TABLE 23. PRECISION OF POINT ESTIMATES FOR VARIOUS SAMPLE TYPES[1]

Test Endpoint	Sample Type	CV (%)[2]		
		Within-lab[3]	Between-lab[4]	Total[5]
IC25	Reference toxicant	22.0	29.1	36.4
	Effluent	7.24	55.5	56.0
	Receiving water	-	-	39.1
	Average	14.6	42.3	43.8

1 From EPA's WET Interlaboratory Variability Study (USEPA, 2001a; USEPA, 2001b).

2 CVs were calculated based on the within-laboratory component of variability, the between-laboratory component of variability, and the total interlaboratory variability (including both within-laboratory and between-laboratory components). For the receiving water sample type, within-laboratory and between-laboratory components of variability could not be calculated since the study design did not provide within-laboratory replication for this sample type.

3 The within-laboratory (intralaboratory) component of variability for duplicate samples tested at the same time in the same laboratory.

4 The between-laboratory component of variability for duplicate samples tested at different laboratories.

5 The total interlaboratory variability, including within-laboratory and between-laboratory components of variability. The total interlaboratory variability is synonymous with interlaboratory variability reported from other studies where individual variability components are not separated.

TABLE 24. FREQUENCY DISTRIBUTION OF HYPOTHESIS TESTING RESULTS FOR VARIOUS SAMPLE TYPES[1]

Test Endpoint	Sample Type	Median NOEC Value	% of Results at the Median	% of Results ±1[2]	% of Results ≥2[3]
Survival NOEC	Reference toxicant	12.5%	72.7	18.2	9.09
	Effluent	25%	38.5	46.1	15.4
	Receiving water	25%	57.1	28.6	14.3
Growth NOEC	Reference toxicant	12.5%	72.7	18.2	9.09
	Effluent	25%	41.7	50.0	8.33
	Receiving water	25%	57.1	28.6	14.3

[1] From EPA's WET Interlaboratory Variability Study (USEPA, 2001a; USEPA, 2001b).
[2] Percent of values at one concentration interval above or below the median. Adding this percentage to the percent of values at the median yields the percent of values within one concentration interval of the median.
[3] Percent of values two or more concentration intervals above or below the median.

SECTION 14
TEST METHOD

MYSID, *MYSIDOPSIS BAHIA*, SURVIVAL, GROWTH, AND FECUNDITY TEST METHOD 1007.0

14.1 SCOPE AND APPLICATION

14.1.1 This method, adapted in part from USEPA (1987d), estimates the chronic toxicity of effluents and receiving waters to the mysid, *Mysidopsis bahia*, during a seven-day, static renewal exposure. The effects include the synergistic, antagonistic, and additive effects of all the chemical, physical, and additive components which adversely affect the physiological and biochemical functions of the test organisms.

14.1.2 Daily observations on mortality make it possible to also calculate acute toxicity for desired exposure periods (i.e., 24-h, 48-h, 96-h LC50s).

14.1.3 Detection limits of the toxicity of an effluent or pure substance are organism dependent.

14.1.4 Brief excursions in toxicity may not be detected using 24-h composite samples. Also, because of the long sample collection period involved in composite sampling and because the test chambers are not sealed, highly volatile and highly degradable toxicants present in the source may not be detected in the test.

14.1.5 This test is commonly used in one of two forms: (1) a definitive test, consisting of a minimum of five effluent concentrations and a control, and (2) a receiving water test(s), consisting of one or more receiving water concentrations and a control.

14.2 SUMMARY OF METHOD

14.2.1 *Mysidopsis bahia* 7-day old juveniles are exposed to different concentrations of effluent, or to receiving water in a static system, during the period of egg development. The test endpoints are survival, growth (measured as dry weight), and fecundity (measured as the percentage of females with eggs in the oviduct and/or brood pouch).

14.3 INTERFERENCES

14.3.1 Toxic substances may be introduced by contaminants in dilution water, glassware, sample hardware, and testing equipment (see Section 5, Facilities, Equipment, and Supplies).

14.3.2 Improper effluent sampling and handling may adversely affect test results (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

14.3.3 The test results can be confounded by (1) the presence of pathogenic and/or predatory organisms in the dilution water, effluent, and receiving water, (2) the condition of the brood stock from which the test animals were taken, (3) the amount and type of natural food in the effluent, receiving water, or dilution water, (4) nutritional value of the brine shrimp, *Artemia* nauplii, fed during the test, and (5) the quantity of brine shrimp, *Artemia* nauplii, or other food added during the test, which may sequester metals and other toxic substances, and lower the DO.

14.3.4 pH drift during the test may contribute to artifactual toxicity when ammonia or other pH-dependent toxicants (such as metals) are present. As pH increases, the toxicity of ammonia also increases (see Subsection 8.8.6), so upward pH drift may increase sample toxicity. For metals, toxicity may increase or decrease with increasing pH. Lead and copper were found to be more acutely toxic at pH 6.5 than at pH 8.0 or 8.5, while nickel and zinc were more toxic at pH 8.5 than at pH 6.5 (USEPA, 1992). In situations where sample toxicity is confirmed

to be artifactual and due to pH drift (as determined by parallel testing as described in Subsection 14.3.4.1), the regulatory authority may allow for control of sample pH during testing using procedures outlined in Subsection 14.3.4.2. It should be noted that artifactual toxicity due to pH drift is not likely to occur unless pH drift is large (more than 1 pH unit) and/or the concentration of some pH-dependent toxicant in the sample is near the threshold for toxicity.

14.3.4.1 To confirm that toxicity is artifactual and due to pH drift, parallel tests must be conducted, one with controlled pH and one with uncontrolled pH. In the uncontrolled-pH treatment, the pH is allowed to drift during the test. In the controlled-pH treatment, the pH is maintained using the procedures described in Subsection 14.3.4.2. The pH to be maintained in the controlled-pH treatment (or target pH) will depend on the objective of the test. If the objective of the WET test is to determine the toxicity of the effluent in the receiving water, the pH should be maintained at the pH of the receiving water (measured at the edge of the regulatory mixing zone). If the objective of the WET test is to determine the absolute toxicity of the effluent, the pH should be maintained at the pH of the sample after adjusting the sample salinity for use in marine testing.

14.3.4.1.1 During parallel testing, the pH must be measured in each treatment at the beginning (i.e., initial pH) and end (i.e., final pH) of each 24-h exposure period. For each treatment, the mean initial pH (e.g., averaging the initial pH measured each day for a given treatment) and the mean final pH (e.g., averaging the final pH measured each day for a given treatment) must be reported. pH measurements taken during the test must confirm that pH was effectively maintained at the target pH in the controlled-pH treatment. For each treatment, the mean initial pH and the mean final pH should be within ± 0.3 pH units of the target pH. Test procedures for conducting toxicity identification evaluations (TIEs) also recommend maintaining pH within ± 0.3 pH units in pH-controlled tests (USEPA, 1996).

14.3.4.1.2 Total ammonia also should be measured in each treatment at the outset of parallel testing. Total ammonia concentrations greater than 5 mg/L in the 100% effluent are an indicator that toxicity observed in the test may be due to ammonia (USEPA, 1992).

14.3.4.1.3 Results from both of the parallel tests (pH-controlled and uncontrolled treatments) must be reported to the regulatory authority. If the uncontrolled test meets test acceptability criteria and shows no toxicity at the permitted instream waste concentration, then the results from this test should be used for determining compliance. If the uncontrolled test shows toxicity at the permitted instream waste concentration, then the results from the pH-controlled test should be used for determining compliance, provided that this test meets test acceptability criteria and pH was properly controlled (see Subsection 14.3.4.1.1).

14.3.4.1.4 To confirm that toxicity observed in the uncontrolled test was artifactual and due to pH drift, the results of the controlled and uncontrolled-pH tests are compared. If toxicity is removed or reduced in the pH-controlled treatment, artifactual toxicity due to pH drift is confirmed for the sample. To demonstrate that a sample result of artifactual toxicity is representative of a given effluent, the regulatory authority may require additional information or additional parallel testing before pH control (as described in Subsection 14.3.4.2) is applied routinely to subsequent testing of the effluent.

14.3.4.2 The pH can be controlled with the addition of acids and bases and/or the use of a CO_2-controlled atmosphere over the test chambers. pH is adjusted with acids and bases by dropwise adding 1N NaOH or 1N HCl (see Subsection 8.8.9). The addition of acids and bases should be minimized to reduce the amount of additional ions (Na or Cl) added to the sample. pH is then controlled using the CO_2-controlled atmosphere technique. This may be accomplished by placing test solutions and test organisms in closed headspace test chambers, and then injecting a predetermined volume of CO_2 into the headspace of each test chamber (USEPA, 1991b; USEPA, 1992); or by placing test chambers in an atmosphere flushed with a predetermined mixture of CO_2 and air (USEPA, 1996). Prior experimentation will be needed to determine the appropriate CO_2/air ratio or the appropriate volume of CO_2 to inject. This volume will depend upon the sample pH, sample volume, container volume, and sample constituents. If more than 5% CO_2 is needed, adjust the solutions with acids (1N HCl) and then flush the headspace with no more than 5% CO_2 (USEPA, 1992). If the objective of the WET test is to determine the toxicity of the effluent in the

receiving water, atmospheric CO_2 in the test chambers is adjusted to maintain the test pH at the pH of the receiving water (measured at the edge of the regulatory mixing zone). If the objective of the WET test is to determine the absolute toxicity of the effluent, atmospheric CO_2 in the test chambers is adjusted to maintain the test pH at the pH of the sample after adjusting the sample salinity for use in marine testing. USEPA (1996) and Mount and Mount (1992) provide techniques and guidance for controlling test pH using a CO_2-controlled atmosphere. In pH-controlled testing, control treatments must be subjected to all manipulations that sample treatments are subjected to. These manipulations must be shown to cause no lethal or sublethal effects on control organisms. In pH-controlled testing, the pH also must be measured in each treatment at the beginning and end of each 24-h exposure period to confirm that pH was effectively controlled at the target pH level.

14.4 SAFETY

14.4.1 See Section 3, Health and Safety.

14.5 APPARATUS AND EQUIPMENT

14.5.1 Facilities for holding and acclimating test organisms.

14.5.2 Brine shrimp, *Artemia*, culture unit -- see Subsection 14.6.12 below and Section 4, Quality Assurance.

14.5.3 Mysid, *Mysidopsis bahia*, culture unit -- see Subsection 14.13 below. This test requires a minimum of 240 7-day old (juvenile) mysids. It is preferable to obtain the test organisms from an in-house culture unit. If it is not feasible to culture mysids in-house, juveniles can be obtained from other sources, if shipped in well oxygenated saline water in insulated containers.

14.5.4 Samplers -- automatic sampler, preferably with sample cooling capability, that can collect a 24-h composite sample of 5 L.

14.5.5 Environmental chamber or equivalent facility with temperature control (26 ± 1°C).

14.5.6 Water purification system -- Millipore Milli-Q®, deionized water or equivalent.

14.5.7 Balance -- Analytical, capable of accurately weighing to 0.00001 g.

14.5.8 Reference weights, Class S -- for checking performance of balance. Weights should bracket the expected weights of the weighing pans and weighing pans plus organisms.

14.5.9 Drying oven -- 50-105°C range, for drying organisms.

14.5.10 Desiccator -- for holding dried organisms.

14.5.11 Air pump -- for oil-free air supply.

14.5.12 Air lines, and air stones -- for aerating cultures, brood chambers, and holding tanks, and supplying air to test solutions with low DO.

14.5.13 Meters, pH and DO -- for routine physical and chemical measurements.

14.5.14 Tray -- for test vessels; approximately 90 X 48 cm to hold 56 vessels.

14.5.15 Standard or micro-Winkler apparatus -- for determining DO and checking DO meters.

14.5.16 Dissecting microscope (350-400X magnification) -- for examining organisms in the test vessels to determine their sex and to check for the presence of eggs in the oviducts of the females.

14.5.17 Light box -- for illuminating organisms during examination.

14.5.18 Refractometer or other method -- for determining salinity.

14.5.19 Thermometers, glass or electronic, laboratory grade -- for measuring water temperatures.

14.5.20 Thermometers, bulb-thermograph or electronic-chart type -- for continuously recording temperature.

14.5.21 Thermometer, National Bureau of Standards Certified (see USEPA Method 170.1, USEPA, 1979b) -- to calibrate laboratory thermometers.

14.5.22 Test chambers -- 200 mL borosilicate glass beakers or non-toxic 8 oz disposable plastic cups or other similar containers. Forty-eight (48) test vessels are required for each test (eight replicates at each of five effluent concentrations and a control). To avoid potential contamination from the air and excessive evaporation of test solutions during the test, the chambers should be covered with safety glass plates or sheet plastic (6 mm thick).

14.5.23 Beakers or flasks -- six, borosilicate glass or non-toxic plasticware, 2000 mL for making test solutions.

14.5.24 Wash bottles -- for deionized water, for washing organisms from containers and for rinsing small glassware and instrument electrodes and probes.

14.5.25 Volumetric flasks and graduated cylinders -- Class A, borosilicate glass or non-toxic plastic labware, 50-2000 mL for making test solutions.

14.5.26 Separatory funnels, 2-L -- Two-four for culturing *Artemia*.

14.5.27 Pipets, volumetric -- Class A, 1-100 mL.

14.5.28 Pipets, automatic -- adjustable, 1-100 mL.

14.5.29 Pipets, serological -- 1-10 mL, graduated.

14.5.30 Pipet bulbs and fillers -- PROPIPET®, or equivalent.

14.5.31 Droppers, and glass tubing with fire polished edges, 4 mm ID -- for transferring organisms.

14.5.32 Forceps -- for transferring organisms to weighing pans.

14.5.33 NITEX® or stainless steel mesh sieves (≤150 µm, 500-1000 µm, 3-5 mm) -- for concentrating organisms.

14.5.34 Depression glass slides or depression spot plates -- two, for observing organisms.

14.6 REAGENTS AND CONSUMABLE MATERIALS

14.6.1 Sample containers -- for sample shipment and storage (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

14.6.2 Data sheets (one set per test) -- for data recording (Figures 2, 7, and 8).

14.6.3 Tape, colored -- for labeling test chambers.

14.6.4 Markers, waterproof -- for marking containers, etc.

14.6.5 Weighing pans, aluminum -- to determine the dry weight of organisms.

14.6.6 Buffers, pH 4, pH 7, and pH 10 (or as per instructions of instrument manufacturer) -- for standards and calibration check (see USEPA Method 150.1, USEPA, 1979b).

14.6.7 Membranes and filling solutions -- for dissolved oxygen probe (see USEPA Method 360.1, USEPA, 1979b), or reagents for modified Winkler analysis.

14.6.8 Laboratory quality assurance samples and standards -- for the above methods.

14.6.9 Reference toxicant solutions -- see Section 4, Quality Assurance.

14.6.10 Reagent water -- defined as distilled or deionized water that does not contain substances which are toxic to the test organisms (see Section 5, Facilities, Equipment, and Supplies).

14.6.11 Effluent, receiving water, and dilution water -- see Section 7, Dilution Water, and Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests. Dilution water containing organisms that might prey upon or otherwise interfere with the test organisms should be filtered through a fine mesh net (with 150 µm or smaller openings).

14.6.11.1 Saline test and dilution water -- The salinity of the test water must be in the range of 20‰ to 30‰. The salinity should vary by no more than ± 2‰ among the chambers on a given day. If effluent and receiving water tests are conducted concurrently, the salinities of these tests should be similar.

14.6.11.2 The overwhelming majority of industrial and sewage treatment effluents entering marine and estuarine systems contain little or no measurable salts. Exposure of mysids to these effluents will require adjustments in the salinity of the test solutions. It is important to maintain a constant salinity across all treatments. In addition, it may be desirable to match the test salinity with that of the receiving water. Two methods are available to adjust salinities – a hypersaline brine (HSB) derived from natural seawater or artificial sea salts.

14.6.11.3 HSB has several advantages that make it desirable for use in toxicity testing. It can be made from any high quality, filtered seawater by evaporation, and can be added to the effluent or to deionized water to increase the salinity. Brine derived from natural seawater contains the necessary trace metals, biogenic colloids, and some of the microbial components necessary for adequate growth, survival, and/or reproduction of marine and estuarine organisms, and may be stored for prolonged periods without any apparent degradation. However, if 100‰ HSB is used as a diluent, the maximum concentration of effluent that can be tested is 80% effluent at 30‰ salinity and 70% effluent at 30‰ salinity.

14.6.11.3.1 The ideal container for making brine from natural seawater is one that (1) has a high surface to volume ratio, (2) is made of a non-corrosive material, and (3) is easily cleaned (fiberglass containers are ideal). Special care should be used to prevent any toxic materials from coming in contact with the seawater being used to generate the brine. If a heater is immersed directly into the seawater, ensure that the heater materials do not corrode or leach any substances that would contaminate the brine. One successful method used is a thermostatically controlled heat exchanger made from fiberglass. If aeration is used, only oil-free air compressors should be used to prevent contamination.

14.6.11.3.2 Before adding seawater to the brine generator, thoroughly clean the generator, aeration supply tube, heater, and any other materials that will be in direct contact with the brine. A good quality biodegradable detergent should be used, followed by several (at least three) thorough deionized water rinses.

14.6.11.3.3 High quality (and preferably high salinity) seawater should be filtered to at least 10 µm before placing into the brine generator. Water should be collected on an incoming tide to minimize the possibility of contamination.

14.6.11.3.4 The temperature of the seawater is increased slowly to 40°C. The water should be aerated to prevent temperature stratification and to increase water evaporation. The brine should be checked daily (depending on the volume being enerated) to ensure that the salinity does not exceed 100‰ and that the temperature does not exceed 40°C. Additional seawater may be added to the brine to obtain the volume of brine required.

14.6.11.3.5 After the required salinity is attained, the HSB should be filtered a second time through a 1 mm filter and poured directly into portable containers (20-L cubitainers or polycarbonate water cooler jugs are suitable). The containers should be capped and labeled with the date the brine was generated and its salinity. Containers of HSB should be stored in the dark and maintained under room temperature until used.

14.6.11.3.6 If a source of HSB is available, test solutions can be made by following the directions below. Thoroughly mix together the deionized water and HSB before mixing in the effluent.

14.6.11.3.7 Divide the salinity of the HSB by the expected test salinity to determine the proportion of deionized water to brine. For example, if the salinity of the brine is 100‰ and the test is to be conducted at 20‰, 100‰ divided by 20‰ = 5.0. The proportion of brine is 1 part in 5 (one part brine to four parts deionized water). To make 1 L of seawater at 20‰ salinity from a HSB of 100‰, 200 mL of brine and 800 mL of deionized water are required.

14.6.11.3.8 Table 2 illustrates the composition of 1800 mL test solutions at 20‰ if they are made by combining effluent (0‰), deionized water and HSB of 100‰ (only). The volume (mL) of brine required is determined by using the amount calculated above. In this case, 200 mL of brine is required for 1 L; therefore, 360 mL would be required for 1.8 L of solution. The volumes of HSB required are constant. The volumes of deionized water are determined by subtracting the volumes of effluent and brine from the total volume of solution: 1800 mL - mL effluent - mL brine = mL deionized water.

14.6.11.4 Artificial sea salts: FORTY FATHOMS® brand sea salts have been used successfully to culture and perform life cycle tests with mysids (Horne, et al., 1983; ASTM, 1993) (see Section 7, Dilution Water). HW MARINEMIX® sea salts have been used successfully to culture mysids and perform the mysid toxicity test (USEPA Region 6 Houston Laboratory; EMSL-Cincinnati). In addition, a slightly modified version of the GP2 medium (Spotte et al., 1984) has been successfully used to perform the mysid survival, growth, and fecundity test (Table 1).

14.6.11.4.1 Synthetic sea salts are packaged in plastic bags and mixed with deionized water or equivalent. The instructions on the package of sea salts should be followed carefully, and the salts should be mixed in a separate container -- not in the culture tank. The deionized water used in hydration should be in the temperature range of 21-26°C. Seawater made from artificial sea salts is conditioned (Spotte, 1973; Spotte, et al., 1984; Bower, 1983) before it is used for culturing or testing. After adding the water, place an airstone in the container, cover, and aerate the solution mildly for 24 h before use.

14.6.11.4.2 The GP2 reagent grade chemicals (Table 1) should be mixed with deionized (DI) water or its equivalent in a container other than the culture or testing tanks. The deionized water used for hydration should be between 21-26°C. The artificial seawater must be conditioned (aerated) for 24 h before use as the testing medium. If the solution is to be autoclaved, sodium bicarbonate is added after the solution has cooled. A stock solution of sodium bicarbonate is made up by dissolving 33.6 g $NaHCO_3$ in 500 mL of deionized water. Add 2.5 mL of this stock solution for each liter of the GP2 artificial seawater.

TABLE 1. REAGENT GRADE CHEMICALS USED IN THE PREPARATION OF GP2 ARTIFICIAL SEAWATER FOR THE MYSID, *MYSIDOPSIS BAHIA*, TOXICITY TEST[1,2,3]

Compound	Concentration (g/L)	Amount (g) Required for 20L
NaCl	21.03	420.6
Na_2SO_4	3.52	70.4
Kcl	0.61	12.2
KBr	0.088	1.76

[1] Modified GP2 from Spotte et al. (1984).
[2] The constituent salts and concentrations were taken from USEPA (1990b). The salinity is 30.89 g/L.
[3] GP2 can be diluted with deionized (DI) water to the desired test salinity.

14.6.12 BRINE SHRIMP, *ARTEMIA*, NAUPLII -- for feeding cultures and test organisms.

14.6.12.1 Newly hatched *Artemia* nauplii are used for food for the stock cultures and test organisms. Although there are many commercial sources of brine shrimp cysts, the Brazilian or Colombian strains are preferred because the supplies examined have had low concentrations of chemical residues and produce nauplii of suitably small size.

TABLE 2. QUANTITIES OF EFFLUENT, DEIONIZED WATER, AND HYPERSALINE BRINE (100‰) NEEDED TO PREPARE 1800 ML VOLUMES OF TEST SOLUTION WITH A SALINITY OF 20‰

Effluent Concentration (%)	Volume of Effluent (0‰) (mL)	Volume of Deionized Water (mL)	Volume of Hypersaline Brine (mL)	Total Volume (mL)
80	1440	0	360	1800
40	720	720	360	1800
20	360	1080	360	1800
10	180	1260	360	1800
5	90	1350	360	1800
Control	0	1440	360	1800
Total	2790	5850	2160	10800

14.6.12.2 Each new batch of *Artemia* cysts must be evaluated for size (Vanhaecke and Sorgeloos, 1980, and Vanhaecke et al., 1980) and nutritional suitability (Leger, et al., 1985, Leger, et al., 1986) against known suitable reference cysts by performing a side-by-side larval growth test using the "new" and "reference" cysts. The "reference" cysts used in the suitability test may be a previously tested and acceptable batch of cysts. A sample of newly-hatched *Artemia* nauplii from each new batch of cysts should be chemically analyzed. The *Artemia* cysts should not be used if the concentration of total organic chlorine exceeds 0.15 µg/g wet weight or the total concentration of organochlorine pesticides plus PCBs exceeds 0.30 µg/g wet weight (For analytical methods see USEPA, 1982).

14.6.12.2.1 *Artemia* nauplii are obtained as follows:

1. Add 1 L of seawater, or an aqueous uniodized salt (NaCl) solution prepared with 35 g salt or artificial sea salts to 1 L of deionized water, to a 2-L separatory funnel, or equivalent.
2. Add 10 mL *Artemia* cysts to the separatory funnel and aerate for 24 h at 27°C. Hatching time varies with incubation temperature and the geographic strain of *Artemia* used (see USEPA, 1985a; USEPA, 2002a; ASTM, 1993).
3. After 24 h, cut off the air supply in the separatory funnel. *Artemia* nauplii are phototactic, and will concentrate at the bottom of the funnel if it is covered for 5-10 minutes. To prevent mortality, do not leave the concentrated nauplii at the bottom of the funnel more than 10 min without aeration.
4. Drain the nauplii into a beaker or funnel fitted with a 150 µm NITEX® or stainless steel screen, and rinse with seawater or equivalent before use.

14.6.12.3 Testing *Artemia* nauplii as food for toxicity test organisms.

14.6.12.3.1 The primary criteria for acceptability of each new supply of brine shrimp, cysts is adequate survival, growth, and reproduction of the mysids. The mysids used to evaluate the acceptability of the brine shrimp nauplii must be of the same geographical origin and stage of development (7 days old) as those used routinely in the toxicity tests. Sufficient data to detect differences in survival and growth should be obtained by using eight replicate test chambers, each containing 5 mysids, for each type of food.

14.6.12.3.2 The feeding rate and frequency, test vessels, volume of control water, duration of the test, and age of the *Artemia* nauplii at the start of the test, should be the same as used for the routine toxicity tests.

14.6.12.3.3 Results of the brine shrimp, *Artemia*, nauplii nutrition assay, where there are only two treatments, can be evaluated statistically by use of a t test. The "new" food is acceptable if there are no statistically significant differences in the survival, growth, and reproduction of the mysids fed the two sources of nauplii.

14.6.13 TEST ORGANISMS, *Mysidopsis bahia* (see Rodgers et al., 1986 and USEPA, 2002a for information on mysid ecology). The genus name of this organism was formally changed to *Americamysis* (Price *et al.*, 1994); however, the method manual will continue to refer to *Mysidopsis bahia* to maintain consistency with previous versions of the method.

14.6.13.1 Brood Stock

14.6.13.1.1 To provide an adequate supply of juveniles for a test, mysid, *Mysidopsis bahia*, cultures should be started at least four weeks before the test animals are needed. At least 200 mysids, *Mysidopsis bahia*, should be placed in each culture tank to ensure that 1500 to 2000 animals will be available by the time preparations for a test are initiated.

14.6.13.1.2 Mysids, *Mysidopsis bahia*, may be shipped or otherwise transported in polyethylene bottles or CUBITAINERS®. Place 50 animals in 700 mL of seawater in a 1-L shipping container. To control bacterial growth and prevent DO depletion during shipment, do not add food. Before closing the shipping container, oxygenate the water for 10 min. The mysids, *Mysidopsis bahia*, will starve if not fed within 36 h, therefore, they should be shipped so that they are not in transit more than 24 h.

14.6.13.1.3 The identification of the *Mysidopsis bahia* stock culture should be verified using the key from Heard (1982), Price (1978), Price, (1982), Stuck et al. (1979a), and Stuck et al. (1979b). Records of the verification should be retained along with a few of the preserved specimens.

14.6.13.1.4 Glass aquaria (120- to 200-L) are recommended for cultures. Other types of culture chambers may also be convenient. Three or more separate cultures should be maintained to protect against loss of the entire culture stock in case of accident, low DO, or high nitrite levels, and to provide sufficient numbers of juvenile mysids, *Mysidopsis bahia*, for toxicity tests. Fill the aquaria about three-fourths full of seawater. A flow-through system is recommended if sufficient natural seawater is available, but a closed, recirculating or static renewal system may be used if proper water conditioning is provided and care is exercised to keep the pH above 7.8 and nitrite levels below 0.05 mg/L.

14.6.13.1.5 Standard aquarium undergravel filters should be used with either the flow-through or recirculating system to provide aeration and a current conducive to feeding (Gentile et al., 1983). The undergravel filter is covered with a prewashed, coarse (2-5 mm) dolomite substrate, 2.5 cm deep for flow-through cultures or 10 cm deep for recirculating cultures.

14.6.13.1.6 The recirculating culture system is conditioned as follows:

1. After the dolomite has been added, the filter is attached to the air supply and operated for 24 h.
2. Approximately 4 L of seed water obtained from a successfully operating culture is added to the culture chamber.
3. The nitrite level is checked daily with an aquarium test kit or with EPA Method 354.1 (USEPA, 1979b).
4. Add about 30 mL of concentrated *Artemia* nauplii every other day until the nitrite level reaches at least 2.0 mg/L. The nitrite will continue to rise for several days without adding more *Artemia* nauplii and will then slowly decrease to less than 0.05 mg/L.

5. After the nitrite level falls below 0.05 mg/L, add another 30 mL of *Artemia* nauplii concentrate and check the nitrite concentration every day.
6. Continue this cycle until the addition of *Artemia* nauplii does not cause a rise in the nitrite concentration. The culture chamber is then conditioned and is ready to receive mysids.
7. Add only a few (5-20) mysids at first, to determine if conditions are favorable. If these mysids are still doing well after a week, several hundred more can be added.

14.6.13.1.7 It is important to add enough food to keep the adult animals from cannibalizing the young, but not so much that the DO is depleted or that there is a buildup of toxic concentrations of ammonia and nitrite. Just enough newly-hatched *Artemia* nauplii are fed twice a day so that each feeding is consumed before the next feeding.

14.6.13.1.8 Natural seawater is recommended as the culture medium, but HSB may be used to make up the culture water if natural seawater is not available. EMSL-Cincinnati has successfully used FORTY FATHOMS® artificial sea salts for culturing and toxicity tests of mysids, and USEPA, Region 6 has used HW MARINEMIX® artificial sea salts.

14.6.13.1.9 Mysids, *Mysidopsis bahia*, should be cultured at a temperature of 26 ± 1°C. No water temperature control equipment is needed if the ambient laboratory temperature remains in the recommended range, and if there are no frequent, rapid, large temperature excursions in the culture room.

14.6.13.1.10 The salinity should be maintained at 30 ± 2‰, or at a lower salinity (but not less than 20‰) if most of the tests will be conducted at a lower salinity.

14.6.13.1.11 Day/night cycles prevailing in most laboratories will provide adequate illumination for normal growth and reproduction. A 16-h/8-h day/night cycle in which the light is gradually increased and decreased to simulate dawn and dusk conditions, is recommended.

14.6.13.1.12 Mysid, *Mysidopsis bahia*, culture may suffer if DOs fall below 5 mg/L for extended periods. The undergravel filter will usually provide sufficient DO. If the DO drops below 5 mg/L at 25°C and 30‰, additional aeration should be provided. Measure the DO in the cultures daily the first week and then at least weekly thereafter.

14.6.13.1.13 Suspend a clear glass or plastic panel over the cultures, or use some other means of excluding dust and dirt, but leave enough space between the covers and culture tanks to allow circulation of air over the cultures.

14.6.13.1.14 If hydroids or worms appear in the cultures, remove the mysids and clean the chambers thoroughly, using soap and hot water. Rinse once with acid (10% HCl) and three times with distilled or deionized water. Mysids with attached hydroids should be discarded. Those without hydroids should be transferred by hand pipetting into three changes of clean seawater before returning them to the cleaned culture chamber. To guard against predators, natural seawater should be filtered through a net with 30 μm mesh openings before entering the culture vessels.

14.6.13.1.15 Mysids, *Mysidopsis bahia*, are very sensitive to low pH and sudden changes in temperature. Care should be taken to maintain the pH at 8.0 ± 0.3, and to limit rapid changes in water temperature to less than 3°C.

14.6.13.1.16 Mysids, *Mysidopsis bahia*, should be handled carefully and as little as possible so that they are not unnecessarily stressed or injured. They should be transferred between culture chambers with long handled cups with netted bottoms. Animals should be transferred to the test vessels with a large bore pipette (4-mm), taking care to release the animals under the surface of the water. Discard any mysids that are injured during handling.

14.6.13.1.17 Culture Maintenance (Also See USEPA, 2002a)

14.6.13.1.17.1 Cultures in closed, recirculating systems are fed twice a day. If no nauplii are present in the culture chamber after four hours, the amount of food should be increased slightly. In flow-through systems, excess food can be a problem by promoting bacterial growth and low dissolved oxygen.

14.6.13.1.17.2 Careful culture maintenance is essential. The organisms should not be allowed to become too crowded. The cultures should be cropped as often as necessary to maintain a density of about 20 mysids per liter. At this density, at least 70% of the females should have eggs in their brood pouch. If they do not, the cultures are probably under stress, and the cause should be found and corrected. If the cause cannot be found, it may be necessary to restart the cultures with a clean culture chamber, a new batch of culture water, and clean gravel.

14.6.13.1.17.3 In closed, recirculating systems, about one third of the culture water should be replaced with newly prepared seawater every week. Before siphoning the old media from the culture, it is recommended that the sides of the vessel be scraped and the gravel carefully turned over to prevent excessive buildup of algal growth. Twice a year the mysids should be removed from the recirculating cultures, the gravel rinsed in clean seawater, the sides of the chamber washed with clean seawater, and the gravel and animals returned to the culture vessel with newly conditioned seawater. No detergent should be used, and care should be taken not to rinse all the bacteria from the gravel.

14.6.13.2 Test Organisms

14.6.13.2.1 The test is begun with 7-day-old juveniles. To have the test animals available and acclimated to test conditions at the start of the test, gravid females must be obtained from the stock culture eight days in advance of the test. Whenever possible, brood stock should be obtained from cultures having similar salinity, temperature, light regime, etc., as are to be used in the toxicity test.

14.6.13.2.2 Eight days before the test is to start, sufficient gravid females are placed in brood chambers. Assuming that 240 juveniles are needed for each test, approximately half this number (120) of gravid females should be transferred to brood chambers. The mysids are removed from the culture tank with a net or netted cup and placed in 20-cm diameter finger bowls. The gravid females are transferred from the finger bowls to the brood chambers with a large-bore pipette or, alternatively, are transferred by pouring the contents of the finger bowls into the water in the brood chambers.

14.6.13.2.3 The mysid juveniles may be collected for the toxicity tests by transferring gravid females from the stock cultures to netted (1000 µm) flow-through containers (Figure 1) held within 4-L glass, wide-mouth separatory funnels. Newly released juveniles can pass through the netting, whereas the females are retained. The gravid females are fed newly hatched *Artemia* nauplii, and are held overnight to permit the release of young. The juvenile mysids are collected by opening the stopcock on the funnel and collecting them in another container from which they are transferred to holding tanks using a wide bore (4 mm ID) pipette. The brood chambers usually require aeration to maintain sufficient DO and to keep the food in suspension.

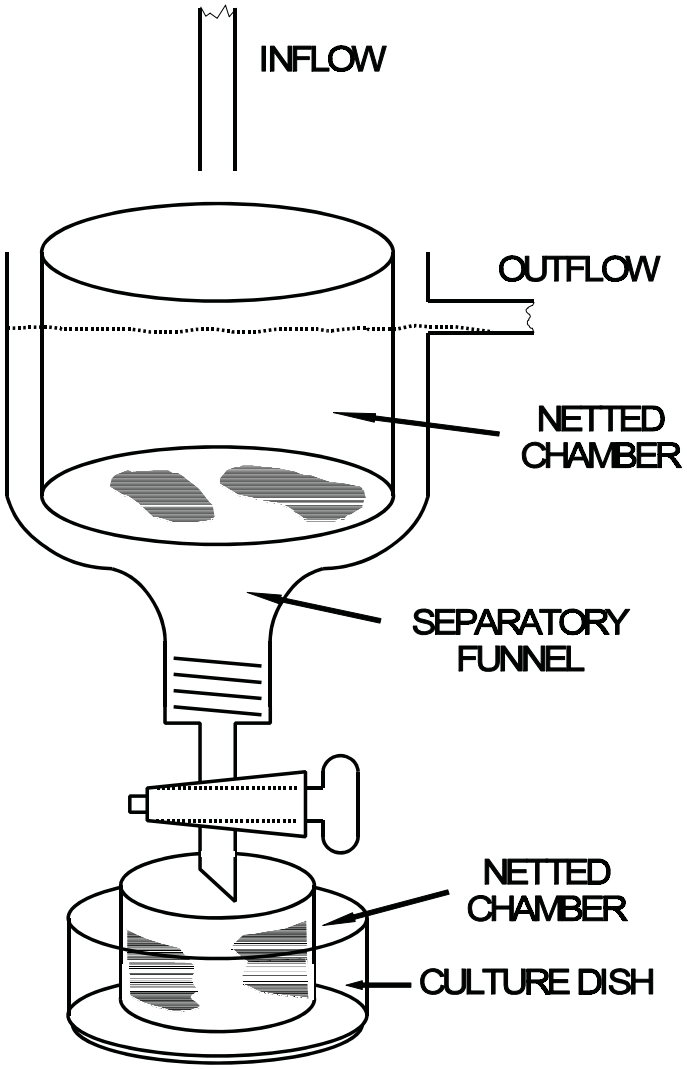

Figure 1. Apparatus (brood chamber) for collection of juvenile mysids, *Mysidopsis bahia*. From USEPA (1987d).

14.6.13.2.4 The temperature in the brood chamber should be maintained at the upper acceptable culture limit (26 - 27°C), or 1°C higher than the cultures, to encourage faster brood release. At this temperature, sufficient juveniles should be produced for the test.

14.6.13.2.5 The newly released juveniles (age = 0 days) are transferred to 20-L glass aquaria (holding vessels) which are gently aerated. Smaller holding vessels may be used, but the density of organisms should not exceed 10 mysids per liter. The test animals are held in the holding vessel for six days prior to initiation of the test. The holding medium is renewed every other day.

14.6.13.2.6 During the holding period, the mysids are acclimated to the salinity at which the test will be conducted, unless already at that salinity. The salinity should be changed no more than 2‰ per 24 h to minimize stress on the juveniles.

14.6.13.2.7 The temperature during the holding period is critical to mysid development, and must be maintained at 26 ± 1°C. If the temperature cannot be maintained in this range, it is advisable to hold the juveniles an additional day before beginning the test.

14.6.13.2.8 During the holding period, just enough newly-hatched *Artemia* nauplii are fed twice a day (a total of at least 150 nauplii per mysid per day) so that some food is constantly present.

14.6.13.2.9 If the test is to be performed in the field, the juvenile mysids, *Mysidopsis bahia*, should be gently siphoned into 1-L polyethylene wide-mouth jars with screw-cap lids filled two-thirds full with clean seawater from the holding tank. The water in these jars is aerated for 10 min, and the jars are capped and packed in insulated boxes for shipment to the test site. Food should not be added to the jars to prevent the development of excessive bacterial growth and a reduction in DO.

14.6.13.2.10 Upon arrival at the test site (in less than 24 h) the mysids, *Mysidopsis bahia*, are gently poured from the jars into 20-cm diameter glass culture dishes. The jars are rinsed with salt water to dislodge any mysids that may adhere to the sides. If the water appears milky, siphon off half of it with a netted funnel (to avoid siphoning the mysids) and replace with clean salt water of the same salinity and temperature. If no *Artemia* nauplii are present in the dishes, feed about 150 *Artemia* nauplii per mysid.

14.6.13.2.11 The pre-test holding conditions of test organisms (as well as the test conditions) have been shown to significantly influence the success of achieving the test acceptability criteria for the fecundity endpoint (egg production by 50% or more of control females). Temperature, feeding, and organism density are important factors in the rate of mysid development. Laboratories should optimize these factors (within the limits of the test procedure) during both the pre-test holding period and the testing period to encourage achieving the test acceptability criteria for the fecundity endpoint. If test organisms are purchased, the testing laboratory should also confer with the supplier to ensure that pre-test holding conditions are optimized to successfully achieve the fecundity endpoint. Lussier *et al.* (1999) found that by increasing holding temperature and test temperature from 26°C ± 1°C to 26°C - 27°C and maintaining holding densities to ≤10 organisms / L, the percentage of tests meeting the test acceptability criteria for fecundity increased from 60% to 97%. While the fecundity endpoint is an optional endpoint, it is often the most sensitive measure of toxicity, and the 7-d mysid test estimates the chronic toxicity of effluents most effectively when all three endpoints (survival, growth, and fecundity) are measured (Lussier *et al.* 1999).

14.7 EFFLUENT AND RECEIVING WATER COLLECTION, PRESERVATION, AND STORAGE

14.7.1 See Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests.

14.8 CALIBRATION AND STANDARDIZATION

14.8.1 See Section 4, Quality Assurance.

14.9 QUALITY CONTROL

14.9.1 See Section 4, Quality Assurance.

14.9.2 The reference toxicant recommended for use with the mysid 7-day test is copper sulfate or sodium dodecyl sulfate.

14.10 TEST PROCEDURES

14.10.1 TEST DESIGN

14.10.1.1 The test consists of at least five effluent concentrations plus a site water control and a reference water treatment (natural seawater or seawater made up from hypersaline brine, or equivalent).

14.10.1.2 Effluent concentrations are expressed as percent effluent.

14.10.1.3 Eight replicate test vessels, each containing 5 to 7 day old animals, are used per effluent concentration and control.

14.10.2 TEST SOLUTIONS

14.10.2.1 Receiving waters

14.10.2.1.1 The sampling point(s) is determined by the objectives of the test. At estuarine and marine sites, samples are usually collected at mid-depth. Receiving water toxicity is determined with samples used directly as collected or with samples passed through a 60 µm NITEX® filter and compared without dilution, against a control. Using eight replicate chambers per test, each containing 150 mL, and 400 mL for chemical analysis, would require approximately 1.6 L or more of sample per test per day.

14.10.2.2 Effluents

14.10.2.2.1 The selection of the effluent test concentrations should be based on the objectives of the study. A dilution factor of 0.5 is commonly used. A dilution factor of 0.5 provides precision of ± 100%, and testing of concentrations between 6.25% and 100% effluent using only five effluent concentrations (6.25%, 12.5%, 25%, 50%, and 100%). Test precision shows little improvement as dilution factors are increased beyond 0.5 and declines rapidly if smaller dilution factors are used. **Therefore, USEPA recommends the use of the ≥ 0.5 dilution factor.** If 100‰ HSB is used as a diluent, the maximum concentration of effluent that can be tested will be 80% at 20‰ and 70% at 30‰ salinity.

14.10.2.2.2 If the effluent is known or suspected to be highly toxic, a lower range of effluent concentrations should be used (such as 25%, 12.5%, 6.25%, 3.12%, and 1.56%). If high mortality is observed during the first 1-to-2 h of the test, additional dilutions at the lower range of effluent concentrations should be added.

14.10.2.2.3 The volume of effluent required for daily renewal of eight replicates per concentration for five concentrations of effluent and a control, each containing 150 mL of test solution, is approximately 1200 mL. Prepare enough test solution (approximately 1600 mL) at each effluent concentration to provide 400 mL additional volume for chemical analyses.

14.10.2.2.4 Just prior to test initiation (approximately 1 h), the temperature of a sufficient quantity of the sample to make the test solutions should be adjusted to the test temperature (26 ± 1°C) and maintained at that temperature during the addition of dilution water.

14.10.2.2.5 Higher effluent concentrations (i.e., 25%, 50%, and 100%) may require aeration to maintain adequate dissolved oxygen concentrations. However, if one solution is aerated, all concentrations must be aerated. Aerate effluent as it warms and continue to gently aerate test solutions in the test chambers for the duration of the test.

14.10.2.2.6 Effluent dilutions should be prepared for all replicates in each treatment in one flask to minimize variability among the replicates. The test chambers (cups) are labeled with the test concentration and replicate number. Dispense 150 mL of the appropriate effluent dilution to each test chamber.

14.10.2.3 Dilution Water

14.10.2.3.1 Dilution water may be uncontaminated natural seawater (receiving water), HSB prepared from natural seawater, or artificial seawater prepared from FORTY FATHOMS® or GP2 sea salts (see Table 1 and Section 7, Dilution Water). Other artificial sea salts may be used for culturing mysid and for the survival, growth, and fecundity test if the control criteria for acceptability of test data are satisfied.

14.10.3 START OF THE TEST

14.10.3.1 The test should begin as soon as possible, preferably within 24 h after sample collection. The maximum holding time following retrieval of the sample from the sampling device should not exceed 36 h for off-site toxicity tests unless permission is granted by the permitting authority. In no case should the test be started more than 72 h after sample collection (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

14.10.3.2 Begin the test by randomly placing five animals (one at a time) in each test cup of each treatment using a large bore (4 mm ID) pipette (see Appendix A for an example of randomization). It is easier to capture the animals if the volume of water in the dish is reduced and the dish is placed on a light table. It is recommended that the transfer pipette be rinsed frequently because mysids tend to adhere to the inside surface.

14.10.4 LIGHT, PHOTOPERIOD, SALINITY AND TEMPERATURE

14.10.4.1 The light quality and intensity under ambient laboratory conditions are generally adequate. Light intensity of 10-20 $\mu E/m^2/s$, or 50 to 100 foot candles (ft-c), with a photoperiod of 16 h light and 8 h darkness. It is critical that the test water temperature be maintained at 26 ± 1°C. It is recommended that the test water temperature be continuously recorded. The salinity should vary no more than ± 2‰ among chambers on a given day. If effluent and receiving water tests are conducted concurrently, the salinities of these tests should be similar.

14.10.4.1.1 If a water bath is used to maintain the test temperature, the water depth surrounding the test cups should be at least 2.5 cm deep.

14.10.4.1.2 Rooms or incubators with high volume ventilation should be used with caution because the volatilization of the test solutions and evaporation of dilution water may cause wide fluctuations in salinity. Covering the test cups with clear polyethylene plastic may help prevent volatilization and evaporation of the test solutions.

14.10.5 DISSOLVED OXYGEN (DO) CONCENTRATION

14.10.5.1 Aeration may affect the toxicity of effluents and should be used only as a last resort to maintain a satisfactory DO. The DO should be measured on new solutions at the start of the test (Day 0) and before daily renewal of test solutions on subsequent days. The DO should not fall below 4.0 mg/L (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests). If it is necessary to aerate, all treatments and the control should be aerated. The aeration rate should not exceed 100 bubbles/minute, using a pipet with a 1-2 mm orifice, such as a 1-mL KIMAX® serological pipet, or equivalent. Care should be taken to ensure that turbulence resulting from aeration does not cause undue stress on the mysid.

14.10.6 FEEDING

14.10.6.1 *Artemia* nauplii are prepared as described above.

14.10.6.2 During the test, the mysids in each test chamber should be fed *Artemia* nauplii, (less than 24-h old), at the rate of 150 nauplii per mysid per day. Adding the entire daily ration at a single feeding immediately after test solution renewal may result in a significant DO depression. Therefore, it is preferable to feed half of the daily

ration immediately after test solution renewal, and the second half 8 - 12 h later. Increase the feeding if the nauplii are consumed in less than 4 h. It is important that the nauplii be washed before introduction to the test chamber.

14.10.7 DAILY CLEANING OF TEST CHAMBERS

14.10.7.1 Before the daily renewal of test solutions, uneaten and dead *Artemia*, dead mysids and other debris are removed from the bottom of the test chambers with a pipette. As much of the uneaten *Artemia* as possible should be removed from each chamber to ensure that the mysids principally eat new hatched nauplii. By placing the test chambers on a light box, inadvertent removal of live mysids can be greatly reduced because they can be more easily seen. Any incidence of removal of live mysids from the test chambers during cleaning, and subsequent return to the chambers should be noted in the test records.

14.10.8 OBSERVATIONS DURING THE TEST

14.10.8.1 Routine Chemical and Physical Determinations

14.10.8.1.1 DO is measured at the beginning and end of each 24-h exposure period in one test chamber at each test concentration and in the control.

14.10.8.1.2 Temperature, pH, and salinity are measured at the end of each 24-h exposure period in one test chamber at each concentration and in the control. Temperature should also be monitored continuously observed and recorded daily for at least two locations in the environmental control system or the samples. Temperature should be measured in a sufficient number of test chambers at least at the end of the test to determine temperature variation in environmental chamber.

14.10.8.1.3 The pH is measured in the effluent sample each day before new test solutions are made.

14.10.8.2 Routine Biological Observations

14.10.8.2.1 The number of live mysids are counted and recorded each day when the test solutions are renewed (Figure 7). Dead animals and excess food should be removed with a pipette before test solutions are renewed.

14.10.8.2.2 Protect the mysids from unnecessary disturbance during the test by carrying out the daily test observations, solution renewals, and removal of the dead mysids, carefully. Make sure the mysids remain immersed during the performance of the above operations.

14.10.9 TEST SOLUTION RENEWAL

14.10.9.1 Before the daily renewal of test solutions, slowly pour off all but 10 mL of the old test medium into a 20 cm diameter culture dish on a light table. Be sure to check for animals that may have adhered to the sides of the test chamber. Rinse them back into the test cups. Add 150 mL of new test solution slowly to each cup. Check the culture dish for animals that may have been poured out with the old media, and return them to the test chamber.

14.10.10 TERMINATION OF THE TEST

14.10.10.1 After measuring the DO, pH, temperature, and salinity and recording survival, terminate the test by pouring off the test solution in all the cups to a one cm depth and refilling the cups with clean seawater. This will keep the animals alive, but not exposed to the toxicant, while waiting to be examined for sex and the presence of eggs.

14.10.10.2 The live animals must be examined for eggs and the sexes determined within 12 h of the termination of the test. If the test was conducted in the field, and the animals cannot be examined on site, the live animals should be shipped back to the laboratory for processing. Pour each replicate into a labeled 100 mL plastic screw capped

jar, and send to the laboratory immediately.

14.10.10.3 If the test was conducted in the laboratory, or when the test animals arrive in the laboratory from the field test site, the test organisms must be processed immediately while still alive as follows:

14.10.10.3.1 Examine each replicate under a stereomicroscope (240X) to determine the number of immature animals, the sex of the mature animals, and the presence or absence of eggs in the oviducts or brood sacs of the females (see Figures 3-6). This must be done while the mysids are alive because they turn opaque upon dying. This step should not be attempted by a person who has not had specialized training in the determination of sex and presence of eggs in the oviduct. NOTE: Adult females without eggs in the oviduct or brood sac look like immature mysids (see Figure 6).

Figure 2. Data form for the mysid, *Mysidopsis bahia*, water quality measurements. From USEPA (1987d).

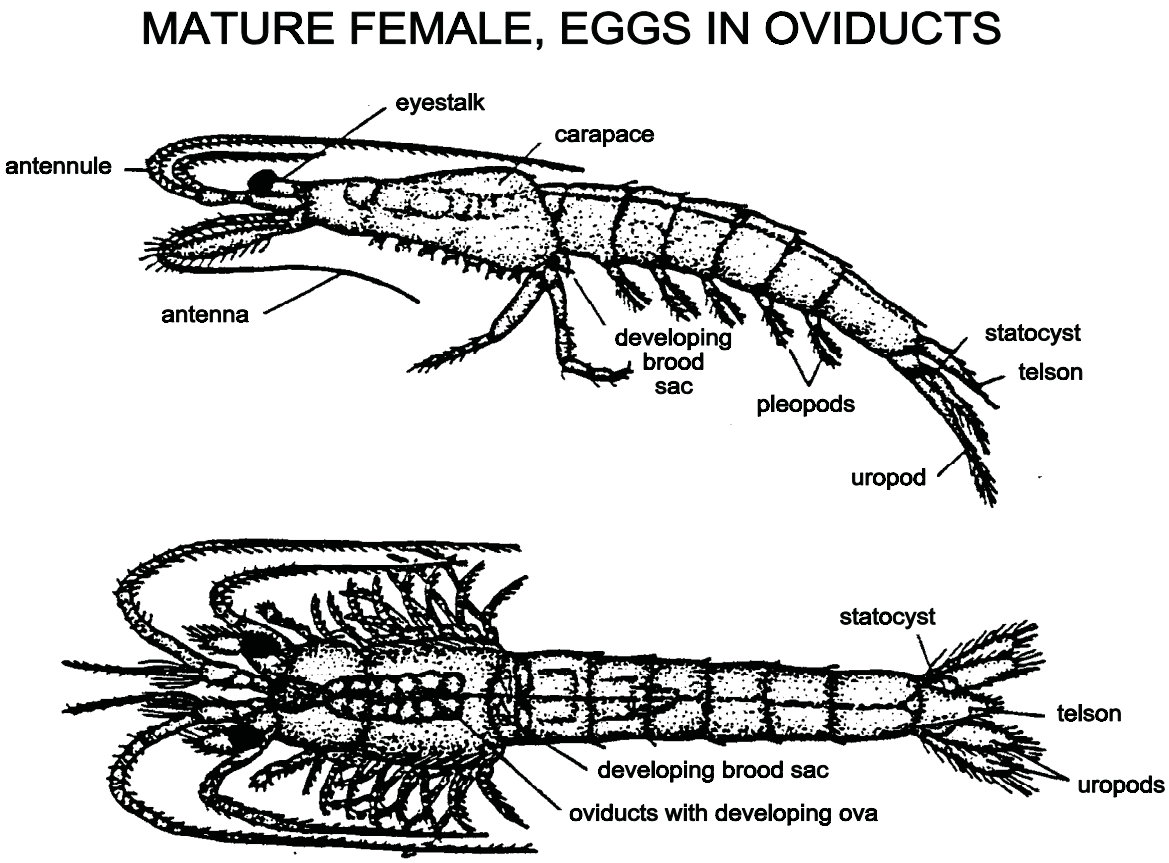

Figure 3. Mature female mysid, *Mysidopsis bahia*, with eggs in oviducts. From USEPA (1987d).

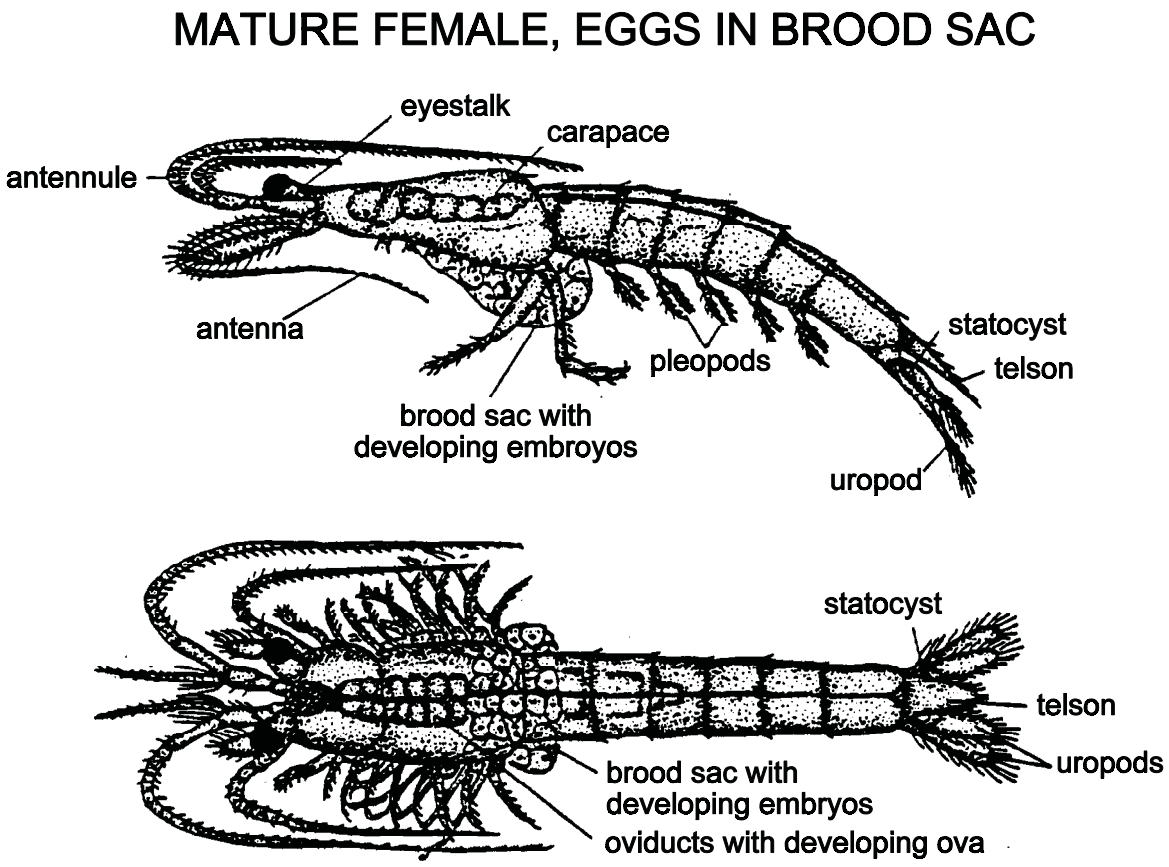

Figure 4. Mature female mysid, *Mysidopsis bahia*, with eggs in oviducts and developing embryos in the brood sac. Above: lateral view. Below: dorsal view. From USEPA (1987d).

14.10.10.3.2 Record the number of immatures, males, females with eggs and females without eggs on data sheets (Figure 7).

14.10.10.3.3 Rinse the mysids by pipetting them into a small netted cup and dipping the cup into a dish containing deionized water. Using forceps, place the mysids from each replicate cup on tared weighing boats and dry at 60°C for 24 h or at 105°C for at least 6 h.

14.10.10.3.4 Immediately upon removal from the drying oven, the weighing pans were placed in a dessicator until weighed, to prevent absorption of moisture from the air. Weigh to the nearest mg. Record weighing pans and subtract the tare weight to determine the dry weight of the mysid in each replicate. Record the weights (Figure 8). For each test chamber, divide the first dry weight by the number of original mysids per replicate to determine the average individual dry weight and record data. For the controls also calculate the mean weight per surviving mysid in the test chamber to evaluate if weights met test acceptability criteria (see Subsection 14.12).

14.10.9.3.5 Pieces of aluminum foil (1-cm square) or small aluminum weighing pans can be used for dry weight analyses. The weighing pans should not exceed 10 mg in weight.

14.10.9.3.6 Number each pan with a waterproof pen with the treatment concentration and replicate number. Forty-eight (48) weigh pans are required per test if all the organisms survive.

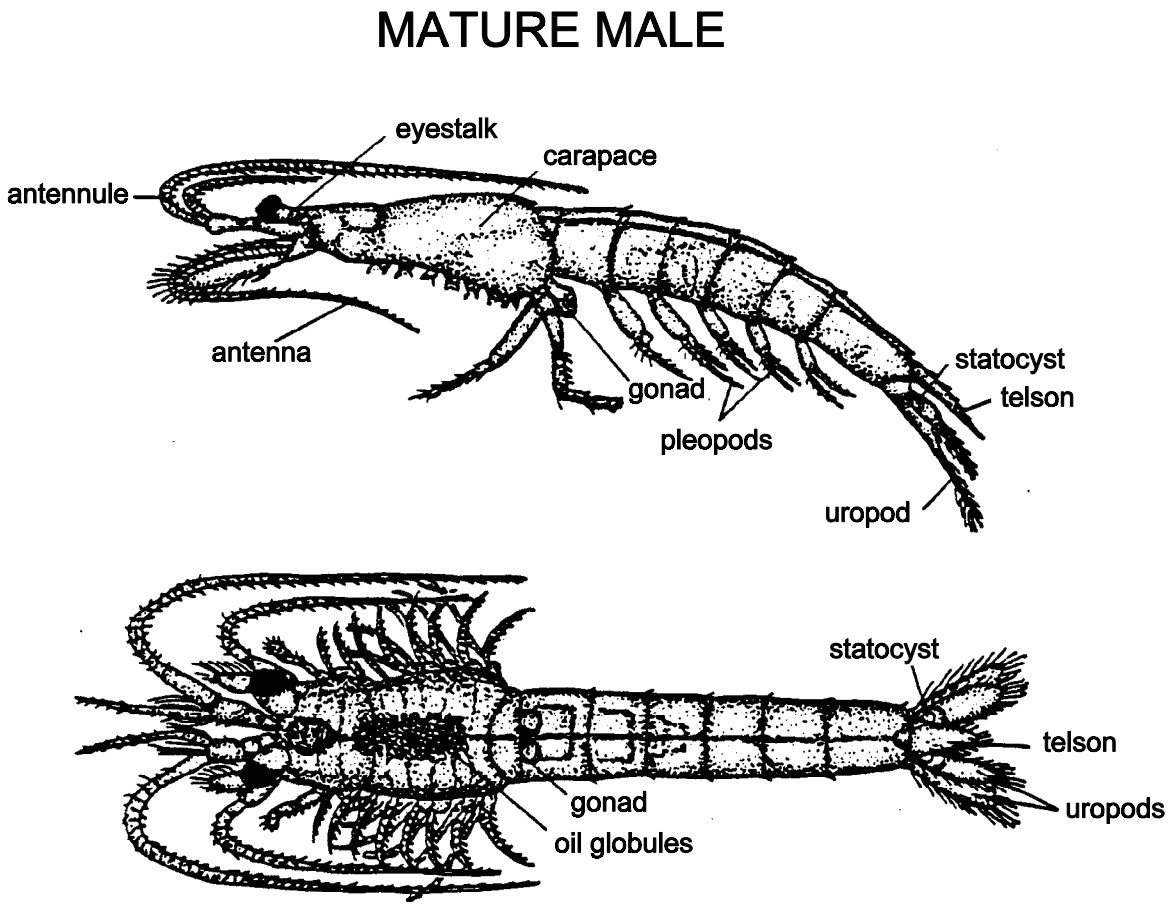

Figure 5. Mature male mysid, *Mysidopsis bahia*. From USEPA (1987d).

14.11 SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA

14.11.1 A summary of test conditions and test acceptability criteria is listed in Table 3.

14.12 ACCEPTABILITY OF TEST RESULTS

14.12.1 The minimum requirements for an acceptable test are 80% survival and an average weight of at least 0.20 mg/surviving mysid in the controls. If fecundity in the controls is adequate (egg production by 50% of females), fecundity should be used as a criterion of effect in addition to survival and growth.

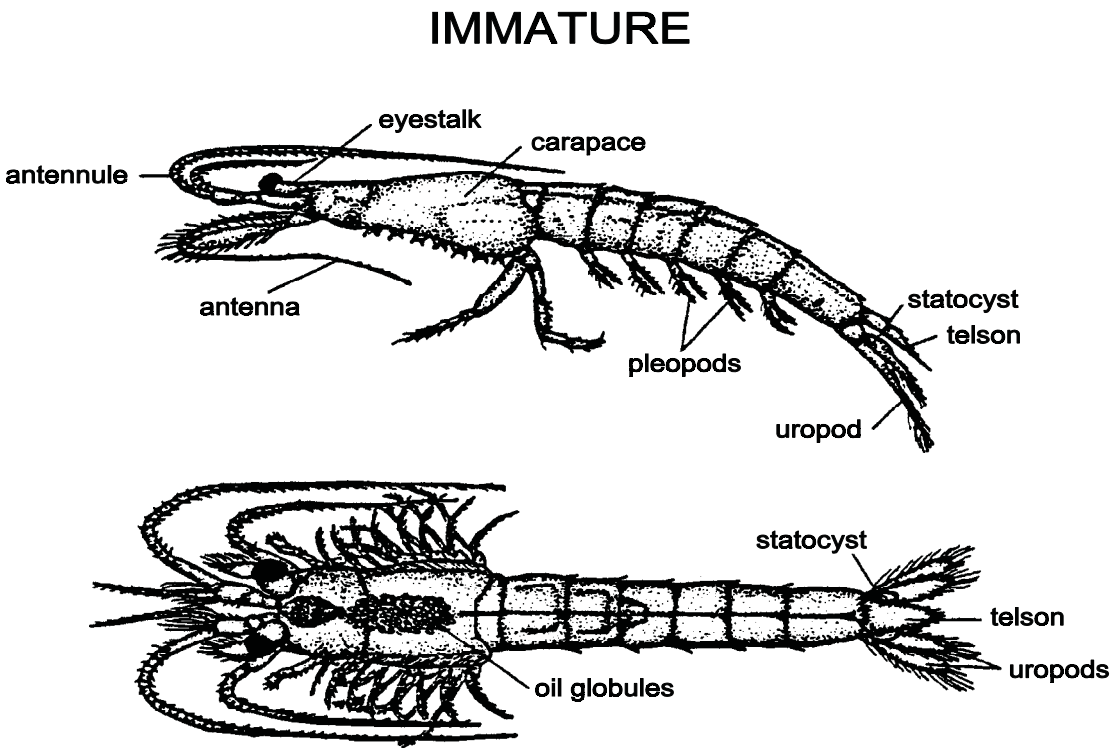

Figure 6. Immature mysid, *Mysidopsis bahia*, (A) lateral view, (B) dorsal view. From USEPA (1987d).

14.13 DATA ANALYSIS

14.13.1 GENERAL

14.13.1.1 Tabulate and summarize the data. Table 4 presents a sample set of survival, growth, and fecundity data.

14.13.1.2 The endpoints of the mysid 7-day chronic test are based on the adverse effects on survival, growth, and egg development. The LC50, the IC25, and the IC50 are calculated using point estimation techniques (see Section 9, Chronic Toxicity Test Endpoints and Data Analysis). LOEC and NOEC values for survival, growth, and fecundity are obtained using a hypothesis testing approach such as Dunnett's Procedure (Dunnett, 1955) or Steel's Many-one Rank Test (Steel, 1959; Miller, 1981) (see Section 9). Separate analyses are performed for the estimation of the LOEC and NOEC endpoints and for the estimation of the LC50, IC25, and IC50. Concentrations at which there is no survival in any of the test chambers are excluded from the statistical analysis of the NOEC and LOEC for survival, growth, and fecundity, but included in the estimation of the LC50, IC25, and IC50. See the Appendices for examples of the manual computations, and examples of data input and program output.

14.13.1.3 The statistical tests described here must be used with a knowledge of the assumptions upon which the tests are contingent. The assistance of a statistician is recommended for analysts who are not proficient in statistics.

TABLE 3. SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA FOR THE MYSID, *MYSIDOPSIS BAHIA*, SEVEN DAY SURVIVAL, GROWTH, AND FECUNDITY TEST WITH EFFLUENTS AND RECEIVING WATERS (TEST METHOD 1007.0)[1]

1.	Test type:	Static renewal (required)
2.	Salinity:	20‰ to 30‰ (± 2‰ of the selected test salinity) (recommended)
3.	Temperature:	26 ± 1°C (recommended) Test temperatures must not deviate (i.e., maximum minus minimum temperature) by more than 3°C during the test (required)
4.	Light quality:	Ambient laboratory illumination (recommended)
5.	Light intensity:	10-20 μE/m^2/s (50-100 ft-c.) (ambient laboratory levels) (recommended)
6.	Photoperiod:	16 h light, 8 h darkness, with phase in/out period (recommended)
7.	Test chamber:	8 oz plastic disposable cups, or 400 mL glass beakers (recommended)
8.	Test solution volume:	150 mL per replicate (recommended minimum)
9.	Renewal of test solutions:	Daily (required)
10.	Age of test organisms:	7 days (required)
11.	No. organisms per test chamber:	5 (required minimum)
12.	No. replicate chambers per concentration:	8 (required minimum)
13.	No. larvae per concentration:	40 (required minimum)
14.	Source of food:	Newly hatched *Artemia* nauplii (less than 24 h old)(required)
15.	Feeding regime:	Feed 150 24 h old nauplii per mysid daily, half after test solution renewal and half after 8-12 h (recommended)
16.	Cleaning:	Pipette excess food from cups daily immediately before test solution renewal and feeding (recommended)

[1] For the purposes of reviewing WET test data submitted under NPDES permits, each test condition listed above is identified as required or recommended (see Subsection 10.2 for more information on test review). Additional requirements may be provided in individual permits, such as specifying a given test condition where several options are given in the method.

TABLE 3. SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA FOR THE MYSID, *MYSIDOPSIS BAHIA*, SEVEN DAY SURVIVAL, GROWTH, AND FECUNDITY TEST WITH EFFLUENTS AND RECEIVING WATERS (TEST METHOD 1007.0) (CONTINUED)

17. Aeration:	None unless DO falls below 4.0 mg/L, then gently aerate in all cups (recommended)
18. Dilution water:	Uncontaminated source of natural seawater, deionized water mixed with hypersaline brine or artificial sea salts (HW MARINEMIX®, FORTY FATHOMS®, GP2 or equivalent) (available options)
19. Test concentrations:	Effluents: 5 and a control (required) Receiving waters: 100% receiving water (or minimum of 5) and a control (recommended)
20. Dilution factor:	Effluents: ≥ 0.5 series (required) Receiving waters: None, or ≥ 0.5 (recommended)
21. Test duration:	7 days (required)
22. Endpoints:	Survival and growth (required); and egg development (recommended)
23. Test acceptability criteria:	80% or greater survival, average dry weight 0.20 mg or greater in controls (required); fecundity may be used if 50% or more of females in controls produce eggs (required if fecundity endpoint used)
24. Sampling requirements:	For on-site tests, samples collected daily and used within 24 h of the time they are removed from the sampling device. For off-site tests, a minimum of three samples (e.g., collected on days one, three, and five) with a maximum holding time of 36 h before first use (see Section 8, Effluent and Receiving Water Sampling, Sample Handling and Sample Preparation for Toxicity Tests, Subsection 8.5.4) (required)
25. Sample volume required:	3 L per day (recommended)

14.13.2 EXAMPLE OF ANALYSIS OF MYSID, *MYSIDOPSIS BAHIA*, SURVIVAL DATA

14.13.2.1 Formal statistical analysis of the survival data is outlined in Figures 9 and 10. The response used in the analysis is the proportion of animals surviving in each test or control chamber. Separate analyses are performed for the estimation of the NOEC and LOEC endpoints and for the estimation of the LC50 endpoint. Concentrations at which there is no survival in any of the test chambers are excluded from statistical analysis of the NOEC and LOEC, but included in the estimation of the LC, EC, and IC endpoints.

14.13.2.2 For the case of equal numbers of replicates across all concentrations and the control, the evaluation of the NOEC and LOEC endpoints is made via a parametric test, Dunnett's Procedure, or a nonparametric test, Steel's Many-one Rank Test, on the arc sine square root transformed data. Underlying assumptions of Dunnett's Procedure, normality and homogeneity of variance, are formally tested. The test for normality is the Shapiro-Wilk's Test, and Bartlett's Test is used to test for homogeneity of variance. If either of these tests fails, the nonparametric test, Steel's Many-one Rank Test, is used to determine the NOEC and LOEC endpoints. If the assumptions of Dunnett's Procedure are met, the endpoints are estimated by the parametric procedure.

14.13.2.3 If unequal numbers of replicates occur among the concentration levels tested, there are parametric and nonparametric alternative analyses. The parametric analysis is a t-test with the Bonferroni adjustment (see Appendix D). The Wilcoxon Rank Sum Test with the Bonferroni adjustment is the nonparametric alternative.

14.13.2.4 Probit Analysis (Finney, 1971; see Appendix H) is used to estimate the concentration that causes a specified percent decrease in survival from the control. In this analysis, the total mortality data from all test replicates at a given concentration are combined. If the data do not fit the Probit model, the Spearman-Karber method, the Trimmed Spearman-Karber method, or the Graphical method may be used (see Appendices I-K).

14.13.2.5 The proportion of survival in each replicate must first be transformed by the arc sine transformation procedure described in Appendix B. The raw and transformed data, means and variances of the transformed observations at each concentration including the control are listed in Table 5. A plot of the survival data is provided in Figure 11.

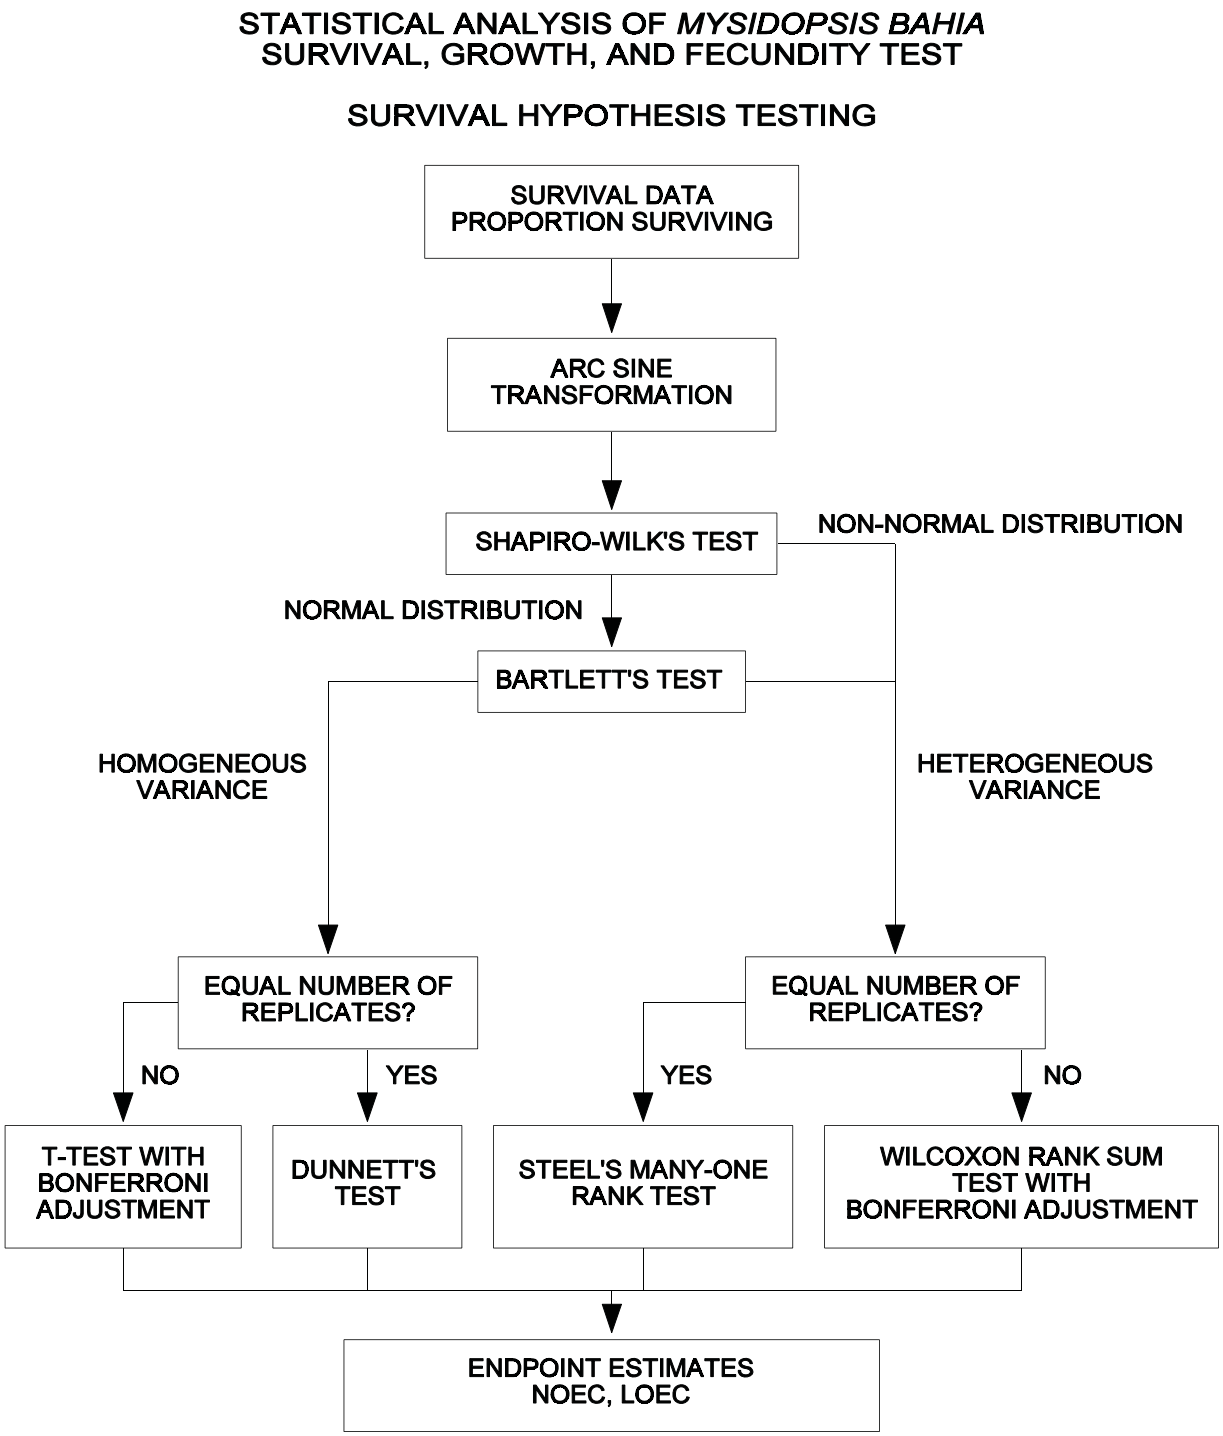

Figure 9. Flowchart for statistical analysis of mysid, *Mysidopsis bahia*, survival data by hypothesis testing.

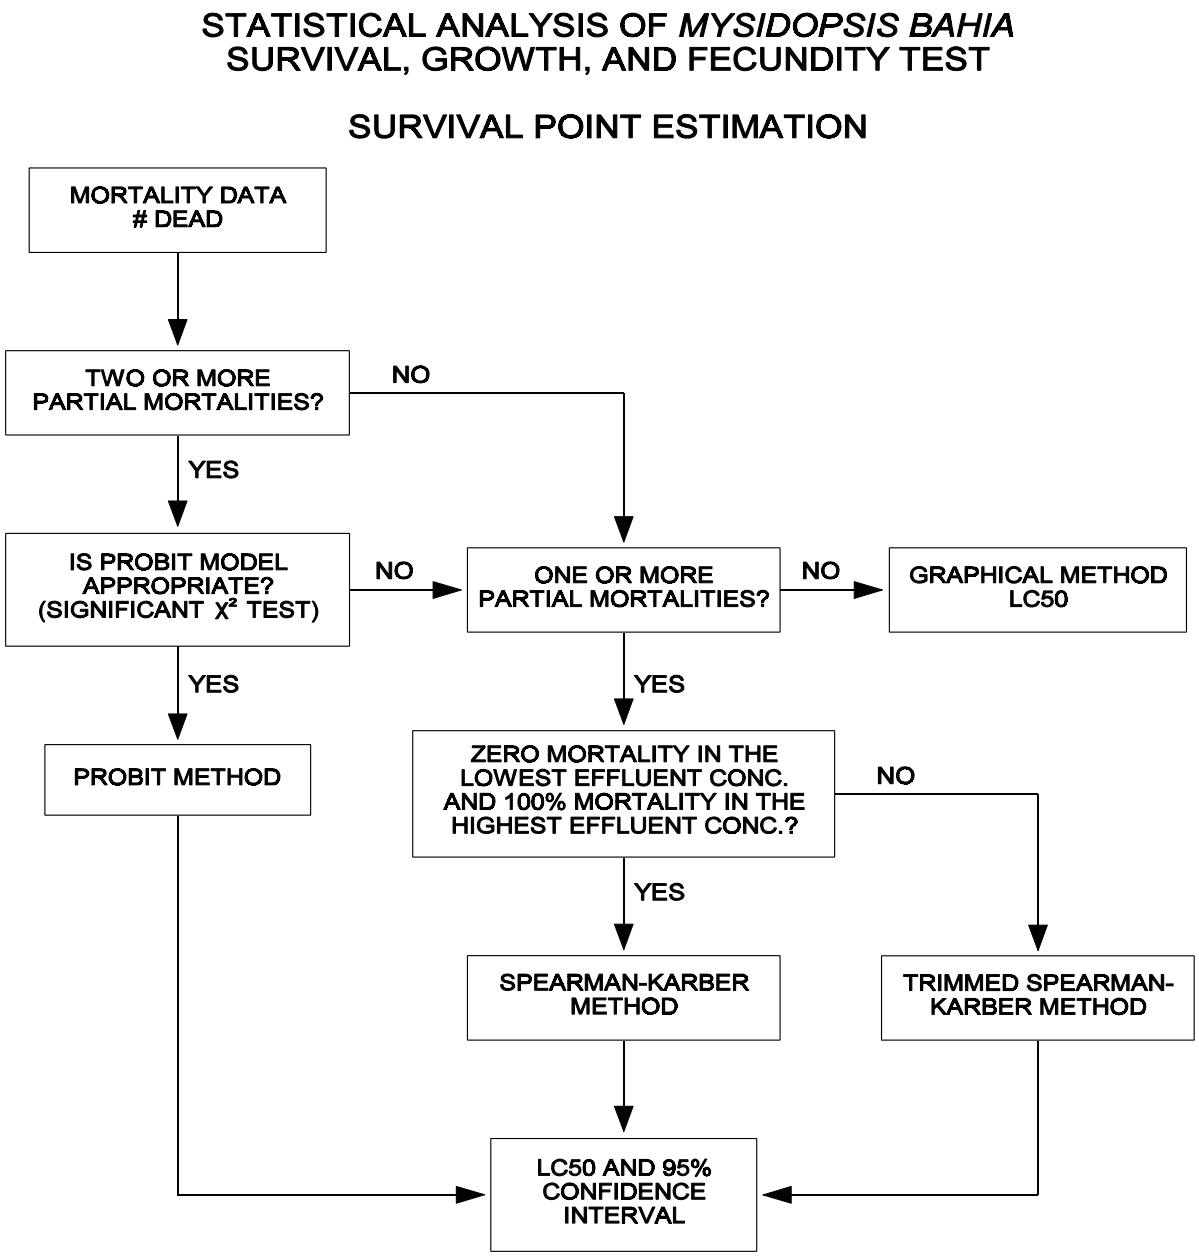

Figure 10. Flowchart for statistical analysis of mysid, *Mysidopsis bahia*, survival data by point estimation.

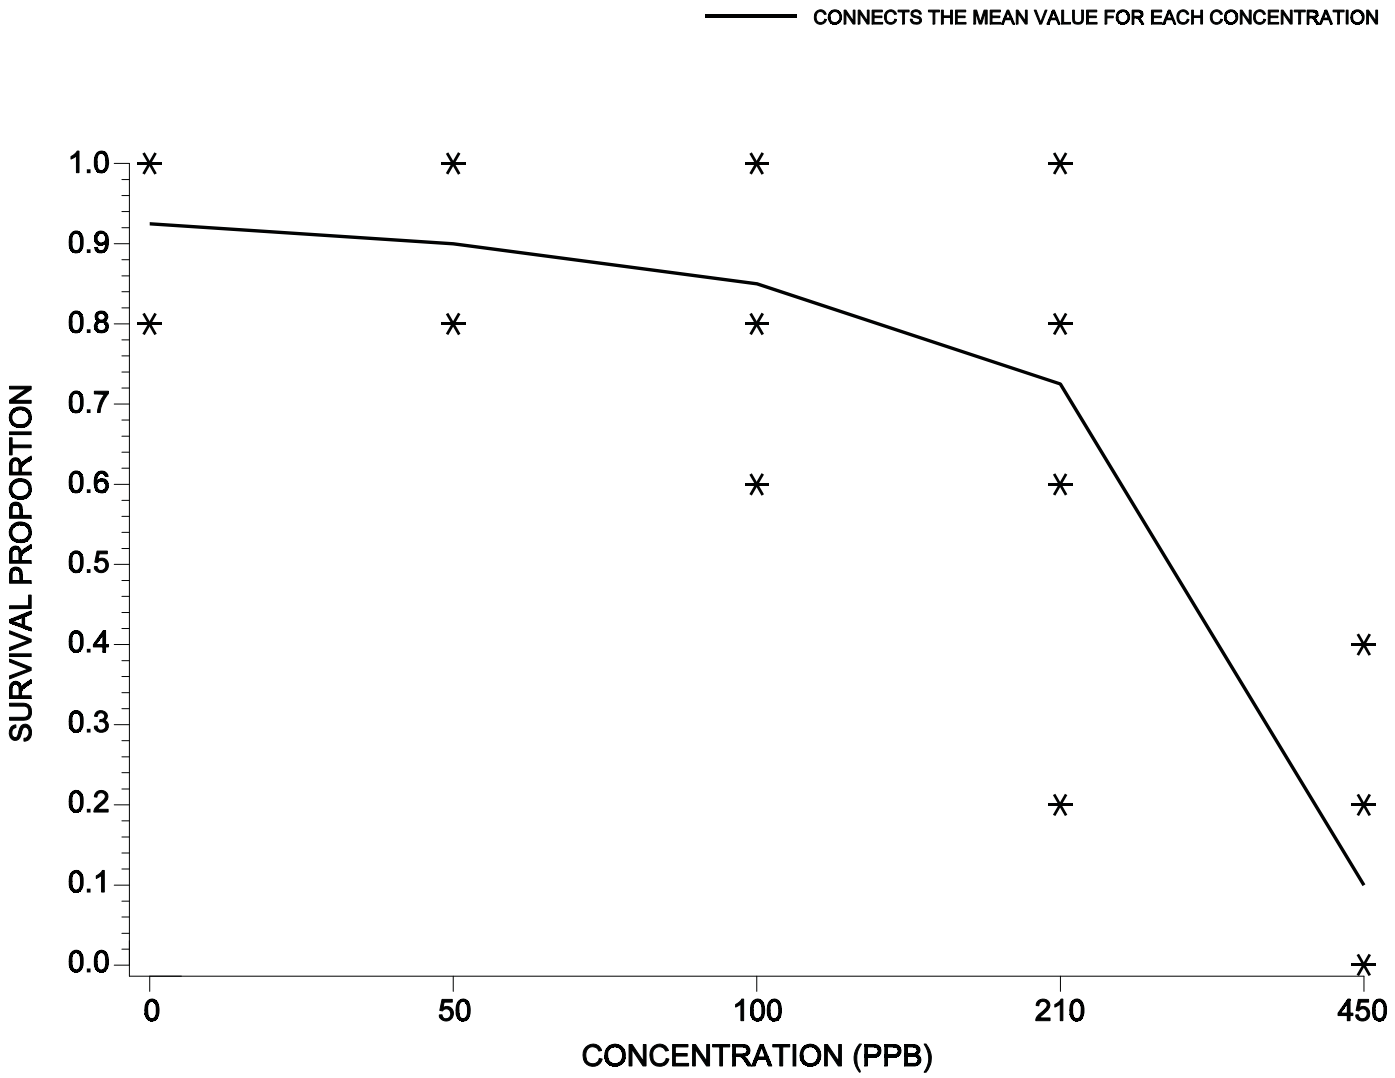

Figure 11. Plot of survival proportions of mysids, *Mysidopsis bahia*, at each treatment level.

i		1	2	3	4	5

14.13.2.6 Test for Normality

14.13.2.6.1 The first step of the test for normality is to center the observations by subtracting the mean of all observations within a concentration from each observation in that concentration. The centered observations are listed in Table 6.

14.13.2.6.2 Calculate the denominator, D, of the test statistic:

$$D = \sum_{i=1}^{n} (X_i - \bar{X})^2$$

Where: X_i = the ith centered observation

$\bar{X}$ = the overall mean of the centered observations

n = the total number of centered observations.

TABLE 6. CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

Replicate	Control (Site Water)	Concentration (ppb) 50.0	100.0	210.0	450.0
1	-0.149	-0.119	-0.285	0.316	-0.117
2	-0.149	0.119	0.174	0.078	0.121
3	0.089	-0.119	0.174	-0.565	-0.117
4	0.089	-0.119	0.174	0.078	0.121
5	0.089	0.119	0.174	-0.142	-0.117
6	0.089	0.119	-0.285	0.078	-0.117
7	0.089	-0.119	-0.064	0.078	-0.117
8	-0.149	0.119	-0.064	0.078	0.342

14.13.2.6.3 For this set of data, $n = 40$

$$\overline{X} = \frac{1}{40}(-0.006) = 0.0$$

$$D = 1.197$$

14.13.2.6.4 Order the centered observations from smallest to largest:

$$X^{(1)} \leq X^{(2)} \leq \ldots \leq X^{(n)}$$

Where $X^{(i)}$ is the ith ordered observation. These ordered observations are listed in Table 7.

14.13.2.6.5 From Table 4, Appendix B, for the number of observations, n, obtain the coefficients $a_1, a_2, \ldots, a_k$ where k is n/2 if n is even and (n-1)/2 if n is odd. For the data in this example, n = 40 and k = 20. The a_i values are listed in Table 8.

14.13.2.6.6 Compute the test statistic, W, as follows:

$$W = \frac{1}{D}\left[\sum_{i=1}^{k} a_i (X^{(n-i+1)} - X^{(i)})\right]^2$$

The differences $X^{(n-i+1)} - X^{(i)}$ are listed in Table 8. For this data in this example:

$$W = \frac{1}{1.197}(1.0475)^2 = 0.9167$$

TABLE 7. ORDERED CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

i	$X^{(i)}$	i	$X^{(i)}$
1	-0.565	21	0.078
2	-0.285	22	0.078
3	-0.285	23	0.078
4	-0.149	24	0.089
5	-0.149	25	0.089
6	-0.149	26	0.089
7	-0.143	27	0.089
8	-0.119	28	0.089
9	-0.119	29	0.119
10	-0.119	30	0.119
11	-0.119	31	0.119
12	-0.117	32	0.119
13	-0.117	33	0.121
14	-0.117	34	0.121
15	-0.117	35	0.174
16	-0.117	36	0.174
17	-0.064	37	0.174
18	-0.064	38	0.174
19	0.078	39	0.316
20	0.078	40	0.342

14.13.2.6.7 The decision rule for this test is to compare W as calculated in Subsection 14.13.2.6.6 with the critical value found in Table 6, Appendix B. If the computed W is less than the critical value, conclude that the data are not normally distributed. For this set of data, the critical value at a significance level of 0.01 and n = 40 observations is 0.919. Since W = 0.9167 is less than the critical value, conclude that the data are not normally distributed.

14.13.2.6.8 Since the data do not meet the assumption of normality, Steel's Many-one Rank Test will be used to analyze the survival data.

14.13.2.7 Steel's Many-one Rank Test

14.13.2.7.1 For each control and concentration combination, combine the data and arrange the observations in order of size from smallest to largest. Assign the ranks (1, 2, ... , 16) to the ordered observations with a rank of 1 assigned to the smallest observation, rank of 2 assigned to the next larger observation, etc. If ties occur when ranking, assign the average rank to each tied observation.

14.13.2.7.2 An example of assigning ranks to the combined data for the control and 50.0 ppb concentration is given in Table 9. This ranking procedure is repeated for each control/concentration combination. The complete set of rankings is summarized in Table 10. The ranks are then summed for each concentration level, as shown in Table 11.

TABLE 8. COEFFICIENTS AND DIFFERENCES FOR SHAPIRO-WILK'S EXAMPLE

i	a_i	$X^{(n-i+1)} - X^{(i)}$	
1	0.3964	0.907	$X^{(40)} - X^{(1)}$
2	0.2737	0.601	$X^{(39)} - X^{(2)}$
3	0.2368	0.459	$X^{(38)} - X^{(3)}$
4	0.2098	0.323	$X^{(37)} - X^{(4)}$
5	0.1878	0.323	$X^{(36)} - X^{(5)}$
6	0.1691	0.323	$X^{(35)} - X^{(6)}$
7	0.1526	0.264	$X^{(34)} - X^{(7)}$
8	0.1376	0.240	$X^{(33)} - X^{(8)}$
9	0.1237	0.238	$X^{(32)} - X^{(9)}$
10	0.1108	0.238	$X^{(31)} - X^{(10)}$
11	0.0986	0.238	$X^{(30)} - X^{(11)}$
12	0.0870	0.236	$X^{(29)} - X^{(12)}$
13	0.0759	0.206	$X^{(28)} - X^{(13)}$
14	0.0651	0.206	$X^{(27)} - X^{(14)}$
15	0.0546	0.206	$X^{(26)} - X^{(15)}$
16	0.0444	0.206	$X^{(25)} - X^{(16)}$
17	0.0343	0.153	$X^{(24)} - X^{(17)}$
18	0.0244	0.142	$X^{(23)} - X^{(18)}$
19	0.0146	0.0	$X^{(22)} - X^{(19)}$
20	0.0049	0.0	$X^{(21)} - X^{(20)}$

14.13.2.7.3 For this example, determine if the survival in any of the concentrations is significantly lower than the survival in the control. If this occurs, the rank sum at that concentration would be significantly lower than the rank sum of the control. Thus compare the rank sums for the survival at each of the various concentration levels with some "minimum" or critical rank sum, at or below which the survival would be considered significantly lower than the control. At a significance level of 0.05, the minimum rank sum in a test with four concentrations (excluding the control) and eight replicates is 47 (See Table 5, Appendix E).

14.13.2.7.4 Since the rank sum for the 450 ppb concentration level is less than the critical value, the proportion surviving in that concentration is considered significantly less than that in the control. Since no other rank sums are less than or equal to the critical value, no other concentrations have a significantly lower proportion surviving than the control. Hence, the NOEC and the LOEC are assumed to be 210.0 ppb and 450.0 ppb, respectively.

14.13.2.8 Calculation of the LC50

14.13.2.8.1 The data used for the Probit Analysis is summarized in Table 12. For the Probit Analysis, run the USEPA Probit Analysis Program. An example of the program output is provided in Figure 12.

14.13.2.8.2 For this example, the chi-square test for heterogeneity was not significant. Thus Probit Analysis appears to be appropriate for this set of data.

TABLE 9. ASSIGNING RANKS TO THE CONTROL AND 50 PPB CONCENTRATION LEVEL FOR STEEL'S MANY-ONE RANK TEST

Rank	Transformed Proportion of Total Mortality	Concentration

14.13.3 EXAMPLE OF ANALYSIS OF MYSID, *MYSIDOPSIS BAHIA,* GROWTH DATA

14.13.3.1 Formal statistical analysis of the growth data is outlined in Figure 13. The response used in the statistical analysis is mean weight per original of males and females combined per replicate. Because this measurement is based on the number of original organisms exposed (rather than the number surviving), the measured response is a combined survival and growth endpoint that can be termed biomass. The IC25 and IC50 can be calculated for the growth data via a point estimation technique (see Section 9, Chronic Toxicity Test Endpoints and Data Analysis). Hypothesis testing can be used to obtain an NOEC and LOEC for growth. Concentrations above the NOEC for survival are excluded from the hypothesis test for growth effects.

