high-level overflow weir located adjacent to the existing sluice gate on the old Duck Creek interceptor outfall can be raised by about 5 feet (1.5 meters) without major modification to the existing diversion structure.
- Emerald Place diversion: Permanently closing this gate will serve to prevent any overflows at this location. Maintenance measures needed to ensure that the gate is properly sealed should be performed. No capital costs are envisioned.
- Grandin Road regulator: This regulator can be relocated upstream in the combined sewer, and the diversion dam can be raised to achieve an overflow elevation of 468.0 feet (142.6 meters). The estimated capital cost of this improvement is less than $50,000.

In general, system optimization results in a 20 percent to 40 percent increase in conveyance in the Little Miami Interceptor. Optimizing interceptor conveyance reduces overall Duck Creek Drainage Area overflows from an average of about 60 per year to about 55 per year, except at the Little Miami WWTP. Across the drainage area, CSO volume and pollutant loads are only reduced about 2 percent under the system optimization scheme. However, it is important to note that about 7 percent of the total CSO volume and pollutant loads generated within the drainage area are diverted from the environmentally sensitive Little Miami River into the Ohio River, which possesses a greater assimilative capacity. In addition, overflows would occur at the Little Miami



COMBINED SEWER OPTIMIZATION ALTERNATIVE IN DUCK CREEK DRAINAGE AREA — FIGURE 5

VOL 12

8368

R0041674

WWTP, where it is more efficient to screen, disinfect, or provide primary treatment for CSOs.

In summary, optimizing the existing Duck Creek Interceptor system increases conveyance between 20% and 40%, but such an improvement is not sufficient by itself to reduce CSOs to 1, 3, 6, or 12 per year. However, in conjunction with alternatives for combined sewer storage and/or local interceptor replacement, modification of specific regulators could lower the overall cost to reduce overflow events. In addition, short-term benefits achieved by optimization is the baseline CSO control level under the U.S.EPA CSO-control strategy. Therefore, system optimization is used here as the baseline for evaluation of other CSO control schemes.

Alternative B: Distributed Storage/Treatment Within Sub-Areas

Small storage/treatment facilities can be distributed throughout the drainage area to hold "first-flush" wet-weather flows until after the rainfall has ceased. Such facilities usually are placed at a combined sewer regulator and/or at the outlet of a 20- to 200-acre (8- to 81-hectare) sub-area of the combined sewer service area. The storage volume required to reduce the frequency of CSOs within each watershed was determined from the STORM simulations, based on the existing wet-weather capacity of the interceptor segment flowing out of each watershed.

Figure 6 presents the conceptual design of a 0.5-mg (1,900 m^3) storage/-sedimentation facility typical of those being implemented in West Germany for CSO control (1) and which is recommended for installation in Cincinnati. Among the unique aspects of this facility which make it ideal for CSO control are that it:

- Captures the "first flush": The facility uses a vortex regulator to capture the portion of the first flush in excess of the interceptor capacity. Following the rainfall event, the pollutants captured are bled back into the interceptor for secondary treatment at the WWTP.
- Provides sedimentation: The dimensions of the facility are established to promote settling at the design hydraulic loading rate.
- Bypasses less frequent large storms: Storm flows in excess of the design capacity are bypassed from the facility, preventing re-suspension of solids captured in the first flush.
- Requires low maintenance: The facility is designed to be self-cleaning, reducing the maintenance required after a storm event.

Providing distributed storage facilities within sub-areas reduces CSO frequency volumes, and pollutant loads sufficiently to achieve the goals of the CSO-control plan. However, this approach has several major disadvantages:

- A large number of facilities is required, over 400 in Duck Creek alone. The unit cost for each facility is higher than for other types of facilities since no economies of scale are realized.
- Many of these facilities would need to be located in residential neighborhoods. Resulting site limitations would restrict construction of many facilities to existing roadway right-of-ways or would result in construction problems (utility interference, traffic disruptions, pavement removal/replacement, etc.) which would in all probability lead to increases in construction costs above those mentioned in the previous sub-section.