TABLE 10. TABLE OF RANKS[1]

		Concentration (ppb)			
Replicate	Control	50	100	210	450
1	1.107(4,5,6.5,10)	1.107(4)	0.886(1.5)	1.345(13.5)	0.225(3)
2	1.107(4,5,6.5,10)	1.345(12)	1.345(12)	1.107(6.5)	0.464(6.5)
3	1.345(12,12,13.5,14)	1.107(4)	1.345(12)	0.464(1)	0.225(3)
4	1.345(12,12,13.5,14)	1.107(4)	1.345(12)	1.107(6.5)	0.464(6.5)
5	1.345(12,12,13.5,14)	1.345(12)	1.345(12)	0.886(2)	0.225(3)

7	1.345(12,12,13.5,14)	1.107(4)	1.107(5)	1.107(6.5)	0.225(3)
8	1.107(4,5,6.5,10)	1.345(12)	1.107(5)	1.107(6.5)	0.685(8)

[1]Control ranks are given in the order of the concentration with which they were ranked.

TABLE 11. RANK SUMS

Concentration	Rank Sum
50	64
100	61
210	49
450	36

14.13.3.2 The statistical analysis using hypothesis tests consists of a parametric test, Dunnett's Procedure, and a nonparametric test, Steel's Many-one Rank Test. The underlying assumptions of the Dunnett's Procedure, normality and homogeneity of variance, are formally tested. The test for normality is the Shapiro-Wilk's Test and Bartlett's Test is used to test for homogeneity of variance. If either of these tests fails, the nonparametric test, Steel's Many-one Rank Test, is used to determine the NOEC and LOEC endpoints. If the assumptions of Dunnett's Procedure are met, the endpoints are determined by the parametric test.

14.13.3.3 Additionally, if unequal numbers of replicates occur among the concentration levels tested, there are parametric and nonparametric alternative analyses. The parametric analysis is a t test with the Bonferroni adjustment. The Wilcoxon Rank Sum Test with the Bonferroni adjustment is the nonparametric alternative. For detailed information on the Bonferroni adjustment, see Appendix D.

14.13.3.5 Test for Normality

14.13.3.5.1 The first step of the test for normality is to center the observations by subtracting the mean of all observations within a concentration from each observation in that concentration. The centered observations are listed in Table 14.

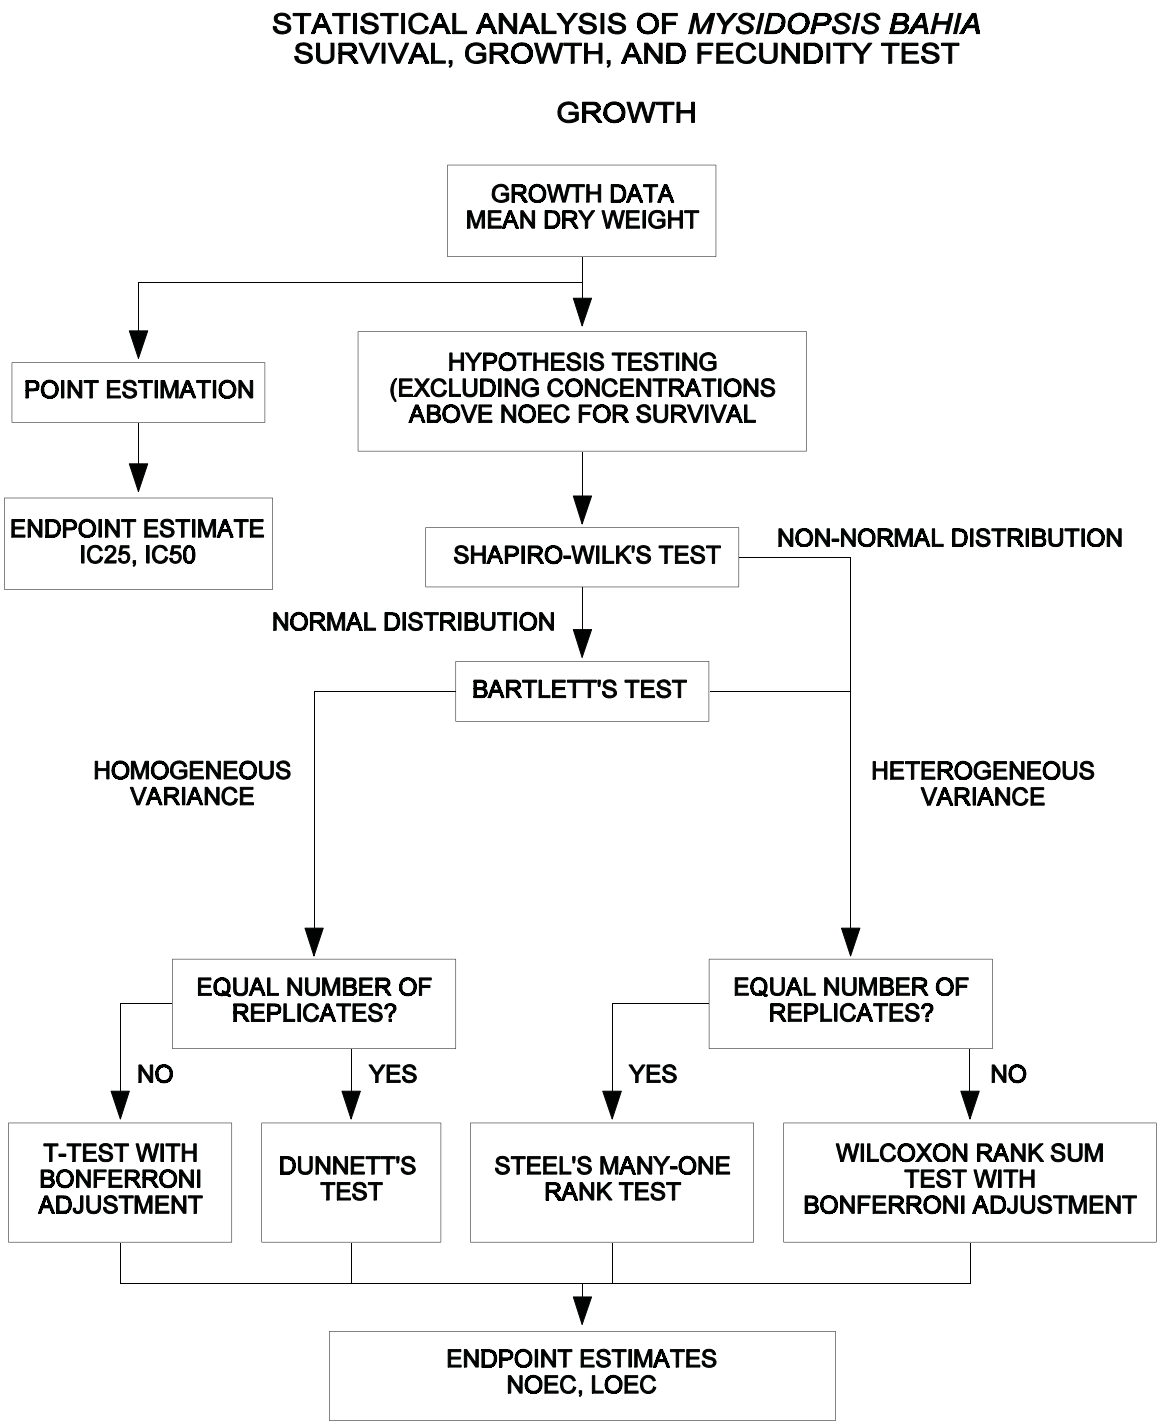

Figure 13. Flowchart for statistical analysis of mysid, *Mysidopsis bahia*, growth data.

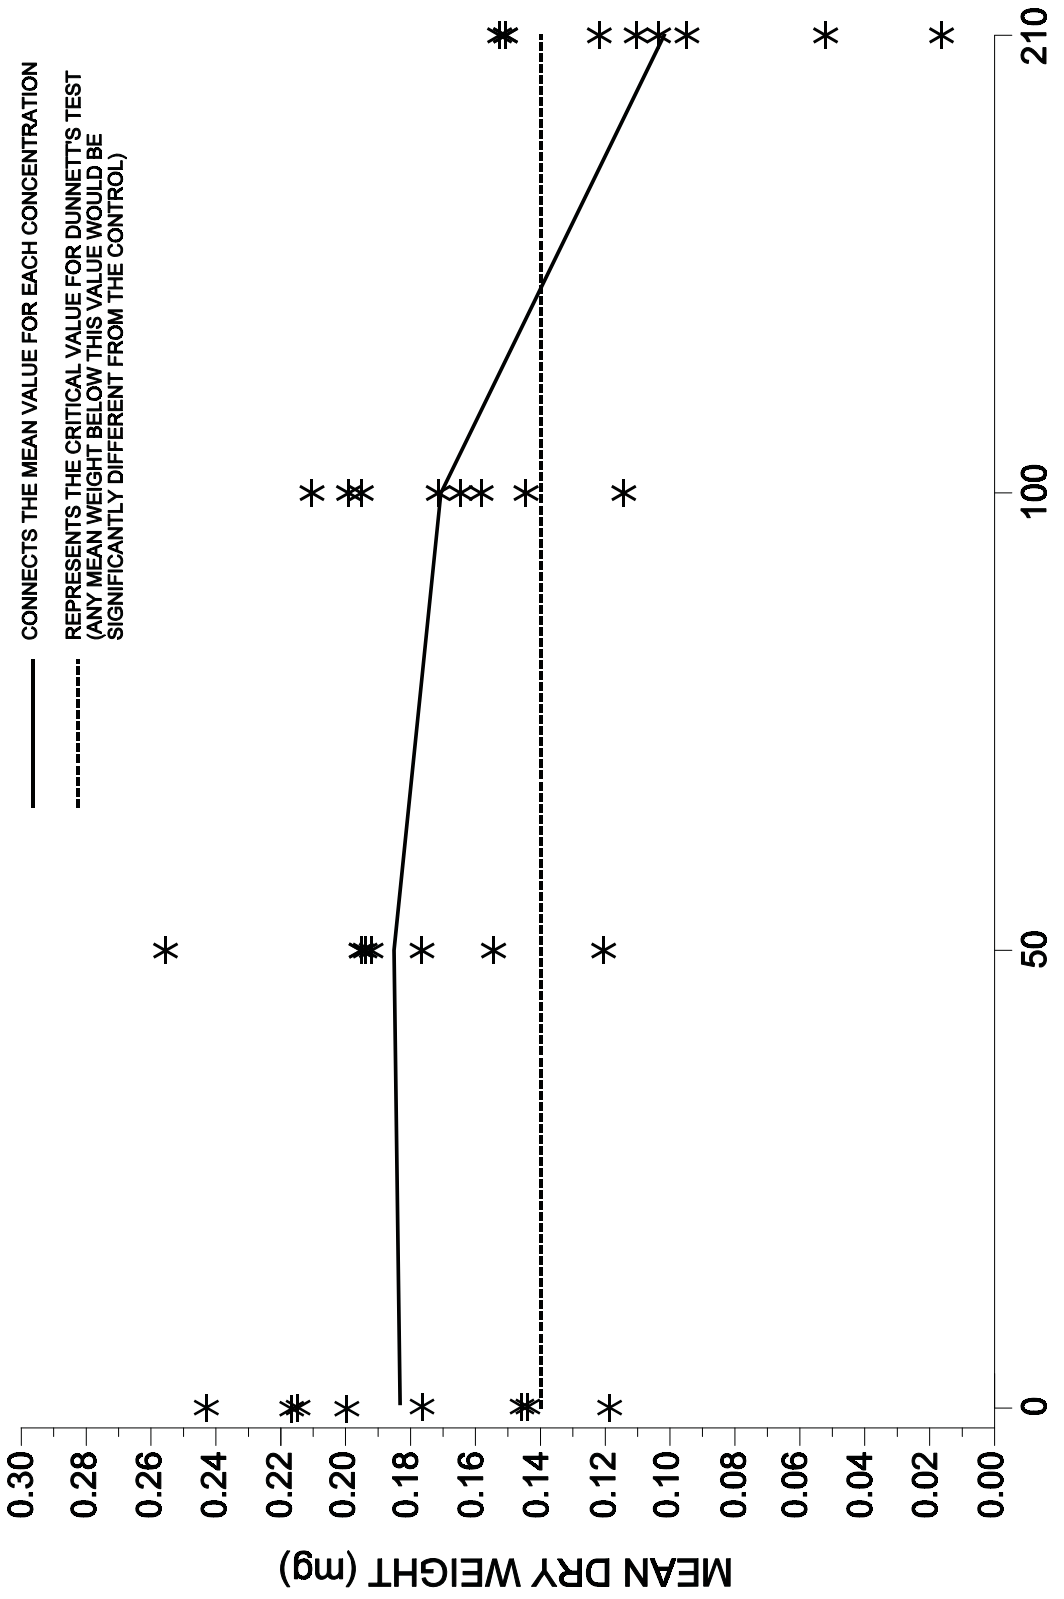

Figure 14. Plot of mean growth data for mysid, *Mysidopsis bahia*, test.

TABLE 14. CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

		Concentration (ppb)		
Replicate	Control	50.0	100.0	210.0
1	-0.036	-0.030	-0.054	0.052
2	-0.064	0.009	0.004	-0.007

8	-0.038	-0.007	0.018	0.002

14.13.3.5.2 Calculate the denominator, D, of the statistic:

$$D = \sum_{i=1}^{n} (X_i - \bar{X})^2$$

Where: X_i = the ith centered observation

$\bar{X}$ = the overall mean of the centered observations

n = the total number of centered observations

14.13.3.5.3 For this set of data, n = 32

$$\bar{X} = \frac{1}{32}(0.007) = 0.000$$

D = 0.0451

14.13.3.5.4 Order the centered observations from smallest to largest

$$X^{(1)} \leq X^{(2)} \leq \ldots \leq X^{(n)}$$

Where $X^{(i)}$ denotes the ith ordered observation. The ordered observations for this example are listed in Table 15.

TABLE 15. ORDERED CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

i	$X^{(i)}$	i	$X^{(i)}$
1	-0.084	17	0.006
2	-0.064	18	0.006
3	-0.062	19	0.007
4	-0.054	20	0.009
5	-0.049	21	0.009
6	-0.038	22	0.017
7	-0.036	23	0.018
8	-0.030	24	0.021
9	-0.023	25	0.031
10	-0.008	26	0.031
11	-0.007	27	0.034
12	-0.007	28	0.039
13	-0.006	29	0.052
14	-0.003	30	0.053
15	0.002	31	0.061
16	0.004	32	0.072

14.13.3.5.5 From Table 4, Appendix B, for the number of observations, n, obtain the coefficients a_1, a_2, ... a_k where k is n/2 if n is even and (n-1)/2 if n is odd. For the data in this example, n = 32 and k = 16. The a_i values are listed in Table 16.

14.13.3.5.6 Compute the test statistic, W, as follows:

$$W = \frac{1}{D}\left[\sum_{i=1}^{k} a_i \left(x^{(n-i+1)} - x^{(i)}\right)\right]^2$$

The differences $X^{(n-i+1)} - X^{(i)}$ are listed in Table 16. For this set of data:

$$W = \frac{1}{0.045}(0.2097)^2 = 0.9752$$

14.13.3.5.7 The decision rule for this test is to compare W as calculated in Subsection 14.13.3.5.6 to a critical value found in Table 6, Appendix B. If the computed W is less than the critical value, conclude that the data are not normally distributed. For this set of data, the critical value at a significance level of 0.01 and n = 32 observations is 0.904. Since W = 0.9752 is greater than the critical value, conclude that the data are normally distributed.

TABLE 16. COEFFICIENTS AND DIFFERENCES FOR SHAPIRO-WILK'S EXAMPLE

14.13.3.6 Test for Homogeneity of Variance

14.13.3.6.1 The test used to examine whether the variation in mean weight of the mysids is the same across all concentration levels including the control, is Bartlett's Test (Snedecor and Cochran, 1980). The test statistic is as follows:

$$B = \frac{[(\sum_{i=1}^{p} V_i) \ln \bar{S}^2 - \sum_{i=1}^{p} V_i \ln S_i^2]}{C}$$

Where: V_i = degrees of freedom for each copper concentration and control, $V_i = (n_i - 1)$

p = number of concentration levels including the control

ln = $\log_e$

i = 1, 2, ..., p where p is the number of concentrations including the control

n_i = the number of replicates for concentration i.

$$\overline{S}^2 = \frac{(\sum_{i=1}^{P} V_i S_i^2)}{\sum_{i=1}^{P} V_i}$$

$$C = 1 + [3(p-1)]^{-1}[\sum_{i=1}^{p} 1/V_i - (\sum_{i=1}^{p} V_i)^{-1}$$

14.13.3.6.2 For the data in this example (see Table 13), all concentrations including the control have the same number of replicates ($n_i = 8$ for all i). Thus, $V_i = 7$ for all i.

14.13.3.6.3 Bartlett's statistic is therefore:

$$B = [(28)\ln(0.00162) - 7\sum_{i=1}^{p} \ln(S_1^2)]/1.06$$

$$= [28(-6.427) - 7(-25.9329)]/1.06$$

$$= [-179.973 - (-181.530)]/1.06$$

$$= 1.469$$

14.13.3.6.4 B is approximately distributed as chi-square with p - 1 degrees of freedom, when the variances are in fact the same. Therefore, the appropriate critical value for this test, at a significance level of 0.01 with three degrees of freedom, is 11.34. Since B = 1.469 is less than the critical value of 11.34, conclude that the variances are not different.

14.13.3.7 Dunnett's Procedure

14.13.3.7.1 To obtain an estimate of the pooled variance for the Dunnett's Procedure, construct an ANOVA table as described in Table 17.

TABLE 17. ANOVA TABLE

Source	df	Sum of Squares (SS)	Mean Square (MS) (SS/df)
Between	p - 1	SSB	S_B^2 = SSB/(p-1)
Within	N - p	SSW	S_W^2 = SSW/(N-p)
Total	N - 1	SST	

Where: p = number of concentration levels including the control

N = total number of observations $n_1 + n_2 \ldots + n_p$

n_i = number of observations in concentration i

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N$$ Between Sum of Squares

$$SST = \sum_{i=1}^{p} \sum_{j=1}^{n} -j\ Y_{ij}^2 - G^2/N$$ Total Sum of Squares

$$SSW = SST - SSB$$ Within Sum of Squares

G = the grand total of all sample observations, $G = \sum_{i=1}^{p} T_i$

T_i = the total of the replicate measurements for concentration i

Y_{ij} = the jth observation for concentration i (represents the mean dry weight of the mysids for concentration i in test chamber j)

14.13.3.7.2 For the data in this example:

$n_1 = n_2 = n_3 = n_4 = 8$

$N = 32$

$T_1 = Y_{11} + Y_{12} + \ldots + Y_{18} = 1.455$

$T_2 = Y_{21} + Y_{22} + \ldots + Y_{28} = 1.473$

$T_3 = Y_{31} + Y_{32} + \ldots + Y_{38} = 1.348$

$T_4 = Y_{41} + Y_{42} + \ldots + Y_{48} = 0.805$

$$G = T_1 + T_2 + T_3 + T_4 = 5.081$$

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N$$

$$= \frac{1}{8}(6.752) - \frac{(5.081)^2}{32} = 0.0372$$

$$SST = \sum_{i=1}^{p} \sum_{j=1}^{n_j} Y_{ij}^2 - G^2/N$$

$$= 0.889 - \frac{(5.081)^2}{32} = 0.0822$$

$$SSW = SST - SSB = 0.0822 - 0.0372 = 0.0450$$

$$S_B^2 = \text{SSB} / (p - 1) = 0.0372 / (4 - 1) = 0.0124$$

$$S_W^2 = \text{SSW} / (N - p) = 0.0450 / (32 - 4) = 0.0016$$

14.13.3.7.3 Summarize these calculations in the ANOVA table (Table 18).

TABLE 18. ANOVA TABLE FOR DUNNETT'S PROCEDURE EXAMPLE

Source	df	Sum of Squares (SS)	Mean Square(MS) (SS/df)
Between	3	0.0372	0.0127
Within	28	0.0450	0.0016
Total	31	0.0822	

14.13.3.7.4 To perform the individual comparisons, calculate the t statistic for each concentration, and control combination as follows:

$$t_i = \frac{(\bar{Y}_1 - \bar{Y}_i)}{S_w\sqrt{(1/n_1) + (1/n_i)}}$$

Where: $\bar{Y}_i$ = mean dry weight for concentration i

$\bar{Y}_1$ = mean dry weight for the control

S_W = square root of the within mean square

n_1 = number of replicates for the control

n_i = number of replicates for concentration i

14.13.3.7.5 Table 19 includes the calculated t values for each concentration and control combination. In this example, comparing the 50.0 ppb concentration with the control the calculation is as follows:

$$t_2 = \frac{(0.182 - 0.184)}{[0.040\sqrt{(1/8) + (1/8)}]}$$

$$= -0.100$$

TABLE 19. CALCULATED T VALUES

Concentration (ppb)	i	t_i
50.0	2	-0.150
100.0	3	0.700
210.0	4	4.050

14.13.3.7.6 Since the purpose of this test is to detect a significant reduction in mean weight, a one-sided test is appropriate. The critical value for this one-sided test is found in Table 5, Appendix C. For an overall alpha level of 0.05, 28 degrees of freedom for error and three concentrations (excluding the control) the approximate critical value is 2.15. The mean weight for concentration "i" is considered significantly less than the mean weight for the control if t_i is greater than the critical value. Therefore, the 210.0 ppb concentration has significantly lower mean weight than the control. Hence the NOEC and the LOEC for growth are 100.0 ppb and 210.0 ppb, respectively.

14.13.3.7.7 To quantify the sensitivity of the test, the minimum significant difference (MSD) that can be detected statistically may be calculated.

$$MSD = d\ S_w\sqrt{(1/n_1) + (1/n)}$$

Where: d = the critical value for Dunnett's Procedure

S_W = the square root of the within mean square

n = the common number of replicates at each concentration
(this assumes equal replication at each concentration)

n_1 = the number of replicates in the control.

14.13.3.7.8 In this example:

$$MSD = 2.15(0.04)\sqrt{(1/8) + (1/8)}$$

$$= 2.15\ (0.04)(0.5)$$

$$= 0.043$$

14.13.3.7.9 Therefore, for this set of data, the minimum difference that can be detected as statistically significant is 0.043 mg.

14.13.3.7.10 This represents a 23.6% reduction in mean weight from the control.

14.13.3.8 Calculation of the ICp

14.13.3.8.1 The growth data from Table 13 are utilized in this example. As seen in, the observed means are not monotonically non-increasing with respect to concentration. Therefore, it is necessary to smooth the means prior to calculating the ICp. In the following discussion, the observed means are represented by $\bar{Y}_i$ and the smoothed means by M_i.

14.13.3.8.2 Starting with the control mean, $\bar{Y}_1 = 0.182$ and $\bar{Y}_2 = 0.184$, we see that $\bar{Y}_1 < \bar{Y}_2$. Calculate the smoothed means:

$$M_1 = M_2 = (\bar{Y}_1 + \bar{Y}_2)/2 = 0.183$$

14.13.3.8.3 Since $\bar{Y}_5 = 0.025 < \bar{Y}_4 = 0.101 < \bar{Y}_3 = 0.168 < M_2$, set $M_3 = 0.168$ and $M_4 = 0.101$, and $M_5 = 0.025$. Table 20 contains the smoothed means and Figure 15 gives a plot of the smoothed response curve.

TABLE 20. MYSID, *MYSIDOPSIS BAHIA*, MEAN GROWTH RESPONSE AFTER SMOOTHING

Toxicant Conc. (ppb)	i	Response Means Y_i (mg)	Smoothed Mean M_i (mg)
Control	1	0.182	0.183
50.0	2	0.184	0.183
100.0	3	0.168	0.168
210.0	4	0.101	0.101
450.0	5	0.012	0.012

14.13.3.8.4 An IC25 and IC50 can be estimated using the Linear Interpolation Method. A 25% reduction in weight, compared to the controls, would result in a mean weight of 0.136 mg, where $M_1(1\text{-}p/100) = 0.183(1\text{-}25/100)$. A 50% reduction in mean dry weight, compared to the controls, would result in a mean weight of 0.091 mg. Examining the smoothed means and their associated concentrations (Table 20), the response, 0.136 mg, is bracketed by $C_3 = 100$ ppb and $C_4 = 210$ ppb. The response, 0.091 mg, is bracketed by $C_4 = 210$ ppb and $C_5 = 450$ ppb.

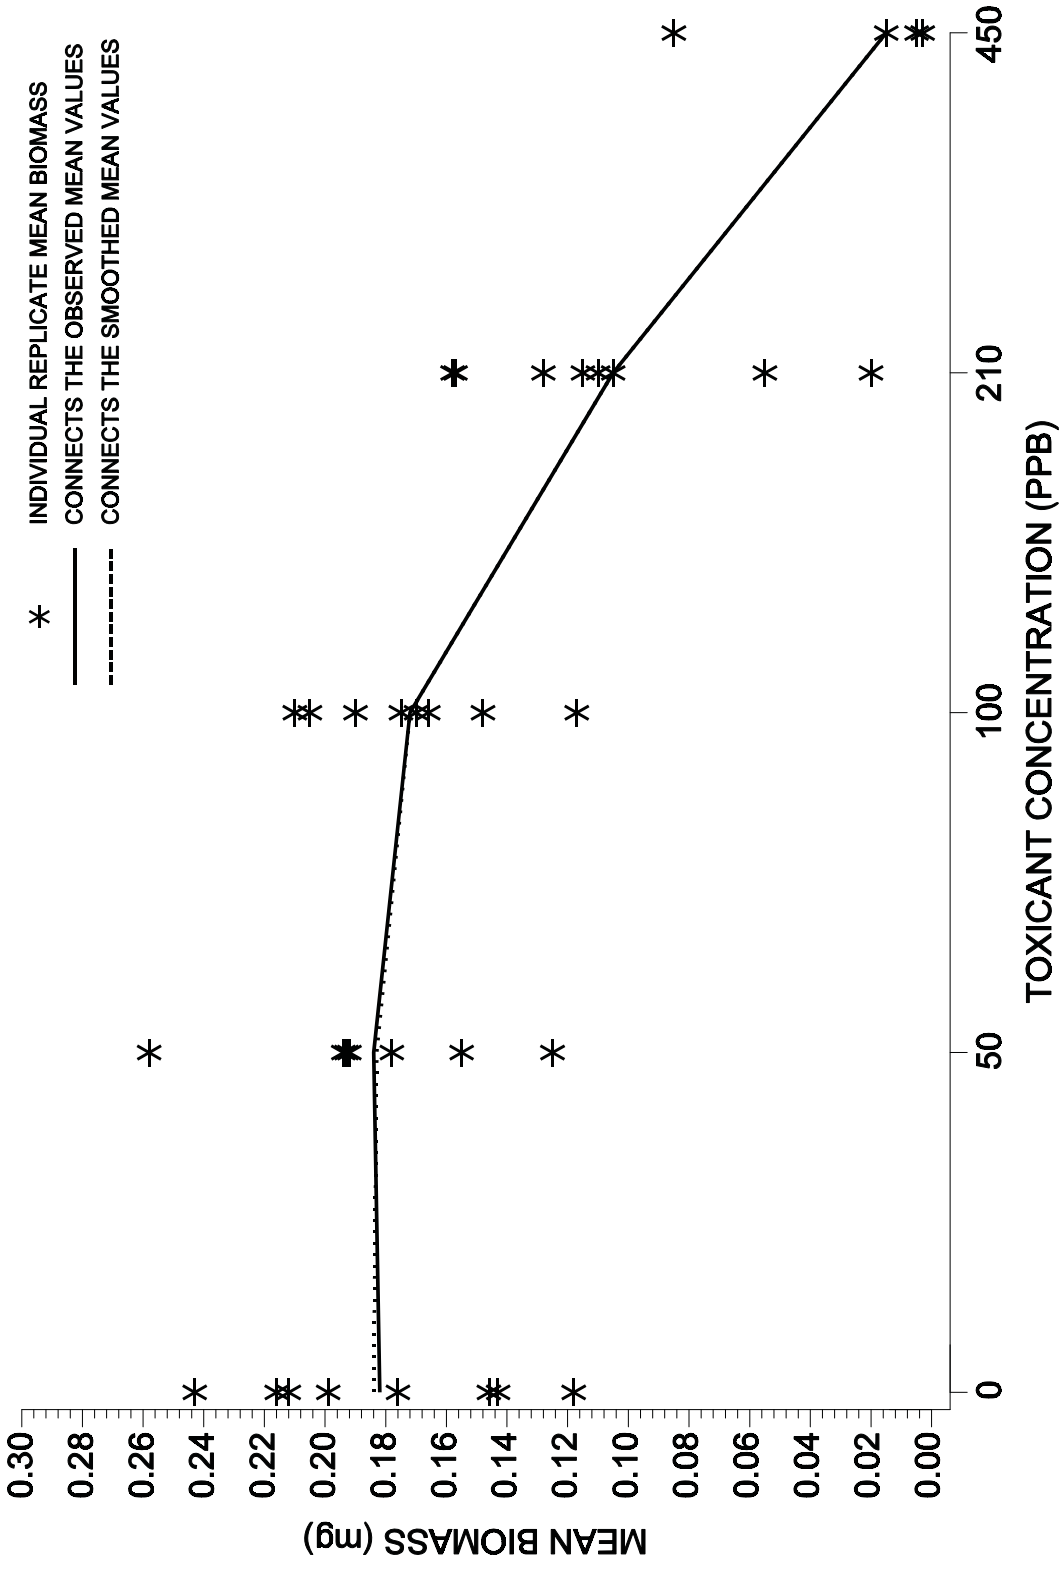

Figure 15. Plot of raw data, observed means, and smoothed means for the mysid, *Mysidopsis bahia*, growth data from Tables 13 and 20.

14.13.3.8.5 Using the equation in Section 4.2 from Appendix L, the estimate of the IC25 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j]\frac{(C_{(j+1)} - C_j)}{M_{(j+1)} - M_j}$$

$$IC25 = 100 + [0.183(1 - 25/100) - 0.168] \quad \frac{(210 - 100)}{(0.101 - 0.168)}$$

$$= 151 \text{ ppb.}$$

14.13.3.8.6 Using Equation 1 from Appendix L, the estimate of the IC50 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j]\frac{(C_{(j+1)} - C_j)}{M_{(j=1)} - M_j}$$

$$IC50 = 210 + [0.183(1 - 50/100) - 0.101] \quad \frac{(450 - 210)}{(0.012 - 0.101)}$$

$$= 236 \text{ ppb.}$$

14.13.3.8.7 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC25 was 150.6446 ppb. The empirical 95.0% confidence interval for the true mean was 97.0905 ppb and 186.6383 ppb. The computer program output for the IC25 for this data set is shown in Figure 16.

14.13.3.8.8 When the ICPIN program was used to analyze this set of data for the IC50, requesting 80 resamples, the estimate of the IC50 was 234.6761 ppb. The empirical 95.0% confidence interval for the true mean was (183.8187 ppb to 277.9211 ppb). The computer program output for the IC50 for this data set is shown in Figure 17.

14.13.4 EXAMPLE OF ANALYSIS OF MYSID, *MYSIDOPSIS BAHIA*, FECUNDITY DATA

14.13.4.1 Formal statistical analysis of the fecundity data is outlined in Figure 18. The response used in the statistical analysis is the proportion of females with eggs in each test or control chamber. If no females were present in a replicate, a response of zero should not be used. Instead there are no data available for that replicate and the number of replicates for that level of concentration or the control should be reduced by one. Separate analyses are performed for the estimation of the NOEC and LOEC endpoints, and for the estimation of the EC, LC, and IC endpoints. The data for a concentration are excluded from the statistical analysis of the NOEC and LOEC endpoints if no eggs were produced in all of the replicates in which females existed. However, all data are included in the estimation of the IC25 and IC50.

Conc. ID	1	2	3	4.	5
Conc. Tested	0	50	100	210	450
Response 1	.146	.154	.114	.153	0
Response 2	.118	.19	.172	.094	.012

Figure 17. ICPIN program output for the IC50.

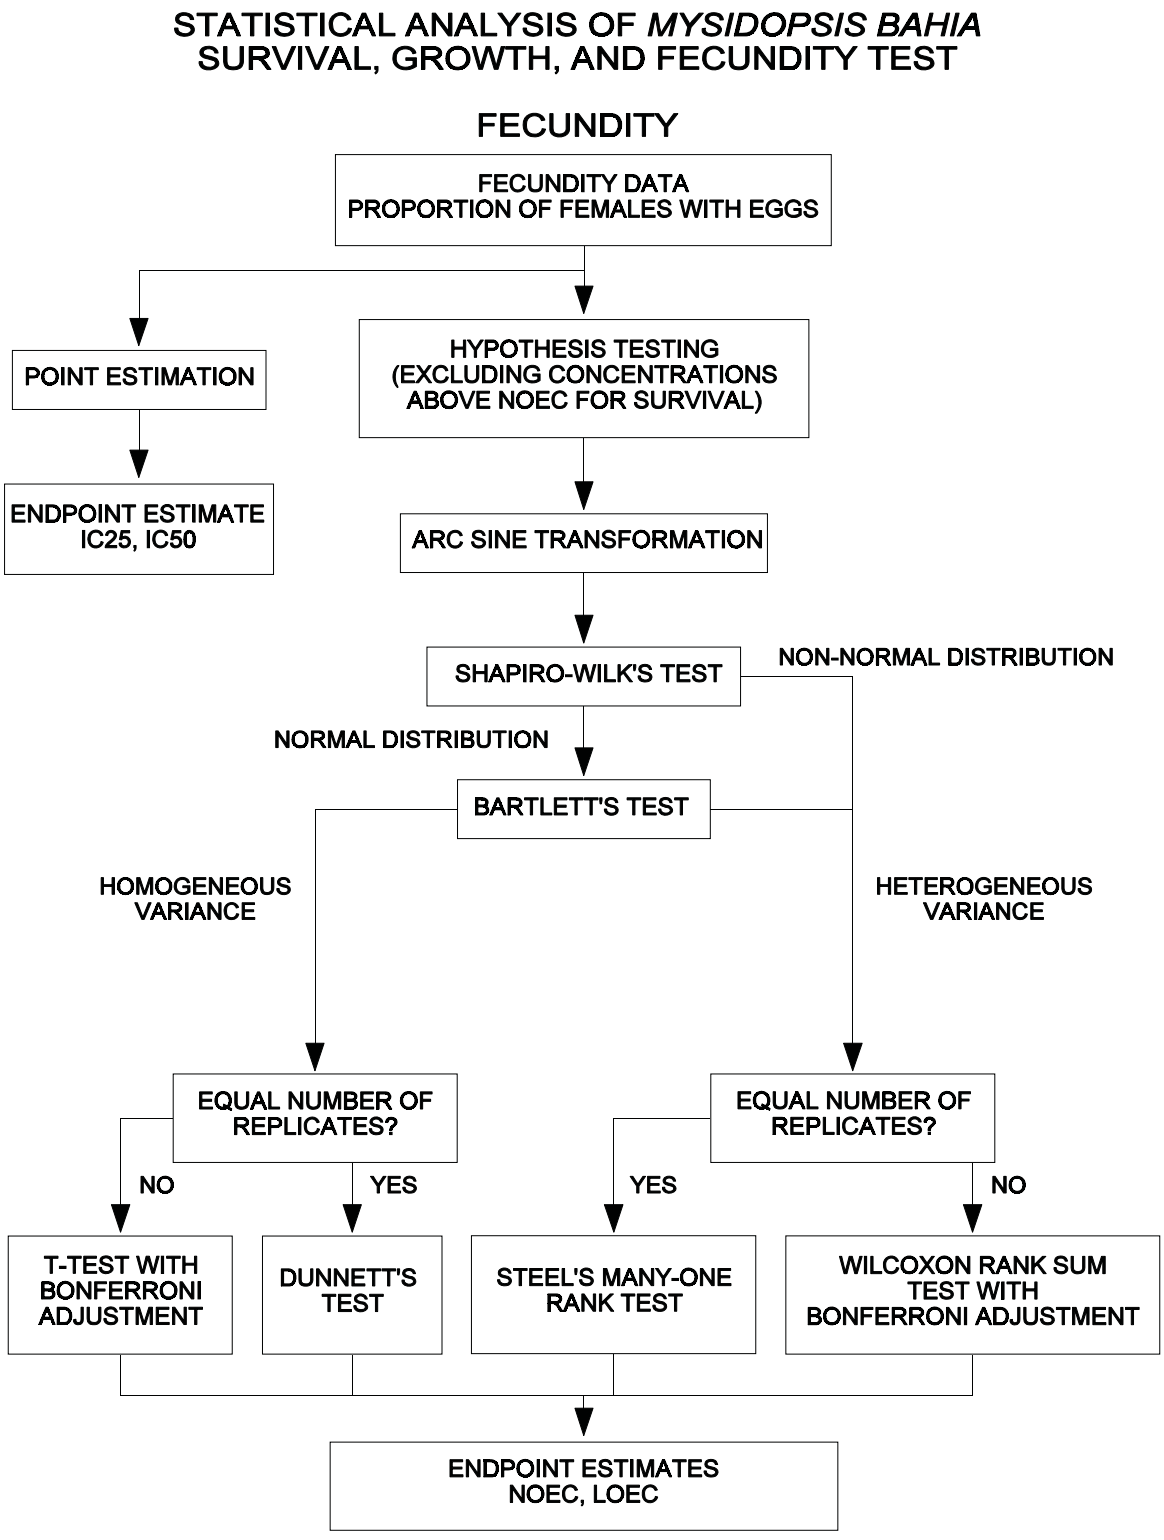

Figure 18. Flowchart for statistical analysis of mysid, *Mysidopsis bahia*, fecundity data.

14.13.4.2 For the case of equal numbers of replicates across all concentrations and the control, the evaluation of the NOEC and LOEC endpoints is made via a parametric test, Dunnett's Procedure, or a nonparametric test, Steel's Many-one Rank Test, on the arc sine square root transformed data. Underlying assumptions of Dunnett's Procedure, normality and homogeneity of variance, are formally tested. The test for normality is the Shapiro-Wilk's Test, and Bartlett's Test is used to test for homogeneity of variance. If either of these tests fails, the nonparametric test, Steel's Many-one Rank Test, is used to determine the NOEC and LOEC endpoints. If the assumptions of Dunnett's Procedure are met, the endpoints are estimated by the parametric procedure.

14.13.4.3 If unequal numbers of replicates occur among the concentration levels tested, there are parametric and nonparametric alternative analyses. The parametric analysis is a t test with the Bonferroni adjustment (Appendix D). The Wilcoxon Rank Sum Test with the Bonferroni adjustment is the nonparametric alternative.

14.13.4.4 The proportion of female mysids, *Mysidopsis bahia*, with eggs in each replicate must first be transformed by the arc sine square root transformation procedure described in Appendix B. Since the denominator of the proportion of females with eggs varies with the number of females occurring in that replicate, the adjustment of the arc sine square root transformation for 0% and 100% is not used for this data. The raw and transformed data, means and variances of the transformed observations at each test concentration including the control are listed in Table 21. Since there is significant mortality in the 450 ppb concentration, its effect on reproduction is not considered. Additionally, since no eggs were produced by females in any of the replicates for the 210 ppb concentration, it is not included in this statistical analysis and is considered a qualitative reproductive effect. A plot of the mean proportion of female mysids with eggs is illustrated in Figure 19.

14.13.4.5 Test for Normality

14.13.4.5.1 The first step of the test for normality is to center the observations by subtracting the mean of all observations within a concentration from each observation in that concentration. The centered observations are listed in Table 22.

14.13.4.5.2 Calculate the denominator, D, of the statistic:

$$D = \sum_{i=1}^{n} (X_i - \bar{X})^2$$

Where: X_i = the ith centered observation

$\bar{X}$ = the overall mean of the centered observations

n = the total number of centered observations

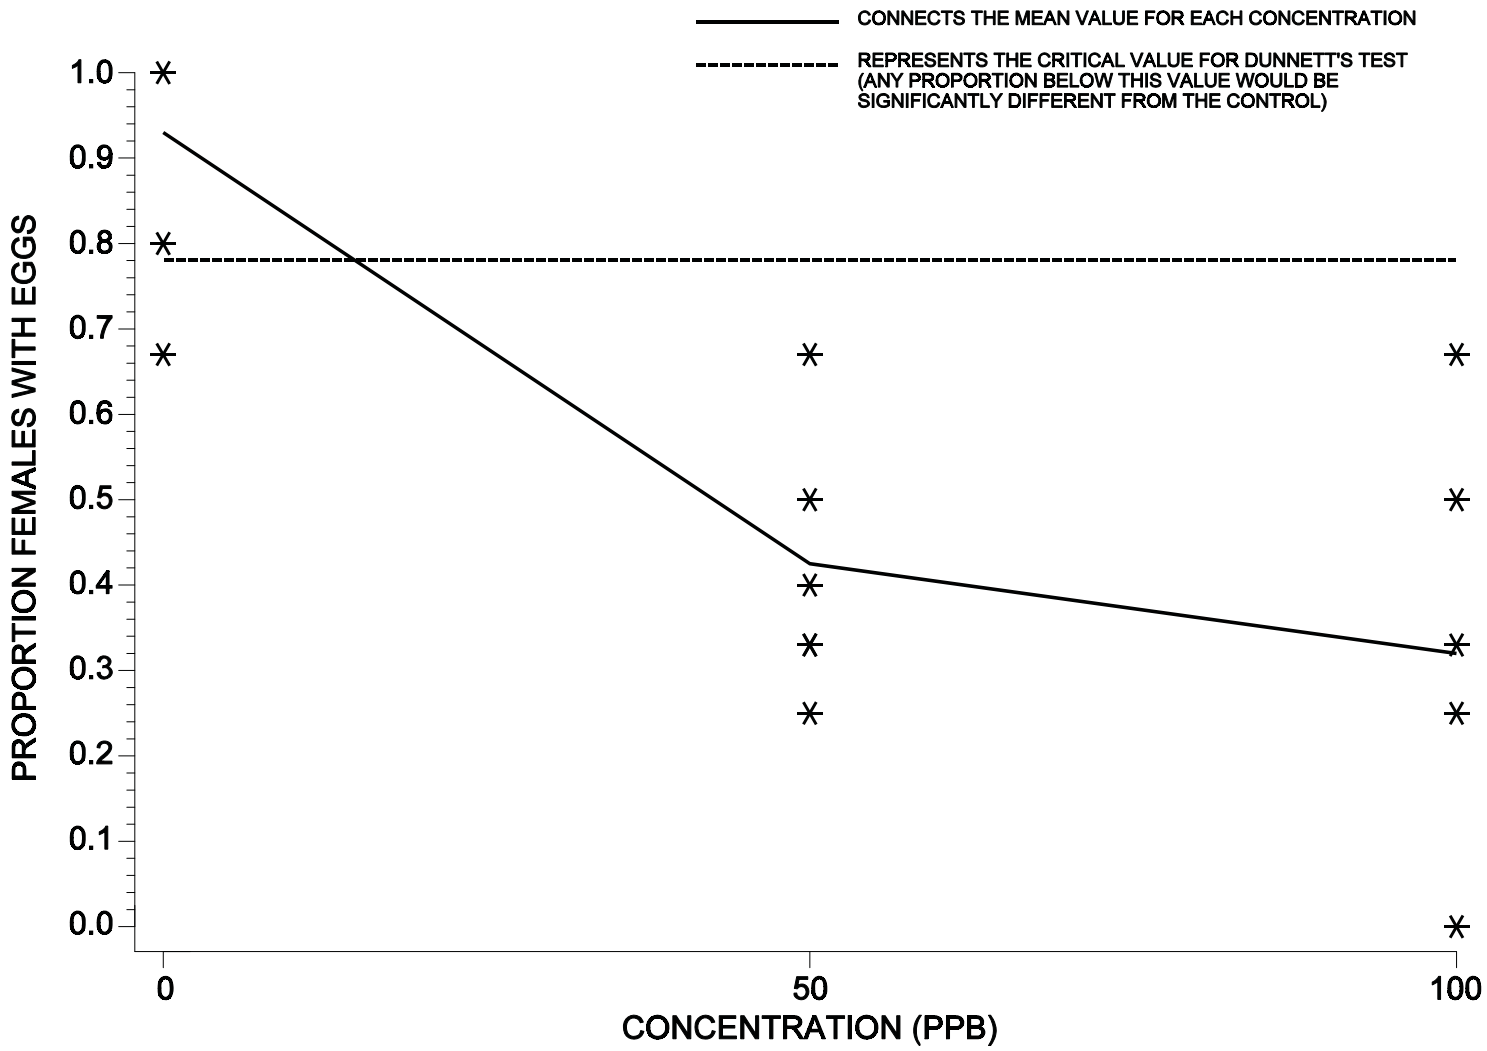

Figure 19. Proportion of female mysids, *Mysidopsis bahia*, with eggs.

TABLE 21. MYSID, *MYSIDOPSIS BAHIA*, FECUNDITY DATA: PERCENT FEMALES WITH EGGS

		Test Concentration (ppb)			
	Replicate	Control	50.0	100.0	210.0
RAW	1	1.00	0.50	0.33	0.0
	2	1.00	0.33	0.50	0.0
	3	0.67	0.67	0.00	0.0

	2	1.57	0.61	0.78	-
	3	0.96	0.96	0.00	-
	4	1.57	-	0.78	-
	5	1.57	0.68	0.96	-
	6	1.12	0.78	0.00	-
	7	1.57	0.52	0.52	-
	8	1.57	0.61	-	-
Mean(Y_i)		1.44	0.71	0.52	-
S^2_i		0.064	0.021	0.147	-
i		1	2	3	4

[1] Since the denominator of the proportion of females with eggs varies with the number of females occurring in that replicate, the adjustment of the arc sine square root transformation for 0% and 100% is not used for this data.

TABLE 22. CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

		Test Concentration (ppb)	
Replicate	Control	50.0	100.0
1	0.13	0.07	0.09
2	0.13	-0.10	0.26
3	-0.48	0.25	-0.52
4	0.13	-	0.26
5	0.13	-0.03	0.44
6	-0.32	0.07	-0.52
7	0.13	-0.19	0.00
8	0.13	-0.10	-

14.13.4.5.3 For this set of data, n = 22

$$X = \frac{1}{22}(0.000) = 0.000$$

$$D = 1.4412$$

14.13.4.5.4 Order the centered observations from smallest to largest:

$$X^{(1)} \leq X^{(2)} \leq \ldots \leq X^{(n)}$$

Where $X^{(i)}$ denotes the ith ordered observation. The ordered observations for this example are listed in Table 23.

14.13.4.5.5. From Table 4, Appendix B, for the number of observations, n, obtain the coefficients $a_1, a_2, \ldots a_k$ where k is n/2 if n is even and (n-1)/2 if n is odd. For the data in this example, n = 22 and k = 11. The a_i values are listed in Table 24.

14.13.4.5.6 Compute the test statistic, W, as follows:

$$W = \frac{1}{D}\left[\sum_{i=1}^{k} a_i (X^{(n-i+1)} - X^{(i)})\right]^2$$

The differences $X^{(n-i+1)} - X^{(I)}$ are listed in Table 24. For the data in this example:

$$W = \frac{1}{1.4412}(1.1389)^2 = 0.900$$

TABLE 23. ORDERED CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

i	$X^{(i)}$	i	$X^{(i)}$

TABLE 24. COEFFICIENTS AND DIFFERENCES FOR SHAPIRO-WILK'S EXAMPLE

	i	a_i	$X^{(n-i+1)} - X^{(i)}$
1	0.4590	0.96	$X^{(22)} - X^{(1)}$
2	0.3156	0.78	$X^{(21)} - X^{(2)}$
3	0.2571	0.74	$X^{(20)} - X^{(3)}$
4	0.2131	0.57	$X^{(19)} - X^{(4)}$
5	0.1764	0.32	$X^{(18)} - X^{(5)}$
6	0.1443	0.23	$X^{(17)} - X^{(6)}$
7	0.1150	0.23	$X^{(16)} - X^{(7)}$
8	0.0878	0.16	$X^{(15)} - X^{(8)}$
9	0.0618	0.13	$X^{(14)} - X^{(9)}$
10	0.0368	0.06	$X^{(13)} - X^{(10)}$
11	0.0122	0.02	$X^{(12)} - X^{(11)}$

14.13.4.5.7 The decision rule for this test is to compare W as calculated in Subsection 14.13.4.5.6 to a critical value found in Table 6, Appendix B. If the computed W is less than the critical value, conclude that the data are not normally distributed. For this set of data, the critical value at a significance level of 0.01 and n = 22 observations is 0.878. Since W = 0.900 is greater than the critical value, conclude that the data are normally distributed.

14.13.4.6 Test for Homogeneity of Variance

14.13.4.6.1 The test used to examine whether the variation in proportion of female mysids with eggs is the same across all concentration levels including the control, is Bartlett's Test (Snedecor and Cochran, 1980). The test statistic is as follows:

$$B = \frac{[(\sum_{i=1}^{p} V_i) \ln \overline{S}^2 - \sum_{i=1}^{p} V_i \ln S_i^2]}{C}$$

Where: V_i = degrees of freedom for each copper concentration and control, $V_i = (n_i - 1)$

p = number of concentration levels including the control

$$\overline{S}^2 = \frac{(\sum_{i=1}^{p} V_i S_i^2)}{\sum_{i=1}^{p} V_i}$$

ln = $\log_e$

i = 1, 2, ..., p where p is the number of concentrations including the control

n_i = the number of replicates for concentration i.

$$C = 1+[3(p-1)^{-1}\ [\sum_{i=1}^{p} 1/V_i - (\sum_{i=1}^{p} V_i)^{-1}]$$

14.13.4.6.2 For the data in this example (see Table 21), $n_1 = 8$, $n_2 = 7$ and $n_3 = 7$. Thus, the respective degrees of freedom are 7, 6 and 6.

14.13.4.6.3 Bartlett's statistic is therefore:

$$B = [(19)\ln(0.077) - (7\ln(0.064) + 6\ln(0.021) + 6\ln(0.147))]/1.07$$

$$= [19(-2.564) - (-53.925)]/1.07$$

$$= [-48.716 - (-53.925)]/1.07$$

$$= 4.868$$

14.13.4.6.4 B is approximately distributed as chi-square with p - 1 degrees of freedom, when the variances are in fact the same. Therefore, the appropriate critical value for this test, at a significance level of 0.01 with two degrees of freedom, is 9.210. Since B = 4.868 is less than the critical value of 9.210, conclude that the variances are not different.

14.13.4.7 T test with the Bonferroni Adjustment

14.13.4.7.1 A t test with the Bonferroni adjustment is used as an alternative to Dunnett's Procedure when, as in this set of data, the number of replicates is not the same for all concentrations. Like Dunnett's Procedure, it uses a pooled estimate of the variance, which is equal to the error value calculated in an analysis of variance. To obtain an estimate of the pooled variance, construct an ANOVA table as described in Table 25.

TABLE 25. ANOVA TABLE

Source	df	Sum of Squares (SS)	Mean Square (MS) (SS/df)
Between	p - 1	SSB	S_B^2 = SSB/(p-1)
Within	N - p	SSW	S_W^2 = SSW/(N-p)
Total	N - 1	SST	

Where: p = number of concentration levels including the control

N = total number of observations $n_1 + n_2 \ldots + n_p$

n_i = number of observations in concentration i

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N$$ Between Sum of Squares

$$SST = \sum_{i=1}^{p} \sum_{j-1}^{n_j} Y_{ij}^2 - G^2/N$$ Total Sum of Squares

$$SSW = SST - SSB$$ Within Sum of Squares

G = the grand total of all sample observations, $G = \sum_{i=1}^{p} T_i$

T_i = the total of the replicate measurements for concentration i

Y_{ij} = the jth observation for concentration i (represents the mean dry weight of the mysids for concentration i in test chamber j)

14.13.4.7.2 For the data in this example:

$n_1 = 8$ $n_2 = 7$ $n_3 = 7$

$N = 22$

$T_1 = Y_{11} + Y_{12} + ... + Y_{18} = 11.5$

$T_2 = Y_{21} + Y_{22} + ... + Y_{27} = 4.94$

$T_3 = Y_{31} + Y_{32} + ... + Y_{37} = 3.65$

$G = T_1 + T_2 + T_3 = 20.09$

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N$$

$$= \frac{132.25}{8} + \frac{24.40}{7} + \frac{13.32}{7} - \frac{403.61}{22} = 3.57$$

$$SST = \sum_{i=1}^{p} \sum_{j=1}^{n_j} Y_{ij}^2 - G^2/N$$

$$= 23.396 - \frac{403.61}{22} = 5.05$$

SSW = SST - SSB = 5.05 - 3.57 = 1.48

S_B^2 = SSB/(p-1) = 3.57/(3-1) = 1.785

S_W^2 = SSW/(N-p) = 1.48/(22-3) = 0.078

14.13.4.7.3 Summarize these calculations in the ANOVA table (Table 26).

TABLE 26. ANOVA TABLE FOR THE T TEST WITH BONFERRONI'S ADJUSTMENT EXAMPLE

Source	df	Sum of Squares (SS)	Mean Square (MS) (SS/df)
Between	2	3.57	1.785
Within	19	1.48	0.078
Total	21	5.05	

14.13.4.7.4 To perform the individual comparisons, calculate the t statistic for each concentration, and control combination as follows:

$$t_i = \frac{(\bar{Y}_1 - \bar{Y}_i)}{S_w\sqrt{(1/n_1) + (1/n_i)}}$$

Where: $\bar{Y}_i$ = mean proportion of females with eggs for concentration i

$\bar{Y}_1$ = mean proportion of females with eggs for the control

S_W = square root of the within mean square

n_1 = number of replicates for the control

n_i = number of replicates for concentration i

14.13.4.7.5 Table 27 includes the calculated t values for each concentration and control combination. In this example, comparing the 50.0 ppb concentration with the control the calculation is as follows:

$$t_2 = \frac{(1.44 - 0.52)}{[0.279\sqrt{(1/8) - (1/7)}]}$$

$$= 5.05$$

TABLE 27. CALCULATED T VALUES

Test Concentration (ppb)	i	t_i
50.0	2	5.05
100.0	3	6.37

14.13.4.7.6 Since the purpose of this test is to detect a significant reduction in mean proportion of females with eggs, a one-sided test is appropriate. The critical value for this one-sided test is found in Table 5, Appendix D, Critical Values for the t test with Bonferroni's adjustment. For an overall alpha level of 0.05, 19 degrees of freedom for error and two concentrations (excluding the control) the approximate critical value is 2.094. The mean proportion for concentration "i" is considered significantly less than the mean proportion for the control if t_i is greater than the critical value. Therefore, the 50.0 ppb and the 100.0 ppb concentrations have significantly lower mean proportion of females with eggs than the control. Hence the LOEC for fecundity is 50.0 ppb.

14.13.4.7.7 To quantify the sensitivity of the test, the minimum significant difference (MSD) that can be detected statistically may be calculated.

$$MSD = t\ S_w\sqrt{(1/n_1) + (1/n)}$$

Where: t = the critical value for the t test with Bonferroni's adjustment

S_W = the square root of the within mean square

n = the common number of replicates at each concentration (this assumes equal replication at each concentration)

n_1 = the number of replicates in the control

14.13.4.7.8 In this example:

$$MSD = 2.094\,(0.279)\sqrt{(1/8) + (1/7)}$$

$$= 2.094\ (0.279)(0.518)$$

$$= 0.303$$

14.13.4.7.9 Therefore, for this set of data, the minimum difference that can be detected as statistically significant is 0.30.

14.13.4.7.10 The MSD (0.30) is in transformed units. To determine the MSD in terms of percent of females with eggs, carry out the following conversion.

1. Subtract the MSD from the transformed control mean.

   1.44 - 0.30 = 1.14

2. Obtain the untransformed values for the control mean and the difference calculated in 4.10.1.

   [Sine (1.44)]^2 = 0.983

   [Sine (1.14)]^2 = 0.823

3. The untransformed MSD (MSD_u) is determined by subtracting the untransformed values from 14.13.4.7.10.2.

   MSD_u = 0.983 - 0.823 = 0.16

14.13.4.7.11 Therefore, for this set of data, the minimum difference in mean proportion of females with eggs between the control and any copper concentration that can be detected as statistically significant is 0.16.

14.13.4.7.12 This represents a 17% decrease in proportion of females with eggs from the control.

14.13.4.8 Calculation of the ICp

14.13.4.8.1 The fecundity data in Table 4 are utilized in this example. Table 28 contains the mean proportion of females with eggs for each toxicant concentration. As can be seen, the observed means are monotonically nonincreasing with respect to concentration. Therefore, it is not necessary to smooth the means prior to calculating the IC. Figure 20 gives a plot of the response curve.

TABLE 28. MYSID, *MYSIDOPSIS BAHIA*, MEAN MEAN PROPORTION OF FEMALES WITH EGGS

Toxicant Conc. (ppb)	i	Response Means Y^i (mg)	Smoothed Mean M_i (mg)
Control	1	0.934	0.934
50.0	2	0.426	0.426
100.0	3	0.317	0.317
210.0	4	0.000	0.000
450.0	5	0.010	0.000

14.13.4.8.2 An IC25 and IC50 can be estimated using the Linear Interpolation Method. A 25% reduction in mean proportion of females with eggs, compared to the controls, would result in a mean proportion of 0.701, where $M_1(1-p/100)$ = 0.934(1-25/100). A 50% reduction in mean proportion of females with eggs, compared to the could would result in a mean proportion of 0.467. Examining the means and their associated concentrations (Table 28), the response, 0.701, is bracketed by C_1 = 0 ppb and C_2 = 50 ppb. The response, 0.467, is bracketed by C_1 = 0 ppb and C_2 = 50 ppb.

14.13.4.8.3 Using the equation in Section 4.2 from Appendix L, the estimate of the IC25 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j] \frac{(C_{(j+1)} - C_j)}{(M_{(j+1)} - M_j)}$$

$$IC25 = 0 + [0.934(1 - 25/100) - 0.934] \quad \frac{(50 - 0)}{(0.426 - 0.934)}$$

$$= 23 \text{ ppb.}$$

14.13.4.8.4 Using the equation in Section 4.2 from Appendix L, the estimate of the IC50 is calculated as follows:

$$ICp = C_j + [M_1 \ (1 - p/100) - M_j] \frac{C_{(j+1)} - C_j)}{(M_{(j+1)} - M_j)}$$

$$IC50 = 0 + [0.934(1 - 50/100) - 0.934] \quad \frac{(50 - 0)}{(0.426 - 0.934)}$$

$$= 46 \text{ ppb.}$$

14.13.4.8.5 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC25 was 29.9745 ppb. The empirical 95.0% confidence interval for the true mean was 20.0499 ppb to 30.5675 ppb. The computer program output for the IC25 for this data set is shown in Figure 21. This value is extrapolated below the lowest test concentration and data should be used cautiously.

14.13.4.8.6 When the ICPIN program was used to analyze this set of data for the IC50, requesting 80 resamples, the estimate of the IC50 was 45.9490 ppb. The empirical 95.0% confidence interval for the true mean was 40.1467 ppb to 63.0931 ppb. The computer program output for the IC50 for this data set is shown in Figure 22.

14.14 PRECISION AND ACCURACY

14.14.1 PRECISION – Data on single-laboratory and multilaboratory precision are described below (Subsections 14.14.1.1 and 14.14.1.2). Single-laboratory precision is a measure of the reproducibility of test results when tests are conducted using a specific method under reasonably constant conditions in the same laboratory. Single-laboratory precision is synonymous with the terms within-laboratory precision and intralaboratory precision. Multilaboratory precision is a measure of the reproducibility of test results from different laboratories using the same test method and analyzing the same test material. Multilaboratory precision is synonymous with the term interlaboratory precision. Interlaboratory precision, as used in this document, includes both within-laboratory and between-laboratory components of variability. In recent multilaboratory studies, these two components of interlaboratory precision have been displayed separately (termed within-laboratory and between-laboratory variability) and combined (termed total interlaboratory variability). The total interlaboratory variability that is reported from these studies is synonymous with interlaboratory variability reported from other studies where individual variability components are not separated.

14.14.1.1 Single-Laboratory Precision

14.14.1.1.1 Data on the single-laboratory precision of the mysid survival, growth, and fecundity using copper (Cu) sulfate and sodium dodecyl sulfate (SDS) in natural seawater and in artificial seawater (GP2) are shown in Tables 29-33. In Tables 29-30 the coefficient of variation for the IC25, ranges from 18.0 to 35.0 and the IC50, ranges from 5.8 to 47.8, indicating acceptable test precision. Data in Tables 31-33 show no detectable differences between tests conducted in natural or artificial seawaters.

14.14.1.1.2 EPA evaluated within-laboratory precision of the Mysid, *Mysidopsis bahia*, Survival, Growth, and Fecundity Test using a database of routine reference toxicant test results from 10 laboratories (USEPA, 2000b). The database consisted of 130 reference toxicant tests conducted in 10 laboratories using a variety of reference toxicants including: chromium, copper, and potassium chloride. Among the 10 laboratories, the median within-laboratory CV calculated for routine reference toxicant tests was 28% for the IC25 growth endpoint. In 25% of laboratories, the within-laboratory CV was less than 24%; and in 75% of laboratories, the within-laboratory CV was less than 32%.

14.14.1.2 Multilaboratory Precision

14.14.1.2.1 In 2000, EPA conducted an interlaboratory variability study of the Mysid, *Mysidopsis bahia*, Survival, Growth, and Fecundity Test (USEPA, 2001a; USEPA, 2001b). In this study, each of 11 participant laboratories tested 4 blind test samples that included some combination of blank, effluent, reference toxicant, and receiving water sample types. The blank sample consisted of bioassay-grade FORTY FATHOMS® synthetic seawater, the effluent sample was a municipal wastewater spiked with KCl, the receiving water sample was a natural seawater spiked with KCl, and the reference toxicant sample consisted of bioassay-grade FORTY FATHOMS® synthetic seawater spiked with KCl. Of the 44 *Mysidopsis bahia* Survival, Growth, and Fecundity tests conducted in this study, 97.7% were successfully completed and met the required test acceptability criteria. Of seven tests that were conducted on blank samples, none showed false positive results for survival, growth, or fecundity endpoints. Results from the reference toxicant, effluent, and receiving water sample types were used to calculate the precision of the method. Table 34 shows the precision of the IC25 for each of these sample types. Averaged across sample types, the total interlaboratory variability (expressed as a CV%) was 41.3% for growth IC25 results. Table 35 shows the frequency distribution of survival and growth NOEC endpoints for each sample type. For the survival endpoint, NOEC values spanned three concentrations for the reference toxicant, effluent, and receiving water sample types. The percentage of values within one concentration of the median was 100% for each of the sample types. For the growth endpoint, NOEC values spanned four concentrations for the reference toxicant sample type and three concentrations for the effluent and receiving water sample types. The percentage of values within one concentration of the median was 92.3%, 100%, and 100% for the reference toxicant, effluent, and receiving water sample types, respectively. For the fecundity endpoint, NOEC values spanned three concentrations for the reference toxicant, the effluent, and the receiving water sample types. The percentage of values within one concentration of the median was 75.0%, 87.5%, and 66.7% for the reference toxicant, effluent, and receiving water sample types, respectively.

14.14.2 ACCURACY

14.14.2.1 The accuracy of toxicity tests cannot be determined.

TABLE 29. SINGLE-LABORATORY PRECISION OF THE MYSID, *MYSIDOPSIS BAHIA*, SURVIVAL, GROWTH, AND FECUNDITY TEST PERFORMED IN NATURAL SEAWATER, USING JUVENILES FROM MYSIDS CULTURED AND SPAWNED IN NATURAL SEAWATER, AND COPPER (Cu) SULFATE AS A REFERENCE TOXICANT[1,2,3,4,5,6]

Test Number	NOEC (µg/L)	IC25 (µg/L)	IC50 (µg/L)	Most Sensitive Endpoint[7]
1	63	96.1	NC[8]	S
2	125	138.3	175.5	S
3	125	156.3	187.5	S
4	125	143.0	179.9	S
5	125	157.7	200.3	S
n:	5	5	4	
Mean:	NA	138.3	185.8	
CV(%):	NA	18.0	5.8	

1 Data from USEPA (1988a) and USEPA (1991a).
2 Tests performed by Randy Cameleo, ERL-N, USEPA, Narragansett, RI.
3 Eight replicate exposure chambers, each with five juveniles, were used for the control and each toxicant concentration. The temperature of the test solutions was maintained at 26 ± 1°C.
4 Copper concentrations in Tests 1-2 were: 8, 16, 31, 63, and 125 mg/L. Copper concentrations in Tests 3-6 were, 16, 31, 63, 125, and 250 µg/L.
5 NOEC Range: 63 - 125 µg/L (this represents a difference of two exposure concentrations).
6 For a discussion of the precision of data from chronic toxicity tests see Section 4, Quality Assurance.
7 Endpoints: G=Growth; S=Survival.
8 NC = No linear interpolation estimate could be calculated from the data, since none of the group response means were less than 50 percent of the control concentrations.

TABLE 30. SINGLE-LABORATORY PRECISION OF THE MYSID, *MYSIDOPSIS BAHIA*, SURVIVAL, GROWTH, AND FECUNDITY TEST PERFORMED IN NATURAL SEAWATER, USING JUVENILES FROM MYSIDS CULTURED AND SPAWNED IN NATURAL SEAWATER, AND SODIUM DODECYL SULFATE (SDS) AS A REFERENCE TOXICANT[1,2,3,4,5,6]

Test Number	NOEC (mg/L)	IC25 (mg/L)	IC50 (mg/L)	Most Sensitive Endpoint[7]

TABLE 34. PRECISION OF POINT ESTIMATES FOR VARIOUS SAMPLE TYPES[1]

Test Endpoint	Sample Type	CV (%)[2]		
		Within-lab[3]	Between-lab[4]	Total[5]
IC25 for Growth	Reference toxicant	8.69	40.0	40.9
	Effluent	5.26	36.6	37.0
	Receiving water	-	-	45.9
	Average	6.98	38.3	41.3

[1] From EPA's WET Interlaboratory Variability Study (USEPA, 2001a; USEPA, 2001b).

[2] CVs were calculated based on the within-laboratory component of variability, the between-laboratory component of variability, and the total interlaboratory variability (including both within-laboratory and between-laboratory components). For the receiving water sample type, within-laboratory and between-laboratory components of variability could not be calculated since the study design did not provide within-laboratory replication for this sample type.

[3] The within-laboratory (intralaboratory) component of variability for duplicate samples tested at the same time in the same laboratory.

[4] The between-laboratory component of variability for duplicate samples tested at different laboratories.

[5] The total interlaboratory variability, including within-laboratory and between-laboratory components of variability. The total interlaboratory variability is synonymous with interlaboratory variability reported from other studies where individual variability components are not separated.

TABLE 35. FREQUENCY DISTRIBUTION OF HYPOTHESIS TESTING RESULTS FOR VARIOUS SAMPLE TYPES[1]

Test Endpoint	Sample Type	Median NOEC Value	% of Results at the Median	% of Results ±1[2]	% of Results ≥2[3]
Survival NOEC	Reference toxicant	25%	53.8	46.2	0.00
	Effluent	12.5%	46.7	53.3	0.00
	Receiving water	12.5%	37.5	62.5	0.00
Growth NOEC	Reference toxicant	25%	53.8	38.5	7.69
	Effluent	12.5%	46.7	53.3	0.00
	Receiving water	12.5%	50.0	50.0	0.00
Fecundity NOEC	Reference toxicant	18.8%	-[4]	75.0	25.0
	Effluent	25%	62.5	25.0	12.5
	Receiving water	9.38%	-[4]	66.7	33.3

[1] From EPA's WET Interlaboratory Variability Study (USEPA, 2001a; USEPA, 2001b).
[2] Percent of values at one concentration interval above or below the median. Adding this percentage to the percent of values at the median yields the percent of values within one concentration interval of the median.
[3] Percent of values two or more concentration intervals above or below the median.
[4] The median NOEC fell between test concentrations, so no test results fell precisely on the median.

SECTION 15

TEST METHOD

SEA URCHIN, *ARBACIA PUNCTULATA*, FERTILIZATION TEST METHOD 1008.0

15.1 SCOPE AND APPLICATION

15.1.1 This method, adapted in part from USEPA (1987e), measures the toxicity of effluents and receiving water to the gametes of the sea urchin, *Arbacia punctulata*, during a 1 h and 20 min exposure. The purpose of the sperm cell toxicity test is to determine the concentration of a test substance that reduces fertilization of exposed gametes relative to that of the control.

15.1.2 Detection limits of the toxicity of an effluent or chemical substance are organism dependent.

15.1.3 Brief excursions in toxicity may not be detected using 24-h composite samples. Also, because of the long sample collection period involved in composite sampling and because the test chambers are not sealed, highly volatile and highly degradable toxicants in the source may not be detected in the test.

15.1.4 This test is commonly used in one of two forms: (1) a definitive test, consisting of a minimum of five effluent concentrations and a control, and (2) a receiving water test(s), consisting of one or more receiving water concentrations and a control.

15.2 SUMMARY OF METHOD

15.2.1 The method consists of exposing dilute sperm suspensions to effluents or receiving waters for 1 h. Eggs are then added to the sperm suspensions. Twenty minutes after the eggs are added, the test is terminated by the addition of preservative. The percent fertilization is determined by microscopic examination of an aliquot from each treatment. The test results are reported as the concentration of the test substance which causes a statistically significant reduction in fertilization.

15.3 INTERFERENCES

15.3.1 Toxic substances may be introduced by contaminants in dilution water, glassware, sample hardware, and testing equipment (see Section 5, Facilities, Equipment, and Supplies).

15.3.2 Improper effluent sampling and handling may adversely affect test results (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

15.4 SAFETY

15.4.1 See Section 3, Health and Safety.

15.5. APPARATUS AND EQUIPMENT

15.5.1 Facilities for holding and acclimating test organisms.

15.5.2 Laboratory sea urchins, *Arbacia punctulata*, culture unit -- See Subsection 15.6.19, culturing methods below and Section 4, Quality Assurance. To test effluent or receiving water toxicity, sufficient eggs and sperm must be available.

15.5.3 Samplers -- automatic sampler, preferably with sample cooling capability, that can collect a 24-h composite sample of 5 L.

15.5.4 Environmental chamber or equivalent facility with temperature control (20 ± 1°C).

15.5.5 Water purification system -- Millipore Milli-Q®, deionized water (DI) or equivalent.

15.5.6 Balance -- Analytical, capable of accurately weighing to 0.00001 g.

15.5.7 Reference weights, Class S -- for checking performance of balance. Weights should bracket the expected weights of materials to be weighed.

15.5.8 Air pump -- for oil-free air supply.

15.5.9 Air lines, and air stones -- for aerating water containing adults, or for supplying air to test solutions with low DO.

15.5.10 Vacuum suction device -- for washing eggs.

15.5.11 Meters, pH and DO -- for routine physical and chemical measurements.

15.5.12 Standard or micro-Winkler apparatus -- for determining DO (optional).

15.5.13 Transformer, 10-12 Volt, with steel electrodes -- for stimulating release of eggs and sperm.

15.5.14 Centrifuge, bench-top, slant-head, variable speed -- for washing eggs.

15.5.15 Fume hood -- to protect the analyst from formaldehyde fumes.

15.5.16 Dissecting microscope -- for counting diluted egg stock.

15.5.17 Compound microscope -- for examining and counting sperm cells and fertilized eggs.

15.5.18 Sedgwick-Rafter counting chamber -- for counting egg stock and examining fertilized eggs.

15.5.19 Hemacytometer, Neubauer -- for counting sperm.

15.5.20 Count register, 2-place -- for recording sperm and egg counts.

15.5.21 Refractometer -- for determining salinity.

15.5.22 Thermometers, glass or electronic, laboratory grade -- for measuring water temperatures.

15.5.23 Thermometers, bulb-thermograph or electronic-chart type -- for continuously recording temperature.

15.5.24 Thermometer, National Bureau of Standards Certified (see USEPA Method 170.1, USEPA, 1979b) -- to calibrate laboratory thermometers.

15.5.25 Ice bucket, covered -- for maintaining live sperm.

15.5.26 Centrifuge tubes, conical -- for washing eggs.

15.5.27 Cylindrical glass vessel, 8-cm diameter -- for maintaining dispersed egg suspension.

15.5.28 Beakers -- six Class A, borosilicate glass or non-toxic plasticware, 1000 mL for making test solutions.

15.5.29 Glass dishes, flat bottomed, 20-cm diameter -- for holding urchins during gamete collection.

15.5.3 Wash bottles -- for deionized water, for rinsing small glassware and instrument electrodes and probes.

15.5.31 Volumetric flasks and graduated cylinders -- Class A, borosilicate glass or non-toxic plastic labware, 10-1000 mL for making test solutions.

15.5.32 Syringes, 1-mL, and 10-mL, with 18 gauge, blunt-tipped needles (tips cut off) -- for collecting sperm and eggs.

15.5.33 Pipets, volumetric -- Class A, 1-100 mL.

15.5.34 Pipets, automatic -- adjustable 1-100 mL.

15.5.35 Pipets, serological -- 1-10 mL, graduated.

15.6.36 Pipet bulbs and fillers -- PROPIPET®, or equivalent.

15.6 REAGENTS AND CONSUMABLE MATERIALS

15.6.1 Sea Urchins, *Arbacia punctulata* minimum 12 of each sex.

15.6.2 Food -- kelp, *Laminaria* sp., or romaine lettuce for the sea urchin, *Arbacia punctulata*.

15.6.3 Standard salt water aquarium or Instant Ocean Aquarium (capable of maintaining seawater at 15°C) -- with appropriate filtration and aeration system.

15.6.4 Sample containers -- for sample shipment and storage (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

15.6.5 Scintillation vials, 20 mL, disposable -- to prepare test concentrations.

15.6.6 Tape, colored -- for labeling tubes.

15.6.7 Markers, waterproof -- for marking containers, etc.

15.6.8 Parafilm -- to cover tubes and vessels containing test materials.

15.6.9 Gloves, disposable; labcoat and protective eyewear – for personal protection from contamination.

15.6.10 Data sheets (one set per test) -- for data recording (see Figures 1, 2, and 3).

15.6.11 Acetic acid, 10%, reagent grade, in seawater -- for preparing killed sperm dilutions.

15.6.12 Formalin, 1%, in 2 mL of seawater -- for preserving eggs (see Subsection 15.10.9 Termination of the Test).

15.6.13 Buffers, pH 4, pH 7, and pH 10 (or as per instructions of instrument manufacturer) -- for standards and calibration check (see USEPA Method 150.1, USEPA, 1979b).

15.6.14 Membranes and filling solutions for dissolved oxygen probe (see USEPA Method 360.1, USEPA, 1979b), or reagents -- for modified Winkler analysis.

15.6.15 Laboratory quality assurance samples and standards -- for the above methods.

15.6.16 Reference toxicant solutions -- see Section 4, Quality Assurance.

15.6.17 Reagent water -- defined as distilled or deionized water that does not contain substances which are toxic to the test organisms.

15.6.18 Effluent, receiving water, and dilution water -- see Section 7, Dilution Water, and Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests.

15.6.18.1 Saline test and dilution water -- the salinity of the test water must be 30‰. The salinity should vary by no more than ± 2‰ among the replicates. If effluent and receiving water tests are conducted concurrently, the salinities of these tests should be similar.

15.6.18.2 The overwhelming majority of industrial and sewage treatment effluents entering marine and estuarine systems contain little or no measurable salts. Exposure of sea urchin eggs and sperm to these effluents will require adjustments in the salinity of the test solutions. It is important to maintain a constant salinity across all treatments. In addition it may be desirable to match the test salinity with that of the receiving water. Two methods are available to adjust salinities – hypersaline brine (HSB) derived from natural seawater or artificial sea salts.

15.6.18.3 Hypersaline brine (HSB): HSB has several advantages that make it desirable for use in toxicity testing. It can be made from any high quality, filtered seawater by evaporation, and can be added to the effluent or to deionized water to increase the salinity. HSB derived from natural seawater contains the necessary trace metals, biogenic colloids, and some of the microbial components necessary for adequate growth, survival, and/or reproduction of marine and estuarine organisms, and may be stored for prolonged periods without any apparent degradation. However, if 100‰ HSB is used as a diluent, the maximum concentration of effluent that can be tested will be 80% at 20‰ salinity and 70% at 30‰ salinity.

15.6.18.3.1 The ideal container for making HSB from natural seawater is one that (1) has a high surface to volume ratio, (2) is made of a noncorrosive material, and (3) is easily cleaned (fiberglass containers are ideal). Special care should be used to prevent any toxic materials from coming in contact with the seawater being used to generate the brine. If a heater is immersed directly into the seawater, ensure that the heater materials do not corrode or leach any substances that would contaminate the brine. One successful method used is a thermostatically controlled heat exchanger made from fiberglass. If aeration is utilized, use only oil-free air compressors to prevent contamination.

15.6.18.3.2 Before adding seawater to the brine generator, thoroughly clean the generator, aeration supply tube, heater, and any other materials that will be in direct contact with the brine. A good quality biodegradable detergent should be used, followed by several (at least three) thorough deionized water rinses.

15.6.18.3.3 High quality (and preferably high salinity) seawater should be filtered to at least 10 µm before placing into the brine generator. Water should be collected on an incoming tide to minimize the possibility of contamination.

15.6.18.3.4 The temperature of the seawater is increased slowly to 40°C. The water should be aerated to prevent temperature stratification and to increase water evaporation. The brine should be checked daily (depending on the volume being generated) to ensure that the salinity does not exceed 100‰ and that the temperature does not exceed 40°C. Additional seawater may be added to the brine to obtain the volume of brine required.

15.6.18.3.5 After the required salinity is attained, the HSB should be filtered a second time through a 1 mm filter and poured directly into portable containers, (20 L cubitainers or polycarbonate water cooler jugs are suitable). The containers should be capped and labeled with the date the brine was generated and its salinity. Containers of HSB should be stored in the dark and maintained under room temperature until used.

15.6.18.3.6 If a source of HSB is available, test solutions can be made by following the directions below. Thoroughly mix together the deionized water and brine before mixing in the effluent.

15.6.18.3.7 Divide the salinity of the HSB by the expected test salinity to determine the proportion of deionized water to brine. For example, if the salinity of the brine is 100‰ and the test is to be conducted at 30‰, 100‰ divided by 30‰ = 3.3. The proportion of brine is 1 part in 3.3 (one part brine to 2.3 parts deionized water). To make 1 L of seawater at 30‰ salinity from a HSB of 100‰, 300 mL of brine and 700 mL of deionized water are required.

15.6.18.3.8 Table 1 illustrates the preparation of test solutions at 30‰ if they are made by combining effluent (0‰), deionized water and HSB (100‰), or FORTY FATHOMS® sea salts.

15.6.18.4 Artificial sea salts: FORTY FATHOMS® brand sea salts have been used successfully at the EMSL-Cincinnati, for long-term (6-12 months) maintenance of stock cultures of sexually mature sea urchins and to perform the sea urchin fertilization test. GP2 seawater formulation (Table 2) has also been used successfully at ERL-Narragansett, RI.

15.6.18.4.1 Synthetic sea salts are packaged in plastic bags and mixed with deionized water or equivalent. The instructions on the package of sea salts should be followed carefully, and the salts should be mixed in a separate container -- not in the culture tank. The deionized water used in hydration should be in the temperature range of 21-26°C. Seawater made from artificial sea salts is conditioned (Spotte, 1973; Spotte, et al., 1984; Bower, 1983).

15.6.18.4.2 The GP2 reagent grade chemicals (Table 2) should be mixed with deionized (DI) water or its equivalent in a container other than the culture or testing tanks. The deionized water used for hydration should be between 21-26°C. The artificial seawater must be conditioned (aerated) for 24 h before use as the testing medium. If the solution is to be autoclaved, sodium bicarbonate is added after the solution has cooled. A stock solution of sodium bicarbonate is made up by dissolving 33.6 g $NaHCO_3$ in 500 mL of deionized water. Add 2.5 mL of this stock solution for each liter of the GP2 artificial seawater.

TABLE 1. PREPARATION OF TEST SOLUTIONS AT A SALINITY OF 30‰ USING NATURAL SEAWATER, HYPERSALINE BRINE, OR ARTIFICIAL SEA SALTS [1]

		Solutions To Be Combined	
Effluent Solution	Effluent Concentration (%)	Volume of Effluent Solution (mL)	Volume of Diluent Seawater (30‰) (mL)
1	100[1]	840	—
2	50	420	Solution 1 + 420
3	25	420	Solution 2 + 420
4	12.5	420	Solution 3 + 420
5	6.25	420	Solution 4 + 420
Control	0.0		420
Total			2080

[1] This illustration assumes: (1) the use of 5 mL of test solution in each of four replicates (total of 20 mL) for the control and five concentrations of effluent, (2) an effluent dilution factor of 0.5, (3) the effluent lacks appreciable salinity, and (4) 400 mL of each test concentration is used for chemical analysis. A sufficient initial volume (840 mL) of effluent is prepared by adjusting the salinity to 30‰. In this example, the salinity is adjusted by adding artificial sea salts to the 100% effluent, and preparing a serial dilution using 30‰ seawater (natural seawater, hypersaline brine, or artificial seawater). Stir solutions 1 h to ensure that the salts dissolve. The salinity of the initial 840 mL of 100% effluent is adjusted to 30‰ by adding 25.2 g of dry artificial sea salts (FORTY FATHOMS®). Test concentrations are then made by mixing appropriate volumes of salinity adjusted effluent and 30‰ salinity dilution water to provide 840 mL of solution for each concentration. If hypersaline brine alone (100‰) is used to adjust the salinity of the effluent, the highest concentration of effluent that could be tested would be 70% at 30‰ salinity.

TABLE 2. REAGENT GRADE CHEMICALS USED IN THE PREPARATION OF GP2 ARTIFICIAL SEAWATER FOR THE SEA URCHIN, *ARBACIA PUNCTULATA*, TOXICITY TEST[1,2,3]

Compound	Concentration (g/L)	Amount (g) Required for 20 L
NaCl	21.03	420.6
Na_2SO_4	3.52	70.4
KCl	0.61	12.2
KBr	0.088	1.76
$Na_2B_4O_7 \cdot 10\ H_2O$	0.034	0.68
$MgCl_2 \cdot 6\ H_2O$	9.50	190.0
$CaCl_2 \cdot 2\ H_2O$	1.32	26.4
$SrCl_2 \cdot 6\ H_2O$	0.02	0.400
$NaHCO_3$	0.17	3.40

[1] Modified GP2 from Spotte et al. (1984).
[2] The constituent salts and concentrations were taken from USEPA (l990b). The salinity is 30.89 g/L.
[3] GP2 can be diluted with deionized (DI) water to the desired test salinity.

15.6.19 TEST ORGANISMS, SEA URCHINS, *ARBACIA PUNCTULATA*

15.6.19.1 Adult sea urchins, *Arbacia punctulata*, can be obtained from commercial suppliers. After acquisition, the animals are sexed by briefly stimulating them with current from a 12 V transformer. Electrical stimulation causes the immediate release of masses of gametes that are readily identifiable by color -- the eggs are red, and the sperm are white.

15.6.19.2 The sexes are separated and maintained in 20-L, aerated fiberglass tanks, each holding about 20 adults. The tanks are supplied continuously (approximately 5 L/min) with filtered natural seawater, or salt water prepared from commercial sea salts is recirculated. The animals are checked daily and any obviously unhealthy animals are discarded.

15.6.19.3 The culture unit should be maintained at 15 ± 3°C, with a water temperature control device.

15.6.19.4 The food consists of kelp, *Laminaria* sp., gathered from known uncontaminated zones or obtained from commercial supply houses whose kelp comes from known uncontaminated areas, or romaine lettuce. Fresh food is introduced into the tanks at approximately one week intervals. Decaying food is removed as necessary. Ample supplies of food should always be available to the sea urchins.

15.6.19.5 Natural or artificial seawater with a salinity of 30‰ is used to maintain the adult animals, for all washing and dilution steps, and as the control water in the tests (see Subsection 15.6.18).

15.6.19.6 Adult male and female animals used in field studies are transported in separate or partitioned insulated boxes or coolers packed with wet kelp or paper toweling. Upon arrival at the field site, aquaria (or a single partitioned

aquarium) are filled with control water, loosely covered with a styrofoam sheet and allowed to equilibrate to 15°C before animals are added. Healthy animals will attach to the kelp or aquarium within hours.

15.6.19.7 To successfully maintain about 25 adult animals for 7 days at a field site, a screen-partitioned, 40-L glass aquarium using aerated, recirculating, clean saline water (30‰) and a gravel bed filtration system, is housed within a water bath, such as FORTY FATHOMS® or equivalent (15°C). The inner aquarium is used to avoid contact of animals and water bath with cooling coils.

15.7 EFFLUENT AND RECEIVING WATER COLLECTION, PRESERVATION, AND STORAGE

15.7.1 See Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sampling Preparation for Toxicity Tests.

15.8 CALIBRATION AND STANDARDIZATION

15.8.1 See Section 4, Quality Assurance.

15.9 QUALITY CONTROL

15.9.1 See Section 4, Quality Assurance.

15.10 TEST PROCEDURES

15.10.1 TEST SOLUTIONS

15.10.1.1 Receiving Waters

15.10.1.1.1 The sampling point is determined by the objectives of the test. At estuarine and marine sites, samples are usually collected at mid-depth. Receiving water toxicity is determined with samples used directly as collected or with samples passed through a 60 µm NITEX® filter and compared without dilution against a control. Using four replicate chambers per test, each containing 5 mL, and 400 mL for chemical analysis, would require approximately 420 mL or more of sample per test.

15.10.1.2 Effluents

15.10.1.2.1 The selection of the effluent test concentrations should be based on the objectives of the study. A dilution factor of 0.5 is commonly used. A dilution factor of 0.5 provides precision of ± 100%, and testing of concentrations between 6.25% and 100% effluent using only five effluent concentrations (6.25%, 12.5%, 25%, 50%, and 100%). Test precision shows little improvement as dilution factors are increased beyond 0.5 and declines rapidly if smaller dilution factors are used. **Therefore, USEPA recommends the use of the ≥ 0.5 dilution factor.** If 100‰ HSB is used as a diluent, the maximum concentration of effluent that can be tested will be 80% at 20‰ and 70% at 30‰ salinity.

15.10.1.2.2 If the effluent is known or suspected to be highly toxic, a lower range of effluent concentrations should be used (such as 25%, 12.5%, 6.25%, 3.12%, and 1.56%).

15.10.1.2.3 Just prior to test initiation (approximately 1 h), a sufficient quantity of the sample to make the test solutions should be adjusted to the test temperature (20 ± 1°C) and maintained at that temperature during the addition of dilution water.

15.10.1.2.4 The test should begin as soon as possible, preferably within 24 h of sample collection. The maximum holding time following retrieval of the sample from the sampling device should not exceed 36 h for off-site toxicity tests unless permission is granted by the permitting authority. In no case should the sample be used for the first time in a test more than 72 h after sample collection (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Test).

15.10.1.2.5 Effluent dilutions should be prepared for all replicates in each treatment in one beaker to minimize variability among the replicates. The test chambers are labeled with the test concentration and replicate number. Dispense into the appropriate effluent dilution chamber.

15.10.1.3 Dilution Water

15.10.1.3.1 Dilution water may be uncontaminated natural seawater (receiving water), HSB prepared from natural seawater, or artificial seawater FORTY FATHOMS® or GP2 sea salts (see Table 2 and Section 7, Dilution Water). Prepare 3 L of control water at 30‰ using HSB or artificial sea salts (see Table 1). This water is used in all washing and diluting steps and as control water in the test. Natural seawater and local waters may be used as additional controls.

15.10.2 COLLECTION OF GAMETES FOR THE TEST

15.10.2.1 Select four females and place in shallow bowls, barely covering the shell with seawater. Stimulate the release of eggs by touching the shell with steel electrodes connected to a 10-12 volt transformer (about 30 seconds each time). Collect the eggs from each female using a 10 mL disposable syringe fitted with an 18-gauge, blunt-tipped needle (tip cut off). Remove the needle from the syringe before adding the eggs to a conical centrifuge tube. Pool the eggs. The egg stock may be held at room temperature for several hours before use. Note: Eggs should be collected first to eliminate possibility of pre-fertilization.

15.10.2.2 Select four males and place in shallow bowls, barely covering the animals with seawater. Stimulate the release of sperm as described above. Collect the sperm (about 0.25 mL) from each male, using a 1-3 mL disposable syringe fitted with an 18-gauge, blunt-tipped needle. Pool the sperm. Maintain the pooled sperm sample on ice. The sperm must be used in a toxicity test within 1 h of collection.

15.10.3 PREPARATION OF SPERM DILUTION FOR USE IN THE TEST

15.10.3.1 Using control water, dilute the pooled sperm sample to a concentration of about 5 X 10^7 sperm/mL (SPM). Estimate the sperm concentration as described below:

1. Make a sperm dilutions of 1:50, 1:100, 1:200, and 1:400, using 30‰ seawater, as follows:

    a. Add 400 µL of collected sperm to 20 mL of seawater in Vial A. Mix by gentle pipetting using a 5-mL pipettor, or by inversion;
    b. Add 10 mL of sperm suspension from Vial A to 10 mL of seawater in Vial B. Mix by gentle pipetting using a 5-mL pipettor, or by inversion;
    c. Add 10 mL of sperm suspension from Vial B to 10 mL of seawater in Vial C. Mix by gentle pipetting using a 5-mL pipettor, or by inversion;
    d. Add 10 mL of sperm suspension from Vial C to 10 mL of seawater in Vial D. Mix by gentle pipetting using a 5-mL pipettor, or by inversion;
    e. Discard 10 mL from Vial D. (The volume of all suspensions is 10 mL).

2. Make a 1:2000 killed sperm suspension and determine the SPM.

    a. Add 10 mL 10% acetic acid in seawater to Vial C. Cap Vial C and mix by inversion.
    b. Add 1 mL of killed sperm from Vial C to 4 mL of seawater in Vial E. Mix by gentle pipetting with a 4-mL pipettor.
    c. Add sperm from Vial E to both sides of the Neubauer hemacytometer. Let the sperm settle 15 min.
    d. Count the number of sperm in the central 400 squares on both sides of the hemacytometer using a compound microscope (100X). Average the counts from the two sides.
    e. SPM in Vial E = 10^4 x average count.

3. Calculate the SPM in all other suspensions using the SPM in Vial E above:

   SPM in Vial A = 40 x SPM in Vial E
   SPM in Vial B = 20 x SPM in Vial E
   SPM in Vial D = 5 x SPM in Vial E
   SPM in original sperm sample = 2000 x SPM in Vial E

4. Dilute the sperm suspension with a SPM greater than 5 x 10^7 SPM to 5 x 10^7 SPM.

   Actual SPM/(5 x 10^7) = dilution factor (DF)

   [(DF) x 10] - 10 = mL of seawater to add to vial.

5. Confirm the sperm count by sampling from the test stock. Add 0.1 mL of test stock to 9.9 mL of 10% acetic acid in seawater, and count with the hemacytometer. The count should average 50 ± 5.

15.10.4 PREPARATION OF EGG SUSPENSION FOR USE IN THE TEST Note: The egg suspension may be prepared during the 1-h sperm exposure.

15.10.4.1 Wash the pooled eggs three times using control water with gentle centrifugation (500xg for 3 minutes using a tabletop centrifuge). If the wash water becomes red, the eggs have lysed and must be discarded.

15.10.4.2 Dilute the egg stock, using control water, to about 2000 eggs/mL.

1. Transfer the eggs to a glass beaker containing 200 mL of control water ("egg stock").

2. Mix the egg stock using an air-bubbling device. Using a wide-mouth pipet tip, transfer 1 mL of eggs from the egg stock to a vial containing 9 mL of control water. (This vial contains an egg suspension diluted 1:10 from egg stock).

3. Mix the contents of the vial by inversion. Using a wide-mouth pipet tip, transfer 1 mL of eggs from the vial to a Sedgwick-Rafter counting chamber. Count all eggs in the chamber using a dissecting microscope at 24X "egg count".

4. Calculate the concentration of eggs in the stock. Eggs/mL = 10X (egg count). Dilute the egg stock to 2000 eggs/mL by the formula below.

   a. If the egg count is equal to or greater than 200:
   (egg count) - 200 = volume (mL) of control water to add to egg stock.
   b. If the egg count is less than 200, allow the eggs to settle and remove enough control water to concentrate the eggs to greater than 200, repeat the count, and dilute the egg stock as in a. above. NOTE: It requires 24 mL of a egg stock solution for each test with a control and five exposure concentrations.
   c. Transfer 1 mL of the diluted egg stock to a vial containing 9 mL of control water. Mix well, then transfer 1 mL from the vial to a Sedgwick-Rafter counting chamber. Count all eggs using a dissecting microscope. Confirm that the final egg count = 2000/mL (± 200).

15.10.5 LIGHT, PHOTOPERIOD, SALINITY AND TEMPERATURE

15.10.5.1 The light quality and intensity should be at ambient laboratory levels 10-20 µE/m^2/s (50-100 ft-c) with a photoperiod of 16 h light and 8 h darkness. The water temperature in the test chambers should be maintained at 20 ± 1°C. The test salinity should be in the range of 28 to 32‰. The salinity should vary by no more that ± 2‰ among the chambers on a given day. If effluent and receiving water tests are conducted concurrently, the salinities of these tests should be similar.

15.10.6 DISSOLVED OXYGEN (DO) CONCENTRATION

15.10.6.1 Aeration may affect the toxicity of effluent and should be used only as a last resort to maintain a satisfactory DO. The DO concentrations should be measured on new solutions at the start of the test (Day 0). The DO should not fall below 4.0 mg/L (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests). If it is necessary to aerate, all treatments and the control should be aerated. The aeration rate should not exceed 100 bubbles/minute, using a pipet with a 1-2 mm orifice, such as a 1 mL KIMAX® serological pipet, or equivalent.

15.10.7 OBSERVATIONS DURING THE TEST

15.10.7.1 Routine Chemical and Physical Observations

15.10.7.1.1 DO is measured at the beginning of the exposure period in one test chamber at each test concentration and in the control.

15.10.7.1.2 Temperature, pH, and salinity are measured at the beginning of the exposure period in one test chamber at each concentration and in the control. Temperature should also be monitored continuously observed and recorded daily for at least two locations in the environmental control system or the samples. Temperature should be measured in a sufficient number of test chambers at least at the end of the test to determine temperature variation in environmental chamber.

15.10.7.1.3 The pH is measured in the effluent sample each day before new test solutions are made.

15.10.7.1.4 Record all the measurements on the data sheet.

15.10.7.2 Routine Biological Observations

15.10.7.2.1 Fertilization will be determined by the presence of a fertilization membrane surrounding the egg.

15.10.8 START OF THE TEST

15.10.8.1 Effluent/receiving water samples are adjusted to salinity of 30‰. Four replicates are prepared for each test concentration, using 5 mL of solution in disposable liquid scintillation vials. A 50% (0.5) concentration series can be prepared by serially diluting test concentrations with control water. Sufficient test solution is prepared at each effluent concentration to provide additional volume for chemical analyses, at the high, medium, and low test concentrations.

15.10.8.2 All test samples are equilibrated at 20°C ± 1°C before addition of sperm.

15.10.8.3 Within 1 h of collection add 100 µL of appropriately diluted sperm to each test vial. Record the time of sperm addition.

15.10.8.4 Incubate all test vials at 20 ± 1°C for 1 h.

15.10.8.5 Mix the diluted egg suspension (2000 eggs/mL), using gentle bubbling. Add 1 mL of diluted egg suspension to each test vial using a wide mouth pipet tip. Incubate 20 min at 20 ± 1°C.

15.10.9 TERMINATION OF THE TEST

15.10.9.1 Terminate the test and preserve the samples by adding 2 mL of 1% formalin in seawater to each vial.

15.10.9.2 Vials should be evaluated within 48 hours.

15.10.9.3 To determine fertilization, transfer about 1 mL eggs from the bottom of a test vial to a Sedgwick-Rafter counting chamber. Observe the eggs using a compound microscope (100X). Count between 100 and 200 eggs/sample. Record the number counted and the number unfertilized. Fertilization is indicated by the presence of a fertilization membrane surrounding the egg. NOTE: adjustment of the microscope to obtain proper contrast may be required to observe the fertilization membrane. Because samples are fixed in formalin, a ventilation hood is set up surrounding the microscope to protect the analyst from prolonged exposure to formaldehyde fumes.

15.11 SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA

15.11.1 A summary of test conditions and test acceptability criteria is listed in Table 3.

15.12 ACCEPTABILITY OF TEST RESULTS

15.12.1 The sperm:egg ratio routinely employed must result in fertilization of 70%-90% of the eggs in the control chambers.

TABLE 3. SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA FOR SEA URCHIN, *ARBACIA PUNCTULATA*, FERTILIZATION TEST WITH EFFLUENT AND RECEIVING WATERS (TEST METHOD 1008.0)[1]

1	Test type:	Static (required)
2.	Salinity:	30‰ (± 2‰ of the selected test salinity) (recommended)
3.	Temperature:	20 ± 1°C (recommended) Test temperatures must not deviate (i.e., maximum minus minimum temperature) by more than 3°C during the test (required)
4.	Light quality:	Ambient laboratory light during test preparation (recommended)
5.	Light intensity:	10-20 μE/m^2/s, or 50-100 ft-c (Ambient laboratory levels) (recommended)
6.	Test chamber size:	Disposable (glass) liquid scintillation vials (20 mL capacity), presoaked in control water (recommended)
7.	Test solution volume:	5 mL (recommended)
8.	No. of sea urchins:	Pooled sperm from four males and pooled eggs from four females are used per test (recommended)
9.	No. egg and sperm cells per chamber:	About 2,000 eggs and 5,000,000 sperm cells per vial (recommended)
10.	No. replicate chambers per concentration:	4 (required minimum)
11.	Dilution water:	Uncontaminated source of natural seawater; deionized water mixed with hypersaline brine or artificial sea salts (HW MARINEMIX®, FORTY FATHOMS®, GP2, or equivalent) (available options)
12.	Test concentrations:	Effluents: 5 and a control (required minimum) Receiving waters: 100% receiving water (or minimum of 5) and a control (recommended)

[1] For the purposes of reviewing WET test data submitted under NPDES permits, each test condition listed above is identified as required or recommended (see Subsection 10.2 for more information on test review). Additional requirements may be provided in individual permits, such as specifying a given test condition where several options are given in the method.

TABLE 3. SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA FOR SEA URCHIN, *ARBACIA PUNCTULATA*, FERTILIZATION TEST WITH EFFLUENT AND RECEIVING WATERS (TEST METHOD 1008.0) (CONTINUED)

13. Dilution factor:	Effluents: ≥0.5 (recommended) Receiving waters: None or ≥0.5 (recommended)
14. Test duration:	1 h and 20 min (required)
15. Endpoint:	Fertilization of sea urchin eggs (required)
16. Test acceptability criteria:	70% - 90% egg fertilization in controls (required)
17. Sampling requirements:	For on-site tests, one sample collected at test initiation, and used within 24 h of the time it is removed from the sampling device. For off-site tests, holding time must not exceed 36 h before first use (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests, Subsection 8.5.4) (required)
18. Sample volume required:	1 L per test (recommended)

15.13 DATA ANALYSIS

15.13.1 GENERAL

15.13.1.1 Tabulate and summarize the data. Calculate the proportion of fertilized eggs for each replicate. A sample set of test data is listed in Table 4.

15.13.1.2 The statistical tests described here must be used with a knowledge of the assumptions upon which the tests are contingent. The assistance of a statistician is recommended for analysts who are not proficient in statistics.

TABLE 4. DATA FROM SEA URCHIN, *ARBACIA PUNCTULATA,* FERTILIZATION TEST

Copper Concentration (µg/L)	Replicate	No. of Eggs Counted	No. of Eggs Fertilized	Proportion Fertilized
Control	A	100	85	0.85
	B	100	78	0.78
	C	100	87	0.87
2.5	A	100	81	0.81
	B	100	65	0.65
	C	100	71	0.71
5.0	A	100	63	0.63
	B	100	74	0.74
	C	100	78	0.78
10.0	A	100	63	0.63
	B	100	66	0.66
	C	100	51	0.51
20.0	A	100	41	0.41
	B	100	41	0.41
	C	100	37	0.37
40.0	A	100	12	0.12
	B	100	30	0.30
	C	100	26	0.26

[1] Tests performed by Dennis M. McMullen, Technology Applications, Inc., EMSL, Cincinnati, OH.

15.13.1.3 The endpoints of toxicity tests using the sea urchin are based on the reduction in proportion of eggs fertilized. The IC25 and the IC50 are calculated using the Linear Interpolation Method (see Section 9, Chronic Toxicity Test Endpoints and Data Analysis). LOEC and NOEC values for fecundity are obtained using a hypothesis testing approach such as Dunnett's Procedure (Dunnett, 1955) or Steel's Many-one Rank Test (Steel, 1959; Miller, 1981) (see Section 9). Separate analyses are performed for the estimation of the LOEC and NOEC endpoints and for the estimation of IC25 and IC50. See the Appendices for examples of the manual computations, and examples of data input and program output.

15.13.2 EXAMPLE OF ANALYSIS OF SEA URCHIN, *ARBACIA PUNCTULATA*, FERTILIZATION DATA

15.13.2.1 Formal statistical analysis of the fertilization data is outlined in Figure 4. The response used in the analysis is the proportion of fertilized eggs in each test or control chamber. Separate analyses are performed for the estimation of the NOEC and LOEC endpoints and for the estimation of the IC25 and IC50 endpoints. Concentrations at which there are no eggs fertilized in any of the test chambers are excluded from statistical analysis of the NOEC and LOEC, but included in the estimation of the IC25 and IC50.

15.13.2.2 For the case of equal numbers of replicates across all concentrations and the control, the evaluation of the NOEC and LOEC endpoints is made via a parametric test, Dunnett's Procedure, or a nonparametric test, Steel's Many-one Rank Test, on the arc sine square root transformed data. Underlying assumptions of Dunnett's Procedure, normality and homogeneity of variance, are formally tested. The test for normality is the Shapiro-Wilk's Test, and

Bartlett's Test is used to test for homogeneity of variance. If either of these tests fails, the nonparametric test, Steel's Many-one Rank Test, is used to determine the NOEC and LOEC endpoints. If the assumptions of Dunnett's Procedure are met, the endpoints are estimated by the parametric procedure.

15.13.2.3 If unequal numbers of replicates occur among the concentration levels tested, there are parametric and nonparametric alternative analyses. The parametric analysis is a t test with the Bonferroni adjustment (see Appendix D). The Wilcoxon Rank Sum Test with the Bonferroni adjustment is the nonparametric alternative.

15.13.2.4 Example of Analysis of Fecundity Data

15.13.2.4.1 This example uses toxicity data from a sea urchin, *Arbacia punctulata*, fertilization test performed with copper. The response of interest is the proportion of fertilized eggs, thus each replicate must first be transformed by the arc sine square root transformation procedure described in Appendix B. The raw and transformed data, means and variances of the transformed observations at each copper concentration and control are listed in Table 5. The data are plotted in Figure 5.

15.13.2.5 Test for Normality

15.13.2.5.1 The first step of the test for normality is to center the observations by subtracting the mean of all observations within a concentration from each observation in that concentration. The centered observations are summarized in Table 6.

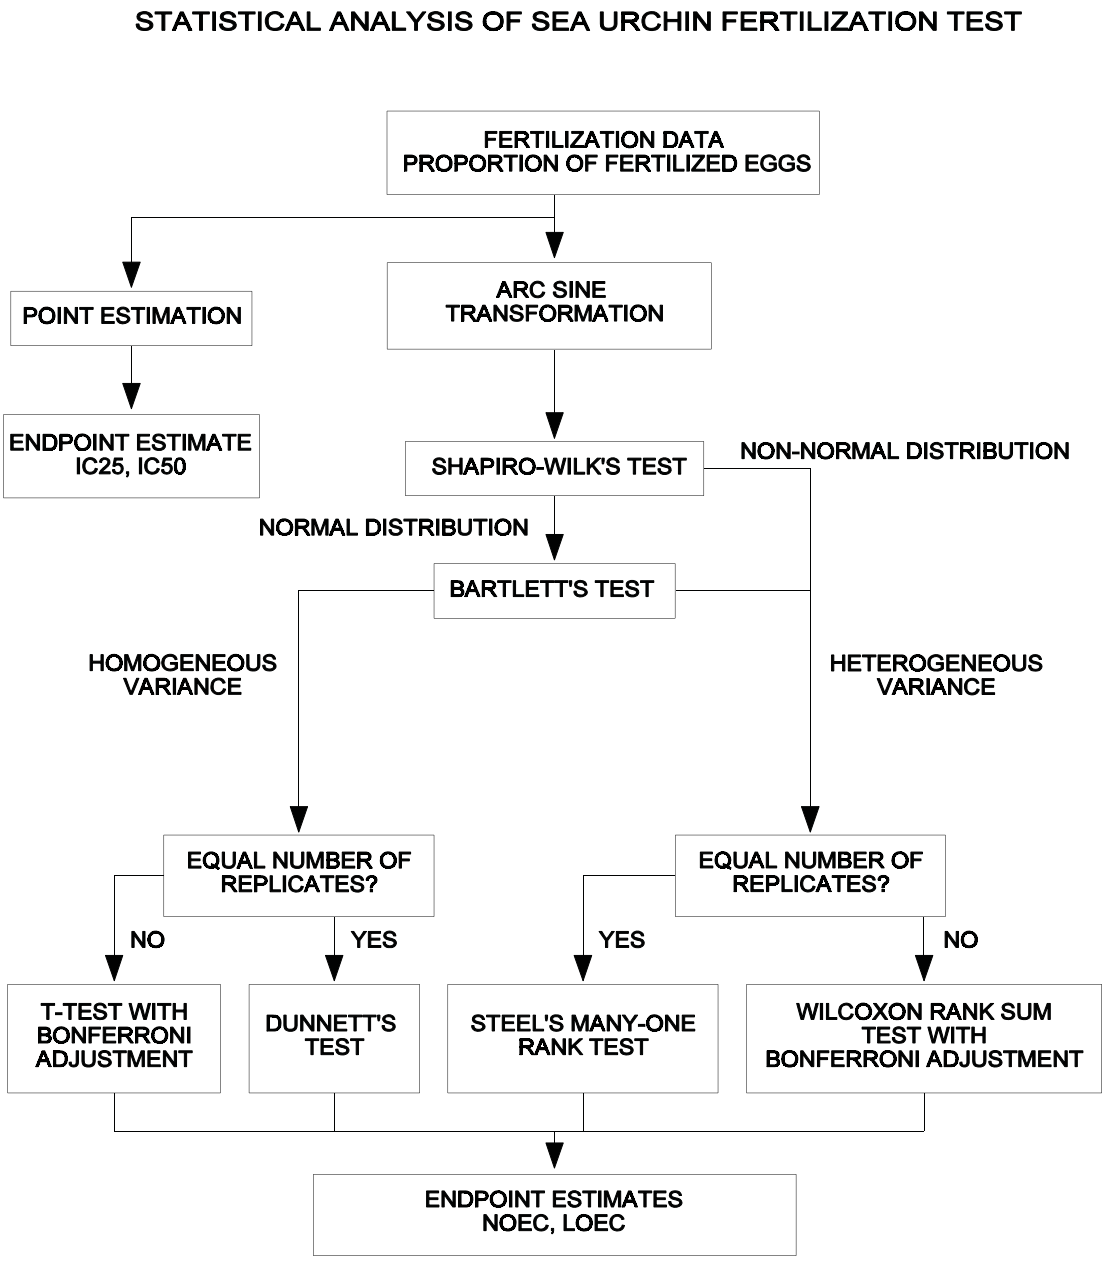

Figure 4. Flowchart for statistical analysis of sea urchin, *Arbacia punctulata*, by point estimation.

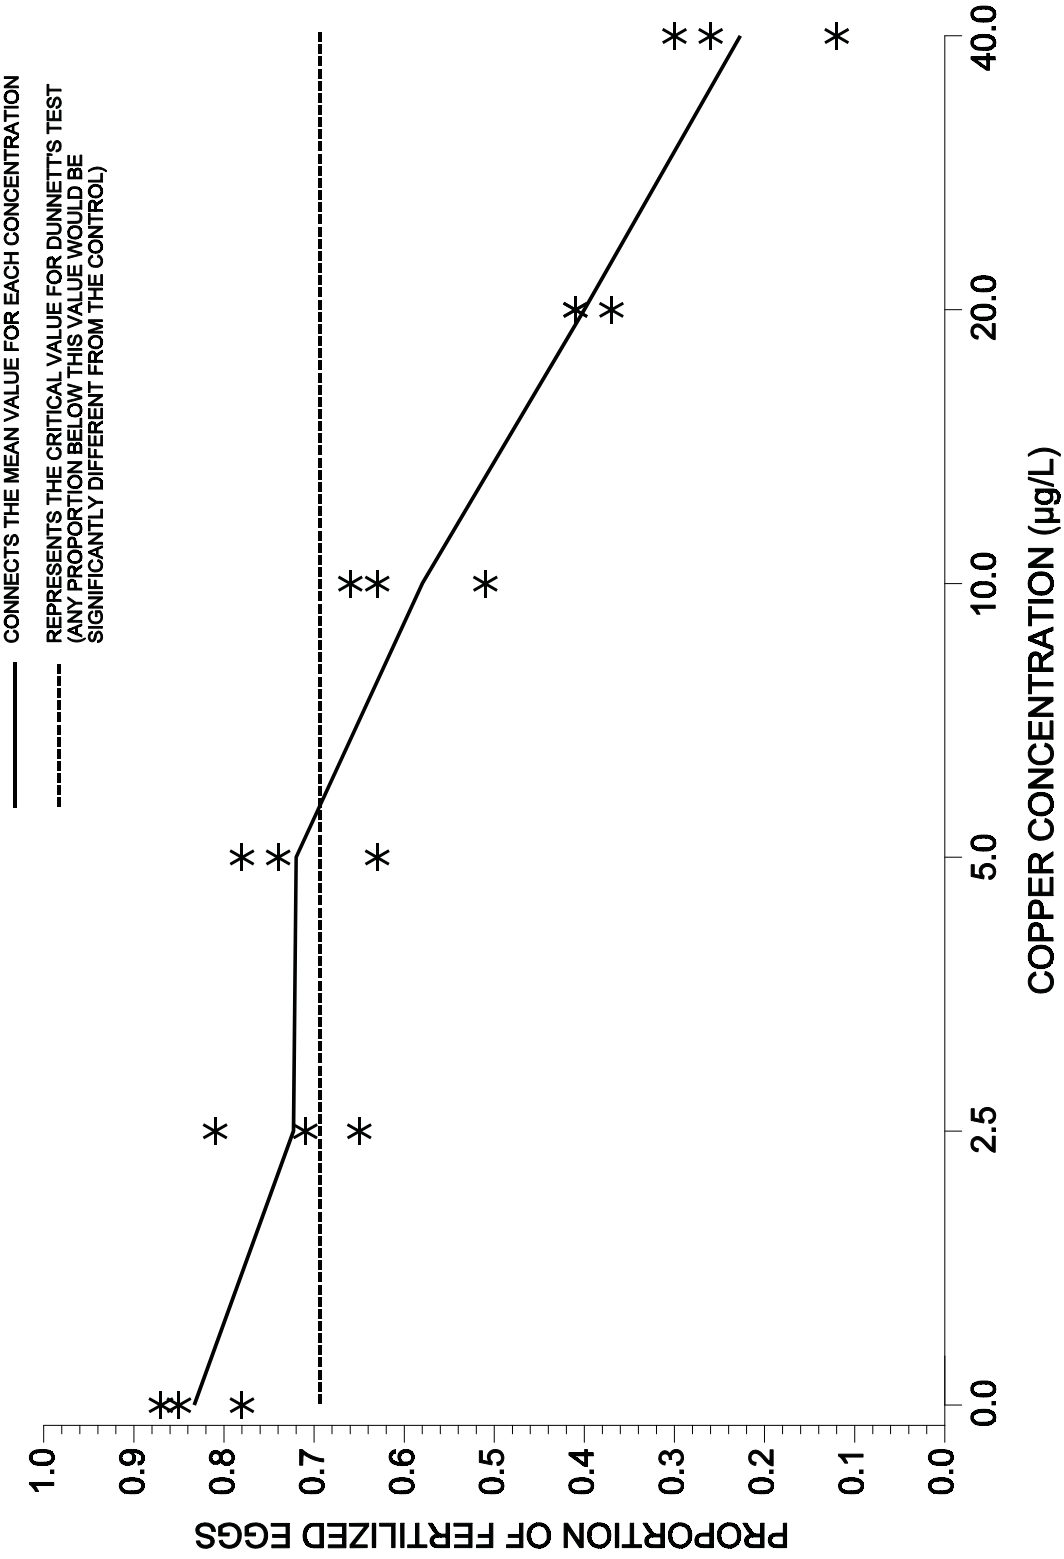

Figure 5. Plot of mean percent of fertilized sea urchin, *Arbacia punctulata*, eggs.

TABLE 5. SEA URCHIN, *ARBACIA PUNCTULATA*, FERTILIZATION DATA

			Copper Concentration (µg/L)				
	Replicate	Control	2.5	5.0	10.0	20.0	40.0

TABLE 6. CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

		Copper Concentration (µg/L)				
Replicate	Control	2.5	5.0	10.0	20.0	40.0
A	0.020	0.100	-0.095	0.030	0.014	-0.136
B	-0.070	-0.082	0.024	0.061	0.014	0.090
C	0.049	-0.018	0.071	-0.092	-0.027	0.045

15.13.2.5.2 Calculate the denominator, D, of the statistic:

$$D = \sum_{i=1}^{n} (X_i - \bar{X})^2$$

Where: X_i = the ith centered observation

$\bar{X}$ = the overall mean of the centered observations

n = the total number of centered observations

15.13.2.5.3 For this set of data, n = 18

$$\bar{X} = \frac{1}{18}(0) = 0$$

$$D = 0.0822$$

15.13.2.5.4 Order the centered observations from smallest to largest

$$X^{(1)} \le X^{(2)} \le \ldots \le X^{(n)}$$

where $X^{(i)}$ denotes the ith ordered observation. The ordered observations for this example are listed in Table 7.

TABLE 7. ORDERED CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

i	$X^{(i)}$	i	$X^{(i)}$
1	-0.136	10	0.020
2	-0.095	11	0.024
3	-0.092	12	0.030
4	-0.082	13	0.045
5	-0.070	14	0.049
6	-0.027	15	0.061
7	-0.018	16	0.071
8	0.014	17	0.090
9	0.014	18	0.100

15.13.2.5.5 From Table 4, Appendix B, for the number of observations, n, obtain the coefficients $a_1, a_2, \ldots a_k$ where k is n/2 if n is even and (n-1)/2 if n is odd. For the data in this example, n = 18 and k = 9. The a_i values are listed in Table 8.

15.13.2.5.6 Compute the test statistic, W, as follows:

$$W = \frac{1}{D}\left[\sum_{i=1}^{k} a_i (X^{(n-i+1)} - X^{(i)})\right]^2$$

The differences, $X^{(n-i+1)} - X^{(i)}$, are listed in Table 8. For the data in this example:

$$W = \frac{1}{0.0822}(0.2782)^2 = 0.942$$

15.13.2.5.7 The decision rule for this test is to compare W as calculated in Subsection 15.13.2.5.6 to a critical value found in Table 6, Appendix B. If the computed W is less than the critical value, conclude that the data are not normally distributed. For the data in this example, the critical value at a significance level of 0.01 and n = 18 observations is 0.858. Since W = 0.942 is greater than the critical value, conclude that the data are normally distributed.

TABLE 8. COEFFICIENTS AND DIFFERENCES FOR SHAPIRO-WILK'S EXAMPLE

i	a_i	$X^{(n-i+1)} - X^{(i)}$	
1	0.4886	0.236	$X^{(18)} - X^{(1)}$

9	0.0163	0.006	$X^{(10)} - X^{(9)}$

15.13.2.6 Test for Homogeneity of Variance

15.13.2.6.1 The test used to examine whether the variation in the proportion of fertilized eggs is the same across all copper concentrations including the control, is Bartlett's Test (Snedecor and Cochran, 1980). The test statistic is as follows:

$$B = \frac{[(\sum_{i=1}^{p} V_i)\ \ln \overline{S}^2 - \sum_{i=1}^{p} V_i\ \ln\ S_i^2]}{C}$$

Where: V_i = degrees of freedom for each copper concentration and control, $V_i = (n_i - 1)$

p = number of levels of copper concentration including the control

n_i = the number of replicates for concentration i.

ln = $\log_e$

i = 1,2, ..., p where p is the number of concentrations including the control

$$\overline{S}^2 = \frac{(\sum_{i=1}^{p} V_i S_i^2)}{\sum_{i=1}^{p} V_i}$$

$$C = 1 + [3(p-1)]^{-1}[\sum_{i=1}^{p} 1/V_i - (\sum_{i=1}^{p} V_i)^{-1}]$$

15.13.2.6.2 For the data in this example (see Table 5), all copper concentrations including the control have the same number of replicates ($n_i = 3$ for all i). Thus, $V_i = 2$ for all i.

15.13.2.6.3 Bartlett's statistic is, therefore:

$$B = [(12)\ln(0.0007) - 2\sum_{i=1}^{p} \ln(S_i^2)]/1.194$$

$$= [12(-4.962) - 2(-31.332)]/1.194$$

$$= 3.122/1.194$$

$$= 2.615$$

15.13.2.6.4 B is approximately distributed as chi-square with p-1 degrees of freedom, when the variances are in fact the same. Therefore, the appropriate critical value for this test, at a significance level of 0.01 with 5 degrees of freedom, is 15.09. Since B = 2.615 is less than the critical value of 15.09, conclude that the variances are not different.

15.13.2.7 Dunnett's Procedure

15.13.2.7.1 To obtain an estimate of the pooled variance for the Dunnett's Procedure, construct an ANOVA table as described in Table 9.

TABLE 9. ANOVA TABLE

Source	df	Sum of Squares (SS)	Mean Square (MS) (SS/df)
Between	p - 1	SSB	S_B^2 = SSB/(p-1)
Within	N - p	SSW	S_W^2 = SSW/(N-p)
Total	N - 1	SST	

Where: p = number of concentration levels including the control

N = total number of observations $n_1 + n_2 \ldots + n_p$

n_i = number of observations in concentration i

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N \qquad \text{Between Sum of Squares}$$

$$SST = \sum_{i=1}^{p} \sum_{j=1}^{n_i} Y_{ij}^2 - G^2/N \qquad \text{Total Sum of Squares}$$

$SSW = SST - SSB$ Within Sum of Squares

G = the grand total of all sample observations, $G = \sum_{i=1}^{p} T_i$

T_i = the total of the replicate measurements for concentration i

Y_{ij} = the jth observation for concentration i (represents the proportion of fertilized eggs for upper concentration i in test chamber j)

15.13.2.7.2 For the data in this example:

$n_1 = n_2 = n_3 = n_4 = n_5 = n_6 = 3$

$N = 18$

$T_1 = Y_{11} + Y_{12} + Y_{13} = 3.458$
$T_2 = Y_{21} + Y_{22} + Y_{23} = 3.060$
$T_3 = Y_{31} + Y_{32} + Y_{33} = 3.036$
$T_4 = Y_{41} + Y_{42} + Y_{43} = 2.660$
$T_5 = Y_{51} + Y_{52} + Y_{53} = 2.044$
$T_6 = Y_{61} + Y_{62} + Y_{63} = 1.469$

$G = T_1 + T_2 + T_3 + T_4 + T_5 + T_6 = 15.727$

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N$$

$= (43.950)/3 - (15.727)^2/18 = 0.909$

$$SST = \sum_{i=1}^{p} \sum_{j=1}^{n_i} Y_{ij}^2 - G^2/N$$

$= 14.732 - (15.727)^2/18 = 0.991$

$SSW = SST - SSB$

$= 0.991 - 0.909 = 0.082$

$S_B^2 = SSB/(p-1) = 0.909/(6-1) = 0.182$

$S_W^2 = SSW/(N-p) = 0.082/(18-6) = 0.007$

15.13.2.7.3 Summarize these calculations in the ANOVA table (Table 10).

TABLE 10. ANOVA TABLE FOR DUNNETT'S PROCEDURE EXAMPLE

Source	df	Sum of Squares (SS)	Mean Square(MS) (SS/df)
Between	5	0.909	0.182
Within	12	0.082	0.007
Total	17	0.991	

15.13.2.7.4 To perform the individual comparisons, calculate the t statistic for each concentration, and control combination as follows:

$$t_i = \frac{(\bar{Y}_1 - \bar{Y}_i)}{S_w\sqrt{(1/n_1) + (1/n_i)}}$$

Where: $\bar{Y}_i$ = mean proportion fertilized eggs for copper concentration i

$\bar{Y}_1$ = mean proportion fertilized eggs for the control

S_W = square root of the within mean square

n_1 = number of replicates for the control

n_i = number of replicates for concentration i

Since we are looking for a decreased response from the control in the proportion of fertilized eggs, the concentration mean is subtracted from the control mean.

15.13.2.7.5 Table 11 includes the calculated t values for each concentration and control combination. In this example, comparing the 2.5 µg/L concentration with the control the calculation is as follows:

$$t_2 = \frac{(1.153 - 1.020)}{[0.084\sqrt{(1/3) + (1/3)}]} = 1.939$$

TABLE 11. CALCULATED T VALUES

Copper Concentration (µg/L)	i	t_i
2.5	2	1.939
5.0	3	2.056
10.0	4	3.878
20.0	5	6.882
40.0	6	9.667

15.13.2.7.6 Since the purpose of this test is to detect a significant decrease in the proportion of fertilized eggs, a one-sided test is appropriate. The critical value for this one-sided test is found in Table 5, Appendix D. For an overall alpha level of 0.05, 12 degrees of freedom for error and five concentrations (excluding the control) the critical value is 2.50. The mean proportion of fertilized eggs for concentration i is considered significantly less than the mean proportion of fertilized eggs for the control if t_i is greater than the critical value. Therefore, the 10.0 µg/L, 20.0 µg/L and 40.0 µg/L concentrations have a significantly lower mean proportion of fertilized eggs than the control. Hence the NOEC is 5.0 µg/L and the LOEC is 10.0 µg/L.

15.13.2.7.7 To quantify the sensitivity of the test, the minimum significant difference (MSD) that can be statistically detected may be calculated:

$$MSD = d\ S_w\sqrt{(1/n_1) + (1/n)}$$

Where: d = the critical value for Dunnett's Procedure

S_W = the square root of the within mean square

n = the common number of replicates at each concentration (this assumes equal replication at each concentration)

n_1 = the number of replicates in the control.

15.13.2.7.8 In this example,

$$MSD = 2.50\,(0.084)\sqrt{(1/3) + (1/3)}$$

$$= 2.50\ (0.084)(0.816)$$

$$= 0.171$$

15.13.2.7.9 The MSD (0.171) is in transformed units. To determine the MSD in terms of proportion of fertilized eggs, carry out the following conversion.

1. Subtract the MSD from the transformed control mean.

$$1.153 - 0.171 = 0.982$$

2. Obtain the untransformed values for the control mean and the difference calculated in step 1 of 15.13.2.7.9.1

$$[\ \text{Sine}\ (1.153)\ ]^2 = 0.835$$

$$[\text{ Sine } (0.982)\ ]^2 = 0.692$$

3. The untransformed MSD (MSD_u) is determined by subtracting the untransformed values from step 2 in 15.13.2.7.9.

$$MSD_u = 0.835 - 0.692 = 0.143$$

15.13.2.7.10 Therefore, for this set of data, the minimum difference in mean proportion of fertilized eggs between the control and any copper concentration that can be detected as statistically significant is 0.143.

15.13.2.7.11 This represents a 17% decrease in the proportion of fertilized eggs from the control.

15.13.2.8 Calculation of the ICp

15.13.2.8.1 The fertilization data in Table 4 are utilized in this example. Table 12 contains the mean proportion of fertilized eggs for each toxicant concentration. As can be seen, the observed means are monotonically non-increasing with respect to concentration. Therefore, it is not necessary to smooth the means prior to calculating the ICp; (see Figure 5 for a plot of the response curve).

15.13.2.8.2 An IC25 and IC50 can be estimated using the Linear Interpolation Method. A 25% reduction in mean proportion of fertilized eggs, compared to the controls, would result in a mean proportion of 0.625, where $M_1(1-p/100) = 0.833(1-25/100)$. A 50% reduction in mean proportion of fertilized eggs, compared to the controls, would result in a mean proportion of 0.417. Examining the means and their associated concentrations (Table 12), the response, 0.625, is bracketed by $C_3 = 5.0$ µg/L copper and $C_4 = 10.0$ µg/L copper. The response, 0.417, is bracketed by $C_4 = 10.0$ µg/L copper and $C_5 = 20.0$ µg/L copper.

TABLE 12. SEA URCHIN, *ARBACIA PUNCTULATA*, MEAN PROPORTION OF FERTILIZED EGGS

Copper Conc. (µg/L)	i	Response Means Y_i (proportion)	Smoothed Mean M_i (proportion)
Control	1	0.833	0.833
2.5	2	0.723	0.723
5.0	3	0.717	0.717
10.0	4	0.600	0.600
20.0	5	0.397	0.397
40.0	6	0.227	0.227

15.13.2.8.3 Using the equation from Section 4.2 in Appendix L, the estimate of the IC25 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j]\ \frac{(C_{(j+1)} - C_j)}{(M_{(j+1)} - M_j)}$$

$$IC25 = 5.0 + [0.833(1 - 25/100) - 0.717]\ \frac{(10.0 - 5.0)}{(0.600 - 0.717)}$$

$$= 8.9 \text{ µg/L.}$$

15.13.2.8.4 Using the equation from Section 4.2 in Appendix L, the estimate of the IC50 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j] \frac{(C_{(j+1)} - C_j)}{(M_{(j+1)} - M_j)}$$

$$IC50 = 10.0 + [0.833(1 - 50/100) - 0.600] \frac{(20.0 - 10.0)}{(0.397 - 0.600)}$$

$$= 19.0 \text{ µg/L.}$$

15.13.2.8.5 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC25 was 8.9286 µg/L. The empirical 95.0% confidence interval for the true mean was 3.3036 µg/L to 14.6025 µg/L. The computer program output for the IC25 for this data set is shown in Figure 6.

15.13.2.8.6 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC50 was 19.0164 µg/L. The empirical 95.0% confidence interval for the true mean was 16.1083 µg/L to 23.6429 µg/L. The computer program output for the IC50 for this data set is shown in Figure 7.

15.14 **PRECISION AND ACCURACY**

15.14.1 PRECISION

15.14.1.1 Single-Laboratory Precision

15.14.1.1.1 Single-laboratory precision data for the reference toxicants, copper (Cu) and sodium dodecyl sulfate (SDS), tested in FORTY FATHOMS® artificial seawater, GP2 artificial seawater, and natural seawater are provided in Tables 13-18. The test results were similar in the three types of seawater. The IC25 and IC50 for the reference toxicants (copper and sodium dodecyl sulfate) are reported in Tables 13-16. The coefficient of variation, based on the IC25, is 28.7% to 54.6% for natural and FORTY FATHOMS® seawater, indicating acceptable precision. The IC50 ranges from 23.3% to 48.2%, showing acceptable precision.

15.14.1.2 Multilaboratory Precision

15.14.1.2.1 No data are available on the multilaboratory precision of the test.

15.14.2 ACCURACY

15.14.2.1 The accuracy of toxicity tests cannot be determined.

SECTION 16

TEST METHOD

RED MACROALGA, *CHAMPIA PARVULA,* SEXUAL REPRODUCTION TEST METHOD 1009.0

16.1 SCOPE AND APPLICATION

16.1.1 CAUTION: The Red Macroalga, *Champia parvula*, Reproduction Test Method 1009.0 is not listed at 40 CFR Part 136 for nationwide use.

16.1.2 This method, adapted in part from USEPA (1987f) measures the effects of toxic substances in effluents and receiving water on the sexual reproduction of the marine red macroalga, *Champia parvula*. The method consists of exposing male and female plants to test substances for two days, followed by a 5-7 day recovery period in control medium, during which the cystocarps mature.

16.1.3 Detection limits of the toxicity of an effluent or chemical substance are organism dependent.

16.1.4 Brief excursions in toxicity may not be detected using 24-h composite samples. Also, because of the long sample collection period involved in composite sampling, highly volatile and highly degradable toxicants present in the source may not be detected in the test.

16.1.5 This test is commonly used in one of two forms: (1) a definitive test, consisting of a minimum of five effluent concentrations and a control, and (2) a receiving water test(s), consisting of one or more receiving water concentrations and a control.

16.2 SUMMARY OF METHOD

16.2.1 Sexually mature male and female branches of the red macroalga, *Champia parvula*, are exposed in a static system for 2 days to different concentrations of effluent, or to receiving water, followed by a 5 to 7 day recovery period in control medium. The recovery period allows time for the development of cystocarps resulting from fertilization during the exposure period. The test results are reported as the concentration of the test substance which causes a statistically significant reduction in the number of cystocarps formed.

16.3 INTERFERENCES

16.3.1 Toxic substances may be introduced by contaminants in dilution water, glassware, sample hardware, and testing equipment (see Section 5, Facilities, Equipment, and Supplies).

16.3.2 Improper effluent sampling and handling may adversely affect test results (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

16.3.3 Adverse effects of high concentrations of suspended and/or dissolved solids, and extremes of pH, may mask the presence of toxic substances.

16.3.4 Pathogenic and/or predatory organisms in the dilution water and effluent may affect test organism survival, and confound test results.

16.4 SAFETY

16.4.1 See Section 3, Safety and Health.

16.5 APPARATUS AND EQUIPMENT

16.5.1 Facilities for holding and acclimating test organisms.

16.5.2 Laboratory red macroalga, *Champia parvula*, culture unit -- see culturing methods below. To test effluent or receiving water toxicity, sufficient numbers of sexually mature male and female plants must be available.

16.5.3 Samplers -- automatic samplers, preferably with sample cooling capability, that can collect a 24-h composite sample of 1 L.

16.5.4 Environmental chamber or equivalent facility with temperature control (23 ± 1°C).

16.5.5 Water purification system -- Millipore Milli-Q®, deionized water (DI) or equivalent.

16.5.6 Air pump -- for oil-free air supply.

16.5.7 Air lines, and air stones -- for aerating cultures.

16.5.8 Balance -- Analytical, capable of accurately weighing to 0.00001 g.

16.5.9 Reference weights, Class S -- for checking performance of balance.

16.5.10 Meter, pH -- for routine physical and chemical measurements.

16.5.11 Dissecting (stereoscope) microscope -- for counting cystocarps.

16.5.12 Compound microscope -- for examining the condition of plants.

16.5.13 Count register, 2-place -- for recording cystocarp counts.

16.5.14 Rotary shaker -- for incubating exposure chambers (hand-swirling twice a day can be substituted).

16.5.15 Drying oven -- to dry glassware.

16.5.16 Filtering apparatus -- for use with membrane filters (47 mm).

16.5.17 Refractometer -- for determining salinity.

16.5.1 Thermometers, glass or electronic, laboratory grade -- for measuring water temperatures.

16.5.19 Thermometers, bulb-thermograph or electronic-chart type -- for continuously recording temperature.

16.5.20 Thermometer, National Bureau of Standards Certified (see USEPA Method 170.1, USEPA, l979b) -- to calibrate laboratory thermometers.

16.5.21 Beakers -- Class A, borosilicate glass or non-toxic plasticware, 1000 mL for making test solutions.

16.5.22 Erlenmeyer flasks, 250 mL, or 200 mL disposable polystyrene cups, with covers -- for use as exposure chambers.

16.5.23 Bottles -- borosilicate glass or disposable polystyrene cups (200-400 mL) for use as recovery vessels.

16.5.24 Wash bottles -- for deionized water, for rinsing small glassware and instrument electrodes and probes.

16.5.25 Volumetric flasks and graduated cylinders -- Class A, borosilicate glass or non-toxic plastic labware, 10-1000 mL for making test solutions.

16.5.26 Micropipettors, digital, 200 and 1000 µL – to make dilutions.

16.5.27 Pipets, volumetric -- Class A, 1-100 mL.

16.5.28 Pipettor, automatic -- adjustable, 1-100 mL.

16.5.29 Pipets, serological -- 1-10 mL, graduated.

16.5.30 Pipet bulbs and fillers -- PROPIPET®, or equivalent.

16.5.31 Forceps, fine-point, stainless steel -- for cutting and handling branch tips.

16.6 REAGENTS AND CONSUMABLE MATERIALS

16.6.1 Mature red macroalga, *Champia parvula*, plants -- see Subsection 16.6.14 below.

16.6.2 Sample containers -- for sample shipment and storage (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests).

16.6.3 Petri dishes, polystyrene -- to hold plants for cystocarp counts and to cut branch tips. Other suitable containers may be used.

16.6.4 Disposable tips for micropipettors.

16.6.5 Aluminum foil, foam stoppers, or other closures -- to cover culture and test flasks.

16.6.6 Tape, colored -- for labeling test chambers.

16.6.7 Markers, waterproof -- for marking containers, etc.

16.6.8 Data sheets (one set per test) -- for data recording.

16.6.9 Buffers, pH 4, pH 7, and pH l0 (or as per instructions of instrument manufacturer) for standards and calibration check (see USEPA Method 150.1, USEPA, 1979b).

16.6.10 Laboratory quality assurance samples and standards for the above methods.

16.6.11 Reference toxicant solutions see Section 4, Quality Assurance.

16.6.12 Reagent water -- defined as distilled or deionized water that does not contain substances which are toxic to the test organisms (see Section 5, Facilities, Equipment, and Supplies).

16.6.13 Effluent, receiving water, and dilution water -- see Section 7, Dilution Water; and Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests.

16.6.13.1 Saline test and dilution water -- the use of natural seawater is recommended for this test. A recipe for the nutrients that must be added to the natural seawater is given in Table 1. The salinity of the test water must be 30‰, and vary no more than ± 2‰ among the replicates. If effluent and receiving water tests are conducted concurrently, the salinity of these tests should be similar.

16.6.13.2 The overwhelming majority of industrial and sewage treatment effluents entering marine and estuarine systems contain little or no measurable salts. Therefore, exposure of the red macroalga, *Champia parvula*, to effluents will usually require adjustments in the salinity of the test solutions. Although the red macroalga, *Champia parvula*, cannot be cultured in 100% artificial seawater, 100% artificial seawater can be used during the two day exposure period. This allows 100% effluent to be tested. It is important to maintain a constant salinity across all treatments. The salinity of the effluent can be adjusted by adding hypersaline brine (HSB) prepared from natural seawater (100‰), concentrated (triple strength) salt solution (GP2 described in Table 2), or dry GP2 salts (Table 2), to the effluent to provide a salinity of 30‰. Control solutions should be prepared with the same percentage of natural seawater and at the same salinity (using deionized water adjusted with dry salts, or brine) as used for the effluent dilutions.

16.6.13.3 Artificial seawater -- A slightly modified version of the GP2 medium (Spotte, et al, 1984) has been used successfully to perform the red macroalga sexual reproduction test. The preparation of artificial seawater (GP2) is described in Table 2.

TABLE 1. NUTRIENTS TO BE ADDED TO NATURAL SEAWATER AND TO ARTIFICIAL SEAWATER (GP2) DESCRIBED IN TABLE 2. THE CONCENTRATED NUTRIENT STOCK SOLUTION IS AUTOCLAVED FOR 15 MINIMUM (VITAMINS ARE AUTOCLAVED SEPARATELY FOR 2 MINIMUM AND ADDED AFTER THE NUTRIENT STOCK SOLUTION IS AUTOCLAVED). THE pH OF THE SOLUTION IS ADJUSTED TO APPROXIMATELY pH 2 BEFORE AUTOCLAVING TO MINIMIZE THE POSSIBILITY OF PRECIPITATION

	Amount of Reagent Per Liter of Concentrated Nutrient Stock Solution	
	Stock Solution For Culture Medium	Stock Solution For Test Medium
Nutrient Stock Solution[1]		
$NaNO_3$	6.35 g	1.58 g
$NaH_2P0_4 \cdot H_2O$	0.64 g	0.16 g
$Na_2EDTA \cdot 2\ H_2O$	133 mg	--
$Na_3C_6H_5O_7 \cdot 2\ H_2O$	51 mg	12.8 mg
Iron[2]	9.75 mL	2.4 mL
Vitamins[3]	10 mL	2.5 mL

1 Add 10 mL of appropriate nutrient stock solution per liter of culture or test medium.

2 A stock solution of iron is made that contains 1 mg iron/mL. Ferrous or ferric chloride can be used.

3 A vitamin stock solution is made by dissolving 4.88 g thiamine HCl, 2.5 mg biotin, and 2.5 mg B_{12} in 500 mL deionized water. Adjust approximately pH 4 before autoclaving 2 min. It is convenient to subdivide the vitamin stock into 10 mL volumes in test tubes prior to autoclaving.

TABLE 2. REAGENT GRADE CHEMICALS USED IN THE PREPARATION OF GP2 ARTIFICIAL SEAWATER FOR USE IN CONJUNCTION WITH NATURAL SEAWATER FOR THE RED MACROALGA, *CHAMPIA PARVULA*, CULTURING AND TOXICITY TESTING[1,2,3,4,5,6,7]

Compound	Concentration (g/L)	Amount (g) Required for 20 L
NaCl	21.03	420.6
Na_2SO_4	3.52	70.4
KCl	0.61	12.2
KBr	0.088	1.76
$Na_2B_4O_7 \cdot 10\ H_2O$	0.034	0.68
$MgCl_2 \cdot 6\ H_2O$	9.50	190.0
$CaCl_2 \cdot 2\ H_2O$	1.32	26.4
$SrCl_2 \cdot 6\ H_2O$	0.02	0.400
$NaHCO_3$	0.17	3.40

1 Modified GP2 from Spotte et al. (1984).
2 The constituent salts and concentrations were taken from USEPA (l990b).
3 The original formulation calls for autoclaving anhydrous and hydrated salts separately to avoid precipitation. However, if the sodium bicarbonate is autoclaved separately (dry), all of the other salts can be autoclaved together. Since no nutrients are added until needed, autoclaving is not critical for effluent testing. To minimize microalgal contamination, the artificial seawater should be autoclaved when used for stock cultures. Autoclaving (120°C) should be for a least 10 minimum for 1-L volumes, and 20 minimum for 10-to-20-L volumes.
4 Prepare in 10-L to 20-L batches.
5 A stock solution of 68 mg/mL sodium bicarbonate is prepared by autoclaving it as a dry powder, and then dissolving it in sterile deionized water. For each liter of GP2, use 2.5 mL of this stock solution.
6 Effluent salinity adjustment to 30‰ can be made by adding the appropriate amount of dry salts from this formulation, by using a triple-strength brine prepared from this formulation, or by using a 100‰ salinity brine prepared from natural seawater.
7 Nutrients listed in Table 1 should be added to the artificial seawater in the same concentration described for natural seawater.

16.6.14 TEST ORGANISMS RED MACROALGA, *CHAMPIA PARVULA*

16.6.14.1 Cultures

16.6.14.1.1 Mature plants are illustrated in Figure 1. The adult plant body (thallus) is hollow, septate, and highly branched. New cultures can be propagated asexually from excised branches, making it possible to maintain clonal material indefinitely.

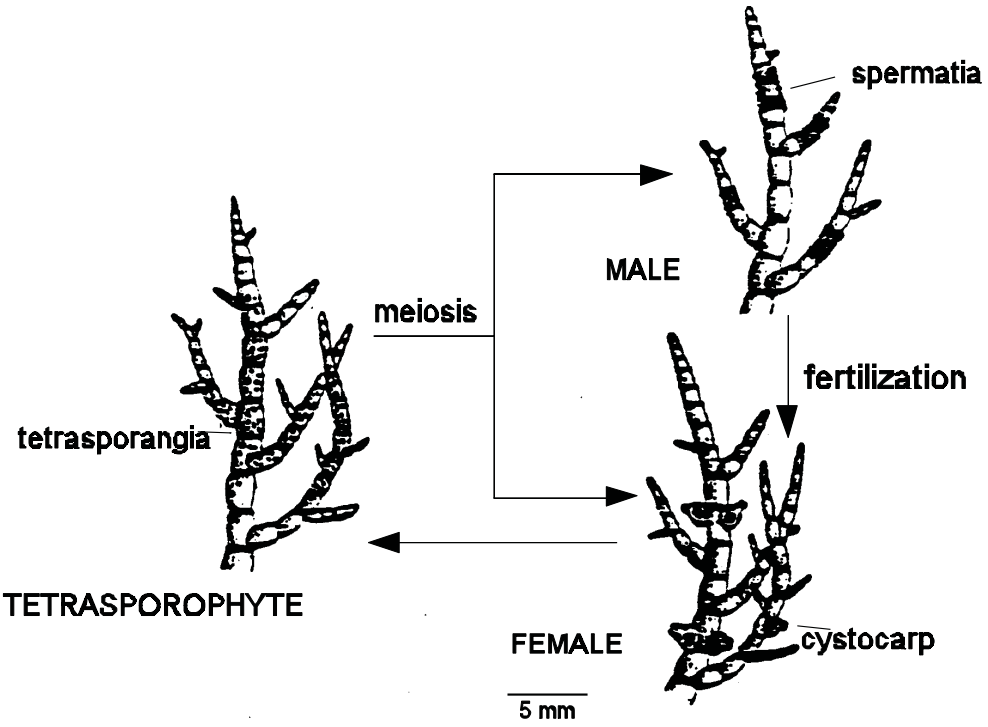

Figure 1. Life history of the red macroalga, *Champia parvula*. Upper left: Size and degree of branching in female branch tips used for toxicity tests. From USEPA (1987f).

16.6.14.1.2 Unialgal stock cultures of both males and females are maintained in separate, aerated 1000 mL Erlenmeyer flasks containing 800 mL of the culture medium. All culture glass must be acid-stripped in 15% HCl and rinsed in deionized water after washing. This is necessary since some detergents can leave a residue that is toxic to the red macroalga, *Champia parvula*. Periodically (at least every 6 months) culture glassware should be baked in a muffle furnace to remove organic material that may build up on its surface. Alternately, a few mL of concentrated sulfuric acid can be rolled around the inside of wet glassware. CAUTION: the addition of acid to the wet glassware generates heat.

16.6.14.1.3 The culture medium is made from natural seawater to which additional nutrients are added. The nutrients added are listed in Table 1. Almost any nutrient recipe can be used for the red macroalga, *Champia parvula*, cultured in either natural seawater or a 50-50 mixture of natural and artificial seawaters. Healthy, actively growing plants are the goal, not a standard nutrient recipe for cultures.

16.6.14.1.4 Several cultures of both males and females should be maintained simultaneously to keep a constant supply of plant material available. To maintain vigorous growth, initial stock cultures should be started periodically with about twenty 0.5 to l.0 cm branch tips. Cultures are gently aerated through sterile, cotton-plugged, disposable, polystyrene l mL pipettes. Cultures are capped with foam plugs and aluminum foil and illuminated with ca. 75 $\mu E/m^2/s$ (500 ft-c) of cool-white fluorescent light on a 16:8 h light:dark cycle. Depending on the type of culture chamber or room used, i.e.,

the degree of reflected light, the light levels may have to be adjusted downward. The temperature is 22 to 24°C and the salinity 28-30‰. Media are changed once a week.

16.6.14.1.5 Prior to use in toxicity tests, stock cultures should be examined to determine their condition. Females can be checked by examining a few branch tips under a compound microscope (100 X or greater). Several trichogynes (reproductive hairs to which the spermatia attach) should be easily seen near the apex (Figure 2).

16.6.14.1.6 Male plants should be visibly producing spermatia. This can be checked by placing some male tissue in a petri dish, holding it against a dark background and looking for the presence of spermatial sori. Mature sori can also be easily identified by looking along the edge of the thallus under a compound microscope (Figures 3 and 4).

16.6.14.1.7 A final, quick way to determine the relative "health" of the male stock culture is to place a portion of a female plant into some of the water from the male culture for a few seconds. Under a compound microscope numerous spermatia should be seen attached to both the sterile hairs and the trichogynes (Figure 5).

16.6.14. Culture medium prepared from natural seawater is preferred (Table 1). However, as much as 50% of the natural seawater may be replaced by the artificial seawater (GP2) described in Table 2.

16.6.14.2.1 Seawater for cultures is filtered at least to 0.45 µm to remove most particulates and then autoclaved for 30 minute at 15 psi (120°C). Carbon stripping the seawater may be necessary before autoclaving to enhance its water quality (USEPA, 1990b). This is done by adding 2 g activated carbon per liter of seawater and stirring on a stir plate for 2 h. After stirring filter through a Whatman number 2 filter, then through a 0.45 membrane filter. The culture flasks are capped with aluminum foil and autoclaved dry, for 10 minute. Culture medium is made up by dispensing seawater into sterile flasks and adding the appropriate nutrients from a sterile stock solution.

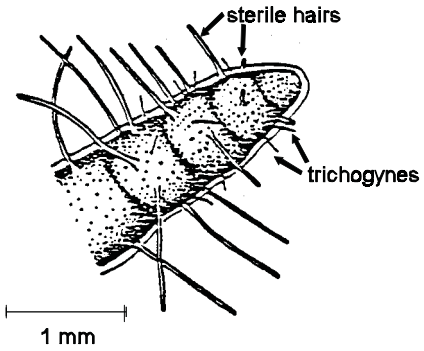

Figure 2. Apex of branch of female plant, showing sterile hairs and reproductive hairs (trichogynes). Sterile hairs are wider and generally much longer than trichogynes, and appear hollow except at the tip. Both types of hairs occur on the entire circumference of the thallus, but are seen easiest at the "edges." Receptive trichogynes occur only near the branch tips. From USEPA (1987f).

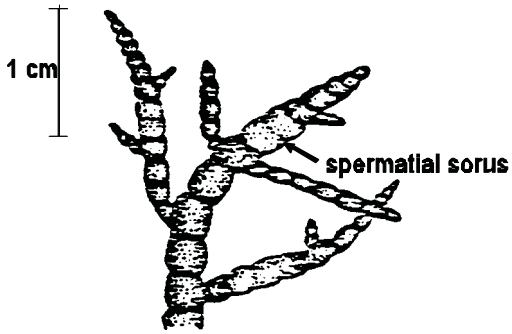

Figure 3. A portion of the male thallus showing spermatial sori. The sorus areas are generally slightly thicker and somewhat lighter in color. From USEPA (1987f).

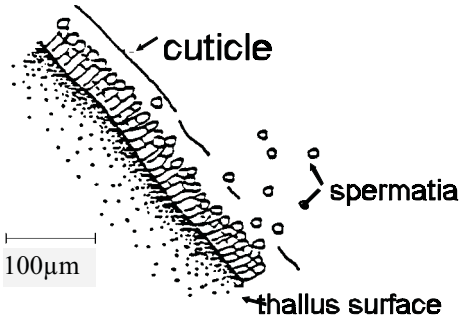

Figure 4. A magnified portion of a spermatial sorus. Note the rows of cells that protrude from the thallus surface. From USEPA (1987f).

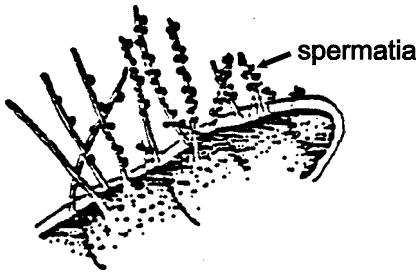

Figure 5. Apex of a branch on a mature female plant that was exposed to spermatia from a male plant. The sterile hairs and trichogynes are covered with spermatia. Note that few or no spermatia are attached to the older hairs (those more than l mm from the apex). From USEPA (1987f).

16.6.14.2.2 Alternately, 1-L flasks containing seawater can be autoclaved. Sterilization is used to prevent microalgal contamination, and not to keep cultures bacteria free.

16.7 EFFLUENT AND RECEIVING WATER COLLECTION, PRESERVATION, AND STORAGE

16.7.1 See Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests.

16.8 CALIBRATION AND STANDARDIZATION

16.8.1 See Section 4, Quality Assurance.

16.9 QUALITY CONTROL

16.9.1 See Section 4, Quality Assurance.

16.10 TEST PROCEDURES

16.10.1 TEST SOLUTIONS

16.10.1.1 Receiving Waters

16.10.1.1.1 The sampling point is determined by the objectives of the test. At estuarine and marine sites, samples are usually collected at mid-depth. Receiving water toxicity is determined with samples used directly as collected or with samples passed through a 60 µm NITEX® filter and compared without dilution, against a control. Using four replicate chambers per test, each containing 100 mL, and 400 mL for chemical analysis, would require approximately 800 mL or more of sample per test.

16.10.1.2 Effluents

16.10.1.2.1 The selection of the effluent test concentrations should be based on the objectives of the study. A dilution factor of 0.5 is commonly used. A dilution factor of 0.5 provides precision of ± 100%, and allows for testing of concentrations between 6.25% and 100% effluent using only five effluent concentrations (6.25%, 12.5%, 25%, 50%, and 100%). Test precision shows little improvement as dilution factors are increased beyond 0.5 and declines rapidly if smaller dilution factors are used. **Therefore, USEPA recommends the use of the ≥ 0.5 dilution factor.**

16.10.1.2.2 If the effluent is known or suspected to be highly toxic, a lower range of effluent concentrations should be used (such as 25%, 12.5%, 6.25%, 3.12%, and 1.56%).

16.10.1.2.3 The volume of effluent required for the test using a 0.5 dilution series is approximately 1800 mL. Prepare enough test solution at each effluent concentration (approximately 800 mL) to provide 100 mL of test solution for each of four (minimum of three) replicate test chambers and 400 mL for chemical analyses and record data (Figure 6).

16.10.1.2.4 Effluents can be tested at 100%. A 100% concentration of effluent can be achieved if the salinity of the effluent is adjusted to 30‰ by adding the GP2 dry salt formulation described in Table 2.

16.10.1.2.5 Just prior to test initiation (approximately 1 h), the temperature of sufficient quantity of the sample to make the test solutions should be adjusted to the test temperature (25 ± 1°C) and maintained at the temperature during the addition of dilution water.

SITE: _____

COLLECTION DATE: _____

TEST DATE: _____

LOCATION	INITIAL SALINITY	FINAL SALINITY	SOURCE OF SALTS FOR[1] SALINITY ADJUSTMENT

[1]Natural seawater, GP2 brine, GP2 salts, etc. (include some indication of amount)

COMMENTS:

Figure 6. Data form for the red macroalga, *Champia parvula*, sexual reproduction test. Receiving water summary sheet. From USEPA (1987f).

16.10.1.2.6 Effluent dilutions should be prepared for all replicated in each treatment in one beaker to minimize variability among the replicates. The test chambers are labeled with the test concentration and replicate number. Dispense into the appropriate effluent dilution chamber.

16.10.1.3 Dilution Water

16.10.1.3.1. The formula for the enrichment for natural seawater is listed in Table 1. Both EDTA and trace metals have been omitted. This formula should be used for the 2-day exposure period, but it is not critical for the recovery period. Since natural seawater quality can vary among laboratories, a more complete nutrient medium (e.g., the addition of EDTA) may result in faster growth (and therefore faster cystocarp development) during the recovery period.

16.10.2 PREPARATION OF PLANTS FOR TEST

16.10.2.1 Once cultures are determined to be usable for toxicity testing (have trichogynes and sori with spermatia), plant cuttings should be prepared for the test, using fine-point forceps, with the plants in a little seawater in a petri dish. For female plants, five cuttings, severed 7-10 mm from the ends of the branch, should be prepared for each treatment chamber. Try to be consistent in the number of branch tips on each cutting. For male plants, one cutting, severed 2.0 to 3.0 cm from the end of the branch, is prepared for each test chamber. Prepare the female cuttings first, to minimize the chances of contaminating them with water containing spermatia from the male stock cultures.

16.10.3 START OF TEST

16.10.3.1 Tests should begin as soon as possible after sample collection, preferably within 24 h. The maximum holding time following retrieval of the sample from the sampling device should not exceed 36 h for off-site toxicity tests unless permission is granted by the permitting authority. In no case should the sample be used for the first time in a test more than 72 h after sample collection (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Test, Subsection 8.5.4).

16.10.3.2 Just prior to test initiation (approximately 1 h), the temperature of a sufficient quantity of the sample to make the test solution should be adjusted to the test temperature (23 ± 1°C) and maintained at that temperature during the addition of dilution water.

16.10.3.3 Label the test chambers with a marking pen. Use of color coded tape to identify each treatment and replicate is helpful. A minimum of five effluent concentrations and a control are used for each effluent test Each treatment (including controls) should have four (minimum of three) replicates.

16.10.3.4 Randomize the position of test chambers at the beginning of the test.

16.10.3.5 Prepare test solutions and add to the test chambers.

16.10.3.6 Add five female branches and one male branch to each test chamber. The toxicant must be present before the male plant is added.

16.10.3.7 Gently hand swirl the chambers twice a day, or shake continuously at 100 rpm on a rotary shaker.

16.10.3.8 If desired, the media can be changed after 24 h.

16.10.4 LIGHT, PHOTOPERIOD, SALINITY, AND TEMPERATURE

16.10.4.1 The light quality and intensity should be at 75 $\mu E/m^2/s$, or 500 foot candles (ft-c) with a photoperiod of 16 h light and 8 h darkness. The water temperature in the test chambers should be maintained at 23 ± 1°C. The test salinity should be in the range of 28 to 32‰. The salinity should vary by no more than ± 2‰ among the chambers

on a given day. If effluent and receiving water tests are conducted concurrently, the salinities of these tests should be similar.

16.10.5 DISSOLVED OXYGEN (DO) CONCENTRATION

16.10.5.1 Aeration may affect the toxicity of effluent and should be used only as a last resort to maintain a satisfactory DO. The DO concentrations should be measured on new solutions at the start of the test (Day 0) and should be measured before renewal of the test solution after 24 h. The DO should not fall below 4.0 mg/L (see Section 8, Effluent and Receiving Water Sampling, Sample Handling, and Sample Preparation for Toxicity Tests) If it is necessary to aerate, all treatments and the control should be aerated. The aeration rate should not exceed 100 bubbles/minute, using a pipet with a 1-2 mm orifice, such as a 1mL KIMAX® serological pipet, or equivalent. Care should be taken to ensure that turbulence resulting from the aeration does not occur.

16.10.6 OBSERVATIONS DURING THE TEST

16.10.6.1 Routine Chemical and Physical Observations

16.10.6.1.1 DO is measured at the beginning and end of each 24-h exposure period in one test chamber at each concentration and in the control.

16.10.6.1.2 Temperature, pH, and salinity are measured at the end of each 24-h exposure period in one test chamber at each concentration and in the control. Temperature should also be monitored continuously, observed and recorded daily for at least two locations in the environmental control system or the samples. Temperature should be measured in a sufficient number of test chambers at least at the end of the test to determine temperature variation in environmental chamber.

16.10.6.1.3 The pH is measured in the effluent sample each day before new test solutions are made.

16.10.6.1.4 Record all the measurements on the data sheet.

16.10.6.2 Routine Biological Observations

16.10.6.2.1 Protect the red macroalga from unnecessary disturbance during the test by carrying out the daily test observations and solution renewals carefully.

16.10.7 TRANSFER OF PLANTS TO CONTROL WATER AFTER 48 H

16.10.7.1 Label the recovery vessels. These vessels can be almost any type of container or flask containing 100 to 200 mL of seawater and nutrients (see Tables 1 and 2). Smaller volumes can be used, but should be checked to make sure that adequate growth will occur without having to change the medium.

16.10.7.2 With forceps, gently remove the female branches from test chambers and place into recovery bottles. Add aeration tubes and foam stoppers.

16.10.7.3 Place the vessels under cool white light (at the same irradiance as the stock cultures) and aerate for the 5-7 day recovery period. If a shaker is used, do not aerate the solutions (this will enhance the water motion).

16.10.8 TERMINATION OF THE TEST

16.10.8.1 At the end of the recovery period, count the number of cystocarps (Figures 7, 8, and 9) per female and record the data (Figure 10). Cystocarps may be counted by placing females between the inverted halves of a polystyrene petri dish or other suitable containers with a small amount of seawater (to hold the entire plant in one focal plane). Cystocarps can be easily counted under a stereomicroscope, and are distinguished from young branches because they possess an apical opening for spore release (ostiole) and darkly pigmented spores.

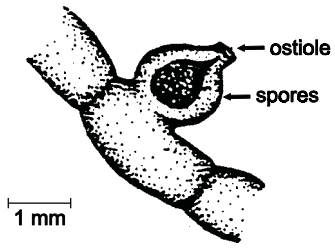

Figure 7. A mature cystocarp. In the controls and lower effluent concentrations, cystocarps often occur in clusters of 10 or 12. From USEPA (1987f).

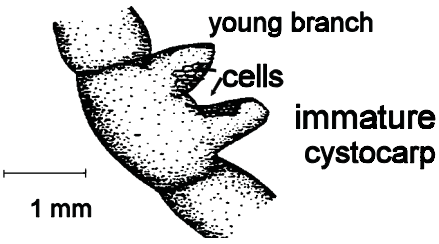

Figure 8. Comparison of a very young branch and an immature cystocarp. Both can have sterile hairs. Trichogynes might or might not be present on a young branch, but are never present on an immature cystocarp. Young branches are more pointed at the apex and are made up of larger cells than immature cystocarps, and never have ostioles. From USEPA (1987f).

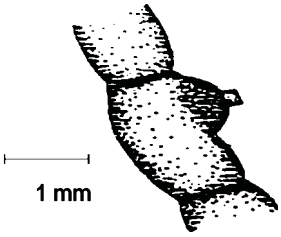

Figure 9. An aborted cystocarp. A new branch will eventually develop at the apex. From USEPA (1987f).

16.10.8.2 One advantage of this test procedure is that if there is uncertainty about the identification of an immature cystocarp, it is necessary only to aerate the plants a little longer in the recovery bottles. Within 24 to 48 h, the presumed cystocarp will either look more like a mature cystocarp or a young branch, or will have changed very little, if at all (i.e., an aborted cystocarp). No new cystocarps will form since the males have been removed, and the plants will only get larger. Occasionally, cystocarps will abort, and these should not be included in the counts. Aborted cystocarps are easily identified by their dark pigmentation and, often, by the formation of a new branch at the apex.

16.11 SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA

16.11.1 A summary of test conditions and test acceptability criteria is listed in Table 3.

16.12 ACCEPTABILITY OF TEST RESULTS

16.12.1 The test is acceptable if (1) control survival equals or exceeds 80% and (2) control plants average 10 or more cystocarps per plant.

16.12.2 If plants fragment in the controls or lower exposure concentrations, it may be an indication that they are under stress.

16.13 DATA ANALYSIS

16.13.1 GENERAL

16.13.1.1 Tabulate and summarize the data. A sample set of reproduction data is listed in Table 4.

16.13.1.2 The endpoints of the red macroalga, *Champia parvula*, toxicity test are based on the adverse effects on sexual reproduction as the mean number of cystocarps. The LC50, the IC25, and the IC50 are calculated using point estimation techniques (see Section 9, Chronic Toxicity Test Endpoints and Data Analysis). NOEC and LOEC values are obtained using a hypothesis testing approach, such as Dunnett's Procedure (Dunnett, 1955) or Steel's Many-one Rank Test (Steel, 1959; Miller, 1981) (see Section 9). Separate analyses are performed for the estimation of the NOEC and LOEC endpoints and for the IC25 and IC50. See the Appendices for examples of the manual computations, program listing, and example of data input and program output.

16.13.1.3 The statistical tests described here must be used with a knowledge of the assumptions upon which the tests are contingent. The assistance of a statistician is recommended for analysts who are not proficient in statistics.

TABLE 3. SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA FOR THE RED MACROALGA, *CHAMPIA PARVULA*, SEXUAL REPRODUCTION TEST WITH EFFLUENTS AND RECEIVING WATERS

CAUTION: This method is not listed at 40 CFR Part 136 for nationwide use.

1. Test type:	Static, non-renewal
2. Salinity:	30‰ (± 2‰ of the selected test salinity)
3. Temperature:	23 ± 1°C
4. Light quality:	Cool-white fluorescent lights
5. Light intensity:	75 µE/m^2/s (500 ft-c)
6. Photoperiod:	16 h light, 8 h darkness
7. Test chamber size:	200 mL polystyrene cups, or 250 mL Erlenmeyer flasks
8. Test solution volume:	100 mL (minimum)
9. No. organisms per test chamber:	5 female branch tips and 1 male plant
10. No. replicate per concentration:	4 (minimum of 3)
11. No. organisms per concentrations:	24 (minimum of 18)
12. Dilution water:	30‰ salinity natural seawater, or a combination of 50% of 30‰ salinity natural seawater and 50% of 30‰ salinity GP2 artificial seawater (see Section 7, Dilution Water)
13. Test concentrations:	Effluents: Minimum of 5 and a control Receiving waters: 100% receiving water or minimum of 5 and a control
14. Dilution factor:	Effluents: ≥ 0.5 Receiving waters: None or≥ 0.5

TABLE 3. SUMMARY OF TEST CONDITIONS AND TEST ACCEPTABILITY CRITERIA FOR THE RED MACROALGA, *CHAMPIA PARVULA*, SEXUAL REPRODUCTION TEST WITH EFFLUENTS AND RECEIVING WATERS (CONTINUED)

15. Test duration:	2 day exposure to effluent, followed by 5 to 7-day recovery period in control medium for cystocarp development
16. Endpoints:	Reduction in cystocarp production compared to controls
17. Test acceptability criteria	80% or greater survival, and an average of 10 cystocarps per plant in controls
18. Sampling requirements:	For on-site tests, one sample collected at test initiation, and used within 24 h of the time it is removed from the sampling device. For off-site tests, holding time must not exceed 36 h before first use (see Section 8, Effluent and Receiving Water Sampling, Sampling Handling, and Sample Preparation for Toxicity Tests, Subsection 8.5.4)
19. Sample volume required:	2 L per test

16.13.2 EXAMPLE OF ANALYSIS OF THE RED MACROALGA, *CHAMPIA PARVULA*, REPRODUCTION DATA

16.13.2.1 Formal statistical analysis of the data is outlined in Figure 11. The response used in the analysis is the mean number of cystocarps per replicate chamber. Separate analyses are performed for the estimation of the NOEC and LOEC endpoints and for the estimation of the IC25 endpoint and the IC50 endpoint. Concentrations that have exhibited no sexual reproduction (less than 5% of controls) are excluded from the statistical analysis of the NOEC and LOEC, but included in the estimation of the IC endpoints.

16.13.2.2 For the case of equal numbers of replicates across all concentrations and the control, the evaluation of the NOEC and LOEC endpoints is made via a parametric test, Dunnett's Procedure, or a nonparametric test, Steel's Many-one Rank Test. The assumptions of Dunnett's Procedures, normality and homogeneity of variance are formally tested. The test for normality is the Shapiro-Wilk's Test and Bartlett's Test is used to test for homogeneity of variance. Tests for normality and homogeneity of variance are included in Appendix B. If either of these tests fails, the nonparametric test, Steel's Many-one Rank Test is used to determine the NOEC and LOEC endpoints. If the assumptions of Dunnett's Procedure are met, the endpoints are determined by the parametric test.

TABLE 4. DATA FROM THE RED MACROALGA, *CHAMPIA PARVULA*, EFFLUENT TOXICITY TEST. CYSTOCARP COUNTS FOR INDIVIDUAL PLANTS AND MEAN COUNT PER TEST CHAMBER FOR EACH EFFLUENT CONCENTRATION[1]

Effluent Concentration (%)	Replicate Test Chamber	Plant 1	2	3	4	5	Mean Cystocarp Count

	C	2	1	0	0	0	0.60

[1] Data provided by the ERL-N, USEPA, Narragansett, RI.

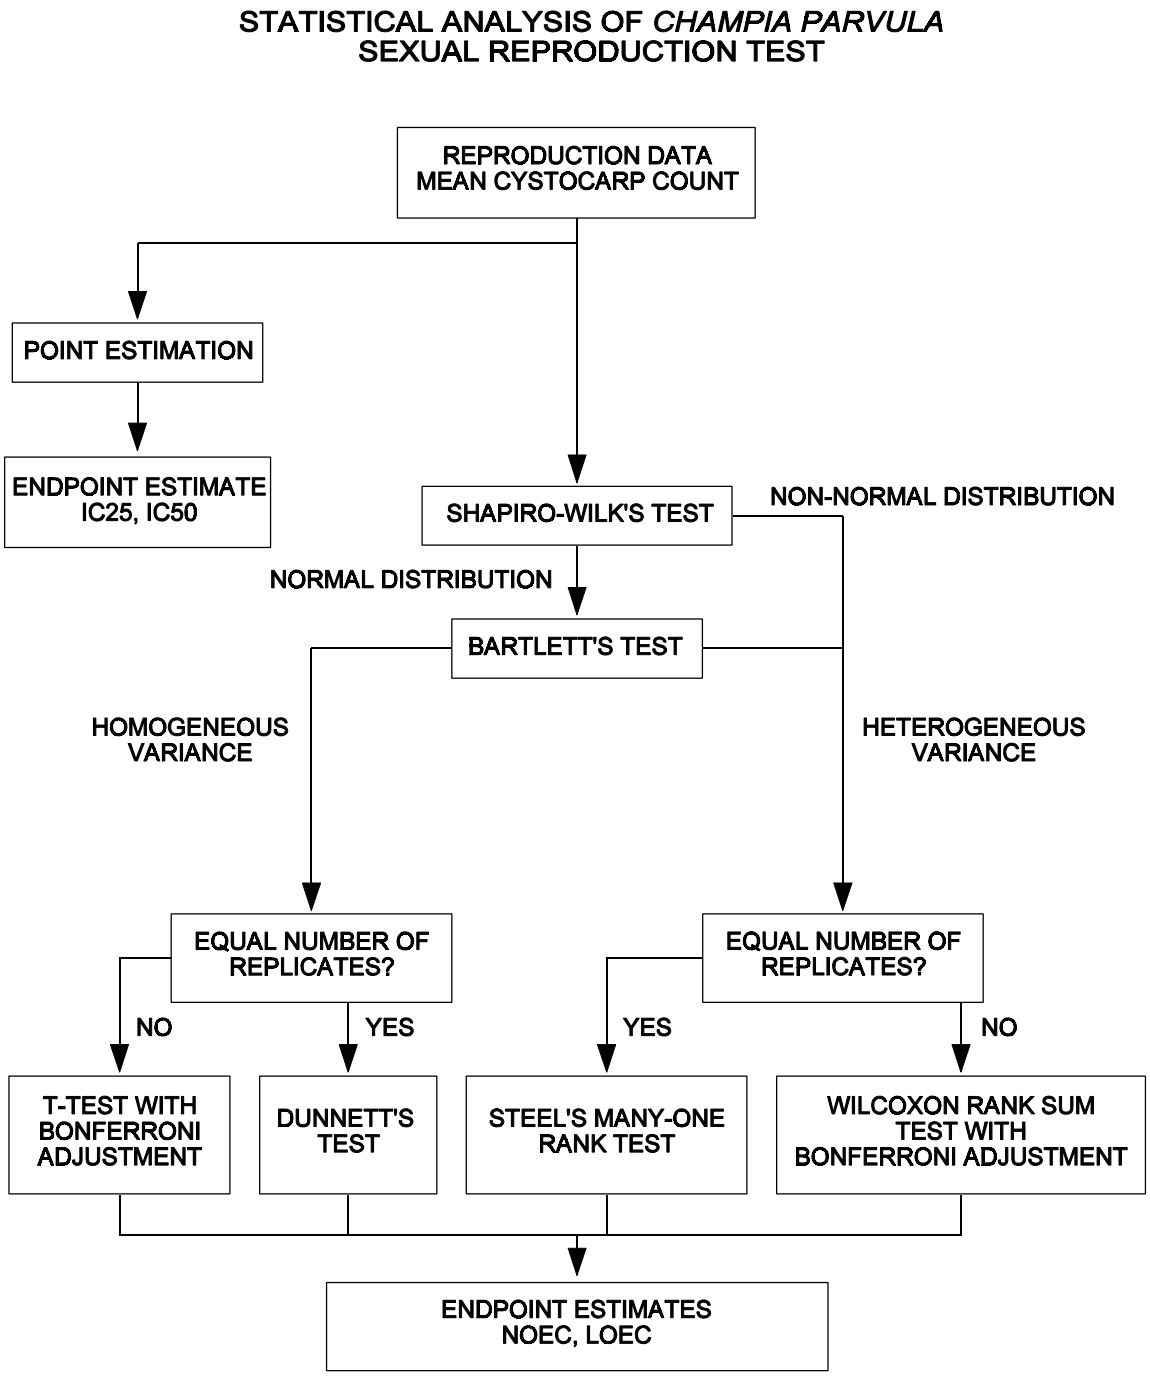

Figure 11. Flowchart for statistical analysis of the red macroalga, *Champia parvula*, data

6.13.2.3 If unequal numbers of replicates occur among the concentration levels tested there are parametric and nonparametric alternative analyses. The parametric analysis is a t test with the Bonferroni adjustment (Appendix D). The Wilcoxon Rank Sum Test with the Bonferroni adjustment is the nonparametric alternative.

16.13.2.4 Example of Analysis of Reproduction Data

16.13.2.4.1 In this example, the data, mean and standard deviation of the observations at each concentration including the control are listed in Table 5. The data are plotted in Figure 12. As can be seen from the data in the table, mean reproduction per chamber in the 10% effluent concentration is less than 5% of the control. Therefore the 10% effluent concentration is not included in the subsequent analysis.

TABLE 5. RED MACROALGA, *CHAMPIA PARVULA*, SEXUAL REPRODUCTION DATA

		Effluent Concentration (%)					
Replicate	Control	0.8	1.3	2.2	3.6	6.0	10.0
A	17.60	12.00	4.40	2.40	1.80	0.20	0.00
B	17.20	9.40	5.20	7.00	3.80	0.80	0.20
C	19.20	10.20	4.00	1.40	2.20	2.20	0.60
Mean($\bar{Y}_i$)	18.00	10.53	4.53	3.60	2.60	1.07	0.27
S_i^2	1.12	1.77	0.37	8.92	1.12	1.05	0.09
i	1	2	3	4	5	6	7

16.13.2.5 Test for Normality

16.13.2.5.1 The first step of the test for normality is to center the observations by subtracting the mean of all the observations within a concentration from each observation in that concentration. The centered observations are summarized in Table 6.

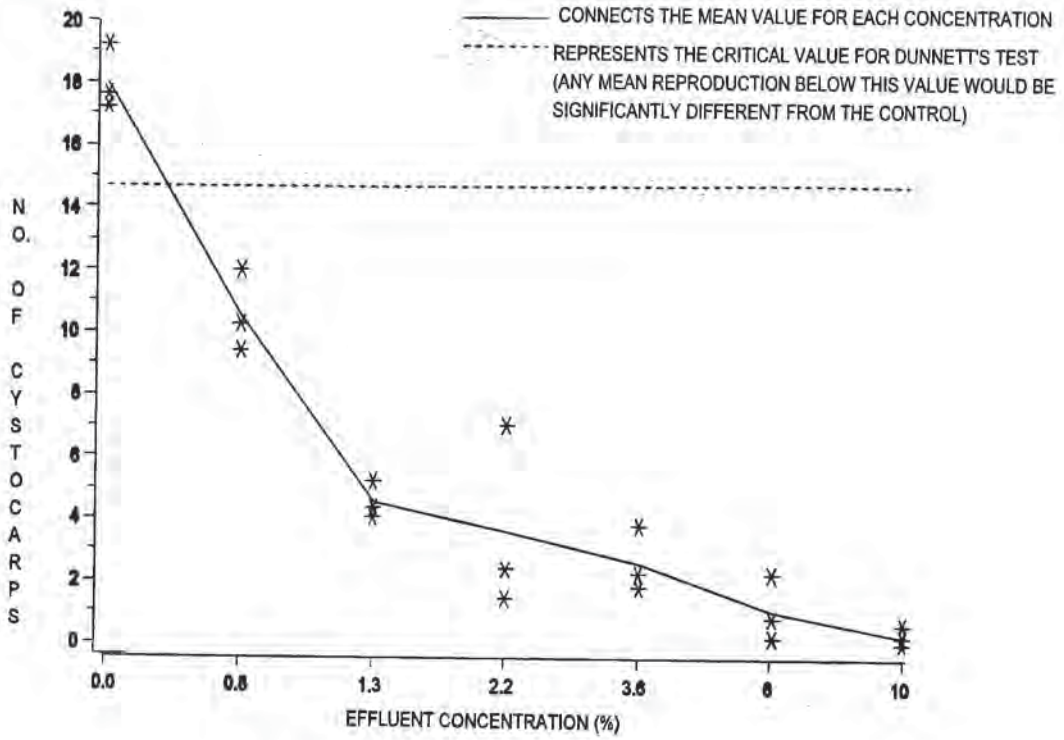

Figure 12. Plot of the number of cystocarps per plant.

TABLE 6. CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

		Effluent Concentration (%)				
Replicate	Control	0.8	1.3	2.2	3.6	6.0
A	-0.40	1.47	-0.13	-1.20	-0.80	-0.87
B	-0.80	-1.13	0.67	3.40	1.20	-0.27
C	1.20	-0.33	-0.53	-2.20	-0.40	1.13

16.13.2.5.2 Calculate the denominator, D, of the test statistic:

$$D = \sum_{i=1}^{n} (x_i - \bar{X})^2$$

Where: X_i = the ith centered observation

x = the overall mean of the centered observations

n = the total number of centered observations.

16.13.2.5.3 For this set of data, n = 18

$$\overline{X} = \frac{1}{8}(0.01) = 0.00$$

$$D = 28.7201$$

16.13.2.5.4 Order the centered observations from smallest to largest

$$X^{(1)} \leq X^{(2)} \leq \ldots \leq X^{(n)}$$

Where $X^{(i)}$ is the ith ordered observation. These ordered observations are listed in Table 7.

TABLE 7. ORDERED CENTERED OBSERVATIONS FOR SHAPIRO-WILK'S EXAMPLE

I	$X^{(i)}$	i	$X^{(i)}$
1	-2.20	10	-0.33
2	-1.20	11	-0.27
3	-1.13	12	-0.13
4	-0.87	13	0.67
5	-0.80	14	1.13
6	-0.80	15	1.20
7	-0.53	16	1.20
8	-0.40	17	1.47
9	-0.40	18	3.40

16.13.2.5.5 From Table 4, Appendix B, for the number of observations, n, obtain the coefficients $a_1, a_2, \ldots, a_k$ where k is n/2 if n is even and (n-1)/2 if n is odd. For the data in this example, n = 18 and k = 9. The a_i values are listed in Table 8.

TABLE 8. COEFFICIENTS AND DIFFERENCES FOR SHAPIRO-WILK'S EXAMPLE

i	a_i	$X^{(n-i+1)} - X^{(i)}$	
1	0.4886	5.60	$X^{(18)} - X^{(1)}$
2	0.3253	2.67	$X^{(17)} - X^{(2)}$
3	0.2553	2.33	$X^{(17)} - X^{(3)}$
4	0.2027	2.07	$X^{(15)} - X^{(4)}$
5	0.1587	1.93	$X^{(14)} - X^{(5)}$
6	0.1197	1.47	$X^{(13)} - X^{(6)}$
7	0.0837	0.40	$X^{(12)} - X^{(7)}$
8	0.0496	0.13	$X^{(11)} - X^{(8)}$
9	0.0163	0.07	$X^{(10)} - X^{(9)}$

16.13.2.5.6 Compute the test statistic, W, as follows:

$$W = \frac{1}{D}[\sum_{i=1}^{k} a_i(X^{(n-i+1)} - X^{(i)}]^2$$

The differences $X^{(n-i+1)} - X^{(i)}$ are listed in Table 8. For the data,

$$W = \frac{1}{28.7201}(5.1425)^2 = 0.921$$

16.13.2.5.7 The decision rule for this test is to compare W as calculated in Subsection 16.3.2.5.6 with the critical value found in Table 6, Appendix B. If the computed W is less than the critical value, conclude that the data are not normally distributed. For this example, the critical value at a significance level of 0.01 and 18 observations (n) is 0.858. Since W = 0.921 is greater than the critical value, conclude of the test is that the data are normally distributed.

16.13.2.6 Test for Homogeneity of Variance

16.13.2.6.1 The test used to examine whether the variation in mean cystocarp production is the same across all effluent concentrations including the control, is Bartlett's Test (Snedecor and Cochran, 1980). The test statistic is as follows:

$$B = \frac{[(\sum_{i=1}^{p} V_i)\ \ln\overline{S}^2 - \sum_{i=1}^{p} V_i \ln S_i^2]}{C}$$

Where: V_i = degrees of freedom for each effluent concentration and control, $V_i = (n_i - 1)$

p = number of levels of effluent concentration including the control

n_i = the number of replicates for concentration i

ln = $\log_e$

i = 1, 2, ..., p where p is the number of concentrations

$$\overline{S}^2 = \frac{(\sum_{i=1}^{p} V_i S_i^2)}{\sum_{i=1}^{p} V_i}$$

16.13.2.6.2 For the data in this example (See Table 5) all effluent concentrations including the control have the same number of replicates ($n_i = 3$ for all i). Thus, $V_i = 2$ for all i.

$$C = 1 + [3(p-1)]^{-1}[\sum_{i=1}^{p} 1/V_i - (\sum_{i=1}^{p} V_i)^{-1}]$$

16.13.2.6.3 Bartlett's statistic is therefore:

$$B = [(12)\ln(2.3917) - 2\sum_{i=1}^{p} \ln(S_i^2)]/1.194$$

$$= [12(0.8720) - 2(1n(1.12)+\ln(1.77)+...+\ln(1.05))]/1.1944$$

$$= (10.4640 - 4.0809)/1.1944$$

$$= 5.34$$

16.13.2.6.4 B is approximately distributed as chi-square with p - 1 degrees of freedom, when the variances are in fact the same. Therefore, the appropriate critical value for this test, at a significance level of 0.01 with five degrees of freedom, is 15.09. Since B = 5.34 is less than the critical value of 15.09, conclude that the variances are not different.

16.13.2.7 Dunnett's Procedure

16.13.2.7.1 To obtain an estimate of the pooled variance for the Dunnett's Procedure, construct an ANOVA table as described in Table 9.

TABLE 9. ANOVA TABLE

Source	df	Sum of Squares (SS)	Mean Square(MS) (SS/df)
Between	p - 1	SSB	S_B^2 = SSB/(p - 1)
Within	N - p	SSW	S_W^2 = SSW/(N - p)
Total	N - 1	SST	

Where: p = number effluent concentrations including the control

N = total number of observations $n_1 + n_2 ... + n_p$

n_i = number of observations in concentration i

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N \qquad \text{Between Sum of Squares}$$

$$SST = \sum_{i=1}^{p}\sum_{j=1}^{n_j} Y_{ij}^2 - G^2/N \qquad \text{Total Sum of Squares}$$

$$SSW = SST - SSB \qquad \text{Within Sum of Squares}$$

G = the grand total of all sample observations,

$$G = \sum_{i=1}^{p} T_i$$

T_i = the total of the replicate measurements for concentration i

Y_{ij} = the jth observation for concentration i (represents the mean (across plants) number of cystocarps for effluent concentration i in test chamber j)

16.13.2.7.2 For the data in this example:

$n_1 = n_2 = n_3 = n_4 = n_5 = n_6 = 3$

$N = 18$
$T_1 = Y_{11} + Y_{12} + Y_{13} = 17.6 + 17.2 + 19.2 = 54$
$T_2 = Y_{21} + Y_{22} + Y_{23} = 12.0 + 9.4 + 10.2 = 31.6$
$T_3 = Y_{31} + Y_{32} + Y_{33} = 4.4 + 5.2 + 4.0 = 13.6$
$T_4 = Y_{41} + Y_{42} + Y_{43} = 2.4 + 7.0 + 1.4 = 10.8$
$T_5 = Y_{51} + Y_{52} + Y_{53} = 1.8 + 3.8 + 2.2 = 7.8$
$T_6 = Y_{61} + Y_{62} + Y_{63} = 0.2 + 0.8 + 2.2 = 3.2$

$G = T_1 + T_2 + T_3 + T_4 + T_5 + T_6 = 121.0$

$$SSB = \sum_{i=1}^{p} T_i^2/n_i - G^2/N$$

$$= \frac{1}{3}(4287.24) - \frac{(121.0)^2}{18} = 615.69$$

$$SST = \sum_{i=1}^{p}\sum_{j=1}^{n_j} Y_{ij}^2 - G^2/N$$

$$= 1457.8 - \frac{(121.0)^2}{18} = 644.41$$

$$SSW = SST - SSB$$

$$= 644.41 - 615.69 = 28.72$$

S_B^2 = SSB/(p-1) = 615.69/(6-1) = 123.14

S_W^2 = SSW/(N-p) = 28.72/(18-6) = 2.39

16.13.2.7.3 Summarize these calculations in the ANOVA table (Table 10).

TABLE 10. ANOVA TABLE FOR DUNNETT'S PROCEDURE EXAMPLE

Source	df	Sum of Squares (SS)	Mean Square(MS) (SS/df)
Between	5	615.69	123.14
Within	12	28.72	2.39
Total	17	644.41	

16.13.2.7.4 To perform the individual comparisons, calculate the t statistic for each concentration, and control combination as follows:

$$t_i = \frac{(\bar{Y}_1 - \bar{Y}_i)}{S_W\sqrt{(1/n_1) + (1/n_i)}}$$

Where: $\bar{Y}_i$ = mean number of cystocarps for effluent concentration i

$\bar{Y}_1$ = mean number of cystocarps for the control

S_W = square root of the within mean square

n_1 = number of replicates for the control

n_i = number of replicates for concentration i

16.13.2.7.5 Table 11 includes the calculated t values for each concentration and control combination. In this example, comparing the 0.8% concentration with the control the calculation is as follows:

$$t_2 = \frac{(18 - 10.53)}{[1.55\sqrt{(1/3) + (1/3)}]} = 5.9$$

16.13.2.7.6 Since the purpose of this test is to detect a significant reduction in cystocarp production, a one-sided test is appropriate. The critical value for this one-sided test is found in Table 5, Appendix C. For an overall alpha level of 0.05, 12 degrees of freedom for error and five concentrations (excluding the control) the critical value is 2.50. Mean cystocarp production for concentration i is considered significantly less control if t_i is greater than the critical value. Therefore, mean cystocarp productions for all effluent concentrations in this example have significantly lower cystocarp production than the control. Hence the NOEC is 0.8% and the LOEC is 0.8%.

TABLE 11. CALCULATED T VALUES

Effluent Concentration(%)	i	t_i
0.8	2	5.90
1.3	3	10.64
2.2	4	11.38
3.6	5	12.17
6.0	6	13.38

16.13.2.7.7 To quantify the sensitivity of the test, the minimum significant difference (MSD) that can be statistically detected may be calculated:

$$MSD = dS_W\sqrt{(1/n_1)+(1/n)}$$

Where: d = the critical value for Dunnett's Procedure

S_W = the square root of the within mean square

n = the common number of replicates at each concentration
(this assumes equal replication at each concentration)

n_1 = the number of replicates in the control.

16.13.2.7.8 In this example,

$$MSD = 2.50(1.55)\sqrt{(1/3)+(1/3)}$$

$$= 2.50\ (1.55)(.8165)$$

$$= 3.16$$

16.13.2.7.9 Therefore, for this set of data, the minimum difference that can be detected as statistically significant is 3.16 cystocarps.

16.13.2.7.10 This represents a 17.6% reduction in cystocarp production from the control.

16.13.2.8 Calculation of the ICp

16.13.2.8.1 The sexual reproduction data in Table 5 are utilized in this example. Table 12 contains the mean number of cystocarps for each effluent concentration. As can be seen, the observed means are monotonically non-increasing with respect to concentration. Therefore, it is not necessary to smooth the means prior to calculating the ICp. Refer to Figure 12 for a plot of the response curve.

TABLE 12. RED MACROALGA, *CHAMPIA PARVULA*, MEAN NUMBER OF CYSTOCARPS

Effluent Conc. (%)	i	Response Means $\bar{Y}_i$ (mg)	Smoothed Means M_i (mg)
Control	1	18.00	18.00
0.8	2	10.53	10.53
1.3	3	4.53	4.53
2.2	4	3.60	3.60
3.6	5	2.60	2.60
6.0	6	1.07	1.07
10.0	7	0.27	0.27

16.13.2.8.2 An IC25 and IC50 can be estimated using the Linear Interpolation Method. A 25% reduction in mean number of cystocarps, compared to the controls, would result in a mean number of 13.50 cystocarps, where $M_1(1-p/100) = 18.00(1-25/100)$. A 50% reduction in mean number of cystocarps, compared to the controls, would result in a mean number of 9.00 cystocarps. Examining the means and their associated concentrations (Table 12), the response, 13.50, is bracketed by $C_1 = 0.0\%$ effluent and $C_2 = 0.8\%$ effluent. The response, 9.00, is bracketed by $C_2 = 0.8\%$ effluent and $C_3 = 1.3\%$ effluent.

16.13.2.8.3 Using the equation from Section 4.2 in Appendix L, the estimate of the IC25 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j] \frac{(C_{(j+1)} - C_j)}{(M_{(j+1)} - M_j)}$$

$$IC25 = 0.0 + [18.00(1 - 25/100) - 18.00] \frac{(0.8 - 0.0)}{(10.53 - 18.00)}$$

$$= 0.5\%.$$

16.13.2.8.4 Using the equation from Section 4.2 from Appendix L, the estimate of the IC50 is calculated as follows:

$$ICp = C_j + [M_1(1 - p/100) - M_j] \frac{(C_{(j+1)} - C_j)}{(M_{(j+1)} - M_j)}$$

$$IC50 = 0.8 + [18.00(1 - 50/100) - 10.53] \frac{(1.3 - 0.8)}{(4.53 - 10.53)}$$

$$= 0.9\%$$

16.13.2.8.5 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC25 was 0.4821%. The empirical 95.0% confidence interval for the true mean was 0.4013% to 0.6075%. The computer program output for the IC25 for this data set is shown in Figure 13.