15 dry-weather-flow
16 storm runoff
17 clarified storm runoff
18 receiving water

Figure 6

TYPICAL STORAGE FACILITY "TANK"
(FROM BROMBACH, 1989)

- Operational problems would be distributed throughout the drainage area rather than being concentrated in a few areas. Among these are the impact of odors on residential neighborhoods and of corrosive sewage stored in these facilities. In addition, all facilities would operate during every rainfall event and potentially could require maintenance once or twice during an event. Also, access to facilities would probably be within roadway right-of-ways, potentially causing traffic disruption.

Alternative C: Regional Storage/Treatment Facilities

Regional storage facilities have distinct advantages where space is available. A typical regional facility is shown in **Figure 7**. The regional storage facility is essentially a set of distributed storage facilities grouped at a single location where space is available, a large drainage area is served, and few consolidation sewers are required to convey flow to the facility. Regional facilities are preferred over distributed storage because the former provide several advantages:

- Economies of scale will reduce construction and operations and maintenance (O & M) costs.
- Sites can be selected which minimize disruption to the community.
- Multiple-use opportunities are greater.
- Storms smaller than the design capacity can be captured in a few of the available tanks, minimizing O & M effort for frequent storms.
- Facility operation can be varied to facilitate O & M activities. For example, some tanks can be taken out of service for repair without decreasing the capture efficiency of the facility for all events except those at or near the design capacity.

In the Duck Creek Drainage Area, sites were selected for regional storage based on considerations such as the availability of vacant and/or under-utilized land or land in an industrial/commercial area, or the possibility of locating a site near combined sewer regulators and/or bottlenecks in the interceptor system.

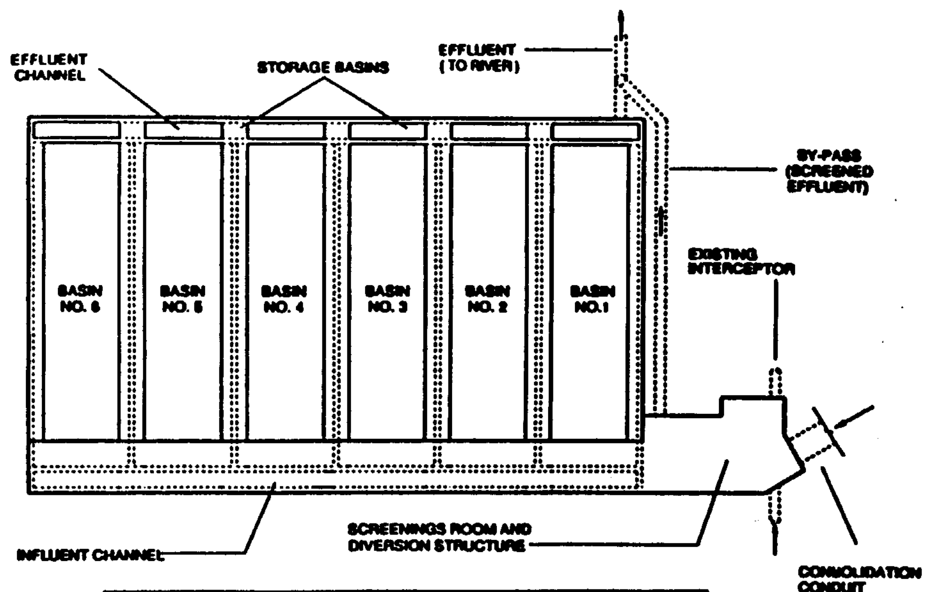
Using these criteria, ten sites were selected; these are shown as small squares in **Figure 8** and are labeled with the names of neighborhoods or nearby geographical landmarks. For each of these sites, the number of 500,000-gallon (1,900 m^3) storage tanks (shown in Figure 6) required to reach specified overflow levels is given. The largest regional storage facilities would be located near the junction of the Duck Creek and Kennedy Heights interceptors (the Norwood and the Kennedy Heights facilities), near the junction of the Duck Creek and Little Duck Creek interceptors (the Little Miami Floodplain facility), at the Delta Avenue Pump Station (the Delta Avenue facility), and at the Little Miami WWTP.

The regional storage facilities should be designed in the following manner:

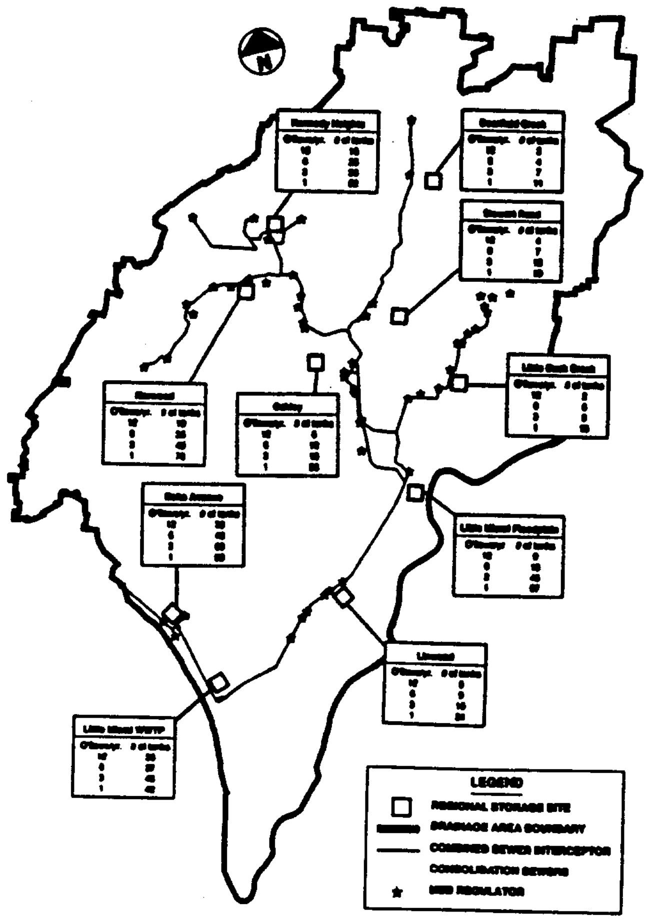
- Each individual tank should operate as shown in Figure 6.
- During storm events, flow should be diverted to the tanks sequentially. Thus, during small storms, only a few tanks would be used and require post-storm maintenance; the entire facility would be full only during the design event.

VOL 12

8371



Typical Regional Storage Facility (Gravity Drained)	Figure 7



Regional Storage Alternatives in the Duck Creek Drainage Area | Figure 6

- The diversion sequence should be varied periodically so that the same tanks would not be used all the time and tanks could be taken out of service occasionally for maintenance.

Alternative D: Deep Tunnel

Where limited sites are available for regional storage facilities, storage can be provided in a deep tunnel. Design considerations for a deep tunnel would include the following:

- The tunnel should be 36 feet (11 m)in diameter, constructed in hard rock 200 to 400 feet (61 to 122 m) below the ground.
- The number of drop shafts into the tunnel should be minimized, since each costs about $5 million to construct.
- Whenever appropriate, consolidation sewers should be built in preference to additional tunneling and drop shafts, since the latter are more expensive.
- Regional storage facilities should be constructed wherever the cost of additional consolidation sewers, tunnel segments, and drop shafts exceeds the cost of regional storage.
- A pump station is required to empty the tunnel and should be sized to equal the capacity of the Little Miami WWTP expansion for wet-weather treatment (54 mgd or 2.4 m^3/s). The pump station would discharge into the existing interceptor system.