16.13.2.8.6 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC50 was 0.9278%. The empirical 95.0% confidence interval for the true mean was 0.7893% and 1.0576%. The computer program output for the IC50 for this data set is shown in Figure 14.

16.14 PRECISION AND ACCURACY

16.14.1 PRECISION

16.14.1.1 Single-Laboratory Precision

16.14.1.1.1 The single-laboratory precision data from six tests with copper sulfate (Cu) and six tests with sodium dodecyl sulfate (SDS) are listed in Tables 13-16. The NOECs with Cu differed by only one concentration interval (factor of two), showing good precision. The precision of the first four tests with SDS was somewhat obscured by the choice of toxicant concentrations, but appeared similar to that of Cu in the last two tests. The IC25 and IC50 are indicated in Tables 13-16. The coefficient of variation, based on the IC25 for these two reference toxicants in natural seawater and a mixture of natural seawater and GP2, ranged from 59.6% to 69.0%, and for the IC50, ranged from 22.9% to 43.7%.

16.14.1.1.2 EPA evaluated single-laboratory (within-laboratory) precision of the Red Macroalga, *Champia parvula*, Reproduction Test using a database of routine reference toxicant test results from two laboratories (USEPA, 2000b). The database consisted of 23 reference toxicant tests conducted in 2 laboratories using reference toxicants including: copper and sodium dodecyl sulfate. The within-laboratory CVs calculated for routine reference toxicant tests at these 2 laboratories were 58% and 59% for the IC25 reproduction endpoint.

16.14.1.2 Multilaboratory Precision

16.14.1.2.1 The multilaboratory precision of the test has not yet been determined.

16.14.2 ACCURACY

16.14.2.1 The accuracy of toxicity tests cannot be determined.

APPENDICES

APPENDIX A

INDEPENDENCE, RANDOMIZATION, AND OUTLIERS

1. STATISTICAL INDEPENDENCE

1.1 Dunnett's Procedure and the t test with Bonferroni's adjustment are parametric procedures based on the assumptions that (1) the observations within treatments are independent and normally distributed, and (2) that the variance of the observations is homogeneous across all toxicant concentrations and the control. Of the three possible departures from the assumptions, non-normality, heterogeneity of variance, and lack of independence, those caused by lack of independence are the most difficult to resolve (see Scheffe, 1959). For toxicity data, statistical independence means that given knowledge of the true mean for a given concentration or control, knowledge of the error in any one actual observation would provide no information about the error in any other observation. Lack of independence is difficult to assess and difficult to test for statistically. It may also have serious effects on the true alpha or beta level. Therefore, it is of utmost importance to be aware of the need for statistical independence between observations and to be constantly vigilant in avoiding any patterned experimental procedure that might compromise independence. One of the best ways to help insure independence is to follow proper randomization procedures throughout the test.

2. RANDOMIZATION

2.1 Randomization of the distribution of test organisms among test chambers, and the arrangement of treatments and replicate chambers is an important part of conducting a valid test. The purpose of randomization is to avoid situations where test organisms are placed serially into test chambers, or where all replicates for a test concentration are located adjacent to one another, which could introduce bias into the test results.

2.2 An example of randomization of the distribution of test organisms among test chambers, and an example of randomization of arrangement of treatments and replicate chambers are described using the Sheepshead Minnow Larval Survival and Growth test. For the purpose of the example, the test design is as follows: Five effluent concentrations are tested in addition to the control. The effluent concentrations are as follows: 6.25%, 12.5%, 25.0%, 50.0%, and 100.0%. There are four replicate chambers per treatment. Each replicate chamber contains ten fish.

2.3 RANDOMIZATION OF FISH TO REPLICATE CHAMBERS EXAMPLE

2.3.1 Consider first the random assignment of the fish to the replicate chambers. The first step is to label each of the replicate chambers with the control or effluent concentration and the replicate number. The next step is to assign each replicate chamber four double-digit numbers. An example of this assignment is provided in Table A.1. Note that the double digits 00 and 97 through 99 were not used.

TABLE A.1. RANDOM ASSIGNMENT OF FISH TO REPLICATE CHAMBERS
EXAMPLE ASSIGNED NUMBERS FOR EACH REPLICATE CHAMBER

Assigned Numbers	Replicate Chamber
01, 25, 49, 73	Control, replicate chamber 1
02, 26, 50, 74	Control, replicate chamber 2
03, 27, 51, 75	Control, replicate chamber 3
04, 28, 52, 76	Control, replicate chamber 4
05, 29, 53, 77	6.25% effluent, replicate chamber 1
06, 30, 54, 78	6.25% effluent, replicate chamber 2
07, 31, 55, 79	6.25% effluent, replicate chamber 3
08, 32, 56, 80	6.25% effluent, replicate chamber 4
09, 33, 57, 81	12.5% effluent, replicate chamber 1
10, 34, 58, 82	12.5% effluent, replicate chamber 2
11, 35, 59, 83	12.5% effluent, replicate chamber 3
12, 36, 60, 84	12.5% effluent, replicate chamber 4
13, 37, 61, 85	25.0% effluent, replicate chamber 1
14, 38, 62, 86	25.0% effluent, replicate chamber 2
15, 39, 63, 87	25.0% effluent, replicate chamber 3
16, 40, 64, 88	25.0% effluent, replicate chamber 4
17, 41, 65, 89	50.0% effluent, replicate chamber 1
18, 42, 66, 90	50.0% effluent, replicate chamber 2
19, 43, 67, 91	50.0% effluent, replicate chamber 3
20, 44, 68, 92	50.0% effluent, replicate chamber 4
21, 45, 69, 93	100.0% effluent, replicate chamber 1
22, 46, 70, 94	100.0% effluent, replicate chamber 2
23, 47, 71, 95	100.0% effluent, replicate chamber 3
24, 48, 72, 96	100.0% effluent, replicate chamber 4

2.3.2 The random numbers used to carry out the random assignment of fish to replicate chambers are provided in Table A.2. The third step is to choose a starting position in Table A.2, and read the first double digit number. The first number read identifies the replicate chamber for the first fish taken from the tank. For the example, the first entry in row 2 was chosen as the starting position. The first number in this row is 37. According to Table A.1, this number corresponds to replicate chamber 1 of the 25.0% effluent concentration. Thus, the first fish taken from the tank is to be placed in replicate chamber 1 of the 25.0% effluent concentration.

TABLE A.2. TABLE OF RANDOM NUMBERS (Dixon and Massey, 1983)

10 09 73 25 33	76 52 01 35 86	34 67 35 43 76	80 95 90 91 17	39 29 27 49 45

69 07 49 41 38	87 63 79 19 76	35 58 40 44 01	10 51 82 16 15	01 84 87 69 38

2.3.3 The next step is to read the double digit number to the right of the first one. The second number identifies the replicate chamber for the second fish taken from the tank. Continuing the example, the second number read in row 2 of Table A.2 is 54. According to Table A.1, this number corresponds to replicate chamber 2 of the 6.25% effluent concentration. Thus, the second fish taken from the tank is to be placed in replicate chamber 2 of the 6.25% effluent concentration.

2.3.4 Continue in this fashion until all the fish have been randomly assigned to a replicate chamber. In order to fill each replicate chamber with ten fish, the assigned numbers will be used more than once. If a number is read from the table that was not assigned to a replicate chamber, then ignore it and continue to the next number. If a replicate chamber becomes filled and a number is read from the table that corresponds to it, then ignore that value and continue to the next number. The first ten random assignments of fish to replicate chambers for the example are summarized in Table A.3.

TABLE A.3. EXAMPLE OF RANDOM ASSIGNMENT OF FIRST TEN FISH TO REPLICATE CHAMBERS

Fish		Assignment	
First	fish taken from tank	25.0% effluent,	replicate chamber 1
Second	fish taken from tank	6.25% effluent,	replicate chamber 2
Third	fish taken from tank	50.0% effluent,	replicate chamber 4
Fourth	fish taken from tank	100.0% effluent,	replicate chamber 4
Fifth	fish taken from tank	6.25% effluent,	replicate chamber 1
Sixth	fish taken from tank	25.0% effluent,	replicate chamber 4
Seventh	fish taken from tank	50.0% effluent,	replicate chamber 1
Eighth	fish taken from tank	100.0% effluent,	replicate chamber 3
Ninth	fish taken from tank	50.0% effluent,	replicate chamber 2
Tenth	fish taken from tank	100.0% effluent,	replicate chamber 4

2.3.5 Four double-digit numbers were assigned to each replicate chamber (instead of one, two, or three double-digit numbers) in order to make efficient use of the random number table (Table A.2). To illustrate, consider the assignment of only one double-digit number to each replicate chamber: the first column of assigned numbers in Table A.1. Whenever the numbers 00 and 25 through 99 are read from Table A.2, they will be disregarded and the next number will be read.

2.4 RANDOMIZATION OF REPLICATE CHAMBERS TO POSITIONS EXAMPLE

2.4.1 Next consider the random assignment of the 24 replicate chambers to positions within the water bath (or equivalent). Assume that the replicate chambers are to be positioned in a four row by six column rectangular array. The first step is to label the positions in the water bath. Table A.4 provides an example layout.

TABLE A.4. RANDOM ASSIGNMENT OF REPLICATE CHAMBERS TO POSITIONS: EXAMPLE LABELING THE POSITIONS WITHIN THE WATER BATH

1	2	3	4	5	6
7	8	9	10	11	12
13	14	15	16	17	18
19	20	21	22	23	24

2.4.2 The second step is to assign each of the 24 positions four double-digit numbers. An example of this assignment is provided in Table A.5. Note that the double digits 00 and 97 through 99 were not used.

TABLE A.5. RANDOM ASSIGNMENT OF REPLICATE CHAMBERS TO POSITIONS: EXAMPLE ASSIGNED NUMBERS FOR EACH POSITION

Assigned Numbers	Position
01, 25, 49, 73	1
02, 26, 50, 74	2
03, 27, 51, 75	3
04, 28, 52, 76	4
05, 29, 53, 77	5
06, 30, 54, 78	6
07, 31, 55, 79	7
08, 32, 56, 80	8
09, 33, 57, 81	9
10, 34, 58, 82	10
11, 35, 59, 83	11
12, 36, 60, 84	12
13, 37, 61, 85	13
14, 38, 62, 86	14
15, 39, 63, 87	15
16, 40, 64, 88	16
17, 41, 65, 89	17
18, 42, 66, 90	18
19, 43, 67, 91	19
20, 44, 68, 92	20
21, 45, 69, 93	21
22, 46, 70, 94	22
23, 47, 71, 95	23
24, 48, 72, 96	24

2.4.3 The random numbers used to carry out the random assignment of replicate chambers to positions are provided in Table A.2. The third step is to choose a starting position in Table A.2, and read the first double-digit number. The first number read identifies the position for the first replicate chamber of the control. For the example, the first entry in row 10 of Table A.2 was chosen as the starting position. The first number in this row was 73. According to Table A.5, this number corresponds to position 1. Thus, the first replicate chamber for the control will be placed in position 1.

2.4.4 The next step is to read the double-digit number to the right of the first one. The second number identifies the position for the second replicate chamber of the control. Continuing the example, the second number read in row 10 of Table A.2 is 79. According to Table A.5, this number corresponds to position 7. Thus, the second replicate chamber for the control will be placed in position 7.

2.4.5 Continue in this fashion until all the replicate chambers have been assigned to a position. The first four numbers read will identify the positions for the control replicate chambers, the second four numbers read will identify the positions for the lowest effluent concentration replicate chambers, and so on. If a number is read from the table that was not assigned to a position, then ignore that value and continue to the next number. If a number is repeated in Table A.2, then ignore the repeats and continue to the next number. The complete randomization of replicate chambers to positions for the example is displayed in Table A.6.

TABLE A.6. RANDOM ASSIGNMENT OF REPLICATE CHAMBERS TO POSITIONS: EXAMPLE ASSIGNMENT OF ALL 24 POSITIONS

Control	100.0%	6.25%	6.25%	6.25%	12.5%
Control	12.5%	Control	25.0%	12.5%	25.0%
100.0%	50.0%	100.0%	Control	100.0%	25.0%
50.0%	50.0%	25.0%	50.0%	12.5%	6.25%

2.4.6 Four double-digit numbers were assigned to each position (instead of one, two, or three) in order to make efficient use of the random number table (Table A.2). To illustrate, consider the assignment of only one double-digit number to each position: the first column of assigned numbers in Table A.5. Whenever the numbers 00 and 25 through 99 are read from Table A.2, they will be disregarded and the next number will be read.

3. **OUTLIERS**

3.1 An outlier is an inconsistent or questionable data point that appears unrepresentative of the general trend exhibited by the majority of the data. Outliers may be detected by tabulation of the data, plotting, and by an analysis of the residuals. An explanation should be sought for any questionable data points. Without an explanation, data points should be discarded only with extreme caution. If there is no explanation, the analysis should be performed both with and without the outlier, and the results of both analyses should be reported.

3.2 Gentleman-Wilk's A statistic gives a test for the condition that the extreme observation may be considered an outlier. For a discussion of this, and other techniques for evaluating outliers, see Draper and John (1981).

APPENDIX B

VALIDATING NORMALITY AND HOMOGENEITY OF VARIANCE ASSUMPTIONS

1. INTRODUCTION

1.1 Dunnett's Procedure and the t test with Bonferroni's adjustment are parametric procedures based on the assumptions that the observations within treatments are independent and normally distributed, and that the variance of the observations is homogeneous across all toxicant concentrations and the control. These assumptions should be checked prior to using these tests, to determine if they have been met. Tests for validating the assumptions are provided in the following discussion. If the tests fail (if the data do not meet the assumptions), a nonparametric procedure such as Steel's Many-one Rank Test may be more appropriate. However, the decision on whether to use parametric or nonparametric tests may be a judgement call, and a statistician should be consulted in selecting the analysis.

2. TEST FOR NORMAL DISTRIBUTION OF DATA

2.1 SHAPIRO-WILK'S TEST

2.1.1 One formal test for normality is the Shapiro-Wilk's Test (Conover, 1980). The test statistic is obtained by dividing the square of an appropriate linear combination of the sample order statistics by the usual symmetric estimate of variance. The calculated W must be greater than zero and less than or equal to one. This test is recommended for a sample size of 50 or less. If the sample size is greater than 50, the Kolmogorov "D" statistic (Stephens, 1974) is recommended. An example of the Shapiro-Wilk's test is provided below.

2.2 The example uses growth data from the Sheepshead Minnow Larval Survival and Growth Test. The same data are used in the discussion of the homogeneity of variance determination in Paragraph 3 and Dunnett's Procedure in Appendix C. The data, the mean and variance of the observations at each concentration, including the control, are listed in Table B.1.

TABLE B.1. SHEEPSHEAD MINNOW, *CYPRINODON VARIEGATUS*, LARVAL GROWTH DATA (WEIGHT IN MG) FOR THE SHAPIRO-WILK'S TEST

		Effluent Concentration (%)			
Replicate	Control	6.25	12.5	25.0	50.0
1	1.017	1.157	0.998	0.837	0.715
2	0.745	0.914	0.793	0.935	0.907
3	0.862	0.992	1.021	0.839	1.044
Mean(Y_i)	0.875	1.021	0.937	0.882	0.889
S_i^2	0.019	0.015	0.016	0.0031	0.027
i	1	2	3	4	5

2.3 The first step of the test for normality is to center the observations by subtracting the mean of all observations within a concentration from each observation in that concentration. The centered observations are listed in Table B.2.

TABLE B.2. EXAMPLE OF SHAPIRO-WILK'S TEST: CENTERED OBSERVATIONS

		Effluent Concentration (%)			
Replicate	Control	6.25	12.5	25.0	50.0
1	0.142	0.136	0.061	- 0.009	- 0.174
2	- 0.130	- 0.107	- 0.144	0.053	0.018
3	- 0.013	- 0.029	0.084	- 0.043	0.155

2.4 Calculate the denominator, D, of the test statistic:

$$D = \sum_{i=1}^{n} (X_i - \overline{X})^2$$

Where: X_i = the centered observations, $\overline{X}$ is the overall mean of the centered observations, and n is the total number of the centered observations. For this set of data, $\overline{X} = 0$, and D = 0.1589.

2.4.1 For this set of data,

n = 15

$\overline{X}$ = 1/50 (0) = 0.0

D = 0.1589

2.5 Order the centered observations from smallest to largest,

$X^{(i)} \leq X^{(2)} \leq \ldots \leq X^{(n)}$

where $X^{(i)}$ denote the ith order statistic. The ordered observations are listed in Table B.3.

TABLE B.3. EXAMPLE OF THE SHAPIRO-WILK'S TEST: ORDERED OBSERVATIONS

i	$X^{(i)}$
1	- 0.174
2	- 0.144
3	- 0.130
4	- 0.107
5	- 0.043
6	- 0.029
7	- 0.013
8	- 0.009
9	0.018
10	0.053
11	0.061
12	0.084
13	0.136
14	0.142
15	0.155

2.6 From Table B.4,for the number of observations, n, obtain the coefficients a_1, a_2, ..., a_k, where k is n/2 if n is even, and (n-1)/2 if n is odd. For the data in this example, n = 15, k = 7, and the a_i values are listed in Table B.5. The differences, $X^{(n-i+1)} - X^{(i)}$, are listed in Table B.5.

2.7 Compute the test statistic, W, as follows:

$$W = \frac{1}{D}\left[\sum_{i=1}^{k} a_i \left(X^{(n-i+1)} - X^{(i)}\right)\right]^2$$

50	0.930	0.938	0.947	0.955	0.974	0.985	0.988	0.990	0.991

2.8 The decision rule for this test is to compare the critical value from Table B.6 to the computed W. If the computed value is less than the critical value, conclude that the data are not normally distributed. For this example, the critical value at a significance level of 0.01 and 15 observations (n) is 0.835. The calculated value, 0.9516, is not less than the critical value. Therefore conclude that the data are normally distributed.

2.9 In general, if the data fail the test for normality, a transformation such as to log values may normalize the data. After transforming the data, repeat the Shapiro Wilk's Test for normality.

3. **TEST FOR HOMOGENEITY OF VARIANCE**

3.1 For Dunnett's Procedure and the t test with Bonferroni's adjustment, the variances of the data obtained from each toxicant concentration and the control are assumed to be equal. Bartlett's Test is a formal test of this assumption. In using this test, it is assumed that the data are normally distributed.

3.2 The data used in this example are growth data from a Sheepshead Minnow Larval Survival and Growth Test, and are the same data used in Appendices C and D. These data are listed in Table B.7, together with the calculated variance for the control and each toxicant concentration.

3.3 The test statistic for Bartlett's Test (Snedecor and Cochran, 1980) is as follows:

$$B = \frac{[(\sum_{i=1}^{P} V_i) \ln \overline{S}^2 - \sum_{i=1}^{P} V_i \ln S_i^2]}{C}$$

Where: V_i = degrees of freedom for each effluent concentration and control, ($V_i = n_i - 1$)

p = number of levels of toxicant concentration including the control

ln = $\log_e$

i = 1, 2, ..., p where p is the number of concentrations including the control

n_i = the number of replicates for concentration i.

$$\overline{S}^2 = \frac{(\sum_{i=1}^{P} V_i S_i^2)}{\sum_{i=1}^{P} V_i}$$

$$C = 1 + [3(p-1)]^{-1}[\sum_{i=1}^{P} 1/V_i - (\sum_{i=1}^{P} V_i)^{-1}]$$

TABLE B.7. SHEEPSHEAD MINNOW, *CYPRINODON VARIEGATUS*, LARVAL GROWTH DATA (WEIGHT IN MG) USED FOR BARTLETT'S TEST FOR HOMOGENEITY OF VARIANCE

		Effluent Concentration (%)			
Replicate	Control	6.25	12.5	25.0	50.0
1	1.017	1.157	0.998	0.873	0.715
2	0.745	0.914	0.793	0.935	0.907
3	0.862	0.992	1.021	0.839	1.044
Mean	0.875	1.021	0.937	0.882	0.889
S_i^2	0.019	0.015	0.016	0.0024	0.027
i	1	2	3	4	5

3.4 Since B is approximately distributed as chi-square with p - 1 degrees of freedom when the variances are equal, the appropriate critical value is obtained from a table of the chi-square distribution for p - 1 degrees of freedom and a significance level of 0.01. If B is less than the critical value then the variances are assumed to be equal.

3.5 For the data in this example, $V_i = 2$, $p = 5$, $\overline{S}^2 = 0.0158$, and $C = 1.2$. The calculated B value is:

$$B = \frac{2[5(\ln\ 0.0158) - \sum_i \ln(S_i^2)]}{1.2}$$

$$= \frac{2[5(-\ 4.1477)\ -\ (-22.1247)]}{1.2}$$

$$= 2.3103$$

3.6 Since B is approximately distributed as chi-square with p - 1 degrees of freedom when the variances are equal, the appropriate critical value for the test is 13.3 for a significance level of 0.01. Since B is less than 13.3, the conclusion is that the variances are not different.

4. TRANSFORMATIONS OF THE DATA

4.1 When the assumptions of normality and/or homogeneity of variance are not met, transformations of the data may remedy the problem, so that the data can be analyzed by parametric procedures, rather than nonparametric technique such as Steel's Many-one Rank Test or Wilcoxon's Rank Sum Test. Examples of transformations include log, square root, arc sine square root, and reciprocals. After the data have been transformed, the Shapiro-Wilk's and Bartlett's tests should be performed on the transformed observations to determine whether the assumptions of normality and/or homogeneity of variance are met.

4.2 ARC SINE SQUARE ROOT TRANSFORMATION (USEPA, 1993).

4.2.1 For data consisting of proportions from a binomial (response/no response; live/dead) response variable, the variance within the ith treatment is proportional to $P_i (1 - P_i)$, where P_i is the expected proportion for the treatment. This clearly violates the homogeneity of variance assumption required by parametric procedures such as Dunnett's Procedure or the t test with Bonferroni's adjustment, since the existence of a treatment effect implies different values of P_i for different treatments, i. Also, when the observed proportions are based on small samples, or when P_i is close to zero or one, the normality assumption may be invalid. The arc sine square root (arc sine $\sqrt{P}$) transformation is commonly used for such data to stabilize the variance and satisfy the normality requirement.

4.2.2 Arc sine transformation consists of determining the angle (in radians) represented by a sine value. In the case of arc sine square root transformation of mortality data, the proportion of dead (or affected) organisms is taken as the sine value, the square root of the sine value is determined, and the angle (in radians) for the square root of the sine value is determined. Whenever the proportion dead is 0 or 1, a special modification of the arc sine square root transformation must be used (Bartlett, 1937). An explanation of the arc sine square root transformation and the modification is provided below.

4.2.3 Calculate the response proportion (RP) at each effluent concentration, where:

RP = (number of surviving or unaffected organisms)/(number exposed).

Example: If 12 of 20 animals in a given treatment replicate survive:

RP = 12/20

= 0.60

4.2.4 Transform each RP to its arc sine square root, as follows:

4.2.4.1 For RPs greater than zero or less than one:

Angle (radians) = arc sine $\sqrt{RP}$

Example: If RP = 0.60:

Angle = arc sine $\sqrt{0.60}$

= arc sine 0.7746

= 0.8861 radians

4.2.4.2 Modification of the arc sine square root when RP = 0.

Angle (in radians) = arc sine $\sqrt{1/4N}$

Where: N = Number of animals/treatment replicate

Example: If 20 animals are used:

Angle = arc sine $\sqrt{1/80}$

= arc sine 0.1118

= 0.1120 radians

4.2.4.3 Modification of the arc sine square root when RP = 1

Angle = 1.5708 radians - (radians for RP = 0)

Example: Using above value:

Angle = 1.5708 - 0.1120

= 1.4588 radians

APPENDIX C

DUNNETT'S PROCEDURE

1. MANUAL CALCULATIONS

1.1 Dunnett's Procedure (Dunnett, 1955; Dunnett, 1964) is used to compare each concentration mean with the control mean to decide if any of the concentrations differ from the control. This test has an overall error rate of alpha, which accounts for the multiple comparisons with the control. It is based on the assumptions that the observations are independent and normally distributed and that the variance of the observations is homogeneous across all concentrations and control. (See Appendix B for a discussion on validating the assumptions). Dunnett's Procedure uses a pooled estimate of the variance, which is equal to the error value calculated in an analysis of variance. Dunnett's Procedure can only be used when the same number of replicate test vessels have been used at each concentration and the control. When this condition is not met, the t test with Bonferroni's adjustment is used (see Appendix D).

1.2 The data used in this example are growth data from a Sheepshead Minnow Larval Survival and Growth Test, and are the same data used in Appendices B and D. These data are listed in Table C.1.

TABLE C.1. SHEEPSHEAD MINNOW, *CYPRINODON VARIEGATUS*, LARVAL GROWTH DATA (WEIGHT IN MG) USED FOR DUNNETT'S PROCEDURE

Effluent Conc (%)	i	Replicate Test Vessel 1	2	3	Total (T_i)	Mean ($\overline{Y}_i$)
Control	1	1.017	0.745	0.862	2.624	0.875
6.25	2	1.157	0.914	0.992	3.063	1.021
12.5	3	0.998	0.793	1.021	2.812	0.937
25.0	4	0.873	0.935	0.839	2.647	0.882
50.0	5	0.715	0.907	1.044	2.666	0.889

1.3 One way to obtain an estimate of the pooled variance is to construct an ANOVA table including all sums of squares, using the following formulas:

Where: p = number of effluent concentrations including the control:

N = the total sample size; $N=\sum_i n_i$

n_i = the number of replicates for concentration "i"

$SST=\sum_{ij} Y_{ij}^2 - G^2/N$ Total Sum of Squares

$SSB = \sum_i T_i^2/n_i - G^2/N$ Between Sum of Squares

$SSW = SST - SSB$ Within Sum of Squares

G = the grand total of all sample observations; $G = \sum_{i=1}^{P} T_i$

T_i = the total of the replicate measurements for concentration i

N = the total sample size; $N = \sum_i n_i$

n_i = the number of replicates for concentration i

Y_{ij} = the jth observation for concentration i

1.4 For the data in this example:

$n_1 = n_2 = n_3 = n_4 = n_5 = 3$

N = 20

$T_1 = Y_{11} + Y_{12} + Y_{13} = 2.624$
$T_2 = Y_{21} + Y_{22} + Y_{23} = 3.063$
$T_3 = Y_{31} + Y_{32} + Y_{33} = 2.812$
$T_4 = Y_{41} + Y_{42} + Y_{43} = 2.647$
$T_5 = Y_{51} + Y_{52} + Y_{53} = 2.666$

$G = T_1 + T_2 + T_3 + T_4 + T_5 = 13.812$

$SST = \sum_{ij} Y_{ij}^2 - G^2/N$

$= 12.922 - (13.812)^2/15$

$= 0.204$

$= 12.763 - (13.812)^2/15$

$= 0.045$

$SSW = SST - SSB$

$= 0.204 - 0.045$

= 0.159

1.5 Summarize these data in the ANOVA table (Table C.2).

TABLE C.2. ANOVA TABLE FOR DUNNETT'S PROCEDURE

Source	df	Sum of Squares (SS)	Mean Square (MS) (SS/df)
Between	p - 1	SSB	S_B^2 = SSB/(p-1)
Within	N - p	SSW	S_W^2 = SSW/(N-p)
Total	N - 1	SST	

1.6 Summarize data for ANOVA (Table C.3).

TABLE C.3. COMPLETED ANOVA TABLE FOR DUNNETT'S PROCEDURE

Source	df	SS	Mean Square
Between	5 - 1 = 4	0.045	0.011
Within	15 - 5 = 10	0.159	0.016
Total	14	0.204	

1.7 To perform the individual comparisons, calculate the t statistic for each concentration and control combination, as follows:

$$t_i = \frac{(\overline{Y}_1 - \overline{Y}_i)}{S_w\sqrt{(1/n_1) + (1/n_i)}}$$

Where: $\overline{Y}_i$ = mean for each concentration i.

$\overline{Y}_1$ = mean for the control

S_w = square root of the within mean square

n_1 = number of replicates in the control.

n_i = number of replicates for concentration i.

1.8 Table C.4 includes the calculated t values for each concentration and control combination.

TABLE C.4. CALCULATED T VALUES

Effluent Concentration (%)	i	t_i
6.25	2	- 1.414
12.5	3	- 0.600
25.0	4	- 0.068
50.0	5	- 0.136

1.9 Since the purpose of the test is only to detect a decrease in growth from the control, a one-sided test is appropriate. The critical value for the one-sided comparison (2.47), with an overall alpha level of 0.05, 10 degrees of freedom and four concentrations excluding the control is read from the table of Dunnett's "T" values (Table C.5; this table assumes an equal number of replicates in all treatment concentrations and the control). Comparing each of the calculated t values in Table C.4 with the critical value, no decreases in growth from the control were detected. Thus the NOEC is 50.0%.

1.10 To quantify the sensitivity of the test, the minimum significant difference (MSD) may be calculated. The formula is as follows:

$$MSD = d\, S_w \sqrt{(1/n_1) + (1/n)}$$

Where: d = critical value for the Dunnett's Procedure

S_w = the square root of the within mean square

n = the number of replicates at each concentration, assuming an equal number of replicates at all treatment concentrations

n_1 = number of replicates in the control

For example:

$$MSD = 2.47(0.126)[\sqrt{(1/3)+(1/3)}] = 2.47(0.126)(\sqrt{2/3})$$

$$= 2.47\ (0.126)(0.816)$$
$$= 0.254$$

TABLE C.5. DUNNETT'S "T" VALUES (Miller, 1981)

1.11 For this set of data, the minimum difference between the control mean and a concentration mean that can be detected as statistically significant is 0.254 mg. This represents a decrease in growth of 29% from the control.

1.11.1 If the data have not been transformed, the MSD (and the percent decrease from the control mean that it represents) can be reported as is.

1.11.2 In the case where the data have been transformed, the MSD would be in transformed units. In this case carry out the following conversion to determine the MSD in untransformed units.

1.11.2.1 Subtract the MSD from the transformed control mean. Call this difference D. Next, obtain untransformed values for the control mean and the difference, D.

$$MSD_u = \text{control}_u - D_u$$

Where: MSD_u = the minimum significant difference for untransformed data

$Control_u$ = the untransformed control mean

D_u = the untransformed difference

1.11.2.2 Calculate the percent reduction from the control that MSD_u represents as:

$$\text{Percent Reduction} = \frac{MSD_u}{Control_u} \times 100$$

1.11.3 An example of a conversion of the MSD to untransformed units, when the arc sine square root transformation was used on the data, follows.

Step 1. Subtract the MSD from the transformed control mean. As an example, assume the data in Table C.1 were transformed by the arc sine square root transformation. Thus:

0.875 - 0.254 = 0.621

Step 2. Obtain untransformed values for the control mean (0.875) and the difference (0.621) obtained in Step 1, above.

$[\text{Sine } (0.875)]^2 = 0.589$

$[\text{Sine } (0.621)]^2 = 0.339$

Step 3. The untransformed MSD (MSD_u) is determined by subtracting the untransformed values obtained in Step 2.

$MSD_u = 0.589 - 0.339 = 0.250$

In this case, the MSD would represent a 42% decrease in survival from the control [(0.250/0.589)(100)].

2. COMPUTER CALCULATIONS

2.1 This computer program incorporates two analyses: an analysis of variance (ANOVA), and a multiple comparison of treatment means with the control mean (Dunnett's Procedure). The ANOVA is used to obtain the error value. Dunnett's Procedure indicates which toxicant concentration means (if any) are statistically different from the control mean at the 5% level of significance. The program also provides the minimum difference between the control and treatment means that could be detected as statistically significant, and tests the validity of the homogeneity of variance assumption by Bartlett's Test. The multiple comparison is performed based on procedures described by Dunnett (1955).

2.2 The source code for the Dunnett's program is structured into a series of subroutines, controlled by a driver routine. Each subroutine has a specific function in the Dunnett's Procedure, such as data input, transforming the data, testing for equality of variances, computing p values, and calculating the one-way analysis of variance.

2.3 The program compares up to seven toxicant concentrations against the control, and can accommodate up to 50 replicates per concentration.

2.4 If the number of replicates at each toxicant concentration and control are not equal, a t test with the Bonferroni adjustment is performed instead of Dunnett's Procedure (see Appendix D).

2.5 The program was written in IBM-PC FORTRAN by Computer Sciences Corporation, 26 W. Martin Luther King Drive, Cincinnati, OH 45268. A compiled version of the program can be obtained from EMSL-Cincinnati by sending a diskette with a written request.

2.6 DATA INPUT AND OUTPUT

2.6.1 Data on the number of surviving mysids, *Mysidopsis bahia*, from a survival, growth and fecundity test (Table C.6) are used to illustrate the data input and output for this program.

2.6.2 Data Input

2.6.2.1 When the program is entered, the user is asked to select the type of data to be analyzed:

1. Response proportions, like survival or fertilization proportions data.
2. Counts and measurements, like offspring counts, cystocarp and algal cell counts, weights, chlorophyll measurements or turbidity measurements.

2.6.2.2 After the type of analysis for the data is chosen, the user has the following options:

1. Create a data file
2. Edit a data file
3. Perform analysis on existing data set
4. Stop

2.6.2.3 When Option 1 (Create a data file) is selected for response proportions, the program prompts the user for the following information:

1. Number of concentrations, including control
2. For each concentration and replicate:
   - number of organisms exposed per replicate
   - number of organisms responding per replicate (organisms surviving, eggs fertilized, etc.)

2.6.2.4 After the data have been entered, the user may save the file on a disk, and the program returns to the main menu (see below).

2.6.2.5 Sample data input is shown in Figure C.1.

2.6.3. Program Output

2.6.3.1 When Option 3 (perform analysis on existing data set) is selected from the menu, the user is asked to select the transformation desired, and indicate whether they expect the means of the test groups to be less or greater than the mean for the control group (see Figure C.2)

2.6.3.2 Summary statistics (Figure C.3) for the raw and transformed data, if applicable, the ANOVA table, results of Bartlett's Test, the results of the multiple comparison procedure, and the minimum detectable difference are included in the program output.

APPENDIX D

T TEST WITH BONFERRONI'S ADJUSTMENT

1. The t test with Bonferroni's adjustment is used as an alternative to Dunnett's Procedure when the number of replicates is not the same for all concentrations. This test sets an upper bound of alpha on the overall error rate, in contrast to Dunnett's Procedure, for which the overall error rate is fixed at alpha. Thus, Dunnett's Procedure is a more powerful test.

2. The t test with Bonferroni's adjustment is based on the same assumptions of normality of distribution and homogeneity of variance as Dunnett's Procedure (See Appendix B for testing these assumptions), and, like Dunnett's Procedure, uses a pooled estimate of the variance, which is equal to the error value calculated in an analysis of variance.

3. An example of the use of the t test with Bonferroni's adjustment is provided below. The data used in the example are the same as in Appendix C, except that the third replicate from the 50% effluent treatment is presumed to have been lost. Thus, Dunnett's Procedure cannot be used. The weight data are presented in Table D.1.

TABLE D.1. SHEEPSHEAD MINNOW, *CYPRINODON VARIEGATUS*, LARVAL GROWTH DATA (WEIGHT IN MG) USED FOR THE T TEST WITH BONFERRONI'S ADJUSTMENT

Effluent Conc (%)		Replicate Test Vessel			Total	Mean
	i	1	2	3	(T_i)	($\overline{Y}_i$)
Control	1	1.017	0.745	0.862	2.624	0.875
6.25	2	1.157	0.914	0.992	3.063	1.021
12.5	3	0.998	0.793	1.021	2.812	0.937
25.0	4	0.873	0.935	0.839	2.647	0.882
50.0	5	0.715	0.907	(Lost)	1.622	0.811

3.1 One way to obtain an estimate of the pooled variance is to construct an ANOVA table including all sums of squares, using the following formulas:

Where: p = number of effluent concentrations including the control

N = the total sample size; $N=\sum_i n_i$

n_i = the number of replicates for concentration i

$SST=\sum_{ij} Y_{ij}^2 - G^2/N$ Total Sum of Squares

$SSB = \sum_i T_i^2/n_i - G^2/N$ Between Sum of Squares

$SSW = SST - SSB$ Within Sum of Squares

Where: G = The grand total of all sample observations; $G = \sum_{i=1}^{P} T_i$

T_i = The total of the replicate measurements for concentration i

Y_{ij} = The jth observation for concentration i

3.2 For the data in this example:

$n_1 = n_2 = n_3 = n_4 = 3$

$N = 20$

$T_1 = Y_{11} + Y_{12} + Y_{13} = 2.624$
$T_2 = Y_{21} + Y_{22} + Y_{23} = 3.063$
$T_3 = Y_{31} + Y_{32} + Y_{33} = 2.812$
$T_4 = Y_{41} + Y_{42} + Y_{43} = 2.647$
$T_5 = Y_{51} + Y_{52} + Y_{53} = 1.622$

$G = T_1 + T_2 + T_3 + T_4 + T_5 = 12.768$

$SSB = \sum_i T_i^2/n_i - G^2/N$

$= 11.709 - (12.768)^2/14$

$= 0.064$

$SST = \sum_{ij} Y_{ij}^2 - G^2/N$

$= 11.832 - (12.768)^2/14$

$= 0.188$

$SSW = SST - SSB$

$= 0.188 - 0.064$

$= 0.124$

3.3 Summarize these data in the ANOVA table (Table D.2).

TABLE D.2. ANOVA TABLE FOR BONFERRONI'S ADJUSTMENT

Source	df	Sum of Squares (SS)	Mean Square (MS) (SS/df)
Between	p - 1	SSB	S_B^2 = SSB/(p-1)
Within	N - p	SSW	S_W^2 = SSW/(N-p)
Total	N - 1	SST	

3.4 Summarize these calculations in the ANOVA table (Table D.3):

TABLE D.3. COMPLETED ANOVA TABLE FOR THE T-TEST WITH BONFERRONI'S ADJUSTMENT

Source	df	SS	Mean Square
Between	5 - 1 = 4	0.064	0.016
Within	14 - 5 = 9	0.124	0.014
Total	13	0.188	

3.5 To perform the individual comparisons, calculate the t statistic for each concentration and control combination, as follows:

$$t_i = \frac{(\overline{Y}_1 - \overline{Y}_i)}{S_w\sqrt{(1/n_1) + (1/n_i)}}$$

Where: $\overline{Y}_i$ = mean for concentration i

$\overline{Y}_1$ = mean for the control

S_w = square root of the within mean square

n_1 = number of replicates in the control.

n_i = number of replicates for concentration i.

3.6 Table D.4 includes the calculated t values for each concentration and control combination.

TABLE D.4. CALCULATED T VALUES

Effluent Concentration (%)	i	t_i
6.25	2	- 1.511
12.5	3	- 0.642
25.0	4	- 0.072
50.0	5	0.592

3.7 Since the purpose of the test is only to detect a decrease in growth from the control, a one-sided test is appropriate. The critical value for the one-sided comparison (2.686), with an overall alpha level of 0.05, nine degrees of freedom and four concentrations excluding the control, was obtained from Table D.5. Comparing each of the calculated t values in Table D.4 with the critical value, no decreases in growth from the control were detected. Thus the NOEC is 50.0%.

d.f. = Degrees of freedom for MSE (Mean Square Error) from ANOVA.
K = Number of concentrations to be compared to the control.

APPENDIX E

STEEL'S MANY-ONE RANK TEST

1. Steel's Many-one Rank Test is a nonparametric test for comparing treatments with a control. This test is an alternative to Dunnett's Procedure, and may be applied to data when the normality assumption has not been met. Steel's Test requires equal variances across the treatments and the control, but it is thought to be fairly insensitive to deviations from this condition (Steel, 1959). The tables for Steel's Test require an equal number of replicates at each concentration. If this is not the case, use Wilcoxon's Rank Sum Test, with Bonferroni's adjustment (See Appendix F).

2. For an analysis using Steel's Test, for each control and concentration combination, combine the data and arrange the observations in order of size from smallest to largest. Assign the ranks to the ordered observations (1 to the smallest, 2 to the next smallest, etc.). If ties occur in the ranking, assign the average rank to the observation. (Extensive ties would invalidate this procedure). The sum of the ranks within each concentration and within the control is then calculated. To determine if the response in a concentration is significantly different from the response in the control, the minimum rank sum for each concentration and control combination is compared to the significant values of rank sums given later in the section. In this table, k equals the number of treatments excluding the control and n equals the number of replicates for each concentration and the control.

3. An example of the use of this test is provided below. The test employs survival data from a mysid 7-day, chronic test. The data are listed in Table E.1. Throughout the test, the control data are taken from the site water control. Since there is 0% survival for all eight replicates for the 50% concentration, it is not included in this analysis and is considered a qualitative mortality effect.

4. For each control and concentration combination, combine the data and arrange the observations in order of size from smallest to largest. Assign the ranks (1, 2, 3, ..., 16) to the ordered observations (1 to the smallest, 2 to the next smallest, etc.). If ties occur in the ranking, assign the average rank to each tied observation.

5. An example of assigning ranks to the combined data for the control and 3.12% effluent concentration is given in Table E.2. This ranking procedure is repeated for each control and concentration combination. The complete set of rankings is listed in Table E.3. The ranks are then summed for each effluent concentration, as shown in Table E.4.

6. For this set of data, determine if the survival in any of the effluent concentrations is significantly lower than the survival of the control organisms. If this occurs, the rank sum at that concentration would be significantly lower than the rank sum of the control. Thus, compare the rank sums for the survival at each of the various effluent concentrations with some "minimum" or critical rank sum, at or below which the survival would be considered to be significantly lower than the control. At a probability level of 0.05, the critical rank sum in a test with four concentrations and eight replicates per concentration, is 47 (see Table E.5).

7. Of the rank sums in Table E.4, none are less than 47. Therefore, due to the qualitative effect at the 50% effluent concentration, the NOEC is 25% effluent and the LOEC is 50% effluent.

APPENDIX F

WILCOXON RANK SUM TEST

1. Wilcoxon's Rank Sum Test is a nonparametric test, to be used as an alternative to Steel's Many-one Rank Test when the number of replicates are not the same at each concentration. A Bonferroni's adjustment of the pairwise error rate for comparison of each concentration versus the control is used to set an upper bound of alpha on the overall error rate, in contrast to Steel's Many-one Rank Test, for which the overall error rate is fixed at alpha. Thus, Steel's Test is a more powerful test.

2. The use of this test may be illustrated with fecundity data from the mysid test in Table F.1. The site water control and the 12.5% effluent concentration each have seven replicates for the proportion of females bearing eggs, while there are eight replicates for each of the remaining three concentrations.

3. For each concentration and control combination, combine the data and arrange the values in order of size, from smallest to largest. Assign ranks to the ordered observations (a rank of 1 to the smallest, 2 to the next smallest, etc.). If ties in rank occur, assign the average rank to each tied observation.

4. An example of assigning ranks to the combined data for the control and effluent concentration 3.12% is given in Table F.2. This ranking procedure is repeated for each of the three remaining control versus test concentration combinations. The complete set of ranks is listed in Table F.3. The ranks are then summed for each effluent concentration, as shown in Table F.4.

5. For this set of data, determine if the fecundity in any of the test concentrations is significantly lower than the fecundity in the control. If this occurs, the rank sum at that concentration would be significantly lower than the rank sum. Thus, compare the rank sums for fecundity of each of the various effluent concentrations with some "minimum" or critical rank sum, at or below which the fecundity would be considered to be significantly lower than the control. At a probability level of 0.05, the critical rank in a test with four concentrations and seven replicates in the control is 44 for those concentrations with eight replicates, and 34 for those concentrations with seven replicates (see Table F.5, for K = 4).

6. Comparing the rank sums in Table F.4 to the appropriate critical rank, only the 25% effluent concentration does not exceed its critical value of 44. Thus, the NOEC and LOEC for fecundity are 12.5% and 25%, respectively.

TABLE F.1. EXAMPLE OF WILCOXON'S RANK SUM TEST: FECUNDITY DATA FOR MYSID, *MYSIDOPSIS BAHIA*, 7-DAY CHRONIC TEST

APPENDIX G

SINGLE CONCENTRATION TOXICITY TEST - COMPARISON OF CONTROL WITH 100% EFFLUENT OR RECEIVING WATER

1. To statistically compare a control with one concentration, such as 100% effluent or the instream waste concentration, a t test is the recommended analysis. The t test is based on the assumptions that the observations are independent and normally distributed and that the variances of the observations are equal between the two groups.

2. Shapiro-Wilk's test may be used to test the normality assumption (See Appendix B for details). If the data do not meet the normality assumption, the nonparametric test, Wilcoxon's Rank Sum Test, may be used to analyze the data. An example of this test is given in Appendix F. Since a control and one concentration are being compared, the K = 1 section of Table F.5 contains the needed critical values.

3. The F test for equality of variances is used to test the homogeneity of variance assumption. When conducting the F test, the alternative hypothesis of interest is that the variances are not equal.

4. To make the two-tailed F test at the 0.01 level of significance, put the larger of the two variances in the numerator of F.

$$F = \frac{S_1^2}{S_2^2} \text{ where } S_1^2 > S_2^2$$

5. Compare F with the 0.005 level of a tabled F value with n_1 - 1 and n_2 - 1 degrees of freedom, where n_1 and n_2 are the number of replicates for each of the two groups.

6. A set of mysid growth data from an effluent (single concentration) test will be used to illustrate the F test. The raw data, mean and variance for the control and 100% effluent are given in Table G.1.

7. Since the variability of the 100% effluent is greater than the variability of the control, S^2 for the 100% effluent concentration is placed in the numerator of the F statistic and S^2 for the control is placed in the denominator.

$$F = \frac{0.00131}{0.000861} = 1.52$$

8. There are 8 replicates for the effluent concentration and 8 replicates for the control. Thus, both numerator and denominator degrees of freedom are equal to 7. For a two-tailed test at the 0.01 level of significance, the critical F value is obtained from a table of the F distribution (Snedecor and Cochran, 1980). The critical F value for this test is 8.89. Since 1.52 is not greater than 8.89, the conclusion is that the variances of the control and 100% effluent are homogeneous.

TABLE G.1. MYSID, *MYSIDOPSIS BAHIA,* GROWTH DATA FROM AN EFFLUENT (SINGLE CONCENTRATION) TEST

	Replicate									
	1	2	3	4	5	6	7	8	$\bar{X}$	S^2
Control	0.183	0.148	0.216	0.199	0.176	0.243	0.213	0.180	0.195	0.000861
100% Effluent	0.153	0.117	0.085	0.153	0.086	0.193	0.137	0.129	0.132	0.00131

9. Equal Variance T Test.

9.1 To perform the t test, calculate the following test statistic:

$$t = \frac{\bar{Y}_1 - \bar{Y}_2}{S_p\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

Where: $\bar{Y}_1$ = mean for the control

$\bar{Y}_2$ = mean for the effluent concentration

$$S_p = \frac{\sqrt{(n_1 - 1)\ S_1^2 + (n_2 - 1)\ S_2^2}}{n_1 + n_2 - 2}$$

S_1^2 = estimate of the variance for the control

S_2^2 = estimate of the variance for the effluent concentration

n_1 = number of replicates for the control

n_2 = number of replicates for the effluent concentration

9.2 Since we are usually concerned with a decreased response from the control, such as a decrease in survival or a decrease in reproduction, a one-tailed test is appropriate. Thus, you would compare the calculated t with a critical t, where the critical t is at the 5% level of significance with $n_1 + n_2 - 2$ degrees of freedom. If the calculated t exceeds the critical t, the mean responses are declared different.

9.3 Using the data from Table G.1 to illustrate the t test, the calculation of t is as follows:

$$t = \frac{0.195 0.132}{0.0329\sqrt{\frac{1}{8} + \frac{1}{8}}} = 3.83$$

Where:

$$S_p = \frac{\sqrt{(8-1)0.000861 + (8-1)0.00131}}{8+8-2} = 0.0329$$

9.4 For an 0.05 level of significance test with 14 degrees of freedom, the critical t is 1.762 (Note: Table D.5 for K = 1 includes the critical t values for comparing two groups). Since 3.83 is greater than 1.762, the conclusion is that the growth for the 100% effluent concentration is significantly lower than growth for the control.

10. UNEQUAL VARIANCE T TEST.

10.1 If the F test for equality of variance fails, the t test is still a valid test. However, the denominator of the t statistic is adjusted as follows:

$$t = \frac{\bar{Y}_1 - \bar{Y}_2}{\sqrt{\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}}}$$

Where: $\bar{Y}_1$ = mean for the control

$\bar{Y}_2$ = mean for the effluent concentration

S_1^2 = estimate of the variance for the control

S_2^2 = estimate of the variance for the effluent concentration

n_1 = number of replicates for the control

n_2 = number of replicates for the effluent concentration

10.2 Additionally, the degrees of freedom for the test are adjusted using the following formula:

$$df' = \frac{(n_1 - 1)\ (n_2 - 1)}{(n_2 - 1)\ C^2 + (1 - C)^2 (n_1 - 1)}$$

Where:

$$C = \frac{\frac{S_1^2}{n_1}}{\frac{S_1^2}{n_1} + \frac{S_2^2}{n_2}}$$

10.3 The modified degrees of freedom is usually not an integer. Common practice is to round down to the nearest integer.

10.4 The t test is then conducted as the equal variance t test. The calculated t is compared to the critical t at the 0.05 significance level with the modified degrees of freedom. If the calculated t exceeds the critical t, the mean responses are found to be statistically different.

APPENDIX H

PROBIT ANALYSIS

1. This program calculates the EC1 and EC50 (or LC1 and LC50), and the associated 95% confidence intervals.

2. The program is written in IBM PC Basic for the IBM compatible PC by Computer Sciences Corporation, 26 W. Martin Luther King Drive, Cincinnati, OH 45268. A compiled, executable version of the program and supporting documentation can be obtained from EMSL-Cincinnati by sending a written request to EMSL at 3411 Church Street, Cincinnati, OH 45244.

2.1 Data input is illustrated by a set of mortality data (Figure H.1) from a sheepshead minnow embryo-larval survival and teratogenicity test. The program begins with a request for the following information:

1. Desired output of abbreviated (A) or full (F) output? (Note: only abbreviated output is shown below.)
2. Output designation (P = printer, D = disk file).
3. Title for the output.
4. The number of exposure concentrations.
5. Toxicant concentration data.

2.2 The program output for the abbreviated output includes the following:

1. A table of the observed proportion responding and the proportion responding adjusted for the controls (see Figure H.2)
2. The calculated chi-square statistic for heterogeneity and the tabular value. This test is one indicator of how well the data fit the model. The program will issue a warning when the test indicates that the data do not fit the model.
3. The estimated LC1 and LC50 values and associated 95% confidence intervals (see Figure H.2).

APPENDIX I

SPEARMAN-KARBER METHOD

1. The Spearman-Karber Method is a nonparametric statistical procedure for estimating the LC50 and the associated 95% confidence interval (Finney, 1978). The Spearman-Karber Method estimates the mean of the distribution of the $\log_{10}$ of the tolerance. If the log tolerance distribution is symmetric, this estimate of the mean is equivalent to an estimate of the median of the log tolerance distribution.

2. If the response proportions are not monotonically non-decreasing with increasing concentration (constant or steadily increasing with concentration), the data must be smoothed. Abbott's procedure is used to "adjust" the concentration response proportions for mortality occurring in the control replicates.

3. Use of the Spearman-Karber Method is recommended when partial mortalities occur in the test solutions, but the data do not fit the Probit model.

4. To calculate the LC50 using the Spearman-Karber Method, the following must be true: 1) the smoothed adjusted proportion mortality for the lowest effluent concentration (not including the control) must be zero, and 2) the smoothed adjusted proportion mortality for the highest effluent concentration must be one.

5. To calculate the 95% confidence interval for the LC50 estimate, one or more of the smoothed adjusted proportion mortalities must be between zero and one.

6. The Spearman-Karber Method is illustrated below using a set of mortality data from a Sheepshead Minnow Larval Survival and Growth test. These data are listed in Table I.1.

7. Let $p_0, p_1, ..., p_k$ denote the observed response proportion mortalities for the control and k effluent concentrations. The first step is to smooth the p_i if they do not satisfy $p_0 \le p_1 \le ... \le p_k$. The smoothing process replaces any adjacent p_i's that do not conform to $p_0 \le p_1 \le ... \le p_k$ with their average. For example, if p_i is less than p_{i-1} then:

$$p_{i-1}^{s} = p_i^{s} = (p_i + p_{i-1})/2$$

Where: p_i^2 = the smoothed observed proportion mortality for effluent concentration i.

7.1 For the data in this example, because the observed mortality proportions for the control and the 6.25% effluent concentration are greater than the observed response proportions for the 12.5% and 25.0% effluent concentrations, the responses for these four groups must be averaged:

$$p_0^{s} = p_1^{s} = p_2^{s} = \frac{0.05 + 0.05 + 0.00 + 0.00}{4} = \frac{0.10}{4} = 0.025$$

TABLE I.1. EXAMPLE OF SPEARMAN-KARBER METHOD: MORTALITY DATA FROM A SHEEPSHEAD MINNOW LARVAL SURVIVAL AND GROWTH TEST (40 ORGANISMS PER CONCENTRATION)

Effluent Concentration %	Number of Mortalities	Mortality Proportion
Control	2	0.05
6.25	2	0.05
12.5	0	0.00
25.0	0	0.00
50.0	26	0.65
100.0	40	1.00

7.2 Since $p_4 = 0.65$ is larger than p_3^s, set $p_4^s = 0.65$. Similarly, $p_5 = 1.00$ is larger than p_5 so set $p_4 = 1.00$. Additional smoothing is not necessary. The smoothed observed proportion mortalities are shown in Table I.2.

TABLE I.2. EXAMPLE OF SPEARMAN-KARBER METHOD: SMOOTHED, ADJUSTED MORTALITY DATA FROM A SHEEPSHEAD MINNOW LARVAL SURVIVAL AND GROWTH TEST

Effluent Concentration %	Mortality Proportion	Smoothed Mortality Proportion	Smoothed, Adjusted Mortality Proportion
Control	0.05	0.025	0.000
6.25	0.05	0.025	0.000
12.5	0.00	0.025	0.000
25.0	0.00	0.025	0.000
50.0	0.65	0.650	0.641
100.0	1.00	1.000	1.000

8. Adjust the smoothed observed proportion mortality in each effluent concentration for mortality in the control group using Abbott's formula (Finney, 1971). The adjustment takes the form:

$$p_i^a = (p_i^s - p_o^2)/(1 - p_o^s)$$

Where : p_o^s = the smoothed observed proportion mortality for the control

p_i^s = the smoothed observed proportion mortality for effluent concentration i.

8.1 For the data in this example, the data for each effluent concentration must be adjusted for control mortality using Abbott's formula, as follows:

$$p_o^a = p_1^a = p_2^a = p_3^a = \frac{p_1^s - p_o^s}{1 - p_o^s} = \frac{0.025 - 0.025}{1 - 0.025} = \frac{0.0}{0.975} = 0.0$$

$$p_4^a = \frac{p_4^s - p_o^s}{1 - p_o^s} = \frac{0.650 - 0.025}{1 - 0.025} = \frac{0.0625}{0.975} = 0.641$$

$$p_5^a = \frac{p_5^s - p_o^s}{1 - p_o^s} = \frac{1.000 - 0.025}{1 - 0.025} = \frac{0.975}{0.975} = 1.000$$

The smoothed, adjusted response proportions for the effluent concentrations are shown in Table I.2. A plot of the smoothed, adjusted data is shown in Figure I.1.

9. Calculate the $\log_{10}$ of the estimated LC50, m, as follows:

$$m = \sum_{i=1}^{k} -1 \frac{(p_{i+1}^a)\ (X_i + X_{i+1})}{2}$$

Where: p_i^a = the smoothed adjusted proportion mortality at concentration i

X_i = the $\log_{10}$ of concentration i

k = the number of effluent concentrations tested, not including the control.

9.1 For this example, the $\log_{10}$ of the estimated LC50, m, is calculated as follows:

m = [(0.000 - 0.000) (0.7959 + 1.0969)]/2 +
[(0.000 - 0.000) (1.0969 + 1.3979)]/2 +
[(0.641 - 0.000) (1.3979 + 1.6990)]/2 +
[(1.000 - 0.641) (1.6990 + 2.0000)]/2

= 1.656527

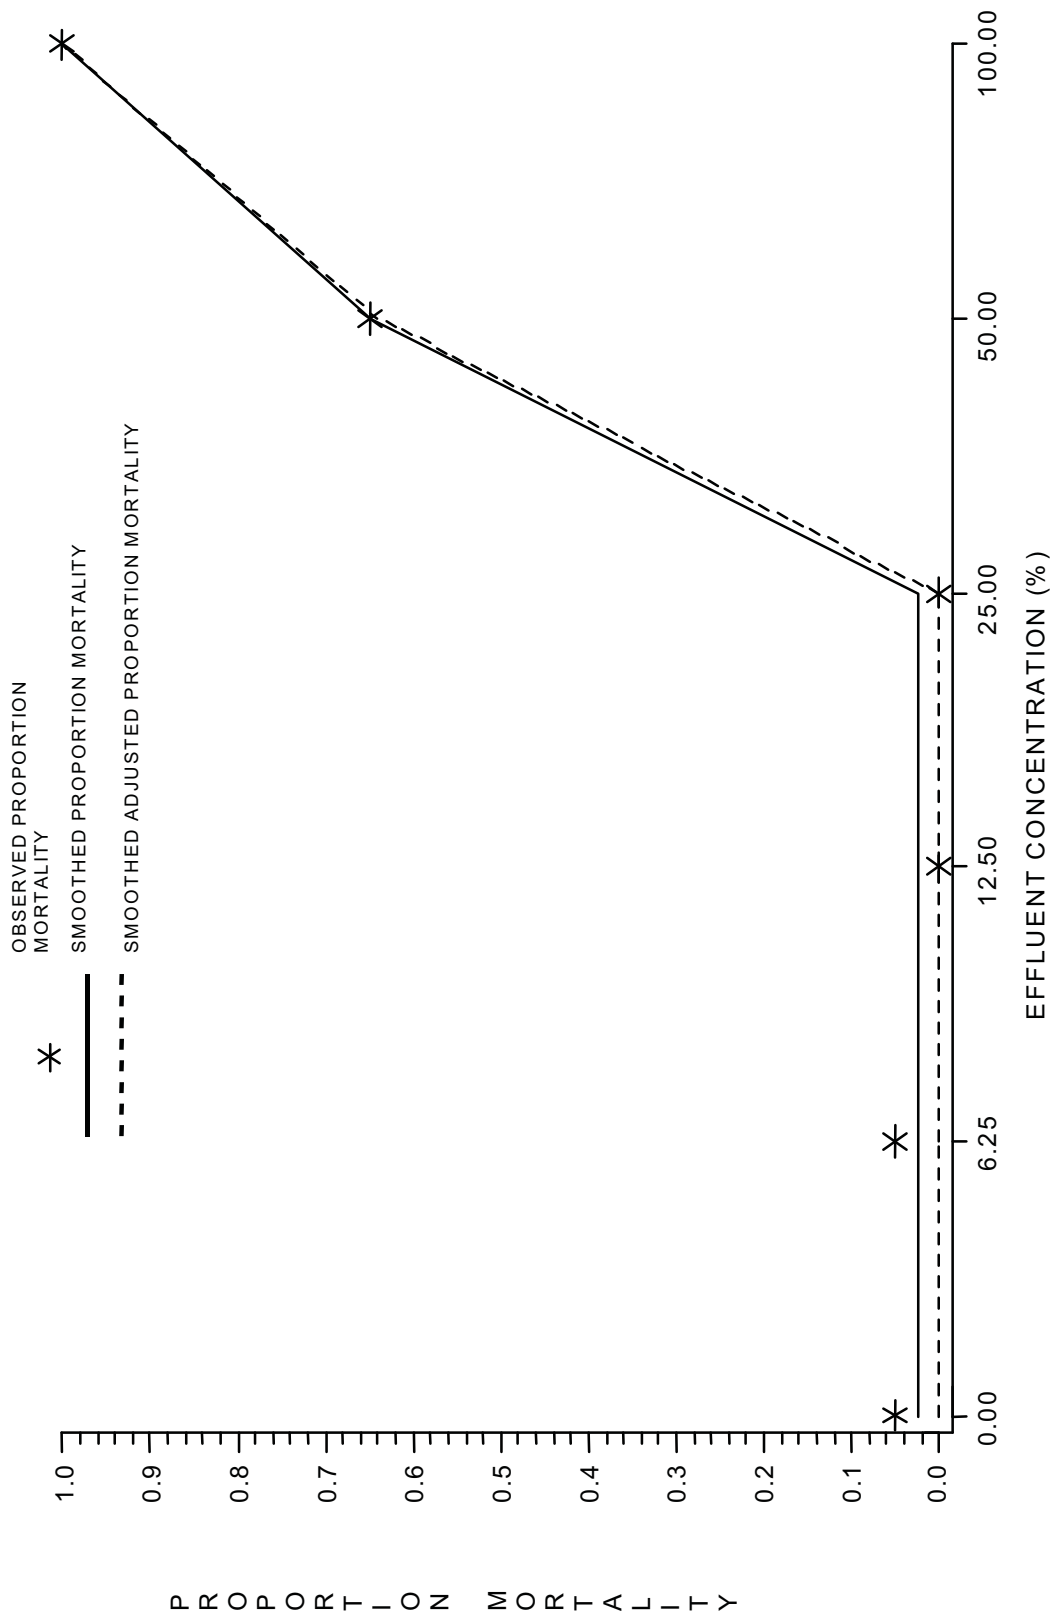

Figure I.1. Plot of observed, smoothed, and adjusted response proportions for sheepshead minnow, *Cyprinodon variegatus*, survival data.

10. Calculate the estimated variance of m as follows:

$$V(m) = \sum_{i=2}^{k} -1 \frac{p_i^a(1-p_i^a)\ (X_{i+1}+X_{i-1})^2}{4(n_i-1)}$$

Where: X_i = the $\log_{10}$ of concentration i

n_i = the number of organisms tested at effluent concentration i

p_i^a = the smoothed adjusted observed proportion mortality at effluent concentration i

k = the number of effluent concentrations tested, not including the control.

10.1 For this example, the estimated variance of m, V(m), is calculated as follows:

V(m) = (0.000)(1.000)(1.3979 - 0.7959)^2/4(39) +
(0.000)(1.000)(1.6990 - 1.0969)^2/4(39) +
(0.641)(0.359)(2.0000 - 1.3979)^2/4(39)

= 0.00053477

11. Calculate the 95% confidence interval for m: $m \pm 2.0\sqrt{V(m)}$

11.1 For this example, the 95% confidence interval for m is calculated as follows:

$$1.656527 \pm 2\sqrt{0.00053477} = (1.610277,\ 1.702777)$$

12. The estimated LC50 and a 95% confidence interval for the estimated LC50 can be found by taking base_{10} antilogs of the above values.

12.1 For this example, the estimated LC50 is calculated as follows:

LC50 = antilog(m) = antilog(1.656527) = 45.3%.

12.2 The limits of the 95% confidence interval for the estimated LC50 are calculated by taking the antilogs of the upper and lower limits of the 95% confidence interval for m as follows:

lower limit: antilog(1.610277) = 40.8%

upper limit: antilog(1.702777) = 50.4%

APPENDIX J

TRIMMED SPEARMAN-KARBER METHOD

1. The Trimmed Spearman-Karber Method is a modification of the Spearman-Karber Method, a nonparametric statistical procedure for estimating the LC50 and the associated 95% confidence interval (Hamilton, et al, 1977). The Trimmed Spearman-Karber Method estimates the trimmed mean of the distribution of the $\log_{10}$ of the tolerance. If the log tolerance distribution is symmetric, this estimate of the trimmed mean is equivalent to an estimate of the median of the log tolerance distribution.

2. If the response proportions are not monotonically non-decreasing with increasing concentration (constant or steadily increasing with concentration), the data must be smoothed. Abbott's procedure is used to "adjust" the concentration response proportions for mortality occurring in the control replicates.

3. Use of the Trimmed Spearman-Karber Method is recommended only when the requirements for the Probit Analysis and the Spearman-Karber Method are not met.

4. To calculate the LC50 using the Trimmed Spearman-Karber Method, the smoothed, adjusted, observed proportion mortalities must bracket 0.5.

5. To calculate the 95% confidence interval for the LC50 estimate, one or more of the smoothed, adjusted, observed proportion mortalities must be between zero and one.

6. Let $p_0, p_1, ..., p_k$ denote the observed proportion mortalities for the control and the k effluent concentrations. The first step is to smooth the p_i if they do not satisfy $p_0 \leq p_1 \leq ... \leq p_k$. The smoothing process replaces any adjacent p_i's that do not conform to $p_0 \leq p_1 \leq ... \leq p_k$, with their average. For example, if p_i is less than p_{i-1} then:

Where: $pi^{s}-1^{s} = p_i^{s} = (p_i + p_{i-1})/2$

p_i^{s} = the smoothed observed proportion mortality for effluent concentration i.

7. Adjust the smoothed observed proportion mortality in each effluent concentration for mortality in the control group using Abbott's formula (Finney, 1971). The adjustment takes the form:

Where: $p_i^{a} = (p_i^{s} - p_o^{s})/(1 - p_o^{s})$

p_o^{s} = the smoothed observed proportion mortality for the control

p_i^{s} = the smoothed observed proportion mortality for effluent concentration i.

8. Calculate the amount of trim to use in the estimation of the LC50 as follows:

Where: Trim = maximum $p_1^{a}, (1 - p_k^{a})$

p_1^{a} = the smoothed, adjusted proportion mortality for the lowest effluent concentration, exclusive of the control

p_k^{a} = the smoothed, adjusted proportion mortality for the highest effluent concentration

k = the number of effluent concentrations, exclusive of the control.

The minimum trim should be calculated for calculated for each data set rather than using a fixed amount of trim for each data set.

9. Due to the intensive nature of the calculation for the estimated LC50 and the calculation of the associated 95% confidence interval using the Trimmed Spearman-Karber Method, it is recommended that the data be analyzed by computer.

10. A computer program which estimates the LC50 and associated 95% confidence interval using the Trimmed Spearman-Karber Method, can be obtained through the EMSL, 3411 Church Street, Cincinnati, OH 45244. The program can be obtained from EMSL-Cincinnati by sending a written request to the above address.

11. The Trimmed Spearman-Karber program automatically performs the following functions:

a. Smoothing.
b. Adjustment for mortality in the control.
c. Calculation of the necessary trim.
d. Calculation of the LC50.
e. Calculation of the associated 95% confidence interval.

12. To illustrate the Trimmed Spearman-Karber method using the Trimmed Spearman-Karber computer program, a set of data from a Sheepshead Minnow Larval Survival and Growth test will be used. The data are listed in Table J.1.

12.1 The program requests the following input (Figure J.1):

a. Output destination (D = disk file or P = printer).
b. Control data.
c. Data for each toxicant concentration.

12.2 The program output includes the following (Figure J.2):

a. A table of the concentrations tested, number of organisms exposed, and the mortalities.
b. The amount of trim used in the calculation.
c. The estimated LC50 and the associated 95% confidence interval.

APPENDIX K

GRAPHICAL METHOD

1. The Graphical Method is used to calculate the LC50. It is a mathematical procedure which estimates the LC50 by linearly interpolating between points of a plot of observed percent mortality versus the base 10 logarithm ($\log_{10}$) of percent effluent concentration. This method does not provide a confidence interval for the LC50 estimate and its use is only recommended when there are no partial mortalities. The only requirement for the Graphical Method is that the observed percent mortalities bracket 50%.

2. For an analysis using the Graphical Method the data must first be smoothed and adjusted for mortality in the control replicates. The procedure for smoothing and adjusting the data is detailed in the following steps.

3. The Graphical Method is illustrated below using a set of mortality data from an Inland Silverside Larval Survival and Growth test. These data are listed in Table K.1.

TABLE K.1. EXAMPLE OF GRAPHICAL METHOD: MORTALITY DATA FROM AN INLAND SILVERSIDE LARVAL SURVIVAL AND GROWTH TEST (40 ORGANISMS PER CONCENTRATION)

Effluent Concentration %	Number of Mortalities	Mortality Proportion
Control	2	0.05
6.25	0	0.00
12.5	0	0.00
25.0	0	0.00
50.0	40	1.00
100.0	40	1.00

4. Let $p_0, p_1, ..., p_k$ denote the observed proportion mortalities for the control and the k effluent concentrations. The first step is to smooth the p_i if they do not satisfy $p_0 \le p_1 \le ... \le p_k$. The smoothing process replaces any adjacent p_i's that do not conform to $p_0 \le p_1 \le ... \le p_k$ with their average. For example, if p_i is less than p_{i-1} then:

Where: $p_{s-1}^{s} = p_i^{s} = (p_i + p_{i-1})/2$

p_i^{s} = the smoothed observed proportion mortality for effluent concentration i.

4.1 For the data in this example, because the observed mortality proportions for the 6.25%, 12.5%, and 25.0% effluent concentrations are less than the observed response proportion for the control, the values for these four groups must be averaged:

$$p_o^s = p_i^s = p_2^s = p_3^s = \frac{0.05+0.00+0.00+0.00}{4} = \frac{0.05}{4} = 0.0125$$

4.2 Since $p_4 = p_5 = 1.00$ are larger then 0.0125, set $p_4^s = p_5^s = 1.00$. Additional smoothing is not necessary. The smoothed observed proportion mortalities are shown in Table K.2.

5. Adjust the smoothed observed proportion mortality in each effluent concentration for mortality in the control group using Abbott's formula (Finney, 1971). The adjustment takes the form:

Where: $p_1^a = (p_i^s - p_o^s)/(1 - p_o^s)$

p_o^s = the smoothed observed proportion mortality for the control

p_i^s = the smoothed observed proportion mortality for effluent concentration i.

5.1 Because the smoothed observed proportion mortality for the control group is greater than zero, the responses must be adjusted using Abbott's formula, as follows:

$$p_o^a = p_1^a = p_2^a = p_3^a = \frac{P_1^s - P_o^s}{1 - p_o^s} = \frac{0.0125 - 0.125}{1 - 0.0125} = \frac{0.0}{0.9875} = 0.0$$

$$p_4^a = p_5^a = \frac{P_4^s - p_o^s}{1 - p_o^s} = \frac{1.00 - 0.0125}{1 - 0.0125} = \frac{0.9875}{0.9875} = 1.00$$

A table of the smoothed, adjusted response proportions for the effluent concentrations are shown in Table K.2.

5.2 Plot the smoothed, adjusted data on 2-cycle semi-log graph paper with the logarithmic axis (the y axis) used for percent effluent concentration and the linear axis (the x axis) used for observed percent mortality. A plot of the smoothed, adjusted data is shown in Figure K.1.

TABLE K.2. EXAMPLE OF GRAPHICAL METHOD: SMOOTHED, ADJUSTED MORTALITY DATA FROM AN INLAND SILVERSIDE LARVAL SURVIVAL AND GROWTH TEST

Effluent Concentration %	Mortality Proportion	Smoothed Mortality Proportion	Smoothed Adjusted Mortality Proportion
Control	0.05	0.0125	0.00
6.25	0.00	0.0125	0.00
12.5	0.00	0.0125	0.00
25.0	0.00	0.0125	0.00
50.0	1.00	1.0000	1.00
100.0	1.00	1.0000	1.00

6. Locate the two points on the graph which bracket 50% mortality and connect them with a straight line.

7. On the scale for percent effluent concentration, read the value for the point where the plotted line and the 50% mortality line intersect. This value is the estimated LC50 expressed as a percent effluent concentration.

7.1 For this example, the two points on the graph which bracket the 50% mortality line (0% mortality at 25% effluent, and 100% mortality at 50% effluent) are connected with a straight line. The point at which the plotted line intersects the 50% mortality line is the estimated LC50. The estimated LC50 = 35% effluent.

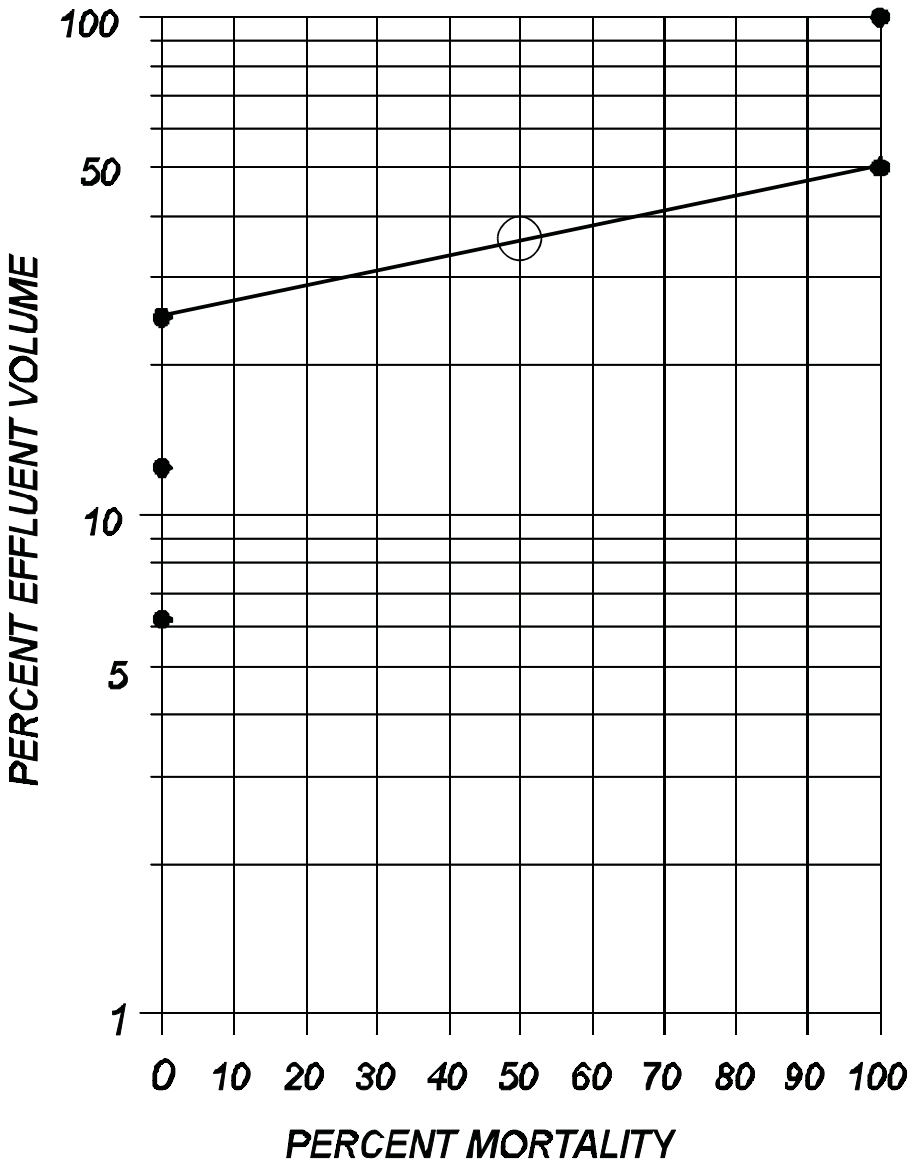

Figure K.1. Plot of the smoothed adjusted response proportions for inland silverside, *Menidia beryllina*, survival data.

APPENDIX L

LINEAR INTERPOLATION METHOD

1. GENERAL PROCEDURE

1.1 The Linear Interpolation Method is used to calculate a point estimate of the effluent or other toxicant concentration that causes a given percent reduction (e.g., 25%, 50%, etc.) in the reproduction or growth of the test organisms (Inhibition Concentration, or IC). The procedure was designed for general applicability in the analysis of data from short-term chronic toxicity tests, and the generation of an endpoint from a continuous model that allows a traditional quantitative assessment of the precision of the endpoint, such as confidence limits for the endpoint of a single test, and a mean and coefficient of variation for the endpoints of multiple tests.

1.2 The Linear Interpolation Method assumes that the responses (1) are monotonically non-increasing, where the mean response for each higher concentration is less than or equal to the mean response for the previous concentration, (2) follow a piecewise linear response function, and (3) are from a random, independent, and representative sample of test data. If the data are not monotonically non-increasing, they are adjusted by smoothing (averaging). In cases where the responses at the low toxicant concentrations are much higher than in the controls, the smoothing process may result in a large upward adjustment in the control mean. Also, no assumption is made about the distribution of the data except that the data within a group being resampled are independent and identically distributed.

2. DATA SUMMARY AND PLOTS

2.1 Calculate the mean responses for the control and each toxicant concentration, construct a summary table, and plot the data.

3. MONOTONICITY

3.1 If the assumption of monotonicity of test results is met, the observed response means ($\bar{Y}_i$) should stay the same or decrease as the toxicant concentration increases. If the means do not decrease monotonically, the responses are "smoothed" by averaging (pooling) adjacent means.

3.2 Observed means at each concentration are considered in order of increasing concentration, starting with the control mean ($\bar{Y}_1$). If the mean observed response at the lowest toxicant concentration ($\bar{Y}_2$) is equal to or smaller than the control mean ($\bar{Y}_1$), it is used as the response. If it is larger than the control mean, it is averaged with the control, and this average is used for both the control response (M_1) and the lowest toxicant concentration response (M_2). This mean is then compared to the mean observed response for the next higher toxicant concentration ($\bar{Y}_3$). Again, if the mean observed response for the next higher toxicant concentration is smaller than the mean of the control and the lowest toxicant concentration, it is used as the response. If it is higher than the mean of the first two, it is averaged with the first two, and the mean is used as the response for the control and two lowest concentrations of toxicant. This process is continued for data from the remaining toxicant concentrations. A numerical example of smoothing the data is provided below. (Note: Unusual patterns in the deviations from monotonicity may require an additional step of smoothing). Where $\bar{Y}_i$ decrease monotonically, the $\bar{Y}_i$ become M_i without smoothing.

4. LINEAR INTERPOLATION METHOD

4.1 The method assumes a linear response from one concentration to the next. Thus, the ICp is estimated by linear interpolation between two concentrations whose responses bracket the response of interest, the (p) percent reduction from the control.

4.2 To obtain the estimate, determine the concentrations C_J and C_{J+1} which bracket the response M_1 (1 - p/100), where M_1 is the smoothed control mean response and p is the percent reduction in response relative to the control response. These calculations can easily be done by hand or with a computer program as described below. The linear interpolation estimate is calculated as follows:

$$ICp = C_J + [M_1(1 - 1p/100) - M_J'] \frac{(C_{J+1} - C_J)}{(M_{J+1} - M_J)}$$

Where: C_J = tested concentration whose observed mean response is greater than $M_1(1 - p/100)$.

C_{J+1} = tested concentration whose observed mean response is less than $M_1(1 - p/100)$.

M_1 = smoothed mean response for the control.

M_J = smoothed mean response for concentration J.

M_{J+1} = smoothed mean response for concentration J + 1.

p = percent reduction in response relative to the control response.

IC*p* = estimated concentration at which there is a percent reduction from the smoothed mean control response. The IC*p* is reported for the test, together with the 95% confidence interval calculated by the ICPIN.EXE program described below.

4.3 If the C_J is the highest concentration tested, the IC*p* would be specified as *greater than* C_J. If the response at the lowest concentration tested is used to extrapolate the ICp value, the ICp should be expressed as a *less than the lowest test concentration.*

5. CONFIDENCE INTERVALS

5.1 Due to the use of a linear interpolation technique to calculate an estimate of the ICp, standard statistical methods for calculating confidence intervals are not applicable for the ICp. This limitation is avoided by use a technique known as the bootstrap method as proposed by Efron (1982) for deriving point estimates and confidence intervals.

5.2 In the Linear Interpolation Method, the smoothed response means are used to obtain the ICp estimate reported for the test. The bootstrap method is used to obtain the 95% confidence interval for the true mean. In the bootstrap method, the test data Y_{ji} is randomly resampled with replacement to produce a new set of data Y_{ji}*, that is statistically equivalent to the original data, but a new and slightly different estimate of the IC*p* (IC*p**) is obtained. This process is repeated at least 80 times (Marcus and Holtzman, 1988) resulting in multiple "data" sets, each with an associate ICp* estimate. The distribution of the ICp* estimates derived from the sets of resampled data approximates the sampling distribution of the ICp estimate. The standard error of the ICp is estimated by the standard deviation of the individual ICp* estimates. Empirical confidence intervals are derived from the quantiles of the ICp* empirical distribution. For example, if the test data are resampled a minimum of 80 times, the empirical 2.5% and the 97.5% confidence limits are approximately the second smallest and second largest ICp* estimates (Marcus and Holtzman, 1988).

5.3 The width of the confidence intervals calculated by the bootstrap method is related to the variability of the data. When confidence intervals are wide, the reliability of the IC estimate is in question. However, narrow intervals do

not necessarily indicate that the estimate is highly reliable, because of undetected violations of assumptions and the fact that the confidence limits based on the empirical quantiles of a bootstrap distribution of 80 samples may be unstable.

5.4 The bootstrapping method of calculating confidence intervals is computationally intensive. For this reason, all of the calculations associated with determining the confidence intervals for the ICp estimate have been incorporated into a computer program. Computations are most easily done with a computer program such as the revision of the BOOTSTRP program (USEPA, 1988; USEPA, 1989) which is now called "ICPIN" which is described below in Subsection 7.

6. MANUAL CALCULATIONS

6.1 DATA SUMMARY AND PLOTS

6.1.1 The data used in this example are the mysid growth data used in the example in Section 14. The data is presented as the mean weight per original number of organisms. Table L.1 includes the raw data and the mean growth for each concentration. A plot of the data is provided in Figure L.1.

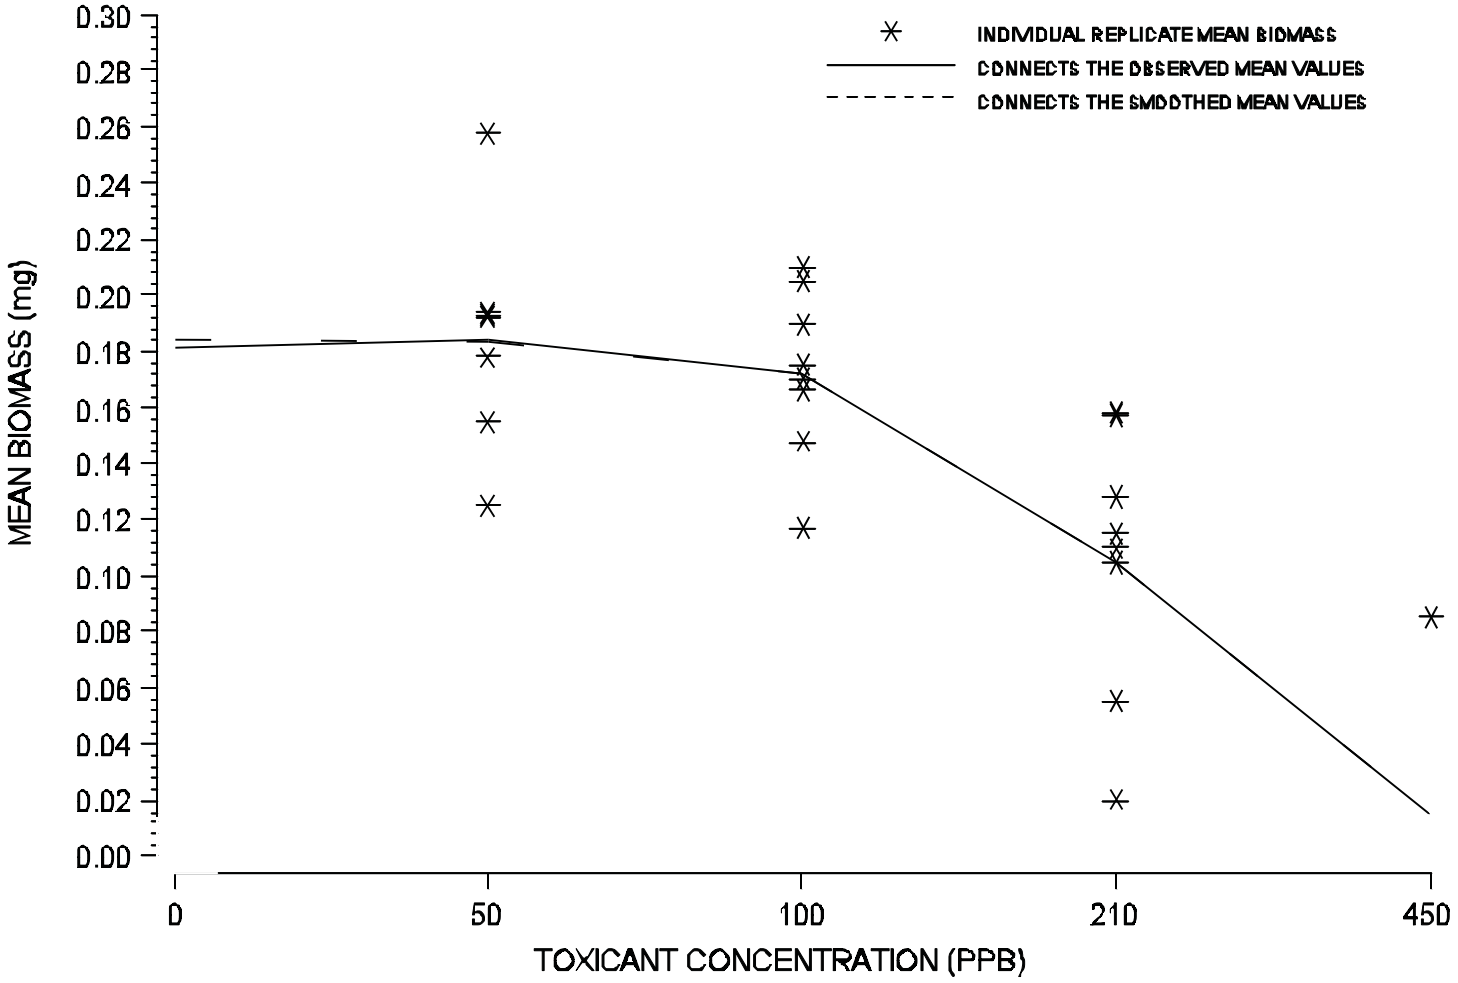

Figure L.1. Plot of raw data, observed means, and smoothed means for the mysid, *Mysidopsis bahia,* growth data.

TABLE L.1. MYSID, *MYSIDOPSIS BAHIA*, GROWTH DATA

Replicate	Control	Toxicant Concentration (ppb) 50	100	210	450
1	0.146	0.154	0.114	0.153	0
2	0.118	0.193	0.172	0.094	0.012

Mean ($\bar{Y}_i$)	0.182	0.184	0.168	0.101	0.012
i	1	2	3	4	5

6.2 MONOTONICITY

6.2.1 As can be seen from the plot in Figure L.1, the observed means are not monotonically non-increasing with respect to concentration. Therefore, the means must be smoothed prior to calculating the IC.

6.2.2 Starting with the control mean $\bar{Y}_1 = 0.186$ and $\bar{Y}_2 = 0.184$, we see that $\bar{Y}_1 < \bar{Y}_2$. Calculate the smoothed means:

$$M_1 = M_2 = (\bar{Y}_1 + \bar{Y}_2)/2 = 0.193$$

6.2.3 Since $\bar{Y}_5 = 0.025 < \bar{Y}_4 = 0.101 < \bar{Y}_3 = 0.168 < M_2$, *set* $M_3 = 0.168$ and $M_4 = 0.101$, and $M_5 = 0.025$. Table L.2 contains the smoothed means and Figure L.1 gives a plot of the smoothed response curve.

6.3 LINEAR INTERPOLATION

6.3.1 Estimates of the IC25 and IC50 can be calculated using the Linear Interpolation Method. A 25% reduction in mean weight, compared to the controls, would result in a mean weight of 0.139, where $M_1(1\text{-}p/100) = 0.185(1\text{-}25/100)$. A 50% reduction in mean weight, compared to the controls, would result in a mean weight of 0.093 mg. Examining the smoothed means and their associated concentrations (Table L.2), the two effluent concentrations bracketing the mean weight per original of 0.139 mg are $C_3 = 100$ ppb and $C_4 = 210$ ppb. The two effluent concentrations bracketing a response of 0.093 mg per total original number of organisms are $C_4 = 210$ ppb and $C_5 = 450$ ppb.

TABLE L.2. MYSID, *MYSIDOPSIS BAHIA*, MEAN GROWTH RESPONSE AFTER SMOOTHING

Toxicant Conc. (ppb)	i	Smoothed Mean M_i (mg)
Control	1	0.183
50	2	0.183
100	3	0.168
210	4	0.101
450	5	0.025

6.3.2 Using the equation from section 4.2, the estimate of the IC25 is calculated as follows:

$$ICp = C_j + [M_1(1 - 1p/100) - M_j'] \frac{(C_{j+1} - C_j)}{(M_{j+1} - M_j)}$$

$$IC25 = 100 + [0.93(1 - 25/100) - 0.164] \frac{(210 - 100)}{(0.101 - 0.164)}$$

$$= 151 \text{ ppb}$$

6.3.3 Using Equation 1 from 4.2, the estimate of the IC50 is calculated as follows:

$$ICp = C_j + [M_1(1 - 1p/100) - M_j'] \frac{(C_{j+1} - C_j)}{(M_{j+1} - M_j)}$$

$$IC50 = 210 + [210 + [0.193(1 - 50/100) - 0.101] \frac{(450 - 210)}{(0.028 - 0.101)}$$

$$= 239 \text{ ppb}$$

6.4 CONFIDENCE INTERVALS

6.4.1 Confidence intervals for the ICp are derived using the bootstrap method. As described above, this method involves randomly resampling the individual observations and recalculating the ICp at least 80 times, and determining the mean ICp, standard deviation, and empirical 95% confidence intervals. For this reason, the confidence intervals are calculated using a computer program called ICPIN. This program is described below and is available to carry out all the calculations of both the interpolation estimate (ICp) and the confidence intervals.

7. COMPUTER CALCULATIONS

7.1 The computer program, ICPIN, prepared for the Linear Interpolation Methods was written in TURBO PASCAL for IBM compatible PCS. The program (version 2.0) has been modified by Computer Science Corporation, Duluth, MN with funding provided by the Environmental Research Laboratory, Duluth, MN (Norberg-King, 1993). The program was originally developed by Battelle Laboratories, Columbus, OH through a government contract supported by the Environmental Research Laboratory, Duluth, MN (USEPA, 1988). A compiled, executable version of the program and supporting documentation can be obtained by sending a written request to EMSL-Cincinnati, 3411 Church Street, Cincinnati, OH 45244.

7.2 The ICPIN.EXE program performs the following functions: 1) it calculates the observed response means ($_I$) (response means); 2) it calculates the standard deviations; 3) checks the responses for monotonicity; 4) calculates smoothed means (M_i) (pooled response means) if necessary; 5) uses the means, M_i, to calculate the initial ICp of choice by linear interpolation; 6) performs a user-specified number of bootstrap resamples between 80 and 1000 (as multiples of 40); 7) calculates the mean and standard deviation of the bootstrapped ICp estimates; and 8) provides an original 95% confidence intervals to be used with the initial ICp when the number of replicates per concentration is over six and provides both original and expanded confidence intervals when the number of replicates per concentration are less than seven (Norberg-King, 1993).

7.3 For the IC*p* calculation, up to twelve treatments can be input (which includes the control). There can be up to 40 replicates per concentration, and the program does not require an equal number of replicates per concentration. The value of p can range from 1% to 99%.

7.4 DATA INPUT

7.4.1 Data is entered directly into the program onscreen. A sample data entry screen in shown in Figure L.2. The program documentation provides guidance on the entering and analysis of data for the Linear Interpolation Method.

7.4.2 The user selects the ICp estimate desired (e.g., IC25 or IC50) and the number of resamples to be taken for the bootstrap method of calculating the confidence intervals. The program has the capability of performing any number of resamples from 80 to 1000 as multiples of 40. However, Marcus and Holtzman (1988) recommend a minimum of 80 resamples for the bootstrap method be used and at least 250 resamples are better (Norberg-King, 1993).

Figure L.2. ICp data entry/edit screen. Twelve concentration identifications can be used. Data for concentrations are entered in columns 1 through 6. For concentrations 7 through 12 and responses 21-40 the data is entered in additional fields of the same screen.

7.5 DATA OUTPUT

7.5.1 The program output includes the following (Figures L.3 and L.4)

1. A table of the concentration identification, the concentration tested and raw data response for each replicate and concentration.
2. A table of test concentrations, number of replicates, concentration (units), response means (Y_i), standard deviations for each response mean, and the pooled response means (smoothed means; M_i).
3. The linear interpolation estimate of the ICp using the means (M_i). *Use this value for the ICp estimate.*
4. The mean ICp and standard deviation from the bootstrap resampling.
5. The confidence intervals calculated by the bootstrap method for the ICp. Provides an original 95% confidence intervals to be used with the initial ICp when the number of replicates per concentration is over six and provides both original and expanded confidence intervals when the number of replicates per concentration are less than seven.

7.6 ICPIN program output for the analysis of the mysid growth data in Table L.1 is provided in Figures L.3 and L.4.

7.6.1 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC25 was 133.5054 (ppb). The empirical 95% confidence intervals for the true mean was 96.8623 to 186.6383 (ppb).

7.6.2 When the ICPIN program was used to analyze this set of data, requesting 80 resamples, the estimate of the IC50 was 234.6761 (ppb). The empirical 95% confidence intervals for the true mean were 184.8692 to 283.3965 (ppb).

LOS ANGELES REGION

MONITORING PROGRAM - No. CI 7388
FOR
ORDER R4-2010-0108
NPDES PERMIT NO. CAS004002
WASTE DISCHARGE REQUIREMENTS

MUNICIPAL SEPARATE STORM SEWER SYSTEM DISCHARGES WITHIN THE VENTURA COUNTY WATERSHED PROTECTION DISTRICT, COUNTY OF VENTURA AND THE INCORPORATED CITIES THEREIN.

July 8, 2010

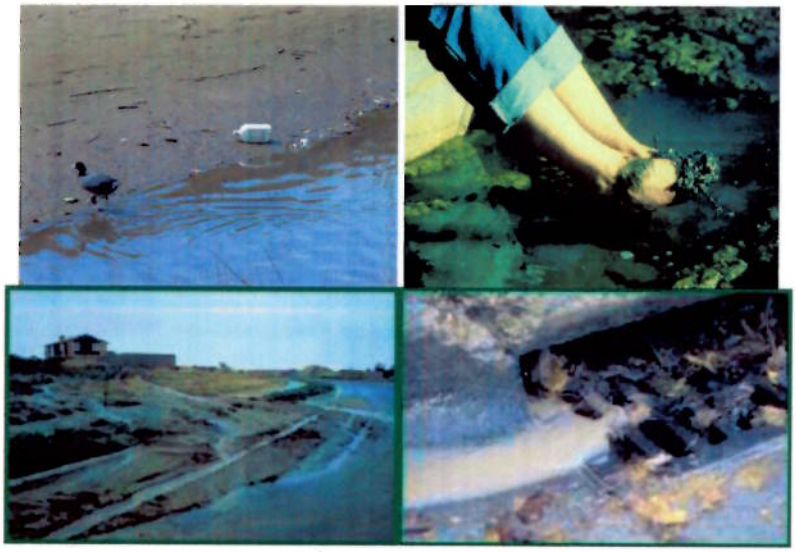

TABLE OF CONTENTS

MONITORING PROGRAM

1. The primary objectives of the Monitoring Program include, but are not limited to:
   (a) Assessing the chemical, physical, and biological impacts of municipal storm water sewer system discharges on receiving waters.
   (b) Assessing the overall health and evaluating long-term trends in receiving water quality.
   (c) Assessing compliance with TMDL targets and water quality objectives.
   (d) Characterization of the quality of storm water discharges.
   (e) Identifying sources of pollutants.
   (f) Measuring and improving the effectiveness of measures implemented under this Order.

2. The results of the monitoring requirements outlined below shall be used to refine BMPs for the reduction of pollutant loading and the protection and enhancement of the beneficial uses of the receiving waters in Ventura County.

3. The Permittees shall implement the Monitoring Program as follows:

CORE MONITORING

A. Mass Emissions

I. The Principal Permittee shall monitor mass emissions to accomplish the following objectives:
   i. Estimate the mass emissions from the MS4 to the watershed.
   ii. Assess trends in the mass emissions over time.
   iii. Determine if the MS4 is contributing to exceedances of water quality objectives by comparing results to applicable water quality objectives in the Water Quality Control Plan Los Angeles Region (Basin Plan) and the California Toxics Rule (CTR).

1. The Principal Permittee shall monitor mass emissions from the following 3 mass emission stations:
   (a) ME-VR2 for Ventura River
   (b) ME-SCR for Santa Clara River
   (c) ME-CC for Calleguas Creek

2. The Principal Permittee shall monitor the 3 mass emission stations on an annual basis as per A.3. below.

3. The Principal Permittee shall monitor each mass emission station each year as follows:
   (a) The first storm event of the wet season that produces a 20% or greater increase in base stream flow, and 2 additional storm events; all storm events shall be separated by 7 days of dry weather (less than 0.1 inch of rainfall) from the previously measurable storm event (0.25 inches of rain).
   (b) A total of 4 monitoring events (3 wet-weather storm events, 1 dry-weather) per mass emission station.

4. Samples for mass emission monitoring may be taken with the same type of automatic sampler used under Order 00-108. Sampling shall be in accordance with USEPA "NPDES Storm Water Sampling Guidance Document, EPA 833-8-92-001, July 1992" or other protocol approved by the Executive Officer.

5. Samplers shall be set to monitor storms that produce a 20% or greater increase in base stream flow.

6. Samples shall be flow-weighted composites, collected during the first 24 hours or for the duration of the storm if it is less than 24 hours.

7. Samples shall be collected from the discharge resulting from a storm event that is 0.25 inches or greater, samples may be analyzed if a predicted storm event produces between 0.15 and 0.24 inches of rain.

8. The flow-weighted composite sample for a storm water discharge shall be taken with a continuous sampler, or it shall be taken as a combination of a minimum of 3 sample aliquots, taken in each hour of discharge for the first 24 hours of the discharge or for the entire discharge if the storm event is less than 24 hours, with each aliquot being separated by a minimum of 15 minutes within each hour of discharge, unless the Regional Water Board Executive Officer approves an alternate protocol.

9. Flow may be estimated using U.S. EPA methods at sites where flow measurement devices are not in place.

10. Grab samples shall be taken only for pathogen indicators, oil & grease, cyanide, and volatile organics. Field measurements shall be taken for pH, temperature, and DO.

11. Each mass emission shall analyze for all of the Pollutants of Concern (POC) in its specific watershed listed in Attachment "B" (Calleguas Creek Watershed, Santa Clara River Watershed, and Ventura River Watershed Pollutants of Concern).

12. Each mass emission station shall screen for all constituents listed in Attachment "G" (Storm Water Monitoring Program's Constituents with Associated Minimum Levels), during the first storm event of the wet season for each year sampled. If a constituent is not detected at the Method Detection Limit (MDL) for its respective test method it need not be further analyzed unless the observed occurrence shows concentrations greater than the state water quality objective, and/ or the California Toxics Rule (CTR) for chronic criteria. If a constituent is detected exceeding a Basin Plan objective, and/ or CTR criteria then the constituent shall be analyzed for the remainder of the Order, at the mass emission station where it was detected.

13. At a minimum, a sufficient sample volume must be collected to perform all of the required biological and chemical tests.

14. When monitoring can not be performed to comply with the requirements of this Order due to circumstances beyond the Permittee's control, then within two working days the following shall be submitted to the Regional Water Board Executive Officer:
    (a) Statement of situation.
    (b) Explanation of circumstance(s) with documentation.
    (c) Statement of corrective action for the future.

15. Monitoring results submitted to the Regional Water Board shall include:
    (a) Rain totals and hydrographs for monitoring events in both narrative and graphic formats.
    (b) A narrative description of the date and duration of the storm event(s) sampled, rainfall estimates of the storm event which generated the sampled discharge and the duration between the storm event sampled and the end of the previous measurable storm event.
    (c) All applicable Standard Monitoring Provisions listed in part "K".

16. Results of monitoring from each mass emission station conducted in accordance with the Standard Operating Procedure submitted under Standard Provision 14 of this Attachment shall be sent electronically to the Regional Water Board's Storm Water site at MS4stormwaterRB4@waterboards.ca.gov, no later than 90 days from sample collection date, highlighting exceedances (Pollutants of Concern, POC) to the Basin Plan objectives for all test results, and the CTR for acute criteria with corresponding sampling dates per mass emission station. The sample data transmitted shall be in the most recent update of the Southern California Municipal Storm Water Monitoring Coalition's (SMC) Standardized Data Transfer Formats (SDTFs).

17. A summary of the annual mass emission monitoring results highlighting exceedances (POC) of the Basin Plan objectives and the CTR for acute criteria, with corresponding sampling dates per mass emission station, shall be included with the Annual Storm Water Report.

B. Major Outfalls

I. The Principal Permittee shall monitor major storm drain outfalls to accomplish the following objectives:
   i. Estimate the annual pollutant load of the cumulative discharges to waters of the State.
   ii. Estimate the event mean concentration of the cumulative discharges to waters of the State.
   iii. Assess trends in the major outfalls over time.
   iv. Estimate the annual pollutant load of discharges to Waters of the U.S.
   v. Estimate the event mean concentration of discharges to Waters of the U.S.
   vi. Assess trends in the major outfalls over time.
   vii. Determine if the MS4 is contributing to exceedences of water quality objectives in the Water Quality Control Plan Los Angeles Region (Basin Plan), and the California Toxics Rule (CTR).

1. The Principal Permittee shall monitor:
   (a) End-of-pipe of major outfalls, identified in Attachment I, transporting representative discharges from each Permittee's Municipal drainage area to:
      (1) Major outfalls listed in Attachment "I" (Storm Water Monitoring Program's Major Outfall Stations).
   (b) The first storm event of the wet season that produces at least 0.25 inches of rain, and 2 additional storm events per year, all storm events shall be separated by 7 days of dry weather (less than 0.1 inch) from the previously measurable storm event (0.25 inches).
   (c) A total of 4 monitoring events (3 wet-weather storm events, 1 dry-weather) shall be sampled per identified major outfall.
   (d) In the first year after permit adoption, 4 major outfall stations shall be monitored. Thereafter, all major outfall stations listed in Attachment "I" are to be monitored annually according to the schedule above.

2. If an identified monitoring site is found to be unworkable due to immitigable factors the sampling location may be relocated upon Executive Officer's approval of another location. Best professional judgment shall be used to balance the site selection rationale and criteria to determine the most appropriate site. Due to limited potential locations of urban outfalls to be monitored, there may be no sites that satisfy all criteria and rationale. Sites will be selected to satisfy the following criteria:

(a) Maximize urban runoff contribution;
(b) Greater than 60% of catchment shall be Permittee's MS4;
(c) Attempt shall be made to avoid outfalls that contain discharge from extra-jurisdictional areas (e.g. agriculture land and other NPDES discharges).
(d) Drainage area should contain representative land uses in a ratio of use as similar as reasonably possible to that found in the Permittee's jurisdiction.
(e) Drainage areas with a higher percentage of the Permittee's MS4 are preferred;
(f) Ability to accurately measure flow
(g) Safety of monitoring personnel is the highest priority. Specific location of sampling collection may be upstream of the actual outfall if field safety or accurate flow measurement require it.

3. Samples shall be collected from the discharge resulting from a storm event that is 0.25 inches or greater, samples may be analyzed if a predicted storm event produces between 0.15 inches and 0.24 inches of rain.

4. Samples shall be collected during the first 24 hours of storm water discharge or for the entire storm water discharge if it is less than 24 hours.

5. Samples shall be flow-weighted composites and can be collected automatically or manually (see subparts A.7 and A.8) in accordance with U.S. EPA protocol or other procedure approved by the Executive Officer.

6. Grab samples shall be taken only for pathogen indicators, oil & grease, cyanide, and volatile organics. Field measurements shall be taken for pH, temperature, and DO.

7. Major outfall samples taken within a subwatershed shall be analyzed for the biological and chemical parameters listed in the preceding subpart B.6.

8. Each major outfall station shall screen for all constituents listed in Attachment "G" (Storm Water Monitoring Program's Constituents with Associated Minimum Levels) twice per wet season, per year, (1st storm event of the wet season and one other storm event of the wet season). If a constituent is not detected at the Method Detection Limit (MDL) for its respective test method it need not be further analyzed unless the observed occurrence shows concentrations greater than the state water quality objective, and/ or the California Toxics Rule (CTR) acute criteria. If a constituent is detected exceeding a Basin Plan objective, and/or chronic CTR criteria then the constituent shall be sampled for the remainder of the Order, at the major outfall station where it was detected.

9. At a minimum, a sufficient sample volume must be collected to perform all of the required biological and chemical tests. Sampling shall be in accordance with USEPA "NPDES Storm Water Sampling Guidance Document, EPA 833-8-92-001, July 1992" or other protocol approved by the Executive Officer.

10. When monitoring can not be performed to comply with the requirements of this Order due to circumstances beyond the Permittee's control, then within 2 working days the following shall be submitted to the Regional Water Board Executive Officer:
    (a) Statement of situation
    (b) Explanation of circumstance(s) with documentation
    (c) Statement of corrective action for the future

11. Monitoring results submitted to the Regional Water Board shall include:
    (a) Rain totals and hydrographs for monitoring events in both narrative and graphic formats.
    (b) A narrative description of the date and duration of the storm event(s) sampled, rainfall estimates of the storm event which generated the sampled discharge and the duration between the storm event sampled and the end of the previous measurable storm event.
    (c) All applicable Standard Monitoring Provisions listed in part "K".

12. Results of monitoring from each major outfall station conducted in accordance with the Standard Operating Procedure submitted under Standard Provision 14 of this Attachment shall be sent electronically to the Regional Water Board's Storm Water Site at MS4stormwaterRB4@waterboards.ca.gov, no later than 90 days from sample collection date, highlighting exceedances to the Basin Plan objectives for all test results, and the CTR for acute criteria with corresponding sampling dates per major outfall station. The sample data transmitted shall be in the most recent update of the Southern California Municipal Storm Water Monitoring Coalition's (SMC) Standardized Data Transfer Formats (SDTFs).

13. A summary of the annual major outfall monitoring results, highlighting exceedences (pollutants of concern POC) to the Basin Plan objectives, and the CTR for acute criteria with corresponding sampling dates per major outfall station, shall be included with the Annual Storm Water Report.

C. Dry Weather Analytical Monitoring

I. The Principal Permittee shall develop and implement a monitoring program to characterize pollutant discharges from representative MS4 outfalls in each municipality and in the unincorporated County area during dry weather. This monitoring program shall be implemented within each jurisdiction and shall begin within the 2010-2011 monitoring year.

1. Dry weather analytical monitoring shall include:
   (a) Analytical monitoring, field measurements and observations at selected stations.
   (b) Reports of analytical data in a SWAMP comparable format.

2. Selection of Dry Weather Analytical Monitoring stations: Based upon a review program data, the storm drain system and land uses, the Co-Permittees shall select dry weather analytical monitoring stations within their jurisdiction. At least 5 dry weather analytical monitoring stations need to be identified per Co-Permittee. The dry weather analytical monitoring stations shall be established using the following guidelines and criteria:
   (a) Stations should be located downstream of municipal land uses where illegal or illicit activity may occur;
   (b) Stations shall be located at accessible downstream locations within the storm drain system of each municipality or at major outfalls;
   (c) Hydrological conditions, total drainage area of the site, traffic density, age of the structures or buildings in the area, history of the area, and land use types shall be considered in locating stations;
   (d) Each Co-Permittee shall determine a primary station and at least 4 alternate stations to be sampled in case primary stations do not have flow in dry weather. The dry weather monitoring may utilize the same outfalls as those used for wet weather monitoring, if such outfalls are found to discharge during dry weather.
   (e) Fact sheets of general information such as site descriptions (i.e., conveyance type, dominant watershed land uses) shall be created.

3. The Principal and Co-Permittees shall develop and/or update written procedures for dry weather analytical monitoring (these procedures must be consistent with 40 CFR part 136), including field observations, monitoring, and analyses to be conducted. At a minimum, the procedures must meet the following guidelines and criteria:
   (a) Dry weather analytical monitoring shall be conducted at each identified station at least once between May 1st and September 30th of each year.
   (b) If flow or ponded runoff is observed at a dry weather analytical monitoring station and there has been at least seventy-two (72) hours of dry weather, make observations and collect at least one (1) grab sample.
   (c) Record general information such as site descriptions (i.e., conveyance type, dominant watershed land uses), flow estimation (i.e., width of water surface, approximate depth of water, approximate flow velocity, flow rate), and visual observations (i.e., odor, color, clarity, floatables, deposits/stains, vegetation condition, structural condition, and biology).

4. At a minimum, collect samples for analytical laboratory analysis of the following constituents:
   (a) Total Hardness
   (b) Total Organic Carbon or Oil and Grease
   (c) Lead (Dissolved)
   (d) Zinc (Dissolved)
   (e) Copper (Dissolved)
   (f) Total Coliform bacteria
   (g) E. Coli bacteria

5. Other required field observations include:
   (a) Flow Estimation
   (b) Temperature
   (c) pH
   (d) Odor
   (e) Color
   (f) Turbidity
   (g) Floatables (foam, oil sheen)
   (h) Staining
   (i) Algal growth

6. If the station is dry (no flowing or ponded runoff), make and record all applicable observations and select another station from the list of alternate stations for monitoring.

7. Visually assess the presence of trash in receiving waters and urban runoff. Assessments of trash shall provide information on the spatial extent and amount of trash present, as well as the nature of the types of trash present.

8. Develop and/or update procedures for source identification follow up investigations in the event elevated levels are found. These procedures shall be consistent with procedures required in IC/ID section.

D. Aquatic Toxicity Monitoring

I. The objective of aquatic toxicity monitoring is to evaluate if storm water (wet weather) discharges are causing or contributing to chronic toxic impacts on aquatic life by the following:
   i. Toxicity testing at mass emission and major outfall stations to assess impacts on the marine and freshwater environments.

1. The Principal Permittee shall collect and analyze mass emission and major outfall samples for toxicity to evaluate the extent and causes of toxicity in receiving waters. Permittees shall utilize documents such as: Ventura County's

Technical Guidance Manual for Storm Water Quality Control Measures and U.S. EPA's National Management Measures to Control Nonpoint Source Pollution from Urban Areas to implement measures to eliminate or reduce sources of toxicity in storm water.

2. Toxicity samples may be flow-weighted composite samples or grab samples for both wet and dry event sampling (see subparts A.7 and A.8).

3. Volume of sample shall be determined by specific test methods to be used. At a minimum it is suggested to collect 5 gallons for baseline testing, and an additional 5 gallons for TIE studies. Sufficient sample volume shall be collected to perform the required toxicity tests.

4. All toxicity tests shall be conducted as soon as possible following sample collection. The 36-hour sample holding time for test initiation shall be targeted. However, no more than 72 hours shall elapse before initial use of a sample.

5. When toxicity tests can not be performed to comply with the requirements of this Order due to circumstances beyond the Permittee's control, then the following shall be submitted to the Regional Water Board Executive Officer within 2 working days:
   (a) Statement of situation
   (b) Explanation of circumstance(s) with documentation
   (c) Statement of corrective action for the future

6. The Principal Permittee shall conduct critical life stage chronic toxicity tests on undiluted samples in accordance with:
   (a) U.S. EPA's Short Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to *West Coast* Marine and Estuarine Organisms, (EPA/600/R-95/136, 1995) for all mass emission stations, and for major outfalls discharging to marine and estuarine environments, or
   (b) U.S. EPA's Short Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Freshwater Organisms, October 2002 (EPA/821/R-02/013, 2002) or current version for major outfalls discharging to freshwater environments.

7. The Principal Permittee shall analyze samples for chronic toxicity according to the schedule below:
   (a) During the first year of the Order, 2 storm events shall be monitored at each mass emission and major outfall station. The first storm event of the wet season that produces at least 0.25 inches of rain, and 1 additional storm event. All storm events shall be separated by 7 days of dry weather (less than 0.1 inch of rain) from the previously measurable storm event.

(1) During the first year of the Order, all 3 test species shall be used for their respective chronic toxicity test method for the 2 storm events monitored, to determine the most sensitive test species for each monitoring station (see subparts D.8 and D.9 below).

(b) During the next 4 years of the Order, the first storm event of the wet season that produces at least 0.25 inches of rain shall be monitored for each mass emission and major outfall station. .

(1) During the next 4 years of the Order, the most sensitive test species determined from the first year of testing at each mass emission and major outfall station shall be used for its respective chronic toxicity test method (see subpart D.6).

8. Marine and Estuarine Species and Test Methods.

(a) Marine and estuarine species and short-term test methods for estimating the chronic toxicity of NPDES effluents shall be used and are found in the first edition of *Short-term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to West Coast Marine and Estuarine Organisms* (EPA/600/R-95/136, 1995) and applicable water quality standards; also see 40 CFR Parts 122.41(j)(4) and 122.44(d)(1)(iv).

(1) The Permittee shall conduct:

(A) A static renewal toxicity test with the topsmelt, *Atherinops affinis* (Larval Survival and Growth Test Method 1006.01)

(B) A static non-renewal toxicity test with the giant kelp *Macrocystis pyrifera* (Germination and Growth Test Method 1009.0); and

(C) A static non-renewal toxicity test with the purple sea urchin, *Strongylocentrotus purpuratus*, (Fertilization Test Method 1008.0)

(b) In no case shall the preceding toxicity test species be substituted with another organism unless written authorization from the Regional Water Board Executive Officer is received.

9. Freshwater Species and Test Methods.

(a) Species and short-term test methods for estimating the chronic toxicity of NPDES effluent shall be used and are found in the fourth edition of *Short-term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Freshwater Organisms* (EPA/821/R-02/013, 2002; Table IA, 40 CFR Part 136).

(1) The Permittee shall conduct

(A) A static renewal toxicity test with the fathead minnow, *Pimephales promelas* (Larval Survival and Growth Test Method 1000.0[1])

[1] Daily observations for mortality make it possible to calculate acute toxicity for desired exposure periods (i.e., 7-day LC50, 96-hour LC50, etc.).

(B) A static renewal toxicity test with the daphnid, *Ceriodaphnia dubia* (Survival and Reproduction Test Method 1002.0[1]); and

(C) A static renewal toxicity test with the green alga, *Selenastrum capricornutum* (also named *Raphidocelis subcapitata*) (Growth Test Method 1003.0)

(b) In no case shall the preceding toxicity test species be substituted with another organism unless written authorization from the Regional Water Board Executive Officer is received.

10. The test endpoint data is analyzed using a standard t-test approach. Statistical analysis methods shall be consistent with U.S. EPA test method manuals.

11. If significant toxicity is found then according to paragraph 10.2.6.2 of the U.S. EPA freshwater test methods manual, all chronic toxicity test results from the multi-concentration tests required by this Order must be reviewed and reported according to U.S. EPA guidance on the evaluation of concentration-response relationships found in *Method Guidance and Recommendations for Whole Effluent Toxicity (WET) Testing (40 CFR 136)* (EPA/821/B-00-004, 2000).

12. Toxic samples shall be immediately subjected to Toxicity Identification Evaluation (TIE) procedures to identify the toxic chemical(s) if toxicity is demonstrated by the standard t-test.

13. A TIE is to be performed to identify the causes of toxicity using the same species and test method and, as guidance, U.S. EPA test method manuals: *Toxicity Identification Evaluation: Characterization of Chronically Toxic Effluents, Phase I* (EPA/600/6-91/005F, 1992); *Methods for Aquatic Toxicity Identification Evaluations, Phase II Toxicity Identification Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA/600/R-92/080, 1993); *Methods for Aquatic Toxicity Identification Evaluations, Phase III Toxicity Confirmation Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA/600/R-92/081, 1993); and *Marine Toxicity Identification Evaluation (TIE): Phase I Guidance Document* (EPA/600/R-96-054, 1996).

14. The Principal Permittee shall complete chronic Phase I (Toxicity Characterization Procedures) TIEs for all sites showing significant toxicity. For the purpose of triggering TIE (Toxicity Characterization Procedures), significant toxicity is defined as at least 50% mortality. The 50% mortality threshold is consistent with the approach recommended in guidance published by USEPA for conducting TIEs (USEPA, 1996), which recommends a minimum threshold of 50% mortality because the probability of completing a successful TIE decreases rapidly for samples with less than this level of toxicity.

(a) The TIE shall be conducted on test species, demonstrating the most sensitive toxicity response at a sampling station. However, a TIE(s) may be conducted on an additional test species with the caveat that once the toxicant(s) has been identified then the most sensitive test species triggering the TIE event needs to be tested additionally to verify that the toxicant has been identified and addressed.

15. A TIE Prioritization Metric may be utilized to rank sites for TIEs.[2]

16. Toxicity Reduction Evaluation (TRE) when toxicity is identified
    (a) When the same pollutant or class of pollutants is identified through 2 consecutive TIE evaluations, a TRE shall be performed for that identified toxic pollutant.
    (b) The TRE development shall be performed by a neutral third party (retained by the Permittees), in consultation with the Regional Water Board staff.
    (c) The TRE shall include all reasonable steps to identify the source(s) of toxicity and discuss appropriate BMPs to eliminate the causes of toxicity. No later than 30 days after the source of toxicity and appropriate BMPs are identified, the Permittees shall submit the TRE Corrective Action Plan to the Regional Water Board Executive Officer for approval. At a minimum, the Plan shall include a discussion of the following items:
        (1) The potential sources of pollutant(s) causing toxicity.
        (2) A list of municipalities and agencies that may have jurisdiction over sources of pollutant(s) causing toxicity.
        (3) Recommended BMPs to reduce the pollutant(s) causing toxicity.
        (4) Proposed post construction control measures to reduce the pollutant(s) causing toxicity.
        (5) Follow-up monitoring to demonstrate that toxicity has been removed.
    (d) The TRE process shall be coordinated with TMDL development and implementation (i.e., If a TMDL for 4,4'-DDD is being implemented when a TRE for 4,4'-DDD is required, the efforts shall be coordinated to avoid overlap).

17. Results of Toxicity monitoring conducted in accordance with the Standard Operating Procedure under Standard Provision 14 of this Attachment shall be sent to the Regional Board's Storm Water Site at MS4stormwaterRB4@waterboards.ca.gov, no later than 90 days from sample collection date for the initial toxicity test and no more than 30 days from completion of each aspect of the analysis for TIEs/TREs. The sample data transmitted shall be in the most recent update of the Southern California Municipal Storm Water Monitoring Coalition's (SMC) Standardized Data Transfer Formats (SDTFs).

[2] Appendix 5. SMC Model Monitoring Program.

18. The Annual Storm Water Report shall include:
    (a) A full laboratory report for all toxicity testing.
    (b) A summary of the years' mass emission and major outfall monitoring station's toxicity test results reported according to the test methods manual chapter on report preparation and test review.
    (c) The dates of sample collection and initiation of each toxicity test.
    (d) All results for effluent parameters monitored concurrently with the toxicity test(s).
    (e) TIE Phase testing (Phase I, Phase II, and Phase III) that has been or is in the process of being conducted per monitoring station.
    (f) The development, implementation, and results for each TRE Corrective Action Plan in the Annual Storm Water Report, beginning the year following the identification of each pollutant or pollutant class causing toxicity.

19. When the SMC Standardized Toxicity Testing Guidance is completed, the Regional Water Board Executive Officer may direct Permittees to replace the current toxicity program with the standardized guidance procedure.

SPECIAL STUDIES

E. Pyrethroid Insecticides Study

I. The Principal Permittee shall perform a Pyrethroid Insecticides study to accomplish the following objectives:
    i. Establish baseline data for major watersheds
    ii. Evaluate whether Pyrethroid Insecticide concentrations are at or approaching levels known to be toxic to sediment-dwelling aquatic organisms.
    iii. Determine if Pyrethroids discovered are from urban sources.
    iv. Assess any trends over the permit term.

1. The Permittees shall incorporate monitoring for Pyrethroid Insecticides within the Calleguas Creek, Santa Clara River and Ventura River Watersheds according to the following:
    (a) No later than the second year of this Order, monitoring shall begin.
    (b) Quality Assurance Project Plan (QAPP) to be submitted to the Regional Board for approval 12 months prior to beginning monitoring.
    (c) In selecting sites to conduct monitoring for Pyrethroid Insecticides, Permittees shall review existing monitoring programs in the watersheds by other public and private entities, watershed coalitions, and citizen volunteers, so as to complement and not duplicate efforts.
    (d) Establish at least 2 stations along the mainstems of each major watershed river that are influenced by urban discharges.

(e) The study shall be repeated every third year following the year monitoring begins.

2. The Principal Permittee shall monitor Pyrethroid Insecticides stations according to the following:
   (a) The Principal Permittee shall monitor 1 sampling event per station per monitoring year.
      (1) Monitoring shall occur after sediment has settled within the waterbody, and safe access can be assured.
   (b) Sufficient sediment is to be collected at each station in a pre-cleaned glass jar by skimming the upper 1 cm of the sediment column with a steel scoop, and held on ice until returned to the laboratory.
   (c) Sediment shall be homogenized in the laboratory by hand mixing, then held at 4 °C (toxicity samples) or -20 °C (chemistry samples).
   (d) All samples taken shall be analyzed for the following Pyrethroids:
      (1) biefenthrin
      (2) cyfluthrin
      (3) cypermethrin
      (4) deltamethrin
      (5) esfenvalerate
      (6) lambda-cyhalothrin
      (7) permethrin
      (8) tralomethrin (if laboratory is capable of analyzing for it)
   (e) Detection limits for all Pyrethroids shall be as close to 1ng/g (dry weight) as reasonably achievable.
   (f) Each sediment sample is to measure the following:
      (1) total organic carbon (TOC).

3. All samples shall be tested for toxicity to 7 to 10 day old ***Hyalella azteca*** according to standard U.S. EPA testing methods.[3]
   (a) Use of the approach described in *Aquatic Toxicity Due to Residential Use of Pyrethroid Insecticides*[4] for toxicity testing shall be used.

4. Analysis by a laboratory that has performed sediment toxicity testing for Pyrethroid Insecticides is preferred.

5. Monitoring results from each station shall be sent electronically to the Regional Board's Storm Water Site at MS4stormwaterRB4@waterboards.ca.gov, no later than 90 days from sample collection date. The sample data transmitted shall be

[3] *U.S. EPA. Methods for Measuring the Toxicity and Bioaccumulation of Sediment-Associated Contaminants with Freshwater Invertebrates*; EPA Publication 600/R-99/064; U.S. Environmental Protection Agency: Washington, DC, 2000; 192 pp.
[4] *Aquatic Toxicity Due to Residential Use of Pyrethroid Insecticides*; Weston, D.P.; Holmes, R.W.; You, J.; Lydy, M.J. Environ. Sci. Technol.; (Article); 2005; 39(24); 9780 pp.

in the most recent update of the Southern California Municipal Storm Water Monitoring Coalition's (SMC) Standardized Data Transfer Formats (SDTFs).

6. If toxicity is attributed to Pyrethroids then consultation with staff at U.S. EPA, the California Department of Pesticide Regulations and the California Stormwater Quality Association's (CASQA) pesticides committee (UP3 Project web site), shall be required to obtain relevant information to use in developing the recommendations to mitigate Pyrethroids in the Final Report.

7. Final Report for the Pyrethroid Insecticides study shall contain the following:
   (a) Executive summary
   (b) Methods
   (c) Results (including map depicting monitoring stations)
   (d) Discussion
   (e) Recommendations to mitigate Pyrethroids

8. The Final Report shall be completed and submitted to the Executive Officer of the Regional Water Board no later than 8 months after completion of the study.

9. The Pyrethroid Insecticides Study requirement may be satisfied by another tributary monitoring program within the Watershed performing a sediment Pyrethroid Insecticides Study that is monitoring to assess pyrethroid concentrations and sediment toxicity, so as to complement other ongoing programs.

F. Hydromodification Control Study

1. The Principal Permittee shall conduct or participate in special studies to develop tools to predict and mitigate the adverse impacts of Hydromodification, and to comply with hydromodification control criteria. This can be achieved by the following:
   (a) Develop a mapping and classification system for streams based on their susceptibility to the effects of hydromodification.
   (b) Establish protocols for ongoing monitoring to assess the effects of hydromodification.
   (c) Develop dynamic models to assess the effects of hydromodification on stream condition.
   (d) Develop a series of tools that managers can easily apply to make recommendations or set requirements relative to hydromodification for new development and redevelopment.

2. The Principal Permittee may satisfy this requirement by participating in the 'Development of Tools for Hydromodification Assessment and Management' Project undertaken by the SMC and coordinated by the SCCWRP.

3. The Principal Permittee shall continue to partner with the SMC and collect data or sponsor its collection for the Ventura County sites to reduce statistical uncertainty and/ or improve model predictability.

4. The Principal Permittee shall submit a letter to the Regional Water Board Executive Officer stating how they will satisfy this requirement, no later than 2 months after Order adoption date.

G. Low Impact Development

1. The Principal Permittee shall conduct or participate in a special study to assess the effectiveness of low impact development techniques in semi-arid climate regimes such as in Southern California.

2. The Principal Permittee may satisfy this requirement by participating in the SMC project titled "Quantifying the Effectiveness of Site Design/ Low Impact Development Best Management Practice in Southern California".

3. The Principal Permittee shall submit a letter to the Regional Water Board Executive Officer stating how they are satisfying this requirement, no later than 2 months after deciding to either conduct or participate in special study.

H. Southern California Bight Project

1. The Principal Permittee and Permittees shall participate with other government organizations regulating discharges in southern California in the collaboration to conduct a regional monitoring survey (Southern California Bight Project (SCBP)), which was started in 2008 and to be continued in successive years. The survey's primary objective is to assess the spatial extent and magnitude of ecological disturbances on the mainland continental shelf of the SCB and to describe relative conditions among different regions of the SCBP.

2. The Principal Permittee shall participate on the Steering Committee for the bight-wide monitoring project, and assist with the estuary and nearshore sampling effort requirement of the proposed monitoring project for Ventura County as defined in the SCBP plan.

I. Bioassessment

1. The Principal Permittee consents to participate in the following regional water quality program for watershed management and planning:
   (a) SMC Regional Monitoring Program
      (1) Southern California Regional Bioassessment
         (A) Level of effort per watershed per year
            (i) Probabilistic sites per watershed
               (I) Ventura River - Six
               (II) Santa Clara River - Three
               (III) Calleguas Creek - Six
            (ii) Integrator sites per watershed
               (A) Ventura River - One
               (B) Santa Clara River - One
               (C) Calleguas Creek – One
   (b) Ventura County Bioassessment: Permittees shall conduct bioassessment at one fixed site in each of the watersheds above on an annual basis. Southern California Regional Bioassessment protocols shall be used to conduct the Ventura County Bioassessment program.

J. Volunteer Monitoring Programs

1. The Permittees shall provide limited assistance if requested in the development and implementation of volunteer monitoring programs in the Ventura watersheds. These include, but are not limited to the following:
   (a) Ventura River - (Ventura Stream Team)
   (b) Santa Clara River - (Santa Clara River Stream Team)
   (c) Calleguas Creek - (Calleguas Creek Watershed Quality Monitoring Program)
   (d) Malibu Creek - (Malibu Creek Watershed Quality Monitoring Program)

K. Standard Monitoring Provisions

I. All monitoring activities shall meet the following requirements.

1. Monitoring and Records [40 CFR 122.41(j)(1)]
   (a) Samples and measurements taken for the purpose of monitoring shall be representative of the monitored activity.

2. Monitoring and Records [40 CFR 122.41(j)(2)] [CWC §13383(a)]
   (a) The Principal Permittee and Permittees shall retain records of all monitoring information, including all calibration and maintenance of monitoring instrumentation, copies of all reports required by this Order, and records of all data used to complete the Report of Waste Discharge (ROWD) and application for this Order, for a period of at least five (5) years from the date

of the sample, measurement, report, or application. This period may be extended by request of the Regional Water Board or U.S. EPA at any time and shall be extended during the course of any unresolved litigation regarding this discharge.

3. Monitoring and Records [40 CFR 122.21(j)(3)]
   (a) Records of monitoring information shall include:
      (1) The date, time of sampling or measurements; exact place, weather conditions, and rain fall amount.
      (2) The individual(s) who performed the sampling or measurements.
      (3) The date(s) analyses were performed.
      (4) The individual(s) who performed the analyses.
      (5) The analytical techniques or methods used.
      (6) The results of such analyses.
      (7) The data sheets showing toxicity test results.

4. Monitoring and Records [40 CFR 122.21(j)(4)]
   (a) All sampling, sample preservation, and analyses must be conducted according to test procedures under 40 CFR Part 136, unless other test procedures have been specified in this Order. If a particular Minimum Level (ML) is not attainable in accordance with procedures set forth in 40 CFR 136, the lowest quantifiable concentration of the lowest calibration standard analyzed by a specific analytical procedure may be used instead.

5. Monitoring and Records [40 CFR 122.21(j)(5)]
   (a)The CWA provides that any person who falsifies, tampers with, or knowingly renders inaccurate any monitoring device or method required to be maintained under this Order shall, upon conviction, be punished by a fine of not more than $10,000, or by imprisonment for not more than 2 years, or both. If a conviction of a person is for a violation committed after a first conviction of such person under this paragraph, punishment is a fine of not more than $20,000 per day of violation, or by imprisonment of not more than four years, or both.

6. All chemical, bacteriological, and toxicity analyses shall be conducted at a laboratory:
   (a) Certified for such analyses by an appropriate governmental regulatory agency.
   (b) Participated in 'Intercalibration Studies' for storm water pollutant analysis conducted by the SMC. [5]

[5] The 'Intercalibration Studies' are conducted periodically by the SMC to establish a consensus based approach for achieving minimal levels of comparability among different testing laboratories for storm water samples to minimize analytical procedure bias. Stormwater Monitoring Coalition Laboratory Document, Technical Report 420 (2004) and subsequent revisions and augmentations.

(c) Which performs laboratory analyses consistent with the storm water monitoring guidelines as specified in, the *Stormwater Monitoring Coalition Laboratory Guidance Document,* 2nd Edition R. Gossettt and K. Schiff (2007), and its revisions.

7. For priority toxic pollutants that are identified in the CTR (65 *Fed. Reg.* 31682), the MLs published in Appendix 4 of the *Policy for Implementation of Toxics Standards for Inland Surface Waters, Enclosed Bays and Estuaries of California* (SIP) shall be used for all analyses, unless otherwise specified. The MLs from the SIP are incorporated into Attachment "G".

8. The Monitoring Report shall specify the analytical method used, the Method Detection Level (MDL) and the ML for each pollutant. For the purpose of reporting compliance with numerical limitations, performance goals, and receiving water limitations, analytical data shall be reported with 1 of the following methods, as appropriate:
   (a) An actual numerical value for sample results greater than or equal to the ML.
   (b) "Not-detected (ND)" for sample results less than the laboratory's MDL with the MDL indicated for the analytical method used.
   (c) "Detected, but Not Quantified (DNQ)" if results are greater than or equal to the laboratory's MDL but less than the ML. The estimated chemical concentration of the sample shall also be reported. This is the concentration that results from the confirmed detection of the substance by the analytical method below the ML value.

9. For priority toxic pollutants, if the Permittee can demonstrate that a particular ML is not attainable, in accordance with procedures set forth in 40 CFR 136, the lowest quantifiable concentration of the lowest calibration standard analyzed by a specific analytical procedure (assuming that all the method specified sample weights, volumes, and processing steps have been followed) may be used instead of the ML listed in Appendix 4 of the SIP. The Principal Permittee must submit documentation from the laboratory to the Regional Water Board Executive Officer for approval prior to raising the ML for any constituent.

10. Monitoring Reports [40 CFR 122.41(I)(4)(ii)]
   (a) If the Principal Permittee monitors any pollutant more frequently than required by the Order using test procedures approved under 40 CFR part 136, unless otherwise specified in the Order, the results of this monitoring shall be included in the calculation and reporting of the data submitted in the Annual Monitoring Reports.

11. Monitoring Reports [40 CFR 122.41(I)(4)(iii)]
    (a) Calculations for all limitations, which require averaging of measurements, shall utilize an arithmetic mean unless otherwise specified in this Order.

12. If no flow occurred during the reporting period, then the Monitoring Report shall, so state.

13. The Regional Water Board Executive Officer or the Regional Board, consistent with 40 CFR 122.41, may approve changes to the Monitoring Program, after providing the opportunity for public comment, either:
    (a) By petition of the Principal Permittee or by petition of interested parties after submittal of the Monitoring Report. Such petition shall be filed not later than 60 days after the Monitoring Report submittal date, or
    (b) As deemed necessary by the Regional Water Board Executive Officer following notice to the Principal Permittee.

14. The Principal Permittee must provide a copy of the Standard Operation Procedures (SOPs) for the Monitoring Program No. CI 7388 to the Regional Water Board upon request. The SOP will consist of five elements: Title page, Table of Contents, Procedures, Quality Assurance/ Quality Control (QA/ QC), and References. Briefly describe the purpose of the work or process, including any regulatory information or standards that are appropriate to the SOP process, and the scope to indicate what is covered. Denote what sequential procedures should be followed, divided into significant sections; e.g., possible interferences, equipment needed personnel qualifications, and safety considerations. Describe QA/ QC activities, and list any cited or significant references.

L. Total Maximum Daily Load (TMDL) Monitoring

1. TMDL monitoring is to determine compliance with the TMDL Waste Load Allocations (WLAs) and numeric targets for the MS4 Permittees that have been adopted by the Regional Water Board and have been approved by the Office of Administrative Law and the U.S. EPA.

2. TMDL monitoring is in accordance with approved TMDLs as discussed in part 5 of the permit. TMDL monitoring for specific watersheds is in accordance with the agreed upon monitoring plans submitted by stakeholders, including MS4 Permittees.

M. Beach Water Quality Monitoring

If funding from state and federal sources is not available for beach water quality monitoring the Principal Permittee shall conduct weekly year-round beach water quality sampling and analysis at a maximum of ten sites in accordance with the procedures and locations used in AB 411 monitoring and listed below:

1. Rincon Beach – 25 yards south of the creek mouth*
2. Oil Piers Beach – south of the drain, bottom of the wood staircase
3. Faria County Park – south of the drain at the north end of the park*
4. Solimar Beach – south (end of east gate access road)*
5. Emma Wood State Beach – 50 yards south of first drain
6. Oxnard Beach – at J Street drain
7. Surfer's Point at Seaside – end of the access path via wooden gate
8. Promenade Park – Figueroa Street
9. Surfer's Knoll – beach adjacent to the parking lot*
10. San Buenaventura Beach – south of drain at San Jon Road

* Not associated with MS4 discharges.

Technical Report #419

EXECUTIVE SUMMARY

This report describes a model monitoring program for receiving waters affected by urban runoff in both wet and dry weather. It provides a common design framework for municipal urban runoff programs and Regional Board staff to use in developing and/or revising program requirements for monitoring receiving waters for impacts, status and trends, toxicity, mass emissions, and source identification. This effort was funded in part by the State Water Resources Control Board (SWRCB), prompted by Senate Bill 72 (Kuehl), which addressed the standardization of sampling and analysis protocols in municipal stormwater monitoring programs. The development of the model monitoring program itself was organized through the Southern California Stormwater Monitoring Coalition (SMC), which impaneled a technical committee including representatives from:

- Regional Water Quality Control Boards (Los Angeles, Santa Ana, San Diego)
- Municipal permittees (Counties of Ventura, Los Angeles, San Bernardino, Riverside, Orange, and San Diego)
- Heal the Bay
- Southern California Coastal Water Research Project (SCCWRP).

As a result of the SMC's role and the makeup of the technical committee, the model stormwater monitoring program reflects issues and contexts of paramount importance in southern California and addresses some, but not all, of the requirements of SB72. Additional technical guidance related to performance standards for laboratory analysis and data reporting formats is detailed in companion documents.

The model program is structured around five fundamental management questions, with the goal of achieving a basic degree of comparability across southern California monitoring programs, while maintaining individual programs' ability to adapt to site-specific and local concerns.

The five core management questions are:

- Question 1: Are conditions in receiving waters protective, or likely to be protective, of beneficial uses?
- Question 2: What is the extent and magnitude of the current or potential receiving water problems?
- Question 3: What is the relative urban runoff contribution to the receiving water problem(s)?
- Question 4: What are the sources to urban runoff that contribute to receiving water problem(s)?
- Question 5: Are conditions in receiving waters getting better or worse?

As illustrated in Figure Ex-1, the questions are linked in a logical progression that defines an efficient sequence of study design steps.

While there is a wide range of beneficial uses defined in the Basin Plans for southern California, the model monitoring program focuses on a subset of these beneficial uses that are common to most urban runoff management programs in the region and relate to human health and habitat protection:

- Contact Water Recreation (REC1)
- Non-contact Water Recreation (REC2)
- Warm Freshwater Habitat (WARM)
- Estuarine Habitat (EST)
- Marine Habitat (MAR)
- Wildlife Habitat (WILD).

For each category of beneficial use (i.e., human health, habitat protection) the model program defines monitoring objectives and study designs. Where adequate historical data were available, statistical analyses were used to develop detailed guidance on appropriate levels of sampling effort. Rather than define a static program, the technical committee develop several tools to serve as adaptive triggers for initiating more monitoring effort if an impact was observed, or a reduction in monitoring effort if no impact (or potential for impact) was found. These tools include triggers for toxicity identification evaluations, upstream source tracking, a prioritization scheme for special studies, and a computer program for estimating sample size based on statistical power to detect trends.

The following types of stations could be integral parts of a stormwater monitoring program that address each of the five key management questions:

- Long-term, fixed, bottom-of-watershed (but above tidal influence) stations to assess cumulative water quality and aggregate loads, with monitoring based primarily on a mass emissions model including wet weather chemistry and toxicity
- Spatially extensive, perhaps randomly sited or rotating, stations to support statistically valid comparisons across multiple watersheds, and with monitoring based primarily on the Triad approach for dry weather sampling and on chemistry and toxicity for wet weather
- Site-specific stations focused on the status of high-priority inland habitats of concern, with monitoring based primarily on the Triad approach for dry weather sampling and on chemistry and toxicity for wet weather
- High-priority inland body contact recreation areas
- Site-specific stations designed to generate information to support key program goals, such as source prioritization or BMP implementation and evaluation
- Coastal estuarine stations to assess status in these key habitats, with monitoring based primarily on the Triad approach
- Coastal ocean stations to assess stormwater plume impacts, conducted primarily as part of the periodic Bight surveys.

While the idealized monitoring design in Figure 5-2 shows each type of monitoring station separately, in practice there may be overlap among two or more types of stations.

The technical committee gave significant consideration to how the model program would be used in practice. It was well aware that stormwater monitoring has been ongoing for some time in southern California and that important basic steps, such as characterization studies, have been completed by many programs. In addition, the degree to which programs have addressed the five management questions in Figure 2-1 varies substantially, in part due to each program's history and in part due to the nature of the surface waters in different parts of the region.

Thus, the model stormwater monitoring program does not assume that each program is starting with a blank sheet of paper. Nor does the model program assume that each permittee will proceed through Figure 2-1 in a linear, stepwise fashion. Instead, the model program is intended to

improve each program's ability to build appropriate linkages among the five core management questions. This is best accomplished through the following steps:

1. Evaluate a program's ability to answer each of the five management questions
2. Identify critical gaps in knowledge (e.g., inability to document impacts, lack of knowledge about potential sources, absence of trend monitoring component) relevant to each program's circumstances
3. Use the monitoring designs in the model monitoring program as a framework for developing monitoring components suited to each program's circumstances.

The SMC's technical committee intended that the model program be used to direct an incremental process of adaptation using the three steps above, rather than one of wholesale change. This incremental change should be based on a prioritization of needs (i.e. using the triad approach in perennial streams before ephemeral streams). Through this process, the ultimate goal of developing regionally consistent programs that directly address key management questions in a scientifically rigorous and cost effective manner can be accomplished.

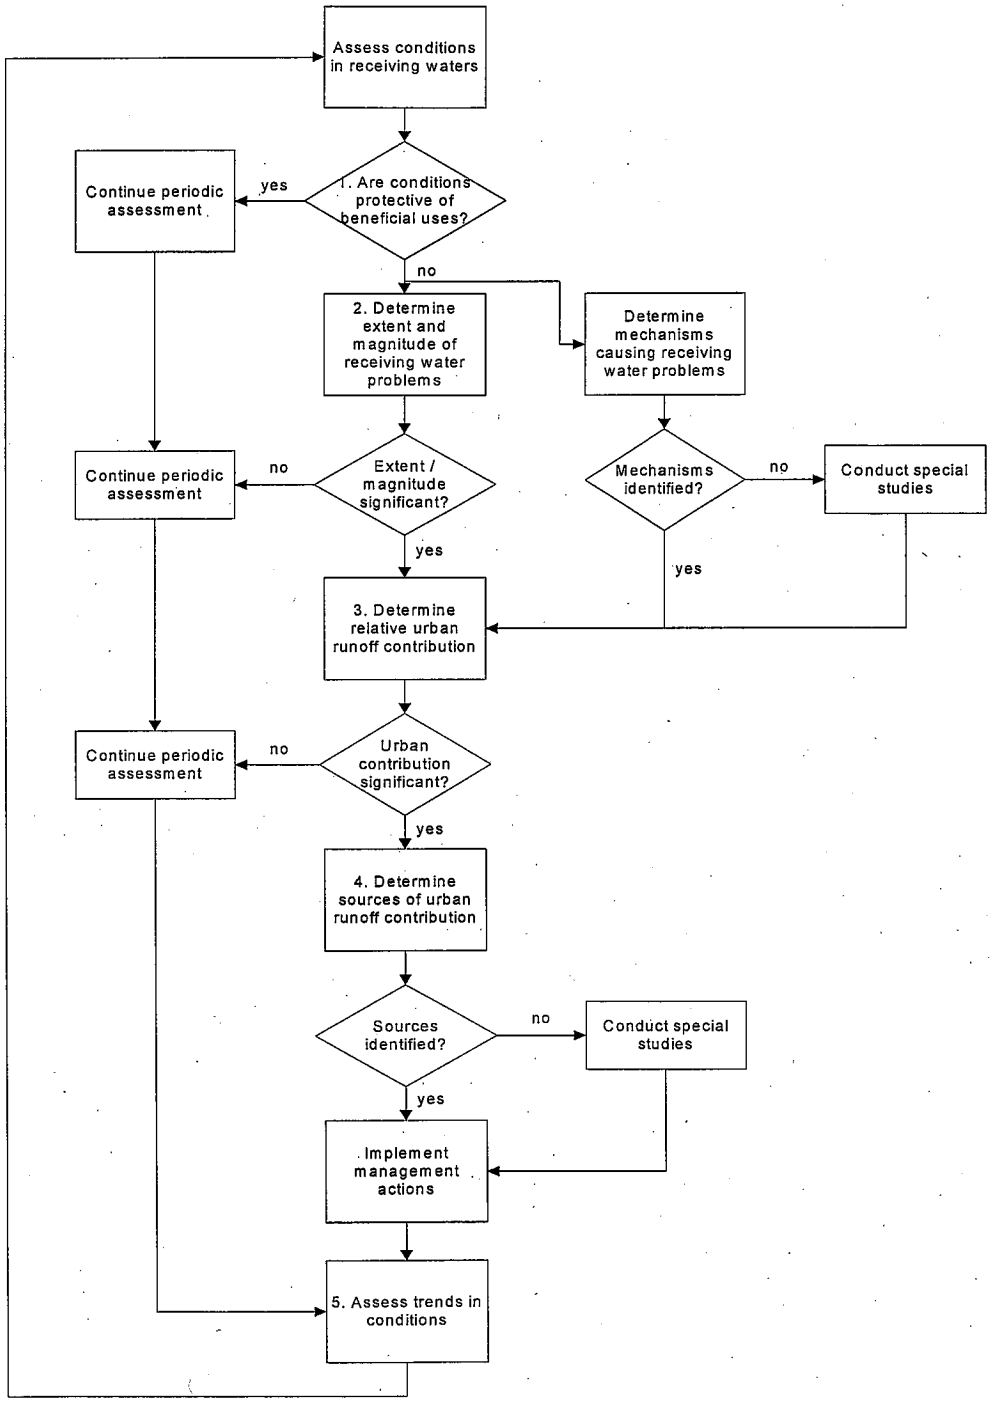

Figure Ex-1. Graphical illustration of the idealized logical flow through the five core management questions (reworded as statements to fit flowchart conventions). The answer to each question provides the basis for developing the monitoring design to answer the next. In actuality, monitoring programs may have addressed questions in parallel or out of sequence, depending on available knowledge and specific information needs.

ACKNOWLEDGEMENTS

This project was partially funded by the State Water Resources Control Board and the Southern California Stormwater Monitoring Coalition. The content of the report was developed over the course of one year a technical committee consisting of regulated, regulatory, environmental and research organizations including:

1.0 INTRODUCTION

1.1 Rationale and approach

Large municipalities in southern California are required, under the Clean Water Act (CWA) and National Pollutant Discharge Elimination System (NPDES) permits from their respective Regional Water Quality Control Boards (RWQCBs), to monitor discharges of urban runoff[1] from municipal separate storm sewer systems (MS4s) and their impacts on receiving waters. However, urban runoff monitoring programs throughout southern California often focus on different monitoring questions, approach the same question in different ways, sample different sets of parameters, and use a range of field and laboratory methods to collect and analyze samples. This inconsistency makes it difficult, if not impossible, to address questions on a broader spatial scale, to compare urban runoff monitoring results across programs, and to improve efficiency by taking advantage of opportunities for exchanging data and coordinating monitoring responsibilities at regional scales.

In response to this set of circumstances, the Southern California Stormwater Monitoring Coalition (SMC) has undertaken a project to develop regionally consistent monitoring approaches and designs. The goal of the study is to produce a "model" monitoring program that will provide a foundation for each of the urban runoff monitoring programs in southern California to build on for their respective agency's needs. The development of the model monitoring program will therefore focus on developing regionally consistent management questions, efficient monitoring designs to answer those questions, creating standardized laboratory analysis protocols, and coordinating necessary quality assurance activities to ensure comparability among programs. This document focuses specifically on management questions and monitoring designs. Standardization of laboratory analysis protocols and data transfer and reporting methods are dealt with in companion documents.

This report reflects the collaborative work of a technical committee impaneled by the SMC. The technical committee included representatives from three southern California RWQCBs (the Colorado Region was not represented), the lead municipal MS4 management programs (commonly referred to as stormwater programs), SCCWRP, Heal the Bay and the State Water Resources Control Board (SWRCB). This report makes recommendations about a model urban runoff monitoring program, assesses current monitoring practice, and recommends adjustments to bring current programs more in line with the model program.

1.2 Relationship to SB72 and State Board efforts

Senate Bill 72 (Kuehl), adopted in October 2001, required the State Water Resources Control Board (SWRCB) to develop "minimum monitoring requirements for regulated municipalities that were subject to a stormwater permit on or before December 31, 2001." The SWRCB therefore has initiated efforts to develop standardized protocols for collection and analysis of stormwater samples, as well as a standardized reporting format. Working in coordination with local stormwater agencies and RWQCBs through the SMC presents an opportunity to gain consensus towards a common shared goal.

---

[1] Urban runoff includes those discharges from residential, commercial, industrial and construction areas within the Permit Area and excludes discharges from feedlots, dairies, farms and open space.

There are, however, some important differences among the SMC and SWRCB goals. On one hand, the SWRCB goals are much larger than the SMC's goals. The SWRCB is mandated to develop statewide consistency while the goal of this project is development of consistency only for the southern California region. On the other hand, the SWRCB goals are more limited than the SMC's goals. The SWRCB is mandated to develop the "how to's" of stormwater monitoring (i.e. sampling, analysis, reporting), whereas this project starts with understanding the "why, where, and what" (i.e. monitoring questions and study designs) of developing an integrated stormwater monitoring program. Finally, the SWRCB and the SMC have different focal points of their monitoring programs. The SWRCB is mandated to develop standardized monitoring protocols for stormwater from all of their regulated discharges (i.e. municipal agencies and industrial facilities). This project, however, only addresses monitoring programs developed for municipal agencies, but examines monitoring designs for both wet and dry weather runoff.

1.3 A note on terminology

It is important to emphasize that the monitoring designs described in subsequent sections of this report focus explicitly on supporting the management of urban runoff to protect receiving water quality, with "receiving water" defined as surface Waters of the State, with the exception of ground water and lakes/reservoirs. While the SMC's technical committee recognized that there are other point and nonpoint sources of receiving water impact, the core focus of municipal stormwater programs is urban runoff, in both wet and dry weather. Thus, references to "stormwater" throughout the body of the report should be understood to refer to urban runoff.

It is also important to recognize that this document focuses on potential water quality problems and impacts, as opposed to water quality impairments. The technical committee opted to avoid the terminology of impairments because it has a distinct regulatory connotation that eventually leads to a Total Maximum Daily Load (see box on TMDLs). Water quality problems and impacts are more broad than impairments, which seemed more appropriate since some monitoring elements are meant to be early warning indicators and hopefully will avoid TMDLs in the future.

Total Maximum Daily Loads (TMDLs)

TMDLs are a regulatory framework for trying to restore beneficial uses in impaired waterbodies. Waterbodies sometimes have impaired water quality, even when all discharges to that waterbody are regulated under national pollutant discharge elimination system (NPDES) permits. The State will often use NPDES monitoring data to create the list of impaired waterbodies, also called the §303(d) list, which refers to the specific section in the Clean Water Act for TMDLs. Once promulgated, TMDLs typically call for additional monitoring either to refine source assessment or to determine if management actions implemented as a result of the TMDL are improving water quality. The model program described in this document is for urban runoff monitoring and, while there is some potential overlap with TMDL monitoring, the intent is to deliberately keep them separate. The reason is twofold. First, TMDLs are inherently site-specific and the goal of this document is to ensure regional applicability. Secondly, urban runoff may, or may not, be the cause of the water quality impairment that leads to a TMDL. If TMDL monitoring is called for, it is prudent to link monitoring from all NPDES dischargers to the impaired waterbody. Regardless of a §303(d) listing, urban runoff monitoring will be a necessity in order to characterize impacts, or lack of impacts, in receiving waters. Additional information on TMDLs in southern California can be found at www.swrcb.ca.gov

2.0 GOALS, OBJECTIVES AND IMPLEMENTATION

This model urban runoff monitoring program is intended as a framework to assist permittees and Regional Board staff in modifying existing monitoring programs, both wet and dry weather, with the goal of improving their ability to answer key management questions common to all programs in a cost effective and scientifically rigorous way. This is described in the following sections:

- The principals and philosophy for developing the model program are given in Section 3.0.
- A description of the key management questions, including rationale and expected data products, are given in section 4.0.
- The specific design elements, such as identifying the number of sampling sites and frequency of sampling, are given in Section 5.0.

This section, however, first addresses the basic program goals, how these goals address universal NPDES permit objectives as defined by the State and the Federal government, and describes an approach for applying the model monitoring program to an existing stormwater permit. Such modifications can occur when permits are periodically renewed and/or when permittees propose monitoring program revisions to their respective Regional Boards.

2.1 Monitoring program goals

Figure 2-1 summarizes the model monitoring program's ultimate goal, which is to ensure that each stormwater program has the ability to assess and manage its overall performance by answering five basic questions:

- Question 1: Are conditions in receiving waters protective, or likely to be protective, of beneficial uses?
- Question 2: What is the extent and magnitude of the current or potential receiving water problems?
- Question 3: What is the relative urban runoff contribution to the receiving water problem(s)?
- Question 4: What are the sources to urban runoff that contribute to receiving water problem(s)?
- Question 5: Are conditions in receiving waters getting better or worse?

These basic questions are universal to all MS4 programs in southern California and were prioritized by their program managers during the technical committees' early meetings.

2.2 Meeting permit objectives

Stormwater monitoring programs in southern California focus on meeting a set of NPDES permit objectives that, with some minor differences, are common to all programs in the region. These include the following (edited slightly for conciseness):

- Define water quality status, trends, and pollutants of concern associated with urban stormwater and non-stormwater discharges
- Evaluate impact of stormwater/urban runoff on biological species in receiving waters

- Identify those waters which cannot reasonably be expected to attain or maintain applicable water quality standards required to sustain beneficial uses
- Identify significant water quality problems related to urban stormwater and non-stormwater discharges
- Estimate annual mass emissions of pollutants discharged to surface waters through the MS4
- Evaluate water column and sediment toxicity in receiving waters
- Determine and prioritize pollutants of concern in stormwater
- Identify sources of urban runoff pollutants
- Identify other sources of pollutants in stormwater and non-stormwater runoff
- Evaluate the effectiveness of existing municipal stormwater quality management programs, including that of BMPs
- Identify and prohibit illicit connections
- Identify and prohibit illicit discharges.

The basic questions outlined in section 2.1 above, and described in detail in sections 4.0 and 5.0, will produce improved information that will help address many of these objectives (Table 2-1). The model program's structure, which moves from assessment monitoring, through source identification, and to tracking of longer-term trends, reflects the range of concerns represented in the set of common permit objectives.

2.3 Applying the model program

The technical committee's intent was to create the model program as guidance, providing sufficient detail to assure consistency in approach, but allowing for site-specific modifications and adaptations as necessary. This document serves as the starting point for negotiating a monitoring and reporting program. It is not a "copy and paste" list of static monitoring requirements, but an attempt to provide useful guidance. Therefore, this section outlines a procedure for implementing this guidance. We strongly recommend the user reread this section after reading sections 3.0, 4.0 and 5.0 in order to more fully understand this important implementation guidebook and place it in context.

The technical committee that developed the model program was well aware that stormwater monitoring has been ongoing for some time in many parts of southern California. Thus, important basic steps, such as stormwater characterization studies, have been completed by many programs (See Box on Discharge Characterization). In addition, the degree to which programs have addressed the five management questions in Figure 2-1 varies substantially, in part due to each program's history and in part due to the nature of the surface waters in different parts of the region. For example, inland programs in general have focused relatively more on identifying sources while coastal programs have allocated much more effort to assessing receiving

Stormwater Discharge Monitoring

The US EPA has published a manual (US EPA 1992) that provides detailed guidance for the basic elements of stormwater monitoring program design and implementation. This guidance is an extremely useful starting point for management programs faced with the necessity of performing initial characterization studies.

The manual describes when and where to sample, including defining storm event criteria, obtaining rainfall data, and dealing with the logistics of locating sampling sites. Alternative sampling methods (e.g., grab vs. composite, manual vs. automatic) are described and evaluated and special attention is given to the issue of measuring or estimating flow rates. In addition, the manual follows the analysis and reporting pathway once sampling is complete, providing detailed instructions on sample documentation, labeling, shipping, and chain of custody procedures.

water impacts, especially in high-use areas such as Newport or Santa Monica Bays.

The model stormwater monitoring program does not assume that each program is starting with a blank sheet of paper, nor that each program will implement the monitoring guidance in a linear, stepwise fashion. Instead, the model program is intended to improve each program's ability to build appropriate linkages among a key set of management questions (see Figure 2-1; Section 4.0). This is best accomplished through the following steps (see also Figure 2-3):

1. Evaluate a program's ability to answer each of the five management questions
2. Identify critical gaps in knowledge (e.g., inability to document impacts, lack of knowledge about potential sources, absence of trend monitoring component) relevant to each program's circumstances
3. Use the model program's monitoring guidance as a framework for developing monitoring components suited to each program's circumstances.

For Step 1, Appendix 1 summarizes current (as of June 2003) stormwater monitoring efforts in southern California, providing a first cut at assessing each program's ability to answer the five management questions. A full assessment under Step 1 would also involve a cumulative analysis of available historical monitoring data for each program. However, the variation among programs demonstrated in Appendix 1 suggests that implementing the model monitoring program would most likely involve focusing on different questions, and thus emphasizing different designs, for different programs. For example, source identification designs (Questions 3 and 4) might be needed for one program, but trend monitoring designs (Question 5) for another.

For Step 2, determining where to focus additional monitoring effort will depend on specific information on source characterization, patterns of development, hydrography and watershed structure, resources at risk, and levels and patterns of contamination. In addition, management initiatives in each program's area can influence decisions about what represents a critical knowledge gap. For example, TMDL development may require additional effort toward source identification. As another example, planned or ongoing BMP implementation may involve allocating additional effort to problem definition and/or to long-term trend monitoring to track BMP effectiveness.

For Step 3, the monitoring designs in the model monitoring program provide a starting point for developing detailed monitoring designs appropriate to the specifics of each program. The model framework is merely the foundation on which to build a permit-specific monitoring and reporting program. For example, the application of habitat monitoring designs based on bioassessment must take into account patterns of stream flow, the nature of biological communities, and the relative importance of urban runoff. The committee also considered the advisability of preparing explicit recommendations on the numbers and locations of sampling sites, and the degree of replication, but concluded that this was inappropriate given the amount of variation from program to program, as well as from place to place within each program. For example, numbers of stations will depend, among other things, on watershed size and complexity, amount and intensity of human use, severity and significance of potential impacts, known patterns of contamination, and hydrography of the study area. The degree of replication will depend on the kinds and amounts of variability in each area, as well as on the relative degree of certainty required by management agencies and the timeframe for decision making. Thus, the committee determined that each program should address the same five management questions and apply the same general monitoring design approaches, but then adapt the specifics of sampling to each individual situation. In this way, the model program will optimize comparability yet provide sufficient flexibility to address permit or site-specific needs

Table 2-1. Relationship between typical stormwater program monitoring objectives, as stated in NPDES permits, and the monitoring elements for which the model stormwater monitoring program provides design guidance. "Q" refers to the management questions described in Section 4.0 (e.g., Q1 refers to Question 1).

	Management question and type of monitoring				
Permit objective	Q1: Assessment	Q2: Extent and magnitude	Q3: Urban runoff contribution	Q4: Source identification	Q5: Trends
Define status, trends, pollutants	X				X
Evaluate impacts	X				X
Identify waters that do not attain uses	X	X			
Estimate mass emissions	X				X
Evaluate toxicity	X	X		X	
Identify polllutants of concern	X	X		X	
Identify sources of urban runoff pollutants			X	X	
Identify other sources			X	X	
Evaluate program effectiveness	X				X
Identify illicit connections				X	
Identify illicit discharges				X	

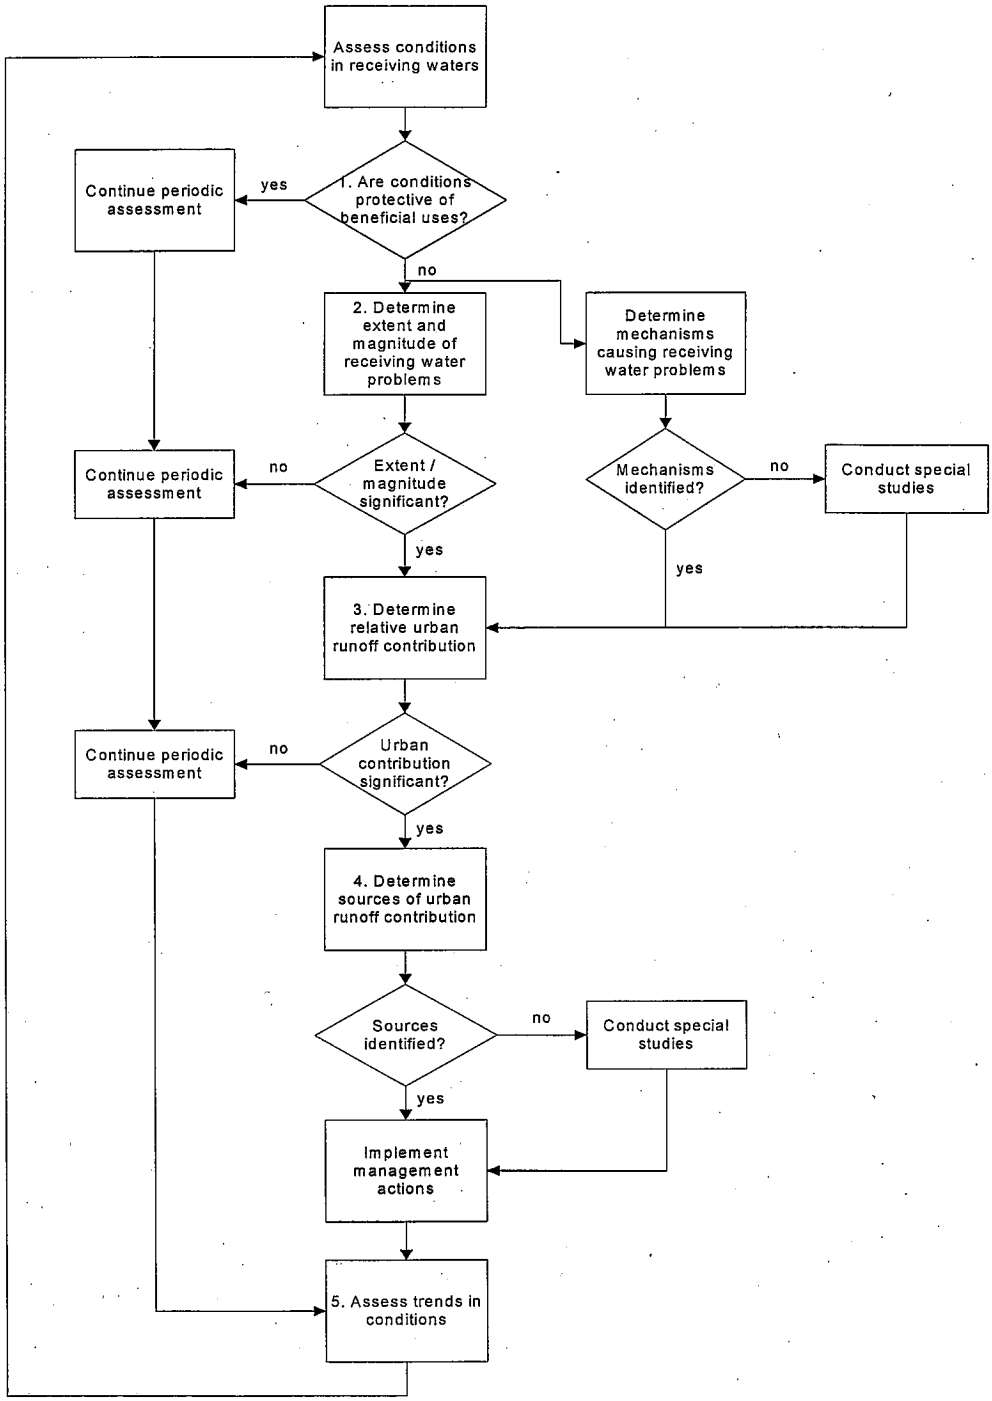

Figure 2-1. Graphical illustration of the idealized logical flow through the five core management questions (reworded as statements to fit flowchart conventions). The answer to each question provides the basis for developing the monitoring design to answer the next. In actuality, monitoring programs may have addressed questions in parallel or out of sequence, depending on available knowledge and specific information needs.

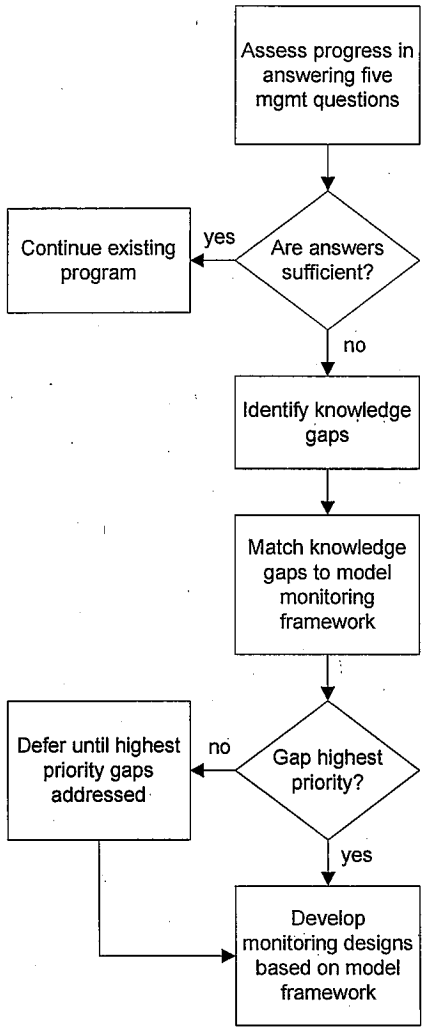

Figure 2-2. Sequence of steps involved in applying the model monitoring program framework to an existing stormwater monitoring program.

3.0 PRINCIPLES AND FRAMEWORK FOR A MODEL MONITORING PROGRAM

3.1 Principles for allocating monitoring effort

In developing the details of monitoring guidance to address the management questions and their related objectives, the committee was guided by three basic principles that provided an overall set of boundary conditions for monitoring design:

- Monitoring should be focused on decision making; data not helpful in making a decision about clearly defined regulatory, management, or technical issues should not be collected.
- The level of monitoring effort should reflect the potential for impact, with more monitoring allocated to situations where the potential impact (in terms both of the probability of an impact's occurrence and its extent and magnitude) is higher and less monitoring to situations where such potential is lower or where monitoring is not likely to provide useful information.
- Monitoring should be adaptive, in terms of its ability to both trigger follow-on studies as needed and make necessary mid-course corrections based on monitoring findings.

In addition, the committee identified three categories of monitoring activities that fulfill different types of information needs and defined them in the monitoring guidance in Section 5.0.

Core monitoring includes long-term monitoring, intended to track compliance with specific regulatory requirements or limits, to conduct ongoing assessments, or to track trends in certain important conditions over time. Thus, core monitoring generally occurs at fixed stations that are sampled routinely over time.

Regional monitoring includes cooperative studies that provide a larger-scale view of conditions in the southern California region. Regional monitoring can be used to assess the cumulative results of anthropogenic and natural effects on the environment. Regional monitoring also helps to place individual stormwater agencies' monitoring in perspective by comparing local results (i.e. core monitoring) to the breadth and depth of human impacts and natural variability found throughout southern California's watersheds. Regional monitoring requires the participation of all dischargers to the environment, not just MS4 permittees, thus potentially making this type of monitoring more cost-effective (see Box on Regional Watershed Monitoring). Finally, regional monitoring is best conducted periodically (i.e.

Regional Watershed Monitoring

There are many agencies in and around southern California in addition to municipal stormwater agencies that are interested in watershed to regional scale monitoring. For instance, the Statewide Ambient Monitoring Program (SWAMP) coordinated by the State Water Resources Control Board conducts monitoring throughout the southern California region in order to assess, among other things, the health of California's watersheds and estuaries. Another is the State's Wetlands Recovery Project, which has a similar goal as SWAMP, but is focused on wetland habitats. In a similar vein, the US Environmental Protection Agency coordinates the Environmental Monitoring and Assessment Program (EMAP), which monitors watersheds in the southern California region, but attempts to integrate these assessments nationally. Several other agencies are also monitoring in southern California's watersheds including the US Geological Survey's National Water Quality Assessment Program (NAWQA), the US Fish and Wildlife Service, numerous water reclamation plants, water districts, citizen monitoring organizations, and universities. Although each agency has a slightly different motive for monitoring, they all have at least one goal in common; to assess the health of the environment. Therefore, each one of these agencies represent an opportunity for a productive partnership in regional monitoring since they bring a different set of skills and perceptions to a meaningful collaboration.

every five years) because of its large spatial scale and integration among program types.

Special projects include specific targeted studies included as adaptive elements within core or regional monitoring designs. These are shorter-term efforts intended to extend or provide more insight into core monitoring results, for example, by investigating the specific sources of a receiving water problem. Special projects also include developmental research, designed to move monitoring science and policy forward. These can be used to demonstrate the value of particular analyses, to illustrate ways in which data can be used, or to develop new skills. These projects have a specified beginning, middle, and end. Stormwater programs may wish to conduct special studies individually or in coordination with the SMC.

3.2 Framework for developing monitoring questions and designs

The first major philosophical approach of the model urban runoff monitoring program is to help ensure that monitoring activities are:

- Linked directly to key management questions
- Integrated into a logically consistent whole
- Designed and structured for both cost effectiveness and scientific rigor.

To accomplish this set of ideals, the committee followed the philosophical framework of Bernstein et al. (1993), which outlines a series of successively more detailed levels of monitoring objectives. This philosophy includes series of logical steps that led from defining the key monitoring questions to specifying the technical detail of monitoring designs. This framework was defined as:

- Level I: broadly stated public and management core concerns (management questions)
- Level II: management and scientific objectives that include specific statements about time and space scales, reference conditions, and the monitoring approach to be used
- Level III: measurement goals that identify the types and amounts of change to be monitored for
- Level IV: specific technical plans and methods for implementing monitoring.

The second philosophical approach of the model program was to develop a framework that would provide broad consistency of approach, but can also be adapted or customized to meet local needs and conditions. One major concern of the technical committee was that, in its attempt to standardize monitoring programs regionwide, the model urban runoff monitoring program would become too inflexible to adapt to local site specific needs. Therefore, this document fully specifies Level I and Level II objectives (See Section 5.0), partially spells out Level III objectives, and provides examples, through technical guidance and brief case studies, of possible Level IV objectives (See Section 5.0). In addition, the companion documents that describe the laboratory intercalibration study and the data transfer and reporting formats do provide detailed Level IV objectives for two aspects of monitoring design that are important for ensuring comparability of data among programs. In this way, the model urban runoff monitoring program is not too restrictive, but provides sufficient guidance to make certain that managers throughout southern California have similar aims and approaches among programs.

4.0 MANAGEMENT QUESTIONS

There are five questions (or Level I objectives) that create a common foundation for monitoring design and urban runoff management in the region. These questions are not strictly independent, but are logically linked (Figure 2-1) where the answer to one question establishes the context for addressing the next. Thus, the management questions provide a means of organizing information about impacts, sources, and long-term trends in receiving water conditions into a logically consistent whole. The five management questions are:

- Question 1: Are conditions in receiving waters protective, or likely to be protective, of beneficial uses?
- Question 2: What is the extent and magnitude of the current or potential receiving water problems?
- Question 3: What is the relative urban runoff contribution to the receiving water problem(s)?
- Question 4: What are the sources to urban runoff that contribute to receiving water problem(s)?
- Question 5: Are conditions in receiving waters getting better or worse?

Each question can be addressed by one or more categories of monitoring effort, as summarized in Table 3-2. That is, some questions are best addressed using core monitoring, others questions are best addressed in a cooperative regional monitoring program, and others by directed special studies. The category(ies) of monitoring effort is identified within each question description.

The committee recognized that there are many beneficial uses enumerated in the region's Basin Plans and agreed that the five core management questions are equally applicable to the entire range of beneficial uses. However, for purposes of developing specific monitoring guidance, it chose to focus on a subset that is common to most municipal stormwater programs in the region and for which monitoring and regulatory approaches are relatively well established. These include:

- Contact Water Recreation (REC1)
- Non-contact Water Recreation (REC2)
- Warm Freshwater Habitat (WARM)
- Estuarine Habitat (EST)
- Marine Habitat (MAR)
- Wildlife Habitat (WILD).

The following subsections describe each question in more detail including background and rationale, explain how they are functionally interrelated (see also Figure 2-1), and describe the specific management and scientific objectives appropriate to each question including expected data products. For each question, the technical committee defined:

- What is the management goal?
- What monitoring strategy is suitable?
- What degree of certainty and precision is possible or required?
- What reference conditions are appropriate?
- What spatial scale is appropriate?

- What temporal scale is appropriate?

These questions and objectives then form the basis for the more detailed monitoring designs described in Section 5.0.

4.1 Question 1: Are conditions in receiving water protective, or likely to be protective, of beneficial uses?

4.1.1 Background to Question 1

Question 1 is a fundamental linch-pin for many, if not most, aspects of stormwater management. The presence of receiving water problems, or at least the potential for such problems, is the justification for a broad range of activities to better identify and reduce sources of contamination from urban runoff that may cause or contribute to such problems. In addition, detailed information about the nature of receiving water problems can greatly improve the effectiveness of a wide range of management actions. In principle, the design of any receiving water monitoring program should be based on reconnaissance and/or characterizations studies that target the likely sources and locations of receiving water problems. However, the southern California stormwater programs have already generated substantial information about where receiving water problems should be monitored for. Thus, the model monitoring program does not include a reconnaissance or characterization step for Question 1. However, where information on conditions in receiving waters is sparse or nonexistent, it may be necessary to initially conduct broad reconnaissance studies and/or evaluations of available historical data to determine the likely sources and locations of current or potential problems in receiving waters. In those cases, USEPA guidance (US EPA 1992) is available to direct the design of such studies.

In general, there are two often competing approaches to assessing whether conditions in receiving waters constitute a "problem", the compliance approach and the assessment approach. The committee described a compliance approach as one in which monitoring is used to determine if the value of an indicator is above or below a quantitative regulatory threshold. In this approach, the indicator measure would be considered as evidence of recreational water quality or habitat problem, acting as a surrogate for more detailed studies involving a larger range of measures. Exceedance of compliance standards would then provide the basis for management actions such as source identification studies, source control efforts, and further iterative monitoring and management actions. In contrast, an assessment approach would not be based primarily on comparison to specific quantitative thresholds or limitations. Rather, it would focus on better understanding actual conditions in the receiving water (i.e., the actual nature of problems) and is based on a weight of evidence approach in which chemical, biological, and ecological data are used to assess impacts. This approach emphasizes developing evidence of actual impacts in receiving waters in addition to, or instead of, evidence derived only from indicator measures.

The model monitoring committee believes that these two approaches should be complementary, rather than competitive or mutually exclusive. Thus, evidence provided by indicators could help initiate further studies to determine actual problem(s) and identify sources. Quantitative thresholds or limitations could be used to trigger or justify needed management actions, and the overall timeframe would be long enough to encompass iterations of monitoring and management efforts. The program design guidance in Section 5.0 illustrate how both approaches can be used in tandem, as in, for example, the use of mortality levels of indicator organisms in toxicity tests as a trigger for follow-up TIEs to identify the source(s) of toxicity.

4.1.2 Recreational water quality objectives

The Level II objective suggested for recreational water quality for Question 1 is described in Table 4-3 that focuses primarily on identifying conditions that may present elevated risk to humans from body contact recreation. The Level II management/monitoring objective can be stated as:

> Monitor a suite of bacterial indicators at high-priority sites selected by qualitative risk characterization and affected by urban runoff, including along beaches; in enclosed bays and estuaries; and along creeks, streams, and rivers at frequencies needed to ensure that relevant freshwater and marine standards are being met, to a moderate degree of certainty and precision.

The types of data products appropriate for answering Question 1 for recreational water quality may include:

- Frequent (daily, weekly, monthly depending on the circumstance) measures of fecal coliform or E. coli, total coliform, and Enterococcus at high-priority (defined in Section 5.1.1 as having both high use and elevated levels of indicator bacteria) beaches, coastal storm drains, lagoons, bays, estuaries, and inland creeks, streams, and rivers (Tables of individual measurements and relevant averages)
- Comparisons of bacterial indicator values with relevant standards (i.e., REC1, REC2, AB411) on spatial and temporal scales that match sampling scales as closely as possible (tables that highlight exceedances, figures that show exceedances over time)
- Summaries that identify the relative degree of contamination at monitored locations (i.e., maps, Heal the Bay's Report Card for beaches in Santa Monica Bay).

4.1.3 Habitat objectives

The Level II objective suggested for habitat health for Question 1 is described in Table 4-4. The Level II management/monitoring objective can be stated as:

> Use the Triad approach as a basis for monitoring both specific sites of high concern, as well as a set of random watershed sites, at least yearly and assess overall habitat health by comparing a suite of measurements to relevant reference conditions, to a moderate degree of certainty and precision. Use the Triad results to trigger an appropriate set of adaptive follow-up studies intended to better characterize conditions.

As might be expected, given both the inherent complexity of ecosystem monitoring and the variety of measurements included in the Triad approach, there is a range of reference conditions potentially applicable to monitoring of this question. The committee therefore recommended a structured framework for using reference conditions in the interpretation of Triad monitoring results (see Section 5.0).

The types of data products appropriate for answering Question 1 for habitat include:

- Site-by-site summaries of each sampled leg of the Triad (tables of individual measurements and relevant averages)
- Site-by-site interpretations and conclusions based on synthesized Triad results (narrative conclusions, decision trees)

- Comparisons across sites for each leg of the Triad (tables highlighting differences, maps)
- Comparisons across sites for synthesized Triad results (narrative conclusions, decision trees, maps)

4.2 Question 2: What is the extent and magnitude of the current or potential receiving water problems?

4.2.1 Background to Question 2

Question 2 is framed as the logical next step once receiving water problems related to urban runoff are found or predicted. Question 2 thus expands on the information provided by Question 1as a basis for describing the spatial and temporal extent of existing or likely impacts, as well as their relative intensity. This information is necessary for assessing the relative severity or importance of different problems, targeting source identification efforts, and planning management actions such as source reduction efforts.

In most cases, monitoring designs to answer Question 1 will include only representative sites within key recreational areas or habitats. Thus, once a receiving water problem is found, data from these sites will most often be insufficient to characterize the full extent and magnitude of the problem and additional studies will normally be called for. This is because most managers need to know the severity of a problem before proceeding with some remedial action. Impacts that cover large areas or extend over long periods of time typically require more immediate attention. The information collected to answer Question 2 is important for scoping the source identification studies that are the focus of Questions 3 and 4 (see Figure 2-1).

In some cases, the extent, magnitude, and/or severity of a receiving water problem will be immediately apparent from the core monitoring data obtained under Question 1. In such cases, for example, very high bacteria counts along a popular beach or severe toxicity in an enclosed lagoon, source identification work as described in Questions 3 and 4 should begin promptly. In addition, un-permitted dry weather discharges are specifically forbidden and such discharges should therefore also be a high priority for prompt source identification studies. In other cases, broader sampling to assess spatial and temporal extent will be required, usually as shorter-term studies that are conducted once or perhaps periodically when there is reason to believe the scale of the problem has changed. In some situations, where the problem is complex and/or covers a large area, addressing Question 2 will involve regional studies that require the cooperative efforts of several agencies. Monitoring under Question 2 would be conducted in either wet or dry weather, depending on the specific issue and in accord with the findings of Question 1.

4.2.2 Recreational water quality objectives

The Level II objective suggested for recreational water quality for Question 2 is described in Table 4-6. The Level II management/monitoring objective can be stated as:

> Monitor a suite of bacterial indicators at a spatially and temporally more intensive set of stations around sites, prioritized by risk, in order to define the extent of problems to a moderate degree of certainty and precision, and compare indicator levels to relevant marine and freshwater standards in order to define the relative severity of the problem, also to a moderate degree of certainty and precision.

The types of data products appropriate for answering Question 2 for recreational water quality include:

- Measures of the spatial extent of bacterial contamination (maps)
- Measures of the temporal patterns of bacterial contamination (figures that show temporal patterns, measures of variance)
- Measures of the relative magnitude of indicator values over space and time (graphs of concentration over time or by site).

4.2.3 Habitat objectives

The Level II objective suggested for habitat for Question 2 is described in Table 4-7. The Level II management objective can be stated as:

> Monitor specific aspects of the Triad, including adaptive elements such as additional chemistry measurements or TIEs, at a spatially and temporally more intensive set of stations where impacts have been observed in order to define the extent of problems to a moderate degree of certainty and precision, and compare measurements to relevant marine and freshwater standards in order to define the relative severity of the problem, also to a moderate degree of certainty and precision.

The types of data products appropriate for answering Question 2 for habitat include:

- Measures of the spatial extent of modified communities, chemical contamination, and/or elevated toxicity (maps)
- Measures of the temporal patterns of modified communities, chemical contamination, and/or elevated toxicity (figures that show temporal patterns, measures of variance)
- Measures of the relative magnitude of indicator values over space and time (graphs of concentration or toxicity over time or by site).

4.3 Question 3: What is the relative urban runoff contribution to the receiving water problem(s)?

4.3.1 Background to Question 3

Once monitoring or other studies demonstrate that there is a current or potential impact to receiving waters (Question 1) and describe the problem's extent and magnitude (Question 2), decisions about any management responses depend on information about the source(s) of the problem. The model monitoring framework breaks this source identification into two parts (Figure 2-1), represented by Questions 3 and 4. The purpose of this two-step process is to prioritize more detailed source identification efforts in Question 4 at only those problems for which urban runoff is a significant contributor. Question 3 begins this process by taking the information from Questions 1 and 2 and beginning to work upstream, both literally and figuratively, to better define the overall contribution of urban runoff to receiving water problems. It is important to clarify that this two-step process involving Questions 3 and 4 is not intended in any way to diminish or replace municipalities' permit requirements to reduce contaminant inputs to the maximum extent practicable. It is rather intended to help determine when additional, more detailed and extensive, upstream source identification efforts should be conducted by a municipality, with the goal of ensuring that the full burden of source identification work not be shifted to the MS4 permittees where action by them would not solve the larger problem.

The model monitoring framework assumes that, if urban runoff contributes only a very small percentage to the receiving water problem, then there would be no need for a municipal permittee to **independently** carry out substantial source identification efforts in addition to those activities usually carried out under the municipal stormwater permit. For a first-cut estimation, therefore, Question 3 requires only minimal resolution, including at least a rough estimate of the identity and magnitude of the non-urban runoff contributions. In many situations, aggregate estimates of the non-urban runoff contribution, rather than source-by-source estimates, may be adequate and may already be available from previous characterization and/or monitoring studies. Only if urban runoff is found to contribute significantly to receiving water problems would a municipality be required to take the lead on conducting further source identification studies at greater resolution (as described in Question 4).

The committee engaged in substantial discussion of criteria for prioritizing source identification work and agreed that several factors should be taken into account in each instance, including:

- The severity of the problem
- The type of pollutant(s) involved
- The potential for human health risk
- The relative certainty of the estimates of relative contribution from different sources. If the estimate of urban contribution is very low, then even high uncertainty might not be important. However, if the estimate is higher, e.g., 10%, and the uncertainty is high (e.g., could be as high as 30%) then that would be a different situation
- Whether the problem occurs during dry and/or wet weather, since dry weather problems may be more easily dealt with
- The biological resources at issue
- Regulations and other legal mechanisms that require source identification and/or control
- Stakeholder involvement such as watershed group planning priorities.

The committee agreed that source identification work should be prioritized based on the factors above, and that the threshold level for further independent source identification efforts by the permittees should be somewhere between 5 – 10%. It is important to emphasize that this threshold is intended as a guideline only in situations where the source of a receiving water problem is not known. Where the source(s) of such problems are known, then relevant permit conditions related to source reduction and cleanup would come into play. As emphasized above, this threshold is not intended to diminish or replace permit requirements to reduce contaminant inputs to the maximum extent practicable (MEP) or other regulations or legal requirements.

4.3.2 Recreational water quality and habitat objectives

The Level II objective suggested for both recreational water quality and habitat for Question 3 is described in Table 4-8. The Level II management objective can be stated as:

> Using parameters relevant to the nature of the receiving water problem, estimate the proportional contribution of urban runoff at the most downstream point of input to the receiving water, based on a loads study performed at minimal to moderate resolution, and repeated every several years as needed.

The types of data products appropriate for answering Question 3 for both recreational water quality and habitat include:

- Description of all potential sources of inputs to the receiving water (maps of potential sources)
- Rough estimates of the relative magnitude of loads from all sources (table of concentrations or loads by source)
- Rough estimate of the proportional contribution of urban runoff to total loads (pie charts or stacked bar charts).

4.4 Question 4: What are the sources of the urban runoff contribution to receiving water problems?

4.4.1 Background to Question 4

Once it has been determined, either through specific studies carried out under Question 3 or through other available data, that urban runoff is, or is likely to be, a significant source of one or more receiving water problems, then more intensive source identification efforts are called for. Question 4 thus involves more thorough source identification studies intended to provide more detailed information about the nature, location, and quantity of inputs to the receiving waters identified in Question 1. This information can help refine receiving water monitoring, improve fundamental understanding of stormwater contamination processes, and help guide management actions intended to reduce sources and their attendant impacts. It can also help focus trend monitoring on those parameters that are potentially most responsive to urban runoff source reduction efforts.

In the context of Question 4, "sources" can refer to multiple layers of sources, such as a golf course that is the source of pesticides, which are in turn the source of toxicity in the receiving water. Thus, questions about sources should be framed carefully in order to clarify both the spatial definition of "upstream source" as well as the level of causality that is the central focus of the investigation.

4.4.2 Recreational water quality and habitat objectives

The Level II objective suggested for both recreational water quality and habitat for Question 4 is described in Table 4-9. The Level II management objective can be stated as:

> Using parameters relevant to the nature of the receiving water problem, prioritize receiving water sites for upstream source identification studies and perform source identification studies at the watershed scale and to a moderate degree of resolution until the appropriate stopping rules are reached.

The types of data products appropriate for answering Question 4 for both recreational water quality and habitat include:

- Prioritization of receiving water sites in terms of severity of impact (ranked list of sites)
- Description of all potential urban runoff sources of inputs to the higher priority receiving waters (map of potential sources)
- Determination of actual sources of urban runoff and their relative magnitude (table of concentrations and flows by source with estimated levels of confidence)
- Quantitative estimates of the loads from urban runoff sources(table of loads by source with estimated levels of confidence).

4.5 Question 5: Are conditions in receiving waters getting better or worse?

4.5.1 Background to Question 5

Assuming that monitoring related to Questions 1 – 4 has resulted in improved information about the nature and source(s) of current and/or potential receiving water problems, and that this in turn has led to management actions to address such sources, Question 5 provides the logical feedback to determine if such actions are improving conditions in receiving waters. Given that changes in receiving water conditions are likely to occur over several years (at the least), Question 5 is a trends monitoring question. The trends of interest are in both discharges and receiving waters and the time frame for this question is the longer-term period needed to determine if management actions are having their intended effects.