Figure 9 shows the location and extent of deep tunnel construction which would be required to reduce overflows in the Duck Creek Drainage Area to one per year. This was the only level of control considered for the deep tunnel, for two reasons:

1) If storage in the tunnel were decreased by changing the alignment shown in Figure 9 (*i.e.*, by significantly shortening it), the tunnel would not capture enough of the combined sewage to be effective.
2) It is not cost-effective to decrease the storage in the tunnel by reducing the tunnel diameter, since the incremental cost of drilling a smaller tunnel is not significantly less than the cost to drill a 36-foot (11m) diameter tunnel as proposed.

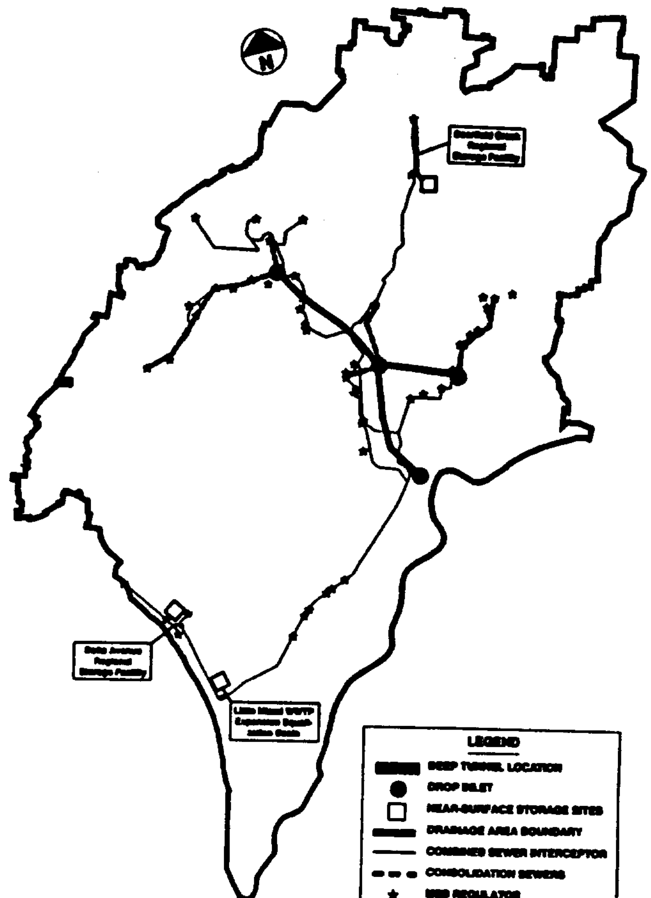
The major advantage of a deep tunnel is that most of the facilities are located below ground, minimizing problems in several areas, including potential utility obstructions, land requirements, and odor. Before selecting this alternative, however, further investigation of the tunnel is necessary to ensure that geological conditions are appropriate for its construction (e.g., to locate the hard-rock layer and any fault lines which could impact the tunnel during an earthquake). Storage at the Little Miami WWTP is provided by a 13-mg (0.6 m^3) equalization basin as described above.

Alternative E: Sanitary/Storm Sewer Separation

Sewer separation is defined as the division of an existing combined sewer system into non-interconnected sanitary and storm sewer systems. Theoretically, complete sewer separation is the only measure which can completely eliminate combined sewer overflows. There are several major disadvantages involved in separating the two systems:

VOL 12

8374



Location of Deep Tunnel Construction Duck Creek Drainage Area	Figure 9

VOL 12

8375

- Stormwater runoff from heavily urbanized areas often becomes contaminated by excrement from domestic animals and by illegal sanitary cross-connections to the storm drain system. CSO discharges also contain a substantial amount of so-called floatable pollutants, such as oils from motor vehicles, paper, and other debris from roadways and parking areas, which are flushed into the system during the early stages of a storm event. When sanitary and storm sewer systems are combined, a portion of these "first-flush" pollutants in the stormwater runoff can be captured by the interceptor and treated at the WWTP. However, when the sewers are separated, these first-flush pollutants are not captured and treated: all runoff is discharged into the receiving water.
- Separation of all or portions of the system would result in substantial construction-related problems. Separation of the service connections from buildings in combined sewer areas would require modifications to existing structural plumbing, which is generally very difficult and often entails extensive renovation. Full-separation projects directly affect large numbers of people due to the need to excavate in virtually every street having a combined sewer, resulting in high costs, extensive time requirements, and disruptions to both traffic and utilities.