In its simplest form, a trend monitoring design involves repeated sampling over time at the same monitoring site(s). The ability of a trend design to detect change depends on:

- The amount of change it is important or necessary to detect
- The timeframe within which decision makers need information about trends
- The variability of the indicator on different time scales, typically shorter term (weekly, monthly) and longer term (yearly)
- The resources available for sampling and analysis.

Developing the specifics of the monitoring design thus involves making a series of tradeoffs among these factors.

The statistical power of a monitoring design is its ability to detect a change of a certain size, if it in fact has occurred. Power analysis, used to estimate the power of a given design, can provide insight into the sampling effort (both in terms of the number of samples per year and the number of years) required to observe trends of different size. In addition, power analyses can reveal important inherent constraints on the ability to detect trends imposed by underlying variability in the system being monitored. This can provide a realistic basis for establishing both management and monitoring goals, as well as a basis for making tradeoffs in the monitoring design (e.g., between the number of samples collected per year and the number of years over which the trend monitoring will extend).

Figure 4-1 provides an example of how site-specific power analysis results might be used. In one instance (Figure 4-1a), trend monitoring would be futile and monitoring resources should be shifted to another site and/or issue. In a second instance (Figure 4-1b), the only way to improve the design's ability to detect a trend is to increase the number of years to be monitored. In such an instance, the length of time needed to detect a trend must be compared against both the management time horizon (i.e., how quickly is information needed?) and the timeframe over which changes are expected to occur (e.g., how rapidly are BMPs expected to reduce loads?). In a third instance (Figure 4-1c), the main way to improve the design's power is to increase the number of samples per year. However, for some questions, there is a natural constraint imposed by the relatively small number of storms per year in southern California. In such cases, the monitoring design will have an inherent limit on its ability to detect trends within a given time period. In a final example (Figure 4-1d), sampling additional times per year and monitoring for more years must be traded off against each other, since increasing both kinds of sampling intensity improves power. Such tradeoffs should be based on both the management time horizon and the timeframe over which changes are expected to occur. Thus, if an answer to Question 5 is

not immediately urgent, then the number of samples per year can be reduced and the timeframe extended into the future.

Appendix 2 uses historical data from the southern California region to provide example power analysis results for trend monitoring of bacteria and mass emissions. Sufficient data for power analyses of other data types (e.g., bioassessment, toxicity) are not yet available. Because power analysis results can vary widely from site to site and across constituents, these results should be considered only as a "starter kit" for trend monitoring designs. The committee strongly recommends that each trend monitoring program conduct its own site-specific power analyses after obtaining three years of trend data, and revise its monitoring design accordingly based on these results. To support such program-specific design efforts, the committee has developed a simple software package that automates the needed power analysis (Go to http://www.sccwrp.org to download a copy of this program). Because trend monitoring programs will typically continue for many years, this approach will enable trend monitoring to begin and then to adjust its design appropriately with little or no loss of information.

The central importance of estimates of variability in trend monitoring highlights the importance of improving our basic understanding of sources of variability in MS4s. Thus, in addition to tracking trends over time, the analysis of monitoring data under Question 5 should include efforts to examine and quantify sources and patterns of variability in monitoring data, with the overall goal of reducing any controllable variability (i.e., variability introduced through sampling techniques and laboratory analysis, or due to spatial and temporal sources that can be accounted for in the structure of the monitoring design itself).

Finally, a full answer to Question 5 should also include an assessment of changes in the extent and magnitude of impacts over time. Such an assessment can be accomplished by repeating the studies described in Question 2.

4.5.2 Recreational water quality objectives

The Level II objective suggested for recreational water quality for Question 5 is described in Table 4-10. The Level II management objective can be stated as:

> Monitor bacterial indicators at fixed stations over a number of years to determine, to a moderate degree of resolution, whether levels have increased or decreased compared to historical data and to relevant standards.

The types of data products appropriate for answering Question 5 for recreational water quality include:

- Graphs of the levels of bacterial indicators over time at each station of concern
- Periodic statistical power analysis results to confirm the power of the trend monitoring design.

4.5.3 Habitat objectives

The Level II objective suggested for habitat for Question 5 is described in Table 4-11. The Level II management objective can be stated as:

Monitor relevant habitat indicators at fixed stations over a number of years to determine, to a moderate degree of resolution, whether levels have increased or decreased compared to historical data and to relevant standards.

The types of data products appropriate for answering Question 2 for habitat include:

- Graphs of the levels of habitat indicators over time at each station of concern
- Periodic statistical power analysis results to confirm the power of the trend monitoring design.

Table 4-1. Relationship between the five key management questions and the three basic categories of monitoring activity. Core monitoring for Questions 1 and 5 typically occurs at fixed stations over a period of time. The design of regional monitoring and special projects under Questions 2, 3, and 4 is contingent on monitoring results from other core management questions. Numbers in italics (e.g., *5.1.1*) refer to report sections that detail specific design guidance for each element of the model monitoring program.

Management Questions	Core Monitoring	Regional Monitoring	Special Projects
1. Are conditions protective?	Recreational water quality assessment (wet & dry) *5.1.1* Ecosystem assessment (dry) *5.1.2*		
2. What is extent / magnitude?		One-time or periodic larger-scale assessment (depends on Question 1) *5.2*	One-time or periodic larger-scale assessment (depends on Question 1) *5.2*
3. What is urban runoff contribution?		One-time characterization, assessment (depends on Questions 1 & 2) *5.3*	One-time characterization, assessment (depends on Questions 1 & 2) *5.3*
4. What are sources of urban contribution?			Site-specific, one-time or periodic source ID studies (wet & dry) (depends on Question 3) *5.4*
5. Are conditions getting better or worse?	Long-term trends monitoring (wet & dry) of: • Bacterial indicators *5.5.1* • Habitat indicators (incl. loads) *5.5.2*		

Table 4-2. Level II objectives for recreational water quality monitoring for Question 1: Are conditions in receiving waters protective of beneficial uses? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q1 recreational water quality	Level II objective – Q1 recreational water quality
Management goal	Protect human health by meeting existing standards
Monitoring strategy	Allocate sampling effort with respect to overall risk (combination of use and contamination) Monitor bacteria indicators (fecal coliform (or E. coli), total coliform, Enterococcus) Use improved indicators when available and approved by health department Adaptive link to magnitude, extent, and upstream urban runoff source identification studies
Degree of certainty and precision	Moderate
Reference conditions	Freshwater standards (REC1, REC2) Marine standards (AB411)
Spatial scale	Open-coast beaches Specific coastal storm drains Bay, lagoons, estuaries Rivers and creeks
Temporal scale	Daily (for health risk) Weekly (for health risk) Seasonal (for health risk, trends)

Table 4-3. Level II objectives for habitat monitoring for Question 1: Are conditions in receiving waters protective of beneficial uses? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q1 habitat	Level II objective – Q1 habitat
Management goal	Protect ecosystem health by tracking the relationship of indicators to relevant reference conditions
Monitoring strategy	Triad approach Coordinated watershed and subwatershed scales Adaptive monitoring triggers depending on triad results Sites targeted at specific management issues
Degree of certainty and precision	Moderate
Reference conditions	Basin Plan Ocean Plan Regional IBI (for stream bioassessment) CTR (for chemistry) Toxicity test reference Historical reference conditions (site-specific) Local reference conditions (site-specific) Other watersheds (regional)
Spatial scale	Site-specific (e.g., Talbert Marsh) Watershed / subwatershed Jurisdictional
Temporal scale	Yearly Several years

Table 4-4. Level II objectives for recreational water quality monitoring for Question 2: What is the extent and magnitude of receiving water problems? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q1 recreational water quality	Level II objectives – Q1 recreational water quality
Management goal	Define the scale of impact
Monitoring strategy	Short-term sampling at broader spatial extent Sampling appropriate to define temporal patterns at weekly to seasonal scales Measure bacteria loads at MS4 discharge locations
Degree of certainty and precision	Moderate
Reference conditions	Freshwater standards (REC1, REC2) Marine standards (AB411) Comparisons across parts of the region
Spatial scale	Watershed / subwatershed Jurisdictional Regional
Temporal scale	For REC1 objective, geomean over a season Process-based (e.g., seasonal) 3 years for impairment (303d)

Table 4-5. Level II objectives for habitat monitoring for Question 2: What is the extent and magnitude of receiving water problems? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q2 ecosystem	Level II objectives – Q2 ecosystem
Management goal	Receiving water conditions improve (if impaired) Receiving water conditions remain the same (if not impaired)
Monitoring strategy	Triad monitoring in key receiving waters Long-term trend monitoring Adaptive toxicity testing Adaptive upstream toxicity testing
Degree of certainty and precision	Moderate
Reference conditions	Basin Plan Ocean Plan Regional IBI (for stream bioassessment) CTR (for toxicity) Toxicity test reference Comparisons across parts of the region
Spatial scale	Watershed / subwatershed Jurisdictional Regional
Temporal scale	Periodic snapshots (yearly)

Table 4-6. Level II objectives for both recreational water quality and habitat monitoring for Question 3: What is the relative urban runoff contribution to the receiving water problem(s)? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q3 recreational water quality & habitat	Level II objective – Q3 recreational water quality & habitat
Management goal	Estimate the proportional contribution of urban runoff to problem(s) in specific receiving water
Monitoring strategy	Loads estimation
Degree of certainty and precision	Minimal to moderate
Reference conditions	Relative severity of local receiving water problem(s) Relative contribution of urban runoff to other receiving waters in the region
Spatial scale	Point of input to receiving water (scales depending on definition of receiving water)
Temporal scale	Periodic assessment (every 5 years)

Table 4-7. Level II objectives for both recreational water quality and habitat monitoring for Question 4: What are the sources to urban runoff that contribute to receiving water problems? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q4 recreational water quality & ecosystem	Level II objectives – Q 4 recreational water quality & ecosystem
Management goal	Urban sources identified and resolved
Monitoring strategy	Prioritize downstream sites Upstream source ID studies
Degree of certainty and precision	Moderate to great
Reference conditions	Internal tests of "signal" strength
Spatial scale	Watershed / subwatershed Jurisdictional Regional
Temporal scale	Until stopping rules reached

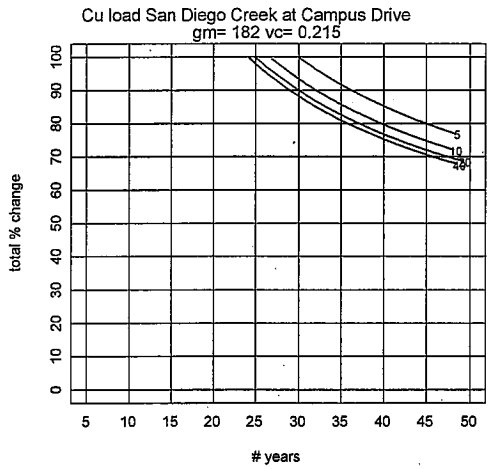
Table 4-8. Level II objectives for recreational water quality monitoring for Question 5: Are conditions in receiving waters getting better or worse? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q5 recreational water quality	Level II objectives – Q5 recreational water quality
Management goal	Reduction in indicator levels Identification and removal of key sources
Monitoring strategy	Repeated monitoring at specific sites over a season Long-term trend monitoring
Degree of certainty and precision	Moderate
Reference conditions	Standards Historical data as a basis of trends
Spatial scale	Specific receiving waters Where use is concentrated Watershed / subwatershed Jurisdictional
Temporal scale	For REC1 objective, geomean over a season Process-based (e.g., seasonal) 3 years for impairment (303d) Permit term (~ 5 years) for trends TMDL implementation phase (~ 10 years)

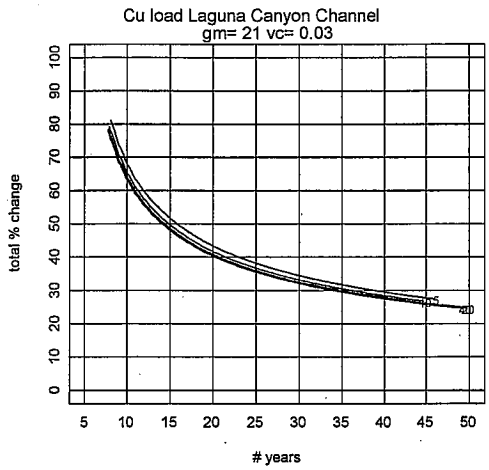
Table 4-9. Level II objectives for habitat monitoring for Question 5: Are conditions in receiving waters getting better or worse? Aspects of the objective are organized around the six categories of information that make up each Level II objective.

Level II category – Q5 habitat	Level II objective – Q5 habitat
Management goal	Conditions improve (if degraded) Conditions remain the same (if not degraded)
Monitoring strategy	Triad approach
Degree of certainty and precision	Moderate
Reference conditions	Basin Plan Ocean Plan Regional IBI (for stream bioassessment) CTR (for chemistry) Toxicity test reference
Spatial scale	Watershed / subwatershed Jurisdictional
Temporal scale	Permit cycle for overall assessment Process-based for specific components Bioassessment (greater than 5 years) Bioaccumulation (e.g., short-term for Se, long-term for DDT) BMP (based on site-specific geomorphology, BMP mechanism) Hydrology (annual) Toxicity (sporadic, seasonal)

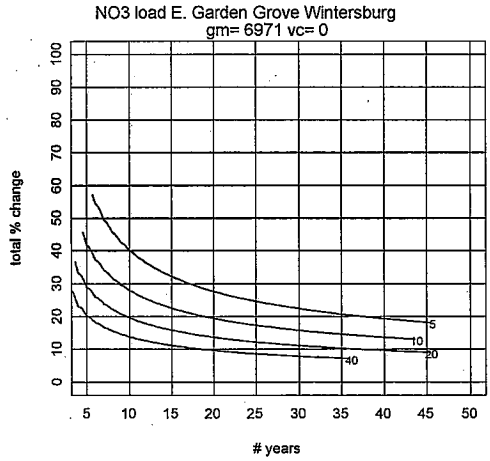
a.



b.



c.



d.

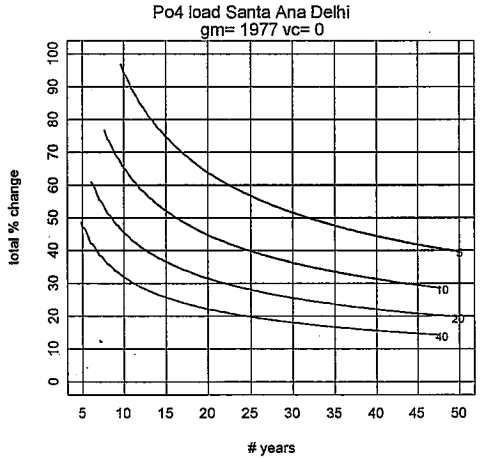


Figure 4-1. An example of the range of site-specific statistical power analysis results that can provide useful guidance for both trend monitoring design and setting management and monitoring goals. In the example figures below, the x-axis shows the number of years over which trend monitoring could continue and the y-axis the amount of change monitoring could detect. The four curves represent different amounts of sampling intensity per year. a. Even large amounts of sampling will not detect trends. b. Increasing the number of sampling events per year will not increase power because virtually all the variability is year-to-year variability. c. Increasing the number of years sampled beyond a certain point will not increase power because virtually all the variability is within-year variability. d. Both within- and between-year variability are important and increasing both kinds of sampling intensity will increase power.

5.0 MONITORING GUIDANCE

The following sections provide specific guidance for the design of core monitoring, regional monitoring, and special projects needed to address each of the core management questions (Table 4-1). The description of each monitoring design follows the same format:

- An overview that quickly summarizes the major features of the design, including a table of key design elements
- A lengthier description of specific design elements, such as station selection, monitoring frequency, indicators, triggers or thresholds for regional monitoring and/or special projects
- A discussion of design issues that describes the underlying rationale for the design and any important constraints that may affect monitoring success.

As the description of the key management questions and objectives (Section 4.0) makes clear, monitoring guidance focuses on recreational water quality and habitat issues. In some cases, distinct monitoring designs are required for each set of issues, while in other cases the same design approach is suitable for both. Where distinct monitoring designs are required, recreational water quality and habitat beneficial uses are presented separately.

5.1 Assessment monitoring

Assessment of recreational water quality and habitat conditions addresses Question 1: Are conditions in receiving waters protective, or likely to be protective, of beneficial uses? Data from such monitoring provides the basis for other aspects of the model program (Figure 3-1) intended to better characterize the extent and magnitude of any problems (Question 2), identify sources (Questions 3 and 4), and track trends in condition over time (Question 5).

Assessment monitoring effort falls exclusively into the core and regional monitoring categories (Table 4-1). Core monitoring is that conducted by individual agencies to evaluate issues related to specific sites or watershed. Regional monitoring is that conducted cooperatively by multiple agencies (see box on regional monitoring) to address issues across broader scales and time periods. In many cases, the same monitoring sites and/or approaches can meet both core and regional monitoring needs.

5.1.1 Recreational water quality assessment

5.1.1.1 Overview and philosophy

Design overview. Table 5-1 presents an overview of the technical design elements for assessment of recreational water quality conditions at beaches; bays and estuaries; and creeks, streams, and rivers. The following discussion does not include inland lakes and reservoirs, which, because they represent a special case, the committee agreed to defer until a later time.

The model monitoring framework allocates core monitoring of bacterial indicators to high-priority locations based on risk of adverse health effects. This risk is defined in terms of a combination of level of contamination and degree of human body contact use. In general, local public health departments have completed risk characterization for many waterbodies with recreational beneficial uses, particularly for marine beaches. Additionally, local health agencies have already established routine monitoring locations at many marine beaches that are sampled at

least weekly. To address the assessment of recreational water quality conditions, the model program recommends that stormwater agencies build upon the monitoring data, local knowledge, and experience of the local public health departments. Thus, the model monitoring committee explicitly assumed that local public health agencies would take the lead in specifying high priority areas based on their knowledge and experience.

Somewhat different monitoring designs are recommended for linear open-coast beaches, enclosed bays and estuaries, and creeks/streams/rivers, based on differences in their basic hydrology. The number of sampling locations is dependent on the size of an area and its level of relative risk, as is the sampling frequency. However, at all monitoring sites, monitoring should measure indicator levels in the discharge itself, as well as upcoast and downcoast (or upstream and downstream) of the discharge. In addition, where the monitoring objective is to determine whether overall conditions constitute a problem as opposed to monitoring for body contact, monitoring may be focused on that portion of the year that represents the worst-case scenario.

At the moment, there are no ongoing regional monitoring efforts focused on recreational water quality, with the exception of the Bight Program's periodic snapshots of shoreline water quality and the new regional harbors monitoring program being developed by the San Diego Regional Water Quality Control Board. Both programs rely on a probability-based design intended to support general conclusions about the relative degree of contamination in different parts of the region.

Design philosophy. The model design framework specifies somewhat different approaches for core monitoring at linear open-coast beaches; enclosed bays and estuaries; and creeks, streams, and rivers. However, all three approaches reflect the basic assumption that monitoring resources should be allocated based on risk. Where the county health departments and the State Board's Beach Water Quality Work Group (BWQWG) have established monitoring approaches and/or designs, the model stormwater program will remain consistent with these. The committee felt that, ultimately, the county health departments are one end-user for much of this data since they have the responsibility for assessing if a beach should be closed or posted for swimming.

Widely accepted risk management principles recommend allocating monitoring and management effort in proportion to the relative degree of risk. The basic design feature of the model urban runoff monitoring program for Question 1 for recreational water quality therefore is to focus effort at those places and times (whether wet or dry weather) where human health risk associated with urban runoff is the highest. The model design assumes that risk, at the population level, is directly related to exposure, and estimates exposure, in turn, as the qualitative combination of estimates of bacterial contamination and the intensity of human use. While these qualitative risk estimates may be improved by future risk assessments, this improved information should not alter the basic principle of allocating monitoring in terms of relative risk.

There are three types of situations that are relevant to stormwater monitoring programs and that require somewhat different monitoring approaches:

- Linear, open-coast beaches
- Enclosed bays and estuaries
- Inland creeks, streams, and rivers.

Both linear, open-coast beaches and enclosed bays and estuaries can have many kinds of bacteria inputs, although they differ somewhat. Open-coast beaches can receive bacteria from storm drains, river discharge, wildlife, intense beach usage, pet waste, terrestrial vegetation

decomposition, improperly maintained toilet facilities, and perhaps kelp decomposition. In addition to these potential sources, enclosed bays and estuaries can also be affected by bacteria from maintenance activities, homeless populations, groundwater, moored boats, failing septic systems, and concentrated populations of birds. The primary urban inputs of bacteria to inland creeks, streams, and rivers are through storm drain discharges, homeless encampments, unauthorized public use, and passage of domestic and wild animals. These and other differences stemming from their basic hydrology lead to a different approach for each situation. For each type of area, risk characterization should be completed in conjunction with the local health department.

The model design framework for regional monitoring adopts the probability-based design approach used by the Bight Program and assumes that, for purposes of assessment, the Bight Program does an adequate job of shoreline assessment. The Bight Program design is being used as a basis for developing a somewhat more spatially intensive regional monitoring program for enclosed bays and estuaries in the San Diego Region. Once this is completed, it can act as a design template for regional monitoring in other enclosed bays and estuaries throughout southern California. The model monitoring committee determined that, at present, concerns about recreational water quality in inland creeks, streams, and rivers were site specific enough to be dealt with by the core monitoring design. If there is a need for a regional assessment in the future, the basic stratified random sampling design used in the Bight Program would also apply here (see Section 5.1.2 Habitat assessment for more detail on regional watershed designs).

5.1.1.2 Design elements

Somewhat different monitoring designs are recommended for core monitoring at the three types of monitoring locations.

Linear open-coast beaches. Monitoring of storm drains (i.e., MS4s) discharging to beaches should conform to the prioritization framework (Table 5-2) established by the State Board's Beach Water Quality Work Group (BWQWG).

In this framework, the highest monitoring frequency of daily to five times per week is targeted at beaches with lifeguards and many potential sources of bacteria and a lower monitoring frequency (e.g., weekly to monthly) is applied to less heavily used beaches and/or beaches with only a few probable sources. Monitoring should measure indicator levels in the discharge itself, as well as upcoast and downcoast of the discharge. The basic monitoring approach includes stations situated both upcoast and downcoast of monitored storm drains because the ocean current direction in a portion of beach can frequently change, and because the dispersion of storm drain discharges in the surfzone can vary widely from place to place (due to discharge volume, bacteria concentration, beach configuration, current patterns, tidal height, and water temperature). The specific location of these stations should be determined after a characterization study of plume behavior to estimate the average seasonal range of influence of the storm drain discharge. This zone of influence will often extend further along the beach in one direction than the other, and will typically be much larger during wet weather. The upcoast and downcoast stations should then be located within the outer bounds of this influence, with a wet weather zone of influence applied to those stations that are routinely sampled during wet weather.

The model monitoring program does not include monitoring of beach coastal stations directly in front of storm drains, or "Point 0", the point in the surfzone where the storm drain discharge meets ocean water. Instead, most of the coastal beach monitoring completed by the local health departments and others is conducted at varying distances from the drain, depending on the sampling agency. Currently, county health departments do not monitor directly in front of storm

drains and freshwater outlets because all flowing outlets are posted with permanent warning signs of poor water quality. The model program follows this approach in accord with its primary intent to maximize coastal monitoring efforts by remaining consistent with the health departments' sampling protocols. However, since the ultimate management goal is to ensure that all locations at the beach are safe for swimming, stormwater monitoring agencies should be aware that the impacts to beaches directly in front of most storm drains and freshwater outlets is unknown, but are conservatively considered impacted by the health departments and the SWRCB. As stormwater monitoring and management programs progress, monitoring near drains and freshwater outlets at the beach may need to be adapted to include Point 0 monitoring. The issue of Point 0 sampling is being reevaluated by the State's Beach Water Quality Workgroup and, if the BWQWG revises the recommended health department sampling protocols, the model stormwater program should adjust to reflect this structure.

Enclosed bays and estuaries. In general, beaches in enclosed bays and estuaries (e.g., Newport Bay, Mission Bay) should be an important concern for allocating monitoring resources. This is because there is more potential for retention of bacteria, such waterbodies often have more numerous inputs, populations of birds are often denser, and children are more likely to engage in body contact recreation at these beaches. As at the open-coast beaches, monitoring effort should be allocated in proportion to relative risk, with high-use areas that have numerous inputs receiving the highest priority (Table 5-2). If all portions of an enclosed beach have equal risk, and it is not possible to monitor all urban runoff inputs, then a random subset of such inputs should be monitored, with the number of samples set based on analyses of the statistical power of alternative subsampling schemes. Monitoring should measure indicator levels in the targeted discharges themselves, as well as upcoast and downcoast of the discharge.

Creeks, streams, and rivers. As for the other two types of areas, monitoring of creeks, streams, and rivers should measure indicator levels in targeted discharges themselves, as well as upstream and downstream of the discharge. Because many inland waters in southern California are seasonal or intermittent, rather than perennial, monitoring should be prioritized with the risk-based approach described in Section 5.1.1. This approach prioritizes potential monitoring locations based on both their amount of body contact recreation and levels of bacteria contamination.

The Aliso Creek watershed in southern Orange County (which has been monitored intensively for the past two years) provides one example of how this approach can be applied. In this watershed, a recreational use survey indicated that human use "where the ingestion of water is reasonably possible" (Basin Plan definition of REC1 beneficial use) is concentrated in the lower portion of the Creek in the summer and early fall, when temperatures are warmest. An examination of two years' of monitoring data showed (Figure 5-2) that the late summer and early fall are also the period when bacterial levels are the highest. (The selection of monitoring sites was based on a field reconnaissance to identify those drains above a threshold size that typically had dry weather flow.) Given that bacterial levels are consistently elevated during this time period, if compliance with the Basin Plan REC1 objective could be demonstrated with one or two 30-day, 5-sample monitoring efforts in the late summer and early fall, which would represent the worst-case scenario, compliance is more likely during the rest of the year. This design is the most efficient approach to assessing the condition of the beneficial use; however, because large portions of the year are not monitored, it does not fulfill public health monitoring requirements.

This example from Aliso Creek illustrates the application of the criterion of allocating monitoring effort based on a qualitative risk assessment. It also demonstrates the difference between monitoring to address Question 1 and monitoring to fulfill public health requirements. Thus, even though exceedances occur during other periods of the year, the purpose of the monitoring design

in the example was to assess receiving water quality during the high-priority period. When bacteria levels in the high-priority period consistently drop to near the Basin Plan objectives in the future, it might be worthwhile at that point to expand monitoring to other parts of the year, on the assumption that indicator levels will have dropped below the objectives by that point (assuming the historical pattern stays the same, with the highest levels typically found in the late summer and early fall).

Indicators. Monitoring should use existing indicators (Table 5-1) and use comparable methods across the region. Laboratory intercalibration exercises for bacterial indicators were conducted as part of the Bight '98 and Bight '03 regional studies. Another intercalibration study, sponsored by the City of Los Angeles, will begin in early 2004 and includes most of the laboratories analyzing monitoring samples for SMC member agencies. With all indicators, the emphasis for assessment of recreational water quality conditions should be on comparison to existing standards, the Basin Plan REC1and REC2 for inland areas and AB411 for beaches.

5.1.1.3 Design issues

In general, there is currently a spatial distribution of responsibility for assessing recreational water quality conditions in the region, with county health departments having primary responsibility for beaches and for major inland water bodies (e.g., rivers, bays, lakes and reservoirs) where substantial body contact recreation occurs. In contrast, stormwater programs (i.e., MS4 permittees) tend to monitor inland storm drains and channels and, in some cases, storm drains that discharge directly to the beach. Thus, while there is some overlap between the two sets of agencies, health departments have a responsibility to protect public health while stormwater agencies focus on receiving water conditions and identifying urban runoff contributions to impaired receiving waters. As a result of their respective responsibilities, health departments typically monitor more frequently than do stormwater agencies.

To address Question 1, stormwater agencies should build upon the existing recreational water monitoring programs already implemented by local county health agencies. As a starting point, the stormwater agency should become thoroughly familiar with the existing health agencies' monitoring programs including risk characterization of beaches, monitoring locations, and sampling frequencies for both wet and dry weather. Next, with consultation from the health agency, the following types of questions should be answered to determine if additional monitoring should be conducted by the stormwater agency to answer Question 1:

- Are there urban runoff discharge points at marine beaches that are currently not monitored by the health agency?
- Are there marine beaches impacted by wet or dry urban runoff that are not monitored by the health agency?
- At marine beaches, what is the distance from the point the discharge enters the surfzone and the local health agency's monitoring location?
- What freshwater locations are frequently used for recreation? Are any of these currently monitored by the health agency or another entity? Which of these are potentially impacted by dry and wet weather urban runoff?
- Does the health agency monitor their routine sites during wet weather?

In general, data gaps in the existing health agency monitoring programs that may require new monitoring locations sampled by the stormwater agencies will likely include marine beaches where the health agencies' monitoring location is located away from the storm drain discharge point (thus, existing data may not indicate if the stormwater discharge is causing a problem on the

beach) and at freshwater locations that are currently not monitored by the health agencies. The stormwater agency should work with the health agencies to identify any new monitoring locations and to develop risk characterizations of these locations.

Stormwater agencies may be already working with local health agencies in southern California in many instances. For example:

- For the Pathogen TMDL in Newport Bay, the Orange County Health Care Agency conducts sampling while the Orange County Stormwater Program reports on the results
- In southern Orange County, the Stormwater Program samples and prioritizes coastal storm drains and reports the data to the Health Care Agency
- The Orange County Stormwater Program contracts with the Health Care Agency to conduct sampling and laboratory analyses
- The Riverside County Flood Control and Water Conservation District and San Bernardino County Flood Control District are conducting a bacterial source identification study on the Santa Ana River
- Orange County and San Diego Counties carry out routine IC/ID programs on their respective MS4s during dry weather, with a major focus on bacteria
- The City of Los Angeles conducts daily monitoring of more than two dozen beaches in Santa Monica Bay.

Such collaborative efforts formed the basis for the model monitoring committee's recommendation that such functional coordination be encouraged and expanded throughout the region, in two primary ways:

- Stormwater monitoring programs should strive to fill gaps in spatial coverage of high-priority areas not monitored by County Health Departments and characterized by the combination of elevated indicator levels and human use
- The application of adaptive triggers that would initiate upstream source identification studies by stormwater management agencies when receiving water monitoring has identified a receiving water problem.

Such a division of labor improves overall efficiency by emphasizing the respective strengths of each type of agency.

5.1.2 Habitat assessment

5.1.2.1 Overview and philosophy

Design overview. Table 5-3 presents an overview of the technical design elements for assessment of habitat status, using six distinct station types that fall into both core and regional monitoring categories (see detailed design elements in Section 5.1.2.2).

The model monitoring framework for habitat assessment is based primarily on the Triad approach, in which bioassessment, chemical, and toxicity data provide a variety of perspectives on conditions at a site. It is especially suited to situations where the primary concern is habitat or ecosystem condition and no single or simple suite of indicators afford an unambiguous measure of status (see Box on Bioassessment and Index of Biological Integrity). The framework identifies six different types of stations designed to capture the range of issues related to habitat condition, and capturing both core and regional monitoring issues. In addition to describing a decision framework for interpreting Triad results, the framework includes adaptive features intended to furnish the flexibility needed to adjust to specific local conditions and to accommodate the needs of both wet weather and dry weather sampling. However, the bioassessment leg of the Triad is best suited to perennial streams. Ephemeral stream systems may not be appropriate for routine bioassessment monitoring because they lack established biological communities except perhaps during periods in the spring.

Bioassessment and the Index of Biological Integrity

Rapid bioassessments of macrobenthic invertebrates are quickly becoming a valuable monitoring tool because biological communities are integrators of anthropogenic impacts. These organisms respond to both physical and chemical disturbances and can integrate these impacts over several storms or an entire wet season. The California department of Fish and Game (CDFG) has developed protocols for rapid bioassessments in wadeable rivers and streams and has conducted numerous surveys throughout the State. The CDFG has also developed an Index of Biological Integrity (IBI) for quantitatively assessing the status of biological communities in the San Diego Region. The Stormwater Monitoring Coalition has formed a partnership with the CDFG and the State Water Resources Control Board to build a monitoring infrastructure and standardize bioassessments throughout southern California, then refine an assessment tool, such as the IBI, for the entire region. The CDFG rapid bioassessment manual can be found at www.dfg.ca.gov/cabw/cabw/professionals.PDF

Design philosophy. The inherent complexity of watershed structure, and the variability in structure across watersheds, leads to a range of concerns about the effects of urban runoff on habitat conditions. Each concern is somewhat distinct, requiring a somewhat different monitoring approach, sampling frequency, and set of indicators. For example, some sites may be intended to measure conditions in specific, high-priority habitats (core monitoring), others to provide information about the watershed as a whole (core and/or regional monitoring), and yet others to improve knowledge about certain management issues related to urban runoff (special projects). This complexity is reflected in the several different types of habitat monitoring stations that can be established. In addition, the model monitoring design framework uses the Triad approach to organize this range of possible monitoring needs. The strength of the Triad approach (which is essentially a weight of evidence approach) is that it relies on multiple types of measures to reduce the chance of mistakenly concluding there is no impact when one in fact does exist.

5.1.2.2 Design elements

Types of monitoring sites. The committee identified several kinds of core and regional monitoring stations that could be required in assessing habitat conditions at the watershed scale:

- Long-term, fixed, bottom-of-watershed (but above tidal influence) mass emissions stations to assess cumulative water quality and aggregate loads, with monitoring based primarily on a mass emissions model and including wet weather chemistry and toxicity (core station)
- Spatially extensive, perhaps randomly sited or rotating, stations to support statistically valid comparisons across multiple watersheds, and with monitoring based primarily on the Triad

approach for dry weather sampling and on chemistry and toxicity for wet weather (regional station)

- Site-specific stations focused on the status of high-priority inland habitats of concern, with monitoring based primarily on the Triad approach for dry weather sampling and on chemistry and toxicity for wet weather (core station)
- Site-specific stations designed to generate information to support key program goals, such as source prioritization or BMP implementation and evaluation (core station, special project)
- Coastal estuarine stations to assess status in these key habitats, with monitoring based primarily on the Triad approach (core and/or regional station)
- Coastal ocean stations to assess stormwater plume impacts, conducted primarily as part of the periodic Bight surveys (regional station).

Given this potential variety of station types, monitoring within any particular watershed must be carefully integrated to achieve design efficiencies as well as an overall picture of the watershed. For example, Figure 5-1 presents an example watershed monitoring design, with a range of types of watershed monitoring stations, that illustrates how individual stations can serve more than one function within the watershed design (also see the US EPA strategy for randomized watershed sampling in US EPA 2002).

While there is an extensive body of experience in the region to support the development of core monitoring designs, this is less so for regional monitoring, or watershed-based, designs. The committee therefore outlined the following types of regional assessment designs that could be developed and implemented:

- Probability based designs, similar to the Bight Program design, in which stations are located randomly in order to provide the ability to draw statistically valid inferences about an area as a whole, rather than just the site itself. For example, the probability design used in the Bight Program permits statements about the percentage of the area that is above/below particular levels of different indicators. Such designs can allocate monitoring sites randomly throughout the entire region, or can subdivide the region into a number of strata that are relatively homogeneous. Strata can be defined on any number of grounds, depending on the questions or concerns that have motivated the program. For example, watershed strata could be based on relative amount of urbanization, general habitat type, or channel morphology, among others. Whatever the stratification scheme, the basic design principle is that samples are allocated randomly among strata, with the number of samples per stratum based on a consistent weighting factor (e.g., area of the respective strata). The level of sampling effort required in probability based designs depends, as in all designs, on the specific questions being asked, the underlying levels of variability in the data, and on the level of precision needed for decision making. The intent of the Bight Program's design, for example, is to be purely descriptive, rather than to test for conformity to a predetermined threshold or to detect a particular amount of change over time. Thus, the Program's requirement of 30 samples per stratum is based on a subjective decision by the Program's designers about the size of the confidence limit they are willing to accept in the descriptive statistics.
- Systematic designs, in which stations are located at set intervals along one or more underlying spatial or conceptual frameworks. For example, regional stations could be located on a 1-mile grid, every 1-mile along each river, creek, or stream, at every major discharge into rivers, and so on. One value of systematic designs is that they allow for more detailed mapping of indicator levels across a region. In addition, if resources permit, systematic designs can provide more thorough coverage than do probability based designs. The sampling

requirements in systematic designs are typically based on the degree of spatial resolution desired.

- Early warning designs, in which stations that are considered to be particularly vulnerable a particular impact are monitored as "canaries in the coal mine." Such monitoring can take place on a regular schedule or after the occurrence of an event thought to increase the probability of an impact past an acceptable level. The number of stations in an early warning design will depend on the number of suitable locations available and whether the potential for impact is homogeneous across the region. If the impact potential is homogeneous, then a subset of locations could adequately represent the entire region. If the impact potential is heterogeneous, then the region should be stratified in terms of impact potential and sampling within each stratum scheduled accordingly.
- Rotating designs, in which a different subset of stations in sampled during each sampling event, with the goal of sampling the entire set of stations over a certain period of time. Such designs have the virtue of maximizing the impact of limited monitoring resources because the entire suite of monitoring stations need not be sampled each time. However, because conditions change over time, rotating designs have a diminished ability to support valid comparisons between sets of stations sampled at different times in the rotation schedule. This can be compensated for to some extent by defining comparisons of interest during the design process and then ensuring that such stations are sampled during similar index periods or seasons. The location of stations in rotating designs can be random, systematic, or early warning depending on the kinds of questions being asked.

Evaluating Triad results. Once monitoring data are available, determining whether conditions are protective of beneficial uses depends on a combination of explicit definitions of reference conditions (see Table 4-4) and the ability to interpret results in the context of individual watershed conditions. Given the potential complexity of ecosystem impacts, the committee agreed that no single benchmark should be automatically used as evidence of impact. Thus, there are no hard and fast rules for determining that a receiving water impact has occurred. However, Table 5-4 provides an organized set of rules of thumb for interpreting Triad results and determining if further studies are warranted. Where the full Triad has not been sampled, Basin Plan, Ocean Plan, and other reference benchmarks listed in Table 4-4 could be applicable.

Adaptations of the basic design. Because of the range of specific situations that may occur in different watersheds, the basic design shown in Figure 5-1 may be adapted with a variety of alternative approaches. For example:

- Chemistry and toxicity could be used in wet weather when the bioassessment leg of the Triad is not feasible (e.g., in high flow conditions when biological communities. Any finding of impact could be investigated further with the complete Triad during dry weather (except in ephemeral streams, which rarely have dry-weather flow)
- Toxicity tests could be used in lieu of broader chemistry scans where historical data demonstrates no evidence of impacts at the site and there is no *a priori* reason to believe there are significant sources of chemical contamination
- Bioassessment could be used in lieu of toxicity tests and chemistry scans where the primary concern is the status of a particular habitat and historical data demonstrates no evidence of impacts from urban runoff at the site
- The spatial and temporal intensity of sampling could be adapted to match the spatial scale of the site and the temporal scale of the processes that influence habitat condition
- The suite of chemical analyses can be adjusted (see Tables 5 and 6, and following subsection) based on prior knowledge about sources of contamination.

Thus, the model framework provides an overall context for assessing and tracking habitat status, while allowing for the flexibility needed to make the best use of available information to adapt to specific management information needs.

Constituent list. While the committee emphasizes that the Triad approach (bioassessment, toxicity testing, chemistry monitoring) works best when all three legs are consistently sampled, it also recognized that certain situations may call for sampling only one or two, rather than all three, legs. Thus, the particular combination of Triad measurements to be collected at any individual site or time could be based on the season of the year (wet vs. dry), the location and purpose(s) of the station, the specific problem or question being addressed, the past history of monitoring results at that location. In general, however, sampling effort might be distributed as in Table 5-3 and Table 5-5 (core monitoring column).

The model monitoring committee gave particular attention to the suite of chemical constituents that should be measured at the watershed stations, attempting to balance a desire for regional comparability with the ability to adapt to the specifics of each situation. The committee developed a short list of common constituents (Table 5-6) to be sampled routinely by all programs and an expanded list, some of which would be sampled if needed. In addition, the full EPA priority pollutant list would be sampled once every several years in concert with the regional Bight Program.

A decision about when to add constituents from the expanded list would be dependent on both available information and the management question(s) being asked. For example, past monitoring data or data on historical land uses indicating the presence of legacy pesticide contamination could cause these constituents to be added to the program. As another example, where the focus is on total loads or trends, as at the mass emissions stations, then total metals would be the appropriate monitoring target. In contrast, where receiving water impacts are the primary concern, as at specific habitat stations, then dissolved metals should be measured. It will thus be important to consider the potential use(s) of the monitoring data when deciding which constituents to monitor. Dissolved metals might also be measured when toxicity has been found, the site is on the 303(d) list, or total metals exceeds the relevant CTR value, which is often used as a benchmark in receiving waters for stormwater effects.

Flow measurement and compositing approaches. Many field sampling methods relevant to stormwater monitoring programs are described and reviewed in BASMAA (1995), as well as in various USEPA guidance documents (e.g., USEPA 1992). Of particular interest are methods for estimating flow and compositing approaches for deriving mass emissions estimates.

In general, there are two basic methods for estimating flow. The first is based on engineering equations that use gravity, the height of water in an idealized pipe, the slope of the pipe, and a friction coefficient to derive the flow. The second is based more on direct measurement of the speed of the flow, combined with an estimate of the cross sectional area of the water (computed from the shape of the channel and the height of the water) to derive the flow. There are variations within each of these basic methods. For example, the engineering equations can use unimpeded flow in a pipe or channel or, alternatively, the height of flow over a weir. Similarly, direct flow measurements can be based on the rate of spin of a paddlewheel or on ultrasonic signals from sensors in the water. In addition, there is a range of methods for measuring the height of the water in a channel, the other key input to flow estimates. These methods range from simple staff gauges to various types of pressure transducers or ultrasonic sensors suspended over the water. As a rule of thumb, the more engineered a hydrologic system is, the easier it is to rate for flow. For

example, a concrete channel will typically have a constant cross section and the slope will be constant.

Different approaches have different strengths and weaknesses depending on the particular situation. For example, flow sensors that are mounted in the water are vulnerable to damage from debris carried in storm flows. Downward looking flow sensors can be more suited to smaller channels with space constraints, however, foam on the surface of the water can degrade the accuracy of the reading. Various pressure transducer models differ in their sensitivity and the maximum height of water they can accurately measure. Where the channel configuration permits, flow can be routed through a flume for more accurate measurements; however, flumes cannot handle large volumes of flow.

The United States Geological Survey (USGS), which is generally recognized as producing the most accurate and precise flow estimates, measures flow velocity at several points along a channel cross section at several times with different water heights. These data are then used to develop a flow rating curve specific to that channel. The rating curve can then be used to estimate flow based simply on the height of water at any given time, on the premise that water at a particular height will be moving at a specific speed. This is an empirically derived relationship as opposed to one based on modeled engineering principles. While this method can be the most accurate, it is also the most difficult to implement in terms of up-front effort and costs. In addition, changes to the channel morphology due, for example, to siltation or erosion can undermine the accuracy of a flow rating curve.

The various approaches to flow measurement also differ in terms of their relative accuracy and precision. The USGS attempts to achieve accuracy to within 5%, but that level can be difficult to achieve in channels with scouring, filling, and other sources of bias. Despite the potential drawbacks of empirical methods, they are considered to have better accuracy than the model-based engineering methods, although it can be very expensive to improve the precision of the empirical estimates. In contrast, the engineering methods can produce relatively precise estimates, but the accuracy may be less than that achievable with empirical methods, depending on the degree to which model assumptions are violated. The model monitoring committee was reluctant to propose specific performance standards for flow monitoring. The preferred approach in any particular situation will depend on site characteristics and the use(s) intended for the data.

In contrast, the committee considered that performance standards for the measurement of mass emissions, especially as part of a long-term trends monitoring program, were more relevant. There are two primary methods for estimating the concentrations of constituents of interest in urban runoff. The first, flow compositing, collects water samples for analysis at specific increments of flow. The second, time compositing, collects water samples at specific increments of time. These two approaches were described in more detail and compared in an intensive year-long sampling program (Leecaster et al., 2002) that found that flow compositing was the most efficient sampling approach to achieve a given degree of accuracy and precision. A minimum of 10 to 12 samples per composite using a flow-weighted scheme efficiently reduced bias and improved precision. Time-weighted composites can achieve similar levels of precision and bias, but required a far greater number of samples; more than 42 samples per composite were necessary.

5.1.2.3 Design issues

Ecosystem perspective. There are four major habitat types in the region:

- Ocean
- Estuaries / wetlands
- Streams, creeks, and channels
- Lakes and reservoirs.

Because they are somewhat of a special case, the committee agreed to set lakes and reservoirs aside for possible consideration at a later time. Based on the Bight '98 study in the coastal ocean, which showed that riverine effects on the benthic ecosystem are small, the committee agreed that further study of stormwater impacts in the coastal zone should be the focus of regional efforts (as in Bight '03). Such regional studies could then provide more concrete guidance to individual programs where urban runoff plume effects (perhaps on the water column) are found to be substantial. Thus, the model monitoring program framework focuses explicitly on streams, creeks, channels, and rivers, and on estuaries and wetlands.

Habitat monitoring for these habitat types can involve a wide range of methods, including:

- Water chemistry
- Sediment chemistry
- Aqueous toxicity
- Sediment toxicity
- Bioaccumulation
- Bioassessment
- Hydrology

Given this variety of potential measurements, the committee determined that monitoring should be based on an ecosystem perspective, rather than consisting of collections of functionally disconnected measurements on the one hand, or focusing on individual species or chemical parameters on the other. The Triad approach, which combines chemistry, toxicity, and bioassessment (including physical habitat measures) provides a practical means of integrating a wide range of measurements, as well as a structure on which to base adaptive follow-up monitoring. It should be noted that the bioassessment leg of the Triad may not be applicable in some situations, such as ephemeral streams, where minimum requirements are not consistently met. However, the overall watershed monitoring framework (see Figure 5-1) also provides a structure for including sites targeted at specific management issues such as problem characterization or BMP evaluation.

5.2 Extent and magnitude monitoring

Evaluation of the extent and magnitude of receiving water problems addresses Question 2: What is the extent and magnitude of the current or potential receiving water problems? Monitoring related to Question 2 provides useful information for prioritization of both source identification studies (Questions 3 and 4) and specific management actions intended to remediate the problem. Monitoring of the extent and magnitude of problems falls primarily into the special projects category (Table 4-1) because these are typically efforts targeted at specific problems and with clear beginning and ending points. However, to the extent that such studies require collaboration among multiple responsible parties and/or extend over large areas, they would also have some of the characteristics of regional monitoring.

5.2.1Extent and magnitude assessment – recreational water quality

5.2.1.1 Overview and philosophy

Table 5-7 presents an overview of the technical design elements for regional monitoring of recreational water quality monitoring focused on estimating the extent and magnitude of receiving water problems.

The model monitoring framework for assessing the extent and magnitude of recreational water quality problems assumes that the stormwater agency will work with local health departments to determine those high-priority (i.e., combination of human use and contamination) locations where extent and magnitude of a bacteria problem should be defined. Currently, coastal beach monitoring by local health agencies near urban runoff discharge points is comprised of one or two fixed stations located at various distances from the point of discharge. Thus, often the length of beach impacted by urban runoff has not been fully characterized. In most cases, even less data is likely available for inland freshwater sites. The monitoring design to determine the extent and magnitude of bacterial contamination should include estimates of bacterial loads, in addition to upcoast/downcoast (at beaches) or upstream/downstream (along creeks, streams, and rivers) arrays of samples. An estimate of temporal persistence would depend on monitoring through at least one complete year.

The extent and magnitude monitoring design is essentially the same for both regional monitoring and special projects aspects of the program, with regional monitoring encompassing a larger area and/or greater numbers and kinds of potential sources (see 5.2.1.2 Design elements).

5.2.1.2 Design elements

Regional monitoring to establish extent and magnitude is distinguished from special projects in its larger geographic scale and/or greater number and kinds of potential sources. The committee did not establish an explicit dividing line between these two categories of monitoring (i.e., regional and special projects), since real-world situations will exist on a continuum of scale and complexity. Regional monitoring will therefore most likely involve a wider range of parties and require more collaborative implementation. However, this is not a substantive design issue because the basic design approach is the same for both regional monitoring and special projects.

A monitoring design to establish the extent and magnitude of bacterial contamination must have the ability to determine:

- The degree of temporal persistence of a particular receiving water problem
- The spatial extent of a particular receiving water problem
- The relative severity of a particular receiving water problem, compared to other parts of the region.

Therefore, the monitoring design for this question should include:

- The core or regional monitoring assessment site(s) in the location of interest
- Measures of bacteria loads, which requires flow estimates
- Measures of the spatial extent of actual impact in receiving waters, which requires an array of upstream/downstream samples in creeks, and upcoast/downcoast samples, regularly spaced grids, or random arrays on the beach and in bays/estuaries
- Measures of temporal persistence or pattern, such as between wet and dry weather, which requires at a minimum samples through one calendar year.

Depending on the extent of existing knowledge, these design elements may be scaled as needed to fill data gaps. For example, where the spatial extent of contamination is well understood, additional sampling at only a few representative stations might be required to define the temporal extent of contamination. Conversely, where the spatial extent is not well understood, a survey of shorter-term but more intensive monitoring at an array of stations (either regularly spaced or random, depending on the site) might be necessary to define the boundary of contamination during periods when human use and contamination combine to create a high-priority period. Finally, if the spatial and temporal extent are well defined, a focused sampling effort during one or more representative subsets of the high-priority period might be used to determine peak loads and/or receiving water levels. A rule of thumb in such studies is to use the highest sampling frequency possible in order to better characterize the nature of variability in extent and magnitude. The key adaptive element of the bacteria monitoring design for assessing extent and magnitude thus includes the ability to modify the spatial and temporal intensity of sampling as needed, both in the discharge and the receiving waters.

Indicators in studies of the magnitude and extent of recreational water quality problems should include the levels and loads of the three main bacterial indicators (Table 5-7), along with other measures that may add useful information (e.g., stream or channel flow, patterns of human use).

5.2.13 Design issues

Existing sampling effort may be adequate in many cases to characterize the spatial and temporal extent of bacterial contamination, along with its severity. For example there already exist substantial monitoring data on levels of bacterial indicators at many coastal monitoring sites. Additional monitoring effort is being initiated along the San Diego and southern Orange County coasts, targeted at coastal storm drains, and at specific inland sites as part of these counties' dry weather reconnaissance and IC/ID programs.

In many cases, however, existing monitoring designs may not be optimal for measuring the extent, magnitude, and severity of bacterial contamination associated with urban runoff. At coastal locations near urban runoff discharges, sampling data that provides length of beach impacted by bacteria densities above the health standards may not available. Many factors can affect the length of beach impacted including the bacteria densities and flow rate of the urban runoff discharge, surfzone conditions including swell, wind and tide, and the configuration of the storm drain and beach relative to the incoming swell. Routine coastal monitoring completed by local health agencies may not capture extent. At freshwater inland sites, less routine monitoring data are collected by local health agencies and data on the extent of the problem will typically be limited to special studies. The extent and magnitude of bacteria problems along inland creeks, streams, and rivers resulting from urban runoff discharges may be particularly difficult to assess because there are often many, diffuse sources of bacteria, including natural sources. For both coastal and freshwater sites, defining extent of impact from individual discharges during wet weather may be difficult because plumes from separate discharges will often overlap and because of increased loading of bacteria from natural sources (particularly at freshwater locations). A further complication stems from the fact that extent and magnitude are likely to be very different in wet and dry weather.

In addition to these issues, data from the various bacterial monitoring programs are not aggregated, making it difficult to identify broad spatial patterns and temporal trends, and only recently has a laboratory intercalibration study for bacteria been undertaken. Further, there are growing concerns that the bacterial indicators, alone, may not provide an accurate picture of the extent and magnitude of actual human pathogen contamination. Not only do the indicators not measure pathogens directly, there is some evidence that the indicators themselves may propagate

in the MS4 system and may derive partly or entirely from animals and birds. Thus, even a data aggregation and mapping exercise that described indicator patterns in detail might not necessarily describe the extent and magnitude of actual pathogen problems associated with urban runoff.

While the model monitoring committee developed quantitative metrics to assist in prioritizing studies under other aspects of the overall program (e.g., TIEs, upstream bacterial source identification, it determined that the expert judgment of health department staff is the best source of information for triggering efforts to determine the extent and magnitude of bacterial contamination in each of the three kinds of areas (linear open-coast beaches; enclosed bays and estuaries; creeks, streams, and rivers). Thus, stormwater program staff would review monitoring data with health department staff and representatives of other potential sources to determine if they have completed additional sampling or have knowledge of data that establish the extent and magnitude of contamination, and to receive recommendations from health agency staff about which monitoring locations should be the first priority for additional efforts.

5.2.2 Extent and magnitude assessment – habitat

5.2.2.1 Overview and philosophy

The model monitoring framework for assessing the extent and magnitude of habitat problems builds on the core monitoring Triad approach, by adding repeated measurements to characterize temporal persistence, upstream sampling of the Triad components to describe spatial extent, and/or adaptive features such as TIEs or targeted upstream source identification studies to better define the magnitude of the problem (see Table 5-4). These latter two types of studies begin to merge into the kinds of special project source identification efforts described in Sections 5.3 and 5.4, illustrating the fact that real-world distinctions between monitoring categories are not always clear cut.

The extent and magnitude monitoring design is essentially the same for both regional monitoring and special projects aspects of the program, with regional monitoring encompassing a larger area and/or greater numbers and kinds of potential sources.

5.2.2.2 Design elements

Regional monitoring to establish extent and magnitude is distinguished from special projects in its larger geographic scale and/or greater number and kinds of potential sources. The committee did not establish an explicit dividing line between these two categories of monitoring (i.e., regional and special projects), since real-world situations will exist on a continuum of scale and complexity. Regional monitoring will therefore most likely involve a wider range of parties and require more collaborative implementation. However, this is not a substantive design issue because the design approach is the same for both regional monitoring and special projects.

Table 5-4 provides an overall framework for a set of adaptive monitoring and special study responses to a finding that there is or could be a receiving water problem, many of which focus on determining the magnitude, extent, and/or severity of any such problem. The type and design of any such adaptive monitoring in a particular instance will depend on the results of the Triad measurements, site-specific factors, and other types of relevant knowledge such as land use data or information on upstream sources. For example, additional toxicity tests at higher dilutions, accompanied in some instances by TIEs, can provide more information about the nature of toxicity (as described above, this is one example where assessment of the extent and magnitude of a problem would overlap somewhat with source identification special projects). Or, repeating toxicity tests with different toxicity test organisms could also improve the understanding of toxicity. In addition, repeating routine measurements over time at a specific station or group of related stations will determine the temporal extent of the problem. Similarly, extending an array

of stations upstream and downstream of the original monitoring station will help assess the spatial extent of the problem.

While Table 5-4 presents a conceptual overview of possible studies, the specific efforts required in any particular situation will depend on which leg(s) of the Triad have been sampled, on the nature of the monitoring findings, and on the characteristics of the environment. Issues that should be considered in designing adaptive studies of extent and magnitude include:

- The nature of the "signal," e.g., which leg(s) of the Triad are involved
- The strength of the "signal"
- Available information about possible causes of actual or potential problems
- The spatial and temporal extent of the habitat of concern
- Local geography and hydrology.

The preferred monitoring design, whether it be regional or a special study, is described in detail within the section on habitat assessment (Section 5.1.2). There are a variety of approaches for allocating sites including stratified random, systematic, or rotating designs depending on the specific area to be evaluated and indicators to be measured. For sure, managers will want to integrate the extent and magnitude designs into design(s) for assessment, which will maximize continuity and cost-efficiency.

5.2.2.2 Design issues

Assessing the extent and magnitude of impacts on ecosystem health will begin with an assessment of results from the suite of core watershed stations. As described in more detail in Section 5.1.2, stations should be located in receiving waters with key beneficial uses, where significant contamination problems related to urban runoff are known to exist, where the likelihood of such problems is high, in high-value habitats whose continued protection is a high priority, at core mass emissions stations, and at distributed locations that will provide a basis for comparisons among watersheds.

5.3 Urban runoff contribution assessment

Assessment of the relative contribution of urban runoff to a receiving water problem addresses Question 3: What is the relative urban runoff contribution to the receiving water problem(s)? Data from this monitoring element are useful primarily in prioritizing more extensive source identification efforts under Question 4. Assessments of the urban runoff contribution fall into the special projects category (Table 4-1) because such studies are targeted, one-time efforts. However, they may also take on the collaborative aspects of regional monitoring if they involve multiple parties and/or cover large areas (Table 4-1).

5.3.1 Overview and philosophy

The model monitoring framework for assessing the relative urban runoff contribution to both recreational water quality and habitat problems is primarily a matter of loads estimation at a fixed downstream reference point. Similar loads estimation approaches apply to both recreational water quality and habitat indicators, as described in the following sections, including expert judgment, visual reconnaissance, land use modeling, empirical tributary monitoring, the use of conservative tracers, and the evaluation of existing data (see Box on Modeling). The actual combination of methods in any particular instance will depend on the quantity and quality of historical data, the

nature of the receiving water problem, the number and types of potential sources, and the physical structure and hydrography of the watershed. In addition, many of the methods applicable to this issue are also directly applicable to the more detailed source identification special projects described in Section 5.3 and 5.4.

The extent and magnitude monitoring design is essentially the same for both regional monitoring and special projects aspects of the program, with regional monitoring encompassing a larger area and/or greater numbers and kinds of potential sources. The source identification case studies in Appendix 3 include examples of both. For example, the Contaminated Sediment Task Force study in Los Angeles Harbor was a regional study involving many participants, while the investigation of elevated total dissolved solids in Orange County was a special project conducted by the County Stormwater Program alone.

Modeling

Watershed modeling is a useful tool for estimating flow, concentrations or loads from unmonitored watersheds or unmonitored storm events. There are a variety of models available to watershed managers, from very simplistic spreadsheet-based techniques to very complex time-variable algorithms. The decision on which model to use is a function of the management questions and types of assumptions watershed managers are willing to make, as well as the availability of data for running the model. Simplistic models (i.e. rational method) answer questions at large temporal and spatial scales, make the most assumptions, and require the least data. Complex models (i.e. HSPF, SWMM, etc.) answer questions at finer temporal and spatial scales, make fewer assumptions, but require the most data. See Singh and Woolheiser (2002) for a recent review of watershed hydrology models.

5.3.2 Design elements

This section describes a general set of approaches to source identification, accompanied by a set of illustrative case studies presented in Appendix 3. The committee chose this approach because the wide variety of specific situations in which source identification studies might be required makes it impossible to define a standard approach.

Assessing the relative urban runoff contribution to a particular receiving water problem involves loads estimation at a fixed downstream point, which is in or near the affected receiving water. Depending on how the receiving water is defined in a particular instance, "downstream" may be at the point where a tributary enters a larger creek, where a creek enters a wetland or estuary, or where a river empties into the ocean. Similar loads estimation approaches apply to both recreational water quality and habitat indicators, including:

- Expert judgment
- Visual reconnaissance and observation
- Land use modeling
- Empirical tributary monitoring
- The use of unique and/or conservative tracers
- Evaluation of existing data.

These approaches can be extended with more detailed information provided in US EPA (1993), Pitt (2001), and SWRCB (2001), which describe a range of methods for identifying sources of stormwater pollution. A decision about which approach(es) to use in any particular instance will depend on the quantity and quality of historical data, the nature of the receiving water problem, the number and types of potential sources, and the physical structure and hydrography of the watershed. Thus, even a preliminary loads estimation for a high-priority bathing beach, such as in Mission Bay in San Diego, might proceed through several steps from expert judgment which provides the basis for targeting visual observation which in turn forms the basis for modeling

and/or empirical measurement. Where information from the Triad approach is available, Table 5-4 provides an example of a decision framework for interpreting monitoring results to better focus preliminary source identification efforts.

One key element of the committee's thinking is that such preliminary loads assessments should ideally be a collaborative effort, undertaken by all the parties responsible for potential inputs to the receiving water. Such regional, collaborative efforts will be more efficient and more productive because they will streamline data acquisition, integration, and evaluation. They can also provide a basis for future, more intensive, collaborative source identification efforts, should they be required.

While in general the needed accuracy and precision is only low to moderate, the degree of accuracy and precision needed will depend in part on the relative size of the urban contribution to the overall loads. For example, if the urban contribution is small (i.e., less than 5% of the cumulative load), there would probably be no need to refine the estimate any further because large variability does not change the answer to the question; urban runoff is still a small contribution. In contrast, if the urban contribution is 15% +/- 15%, there would be a need to refine the estimate to determine whether and to what extent to proceed to the more detailed source identification work described in Section 5.4. Thus, monitoring designs for this issue might proceed through multiple iterations.

When identifying and characterizing potential sources, it is important to use terminology that is consistent with standard USEPA usage. Thus:

- Urban runoff: both wet (stormwater) and dry weather (non-stormwater) runoff from urban land uses
- Dry weather runoff: runoff from urban land uses in dry weather
- Stormwater runoff: runoff from urban land uses during storms

In addition, there are other land uses and sources that discharge to MS4s but that are typically not under the jurisdiction of municipalities, including:

- Industry and POTW discharges (which are regulated by state permit)
- Other discharges permitted by the RWQCB
- State and federal facilities
- Agriculture
- Augmented water
- Open lands
- Native American lands
- Special districts, school districts, parks
- Utilities
- Aerial deposition.

5.3.3 Design issues

There are two primary design issues associated with determining the relative urban runoff contribution to a receiving water problem. The first is the fact that the wide variety of specific situations likely to be encountered makes it infeasible to recommend a standard design. The committee resolved this issue by providing general guidance on study design, referencing two reports that describe detailed monitoring methods, and including a set of representative case

studies in Appendix 3. The second is that there may be cases in which the relative urban runoff contribution is small. In such cases, the committee agreed that a municipal permittee should not be obligated to **independently** conduct detailed source identification studies beyond the activities already required in their respective NPDES permits. The committee therefore recommended a threshold level of urban runoff contribution above which permittees would be required to independently perform detailed source identification studies, and set this level at 5 – 10%. A lengthier discussion of the threshold issue is provided in Section 4.3.

5.4 Source identification studies

More detailed source identification studies address Question 4: What are the sources to urban runoff that contribute to receiving water problems? These are almost always special studies and are conducted when preliminary source identification work under Question 3 (Table 4-1) shows that urban runoff constitutes a significant portion of the source(s) of a receiving water problem. Information from these more detailed special projects can help refine receiving water monitoring, improve fundamental understanding of stormwater contamination processes, and help guide management actions intended to reduce sources and their attendant impacts.

5.4.1 Overview and philosophy

Table 5-8 presents an overview of the technical design elements for special projects monitoring of recreational water quality and habitat focused on source identification. Since the primary philosophy of the model program is not to design site-specific studies, this section provides guidance on adaptive triggers for special studies. Therefore, this section creates a series of starting and stopping rules for when to initiate detailed source identification studies and tools for prioritizing locations on where to conduct them.

The model monitoring framework for detailed source identification for both recreational water quality and habitat involves two kinds of studies. The first are studies at downstream stations to gain additional insight into the sources of the problem. For bacteria, this may include more traditional sanitary survey methods and/or more sophisticated biological testing. For habitat, this may include toxicity tests with a broader suite of test organisms, TIEs, or more detailed analyses of the pattern of impact in communities or on key organisms. The second kind of study will be upstream source tracking and source identification studies that may use a variety of methods. In general, however, they will share the same design, which will involve using a basic indicator of impact (e.g., bacterial indicator, toxicity) to trace the strength of the impact signal upstream, in either wet or dry weather, combined with more powerful and/or targeted methods (e.g., genetic source identification, TIEs, chemical reconnaissance, physical reconnaissance) to locate the specific source(s) of pollution.

5.4.2 Design elements – recreational water quality

There are two primary design elements for source identification related to recreational water quality. The first is to identify and then prioritize the upstream sites at which source identification efforts will be conducted. The second is to identify a core set of methods for bacterial source tracking at these sites. The approaches for these issues are somewhat different for beaches and for inland waters because inland waters (i.e., creeks, streams, and rivers) have a clear upstream – downstream morphology while beaches may not. Instead, contamination from a discharge can often spread out in both directions along a beach.

Open-coast and enclosed beaches. In contrast to creeks, there is no consistent and obvious upstream – downstream relationship between urban runoff inputs (typically storm drains) and the receiving water. Thus, it is not possible to estimate impact in terms of the difference between an upstream and a downstream station. The committee therefore proposed a prioritization approach based on the relationship between bacterial levels in individual storm drains and levels in the nearby receiving water.

Figure 5-3 demonstrates this approach with bacterial monitoring data from San Diego County. The figure is divided into five sections that reflect different relationships between indicator levels in the receiving water and those in the outflow of the coastal storm drain itself. In general, higher priority is given to storm drain discharges that are consistently high and receiving water densities that exceed health standards. While Figure 5-3 illustrates a prioritization approach specifically for fecal coliform, parallel methods could readily be developed for total coliforms and Enterococcus, since standards for these indicators in marine waters have been developed.

Once a subset of inputs has been identified for further source identification efforts, the well-accepted approaches described in US EPA (1993), Pitt (2001), and SWRCB (2001) are excellent sources of guidance. When implementing such approaches, it will be important to be systematic and thorough yet also have clear stopping points (Figure 5-4). In particular, the stopping rules are prioritized to focus on determining, first, whether there identifiable sources of human sewage and, second, whether there are other controllable anthropogenic sources. First and foremost, stormwater agencies need to identify and remove all sources of human inputs (See Box on Microbial Source Tracking). The committee agreed that further source identification efforts for nonhuman inputs should await the development of more powerful microbial source identification tools with the ability to more accurately distinguish among a range of specific sources (e.g., livestock, pets, birds, other wildlife). This testing is currently being conducted by the SMC and others (Griffith *et al* 2003).

Microbial Source Tracking

Microbial Source Tracking (MST) is a class of potentially powerful tools for identifying sources of bacteria in receiving waters. The traditional fecal indicator bacteria typically measured by county health departments are not human specific and can arise from any warm-blooded organism including birds, dogs, cats, livestock, horses or other mammals. Thus, the goal of most MST techniques is to determine if the measured indicator bacteria are of human origin and, if not, what was their host of origin. There are numerous MST techniques available, but all are still experimental. The Stormwater Monitoring Coalition co-sponsored a study in 2002 to test 11 MST techniques by 22 of the nations' leading researchers for their accuracy and precision in southern California. The results, which are summarized in the *Journal of Water and Health* (Volume 1, No. 4, November 2003), show that none of techniques worked perfectly and many were susceptible to false positives. As a result of the intercalibration study, research continues on refining and improving the more promising methods, but a single definitive technique(s) is still unavailable.

Creeks, streams, and rivers. Source identification studies in creeks, streams, and rivers are particularly problematic because bacteria are not conservative in the MS4, may originate from a wide range of small, diffuse sources, and can be highly variable in both space and time. However, because bacteria die off due to ultraviolet (UV) exposure as they flow downstream, there may be an upper limit on the distance bacteria can travel in longer natural creeks and streams and still impact high-priority areas of concern. (Bacteria can also be removed through sedimentation; however, during the low flow conditions characteristic of dry weather in southern California, UV exposure is the dominant factor.) Therefore, the committee developed a conceptual model (Figure 5-5; Appendix 4) to identify and prioritize inputs for upstream source identification work. This conceptual model also assumes that core monitoring has shown there is an exceedance of a bacteria water quality objective in a high-priority recreational use area, and

that either regional monitoring or special projects that it is persistent and large enough to warrant further action, and that urban runoff constitutes a substantial proportion of the source(s).

The following steps describe how to apply this conceptual model in a particular situation:

1. Locate high-priority use area
2. Define upstream boundary of high-priority use area
3. Calculate the number of days required for 95% of bacteria to die off, using the equation in Appendix 4 and an inactivation rate selected from the range presented in Appendix 4
4. Calculate average net downstream flow rate of the creek or stream in meters/day
5. Calculate the linear distance required for 95% of bacteria to die off, using the following equation:

   Days required for 95% die off x flow rate in meters/day = X meters
6. Define an upstream segment with its bottom edge at the upstream boundary of the high-priority use area and its upstream edge X meters upstream above that.

There are two constraints that would affect the application of this conceptual model. First, it may be most appropriate in dry weather in longer natural creeks and streams with relatively slow flow rates, because bacteria die off rates in creeks that are partially or fully concrete-lined may be less than transport times. For example, it would be less applicable to systems with discontinuous flow. Second, spatial and temporal variability in bacteria densities mean that deriving more than rough estimates of the upstream segment may require substantial sampling effort. However, even a somewhat rough estimate could prove valuable in focusing upstream source identification studies. Thus, this conceptual model is not directly applicable to all situations and should be applied carefully. For example, in the Santa Ana River above Prado Dam, flow during dry weather is discontinuous and consists of disinfected POTW effluent and rising groundwater. Though bacteria levels in this case exceed REC1 standards, there are no dry weather urban runoff discharges and the conceptual model would not be directly applicable.

Within this upstream portion of the drainage system, termed a "potential source segment," there may be a number of discharges or other inputs that must be prioritized for source identification study. The committee developed a unique tool for prioritizing such inputs, based on a combination of their loads and local impact on the receiving water, as explained in the following paragraph.

The influence of inputs within the potential source segment on the downstream high-priority recreational use area will result from a combination of the size of the input (bacterial load) and the effect of each input on the receiving water (impact). This is because loads alone do not reflect a discharge's potential impact on the receiving water. A large load discharged into a creek section with high flow may have little downstream effect, while a small load discharged into a creek section with low flow may have a disproportionately large downstream effect. Thus, prioritization of inputs for upstream source identification efforts, as well as monitoring of the inputs in the potential source area, should be based on both loads and impact, with impact measured as the difference between bacterial indicator levels at upstream and downstream stations. Table 5-9 demonstrates the committee's approach for combining measurements of both load and impact into a single metric for prioritizing a series of inputs. Generating this metric involves the following steps:

1. Calculate the bacterial load of each direct input to the creek within the potential source segment

2. Calculate the receiving water impact of each direct input, measured as the simple difference in bacterial concentration between stations 25 feet upstream and downstream of the input
3. Scale loads values from 0 – 1, with the lowest load assigned the value of 0 and the highest the value of 1
4. Scale impact values from 0 – 1
5. For each input, calculate the average of the scaled loads and impact values as:

$$\frac{\text{Scaled load} + \text{scaled impact}}{2}$$

6. Rank inputs within the potential source segment in terms of their average scaled value
7. Select highest ranked inputs for further source identification efforts upstream of each input.

If desired, loads and/or impact estimates could be weighted to emphasize one or the other to a greater degree. The highest ranked inputs would be selected for further source identification efforts, with the threshold established based on the pattern of average scaled values and cost and logistical constraints. It will be important to ensure that the data used for calculating this metric be gathered during that portion of the year when human health risk is the highest. It is also important to recognize that the relationship of each individual input in potential source segment to health-based water quality objectives in their immediate vicinity is not directly relevant to the prioritization exercise. There are two reasons for this. First, the prerequisite for the upstream prioritization exercise is that the downstream high-priority recreational use area has been determined to exceed water quality objectives on a regular basis. Second, a series of inputs could all contribute to a cumulative problem at the downstream use area, even if none of them individually exceeds water quality objectives.

Similar to the approach for beaches, once a set of inputs have been identified as potential sources of receiving water problems, upstream source identification studies on creeks, streams, and rivers should be conducted. The stopping rules described above for beaches and in Figure 5-4, are also directly applicable to creeks, streams, and rivers.

5.4.3 Design elements – habitat

The design elements for source identification for habitat are somewhat more complex than for recreational water quality. There are two main reasons for this. First, it is more difficult to quantitatively prioritize sites because the Triad approach involves three distinct types of data and there are no established standards or benchmarks for two of these, toxicity and bioassessment. Second, because these three data types sometimes produce inconsistent results (see Table 5-4 for examples), it can be difficult to establish clear benchmarks for when the weight of evidence calls for upstream source identification efforts. In addition, the availability of complete Triad data, as well as the interpretation of monitoring results, may be more complex in certain situations, such as ephemeral streams.

Rather than a quantitative metric, such as that shown for bacterial indicators in Table 5-9, the committee developed an overall framework for implementing a weight of evidence approach to triggering additional, targeted source identification studies (Tables 5-10 and 11). Table 5-10 provides expanded definitions of the thresholds in Table 5-4 that would trigger additional adaptive studies in response to combinations of Triad results. Table 5-11 then assigns a priority for source identification studies to each possible combination of Triad results from Table 5-4. Thus, in Table 5-11, the combination of results represented by Row 3 of Table 5-4 (persistent chemical exceedances, no toxicity, no benthic impact) would have a low priority for source identification studies. In contrast, the combination of results represented in Table 5-11 by Row 7 (no chemical exceedances, high toxicity, benthic impact) would have a high priority.

Monitoring results should be evaluated, using Table 5-4 as guidance, to determine whether the probable source(s) of impact is physical, chemical, or unknown. Upstream source identification efforts should then be initiated according to the set of priorities suggested in Table 5-21. Upstream source identification efforts should build on those performed to preliminarily assess the urban runoff contribution to receiving water problems, and should include detailed visual inspection of MS4s, water courses, and drainage areas as a first step. Visual inspections can then be followed with the water quality based source identification methods described in U.S. EPA (1993) and Pitt (2001).

As part of this overall framework, the committee did develop a quantitative method for combining toxicity testing results into a single metric (see Appendix 5) that would assist in ranking stations in terms of their aggregate toxicity. This ranking can then be used to assign priorities to stations for follow-up TIEs, as part of a source identification effort. The metric combines information about the degree of toxicity, the persistence of toxicity at a station throughout the year, and the percentage of test species found to exhibit toxicity.

Table 5-11 sets forth a set of starting rules for source identification efforts targeted at habitat impacts. Stopping rules are similar to those described for recreational water quality (Figure 5-6), with the same emphasis on identifying controllable sources.

5.4.4 Design issues

The same basic methods for detailed source identification apply to both recreational water quality and habitat. While the specific methods used in any instance will, of course, differ somewhat depending on the watershed structure and the constituents involved, they will include one or more of the following set of approaches, which are listed in order of increasing effort involved:

1. Evaluation of existing data
2. Visual reconnaissance and observation
3. Empirical tributary monitoring, which involves sampling tributary mouths upstream of the receiving water impact in order to identify the most likely point(s) of input
4. Sampling, or chemical "fingerprinting" of individual sources, including further upstream along tributaries, which can include the use of unique and/or conservative tracers.

These are similar to the methods described for the preliminary source identification in Question 3. However, Question 4 involves a more detailed focus on identifying specific sources of urban runoff and a greater degree of quantification than needed for Question 3. These methods are described more fully in US EPA (1993), Pitt (2001), and SWRCB (2001), which provide detailed descriptions of study designs, field sampling, and data analysis and interpretation appropriate for tracking sources of both bacteria and chemical pollutants.

The committee also recognized the need to supplement these methods descriptions with more explicit starting and stopping rules for detailed source identification studies. Starting rules are necessary for ensuring that source identification studies, which can be costly and time consuming, are triggered where and when monitoring data strongly suggest the presence of a persistent problem. Such rules are also needed to focus available resources on the highest priority problems. Stopping rules are essential for ensuring that source identification studies do not continue indefinitely, but end when reasonable and realistic expectations have been met. Such rules are proposed for receiving water problems associates with both recreational water quality and habitat.

5.5 Trend monitoring

Assessment of trends, for both recreational water quality and habitat, addresses Question 5: Are conditions in receiving waters getting better or worse? Question 5 provides the logical feedback to determine if management actions are having their intended effects. While this is a core monitoring element, the locations of stations and the relative emphasis on specific indicators may depend on information developed in answer to other questions (Table 4-1) related to the where problems exist (Question 1), the extent and magnitude of such problems (Question 2), and the nature and number of sources (Questions 3 and 4). Trends monitoring is a core monitoring program element (Table 4-1).

5.5.1 Recreational water quality trends

5.5.1.1 Overview

Table 5-12 presents an overview of the technical design elements for trend monitoring of recreational water quality at beaches; bays and estuaries; and creeks, streams, and rivers.

The model monitoring framework for trend monitoring of recreational water quality is based on statistical power analysis of a monitoring design that involves repeated sampling over time at fixed stations. For recreational water quality, sampling data from one inland watershed (Aliso Creek) suggests that trend monitoring might productively focus on one period of the year when both bacteria levels and human use are highest. Power analysis results from this watershed also suggest that the statistical power of the trend monitoring design can vary widely from station to station, as well as across indicators. However, comparable data were not available to support analogous conclusions for beaches and bays and estuaries. Thus, the committee recommends that programs begin trend monitoring with ten to fifteen weekly samples per year for three years, and then conduct site-specific power analyses with the software package developed by the committee and made available on the SCCWRP website. Power analyses on available data from southern California show clearly that differences across sites mean that a "one size fits all" approach to trend monitoring design will not work. The recommended approach will therefore ensure appropriate levels of both within-year replication and number of years of trend monitoring. Given that trend monitoring will most likely need to continue for a minimum or ten or fifteen years, devoting the first three years to obtaining site-specific data will not result in any substantial reduction in the longer-term power of the trend monitoring design. Any such reduction will be outweighed by gains in site-specific efficiency and statistical power.

See Section 4.5, for an expanded discussion of the use of statistical power analysis in the core trend monitoring aspects of the model monitoring design.

5.5.1.2 Design elements

The following subsections address, in turn, trend monitoring design in high-priority recreational areas where use is concentrated and then in the upstream areas that are the sources of contamination. Where such upstream source areas have been identified and are the targets of active source reduction efforts, it may be useful to monitor trends in the levels of these sources.

Conditions in high-priority recreational areas. Figure 5-2 shows that fecal coliform levels (the basis of the REC1 Basin Plan standard in this case) vary considerably among months in the high-priority area in lower Aliso Creek. While there are not equally intensive data records from other creeks throughout the region, it is reasonable to assume that similar variability would be present elsewhere. Thus, it would statistically be most efficient to stratify trend analyses by month, with separate trend analyses for each month. Lumping months that normally have highly divergent

fecal coliform counts would increase the within-year variability and make it more difficult to detect trends over time.

Power tests (see Section 4.5.1 and Figure 4-1 for a discussion of the importance of statistical power analyses as part of a trend monitoring design) on the monthly Aliso Creek data were thus conducted to estimate the number of years and number of samples within a 30-day period that might be required to detect different percentages of decrease in fecal coliform counts. Power tests were performed only at stations and for months for which more than one year was sampled because the power tests require an estimate of between-year variability. Figure A2.1 (Appendix 2), with plots for each station organized in order of increasing geomean, shows that the ideal months to sample differ from station to station. For example, the highest power for a given sampling effort occurs in August for the SOCWA treatment plant site (Figure A2.1d) but in June for the Aliso Wood Canyon Park Site (Figure A2.1c).

These results provide guidance that illustrates how the details of a trend monitoring design could be developed. Figure 5-5 shows that in the study of Aliso Creek the peak bacteria levels coincide with the period of highest recreational use in the late summer and early fall. Thus, it would be most efficient to target a trend monitoring program at one or more of the months in that portion of the year. Once a monitoring period is chosen, power analyses such as those in Figure A2.1 can be used to determine a preferred combination of reduction in indicator values, short-term sampling intensity, and length in years of the monitoring program. As mentioned above, the software package available on the SCCWRP website provides a straightforward means for each program to conduct power analysis with site-specific data.

High-priority inputs. Trend monitoring may also be useful where specific upstream inputs have been identified that contribute to contamination at a high-priority recreational use area. The key trend monitoring question for such inputs is whether the loads of bacteria, and their local impacts on the receiving water, are decreasing over time. Loads are a clear measure of the size of the input itself, and directly reflect the relative success of BMPs in the local drainage area. However, loads alone are insufficient to measure a discharge's potential impact on the receiving water. Thus, trend monitoring of high-priority inputs should include both loads and impact (measured as the difference between stations upstream and downstream of the discharge). A quantitative method for prioritizing upstream inputs for management actions and for trend monitoring is described above in Section 5.4.2, which discusses source identification approaches.

The monitoring data from Aliso Creek provide a useful illustration of how power analysis can be used to design a site-specific trend monitoring program. Figure A2.2 (Appendix 2) shows that bacterial levels in the high-priority drains in Aliso Creek, as well as at the upstream and downstream stations associated with each, are typically highest in the June – September period and lower throughout the rest of the year. The illustrative power analyses therefore focused on this period in order to reduce the within-year variability. Power analyses were performed for two measures, the load from each drain (Figure A2.3) and the impact of each drain (Figure A2.4) measured as the difference between the downstream and upstream stations. These results suggest that it will not be feasible to track loads at station J06 (Figure A2.3) nor to track impacts at station J01P08 (Figure A2.4). With the exception of these parameters at these stations, however, the power analysis also suggests that a sampling frequency of 20 samples, collected in the June – September period, would be adequate to detect an average 50% reduction in loads and an average 30% reduction in impact over a ten year period.

5.5.1.3 Design issues

Trends monitoring of existing bacterial indicators is complicated by their extreme variability in space and time. Thus, there may be limitations on our ability to detect change with current monitoring technology.

There are two aspects of trend monitoring with regards to recreational water quality. The first is related to conditions in the high-priority recreational use area(s) that are the major focus of concern. The question here is therefore whether indicator levels are trending downward toward applicable water quality objectives. The second aspect of such trend monitoring is related to whether the high-priority inputs upstream of the high-priority recreational area are improving. The question here is somewhat different, instead being whether loads and localized impacts (a measure of the direct effect on the receiving water) are declining. This is why the recommended indicators include both a measure of concentration and a measure of loads.

5.5.2 Habitat trends

5.5.2.1 Overview

Assessment of habitat trends addresses Question 5: Are conditions in receiving waters getting better or worse? Question 5 provides the logical feedback to determine if management actions are having their intended effects. While this is a core monitoring element, the locations of stations and the relative emphasis on specific indicators may depend on information developed in answer to other questions (Table 4-1) related to the where problems exist (Question 1), the extent and magnitude of such problems (Question 2), and the nature and number of sources (Questions 3 and 4).

Table 5-13 presents an overview of the technical design elements for trend monitoring of habitat conditions.

The model monitoring framework for trend monitoring of habitat conditions is based on statistical power analysis of a trend monitoring design that involves repeated sampling over time at fixed stations. For habitat, the timing of trend monitoring will differ depending on the parameters being tracked, with mass emissions monitored during wet weather and bioassessment during dry weather. Available data indicate that power analysis results can vary widely from station to station, as well as across parameters. Thus, the committee recommends that programs begin trend monitoring with two or three samples per year for three years, and then conduct site-specific power analyses with the software package developed by the committee and made available on the SCCWRP website.

5.5.2.2 Design elements

Trend monitoring is relevant to all aspects of habitat monitoring in the watershed design. Trend monitoring can occur at one or more of the core monitoring assessment stations depending on criteria such as the level of management concern or whether a receiving water problem has previously been documented.

Appendix 2 provides example statistical power analysis results for two aspects of a trend monitoring design (event mean concentration (EMC) and mass emissions) for which sufficient data currently exist for such an analysis. These results Figures A2.5 - and A2.14, which use data from several representative long-term stations in Orange County, reflect, as do the bacteria results described above, large differences in power from station to station and across parameters. (Data from other monitoring programs were not suitable for power analysis.) As a result, it is not possible to recommend levels of sampling effort that would be generally applicable across the

region. Therefore, the committee recommends that trend monitoring programs for habitat begin by collecting two or three samples per year for three years and then use these data to conduct site-specific power analyses to refine the following aspects of the design:

- The amount of change expected or desired
- The number of samples to be collected per year
- The number of years before the expected change is detected.

These analyses can be carried out with the software package available on the SCCWRP website. While results will undoubtedly vary from site to site, the committee's analyses of available historical monitoring data (Appendix 2) suggests that it is unlikely that substantial amounts of change (e.g., reductions of 50% or more) will be observable in less than ten years and that management targets and monitoring designs should be developed accordingly.

5.5.2.3 Design issues

Trends monitoring of habitat indicators is complicated by the variety of station types, the long list of monitored constituents, and the complexity of ecosystem processes that influence observed trends. Therefore, general guidance is presented for two main categories of monitoring data – mass emissions and toxicity. As for the recreational water quality aspect of Question 5, the power analysis software available on the SCCWRP website will enable each program to perform relevant site-specific power analyses as required

Table 5-1. Design overview for assessment monitoring of recreational water quality.

Type of area	Site location	Frequency	Indicator(s)
Open-coast beach	Gaps in Health Department coverage • High-priority areas • Flowing stormdrains Drain itself Upcoast and downcoast of drain Characterize dispersion of drain plume prior to siting upcoast and downcoast stations	Based on BWQWG prioritization Daily – monthly (see Table 5-2)	Total coliform Fecal coliform Enterococcus
Enclosed bays and estuaries	Gaps in Health Department coverage High priority areas Subsample of flowing stormdrains Drain itself Upcoast and downcoast of drain	Based on BWQWG prioritization Daily – monthly (see Table 5-2)	Total coliform Fecal coliform Enterococcus
Creeks, streams, and rivers	High-priority areas Drain or other input Upstream and downstream of input	Weekly in high-use season	Total coliform or E. coli Fecal coliform Enterococcus

Table 5-2. The Beach Water Quality Workgroup's risk-based approach for determining sampling frequency. The presence of lifeguards is an indicator of high-use beaches that are most likely above the 50,000 users threshold in Assembly Bill 411.

	Likelihood of Contamination			
Usage	**High**: e.g., stormdrains that flow continuously, frequently exceeding bacterial standards; pier areas	**Medium**: e.g., stormdrains that flow intermittently or continuously with infrequent exceedances of standards	**Low**: source nearby, do not expect a problem, stormdrain not flowing but if had a sewage spill it would flow to beach, if a problem it would be long term	**No known source**
High use beach: lifeguarded, high use surf/dive area	Daily or 5X per week	5X per week	Weekly or 5X per month	Weekly or 5X per month
Accessible sandy beach: low use surf/dive area or other water contact recreation area (wind surfing, kayaking)	2 – 3X per week	Weekly or 5X per month	Weekly or 5X per month	None
Other accessible shoreline: rocky coastline, small coves accessible by trails, private homes limit access	Weekly or 5X per month	Weekly or 5X per month	Monthly or other identification system	None
Inaccessible: beach area > 1 mile from access area	None	None	None	None

Table 5-3. Design overview for assessment monitoring of habitat.

Type of area	Site location	Frequency	Indicator(s)
Mass emissions	Bottoms of watersheds	3 storms / yr for 3 yrs, then modify per results of power analyses	Chemistry (see Table 5-16) Toxicity
Watershed	Random or rotating, perhaps per Bight design	Every few years, perhaps per Bight Program schedule	Triad in dry weather Chemistry, toxicity in wet weather
High-priority inland habitat	High-value habitat either impacted or threatened	1 or 2 / yr in dry weather	Triad
Program goals	As needed based on nature of specific goal(s)	Dependent upon problem, question	Dependent upon problem, question
Estuaries	Random per Bight design Key habitats and/or downstream of major inputs	Every few years per Bight design 1 or 2 / yr, in wet and/or dry, depending on problem, question	Chemistry (see Table 5-16) Toxicity
Nearshore ocean	Random and/or clustered in plumes, per Bight design	Every few years per Bight design	Chemistry (see Table 5-16) Toxicity

Table 5-4. Decision framework for interpreting triad results. Possible conclusions and actions/decisions are intended as general guidance, dependent on the specific monitoring results found and the actual relationships among chemistry, toxicity, and benthic data.

	Chemistry	Toxicity	Benthic Alteration	Example Conclusions	Example Actions or Decisions
1.	Persistent exceedance of water quality objectives	Evidence of toxicity	Indications of alteration	Strong evidence of pollution-induced degradation	Toxicity tests at higher dilutions to better quantify toxicity Use TIE to identify contaminants of concern, based on TIE metric Initiate upstream source identification as a high priority
2.	No persistent exceedances of water quality objectives	No evidence of toxicity	No indications of alteration	No evidence of current pollution-induced degradation Potentially harmful pollutants not yet concentrated enough to cause visible impact	No immediate action necessary Conduct periodic broad scans for new and/or potentially harmful pollutants
3.	Persistent exceedance of water quality objectives	No evidence of toxicity	No indications of alteration	Contaminants are not bioavailable Test organisms not sensitive to problem pollutants	TIE would not provide useful information with no evidence of toxicity Continue monitoring for toxic and benthic impacts Consider whether different or additional test organisms should be evaluated Initiate upstream source identification as a low priority
4.	No persistent exceedances of water quality objectives	Evidence of toxicity	No indications of alteration	Unmeasured contaminant(s) or conditions have the potential to cause degradation Pollutant causing toxicity at very low levels Synergistic effects of multiple chemicals at low levels causing toxicity	Recheck chemical analyses and evaluate detection limits relative to reported toxic levels Verify toxicity test results Consider additional advanced chemical analyses Toxicity tests at higher dilutions to better quantify toxicity Use TIE to identify contaminants of concern, based on TIE metric Initiate upstream source identification as a medium priority

	Chemistry	Toxicity	Benthic Alteration	Example Conclusions	Example Actions or Decisions
5.	No persistent exceedances of water quality objectives	No evidence of toxicity	Indications of alteration	Alteration may be due to physical impacts, not toxic contamination Test organisms not sensitive to problem pollutants Synergistic effects of multiple chemicals at low levels causing toxicity	No action necessary due to toxic chemicals Initiate upstream source identification (for physical sources) as a high priority Consider whether different or additional test organisms should be evaluated
6.	Persistent exceedance of water quality objectives	Evidence of toxicity	No indications of alteration	Toxic contaminants are bioavailable, but in situ effects are not demonstrable Benthic analysis not sensitive enough to detect impact Potentially harmful pollutants not yet concentrated enough to change community	Determine if chemical and toxicity tests indicate persistent degradation Recheck benthic analyses; consider additional data analyses Toxicity tests at higher dilutions to better quantify toxicity If recheck indicates benthic alteration, perform TIE to identify contaminants of concern, based on TIE metric Initiate upstream source identification as a high priority If recheck shows no effect, use TIE to identify contaminants of concern, based on TIE metric Initiate upstream source identification as a medium priority
7.	No persistent exceedances of water quality objectives	Evidence of toxicity	Indications of alteration	Unmeasured toxic contaminants are causing degradation Pollutant causing toxicity at very low levels Synergistic effects of multiple chemicals at low levels causing toxicity Benthic impact due to habitat disturbance, not toxicity	Recheck chemical analyses and consider additional advanced analyses Toxicity tests at higher dilutions to better quantify toxicity Use TIE to identify contaminants of concern, based on TIE metric Initiate upstream source identification as a high priority Consider potential role of physical habitat disturbance
8.	Exceedance of water quality objectives	No evidence of toxicity	Indications of alteration	Test organisms not sensitive to problem pollutants Benthic impact due to habitat disturbance, not toxicity	TIE would not provide useful information with no evidence of toxicity Initiate upstream source identification as a high priority Consider whether different or additional test organisms should be evaluated Consider potential role of physical habitat disturbance

Table 5-5. Example distribution of monitoring effort among the various kinds of stations in the watershed design. Special studies would be implemented when results of core or regional monitoring indicated a need for them. Specific triggers initiate adaptive monitoring and special studies designed to answer questions about the magnitude, extent, and source(s) of problems.

Station type	Core monitoring	Regional monitoring	Further monitoring / special studies
Mass emissions	Triad, including broader suite of chemistry		TIEs (Q4) Upstream source ID (Q4)
Watershed		Bioassessment Basic chemistry Some toxicity	Expanded toxicity, chemistry (Q2) TIEs (Q4) Upstream source ID (Q4)
High-priority habitat	Bioassessment Chemistry (if prior reason) *		Toxicity, chemistry (Q1, 2) TIEs (Q4) Upstream source ID (Q4)
Program goals	Dependent on question(s)		
Estuaries	Toxicity Chemistry (if prior reason) *		TIEs (Q4) Upstream source ID (Q4) Process studies (Q1 – 4) Biology (e.g., benthos, bioaccumulation) (Q1, 2)
Nearshore ocean +		Plume tracking Plume toxicity Plume chemistry	

* Chemical monitoring could be deferred until bioassessment or toxicity results suggest a potential problem.
+ Conducted as part of the periodic regional Bight program.

Table 5-6. The short list of chemical constituents that should be sampled routinely by all programs and an expanded list to be sampled where routine monitoring data or other information suggest the need for additional information and/or where appropriate to the management question being asked.

Category	Short list	Expanded list
Trace metals	total Cd, Cr, Cu, Ni, Pb, Zn	dissolved (with hardness)
Nutrients	NH_3, total Kjeldahl Nitrogen (TKN), NO_3, total P	
Bacteria	total coliform, fecal coliform or E. coli, Enterococcus	
Pesticides	diazinon, chlorpyrifos, other OP pesticides	others as necessary, e.g., legacy pesticides (DDT, chlordane, lindane), emergent pesticides (e.g., pyrethroids)
Conventionals	temperature, pH, hardness, specific conductance, dissolved oxygen	chemical oxygen demand (COD), sulfides
PAHs	if methods are available that are suitable for measuring on particles, at low detection limits	
Volatiles		dry weather only
Suspended solids	total suspended solids (TSS)	
Priority pollutants	every 5 years, with Bight Program	

Table 5-7. Design overview for extent and magnitude monitoring of recreational water quality problems. Regional monitoring is distinguished from special projects in its larger geographic scale and/or greater number and kinds of potential sources

Type of area	Site location	Frequency	Indicator(s)
Open-coast beach	Input(s) of concern Spaced array upcoast and downcoast of input of concern	One calendar year to establish basic pattern, then: Daily within representative periods (e.g., storms, dry weather, dominant current regimes)	Concentration and loads: • Total coliform • Fecal coliform • Enterococcus Dye
Enclosed bays and estuaries	Input(s) of concern Based on nature of problem, either: • Spaced array around input of concern • Regular grid throughout area of concern • Random array throughout area of concern • Gradient array downcurrent of input of concern	One calendar year to establish basic pattern, then: Daily within representative periods (e.g., storms, dry weather, dominant current regimes)	Concentration and loads: • Total coliform • Fecal coliform • Enterococcus Dye
Creeks and streams	Regular grid throughout high-priority use area	One calendar year to establish basic pattern, then: Daily within subsample of high-use period	Total coliform or E. coli Fecal coliform Enterococcus Dye

Table 5-8. Design overview for both recreational water quality and habitat source identification under Question 4: What are the sources to urban runoff that contribute to receiving water problems?

Type of area	Site location	Frequency	Indicator(s)
Recreational water quality			
Open-coast beach	Inputs that fall in upper right section of Figure 5-3	Ongoing until reach stopping rules in Figure 5-7	Total coliform Fecal coliform Enterococcus
Enclosed bays and estuaries	Inputs that fall in upper right section of Figure 5-3	Ongoing until reach stopping rules in Figure 5-7	Total coliform Fecal coliform Enterococcus
Creeks and streams	High-priority inputs as identified with conceptual model in Figure 5-3	Ongoing until reach stopping rules in Figure 5-7	Total coliform or E. coli Fecal coliform Enterococcus
Habitat			
All areas except coastal ocean	At core monitoring site Upstream of core monitoring site	Ongoing until reach stopping rules in Figure 5-8	Constituents identified in Questions 1 - 3

Table 5-9. Aliso Creek stations in order of scaled load and impact. Impact = downstream concentration – upstream concentration on each date. Load = factor x flow (csf) x concentration in pipe on each date. Scaled values are rescaled to 0 – 1. Average scaled values = average of scaled impact and load values. Stations are ranked in order of average scaled values.

Station	Avg scaled	Impact scaled	Load scaled	Impact	Load

Table 5-10. Definitions of the triggers in Table 5-4, the Triad interpretation framework, designed to initiate further adaptive studies to identify potential sources of impact. "BRI" refers to the regional Benthic Response Index for estuaries developed by the Bight Program. "IBI" refers to the Index of Biotic Integrity, a regional bioassessment index under development by the Stormwater Monitoring Coalition.

Possible trigger in Table 5-4	Definition of trigger
Persistent exceedance of water quality objectives	Exceedance of relevant Basin Plan or CTR objectives by 20% for 3 sampling periods
Evidence of toxicity	High score, in relation to other stations, on metric that combines magnitude and persistence of toxicity observed over an entire year (see Appendix 5: TIE Metric)
Evidence of benthic alteration	BRI score that indicates substantially degraded community (in estuaries) IBI score that indicates substantially degraded community (in freshwater creeks, streams, and rivers)

Table 5-11. Summary of the upstream source identification priorities from Table 4-7, based on combinations of the chemical, toxicity, and benthic components of the triad approach. "Yes" and "No" refer to whether or not data from each component exceeded the triggers described in Table 5-20.

Table 4-7 Row	Triad Component	Yes	No	Source ID Priority
1	chemistry	X		
	toxicity	X		
	benthos	X		High
2	chemistry		X	
	toxicity		X	
	benthos		X	None
3	chemistry	X		
	toxicity		X	
	benthos		X	Low[1]
4	chemistry		X	
	toxicity	X		
	benthos		X	Medium
5	chemistry		X	
	toxicity		X	
	benthos	X		High (for physical components)
6	chemistry	X

7	chemistry		X	
	toxicity	X		
	benthos	X		High
8	chemistry	X		
	toxicity		X	
	benthos	X		High

[1] If further testing indicates appropriate and sensitive enough toxicity tests were used and analytical results suggest pollutant is not bioavailable.

Table 5-12. Design overview for trends monitoring of recreational water quality.

Type of area	Site location	Frequency	Duration	Indicator(s)
Open-coast beach	Input(s) of concern at high-priority beaches Upcoast and downcoast stations	Weekly within representative periods (e.g., storms, dry weather, dominant current regimes) Repeated yearly	10 – 15 per year for 3 years, then based on power analysis	Concentration and loads: • Total coliform • Fecal coliform • Enterococcus Dye
Enclosed bays and estuaries	Input(s) of concern at high-priority sites Stations bracketing input(s)	Weekly within representative periods (e.g., storms, dry weather, dominant current regimes) Repeated yearly	10 – 15 per year for 3 years, then based on power analysis	Concentration and loads: • Total coliform • Fecal coliform • Enterococcus Dye
Creeks and streams	High-priority use area High-priority upstream inputs	Weekly with representative periods (e.g., storms, dry weather, dominant current regimes) Repeated yearly	10 – 15 per year for 3 years, then based on power analysis	Concentration and loads: • Total coliform or E. coli • Fecal coliform • Enterococcus Dye

Table 5-13. Design overview for trends monitoring of habitat.

Type of area	Site location	Frequency	Duration	Indicator(s)
Mass emissions	Bottoms of watersheds	3 storms / yr for 3 yrs, then modify per results of power analyses	Based on power analysis	Chemistry (see Table 4-8) Toxicity
Watershed	Random or rotating, perhaps per Bight design	Every few years, perhaps per Bight Program schedule	Ongoing	Triad in dry weather Chemistry, toxicity in wet weather
High-priority habitat	High-value habitat either impacted or threatened	1 or 2 / yr in dry weather	Based on power analysis Revisit when habitat status changes	Triad
Program goals	As needed	Dependent upon problem, question	Based on power analysis Until goals met / change	Dependent upon problem, question
Estuaries	Random per Bight design Key habitats and/or downstream of major inputs	Every few years per Bight design 1 or 2 / yr, in wet and/or dry, depending on problem, question	Ongoing for Bight Based on power analysis for key habitats and downstream stations	Chemistry (see Table 4-8) Toxicity
Nearshore ocean	Random and/or clustered in plumes, per Bight design	Every few years per Bight design	Ongoing	Chemistry (see Table 4-8) Toxicity

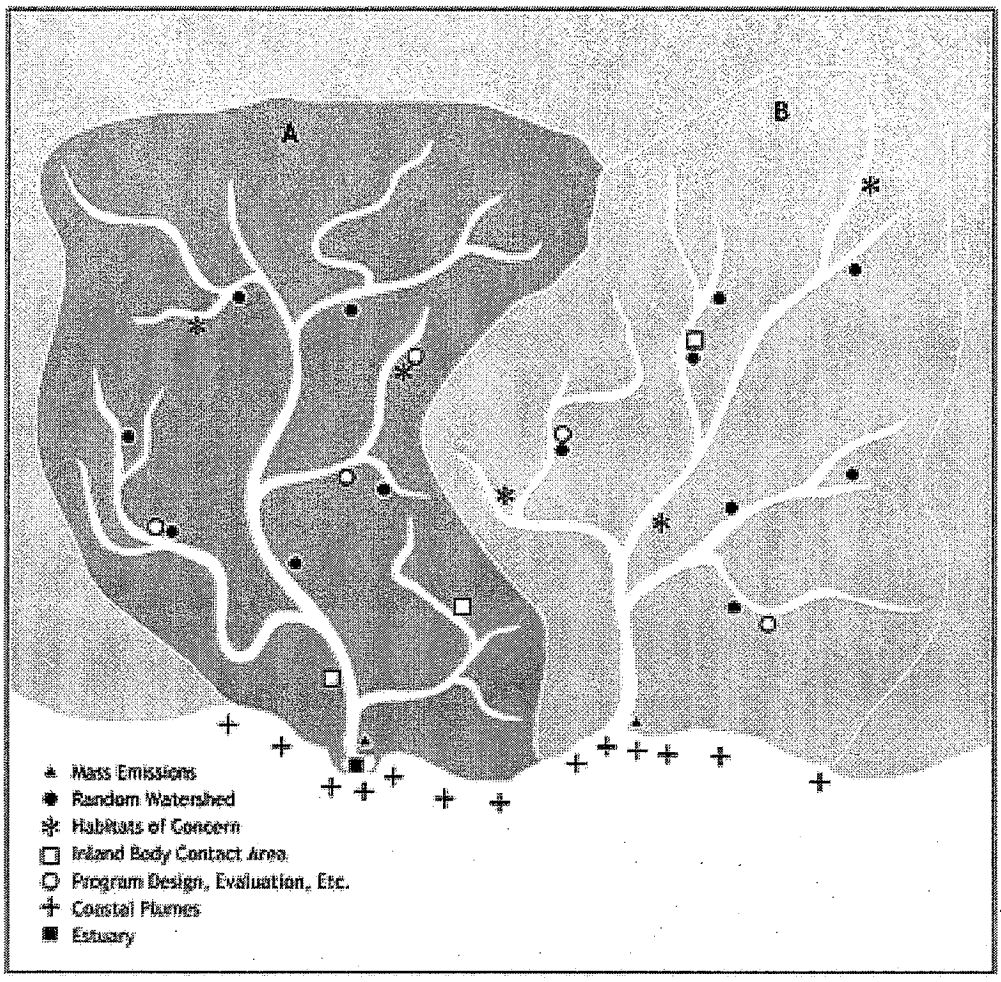

Figure 5-1. Example model monitoring program design in an idealized watershed.

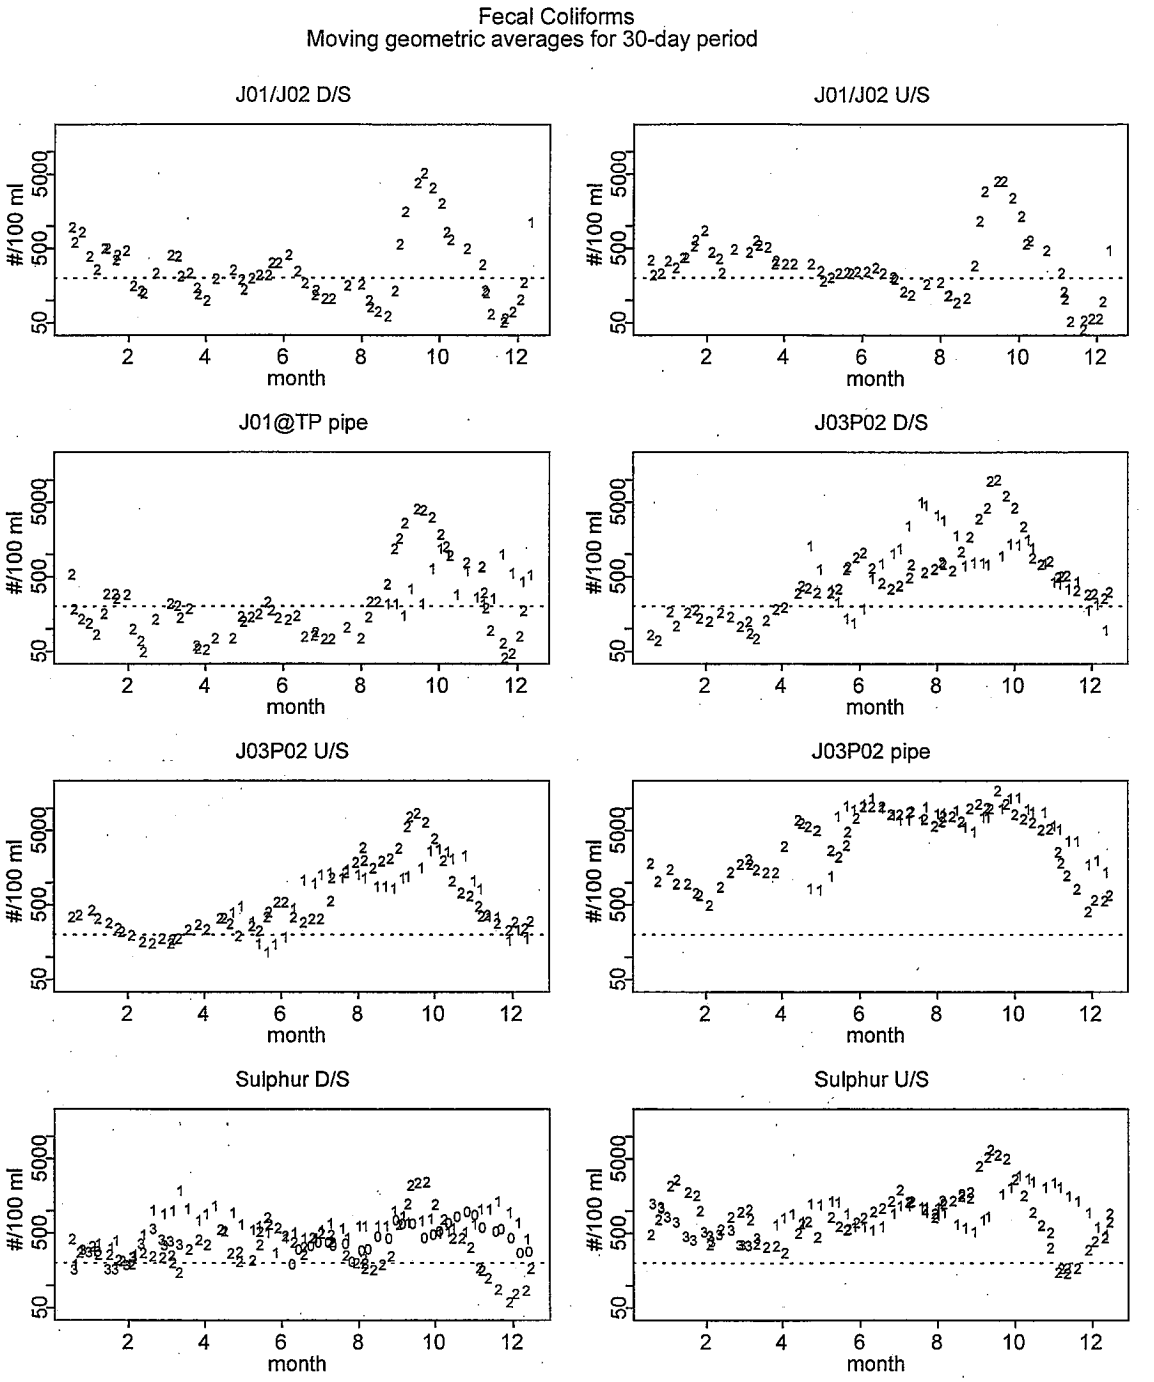

Figure 5-2a. Fecal coliform measurements at and upstream/downstream of discharge points in lower Aliso Creek. Data points are 5-sample moving geometric averages. The horizontal dashed line represents the Basin Plan REC1 objective for fecal coliforms (geomean not higher than 200/100 ml). The point symbols indicate the year of sampling (i.e., 1 for 2001, 2 for 2002).

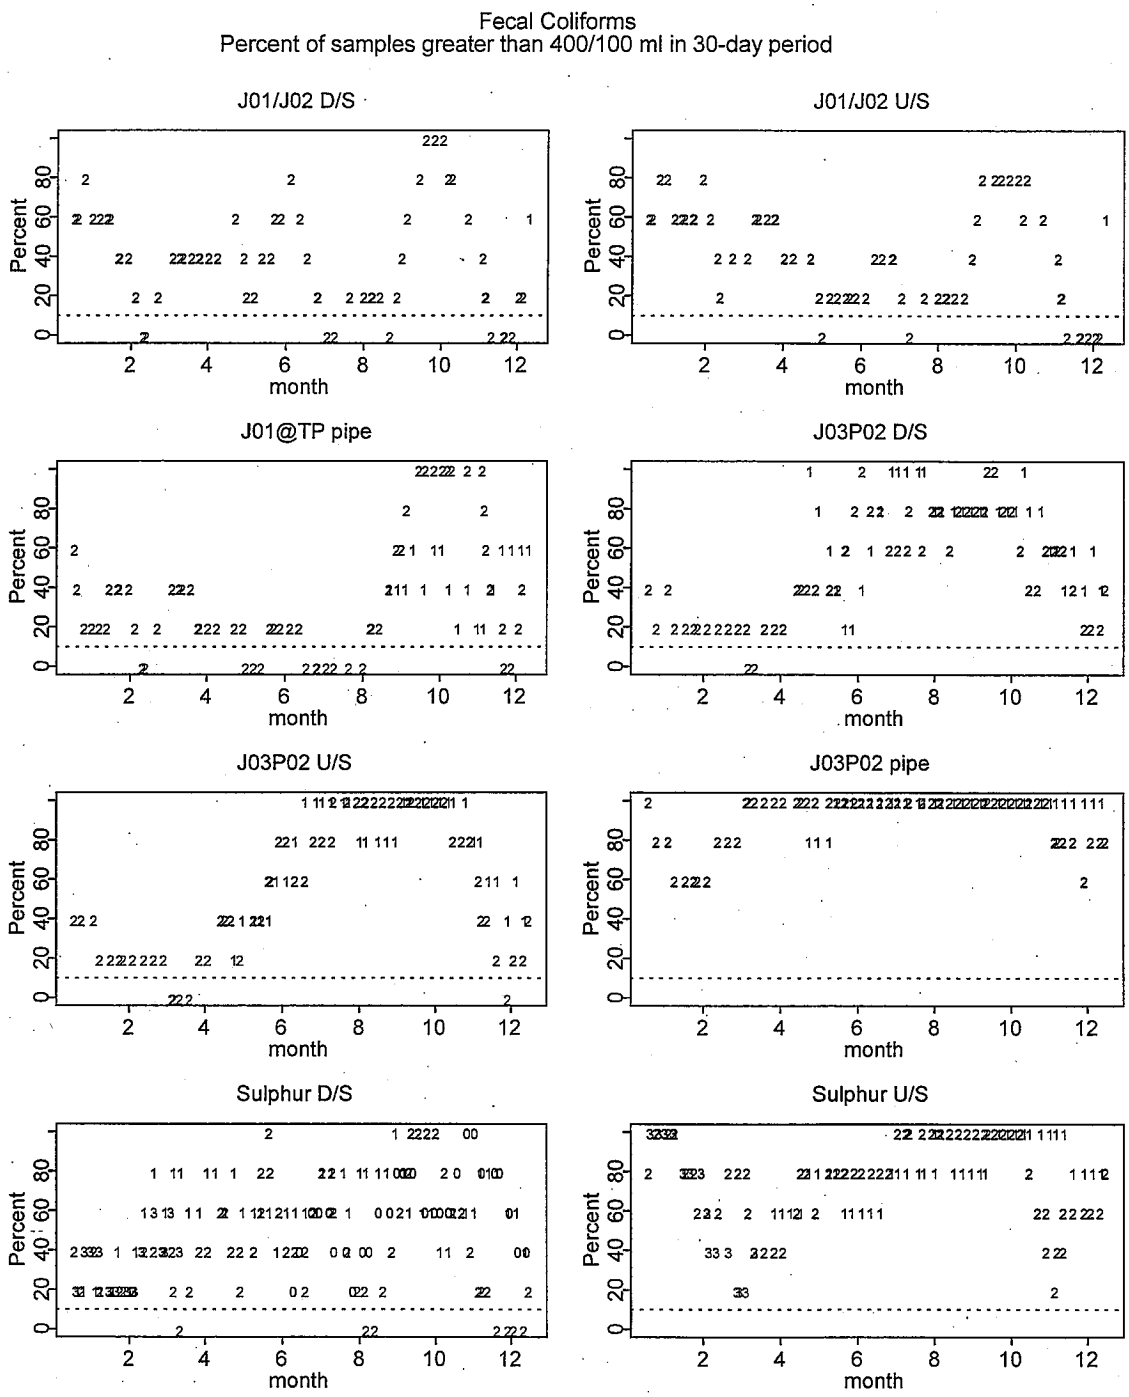

Figure 5-2b. Fecal coliform measurements at and upstream/downstream of discharge points in lower Aliso Creek. The data points are the percent of fecal coliform samples above 400/100 ml in the five most recent samples. The horizontal dashed line represents the Basin Plan REC1 objective for fecal coliforms (no more than 10% above 400/100 ml). The point symbols indicate the year of sampling (i.e., 1 for 2001, 2 for 2002).

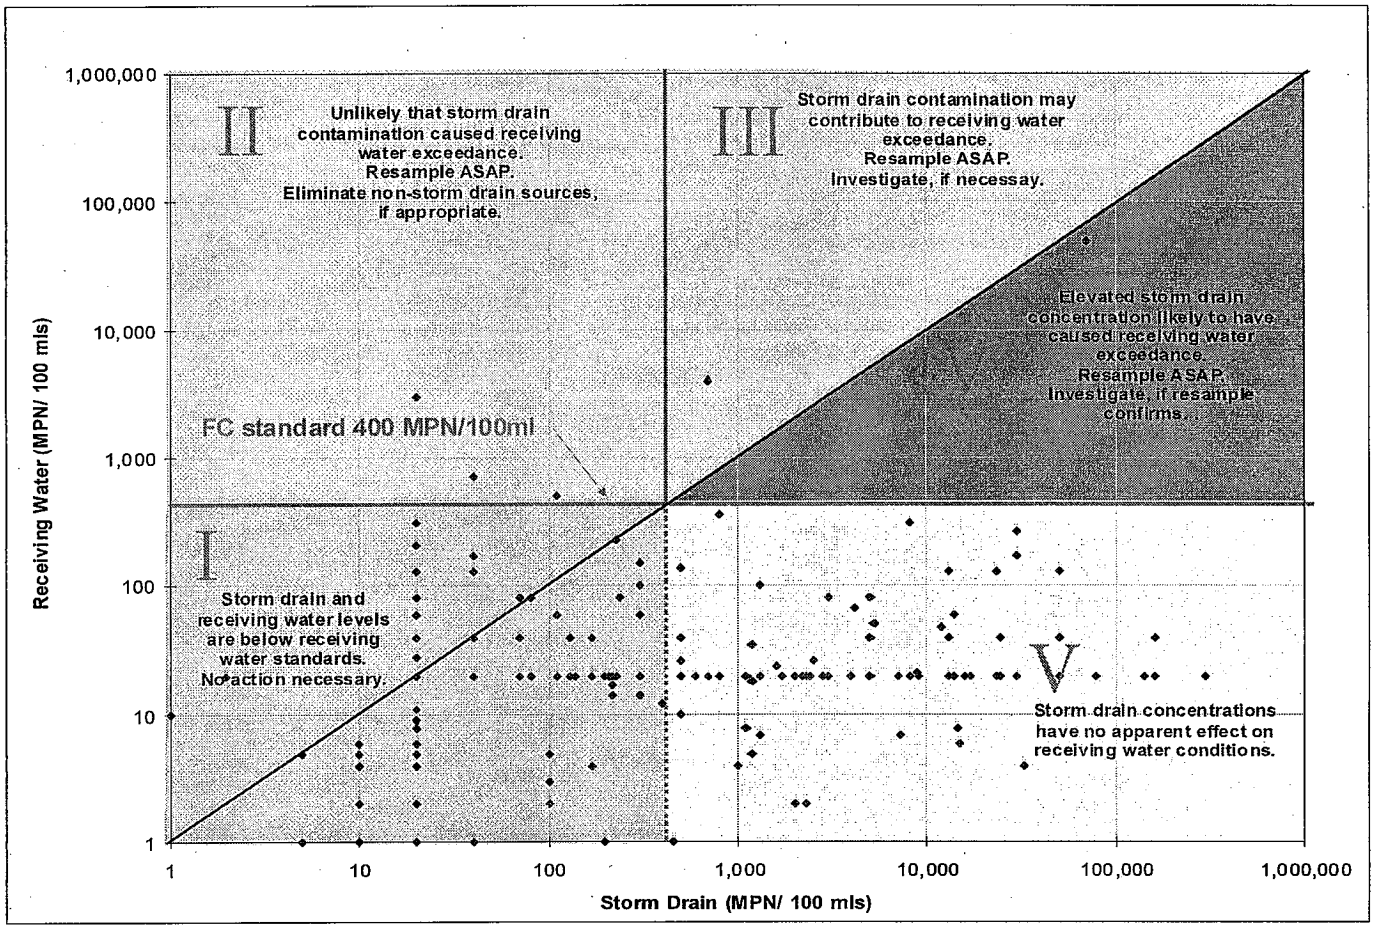

Figure 5-3. Approach for prioritizing coastal and estuarine bacterial inputs for further upstream source identification efforts. The highest priority is given to situations in which elevated bacterial indicator levels in the discharge are matched with elevated levels in the receiving water. This figure shows an example using fecal coliform, and analagous figures could be prepared with other indicator data.

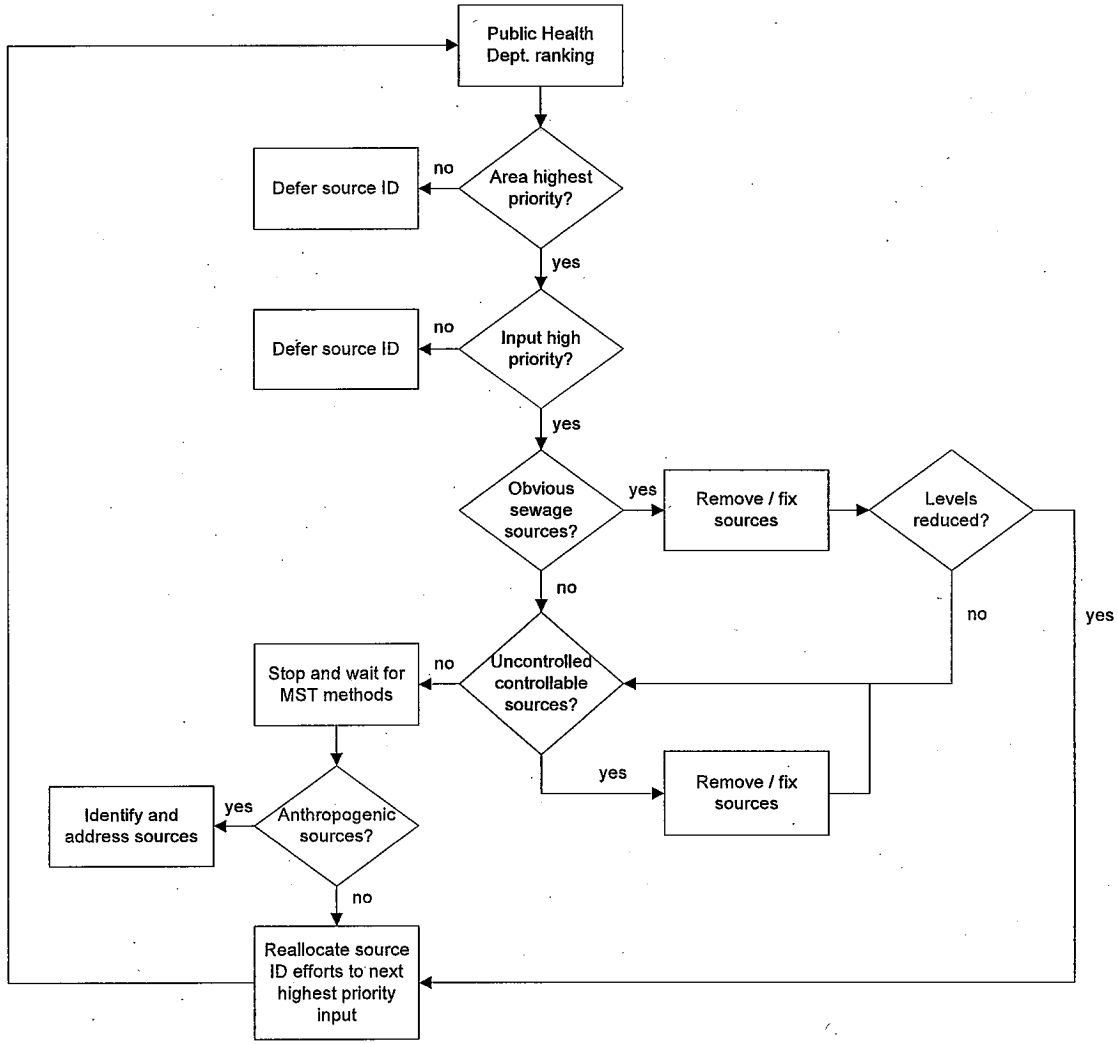

Figure 5-4. Decision tree that organizes starting and stopping rules for upstream bacterial source identification efforts. MST refers to microbial source tracking methods.

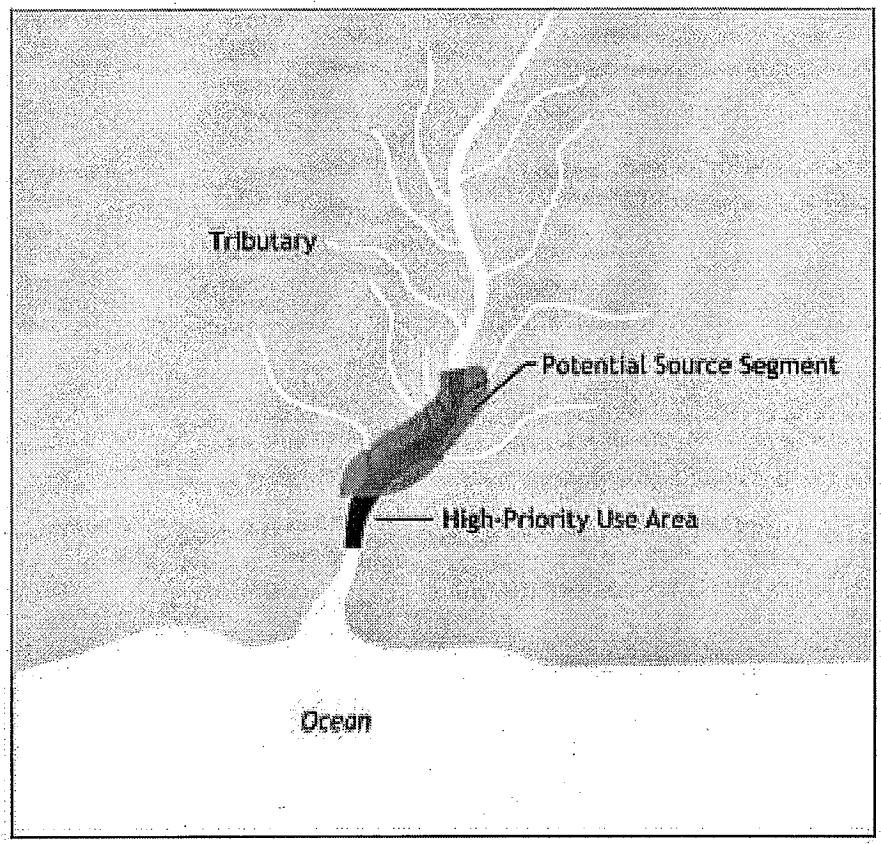

Figure 5-5. Conceptual model for determining the upstream segment of a creek or stream that should be the focus of source identification efforts for bacterial contamination. The model assumes that bacterial dieoff as water flows downstream places an upper limit on the distance bacteria can travel and still impact the high-priority use area.

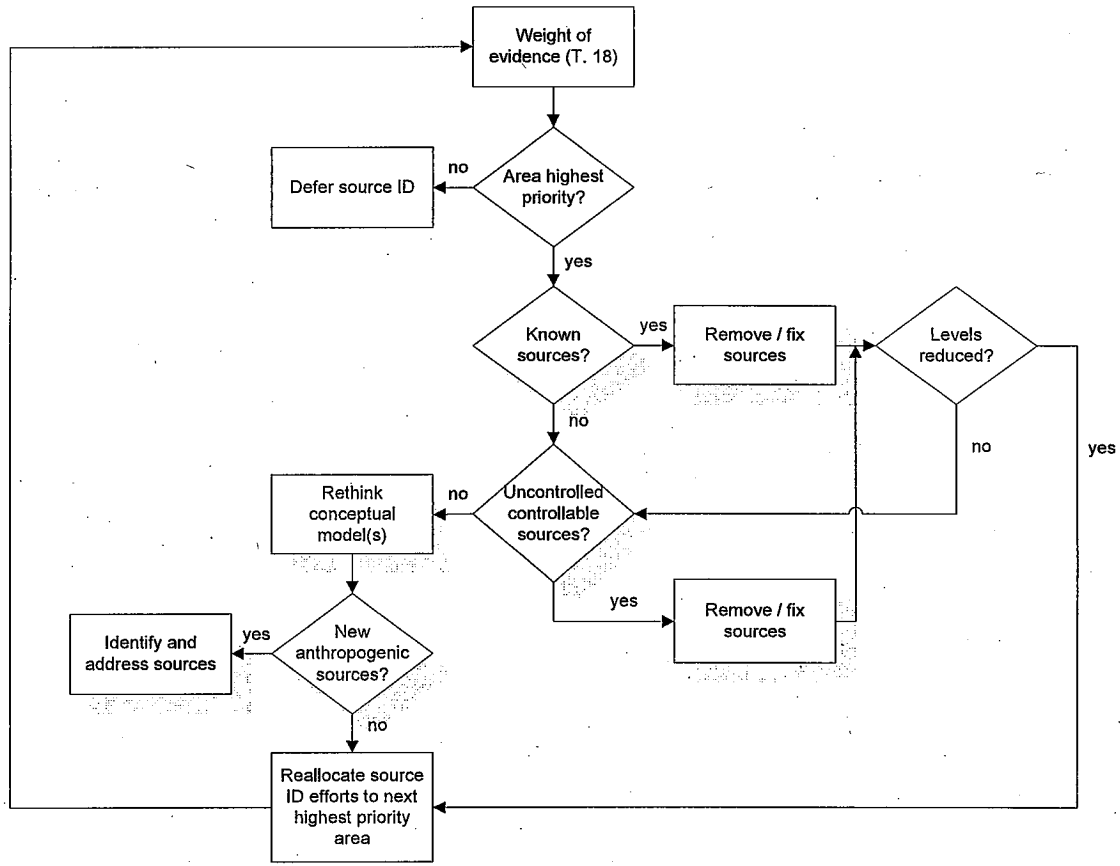

Figure 5-6. Decision tree that organizes starting and stopping rules for upstream source identification efforts targeted at habitat.

7.0 APPENDICES

Appendix 1: Summary of Existing Municipal Stormwater Monitoring Programs in Southern California

June 2003

As part of the effort to develop a model stormwater monitoring program, we have reviewed and summarized the existing monitoring designs being implemented by each of the major stormwater programs in southern California. This information will be used, in a later step of the project, as a starting point for assessing what sorts of changes might be advisable to bring existing monitoring efforts more into line with the recommendations of the model program.

Program-specific details

There are six basic types of monitoring approaches currently used in NPDES stormwater monitoring programs throughout southern California, including:

- End of watershed designs that typically measure the cumulative mass emissions from all discharges
- Dispersed watershed designs that assess overall conditions and impacts in freshwater habitats
- Site-specific watershed designs that assess conditions and trends in freshwater or estuarine habitats of particular concern
- Beach stormdrain designs that assess stormwater impacts on the surfzone
- Near-coastal designs that assess the impact of stormwater plumes on near-coastal habitats
- Dry-weather reconnaissance designs focused on identifying sources of pollution to the MS4 system.

While all of these approaches can be found in the region, not every stormwater program includes all six, as illustrated in Table A1-1.

Table A1-1. Distribution of monitoring approaches across the separate stormwater programs in southern California.

Program	End of watershed	Dispersed watershed	Site-specific watershed	Beach	Near-coastal	Recon-naissance
Ventura		X				
Los Angeles	X		X			
Long Beach	X		X			
Orange	X	X	X	X	X	X
San Bernardino	X					
Riverside	X	X				
San Diego	X	X	X	X		X

In addition, the relative attention paid to each type of monitoring varies across programs. This reflects differences in habitat types, regulatory emphasis, stage of program development, and patterns of urbanization across the region. For example, monitoring in the northern part of Orange County focuses more heavily on problems intrinsic to more urbanized areas than does monitoring in Ventura County, which has a larger proportion of agricultural and open space land uses.

The following set of tables summarizes the existing distribution of effort in each of the programs. Information was drawn from the most recent set of program documents available for each program.

Table A1-2 shows the distribution of end of watershed monitoring efforts across the region's programs. All the programs except for San Bernardino County and Riverside County have ongoing end of watershed designs focused primarily on estimating mass loads from larger watersheds. The lack of such stations from San Bernardino and Riverside Counties partly reflects the fact that these inland areas are at the upper ends of large watersheds (such as for the Santa Ana River), which is a quite different situation than in the coastal counties. However, the lack of mass emissions stations in the inland counties also hampers their ability to estimate the proportional contribution of these inland areas to cumulative loads downstream.

Table A1-2. End of watershed monitoring efforts in each stormwater program.

Program	No. Sites	No. Events/Yr	Indicators	Notes
Ventura	3	2 wet, 5 dry		
Los Angeles	7 6/trib	3 storms, 2 dry 4 storms, 1 dry	Water qual, tox, trash Water qual	Adaptive TIE Rotate among tributaries each year
Long Beach	4	4 storms, 2 dry	Water qual, tox	Adaptive TIE Additional sites in LA and San Gabriel river watersheds as decided by Reg. Board
Orange	12 * 6	3 storms, 3 dry 3 storms	Water qual, tox Water qual, tox	Adaptive tox, TIE, source ID Adaptive TIE
San Bernardino	-			
Riverside	-			
San Diego	11	3 storms	Water qual, tox	Link to bioassessment at other sites

* For Orange County, the upper set of information refers to the Santa Ana Region of the County and the lower to the San Diego Region of the County, which have somewhat different monitoring programs.

Table A1-3 shows the distribution of dispersed watershed monitoring efforts across the monitoring programs in the region. Dispersed watershed monitoring efforts are typically used to assess the extent and magnitude of impact on watersheds and their beneficial uses. All the programs except for Long Beach (which is a relatively small, heavily urbanized area) include this approach, and four of these six programs contain bioassessment sampling. This reflects a growing awareness that chemical measurements alone, or even chemical measurements combined with toxicity testing, will not necessarily capture impacts to aquatic habitats. The inclusion of bioassessment monitoring is an effort to directly measure habitat quality in areas where this is of concern. The model program will identify the types of locations where dispersed watershed monitoring should occur and define the measurement indicators, including bioassessment, that should be monitored at these sites.

Table A1-3. Dispersed watershed monitoring efforts in each stormwater program.

Program	No. Sites	No. Events/Yr	Indicators	*Notes*
Ventura	3 landuse	1 dry	Water qual	Characterize landuse
	2 rec. water	1 dry	Water qual	discharges
	14 bioass	1 dry	Bioassessment	Characterize receiving water quality in smaller tributaries
Los Angeles	20	1 dry	Bioassessment	CDFG methods
Long Beach	-			
Orange	11	2 dry	Water qual, tox, bioassessment	Includes reference sites
	15	2 dry	Water qual, tox, bioassessment	Adaptive chem, tox, TIEs, source ID
San Bernardino	5	4 storms	Water quality	
Riverside	25	1 – 5 wet	Water qual	
	25	3 dry	Water qual	
San Diego	23	2 dry	Bioassessment	Link to mass emissions, tox at other sites

Table A1-4 shows the distribution of site-specific watershed monitoring across the region. These efforts are targeted at locations that are considered of concern because of their high ecological and societal value. The uneven distribution of such effort across the region reflects the uneven distribution of high-value habitats such as lagoons and estuaries (e.g., Newport Bay), as well as the varying degree to which management agencies have addressed this issue. The effect of sample size has not been fully evaluated in southern California. Too few samples will lead to conclusions with low confidence or even erroneous conclusions while oversampling leads to wasted resources. The model program will address this issue through power analysis of historical data to assess the optimal number of samples.

Table A1-4. Site-specific watershed monitoring efforts in each stormwater program.

San Bernardino	-			
Riverside	11	4	Water qual	
San Diego	13 lagoon	1 dry	Sed chem, tox, benthos	Adaptive prioritization using triad

Table A1-5 shows the distribution across the region of monitoring efforts targeted at storm drains discharging directly to the beach or coastal zone. The absence of such sites in San Bernardino and Riverside Counties is due to their inland location. In other coastal counties, beach monitoring may be conducted by county health departments rather than by stormwater programs. The stormwater model monitoring technical workgroup has teamed up with the SWRCB's Beach Water Quality Workgroup to evaluate potential collaborative monitoring designs that would coordinate with the county health department and other shoreline monitoring efforts.

Table A1-5. Beach drain monitoring efforts in each stormwater program.

San Bernardino	-			
Riverside	-			
San Diego	60	Weekly	Bacteria	Cities conduct program, monitor drain and receiving water, adaptive source ID

Table A1-6 shows the distribution of near-coastal monitoring effort across the programs in the region. This is a relatively new priority for stormwater programs, as reflected in the fact that only the Los Angeles County and Orange County programs include this component. The model monitoring program is looking to integrate this monitoring with existing near coastal monitoring through southern California Regional Monitoring.

Table A1-7 shows the distribution of dry-weather reconnaissance monitoring efforts across the region's stormwater monitoring programs. This type of monitoring is targeted specifically at source identification, and is contained only in the Orange and San Diego County programs. Source characterization monitoring is important and the model monitoring program is looking to integrate this design as an adaptive element, triggered by the extent and magnitude of impacts described in Table A1-3.

Summary and Discussion

The monitoring programs described above were designed and implemented to address issues specific to each county or city. Thus, many of the differences between the programs reflect a logical amount of variety, given the variability across the entire region in factors such as degree

of urbanization, type and amount of critical habitat, design of the MS4 system, and kinds of beneficial uses. However, there are other differences that are more arbitrary in nature, for example the frequency of sampling events, the analyte list, and whether to include a dry weather reconnaissance program. In addition, some programs have moved aggressively to include adaptive elements, while others have chosen designs that remain relatively constant across sampling events throughout the permit term.

In addition, the monitoring programs currently in place in the region have to some extent accreted over time, with new elements being added as permits are renewed. Thus, programs have not all been designed with the goal of addressing, in a logical and integrated way, the core management questions the technical committee has identified:

1. Are conditions in receiving water protective of beneficial uses?
1a. What are the mechanism(s) causing receiving water problems?
2. What is the extent and magnitude of the receiving water problems?
3. What is the relative urban runoff (both storm and non-storm, wet and dry) contribution to the receiving water problem(s)?
4. What are the sources of the urban runoff contribution to receiving water problems?
5. Are conditions in receiving waters getting better or worse?

As a result, information about the extent and magnitude of impacts on receiving waters is not always available, nor are loadings estimates (Question 3) that separate out the urban runoff component always an integral part of monitoring designs. In addition, upstream source identification efforts occur in some programs but not others, and are designed to different standards of rigor.

This overview of current monitoring practice provides a concrete starting point for two distinct but complementary considerations. First, the variety across programs provides insight into the breadth and flexibility the model program needs to encompass to be applicable to programs throughout the region. Second, the overview presents information needed for assessing what adjustments could be made to individual programs to bring them more into accord with the model monitoring program, once it is fully fleshed out. The model monitoring program must balance the desire for consistency, standardization, and regional efficiency with reasonable requirements for program-specific differences in design needed to address site-specific issues.

Appendix 2: Power Analysis Results

This appendix contains results of statistical power analyses for long-term trend with several types of historical monitoring data from southern California, including:

- Bacteria indicators at a high-priority recreational use area on Aliso Creek
- Bacteria indicators at stations upstream of the high-priority use area
- Bacteria loads from discharges upstream of the high-priority use area
- Bacteria impacts from discharges upstream of the high-priority use area
- Event mean concentrations (EMC) at a series of mass emissions stations
- Loads at a series of mass emissions stations.

Bacteria loads were calculated as the difference between indicator levels 25 feet upstream and 25 feet downstream of the discharge. The specific figures included in this appendix are listed in the following table:

Figure	Content
Fig A3.1	Aliso Creek, downstream use area power analysis results
Fig A3.2	Levels of bacterial indicators at upstream Aliso Creek stations
Fig A3.3	Power analysis results for bacteria loads at upstream Aliso Creek stations
Fig A3.4	Power analysis results for bacteria impact at upstream Aliso Creek stations
Fig A3.5	Power analysis results for EMC, Anaheim Barber Channel
Fig A3.6	Power analysis results for EMC, Westminster Channel
Fig A3.7	Power analysis results for EMC, Santa Ana Delhi Channel
Fig A3.8	Power analysis results for EMC, San Diego Creek at Campus
Fig A3.9	Power analysis results for EMC, Oso Creek
Fig A3.10	Power analysis results for loads, Anaheim Barber Channel
Fig A3.11	Power analysis results for loads, Westminster Channel
Fig A3.12	Power analysis results for loads, Santa Ana Delhi Channel
Fig A3.13	Power analysis results for loads, San Diego Creek at Campus
Fig A3.14	Power analysis results for loads, Oso Creek

In each figure, the X-axis shows the number of years over which monitoring may continue, the Y-axis the cumulative percent change to be detected, and the four curves options for the number of samples per year that could be taken. Thus, each figure shows the amount of change that could be detected (at a statistical power of 80%) at each combination of within- and between-year sampling intensity.

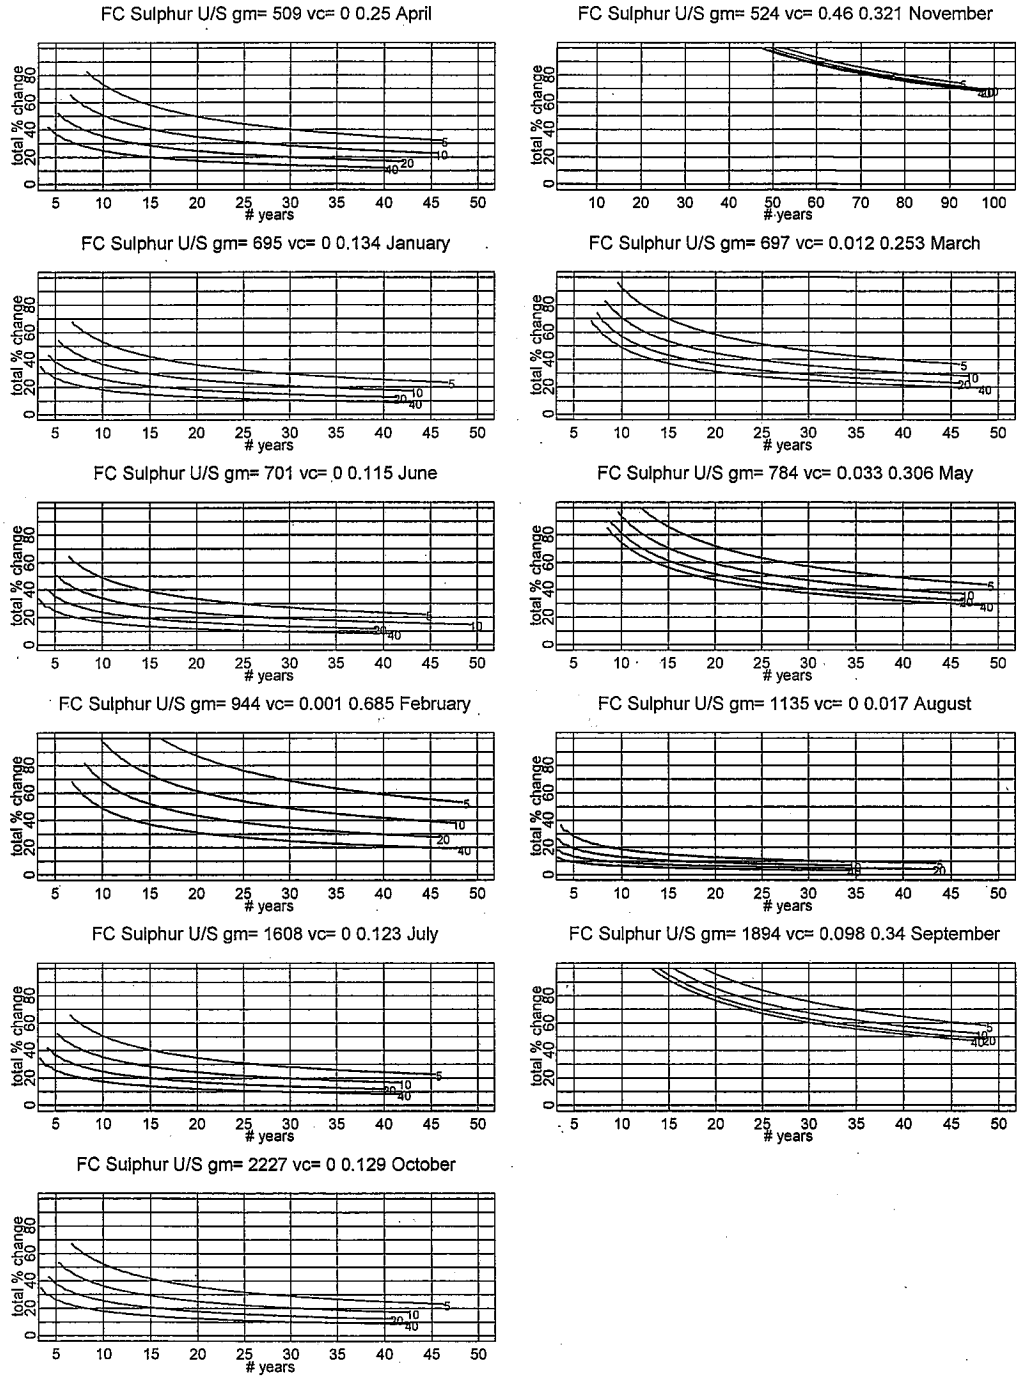

Figure A2.1a. Power analysis of a trend monitoring design at the AWMA ROAD Bridge, station Sulphur Creek upstream. The y-axis shows the amount of change detectable, the x-axis the years of sampling, and the different curves the number of samples in a given 30-day period (5, 10, 20, 40) needed for 80% power.

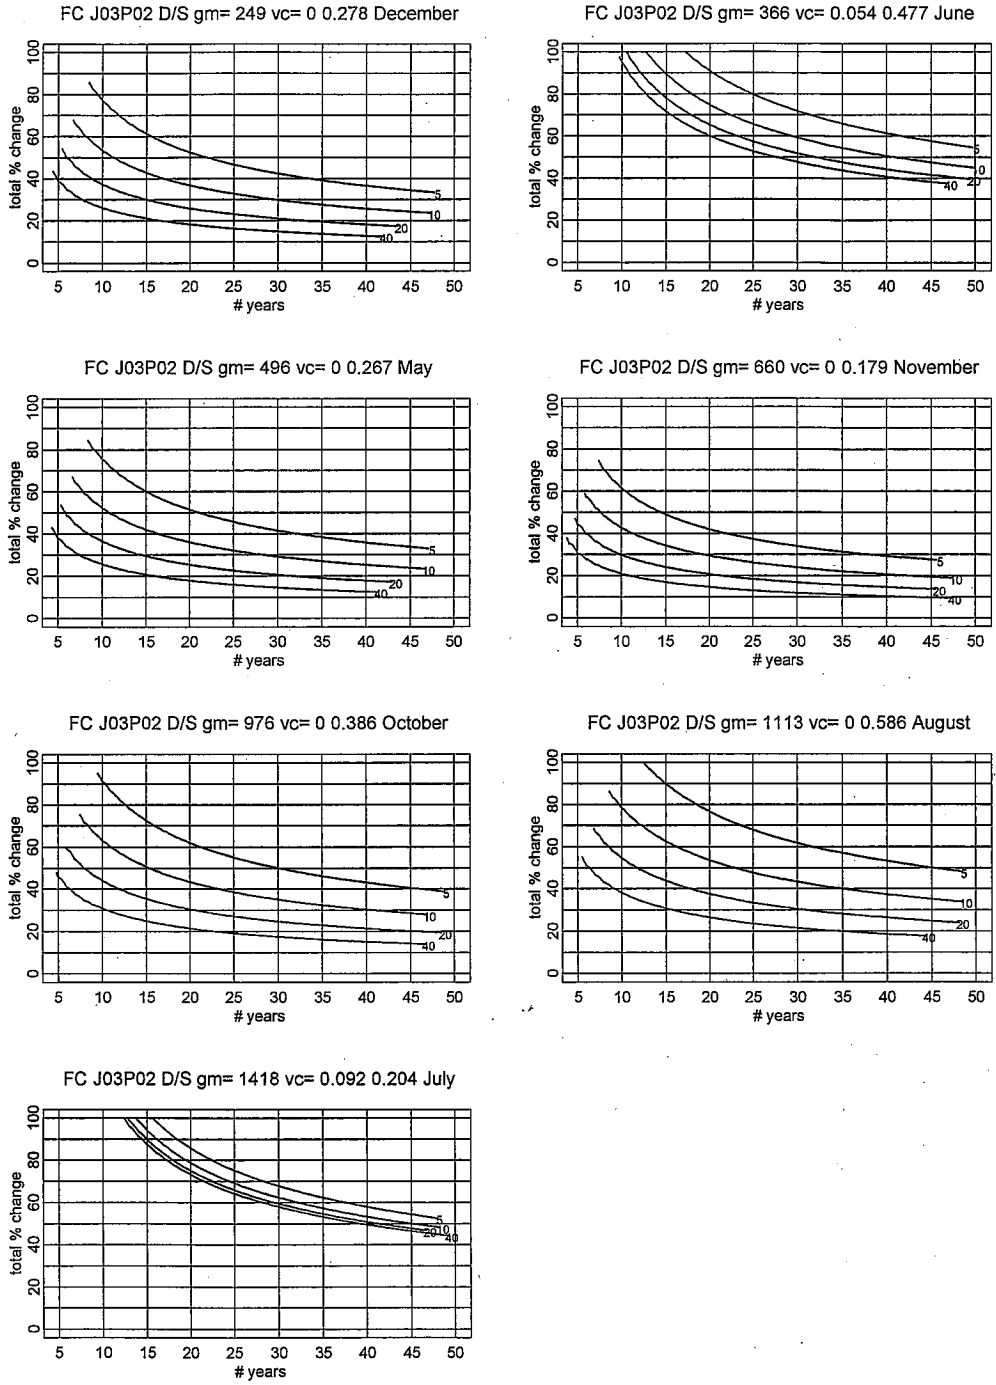

Figure A2.1b. Power analysis of a trend monitoring design at the confluence of Aliso and Sulphur Creeks, station J03P02 downstream. The y-axis shows the amount of change detectable, the x-axis the years of sampling, and the different curves the number of samples in a given 30-day period (5, 10, 20, 40) needed for 80% power.

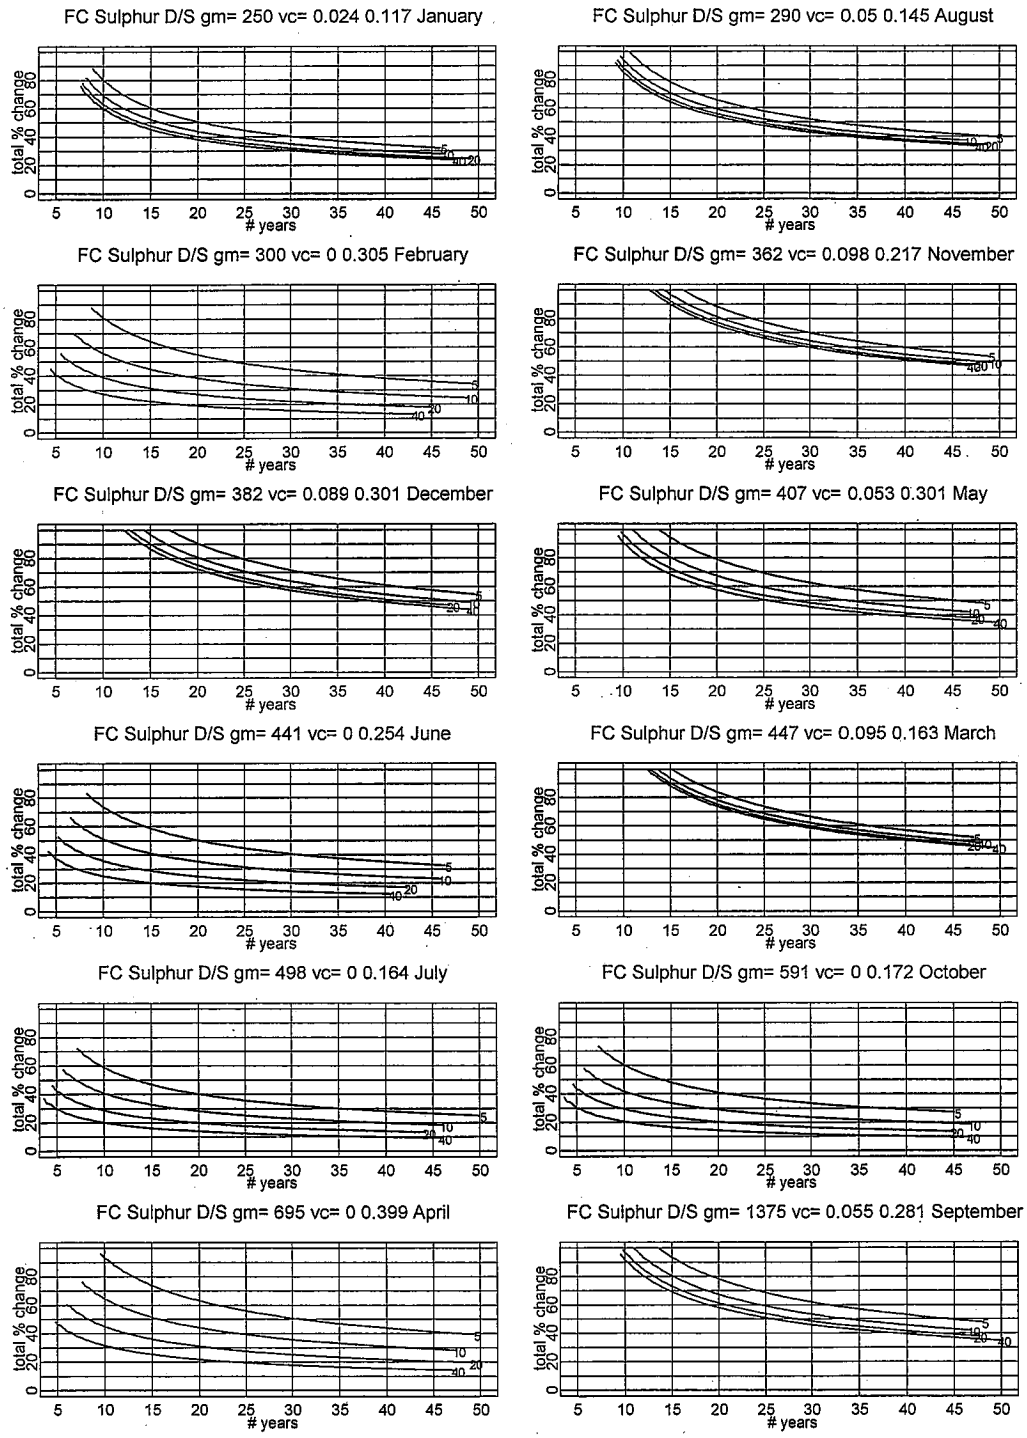

Figure A2.1c. Power analysis of a trend monitoring design at Aliso Wood Canyon Park, station Sulphur Creek downstream. The y-axis shows the amount of change detectable, the x-axis the years of sampling, and the different curves the number of samples in a given 30-day period (5, 10, 20, 40) needed for 80% power.

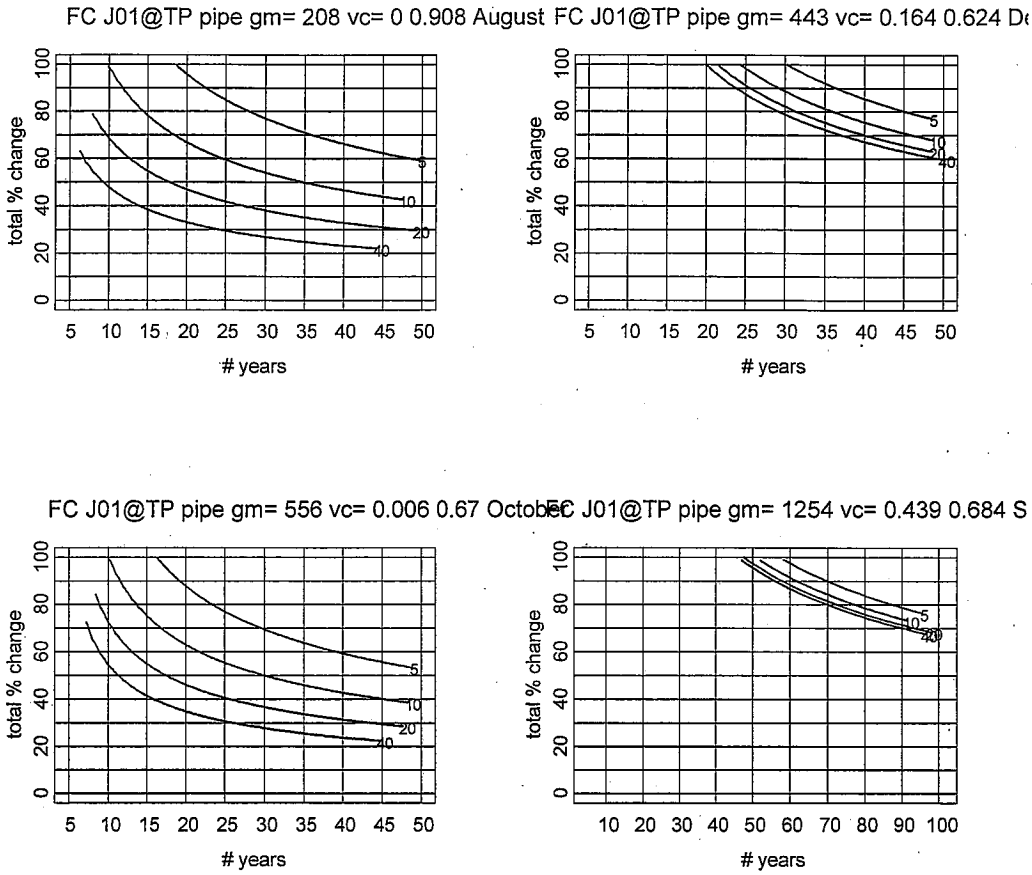

Figure A2.1d Power analysis of a trend monitoring design at the SOCWA treatment plant, station J01@TP. The y-axis shows the amount of change detectable, the x-axis the years of sampling, and the different curves the number of samples in a given 30-day period (5, 10, 20, 40) needed for 80% power.

Appendix 3: Source Identification Case Studies

The following case studies present examples of source identification efforts conducted to determine the rough proportion of input from urban runoff sources. They include several different kinds of problems and study approaches and exemplify the variety of methods that might be employed to address Question 3. The majority of the case studies were conducted in dry weather. This reflects difficulties of performing source identification studies in wet weather, given the large flow volumes and the typically increased number of possible sources. The cases also exhibit a range of level of effort, from evaluation of routine monitoring data and interviews to a series of iterative special field studies.

A3.1 Contaminated sediment taskforce (LA Harbor)

Sediments in ports, harbors, and marinas are subject to numerous pollutant inputs including sediments, trace metals, and organic contaminants. These sediments eventually need to be dredged to maintain navigable waterways, but the level of sediment contamination has a tremendous effect on the eventual disposal of these dredged materials. Clean sediments can be used for beach replenishment or even disposed at sea, but contaminated sediments need to be sent to a landfill or some other confined disposal area so they will not harm the environment. As the Port Districts, RWQCB and Coastal Commission (collectively known as the Contaminated Sediment Task Force) design a long-term dredged material management program, they are carefully considering ways to reduce the inputs of pollutants to the areas that need periodic maintenance dredging. One way to accomplish this is to identify and reduce or eliminate the sources of pollutants to these locations.

In order to begin reducing pollutant loads, the Contaminated Sediments Task Force asked SCCWRP to estimate the relative magnitude of pollutant loading from several potential sources to Los Angeles and Long Beach Harbors and Marina del Rey. A particular emphasis of the study was estimating loads from the Los Angeles River and Dominguez Channel to San Pedro Bay and from Ballona Creek to Marina del Rey. Primary questions addressed included:

- What are the predominant sources of contaminants?
- What are the long-term (i.e. decadal) trends in annual loading?
- What is the typical range of annual loading that should be expected?
- Which watersheds typically contribute the greatest annual loading?
- What land use types are the largest contributors to annual loading?

These questions were evaluated with an assessment study that involved existing data and limited modeling to estimate watershed loading patterns. Because historic data were somewhat limited, SCCWRP estimated loads with a ratio estimation technique. This involves establishing a relationship between flow and loads using available data and then applying this relationship to an entire storm season. Flow was estimated by applying rainfall data and standard runoff coefficients to different land use types. This combination of methods allowed loads to be approximated for a variety of land uses for entire years in the periods 1971-72, 1979-80, 1986-87, and 1987-88.

The analysis confirmed that the largest source of contamination to San Pedro Bay is watershed-derived loading from the Los Angeles River and Dominguez Channel watersheds. The Los Angeles River watershed contributed the greatest overall mass loading, but the Dominguez Channel watershed contributed the largest proportional loading (i.e. loading normalized for

watershed size). In general, industrial and residential land uses are the largest contributors of contaminants. Data from the 1990s also revealed that dry season (i.e. non-storm) loading may make up a significant portion of total annual loading, and in dry years, can be the predominant source of contaminants to the harbor. Analysis of temporal trends in the data showed that metals loading has not substantially changed since the 1970s, but loading of DDT and PCBs has declined.

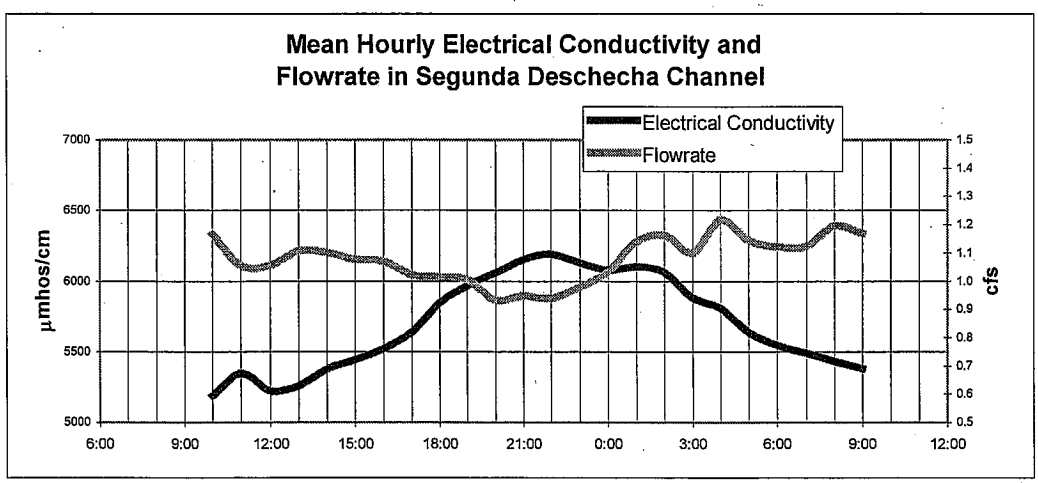
Annual loadings of metals varied between 10^3 and 10^5 kg/year, with zinc and copper loading typically exceeding loads of other metals. Variations in annual loading appear to correspond with changes in rainfall and runoff; however, direct analysis of the relationship between rainfall intensity and duration and loading produced only weak correlation coefficients. This correlation would likely be improved by analyzing a larger data set on more homogenous land use types.

Because the study depended on available data, not all possible sources of loading could be evaluated and key data gaps remained. These included the lack of data on loading of PAH and pesticides, lack of long-term data on dry season loading, lack of information on inputs from the Dominguez Channel Watershed, and the need for more temporally resolved loading data from specific land use types. Information on the transport and fate of runoff-derived contaminants within the study area would also be needed to improve estimates of the impact of loadings on sediment contamination.

Summary based on SCCWRP Technical Report #143. Watershed-based sources of contaminants to San Pedro Bay and Marina del Rey: Patterns and trends. October 13, 2003. ftp://ftp.sccwrp.org/pub/download/PDFs/413_cstf_watershed.pdf

A3.2 Elevated total dissolved solids in Prima and Segunda Deshecha channels (Orange County)

Routine monitoring during the 2001-2002 monitoring year documented elevated levels of total dissolved solids (TDS) at monitoring stations in Prima and Segunda Deshecha channels in Orange County. Special studies involving hourly measurements of conductivity and flow rate, conducted in both channels, showed that the peak TDS concentration was not a function of tide (i.e., did not reflect a higher concentration of saltwater) and that the TDS concentration was inversely proportional to flow rate in the channel (see the figure below).



This strongly suggested that urban runoff diluted a naturally high level of dissolved solids in the channels. Subsequent to this finding, an upstream reconnaissance survey identified the presence of hundreds of weepholes in the concrete sidewalls of the channel. These weepholes appeared to be allowing subsurface drainage to leach salts from soils and carry them into the channel. Preliminary sampling of three weepholes during the reconnaissance survey showed them to have extremely high levels of electrical conductivity, an indicator of TDS. In addition, the crystalline residue on the channel walls near the routine monitoring location was found to have high concentrations of sodium and soluble sulfate.

These findings provided the basis for a more substantial upstream source identification study in the Prima Deshecha channel in March 2002 that included monitoring at several weepholes, as well as upstream and downstream of the weepholes. The resulting data (see following table) indicate that the seepage from the channel seams and weepholes increases the concentrations of dissolved solids in the channel downstream of the seepage.

Reach of Channel	Time	Monitoring Point	EC (mhos)	TDS (mg/L)
At Diamante	13:00	Prima Deshecha Channel (M01)	Dry	
At Calle Nuevo	13:40	M01	5,150	
u/s Avenida Vacquero	14:48	M01 50' u/s weeping seam	5,510	4,880
	14:45	weeping seam	19,870	18,900
	14:42	M01 50' d/s weeping seam	7,510	7,330
	14:50	36" pipe discharging to M01	3,800	
d/s I-5	15:20	M01 in Shorecliff Golf Course	7,550	
u/s Calle Grande Vista	15:37	M01 50' u/s bubbling weepholes	7,750	7,490
	15:34	Bubbling weepholes	14,480	12,800
	15:40	48"pipe discharging to M01, 20' d/s weepholes	5,850	
At Calle Grande Vista	15:30	M01	8,480	

The conclusion was corroborated by soil samples collected from the levee of the Prima Deshecha channel above a weeping seam and from the levee of San Juan Creek, a channel with no history of elevated TDS levels (see following table).

Location	Chloride	Soluble Sulfate	Calcium	Magnesium	Potassium	Sodium
	mg/kg	%	mg/kg	mg/kg	mg/kg	mg/kg
Prima Deshecha Ch. Levee	61.3	0.447	861	275	37.2	582
San Juan Creek levee	13/7	0.048	34.1	11.1	15.4	202

Information obtained from the 2001-2002 annual report of the Orange County Stormwater Program

A3.3 SCCWRP's study of sources of loads to the LA River

The Los Angeles River drains most of Los Angeles County and extends 56 miles, starting from its headwaters in the San Fernando Valley, flowing past downtown Los Angeles, and eventually draining to San Pedro Bay near Long Beach. The highly developed watershed is 834 mi^2 and is comprised of residential (35%), commercial (5%), industrial (8%), and open land (51%) uses. The river's mainstem and tributaries are listed as impaired waterbodies for many constituents including nutrients (N), bacteria (fecal coliform), and trace metals (copper, lead, and zinc). The three primary sources of these pollutants included water reclamation plants (WRPs), major

tributaries, and storm drain outfalls. As part of efforts to establish TMDLs for the river, SCCWRP conducted a short-term study to characterize the water quality in the Los Angeles River and the various loads to the system.

This study was comprised of two parts. The first identified and sampled the inputs to the Los Angeles River and major tributaries. The second sampled the mainstem of the river to assess spatial distributions of water quality. The input monitoring was conducted using citizen volunteers while the spatial distribution monitoring was conducting using professionals. Visual observations were made of the outfall size and location, flow, and general characteristics (such as water discoloration; the presence of foam or oily sheens, trash or algae; and water quality). Flow was measured using either timed-volumetric or depth-velocity methods.

Water quality parameters included flow, total suspended solids (TSS), total organic carbon (TOC), biological oxygen demand (BOD5), nutrients (nitrate, nitrite, ammonia, TKN, and total phosphorous), and trace metals (cadmium, chromium, copper, iron, lead, nickel, mercury, and zinc). Sampling was accomplished on September 11, 2000 and included eight locations along the mainstem of the Los Angeles River and at the head of all seven tributaries Existing flow gages maintained by the Los Angeles County Department of Public Works provided flow information.

Table A3-3 shows the relative magnitude of the various inputs to the LA River. The majority of the dry weather flow in the river arose from the three inland POTW discharges in this watershed. In accordance, POTWs were the largest source of nutrients and some trace metals. In contrast, storm drains were the major source of bacteria and the remaining trace metals during dry weather. This preliminary sampling effort provided data sufficient to characterize the relative contributions of the major sources of pollutant loads to the system and a basis for more detailed source identification and loadings studies in the future.

Table A3-3. Total pollutant loads and the relative contributions among major sources to theLos Angeles River on September 10-11, 2000.

Constituent		Total Mass Emissions	Units	% Contribution POTWs	Tributaries	Storm Drains
Bacteria						
	E. coli	12,022	(10^9)/day	0	11	89

Ackerman, D., K. Schiff, H. Trim, and M. Mullin. 2003. Characterization of water quality in the Los Angeles River. *Bulletin of the Southern California Academy of Sciences* 102:17-25 or at ftp://ftp.sccwrp.org/pub/download/PDFs/2001_02ANNUALREPORT/08_ar08-drew.pdf.

A3.4 Elevated levels of diazinon in Bouquet Canyon Creek (Los Angeles County)

Toxicity tests conducted in late 2001 on water from Bouquet Canyon Creek documented elevated toxicity (4 – 5 toxic units). Subsequent TIEs showed the toxicity to be due primarily to diazinon, and water samples collected through late 2002 from inputs to the Creek (tributaries and storm drains) showed extremely high levels of diazinon (as high as 4000 ng/l). Following these findings, the Regional Board instructed Los Angeles County and the City of Santa Clarita to investigate the potential sources of diazinon and to eliminate any illicit discharges found.

By late November 2002, preliminary reconnaissance efforts, which included qualitative land use characterization) had identified several potential sources, including homeowner associations, exterminator companies, landscaping companies, and discharge outfalls. These efforts, including review of sales reports from hardware stores, suggested that there was no dominant single source of diazinon but, rather, that the diazinon contamination stemmed from widespread use by residents in the area. This conclusion led to the implementation of an aggressive pollution prevention approach in the area.

Monitoring continued at several key sites in parallel with the ongoing pollution prevention efforts. Monitoring data showed that, through March 2003, diazinon levels had dropped substantially (see following table), although some levels remained above the California Department of Fish and Game acute (0.08 ug/l) and chronic (0.05 ug/l) water quality criteria for diazinon.

Sample date	NR1	NR5	S2	S3	S7
08/28/02	5.698[1]	No data	4.214	No data	No data
10/16/02	0.95	3.76	1.19	0.46	0.53
11/20/02	0.20	0.02	0.17	No sample	No sample
01/14/03	0.34	No sample	0.16	0.41	0.31
02/03/03	0.05	No sample	0.04	0.08	0.08
03/05/03	0.15	No sample	0.10	0.22	0.08

[1] All data values reported as ug/l

The City of Santa Clarita is continuing with their educational outreach program, as part of ongoing pollution prevention efforts, to reduce diazinon levels to below State standards.

Information obtained from correspondence between the Los Angeles Regional Water Quality Control Board and the City of Santa Clarita.

A3.5 Elevated ammonia in Calleguas Creek stormwater flow (Ventura County)

Routine monitoring during the November 2001 detected an extremely high value of ammonia (52 mg/l) in Calleguas Creek. After the value was confirmed by reanalysis at the chemistry laboratory, Program staff conducted reconnaissance in the Calleguas watershed to attempt to identify the source of the ammonia. The reconnaissance was carried through in-person and telephone interviews to assess uses of ammonia in the watershed, which has a large percentage of agricultural land use. These interviews revealed that celery farmers typically inject ammonia into celery during wet weather to prevent the celery from becoming pithy.

Based on this information, the Program established five additional sites at the confluence of tributaries and at the inputs of major drains entering the creek from agricultural lands. This

sampling, conducted in dry weather, found no additional "hits" of ammonia. Nor did routine wet weather monitoring detect any further instances of elevated ammonia. Based on the information obtained about the use of ammonia by celery farmers, the presence of several celery farms upstream of the monitoring point, and the absence of any additional findings of elevated levels in either wet or dry weather samples, Program staff concluded that the elevated ammonia was most likely due to an unreported spill that occurred during the injection process. Because agriculture is exempt from the municipal NPDES permit, this was not pursued further.

Information obtained from personal communication with Ventura County Public Works Agency staff.

Appendix 4: Bacterial Die-off Rates in Freshwater Streams

This appendix reviews data on the inactivation of indicator microorganisms in freshwater as a basis for prioritizing sources of fecal contamination in southern California for further source identification work.

Fecal indicator bacteria, and the pathogenic organisms that they are meant to be the proxies for, have a limited ability to survive in most aquatic environments. Factors such as pH, temperature, solar (both UV and visible) irradiation, predation, osmotic stress, nutrient deficiencies, particulate levels, turbidity, oxygen concentrations, and microbial community composition affect bacteria inactivation once they reach receiving waters (Berry and Noton 1976, Mancini 1978, Kapuscinski and Mitchell 1980, Fujioka *et al.* 1981, Gerba and Bitton 1984, Auer and Niehaus 1992, Davies-Colley *et al.* 1994 , and Johnson *et al.* 1997). Indicator bacteria inactivation, that is, the rate at which the indicator bacteria die, is considered to be adequately represented by a first-order equation (see Thomann and Mueller, 1987). The first order decay rate (or inactivation) is usually referred to as k_D, and is usually reported as a per hour, or per day rate (e.g. 0.1 h^{-1}). In practice, people often use the term T_{90}, which describes the decline of bacteria in the time that it takes to obtain 90% mortality of the original number of bacteria, assuming a first-order loss. Throughout the rest of this document, the process will be referred to as inactivation, rather than decay, due to the fact that inactivation refers more specifically to the loss of the metabolic capabilities of the cell.

It is possible, with an adequate knowledge of environmental conditions, to create simple models of indicator bacteria inactivation using first order decay constants. In addition, several die-off equations can potentially be used in sequence with each other in order to estimate inputs from several stream inputs. There are existing models, like QUAL2E, that will permit the input of a particular coliform bacteria concentration, with temperature information, to estimate indicator bacteria levels downstream.

This document will outline a range of inactivation rates that could potentially be utilized to model bacterial inactivation in freshwater streams of southern California. However, it is particularly important to remember key points regarding bacterial inactivation rates, and the attempt to model such. First, even though most studies of rates of inactivation of indicator bacteria have been focused on single factors, we know that the process of inactivation is complex, and dependent upon multiple factors. For this reason, most of the studies that have been conducted in the laboratory to date should be reviewed suspiciously. Most of the studies have focused on analyzing the effects of one, two, or three factors independently (like temperature, pH, and TSS), and in doing so have ignored the biological complexities of the inactivation process. Second, solar irradiation/UV light is known to be one of the most important factors governing bacterial inactivation, and many studies have simply been conducted in the laboratory using UV lamps, ignoring the range of damage caused by visible, UV A, UV B, and UV C. Third, most studies have been conducted using laboratory strains of either *E. coli* or *enterococcus spp.* bacteria. These bacteria may not reflect the naturally found phylogenetic diversity of indicator bacteria inoculated into aquatic environments. Therefore the laboratory strains may be more susceptible to degradation than their outdoor counterparts. Finally, many different methods have been used to assess inactivation/decay/degradation. This is an issue that deserves much attention but in the interest of brevity, an example might be more useful. If two methods, membrane filtration, and chromogenic substrate kits (like Colilert-18®), were used to study rates of inactivation of *E. coli* in freshwater, the rate of inactivation determined with the use of the membrane filtration method would be much more rapid than that observed using the chromogenic substrate kits. The reason

for this discrepancy is that bacterial cells find it much more difficult, energetically speaking, to form a colony on a plate (the criteria for growth by membrane filtration), than to breakdown a growth substrate enzymatically (the criteria for growth by chromogenic substrate kits).

Given the cautions outlined above in interpreting data on bacterial inactivation, there are many useful studies that have been conducted that can be used to provide some general estimates of bacterial inactivation rates. Most studies have been conducted at a variety of temperatures, but presented here are the studies that have been conducted at temperate water temperatures that are applicable to southern California waters (ranging from 8-22° C).

One of the first things to do to understand the inactivation process is to determine whether or not sunlight will be considered in your estimates of bacterial inactivation rates. The detrimental effect of sunlight on survival of enteric bacteria in aquatic systems has been recognized for decades (Fujioka *et al.* 1981). Sunlight is capable of increasing inactivation rates by at least a factor of five compared to dark inactivation rates. Barcina *et al.* (1990) reported that EC was more resistant to damage by sunlight than *E. coli,* but Noble et al. (2003) demonstrated greater inactivation rates for EC than for *E. coli* even under low solar irradiation levels. The effect of sunlight is important to note, especially in sub-temperate latitudes such as southern California, where fluctuations in solar irradiation need to be considered. Published kD values for *E. coli* in freshwater can range from 0.03 to 0.06 h^{-1} (e.g., Barcina *et al.* 1986, Auer and Niehaus 1992, Menon 1993, and Mezrioui *et al.* 1995). However, other reports with kD as low as 0.001 h^{-1} and as high as 0.29 h^{-1} have been reported by Davies and Evison (1991), and Sinton *et al.* (2002), respectively. Obviously, different studies have revealed different rates of inactivation.

Given the concentration of the indicator bacteria of interest (C, in cfu or MPN/100 ml), an average decay coefficient (k_D, h^{-1}), a distance (D, meters or kilometers), and a stream or river velocity (U, translate into meters or kilometers per hour). An expected concentration of indicator bacteria can be calculated by:

$$C = C_0 * \exp(-k_D * D/U)$$

A general recommendation might be to assess the given conditions (high sunlight, low sunlight, etc.) and use a low rate of inactivation (conservative estimate), and a high rate of inactivation (liberal estimate) to provide a range of values of indicator bacteria that you will achieve downstream. The following table provides estimates of rates of inactivation, from several well-conducted and rigorously designed studies. Most rates of inactivation fall within the ranges observed here. In addition, the studies conducted by Noble et al. (2003) were specifically conducted in southern California waters, and so are a system specific representation of inactivation.

Table A4-1: Rates of inactivation for a range of studies.

Indicator	k_D (hr^{-1})	Notes	Reference
Total coliform	0.041-0.23	Ranges, freshwater, measured for 20° C	Thomann and Mueller, 1987
Total coliform	0.02	Riverine freshwater	Baudisova, 1997
Fecal coliforms	0.0162 0.007	Waste stabilization pond Raw sewage (conducted in the dark)	Sinton et al. 2002

Fecal coliforms	0.086 0.275	Waste stabilization pond Raw sewage (conducted in sunlight)	Sinton et al. 2002
E. coli	0.008	Natural surface water	Medema et al. 1997
E. coli	0.134	High solar radiation	Noble et al. 2003
E. coli	0.054	Low solar radiation	Noble et al. 2003
E. coli	0.001	Freshwater, dark	Davies and Evison 1991
E. coli	0.0171 0.023	Waste stabilization pond Raw sewage (conducted in the dark)	Sinton et al. 2002
E. coli	0.078 0.287	Waste stabilization pond Raw sewage in freshwater (conducted in sunlight)	Sinton et al. 2002
E. coli	0.03-0.06	Freshwater	Barcina et al. 1986,
Enterococci	0.27	High solar radiation	Noble et al. 2003
Enterococci	0.24	Low solar radiation	Noble et al. 2003
Enterococci	0.0168 0.012	Waste stabilization pond Raw sewage (conducted in the dark)	Sinton et al. 2002
Enterococci	0.276 0.137	Waste stabilization pond Raw sewage (conducted in sunlight)	Sinton et al. 2002
Enterococcus faecalis	0.016-0.038	Freshwater at 20° C	Thomann and Mueller, 1987

Appendix 5: TIE Prioritization Metric

This appendix describes the calculation of a metric for prioritizing TIEs (Toxicity Identification Evaluations) to better identify the potential source(s) of toxicity in receiving waters. As discussed in the main body of the report, the model monitoring design recommends that a full year of toxicity testing be conducted and then TIEs be performed in the subsequent year, based on the relative magnitude and persistence of toxicity at the monitoring stations. The metric described below results in a single number for each site for each year and is an approach for combining the magnitude of toxicity (measured as mortality relative to a control), the breadth of toxicity across multiple test species, and the persistence of toxicity over multiple monitoring events in a given year. The metric provides users the ability to weight each of these three components differently, depending on the nature of toxicity and the specific management concern(s). However, all sites being considered for TIEs must be evaluated with the same metric weighting in order to ensure a consistent comparison among sites.

The experimental design is illustrated below:

	Time 1	Time 2	Time 3
Species 1			
Species 2			
Species 3			

At a specific site, three different species toxicity tests are performed at three different times over the course of the monitoring year. Each cell of the design contains a measure of the strength of water toxicity. A test with no measured toxic effects is represented by a value of zero.

The index is computed as the cell average toxicity value adjusted for consistency of toxic hits within species (rows) and/or time (columns). A toxic hit is defined as a toxicity value greater than zero. The consistency of toxicity within columns (across species) is measured by a cumulative score that depends on the numbers of toxic hits in the columns. For each column with three toxic hits, 1 is added to the total score (see the tables below), and for each column with two toxic hits, ½ is added to the total score. Nothing is added to the total score for 0 or 1 toxic hits in a column. A similar total score based in toxic hits in the rows is computed for consistency within rows.

Variables used to compute the index value are:

C_{col} = the column consistency score,

C_{row} = the row consistency score,

A_{col}=percent adjustment for column consistency,

A_{row}=percent adjustment for row consistency, and

M=the mean of all cells.

The index is computed as

$$I = M\left(1 + \frac{A_{col}}{100}\frac{C_{col}}{3} + \frac{A_{row}}{100}\frac{C_{row}}{3}\right). \qquad (1)$$

The value 3 in equation (1) is the maximum consistency score for rows (C_{row}) or columns (C_{col}). Thus, when the consistency score is maximal, the full percent adjustment (A) is added to the value in the parentheses, and lesser amounts are added for less than maximal scores. The values of 100 in equation (1) convert the adjustment percents to proportions.

It can be seen that equation (1) is the cell mean with upward adjustments for consistency within rows or columns. The user must decide what percent adjustment of the cell mean will be associated with the maximum score for both rows and columns. For example, if the user wants to emphasize consistency of toxicity across species at the same time, the user could set A_{col}=30 and A_{row}=0, which will adjust the cell mean upward by 30% for maximal within-column consistency, and ignore within-row consistency. Some example calculations with these A values are provided for below.

Example data with minimum within-column consistency might be as follows:

	Time 1	Time 2	Time 3	# hits
Species 1	30	40	20	3
Species 2	0	0	0	0
Species 3	0	0	0	0
# hits	1	1	1	

The calculations for these data with A_{col}=30 and A_{row}=0 are shown in equation (2).

$$I = M\left(1 + \frac{A_{col}}{100}\frac{C_{col}}{3} + \frac{A_{row}}{100}\frac{C_{row}}{3}\right) = 10\left(1 + \frac{30}{100}\frac{0}{3} + \frac{0}{100}\frac{1}{3}\right) = 10 \qquad (2)$$

Example data with some within-column consistency might be as follows:

	Time 1	Time 2	Time 3	# hits
Species 1	30	0	0	1
Species 2	40	0	0	1
Species 3	20	0	0	1
# hits	3+1	0	0	

The calculations for these data with A_{col}=30 and A_{row}=0 are shown in equation (3).

$$I = M\left(1 + \frac{A_{col}}{100}\frac{C_{col}}{3} + \frac{A_{row}}{100}\frac{C_{row}}{3}\right) = 10\left(1 + \frac{30}{100}\frac{1}{3} + \frac{0}{100}\frac{0}{3}\right) = 11 \qquad (3)$$

Note that the index value for the data used in equation (3) is higher than the index value for the data used in equation (2). This is because the equation (3) data have more within-column consistency and the A values were set to emphasize the within-column consistency. A more dramatic difference between the two index values would have resulted if a higher value for A_{col} was used.

It is important to stress that the intended use of the index (I) values is to help prioritize stations for follow-up TIEs. Thus, stations with higher index values would be a higher priority when allocating a fixed amount of resources for TIEs.

Technical Report #420

TABLE OF CONTENTS

1.0 INTRODUCTION

One goal of the southern California Stormwater Monitoring Coalition (SMC) is to compile monitoring data from separate programs to make region-wide assessments. This task has been difficult, thus far, because the various monitoring programs have differing project goals and objectives, differing mandates from regulatory agencies, differing sampling designs, and differing laboratory analytical methods. The goal of this document is to increase the comparability among stormwater monitoring agencies by minimizing the differences in results due to laboratory analysis. The comparability issues that revolve around goals, objectives, and study designs are being addressed through a related, but separate document.

There are at least three reasons that laboratory analytical data are not comparable including differences in target analytes, reporting levels (detection limits), and laboratory methods. Reviews of the current monitoring programs have identified some of the difficulties in laboratory analysis (Ackerman and Schiff, 2003). First, some monitoring programs measure as few as 32 analytes while others measure as many 128 analytes. Second, the range in reporting levels can vary by more than an order of magnitude among programs for some constituents. As an example, one program had a reporting limit for zinc of 5 µg/l while for another it was 50 µg/l. As a result, the frequency of non-reportable quantities was approximately 5% and 20% for each of the programs, respectively. To date, no one has attempted to compare the laboratory procedures among laboratories to assess any bias associated with this analytical component.

Many of these obstacles have been surmounted through the intercalibration studies of the SMC (Appendix A). This intercalibration study, which was conducted with most of the major laboratories currently analyzing stormwater samples throughout the region (Table 1), was aimed at developing a consensus based approach for achieving minimal levels of comparability among typically disparate laboratories. The success of this study was primarily due to three factors including communication and commitment among laboratory personnel, setting performance-based criteria for establishing standards of success, and round robin testing using locally derived reference materials. This was the same model that was used in developing consistency among laboratories that conduct marine monitoring in the southern California region (Noble *et al* 2002 and Gossett *et al* 2003).

1.1 Objectives and Goals of this Document

The objective of this guidance manual is to capture the performance-based guidelines established during the SMC intercalibration studies for ongoing analysis of stormwater samples for municipal agencies throughout southern California. The goal of this document is to set minimum standards of sensitivity, precision, and accuracy across laboratories so that individual data sets can be combined with estimated levels of confidence for making regional assessments of stormwater quality. The philosophy of performance-based guidelines is key to achieving this comparability. Although every laboratory involved in the stormwater intercalibration study was certified by the State of

California Environmental Laboratory Accreditation Program (ELAP), inventories of existing methods demonstrated that most analytes were not analyzed in exactly the same manner across all laboratories. This will continue as new laboratories, or new equipment at existing laboratories, continue to proliferate. Rather than mandate specific methods that are inflexible and discourages existing laboratories to achieve faster, more sensitive, and more inexpensive methods, this document merely sets minimum levels of comparability so that data sets can be combined no matter what technology currently exists. In a few cases, the workgroup experimentally demonstrated that greater specificity of sample preparation procedures maximized comparability. These procedures are also outlined herein.

This guidance manual is a living document. It should be revisited each time an intercalibration exercise is conducted and can be expanded to include additional constituents, additional laboratories, or to refine the recommended performance-based sensitivity, accuracy, and precision requirements as new information becomes available.

This document and laboratory intercalibration study is not a certification program. The guidelines set by this document merely express the desired needs of the stormwater agencies throughout the southern California region. Therefore, these stormwater agencies may wish to use these guidelines in establishing specifications for work assignments or requests for proposals to conduct stormwater analyses. Alternatively, or in combination, stormwater regulatory agencies may use these specifications in the development of regulatory expectations for laboratory performance by monitoring agencies.

2.0 GUIDANCE INFORMATION

This document consists of four elements. First is a list of target analytes and minimum levels of sensitivity (reporting levels). Second are minimum levels of accuracy and precision. Third are recommended protocols for method specific comparability. Fourth are participation requirements for intercalibration studies.

2.1 Analytes and Reporting Levels

2.1.1 Target Analytes

A core group of target analytes was specified for comparability (Table 2). This list includes total suspended solids (TSS), nutrients, and trace metals. This list was based on three criteria. First, these analytes are consistently measured by the existing monitoring programs throughout the region. Second, these constituents are routinely detected in stormwater samples. Third, although standard methods exist, there is sufficient disparity in protocols among laboratories that consistency guidance is warranted.