Because of these major disadvantages, system-wide sewer separation was not considered to be a viable alternative for CSO control in the Duck Creek Drainage Area. Sewer separation is viable in those locations where the area tributary to a regulator is small (less than 20 acres or 8.1 hectares) and/or where providing other control measures is not cost-effective.

IMMEDIATE-ACTION PLAN

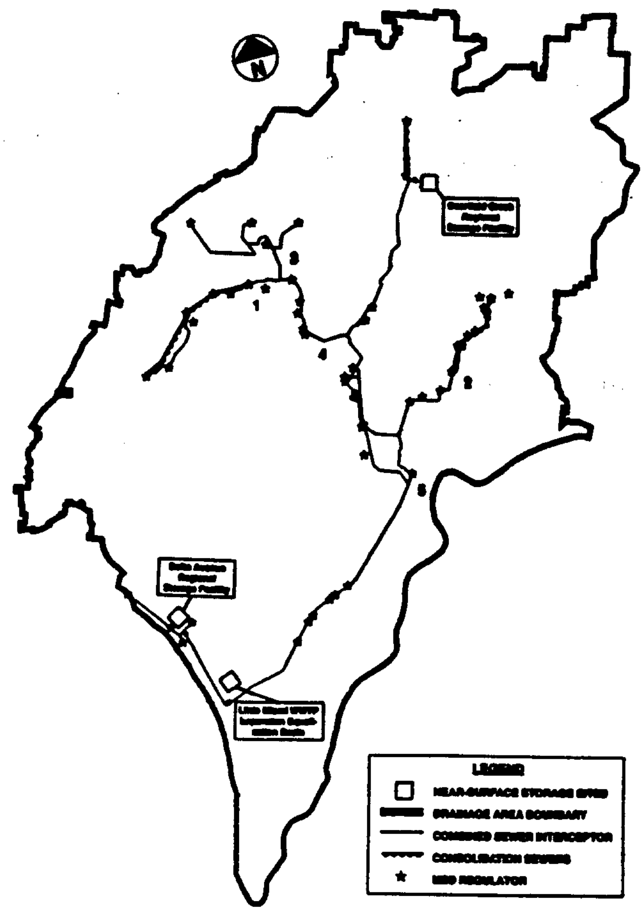
Figure 10 presents a graphic summary of short-term alternatives for CSO control involving facilities which meet a clear, immediate need and are common to several of the alternative control plans. These facilities also play an integral part in long-term CSO management. Important considerations about these facilities include the following:

- A 20-mgd (0.9 m^3) expansion of the Little Miami WWTP (or construction of a new plant elsewhere) is recommended to meet projected increases in dry-weather wastewater flows. Implementation of the 20-mgd (0.9 m^3) expansion will prevent CSOs from increasing as development occurs. In order to meet design goals for other CSO-control facilities, additional treatment capacity at the WWTP is required. Therefore, a total increase in treatment capacity of 34 mgd (1.5 m^3/s) is required for wet-weather flows captured under alternative CSO control plans designed to reduce CSOs to one per year. Without this capacity, storage facilities would not be emptied fast enough to capture flows in combined sewers from subsequent storms to meet the objectives of the long-term plan.
- The wet-weather conveyance capacity of the Little Miami interceptor can be increased by about 20 percent to 40 percent by raising the overflow elevations of three regulators. These modifications reduce total CSO pollution by about 2 percent but also divert about 7 percent of the remaining CSO pollution from the environmentally sensitive Little Miami River to the Ohio River.

VOL 12

8376

R0041682



Location of Elements Common to Recommended CSO Facilities Plans	Figure 10

- About 8,700 feet (2,650 m) of consolidation sewer should be installed along Deerfield and Little Duck Creeks. A regional storage facility can be placed at the outlet of the Deerfield Creek consolidation sewer to reduce overflows to one per year.
- Implementation of the Delta Avenue regional storage facility is recommended, sized to reduce overflows to between one per month and one per year.
- Either vortex separators or swirl concentrators will provide additional short-term control of CSOs, but have relatively short service lives and will likely require replacement under a long-term control plan. These facilities should be placed at the following locations, shown on Figure 10:
  - Outlets of proposed consolidation sewers (Norwood, shown as point 1, Little Duck Creek, shown as point 2)
  - At locations where CSO volumes are large (the outlet of the Kennedy Heights combined sewer into Yononte Creek, shown as point 3; the outlet of the Oakley relief sewer, shown as point 4; and the diversion at the junction of the Duck Creek, Little Duck Creek, and Little Miami interceptors, shown as point 5)

LONG-TERM PLAN

The long term CSO control measures presented under Alternatives A through E build upon the facilities which are recommended under the short-term plan. The ultimate decision of the alternative methodology selected for long-term CSO control depends on evolving technological, regulatory, and financial criteria.

An important element of the long-term plan is that no explicit level of control is defined, although the capability ultimately to control to one overflow per year is provided. The approach is first to build storage facilities to control overflows to twelve per year, then monitor the effectiveness of this level of control on improving receiving water quality. Where further improvement is required, additional facilities can be built using the Master Plan as a blueprint or guide. It is important to note that, under this plan, transport facilities such as consolidation conduits are sized for the ultimate level of control, *i.e.*, the one-year storm, so that these facilities do not have to be replaced if it is determined that CSOs must be reduced to fewer than twelve per year.

The deep tunnel plan, however, is not flexible in terms of level of control. It is an "all-or-nothing" proposition (meaning that a certain level of control must be committed to at the inception of the project) while other alternatives can be phased in over time (meaning that additional levels of control can be provided over time if they are needed).

SUMMARY

Combined sewers serve about half of the Duck Creek Drainage Area and collect both stormwater and wastewater. On average, each of these combined sewers overflows approximately 55-60 times each year, severely impacting the water quality of Duck Creek and its tributaries, which then carry this pollution into the Little Miami and Ohio Rivers.

The objective of the CSO master plan for the Duck Creek Drainage Area was to locate and quantify CSOs in the drainage area, to develop alternative schemes to

VOL 12

8378

alleviate them in the long term, and to propose short-term measures which will control, eliminate, or consolidate those CSOs having the greatest impact. Basic findings obtained as a result of this study can be summarized as follows:

- CSOs occur at the Delta Avenue pump station and the Little Miami WWTP over 60 times each year. These two facilities have the lowest wet-weather capacity in the drainage area.
- The Little Miami WWTP has a treatment capacity adequate for existing dry-weather flows but cannot handle the projected 20-mgd (0.9 m^3/s) increase in peak dry-weather flow or the additional wet-weather flows which the combined sewer interceptor is capable of conveying. To reduce overflows into the Ohio River, therefore, a 54-mgd (2.4 m^3/s) expansion of the plant's wet-weather treatment facilities is required, along with a 13-mg (0.6 m^3/s) equalization basin.
- Annually, about 55 CSOs are caused by insufficient wet-weather capacity in the gravity-combined sewer interceptor as a whole, with this capacity generally decreasing as flows move downstream in the interceptor. In certain watersheds within the drainage area, between 25 and 60 CSOs per year result from this inadequate interceptor capacity.
- CSOs also occur due to insufficient regulator capacity, although, in general, regulators can convey more wet-weather flow to the gravity-combined sewer interceptor than the interceptor can accept.
- Schemes to optimize the performance of the combined sewer interceptor will only cost about $50,000, but they do not significantly increase the wet-weather interceptor capacity except in the Little Miami interceptor, where wet-weather interceptor capacity increases by about 20% to 40% but CSOs are only reduced by about 2%. Since optimization of the interceptor performance will increase flows to the Little Miami WWTP, additional overflows to the Ohio River will occur unless interceptor optimization is accompanied by the construction of additional storage/treatment facilities at the plant.
- Over 400 distributed storage facilities with a volume of 0.5 million gallons (1,900 m^3) are required within the Duck Creek Drainage Area to reduce CSOs to one per year. Construction of these facilities would disrupt many neighborhoods, and the facilities themselves, once operational, are likely to cause odor problems. Unit capital and O & M costs are significantly higher than for other storage alternatives since virtually no economies of scale are present. The total capital cost required to implement Alternative B, which is based on wide-scale use of distributed storage facilities, is about $431.5 million.
- Alternative C, regional storage/treatment facilities, concentrates the storage required to control CSOs to ten strategically-located facilities within the drainage area. These regional facilities involve about the same amount of storage as is required under Alternative B but are large enough to achieve significant economies of scale. Three consolidation sewers are also required under this alternative in order to convey combined sewerage to the strategic sites.
- Storage requirements for CSO control can also be provided by a deep hard-rock tunnel. In Duck Creek, two segments of 36-foot diameter tunnel are required: The tunnel would be drained with a 54-mgd (2.4 m^3/s) pump

8379

station located at the junction of the Duck Creek/Little Duck Creek/Little Miami Interceptors.

- Separation of all combined sewers in the Duck Creek Drainage Area would eliminate all CSOs but would cause severe disruptions to the community during implementation, would not provide treatment for any stormwater runoff as is now being provided by the existing combined sewer system, and would likely result in a separate sewer system with high levels of inflow/infiltration, many cross-connections, and numerous illicit connections. Therefore, separation is not recommended unless other methods are not cost-effective.
- Short-term alternatives for CSO control and adequate wastewater conveyance and treatment involve facilities which meet a clear, immediate need and which are common to several of the alternative control plans. Facilities which are recommended for implementation during the next twenty years will also play an integral part in long-term wastewater/CSO management. Installing vortex separators or swirl concentrators will provide further short-term control of CSOs, but such facilities have relatively short service lives and will likely require replacement under a long-term control plan.

SWEDISH TRENDS IN CSO PLANNING AND CONTROL

Johan Larsson[1] and Jan Falk[2]

Introduction

Urban drainage is a conservative business where trends and policies are not easily established or abandoned. Seen in a 50-year perspective, one can observe that every major shift in Sweden is preceeded by a decade of discussion and a decade of transition. When consensus among engineers is finally reached, it seems to be the starting point for a re-evaluation by a new generation of engineers.

In this paper, we will describe Swedish sewer system policies in a 50-year perspective, focusing on the transition to a new policy during the 1980's. In many respects, these policy changes have been parallel with international trends. Of special interest, however, is the persistent and in the 1970's even mandatory policy of separating all existing combined sewer systems.

Key figures for the Swedish severage system are:

Population	8.5 million
Urban population	7.3 million
Water production for municipal use	975 million m³
Sewers, total length	80,500 km

[1] VBB Consulting Ltd, Box 5038, S-102 41 STOCKHOLM, Sweden

[2] Swedish Water and Waste Water Works Association, Regeringsgatan 86, S-111 39 STOCKHOLM, Sweden

Total value of the sewerage system	100 billion SEK
Annual costs of operation and maintenance	3 billion SEK
Annual investments	1.3 billion SEK
Per cent of severed areas which are combined	25
Average price for drinking water incl. sewage services	10 SEK per m³

The period 1940-1970

In the early 1940's there was a consensus among Swedish engineers of the merits of the combined sewer system, as illustrated by a quotation from an official study in 1941 (Bäckman, 1984):