The list of target analytes is not meant to be an exhaustive list of all constituents that could or should be measured in individual programs. For example, there are no pesticides, herbicides, or polynuclear hydrocarbons on the list of target analytes. Any or all of these target analytes may be the focus of individual monitoring programs. At this point in time, however, there has not been an intercalibration study conducted for these constituents to make performance-based recommendations for stormwater laboratories.

While the list of target analytes focuses on total trace metals, they can be applied to dissolved trace metals. Since the analytical methodology is similar among both total and dissolved metals, the performance-based guidelines may be applied to both.

2.1.2 Reporting levels

Targeted reporting levels (RLs) are provided in Table 2. This guidance was based on the philosophy that analyses should be sufficient to assess if samples are below water quality thresholds of concern. In this instance, the water quality thresholds of concern are established in the California Toxics Rule (CTR). Further, reporting levels should be technologically achievable, but far enough below water quality thresholds that exceedences cannot be attributable to methodological uncertainty. Therefore, the philosophical approach for selecting RLs was to select guidelines that were one-half of the lowest water quality threshold. In the case of the CTR, there are thresholds for both marine and fresh waters. For a participating laboratory to achieve these reporting levels, it should include a calibration standard at or below this level (e.g. the reporting level is a quantitation level and not an MDL).

Table 2. Target analytes and Reporting Levels for the Stormwater Monitoring Coalition Monitoring Program.

Analyte	SMC Target Reporting Level	California Toxics Rule Limit (Freshwater)	California Toxics Rule Limit (Seawater)	Units
General Constituents				
TSS	5	-	-	mg/L
Nitrate+Nitrite as N	0.2	-	-	mg/L
Ammonia as N	0.1	-	-	mg/L
Total Phosphorus as P	0.1	-	-	mg/L
Total Kjeldahl Nitrogen	0.2	-	-	mg/L
Total Organic Carbon	1	-	-	mg/L
		-	-	
Total Metals				
Arsenic	2	150	36	µg/L
Cadmium	1	2.2	9.3	µg/L
Chromium (total)	5	11	50	µg/L
Copper	2	9	3.1	µg/L
Nickel	4	52	8.2	µg/L
Lead	1	2.5	8.1	µg/L
Selenium	2	5	71	µg/L
Silver	1	3.4	1.9	µg/L
Zinc	10	120	81	µg/L

2.2 Accuracy and Precision

2.2.1 Laboratory Intercalibration Studies

Intercalibration studies evaluate the accuracy and precision of analysis among laboratories. For this document, interlaboratory precision guidelines were developed by analyzing one set of three replicate samples for each of three matrices by eleven different laboratories throughout southern California (Appendix A). These matrices included a specially-prepared performance evaluation (PE) sample, an urban runoff sample, and a rural runoff sample (Table 3). Each of the laboratories demonstrated competence with the easiest of matrices, the PE sample. Interlaboratory variability increased with the more difficult stormwater matrices, but iterative intercalibrations focused on understanding and minimizing the source of variability. This improved laboratory comparability until it approached the variability associated with the PE sample (i.e. 25% CV among labs).

Unlike the PE sample where the concentrations are known, the runoff samples contained unknown levels of constituents so assessing accuracy and precision becomes more

difficult. A population-based estimator was used to assess meaningful differences for interlaboratory variability similar to the approach used by Gossett et al (2003). Acceptable performance for the simulated rainfall samples was achieved if the results were within ± 2 standard deviations of the mean for the pooled results. Population-based estimators provide an unbiased method for assessing extreme variability; at least 90% of all laboratories will pass this guideline if the variability is normally distributed. The actual guidelines established from the intercalibration exercises during 2003 are shown as an example in Table 3. Each subsequent intercalibration exercise will result in specific numerical guidelines that will likely differ from those in 2003 since different runoff samples will be used. It should also be noted that some parameters were more precise than others. Data users should recognize that these ranges represent the current "state-of-the-art" for accuracy of routine analytical conditions in laboratories analyzing stormwater samples.

Table 3 Laboratory replicate analysis data quality objectives (DQOs) for Accuracy.

		ERA[a]			LU[b]			LR[c]

2.2.2 *Ongoing Analyses*

Reproducibility among replicate sample analyses provides a determination of within laboratory precision. Analysis of spiked samples or reference materials provides a mechanism for assessing within laboratory accuracy. General guidance provided by the ELAP and the US EPA (40 CFR 136) are recommended for assessing within laboratory precision and accuracy on an ongoing basis. Laboratories should assess ongoing precision by analyzing two replicate sample matrix spikes per sample batch of 20 samples or less. It is also recommended that a set of laboratory replicate samples are analyzed with each batch of samples to indicate precision using actual sample matrices as compared to spikes. The relative percent difference (RPD) between these replicate analyses and replicate spikes should meet the guidelines specified in Table 4 for results that are at least 10 times the RL, unless the samples are grossly contaminated. If samples contain such large quantities of contaminants that the laboratory feels the MS/MSD results can not be reasonably met, then a detailed case narrative should accompany the analytical results. RPD criteria are not specified for concentrations less than 10x the RL because the variability increases significantly as you approach the RL.

Table 4. Laboratory precision guidelines for ongoing analysis of stormwater samples

Analyte	RPD Limits for Results >10x the RL
General Constituents	
TSS	0-20%
Nitrate-N+Nitrite-N	0-20%
Ammonia-N	0-20%
Total Phosphorus as P	0-20%
Total Kjeldahl Nitrogen	0-20%
Total Organic Carbon	0-20%
Metals, Total	
Arsenic	0-20%
Cadmium	0-20%
Chromium (total)	0-20%
Copper	0-20%
Nickel	0-20%
Lead	0-20%
Selenium	0-20%
Silver	0-20%
Zinc	0-20%

Accuracy of the method used is defined as the degree of difference between observed values and true values from the analysis of certified or standard reference materials, matrix spikes, or blank spikes. The extent to which it will be a good measure of accuracy depends on the complexity of the selected matrix; stormwater matrix is typically a very complex mixture of

unknown constituents and potential interferences. Therefore, these guidelines recommend ongoing analysis of a Matrix Spike (MS) and Matrix Spike Duplicate (MSD) for all parameters except Total Suspended Solids (TSS) on a once per batch of 20 or less samples. For TSS, a Certified Reference Material is recommended for testing accuracy since spike samples for this parameter are infeasible. Accuracy limits for MS and MSD are provided in Table 5. These accuracy limits mimic ELAP and US EPA guidelines. Accuracy limits for Certified Reference Materials are provided by the supplier.

Table 5. Laboratory accuracy guidelines for ongoing analysis of stormwater samples.

Analyte	Percent Recovery Limits for MS/MSD results with concentrations > 10x the RL
General Constituents	
TSS	-[a]
Nitrate-N+Nitrite-N	80-120%
Ammonia-N	80-120%
Total Phosphorus as P	70-130%
Total Kjeldahl Nitrogen	70-130%
Total Organic Carbon	80-120%
Metals, Total	
Arsenic	80-120%
Cadmium	80-120%
Chromium (total)	80-120%
Copper	80-120%
Nickel	80-120%
Lead	80-120%
Selenium	80-120%
Silver	80-120%
Zinc	80-120%

[a] defined by supplier of CRM

Additional QAQC requirements listed in the methods referenced by each laboratory should conform to the requirements listed within that method by Standard Methods or the US EPA (i.e. Blank Spikes). Since spiked samples can be complicated by matrix interferences and this can confound assessments of accuracy, the analysis of a Certified Reference Material is also a recommended option for the monitoring agency.

3.0 STANDARDIZATION

Although this document is founded on performance-based guidelines enabling flexibility within each laboratory to achieve consistency, the laboratory intercalibration studies have identified four protocols whereby recommended standardization can dramatically increase comparability. This standardization includes sub-sampling, Total Phosphorus digestion, TKN digestion, and trace metal digestion techniques.

3.1 Sub-sampling Techniques

Sub-sampling techniques are an important component of both within and among lab variability. This was especially true for particle-laden samples, such as those from more rural catchments with unlined channels. Particle-bound constituents have the potential to be dramatically biased if sub-sampling techniques selectively target or avoid particles within samples. To this end, standardized laboratory techniques for sub-sampling were developed for splitting large volume stormwater samples collected in the field into smaller bottles for distribution to the laboratory and for subsequent sampling of smaller aliquots in the laboratory at the time of analysis.

3.1.1 Sub-sampling of large volume field samples (courtesy of Kinnetic Laboratories)

In order to ensure that sample containers destined for an analytical laboratory all contain water that is similar and representative of the original composite sample, it is important to maintain a well-mixed composite sample during sub-sampling and to prevent stratification and the settling out of heavier particles. This is accomplished by the use of a large-capacity stirrer and a 2 to 3-inch, pre-cleaned, Teflon-coated stir bar; larger stir bars can be used for larger volume containers. Adjustment of stirring speed is important. Speeds that are too fast will create a large vortex within the composite bottle that can actually concentrate heavier particles and should be avoided. Speed should be based on a visual assessment of the most even mixing throughout the composite bottle.

Sub-sampling from the homogenized composite bottle is accomplished using a peristaltic pump and pre-cleaned (inside and outside) sub-sampling hose. Filling sample containers by pumping from the composite bottle is best performed by two people. One person is responsible for filling individual sample containers and one person is responsible for constantly moving the intake tubing up and down in the water column of the composite sample. Based on experimental evidence, this up and down movement of the intake is a procedure that helps obtain a more representative sub-sample. This is because there can still be some stratification of heavier particles in the composite sample despite the mixing created by the stirrer. The up and down movement of the intake tubing should be limited to approximately 80-90 percent of the depth of the water column and should never touch the bottom of the composite bottle.

3.1.2 Sub-sampling of sample containers for analysis

The goal of sub-sampling bottles in the laboratory for analysis is similar to field sampling techniques, to maintain a homogeneous particle distribution. Analysis of particle-associated constituents will be biased if non-representative particle suspensions are used for analysis. In order to maintain homogeneous particle distributions, we recommend the use of sub-sampling techniques described by the US Geological Survey (Charles J. Patton, USGS National Water Quality Laboratory, Denver, CO). Appropriately, a similar technique to large container sub-sampling is used (Section 3.1.1). Briefly, a "+" shaped magnetic stirring bar is placed into the sample container and the sample is stirred while a sub-sample is aspirated and dispensed into the processing container.

3.2 Total Kjeldahl Nitrogen

Total Kjeldahl Nitrogen analysis was affected by the digestion technique during the laboratory intercalibration exercise. This was due to the influence caused by particle content and size distribution. Therefore, minimum standardization of the digestion procedure is recommended. Either micro or macro Kjeldahl digestions are acceptable. However, the length of time of digestion should be set at a minimum of 1 hour at 380°C, until copious fumes are generated and the digestion solution turns yellow, and then for an additional 30 minutes (to ensure adequate recovery) prior to analysis.

3.3 Total Phosphorus

Total Phosphorus analysis was also affected by the digestion technique during the laboratory intercalibration exercise. Therefore, minimum standardization of this digestion procedure is also recommended. The US Geological Survey National Water Quality Laboratory compared several digestion techniques using our simulated stormwater sample. These results suggest that the Kjeldahl digestion and acid persulfate digestions were higher than the alkaline persulfate digestions. However, most of the laboratories in both rounds of the intercalibration exercise used the acid persulfate digestion and the results were still quite variable. Kjeldahl digestion may reduce this variation because it is more rigorous, but this technique has not been tested by the SMC laboratories and is not presently an approved technique. Therefore, we are recommending that an acid persulfate digestion be used until this issue can be resolved during the next intercalibration exercise.

3.4 Trace Metals

Trace metal analysis was also affected by the digestion technique during the laboratory intercalibration exercise. This is because trace metal concentration may be influenced by particle content and size distribution. Therefore, minimum standardization of trace metal digestion is recommended. Trace metals should be digested using a nitric/hydrochloric acid digestion at 95°C for 2-4 hours until the sample has evaporated from 50mL down to 10mL.

Dissolved metals analysis should be performed on filtered samples and do not require digestion if the Turbidity is < 1. Sample spiking for the Matrix Spikes should be done prior to filtering. All other criteria for trace metals in this guidance document are applicable to both total and dissolved metals.

4.0 PARTICIPATION REQUIREMENTS

4.1 Proficiency Testing

The SMC recommends laboratories performing analyses for Stormwater Monitoring Programs pass a SMC performance evaluation (PE) sample and participate successfully in SMC intercalibration exercises. The PE and intercalibration exercises are strongly recommended to be performed on an annual basis. This frequency is recommended because: 1) new laboratories may wish to participate; 2) existing laboratories need to evaluate new personnel; and 3) new and existing laboratories with new equipment or altered laboratory techniques need to be evaluated. Intercalibrations must occur within the first six months of the calendar year to ensure evaluation prior to the following wet season that typically begins on October 15th .

SMC PE samples are to be spiked between 1 and 10 times the established reporting limit (Table 2) for the analytes of concern for minimum proficiency. All sample results must meet the criteria provided by the commercial supplier of the sample to evaluate accuracy. PE samples are to be coordinated through the SMC, or their representives on a Chemistry subcommittee, and can be purchased from private company such as Environmental Resources Associates, Inc (ERA), Wibby Environmental, APG, or other proficiency test sample providers.

Intercalibration studies require laboratories to analyze three replicates of two runoff samples, one from an urban and one from a rural catchment. Each intercalibration study should be performed with two iterations to evaluate consistency and allow for laboratory corrective actions if deficient analysis resulted from the first iteration. Sample results must fall within ± 2 standard deviations of the mean of the pooled results as determined by the Chemistry Committee (see Section 2.2.1).

4.2 New Laboratories

New labs that have not participated in previous intercalibration exercises may still be able to analyze stormwater samples during the present wet season. These labs, however, will need to provide resources to purchase a PE sample with the same requirements used in the intercalibration study in Section 4.1 (i.e. samples will be spiked at 1 to 10 times the established reporting limit in Table 2). These samples must be delivered to the new laboratory blind and as whole volume samples. All new laboratories are required to participate in the next intercalibration exercise to remain qualified for the SMC program.

5.0. DEFINITIONS

Batch – An analytical batch consists of 20 or fewer client samples.

Method Blank (MB) – Analyte free water that is carried through the entire analytical process. The method blank is used to evaluate contamination contributed from the method. Analyte detections in the method blank must be less than 10x the analyte result for a client sample to be considered usable without flagging.

Duplicate – A client sample analyzed in duplicate. Duplicate RPD should be summarized in the report.

Blank Spike/Blank Spike Duplicate – A blank spike (laboratory control sample) is a certified standard reference material that is spiked into a reagent blank. It is carried through all steps of sample preparation to demonstrate method performance inclusive of sample preparation steps. The blank spike should be spiked near the mid point of the calibration curve.

Matrix Spike/Matrix Spike Duplicate – A matrix spike is a regular sample that is split into three sub-samples. Two of the replicates are spiked with analyte solution at the same concentration and are defined as the matrix spike and matrix spike duplicate (MS/MSD). The MS/MSD samples are carried through the sample preparation and analysis procedure with each batch of 20 or less samples. The MS/MSD results provide information regarding laboratory precision, sample matrix effects, and method efficiency.

RPD- Relative Percent Difference is calculated using the following formula:

$$RPD = (Result1 - Result2)/((Result1 + Result2)/2)*100$$

January 30, 2003

ABSTRACT

Despite spending large resources on monitoring in southern California, stormwater agencies lack the ability to assess cumulative runoff inputs, make comparisons among watersheds in different counties, or efficiently track trends in stormwater concentrations or loads at regional spatial scales. Data compilation among the various monitoring programs is due to a lack of comparability in their lists of target analytes, methods used for measuring these constituents, varying levels of sensitivity (i.e. detection and reporting limits), and unequal levels of quality assurance and quality control. The goal of this study was to quantify the comparability of chemical analysis among multiple analytical laboratories for a standard list of constituents to be measured in stormwater runoff. In order to accomplish this goal, all of the laboratories that conduct analysis of stormwater samples for large municipalities throughout the region were given three types of samples (in triplicate) including a reference sample, a runoff sample from an urban catchment, and a runoff sample from a rural catchment. Most laboratories performed well on the reference material, typically reporting results less than 20% different from the true value. The more challenging urban runoff sample generated greater interlaboratory variability. The coefficient of variation (CV) averaged 20% for nutrients (NH3-N, NO2+NO3, TKN, Total P) and 38% for trace metals (arsenic, cadmium, chromium, copper, lead, nickel, selenium, silver and zinc). The greatest interlaboratory variability was for the rural runoff sample, which averaged 56% CV for both nutrients and trace metals. The greater variability in the runoff samples was attributable to increasing particulates; mean TSS ranged from <0.1 mg/L in the reference material to 3,200 mg/L in the rural runoff sample. After standardizing methods for potential subsampling bias and digestion efficiencies, interlaboratory precision improved with the re-analysis of the rural runoff sample.

INTRODUCTION

Municipal stormwater agencies expend remarkable effort monitoring the water quality of wet and dry weather discharges and their impacts in Southern California aquatic ecosystems. Schiff et al. (2002) estimated that the four coastal stormwater management agencies spend nearly $2M annually on monitoring circa 1997. At that time, the majority of monitoring costs arose from sampling storm events and measuring an array of chemical constituents. These results were then used to estimate mass emissions of these constituents from urbanized watersheds, compare concentrations to water quality thresholds, and identify potential pollutant-related impacts to receiving waters.

Despite this relatively large effort in Southern California, integrating stormwater monitoring data among these programs is difficult. Schiff (1997) attempted to use these monitoring data to make multi-county, regionwide assessments of stormwater loading. Several factors limited the ability to compile data including both sampling and laboratory parameters. Specifically for laboratory parameters, programs lacked comparability in their lists of target analytes, methods used for measuring these constituents, varying levels of sensitivity (i.e. detection and reporting limits), and unequal levels of quality assurance and quality control.

These differences are likely the result of a monitoring focus on site specific needs, rather than an attempt to integrate individual programs to assess cumulative runoff inputs, make comparisons among watersheds, efficiently track trends in stormwater concentrations or loads at regional spatial scales or find ways to reduce monitoring redundancy thereby increasing efficiency. Most runoff monitoring is mandated by the National Pollutant Discharge Elimination System (NPDES) administered by the state and/or federal government. In the case of southern California, there are at least 11 different municipal stormwater NPDES permits distributed across seven counties and three state regulatory agencies. The regulatory jigsaw puzzle, which typically follows jurisdictional boundaries and not watershed boundaries, has (at least in part) led to the widely varying monitoring programs we see today.

The goal of this study was to assess the comparability of laboratory analysis among multiple analytical laboratories for a standard list of constituents to be measured in stormwater runoff. In order to accomplish this goal, we gathered all of the laboratories that conduct analysis of stormwater samples as part of the NPDES monitoring programs for large municipalities in southern California. The objective was to determine if comparability among these laboratories was sufficient, or could be reasonably altered, to enable the compilation of data sets among individual monitoring programs to make regionwide assessments.

METHODS

The intercalibration for stormwater samples was conducted with the 11 most active laboratories in southern California that perform analyses in this matrix (Table 1). All but one of these laboratories are privately-held firms. The laboratories proceeded through a three-step process following a similar study by Gossett et al (2003): 1) create an inventory of existing methods and protocols; 2) conduct an intercalibration study to assess comparability; and 3) conduct iterative studies to improve comparability.

The core set of target analytes selected for intercalibration included total suspended solids (TSS), nutrients, and trace metals. This list was based on three criteria derived from the inventory. First, these analytes were consistently measured by the existing monitoring programs throughout the region. Second, these constituents were routinely detected in stormwater samples. Third, although all of the laboratories used standard methods (Table 2 and 3), there was sufficient disparity in protocols among laboratories that comparability examination was warranted.

Three types of samples were distributed to each of the participating laboratories for step 2 in the intercalibration study. The first sample was a reference material with known concentrations (Environmental Resources Associates, CO). This sample, prepared in the easiest of matrices, was selected because it provided a minimal base of comparison without confounding factors inherent in a stormwater runoff matrix. The second sample was runoff from an urban catchment, which was comprised of a parking lot (approximately 36 m^2) that received primarily weekday use. The third sample was runoff from a rural catchment comprised of undeveloped Mediterranean scrub/chaparral landscape (approximately 42 m^2) in the Santa Monica Mountains National Forest. These two runoff samples were selected because they represent the range of sample matrices that might be encountered by any of the laboratories as part of their stormwater monitoring programs. There was no attempt to standardize methods among labs prior to analysis of these three samples for step 2.

Simulated rainfall was used to generate runoff from the urban and rural sites for this study. Rainfall was simulated following Tiefenthaler and Schiff (2003) using distilled water and applied using a low flow spray nozzle attached to a battery operated pump. Rainfall continued until sufficient runoff was collected (approximately 50L) in a large volume container. Subsamples from this large composite sample were placed in smaller containers for shipment to the individual laboratories. A sufficient number of subsamples were collected so that three replicate bottles, selected at random, were sent to each lab on ice within 24 hours. In order to ensure that subsample containers destined for analytical laboratories all contained samples that were similar and representative of the original composite sample, a 3-inch "+" stirring bar was used during subsampling to prevent stratification and the settling of heavier particles. Stirring speed was adjusted so that no vortex was created and subsamples were collected using a peristaltic pump with an intake that was raised and lowered through the water column of the composite sample bottle during pumping. At no time did the pump intake touch the bottom of the composite bottle.

Step 3 of the intercalibration was an iterative analysis for those constituents that appeared to be problematic in step 2. The iterative analysis focused on particulate associated constituents (TKN, Total P, and trace metals). Two specific changes were made between steps 2 and 3. First, each laboratory was supplied with the exact volumes needed for digestion and analysis so no subsampling of the laboratory containers was needed. Since different laboratories used differing volumes, particles were collected dry from the same urban and rural sampling sites and weighed to create samples with identical TSS concentrations. The collected particles were dried (60C for 24 hrs) and thoroughly mixed to ensure representative distribution, then brought to the appropriate volume with distilled water. The premeasured sample containers were randomly selected and shipped in triplicate to each of the analytical laboratories on ice within 24 hours. The second specific change was standardization of digestion methods for trace metals. All labs digested their trace metal samples using nitric/hydrochloric acid at 95°C for 2-4 hours until the sample evaporated from 50mL down to 10mL.

Data analysis for this study required three steps. The first step was to identify the characteristics of the three different samples used in the study. To accomplish this evaluation we examined the mean concentration of each constituent for all laboratories combined. The second step was to identify the interlaboratory variability for each sample independently. To accomplish this comparison, we examined the coefficient of variation (CV) cumulatively for all constituents, by class of constituents (general constituents and trace metals), and by individual constituent. For the reference material, we also examined accuracy since we knew the true value *a priori*. The third step was to identify if interlaboratory variability improved in subsequent iterations as a result of standardization in subsampling and digestion techniques. To accomplish this evaluation, we compared the CV in the first and second iteration for the rural runoff sample on a constituent -by- constituent basis.

RESULTS

The reference material, the urban runoff, and the rural runoff samples had varying levels of target analytes (Table 4). For example, the reference material consisted of distilled water spiked with dissolved components (i.e. no TSS), while the TSS from the urban sample averaged 74 mg/L and the TSS from the rural sample averaged 3200 mg/L. The mean concentrations of NO2+NO3-N, TKN, TOC, copper, lead and zinc were lowest in the reference material. In contrast, the rural runoff sample had the highest mean concentrations of NO2+NO3-N, TKN, Total P, arsenic, cadmium, chromium, copper, nickel and lead. Finally, the urban runoff sample had mixed results compared to the reference material or rural runoff samples. The urban runoff sample had the highest concentrations of NH3-N, TOC, and zinc, but had the lowest concentrations of Total P, arsenic, cadmium, chromium, nickel, and selenium.

Analysis of the reference material demonstrated that, on average, the laboratories performed quite well with this type of sample (Table 5). The mean concentration for all

laboratories was less than 5% different from the true value for NH3-N, NO3+NO2-N, Total-P, arsenic, cadmium, chromium, nickel, selenium, silver, and zinc. TKN, copper, and lead were greater than 5%, but still less than 25% different from the True Value. In addition, the interlaboratory variability was reasonably precise. The CV among labs ranged from 9 to 42% (depending upon the constituent), averaging 12% for all constituents combined. The precision was better for general constituents (average CV of 7%) compared to trace metals (average CV of 22%).

The laboratories had mixed success with the comparability of nutrient and trace metal results in the urban runoff sample (Table 6a). The range of precision for the 10 laboratories varied between eight and 79% CV, averaging 32% CV for all constituents combined. Laboratory precision was slightly better for the general constituents (average of 20% CV) compared to trace metals (average of 38% CV). The greatest interlaboratory variability for general constituents was observed for NH3-N and Total P. This variation could be reduced with the removal of one or two data points (i.e. lab C for NH3-N or lab E for Total P). Where trace metal concentrations were routinely detectable, interlaboratory comparability was reduced. The range of precision for the 10 laboratories varied from 13% CV for copper to 55% for lead. Once again, much of the variability was attributable to one or two labs (i.e. lab H for lead).

The interlaboratory precision decreased in the rural runoff sample (Table 6b). The range of precision for the 10 laboratories varied between eight and 169% CV, averaging 56% CV for all constituents combined. Laboratory precision was similar for the general constituents (average of 57% CV) compared to trace metals (average of 56% CV). The greatest interlaboratory variability for general constituents was observed for NH3-N and TKN. Once again, some laboratories stood out as distinctly different (i.e. lab C for NH3-N). Even with the removal of this potential outlier, the resulting precision was poor (45% CV) most likely due to its relatively low levels (two labs were non-detectable). The Total P concentrations, in contrast, ranged from 1.1 to 3.5 mg/L with a relatively even distribution among labs. Where trace metal concentrations were routinely detectable, interlaboratory comparability still averaged 56% CV. The greatest interlaboratory variability was arsenic (80% CV) and the least was for cadmium (24% CV). In this instance, we found that three labs were routinely lower for many metals (i.e. labs F, H, and J), while another four were routinely higher than the grand mean (labs A, C, G, and I).

Improvements in sub-sampling and adjustments to digestion techniques resulted in improved comparability among laboratories for analysis of the simulated rural runoff sample (Figure 1). Despite decreases in concentration of 50 to 75% for each of the constituents (Table 4), precision increased in seven of the 10 constituents evaluated in the rural runoff sample. For two of the constituents where precision decreased, the differences between the two iterations were marginal (cadmium, and lead). These two constituents had the greatest precision of all the trace metals in the first iteration. The most noticeable lack of increased precision was for Total P where concentrations ranged from less than 0.1 to 0.57 mg/L among laboratories.

DISCUSSION

This study demonstrated that, in general, a performance-based approach could be an effective mechanism for ensuring comparability among multiple labs conducting stormwater analysis. All of the laboratories used in this study were using standard methods, but none of the laboratories were using exactly the same protocols. This is because standard methods allows for flexibility in methods and analytical techniques. Despite these differences, we could reach a level of precision among labs that approached the precision expected within a lab.

The largest hurdles to accomplishing regional scale comparability was performing intercalibration studies on the typical matrices that might be encountered, which for stormwater runoff is often very complex. All of the laboratories performed well on samples conducted in the easiest of matrices; the reference material was comprised of a very clean matrix. Other than the fact that we used relatively low levels of spiked compounds, these samples are no different than the ongoing Performance Evaluation standards they receive from the US EPA or are used by the State of California for laboratory accreditation. The key to success for this study was the use of runoff samples for intercalibration. Runoff samples are inherently turbid with many potential interferences. We found that the presence of particulates was amongst the most confounding factors in the comparability among laboratories. In fact, the greater the particulate concentration, the more dissimilar the intercalibration results became. The presence of particulates, though, is the nature of stormwater runoff samples. TSS concentrations throughout southern California range from 1 mg/L to 8,700 mg/L and averages near 300 mg/L (Ackerman and Schiff 2003).

We do not think that the increased interlaboratory variability we observed for the runoff samples with particulates was a result for poor subsampling and distribution among the participating laboratories. Conservative tracers such as TSS, TOC, pH, and conductivity indicated that the samples were relatively well-mixed prior to sample distribution. For example, TSS results from the urban runoff sample varied, on average, by 4% CV for all laboratories combined; four laboratories were within 1 percent of the overall mean. Similarly, laboratories were within 5% CV for the highly turbid rural runoff sample.

The presence of particulates confounds laboratory comparability, especially for particle-bound constituents such as trace metals and some nutrients. There were two sources of variability examined in this study. The first was inconsistent sub-sampling techniques in the laboratory that will lead to differences in particulate concentrations and ultimately to different overall concentrations. The second source of particulate-associated variability was differences in digestion technique. More rigorous digestions will liberate more constituent and ultimately lead to differences in total concentrations. Although these two factors weren't altered independently, this study found that they cumulatively contribute to overall variability in highly turbid samples like rural runoff. Based on these findings, recommendations for standardizing subsampling and digestion techniques for trace metals and TKN are warranted. Increased comparability for Total P, however, was not

achieved through improved sub-sampling and further work on standardizing laboratory procedures for this constituent will likely be needed for this constituent.

There were several intangible effects from the intercalibration study that will enhance comparability region-wide. Studies such as these foster communication among laboratories. While not a hard and fast rule, many laboratories savored the communication with their peers, which often does not happen in a competitive market like laboratory analysis. The communication about methodological details helped elucidate differences among methods, even though all were certified by the State and were following standard methods. Much of this communication was fostered in the early stages of the study as they helped develop the design of the study and the process by which they were going to be evaluated. Involvement in the process led to vestment on the part of the laboratories in not just passing a performance evaluation sample, but improving their overall laboratory performance on an ongoing basis. The final factor that helped ensure success was recognizing the end use of the data they were generating. Traditionally, laboratories in southern California have not attempted to become regionally consistent because no one has suggested that regional application of the data was needed. While most laboratories can treat samples as commodity-based work, laboratory personnel are typically well-trained scientists and recognize the effort attributable to data end users.

Technical Report 521

TABLE OF CONTENTS

INTRODUCTION

A continuing goal of the southern California Stormwater Monitoring Coalition (SMC) is to compile monitoring data from separate programs to make region-wide assessments. This task has been difficult, thus far, because the various monitoring programs have differing project goals and objectives, differing mandates from regulatory agencies, differing sampling designs, and differing laboratory analytical methods. The goal of this document is to provide the basis for ensuring comparability among stormwater chemical analytical laboratories. The comparability issues that revolve around goals, objectives, and study designs were addressed through a related, but separate document (Bernstein and Schiff, 2003).

There are at least three reasons why laboratory analytical data are not comparable including differences in target analytes, reporting levels (detection limits), and laboratory methods. In 2003, a laboratory intercalibration study sponsored by the SMC established common reporting levels, target analytes, and iterative round robin exercises that surmounted many of these obstacles (Gossett, Renfrew, and Schiff, 2003). However, there are new laboratories, or new staff within existing laboratories, which have not been evaluated and periodic intercalibrations are a necessity. In an effort to improve and update laboratory performance, a new intercalibration study was conducted with 14 laboratories that conduct stormwater analysis in California (Table 1). Like the previous exercise, this study was aimed at developing a consensus-based approach for achieving minimal levels of comparability among typically disparate laboratories. The success of the 2003 exercise and this subsequent study was primarily due to three factors including communication and commitment among laboratory personnel, setting performance-based criteria for establishing standards of success, and round robin testing using locally derived reference materials.

Objectives and Goals of this Document

The objective of this guidance manual is to update and present the performance-based guidelines established during the SMC interlaboratory studies of 2003 and 2007. This document sets the minimum standards of sensitivity, precision, and accuracy across laboratories so that individual data sets can be combined with estimated levels of confidence for making regional assessments of stormwater quality. The philosophy of performance-based guidelines is key to achieving this comparability. Although every laboratory involved in the stormwater intercalibration study was certified by the State of California Environmental Laboratory Accreditation Program (ELAP), inventories of existing methods demonstrated that most analytes are not analyzed in exactly the same manner. This will continue as new laboratories, or new equipment at existing laboratories continues to proliferate. Rather than mandate specific methods that are inflexible and discourages existing laboratories from achieving faster, more sensitive, and more cost-effective methods, this document merely sets minimum levels of comparability so that data sets can be combined no matter what technology currently exists. These procedures are also outlined herein.

This guidance manual is a living document. It should be revisited each time an intercalibration exercise is conducted and can be expanded to include additional constituents, additional laboratories, or to refine the recommended performance-based sensitivity, accuracy, and precision requirements as new information becomes available.

This document and laboratory intercalibration study is not a certification program. The guidelines set by this document merely express the desired needs of the stormwater agencies throughout the southern California region. Therefore, these stormwater agencies can use these guidelines in establishing specifications for work assignments or requests for proposals to conduct stormwater analyses. Alternatively, or in combination, stormwater regulatory agencies may use these specifications in the development of regulatory expectations for laboratory performance by monitoring agencies.

GUIDANCE INFORMATION

This document consists of four elements. First is a list of target analytes and minimum levels of sensitivity (reporting levels). Second are minimum levels of accuracy and precision. Third are recommended protocols for method specific comparability. Fourth are participation requirements for intercalibration studies and the laboratory evaluation criteria and results.

Analytes and Reporting Levels

Target Analytes

A core group of target analytes was specified for comparability (Table 2). This list includes total suspended solids (TSS), total organic carbon (TOC), nutrients, and trace metals. This list was based on three criteria. First, these analytes are consistently measured by existing monitoring programs throughout the region. Second, these constituents are routinely detected in stormwater samples. Third, although standard methods exist, there is sufficient disparity in protocols among laboratories that consistency guidance is warranted.

The list of target analytes is not meant to be an exhaustive list of all constituents that could or should be measured in individual programs. For example, there are no pesticides, herbicides, or polynuclear hydrocarbons on the list of target analytes. Any or all of these target analytes may be the focus of individual monitoring programs. At this point in time, however, there has not been an intercalibration study conducted for these constituents to make performance-based recommendations for stormwater laboratories.

While the list of target analytes focuses on total trace metals, they can be applied to dissolved trace metals. Since the analytical methodology is similar among both total and dissolved metals, the performance-based guidelines may be applied to both. Bear in mind that for dissolved trace metals, the preparation step of filtration is a major source of potential contamination and was not evaluated in this study.

Reporting Levels

Targeted reporting levels (RLs) are provided in Table 2. This guidance was based on the philosophy that analyses should be sufficient to assess if samples are below water quality thresholds of concern. In this instance, the water quality thresholds of concern are established in the California Toxics Rule (CTR). Further, reporting levels should be technologically achievable, but far enough below water quality thresholds that exceedences cannot be attributable to methodological uncertainty. Therefore, the philosophical approach for setting RLs was to select guidelines that were one-half of the lowest water quality threshold concentration. In the case of the CTR, there are thresholds for both marine and fresh waters. For a participating laboratory to achieve these reporting levels, it should include a calibration standard at or below this level (e.g. the reporting level is a quantitation level and not an MDL).

Table 2. Target analytes and Reporting Levels for the Stormwater Monitoring Coalition Monitoring Program.

Analyte	Units	SMC Target Reporting Level	California Toxics Rule Limit (Freshwater)	California Toxics Rule Limit (Seawater)
General Constituents				
TSS	mg/L	5	-	-
Nitrate+Nitrite as N	mg/L	0.2	-	-
Ammonia as N	mg/L	0.1	-	-
Total Phosphorus as P	mg/L	0.1	-	-
Total Kjeldahl Nitrogen	mg/L	0.2	-	-
Total Organic Carbon	mg/L	1	-	-
			-	-
Total Metals				
Arsenic	µg/L	2	150	36
Cadmium	µg/L	1	2.2	9.3
Chromium (total)	µg/L	5	11	50
Copper	µg/L	2	9	3.1
Nickel	µg/L	4	52	8.2
Lead	µg/L	1	2.5	8.1
Selenium	µg/L	2	5	71
Silver	µg/L	1	3.4	1.9
Zinc	µg/L	10	120	81

Accuracy and Precision

Analysis of spiked samples or reference materials provides a mechanism for assessing within laboratory accuracy. Reproducibility among replicate sample analyses provides a determination of within laboratory precision. General guidance provided by ELAP and the US EPA (40 CFR Part 136) are recommended for assessing within laboratory accuracy and precision by analyzing two replicate sample matrix spikes per batch of 20 or less samples. Matrix spike concentrations of approximately 10 times the lab reporting level are recommended for most meaningful spike recovery measurements. As general guidance, matrix spike concentrations should be in the same general range as relevant regulatory limits to truly represent accuracy and precision at these concentrations. It is also recommended that a set of laboratory replicate samples are analyzed with each batch of samples to indicate precision using actual sample matrices, which is typically larger due to natural variation of sample homogeneity. The relative percent difference (RPD) between replicate spikes for the parameters listed in Table 2 should be less than 20%. Accuracy limits for MS and MSD are provided in Table 3. These accuracy limits mimic ELAP and US EPA guidelines. Accuracy limits for Certified Reference Materials are provided by the supplier.

Additional QAQC requirements in the methods referenced by each laboratory should conform to the requirements listed within that method by Standard Methods or the US EPA

(i.e. Blank Spikes). Project specific QAQC requirements may also be listed in the Quality Assurance Project Plan (QAPP). Since spiked samples can be complicated by matrix interferences, this can confound assessments of accuracy. Therefore, the analysis of Certified Materials, when available, is also a recommended (but not required) option for the monitoring agency.

Intercalibration studies evaluate the accuracy and precision of analysis among laboratories. For this document, interlaboratory precision guidelines were developed by analyzing each of three matrices by fourteen different laboratories (Table 1) throughout southern California. These matrices included a specially prepared performance evaluation (PE) sample, an urban runoff sample, and a rural runoff sample.

Table 3. Laboratory accuracy and precision guidelines for concentrations greater than 10x the RL for ongoing analysis of stormwater samples.

Target Analyte	Precision (RPD of Duplicate Samples)	Accuracy (Percent Recovery of MS or MSD [a])
General Constituents		
TSS	0 - 20	-[b]
Ammonia-N	0 – 20	80 – 120
Nitrate-N+Nitrite-N	0 – 20	80 - 120
Total Kjeldahl Nitrogen	0 – 20	70 – 130
Total Phosphorus as P	0 – 20	70 – 130

Copper	0 – 20	80 – 120
Lead	0 – 20	80 – 120
Nickel	0 – 20	80 – 120
Selenium	0 – 20	80 – 120
Silver	0 – 20	80 – 120
Zinc	0 – 20	80 – 120

[a]- For certified reference materials, use supplier recommendations
[b]- defined by supplier

For each of the 3 matrices, the grand mean and standard deviation were calculated using the pooled results from all fourteen laboratories (Table 4). A Grubb's test was used to identify outliers that were removed along with the "not detected" values from the data set prior to calculating the grand means and standard deviations. It should be noted that not all laboratories analyzed every target analyte so that the number of results varied by parameter. Upper and lower "Warning" limits were based on two standard deviations within the grand mean and upper and lower "Control" limits were based on three standard deviations within the grand mean.

Table 4. Grand mean, warning limits, and control limits of each matrix from the combined results of all fourteen laboratories participating in the intercalibration. Warning limits and control limits are indicated as maximum difference from the mean (e.g., TSS for LU control limits are 106 to 138 ppm).

[a] certified reference material
[b] simulated rainfall runoff from an urban catchment
[c] simulated rainfall runoff from a rural catchment
- no limit

Using the same data set as the grand means and standard deviations, the overall relative standard deviation (RSD) for each matrix was calculated and is presented in Table 5. Precision among laboratories is expected to be less than 30% for those analytes that are present at concentrations at least 10 times the MDL. The RSD for Ammonia and TKN was greater than 30% for the ERA sample but within 30% for the LU and LR samples. Total P RSD was greater than 30% for the LU and LR samples, but the concentration was below 10 times the MDL. The same was true for Silver in the LR sample.

Table 5. Relative standard deviation results for each matrix for the combined results from all fourteen laboratories.

		Relative Standard Deviation

Standardization

Although this document is founded on performance-based guidelines enabling flexibility within each laboratory to achieve consistency, the laboratory intercalibration studies have identified four protocols whereby recommended standardization can dramatically increase comparability. This standardization includes sub-sampling, Total Phosphorus digestion, TKN digestion, and trace metal digestion techniques.

Sub-Sampling Techniques

Sub-sampling techniques are an important component of both within and among laboratory variability. This was especially true for particle-laden samples, such as those from more rural catchments with unlined channels. Particle-bound constituents have the potential to be dramatically biased if sub-sampling techniques selectively target or avoid particles within samples. To this end, standardized laboratory techniques for sub-sampling were developed for splitting large volume stormwater samples collected in the field into smaller bottles for distribution to the laboratory and for subsequent sampling of smaller aliquots in the laboratory at the time of analysis.

Sub-sampling of large-volume composite containers

In order to ensure that sample containers destined for an analytical laboratory all contain water that is similar and representative of the original composite sample, it is important to maintain a well-mixed composite sample during sub-sampling and to prevent stratification and the settling out of heavier particles. This is accomplished by the use of a large-capacity stirrer and a 2 to 3-inch, pre-cleaned, Teflon-coated stir bar; larger stir bars can be used for larger volume containers. Adjustment of stirring speed is important. Speeds that are too fast will create a large vortex within the composite bottle that can actually concentrate heavier particles and should be avoided. Speed should be based on a visual assessment of the most even mixing throughout the composite bottle.

Sub-sampling from the homogenized composite bottle is accomplished using a peristaltic pump and pre-cleaned (inside and outside) sub-sampling hose. Filling sample containers by pumping from the composite bottle is best performed by two people. One person is responsible for filling individual sample containers and one person is responsible for constantly moving the intake tubing up and down in the water column of the composite sample. Based on experimental evidence, this up and down movement of the intake is a procedure that helps obtain a more representative sub-sample. This is because there can still be some stratification of heavier particles in the composite sample despite the mixing created by the stirrer. The up and down movement of the intake tubing should be limited to approximately 80-90 percent of the depth of the water column and should never touch the bottom of the composite bottle.

Sub-sampling of sample containers for analysis

The goal of sub-sampling bottles in the laboratory for analysis is similar to field sampling techniques, to maintain a homogeneous particle distribution. Analysis of particle-

associated constituents will be biased if non-representative particle suspensions are used for analysis. In order to maintain homogeneous particle distributions, we recommend the use of sub-sampling techniques described by the US Geological Survey (Charles J. Patton, USGS National Water Quality Laboratory, Denver, CO). Appropriately, a similar technique to large composite container sub-sampling is used. Briefly, a "+" shaped magnetic stirring bar is placed into the sample container and the sample is stirred while a sub-sample is aspirated and dispensed into the processing container.

Total Kjeldahl Nitrogen

Total Kjeldahl Nitrogen (TKN) analysis was affected by the digestion technique during the laboratory intercalibration exercise. This was due to the influence caused by particle content and size distribution. Therefore, minimum standardization of the digestion procedure for stormwater samples is recommended. Either micro or macro Kjeldahl digestions are acceptable. However, the length of time of digestion should be set at a minimum of 1 hour at 380ºC, until copious fumes are generated and the digestion solution turns yellow, and then for an additional 30 minutes (to ensure adequate recovery) prior to analysis.

Total Phosphorus

Total Phosphorus analysis was also affected by the digestion technique during the laboratory intercalibration exercise. Therefore, we are recommending standardization of the digestion procedure to the use of an acid persulfate digestion.

Trace Metals

Trace metal analysis was also affected by the digestion technique during the laboratory intercalibration exercise. This is because trace metal concentration may be influenced by particle content and size distribution. Therefore, minimum standardization of trace metal digestion is recommended for stormwater samples. Trace metals should be digested using a nitric/hydrochloric acid digestion at 95ºC for 2-4 hours until the sample has evaporated from 50mL down to 10mL.

Dissolved metals analysis should be performed on filtered samples and does not require digestion if the turbidity is <1. Sample spiking for the Matrix Spike should be done after filtering. Filtration is a common source of contamination and when measuring dissolved metals. All other criteria for trace metals in this guidance document are applicable to both total and dissolved metals.

Participation Requirements

Proficiency Testing

Laboratories performing analyses for SMC Stormwater Monitoring Programs should pass a SMC performance evaluation (PE) sample and participate successfully in SMC intercalibration exercises. The PE and intercalibration exercises are strongly recommended to be performed on an annual basis. This frequency is recommended

because: 1) new laboratories may wish to participate; 2) existing laboratories need to evaluate new personnel; and 3) new and existing laboratories with new equipment or altered laboratory techniques need to be evaluated. Intercalibrations should occur within the first six months of the calendar year to ensure evaluations prior to the following wet season that typically begins on October 15th.

SMC PE samples should be spiked between 1 and 10 times the established reporting limit (Table 2) for the analytes of concern for minimum proficiency. All sample results should meet the criteria provided by the commercial supplier of the sample to evaluate accuracy. PE samples are to be coordinated through the SMC, or their representatives on a Chemistry subcommittee, and can be purchased from private companies such as Environmental Resource Associates, Inc. (ERA), Wibby Environmental, APG, or other NELAC approved proficiency testing sample providers.

Intercalibration studies require laboratories to analyze one PE sample and three replicates of two runoff samples, one from an urban area and one from a rural catchment. Each intercalibration study should be performed with one or more iterations to evaluate consistency and allow for laboratory corrective actions if deficient analysis resulted from the first iteration.

New Laboratories

New laboratories that have not participated in previous intercalibration exercises may still be able to analyze stormwater samples during the present wet season. These labs, however, will need to provide resources to purchase a PE sample with the same requirements used in the intercalibration study in Section 3.1 (i.e. samples will be spiked at 1 to 10 times the established reporting limits in Table 2). These samples should be delivered to the new laboratory blind and as whole volume samples. All new laboratories are required to participate in the next intercalibration exercise to remain qualified for the SMC program.

Laboratory Intercalibration Exercise Evaluation Criteria

Laboratories participating in the intercalibration exercise will be evaluated to determine if their results are within acceptable accuracy and precision insuring comparability of data between the different SMC stormwater monitoring programs. For the present study, a scoring system was used to assign a numeric value and letter grade to each laboratory indicating the quality of their performance in the exercise. A grade of “C” or better is recommended for a laboratory to be eligible to perform analyses for SMC programs.

Scoring System and Results

Based on the combined results from all fourteen laboratories participating in the exercise, a Grubb’s test was performed to identify outlier data points. After removal of the outlier data, the “not detected” results were removed and the grand mean and standard deviation were calculated for each analyte. Upper and lower warning and control limits were based on 2 and 3 times the standard deviation, respectively (see table 4). The results, upper and

lower warning, and upper and lower control limits are presented in graph form in Appendix I.

A scoring system was established to rate each laboratory's performance. Each replicate analysis by a laboratory was given 3 points if the result for that sample-analyte combination was within the warning limit and 2 points if the result was within the control limit (Figure 1). Zero points were given if the result was outside the control limit. For example, if a laboratory got all three replicate results within 2 SD, then they received 9 points for that analyte. If two results were within 2SD and one was within 3SD, then the laboratory was given 3+3+2 or 8 points out of 9. The Relative Standard Deviation (RSD) was also calculated for each parameter and 1 point was given for each analyte/matrix with an RSD of < 20%. The total points awarded to each laboratory were combined for the General Constituents (TSS, Ammonia-N, Nitrate-N + Nitrite-N, TKN, TOC, and Total P) and then divided by the total possible points, then multiplied by 100 for the final score. Trace metals were all combined as a separate score using the same criteria.

Laboratories that did not analyze a particular analyte were not given a score for that parameter so that they were not penalized. The omitted analyte is listed in the scoring results summary so that SMC programs managers have the option of using another laboratory for that specific analysis. A letter grade was assigned based on 90-100% being an "A", 80-89% being a "B", 70-79% being a "C", and below 70% being an "F".

The results from the 2007 laboratory intercalibration exercise are presented in Table 6a and b. Since this is a public document and participation in this exercise is intended to be kept anonymous, the laboratories are listed by randomly assigned number. SMC member agencies will be given the key to the laboratory names upon request.

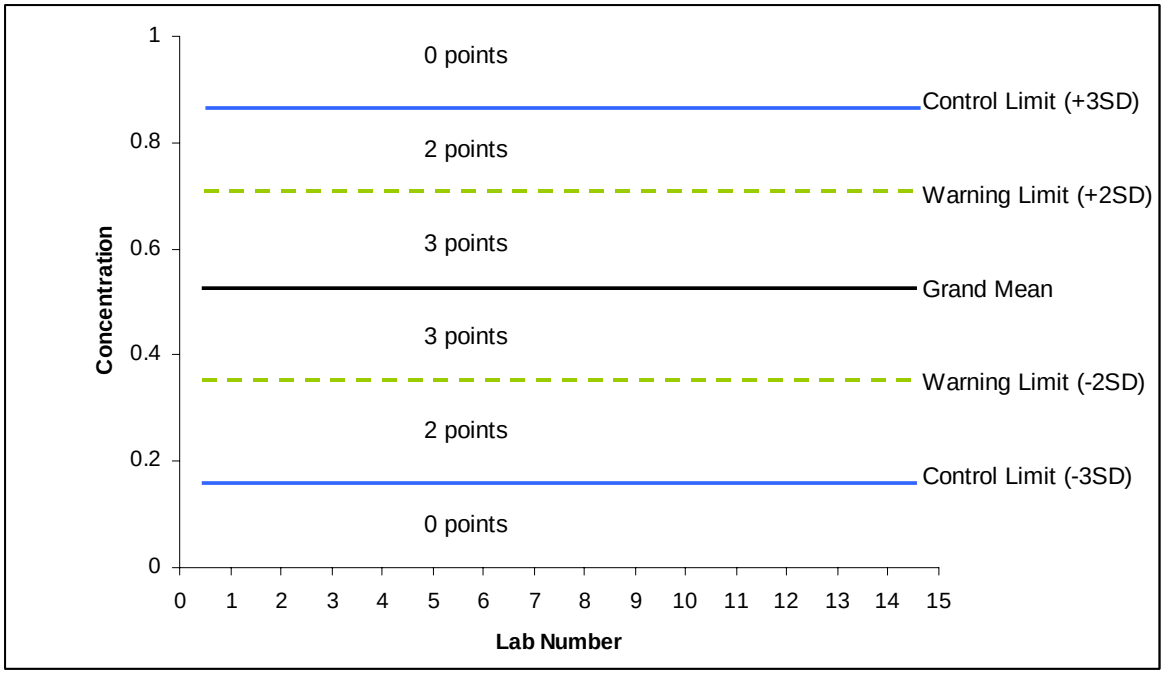

Figure 1. Example of scoring system for SMC intercalibration studies without any specific data shown.

Table 6a. Scoring results for General Constituents in the 2007 Laboratory Intercalibration Exercise.

Laboratory Number	Analytical Result Score	RSD Score	Percent Success	Letter Grade
1	93 out of 120	11 out of 12	79 %	C
2	120 out of 120	12 out of 12	100%	A
3 (did not analyze TKN or TOC)	79 out of 81	8 out of 8	98 %	A
4	116 out of 120	12 out of 12	97%	A
5	118 out of 120	12 out of 12	98%	A
6	98 out of 120	11 out of 12	83%	B
7	120 out of 120	12 out of 12	100%	A
8 (did not analyze TOC)	110 out of 120	11 out of 12	92%	A
9	112 out of 120	11 out of 12	93%	A
10 (did not analyze Nitrate-N + Nitrite-N or TOC)	11 out of 11	0 out 8	58%	F
11 (did not analyze TOC)	91 out of 102	9 out of 10	89%	B
12	117 out of 120	12 out of 12	98%	A
13 (did not analyze TSS, TKN, TOC, or Total P)	42 out of 42	4 out of 4	100%	A
14 (did not analyze TKN or TOC)	79 out of 81	8 out of 8	98%	A

Table 6b. Scoring results for Trace Metals in the 2007 Laboratory Intercalibration Exercise.

Laboratory Number	Analytical Result Score	RSD Score	Percent Success	Letter Grade

13	not analyzed	-	-	-
14	178 out of 189	18 out of 18	95%	A

DEFINITIONS

Batch – An analytical batch consists of 20 or fewer client samples.

Method Blank (MB) – Analyte free water that is carried through the entire analytical process. The method blank is used to evaluate contamination contributed from the method. Analyte detections in the method blank must be less than 10x the analyte result for a client sample to be considered usable without flagging.

Duplicate – A client sample analyzed in duplicate. Duplicate RPD should be summarized in the report.

Blank Spike/Blank Spike Duplicate – A blank spike (laboratory control sample) is a certified standard reference material that is spiked into a reagent blank. It is carried through all steps of sample preparation to demonstrate method performance inclusive of sample preparation steps. The blank spike should be spiked near the mid point of the calibration curve.

Matrix Spike/Matrix Spike Duplicate – A matrix spike is a regular sample that is split into three sub-samples. Two of the replicates are spiked with analyte solution at the same concentration and are defined as the matrix spike and matrix spike duplicate (MS/MSD). The MS/MSD samples are carried through the sample preparation and analysis procedure with each batch of 20 or less samples. The MS/MSD results provide information regarding laboratory precision, sample matrix effects, and method efficiency.

RPD- Relative Percent Differnce is calculated using the following formula:

RPD=(Results1-Result2)/(Result1+Result2)/2)*100

RSD- Relative Standard Deviation is calculated using the following formula:

RSD=(Standard Deviation)/(Mean)*100

Technical Report 510

EXECUTIVE SUMMARY

Storm water runoff and the associated contaminants from urban areas is one of the leading sources of water quality degradation in surface waters (US EPA 2000). Runoff from pervious and impervious areas (i.e., streets, parking lots, lawns, golf courses and agricultural land) carries accumulated contaminants (i.e., atmospheric dust, trace metals, street dirt, hydrocarbons, fertilizers and pesticides) directly into receiving waters (Novotny and Olem 1994). Because of the environmental effects of these contaminants, effective storm water monitoring and management requires identification and characterization of the sources, patterns, and mechanisms that influence pollutant concentrations and loads. Concentrations and loads of pollutants in urban storm water have been documented in some portions of the country (Hoffman et al. 1984; Buffleben et al. 2002; Simpson et al. 2002); however, little is known about the mechanisms and processes that influence spatial and temporal factors that affect the magnitude and patterns of constituent loading from specific land uses. Specifically, storm water managers need to understand how sources vary by land use type, how patterns of loading vary over the course of a single storm, how loading varies over the course of a storm season, and how applicable national or regional estimates of land use-based loading are to southern California.

To investigate these issues, the Southern California Coastal Water Research Project (SCCWRP) conducted a storm water sampling program over five seasons (2000-01 through 2004-2005). Constituent concentrations were measured over the entire storm duration from eight different land use types over 11 storm events in five watersheds in the greater Los Angeles, CA region (Figure ES-1). In addition, runoff samples were also collected from twelve mass emission sites (in-river) during 15 different storm events. A total of 71 site-events were sampled, comprised of 33 land use site-events and 38 mass-emission site events. These data were collected to better characterize contributions of specific land use types to loading of bacteria, trace metals, and organic compounds and to provide data for watershed model calibration. The specific goals of this study were (1) to examine constituent event mean concentrations (EMC), fluxes, and mass loadings associated with storm water runoff from representative land uses; (2) to investigate within storm and within season factors that affect constituent concentrations and fluxes; (3) to evaluate how constituent loadings compare to loadings from point sources, and (4) to assess how the concentrations of constituents in runoff compare to published data and water-quality criteria.

To understand the complex spatial and temporal patterns that affect storm water runoff in the greater Los Angeles region, runoff and constituent concentrations from a variety of land uses and mass emission sites were sampled over a range of different storm sizes and antecedent conditions. Between 10 and 15 discrete grab samples were collected for each site-event and the samples analyzed individually to provide time vs. concentration plots (i.e., pollutographs) for each site-event. Samples were analyzed for a broad range of constituents including trace metals, organic compounds and bacteria. Storms were targeted to capture early vs. late season conditions and large vs. small rainfall events. Understanding both intra-storm and inter-storm variability provides a more complete assessment of factors that influence constituent loading, and will allow us to develop dynamic watershed models that are able to predict pollutant runoff from specific land use types and watersheds under a variety of conditions.

General Conclusions

1. Storm water runoff from watershed and land use based sources is a significant contributor of pollutant loading and often exceeds water quality standards

Results of this study indicate that urban storm water is a substantial source of a variety of constituents to downstream receiving waters. Substantially high constituent concentrations were observed throughout the study at both mass emission (ME) and land use (LU) sites. Constituent concentrations frequently exceeded water quality criteria. Storm water concentrations of trace metals exceeded California Toxic Rule (USEPA 2000) water quality criteria in more than 80% of the wet weather samples collected at ME sites. This was partly due to industrial land use sites where 100% and 87% of runoff samples exceeded water quality criteria for zinc and copper, respectively. Furthermore, fecal indicator bacteria (FIB) at both ME and LU sites consistently exceeded California single-sample water quality standards. In fact levels of FIB at the recreational (horse) and agricultural LU sites were as high as those found in primary wastewater effluent in the U.S., with densities of 10^{6}-10^{7} MPN/100mL.

2. All constituents were strongly correlated with total suspended solids

Land use had a strong influence on constituent concentrations. Total suspended solids (TSS) was strongly correlated with constituent EMCs at most land use sites, although not all correlations were statistically significant. This correlation was primarly influenced by highly urbanized land uses and a single undeveloped open space land use. High TSS loads in rivers contribute to water quality impairments, habitat loss and to excessive turbidity resulting in impairments in recreational, fish/wildlife, and water supply designated uses of the rivers. These results suggest that controlling TSS at specific land uses may result in reducing other particle-bound constituents.

3. Storm water EMCs, fluxes and loads were substantially lower from undeveloped open space areas when compared to developed urbanized watersheds

Storms sampled from less developed watersheds (i.e., Santa Monica Canyon and Arroyo Sequit) produced constituent EMCs and fluxes that were one to two orders of magnitude lower than comparably sized storms in urbanized watersheds (i.e., Los Angeles River and Ballona Creek) (Figure ES-2). Furthermore, the higher fluxes from developed watersheds were generated by substantially less rainfall than the lower fluxes from the undeveloped watersheds, presumably due to increased impervious surface area in developed watersheds. Stein and Yoon (2007) reported similar wet weather runoff results from undeveloped land uses while investigating pollutant contributions from natural sources. The contrasts between the different watershed scale mass-emission sites were also apparent at the small, homogeneous land use sites.

4. Land use based sources of pollutant concentrations and fluxes varied by constituent

No single land use type was responsible for contributing the highest loading for all constituents measured. For example industrial land use sites, contributed higher storm EMCs and fluxes of all trace metals than other land use types. (Figure ES-3). Recreational (horse) land use sites contributed significantly higher storm fluxes for *E. coli* while agricultural land use sites contributed the highest TSS fluxes. Substantially higher TSS fluxes were also observed at the industrial sites. PAHs were not preferentially generated by any one land use type, rather

analyses of individual PAHs demonstrated a consistent predominance of high molecular weight (HMW) PAH compounds indicative of regional pyrogenic PAHs (i.e., atmospheric deposition) as a major source material of the PAHs found in urban storm water.

5. Storm water runoff contributed a similar range of constituent loading to regional point sources

Storm water runoff of trace metals from the urban watersheds in this study produced a similar range of annual loads as those from point sources; such as large publicly owned treatment plants (Table ES-1). Nevertheless, when combined with dry estimates of pollutant loading from Stein and Tiefenthaler (2005), the total non-point source contribution from all watersheds in the greater Los Angeles area far exceeds that of the point sources (Table ES-1).

6. The Los Angeles region contributed a similar range of storm water runoff pollutant loads as that of other regions of the United States

Comparison of constituent concentrations in storm water runoff from land use sites from this study reveal median EMCs that are comparable to current U.S. averages reported in the National Storm water Quality Database (NSQD; Pitt *et al*, 2003) (Figure ES-4). Comparison to the NSQD data set provides insight to spatial and temporal patterns in constituent concentrations in urban systems. Similarities between levels reported in the NSQD and this study suggest that land-based concentrations in southern California storm water are generally comparable to those in other parts of the country.

7. Storm water runoff concentrations improved over time when compared with the Nationwide Urban Runoff Program (NURP.

Results showed an improvement in water quality between constituent concentrations reported by NURP in 1983 and those observed in this study (Los Angeles River Watershed (LARW). Long-term overall trends of decreasing median constituent EMCs were observed at all land uses with the exception of total zinc, which showed an increase in median EMCs over the course of the studies (Figure ES-4). For example, lead concentrations have exhibited a 10-fold reduction over the last 20 years. Relatively low lead concentrations may reflect fate and transport characteristics of the particular systems sampled. However, a more likely explanation is that low concentrations of lead observed in these studies can be attributed to regulations banning the use of leaded gasoline.

8. Peak concentrations for all constituents were observed during the early part of the storm

Constituent concentrations varied with time over the course of storm events. For all storms sampled, the highest constituent concentrations occurred during the early phases of storm water runoff with peak concentrations usually preceding peak flow (Figure ES-5). In all cases, constituent concentrations increased rapidly, stayed high for relatively short periods and often decreased back to base levels within one to two hours. In contrast, the developed LU (recreational (horse) site; Figure ES 1-5c) had a peak concentration followed by intra-storm variable concentrations that mimicked flow. Although the pattern of an early peak in concentration was comparable in both large and small developed watersheds (Ballona Creek; Figure ES-5a, Los Angeles River Figure ES-5b), the peak concentration tended to occur later in the storm and persist for a longer duration in the smaller developed watersheds. Therefore

monitoring programs must capture the early portion of storms and account for intra-storm variability in concentration in order to generate accurate estimates of EMC and contaminant loading. Programs that do not initiate sampling until a flow threshold has been surpassed may severely underestimate storm EMCs.

9. The magnitude of a mass first flush effect at land use sites was a function of watershed size

Storm mass loading is a function of both concentration and magnitude of flow at various points during a storm. Cumulative mass loading of constituents from ME sites generally exhibited a weak "first flush" for trace metals and bacteria. For PAHs, a moderate first flush was observed where between 40% and 60% of the load was discharged during the first 25% of storm volume. In contrast to the ME sites, cumulative mass loading plots from small, homogenous land use sites exhibited moderate first flush for all constituents sampled. When all developed sites were analyzed together, the magnitude of the first flush effect decreased with increasing watershed size (Figure ES-6). The inverse relationship between first flush and catchment size has several potential mechanistic explanations including differences in relative pervious area, spatial and temporal patterns in rainfall, and pollutant transport through the catchment. Ultimately, the differences in first flush, whether due to imperviousness, travel time, or rainfall variability, suggest that management strategies aimed at capturing constituent loads should focus on more than just the initial portion of the storm at moderate to large catchments.

10. Highest constituent loading was observed early in the storm season with intra-annual variability driven more by antecedent dry period than amount of rainfall

Seasonal differences in constituent EMCs and loads were consistently observed at both ME and LU sites. In general, early season storms (October – December) produce significantly higher constituent EMCs and loads than late season storms (April-May), even when rainfall quantity was similar (Figure ES-7). This suggests that the magnitude of constituent load associated with storm water runoff depends, at least in part, on the amount of time available for pollutant build-up on land surfaces. The extended dry period that typically occurs in arid climates such as southern California maximizes the time for constituents to build-up on land surfaces, resulting in proportionally higher concentrations and loads during initial storms of the season. This seasonal pattern suggests that focusing management actions on early season storms may provide relatively greater efficiency than distributing lower intensity management actions throughout the season.

Further Research

This study establishes the relative contributions of land uses and watersheds to constituent loading in receiving water bodies. Having statistically significant data sets at regional, seasonal, and land use levels enables modelers to use the information for more sensitive calibration of models that may be used for contaminant load allocations. Similarly, these data sets can assist storm water engineers in the design of more effective monitoring programs and better performing treatment practices (i.e., BMPs) that address specific rainfall/runoff conditions.

Further research is needed to directly assess the relationship between constituent concentrations and particle-size distributions in storm water runoff from mass emission and land use sites to better understand the fate, transport and treatment of constituents in urban runoff.

Storm water borne metals, PAHs and (to a lesser extent) bacteria are typically associated with particulates to varying degrees depending on the constituent and the size distribution of suspended solids in the storm water runoff. Furthermore, the particle size distribution, and constituent partitioning can change over the course of a storm event (Furumai et al. 2002, Stein and Yoon 2007). Understanding the dynamic partitioning of constituents to various size particles is important to being able to estimate temporal and spatial patterns of constituent deposition in estuaries and harbors, and should be an area of future investigation.

Our understanding of the mechanisms of constituent loading from urban land uses could also be improved by estimating the percent of directly connected impervious area (DCIA) in each land use category (i.e., percent rooftop, sidewalks, paved driveways and streets) and its impacts on storm water runoff concentrations and loads. This could allow identification of critical source areas, which in turn could provide for more precise estimates of loading and more focused application of best management practices.

Table ES-1. Mean annual (± 95% confidence intervals) trace metal loading in the Los Angeles coastal region from different sources (mt = metric tons).

Source	Mean Annual Load / Year (mt ± 95% CI)		
	Total Copper	Total Lead	Total Zinc

SECTION 1. INTRODUCTION

Urban storm water runoff has been identified as a major cause of degradation of surface water quality (Characklis and Wiesner 1997, Davis et al. 2001, Buffleben et al. 2002). Studies in southern California have documented trace metals, polycyclic aromatic hydrocarbons (PAHs) and fecal indicator bacteria (FIB) as major constituents of concern in storm water runoff (Buffleben et al. 2002, McPherson et al. 2002; Gigliotti 2000; Menzie et al. 2002). As a result numerous stream reaches in the greater Los Angeles Basin are listed as impaired waterbodies under Section 303(d) of the Clean Water Act for a range of constituents (LARWQCB 1998a and 2002).

Past monitoring and assessment efforts have provided important insight into the general patterns of storm water loading. Previous studies have documented that the most prevalent metals in urban storm water are zinc, copper, lead, and to a lesser degree nickel and cadmium (Sansalone and Buchberger 1997, Davis et al. 2001). Recent FIB studies using *Escherchia coli* (*E. coli*), *Enterococcus* spp. and total coliforms (Noble et al. 2003 and Stein and Tiefenthaler 2005) have documented freshwater outlets such as storm drains to be especially high contributors of bacterial contamination. Routine storm water monitoring programs focus on quantification of average concentration or load at the terminal watershed discharge point. While important for overall status and trends assessment, such monitoring provides little insight into the mechanisms and processes that influence constituent levels in storm water.

To effectively manage storm water, managers need to gain a deeper understanding of factors that affect storm water quality. In particular, managers need to understand the sources, processes and mechanisms that affect runoff and associated constituent loading. Specifically, managers need to understand how sources vary by land use (LU) type, how patterns of loading vary over the course of a single storm, how loading varies over the course of a storm season, and how applicable national or regional estimates of LU based loading are to southern California. Such information is critical to designing and implementing effective management strategies and for calibrating watershed models that can be used to evaluate proposed strategies.

The goal of this study is to quantify the sources, patterns of concentrations, fluxes, and loads of trace metals, PAHs and fecal indicator bacteria from representative land use types in the greater Los Angeles, California region. In addition to quantifying differences between land use categories, our goal is to investigate within storm and within season patterns in order to identify mechanisms that influence patterns of constituent loadings. Finally, we compare the estimates of storm water metals, total suspended solids (TSS) and *E. coli* loading to data from point and non-point sources and to existing water quality standards to provide context for the magnitude of importance of storm water to overall metals, TSS and *E. coli* loading for the region.

SECTION 2. METHODS

Study Areas

Storm water runoff was sampled from 19 different land use (LU) sites and 12 mass emission (ME) sites throughout the greater Los Angeles area (Figure 2-1). The 19 LU sites represented homogeneous distributions of eight land use types including high density residential, low-density residential, commercial, industrial, agricultural, recreational (horse), transportation or open space. The LU sites ranged in size from 0.002 to 2.89 km^2 (see Appendix A for more detailed land use information). In contrast to the smaller, homogeneous LU sites, ME sites had much larger catchments and consisted of heterogeneous land use distributions that commingle and ultimately discharge to recreational beaches and harbors along the Pacific Ocean. There were 10 urban ME sites and two nonurban ME sites sampled. Developed land use ranged from 49% to 94% of total watershed area in the 10 urban watersheds. Developed land use comprised less than 5% of the watershed area in the two non urban watersheds examined in this study. The 12 ME sites ranged in size from 31 to 2,161 km^2.

Rainfall

All of the LU and ME sites were sampled during the 2000–2001 through 2004–2005 storm seasons. Winter storms typically occur between October and May, providing 85% to 90% of the annual average rainfall (38.4 cm; Ackerman and Weisberg 2003). Annual precipitation in Los Angeles can be highly variable. For example, the 2004-2005 rainfall season brought 94.6 cm of precipitation to downtown Los Angeles making it the second wettest season in Los Angeles since records began in 1877 (National Weather Service; http://www.wrh.noaa.gov/lox/). In contrast, the 2001-2002 rainfall season totaled a mere 11.2 cm, 27 cm below the seasonal average. Consequently, the study period encompassed a wide range of precipitation conditions.

Sampling and Analysis

Twenty discrete storms were sampled, with each site sampled between one to seven individual storm events (Tables 2-1a and 2-1b). Rainfall amounts ranged from 0.12 to 9.68 cm and antecedent conditions ranged from 0 to 142 d without measurable rain. Rainfall at each site was measured using a standard tipping bucket that recorded in 0.025-cm increments. Antecedent dry conditions were determined as the number of days following the cessation of previous measurable rain. Water quality sampling was initiated when flows were greater than base flows by 20%, continued through peak flows, and ended when flows subsided to less than 20% of base flow. Because watersheds in southern California have highly variable flows that may increase orders of magnitude during storm events, these criteria are considered conservative. Flow at ME sites was estimated at 15-min intervals using existing, county-maintained flow gauges, or stage recorders in conjunction with historically derived and calibrated stage-discharge relationships. At ungauged ME sites and previously unmonitored LU sites, stream discharge was measured as the product of the wetted cross-sectional area and flow velocity. Velocity was measured using an acoustic Doppler velocity (AV) meter. The AV meter was mounted to the invert of the stream channel, and velocity, stage, and instantaneous flow data were transmitted to a data logger/controller on query commands found in the data logger software.

Between 10 and 15 discrete grab samples per storm were collected at approximately 30 to 60 min intervals for each site-event based on optimal sampling frequencies in southern California described by Leecaster et al. (2001). Samples were collected more frequently when flow rates were high or rapidly changing and less frequently during low-flow periods. All water samples were collected by one of three methods: 1) by peristaltic pumps with Teflon® tubing and stainless-steel intakes that were fixed at the bottom of the channel or pipe pointed in the upstream direction in an area of undisturbed flow, 2) by direct filling of the sample bottle either by hand or affixed to a pole, or 3) by indirect filling of intermediate bottles for securing large volumes. After collection, the samples were stored in precleaned glass bottles on ice with Teflon®-lined caps until they were shipped to the laboratory for analysis.

Chemical Analysis

Total Suspended Solids (TSS)

Total suspended solids (TSS) were analyzed by filtering a 10-mL to 100-mL aliquot of storm water through a tared 1.2-µm Whatman GF/C filter. The filters plus the solids were dried at 60°C for 24 h, cooled, and weighed.

Trace Metal Analysis

Whole samples (particulate plus dissolved) were prepared by nitric acid digestion followed by analysis using inductively coupled plasma-mass spectroscopy (ICPMS) according to USEPA Method 200.8 (US EPA 1991). Target analyses included aluminum, antimony, arsenic, beryllium, cadmium, chromium, copper, iron, lead, mercury, nickel, selenium, silver, and zinc. Quality assurance measurements indicated that all laboratory blanks were below method detection limits with duplicate samples within 10% reproducible difference.

Polycyclic Aromatic Hydrocarbon (PAHs) Analysis

Total PAH (∑PAH) was computed as the sum of the 26 individual PAH compounds quantified (Table 2-2). The individual PAHs were divided into low-molecular-weight (LMW) PAH compounds (<230, two to three rings) and high-molecular weight (HMW) PAH compounds (>230, four to six rings) for source analysis. The 26 specific PAHs were extracted, separated, and quantified by capillary gas chromatography coupled to mass spectrometry according to U.S. Environmental Protection Agency (US EPA) method 625 (US EPA 1991).

Fecal Indicator Bacteria Analysis

Concentrations of *E. coli* and *Enterococcus* spp.were measured by defined substrate technology using kits supplied by IDEXX Laboratories, Inc. (Westbrook, ME) according to the manufacturer's instructions. Briefly, 10-fold and 100-fold dilutions of the water samples were made with deionized water containing the appropriate media and sodium thiosulfate, mixed to dissolve, dispensed into trays (Quanti-Tray/2000), and heat sealed. *E. coli* was measured using the Colilert-18 reagents, while *Enterococcus* spp. were measured using Enterolert reagents. Samples were incubated overnight according to the manufacturer's instructions and inspected for positive wells. Conversion of positive wells from these tests to a most probable number (MPN) was done following Hurley and Roscoe (1983).

Data Analysis

Data analyses was broken into three sections; 1) comparison between LU sites; 2) comparison between developed and undeveloped watershed; and 3) assessment of within-season and within-storm variability. Comparison between LU sites focused on event mean concentrations (EMCs), load, flux, and principle components analysis (PCA). Prior to analysis constituent concentrations were log-transformed to improve normality. In all cases, non-detectable results were assigned a value of 1/2 the minimum detection limit, based on the inability to log transform a value of zero.

The EMC was calculated using Equation 1:

$$EMC = \frac{\sum_{i=1}^{n} C_i * F_i}{\sum_{i=1}^{n} F_i} \qquad \text{(Equation 1)}$$

where: EMC = flow-weighted mean for a particular storm; C_i = individual runoff sample concentration of ith sample; F_i = instantaneous flow at the time of ith sample; and n = number of samples per event. Constituent concentrations were log-transformed prior to calculations to improve normality. In all cases, non-detectable results were assigned a value of one-half the minimum detection limit, based on the inability to log transform a value of zero. Mass loading was calculated as the product of the EMC and the storm volume. Flux estimates facilitated loading comparisons among watersheds of varying sizes. Flux was calculated as the ratio of the mass load per storm and watershed area. Differences in concentration or flux between LU sites were tested using a one-way ANOVA, with a significance level (p) <0.05 , followed by Tukey-Kramer *post-hoc* test for multiple comparisons (Sokal and Rohlf 1969).

The PCA was used to identify the most important factors (i.e., groups of parameters, storm size and storm season) controlling data variability (Helene *et al*. 2000, SAS Inc. 2003, http://www.sas.com/textbook). As a multivariate data analysis technique, PCA reduces the number of dependent variables without sacrificing critical information (Qian et al. 1994). The number of principal components (PCs) extracted (to explain the underlying data structure) was defined by using the Kaiser criterion (Kaiser 1960) where only the PCs with eigenvalues greater than unity are retained. Scores derived from the PCA were plotted along the first two PC axes and examined visually for relationships that differentiate constituent concentrations among subclasses (e.g., land use types). PCA and ANOVA were used in a two-step process: The PCA was used to identify factors influencing variability and to group data into different sets based on the factors identified. ANOVA was then used to test for significant differences between the classes identified by the PCA.

The second analysis that compared developed and undeveloped ME sites followed similar approach as the LU sites focusing on EMCs, load, and flux. Differences between watershed types were determined using ANOVA.

The third analysis bifurcated into two approaches. The first compared seasonal patterns of total metal loading by plotting mass emissions against storm season (early = October to December, mid = January to March, and late = April to May) and cumulative annual rainfall. For this analysis, all ME sites were analyzed as a group to examine differences between early- and late-season storms across the sampling region.using ANOVA. The second approach compared flow and constituent concentration within-storm events. This comparison examined the time-concentration series relative to the hydrograph plots using a pollutograph. A first flush in concentration from individual ME storm events was defined as a circumstance when the peak in concentration preceded the peak in flow. This was quantified using cumulative loading plots in which cumulative mass emission was plotted against cumulative discharge volume during a single storm event (Bertrand-Krajewski et al. 1998). When these curves are close to unity, mass emission is a function of flow discharge. A strong first flush was defined as ≥75% of the mass was discharged in the first 25% of runoff volume. A moderate first flush was defined as ≥30% and ≤75% of the mass discharged in the first 25% of runoff volume. No first flush was assumed when ≤30% of the mass was discharged in the first 25% of runoff volume.

Further Analyses for Individual Constituents

Total Metal Comparison to The California Toxics Rules (CTR)

In order to investigate the percent of samples exceeding water quality standards total metals concentrations were compared to the California Toxics Rules (CTR) for inland surface waters (acute freshwater aquatic life protection standards, US EPA 2000). The standards for total copper, total lead and total zinc are 14.00, 81.65, and 119.82 respectively based on a hardness value of 100 mg/L.

The formula for calculating the acute objectives for copper, lead, and zinc in the CTR take the form of the following equation:

CMC = WER * ACF * exp[(ma)(ln(hardness)+ba]

Where: WER = Water Effects Ratio (assumed to be 1), ACF = Acute conversion factor (to convert from the total to the dissolved fraction), m_A = slope factor for acute criteria, and b_A = y intercept for acute criteria.

The CTR allows for the adjustment of criteria through the use of a water-effect ratio (WER) to assure that the metals criteria are appropriate for the site-specific chemical conditions under which they are applied. A WER represents the correlation between metals that are measured and metals that are biologically available and toxic. A WER is a measure of the toxicity of a material in site water divided by the toxicity of the same material in laboratory dilution water. No site-specific WER has been developed for any of the waterbodies in the Los Angeles River or San Gabriel River watersheds. Therefore, a WER default value of 1.0 was assumed. The coefficients needed for the calculation of objectives are provided in the CTR for most metals.

PAH Source Identification

PAHs were also analyzed to examine sources of PAHs. First, the FWM concentrations from the homogenous land use sites were compared. Differences between land use sites were investigated using a one-way analysis of variance (ANOVA) with a $p < 0.05$ significance level (Sokal and Rohlf 1969). Next, the relative proportion of individual PAH compounds and their ratios were evaluated to determine if the sources of PAHs suggested a pyrogenic (i.e., combustion by-products) or petrogenic (i.e., unburnt petroleum) signature. The ratio of fluoranthene (F) to pyrene (P; F/P) and the ratio of phenanthrene (P) to anthracene (A; P/A) were used to determine pyrogenic versus petrogenic sources of PAH. Pyrogenic sources predominate when F/P ratios approach 0.9 (Maher and Aislabe 1992). Pyrogenic sources predominate when P/A ratios ranged from 3 to 26 (Lake et al. 1979, Gschwend and Hites 1981).

Correlations between TSS, Flow and FIB

To explore the potential link between storm water runoff, TSS and FIB concentrations Spearman Rank correlation coefficients (a nonparametric measure of correlation) were computed between FIB, TSS and stream flow (Townsend 2002).

Cumulative Density Frequency Plots (CDFs) - Bacteria

Fecal indicator bacteria were used to assess whether storm water samples met State of California water quality thresholds by examining the relative frequency of exceedence for all storms combined at both ME and LU sites. Fecal indicator bacterial counts were plotted on logarithmic scales (a scale that minimizes differences and allows widely varying numbers to be shown) and compared to the CA single-sample criterion to estimate percent exceedances. The CA single-sample standard (assembly bill AB411) for ocean beaches has limits of 104 *Enterococcus* spp. bacteria in 100 ml of water, 400 *E. coli* colonies (400 MPN/100ml) and 10,000 total coliforms colonies (10,000 MPN/100mL). Cumulative density frequency plots (CDFs) were produced to compare observed bacterial concentrations to the CA quantitative standards and to calculate accumulated relative exceedance percentages.

An additional data analysis element examined the incidence of exceedences of California's AB411 water quality standards for fecal indicator bacteria compared to the size of the watershed. Watersheds were broken into small (<25 km^2), medium (20 km^2 - 99 km^2), and large (>100 km^2), with at least three watersheds falling into each category.

Constituent Comparison to Nationwide Results

Existing data sets provide insight into land use based loading, but do not provide the mechanistic understanding needed by storm water managers. Between 1977 and 1983 the U.S. EPA funded The Nationwide Urban Runoff Program (NURP), which compiled discharge data from separate storm sewers in different land uses to receiving waters. This project used 81 sites in 28 cities throughout the U.S. and included the monitoring of approximately 2,300 individual storm events (US EPA 1983a). The utility of the NURP data set is somewhat limited because it is 23 years old and only contains data from storm drains (vs. in-river measures). The National Storm water Quality Database (NSQD) was created in 2003 by the University of Alabama and the Center for Watershed Protection to examine more recent storm water data from a

representative number of National Pollutant Discharge Elimination System (NPDES) municipal separate storm sewer system (MS4) storm water permit holders (Pitt et al. 2003). The NSQD includes Phase I storm water monitoring data from 369 stations from 17 states and 9 rain zones and a total of 3,770 individual storm events between 1992 and 2003. Unfortunately, the NSQD does not contain any samples from the arid west. Furthermore, neither the NURP nor the NSQD provides time variable measurements that provide an understanding of the temporal processes that affect storm water loading.

Table 2-1a. Summary of storm events sampled at mass emission sites during 2001-2005 in Los Angeles, CA, USA.

Mass Emission Sites	Date of Storm Event	Size (km^2)	Rainfall (cm)	Antecedant Dry Days	Mean Flow (cm/s)	Peak Flow (cm/s)

SECTION 3. TRACE METALS AND TOTAL SUSPENDED SOLIDS

Results

Comparison Between LU Sites

Industrial LU sites contributed a substantially higher flux of copper and zinc compared to the other LU sites evaluated (Figure 3-1). For example, mean total copper flux from the industrial LU was 1,238.0 g/km^2 while mean total copper flux from high density residential and recreational (horse) LU was 100.5 g/km^2 and 190.1 g/km^2, respectively. Trace metal flux from undeveloped LU sites was lower than those observed in developed LUs. For example, mean copper flux at open space LU sites was 23.6 g/km^2. In contrast to copper and zinc, the mean flux of total lead was greatest at agriculture, high density residential, and recreational (horse) LU sites (Figure 3-1). The mean flux of total lead at these three LU sites was at least an order of magnitude greater than any other LU sampled.

Industrial LU had the greatest mean EMC for copper and zinc relative to all other LU sites (Figure 3-2). For example, zinc EMCs at the industrial LU averaged 599.1 µg/l compared to 362.2 µg/l and 207.7 µg/l for commercial and high density residential LU sites, respectively. High density residential had the greatest EMC for lead relative to all other LU sites (Figure 3-2). For example, lead EMCs at high density residential LU averaged 28.4 µg/l compared to 24.1 µg/l and 7.8 µg/l for industrial and agricultural LU sites, respectively. Mean EMCs for all three metals from undeveloped LU sites were lower than those observed in developed LU sites. For example, mean copper, lead, and zinc EMCs from open space LU sites was 7.6 µg/l, 1.2 µg/l, and 23.2 µg/l, respectively.

Both industrial and agricultural LU sites contributed substantially higher fluxes of TSS compared to the other LU sites evaluated (Figure 3-1). For example, mean TSS flux from the industrial and agricultural LU sites were comparable around 3,150.3 kg/km^2 while mean TSS flux from recreational (horse) and high density residential LU was 2,211.1 kg/km^2 and 91.1 kg/km^2, respectively. Mean TSS flux from undeveloped LU sites were comparable to the remaining developed LU sites. For example mean TSS flux from open space LU sites was 513.8 kg/km^2 compared to 160.8 kg/km^2 and 94.0 kg/km^2 for low density residential and commercial LU sites, respectively.

Recreational (horse) LU had the greatest mean TSS EMC compared to all other LU sites. For example, TSS EMCs at the recreational (horse) LU averaged 530.7 mg/l compared to 111.1 mg/l and 92.0 mg/l for agricultural and industrial LU sites, respectively. Mean TSS EMCs from undeveloped LU sites were comparable to those observed in developed agricultural and industrial LU sites. TSS EMCs from open space LU sites averaged 134.8 mg/l.

Results of the PCA indicated that the land use was a predominate source of variability and that land use categories can be grouped based on differences in their intrinsic runoff and loading characteristics (Figure 3-3). Two Principal Components (PCs) had eigenvalues greater than one, with PC1 and PC2 accounting for 63% and 17% of the total variance, respectively. Factor loadings indicated that PC1 and PC2 described concentrations of copper, cadmium, lead, nickel, zinc, and TSS. The two dimensional plot of scores from PC1 and PC2 revealed that

industrial, recreational (horse), and open space LU types were distinct from other LU types based on the concentrations of these constituents. Comparison of the PC scores (or eigenvectors) using a one-way ANOVA indicated that both industrial (group D) and recreational (horse) (group F) sites were significantly different ($p < 0.001$) than open space (group H) sites. All other LU types were indistinguishable.

Comparison Between Developed and Undeveloped Watersheds

The contrasts between the different small, homogeneous LU sites were also apparent at the watershed scale (Figure 3-4). Total copper, total lead and total zinc EMCs and fluxes were significantly greater at ME sites from developed compared to undeveloped watersheds (ANOVA, $p = <0.001$). For the 15 storm events measured, the mean flux of total copper, total lead and total zinc from developed ME watersheds was 0.6, 0.5 and 3.0 kg/km^2 respectively. The mean flux of total copper, total lead and total zinc from undeveloped ME watersheds were 0.06 kg/km^2, 0.01 kg/km^2 and 0.1 kg/km^2 (Figure 3-1), respectively. Furthermore, the higher fluxes from developed ME watersheds were generated by substantially less rainfall than the lower fluxes from the undeveloped ME watersheds (2.8 ± 0.8 cm for storms in developed ME watersheds vs. 4.4 ± 0.8 cm for storms in undeveloped ME watersheds), presumably due to increased impervious surface area in developed watersheds. Similarly, total copper, total lead, and total zinc mean EMC concentrations from developed ME watersheds significantly exceeded those from undeveloped ME watersheds (46.1 ± 14.8 µg/L, 36.3 ± 15.3 µg/L, 251.9 ± 76.9 µg/L vs. 12.6 ± 3.0 µg/L, 2.2 ± 0.8 µg/L, and 27.0 ± 8.4 µg/L, respectively; ANOVA, $p = <0.001$).

The TSS concentrations from less developed ME watersheds were within the same order of magnitude as those from more developed ME watersheds. For example, annual TSS EMCs for developed ME watersheds averaged 246.3 mg/L for Los Angeles River compared to 217.0 mg/L for the undeveloped ME watersheds. However, TSS fluxes were substantially higher for developed ME watersheds. For the 15 storm events measured, mean TSS flux from the developed Los Angeles River and San Gabriel River watersheds were 3,116.8, and 398.8 kg/km^2 respectively, while mean TSS flux from undeveloped watersheds was 62.8 kg/km^2.

Within-Season and Within-Storm Variability

There were significant seasonal differences in total metal loading ($p < 0.001$). Early season storms had significantly higher total metal load than late season storms both within and between watersheds, even when rainfall quantity was similar (Figure 3-5). For example, the two early-season storms from Ballona Creek in water years 2001-2002 and 2003-2004 had total copper loadings that were approximately four times larger (ranging from 154.7 ± 16.0 to 160.8 ± 9.4 kg) than the two storms that occurred at the end of the rainy season (42.6 ± 3.8 to 64.2 ± 4.6 kg), despite the early- and late-season storms resulting from comparable rainfall. The results for total lead and total zinc showed a similar pattern.

Trace metal concentrations varied with time over the course of storm events (Figure 3-6). For all storms sampled, both the highest trace metal concentrations and the peak flow occurred in the early part of a storm event. In all cases, metal concentrations increased rapidly, often preceding peak flow. Concentrations stayed high for relatively short periods and often decreased

back to base levels within one to two hours. In contrast, the undeveloped watershed (Arroyo Sequit; Figure 3-6a) had appreciably lower peak concentrations than the developed watershed (Ballona Creek; Figure 3-6b). Although the pattern of an early peak in concentration was comparable in both undeveloped and developed watersheds, the peak concentration tended to occur later in the storm and persist for a longer duration in the undeveloped watersheds. Due to the small number of storms sampled in undeveloped watersheds, consistency of these patterns is inconclusive.

Cumulative mass loading of all trace metals from ME sites showed little variation over flow implying there was a weak "first flush" effect at these locations (Figure 3-7). In contrast, cumulative mass loading plots for total copper, lead and zinc from LU sites exhibited moderate first flush patterns in the residential, commercial, industrial, agricultural and open space LU categories. When all developed catchments were analyzed together, the magnitude of the first flush effect decreased with increasing watershed size (Figure 3-8). For the developed LU sites that had catchments generally less than 3 km^2 in size, between 30 and 50% of the total copper, total lead and total zinc load was discharged during the first 25% of storm volume. For the ME sites, where runoff was integrated across larger and more diverse landscapes, between 15 and 35% of the total mass of copper, lead, and zinc was discharged during the first 25% of storm volume.

Discussion

Concentrations, flux, and loading in storm water runoff exhibited some key patterns with important implications for managers tasked with controlling trace metals. First, the magnitude of trace metal concentrations and loads were higher at industrial land uses than other land use types. High pollutant loading from industrial sites observed in this study results, at least in part, from intrinsic properties of the industrial land use themselves. These intrinsic properties include high impervious cover (typically greater than 70%) and on-site source generation. Other authors have reported similar results. Sanger et al. (1999) reported that total metal concentrations in runoff from industrial catchments tended to be higher than those from residential and commercial catchments. Park and Stenstrom (2004) used Bayesian networks to estimate pollutant loading from various land uses in southern California and concluded that zinc showed higher EMC values at commercial and industrial land uses. Bannerman et al. 1993 identified industrial land uses as a critical source area in Wisconsin storm water producing significant zinc loads. Bannerman *et al.* 1993 further suggested that targeting best-management practices to 14% of the residential area and 40% of the industrial area could significantly reduce contaminant loads by up to 75%. In this study high density residential sites had considerably higher lead EMCs than low density residential sites. This difference likely results from greater impervious cover and higher source generation at high density residential sites. High density sites typically have greater road surface and more vehicular use, resulting in more lead. In addition, higher impervious cover more effectively conveys accumulated pollutants to streams and creeks. Substantially higher TSS fluxes were also observed at the industrial sites, which may explain the high trace metal concentrations often associated with fine particles. The City of Austin (City of Austin 1990) found lead and zinc EMCs were related to the TSS EMCs. Consequently, controlling TSS at industrial sites may also result in reducing other constituents with the same particle sizes.

A second key conclusion that may affect storm water management is that seasonal flushing was consistently observed at both land use and mass emission sites. This suggests that the magnitude of trace metal loads associated with storm water runoff depends, at least in part, on the amount of time available for build-up on land surfaces. The extended dry period that typically occurs in arid climates such as southern California maximizes the time for trace metals to build-up on land surfaces, resulting in proportionally higher concentrations and loads during initial storms of the season. Similar seasonal patterns were observed for polycyclic aromatic hydrocarbons (PAHs) in the Los Angeles region (Sabin and K. 2004, Stein et al. 2006). Han et al. (2006) also reported that antecedent dry period was the best predictor of the magnitude of pollutant runoff from highways. Other researchers (Anderson and Rounds 2003, Ngoye and Machiwa 2004) have reported corresponding temporal trends for other particle-bound contaminants. This seasonal pattern suggests that focusing management actions on early season storms may provide relatively greater efficiency than distributing lower intensity management actions throughout the season.

A third key conclusion is that trace metal concentrations varied throughout the duration of storm hydrographs. The greatest total metal concentrations occurred at or just before the peak in flow of the storm hydrograph for nearly every storm sampled. This hydrograph/pollutograph pattern was also observed for PAHs in the greater Los Angeles area (Stein et al. 2006). Tiefenthaler et al. (2001) observed similar pollutographs that showed peak suspended-sediment concentrations preceding the peak in discharge for the Santa Ana River. Similar time vs. concentration relationships were observed by Characklis and Wiesner (1997), who reported that the maximum concentrations of zinc, organic carbon and solids coincided with early peak storm water flows. The early occurrence of peak concentrations indicates that monitoring programs must capture the early portion of storms to generate accurate estimates of EMC and contaminant loading. Programs that do not initiate sampling until a flow threshold has been surpassed may severely underestimate storm EMCs.

Despite a strong and consistent pattern of high metal concentrations early in the storm hydrograph, cumulative mass loading plots exhibited only a moderate first flush of total copper, lead and zinc at the small land use sites and a weak first flush at the larger mass emission sites. Lee et al. (2002) also found that the magnitude of first flush varied by constituent, with metals generally showing the weakest first flush. Furthermore, first flush phenomena were strongest for small catchments and generally decreased with increasing catchment size. Han et al. (2006) reported that first flush characteristics increased with decreasing drainage area size. Characklis and Wiesner (1997) reported that storm water runoff of trace metals from the urban areas of Houston exhibited no discernable first flush effect; however, these measurement were from larger mass emission catchments.

The inverse relationship between first flush and catchment size has several potential mechanistic explanations including relative pervious area, spatial and temporal patterns in rainfall, and pollutant transport through the catchment. Smaller LU catchments have increased impervious area that allows contaminants to be easily washed off relative to larger ME watersheds with less impervious area that requires greater rainfall energy to washoff particles and associated contaminants. In our study, industrial, commercial and high-density residential LU sites were comprised of 72%, 72% and 33% imperviousness, respectively. In contrast, the

larger ME watersheds (>40 km^2) ranged from 32 to 59% impervious area. The undeveloped ME watersheds, which had the least within storm variability, were comprised of only 1% imperviousness. Pitt (1987) also found a first flush on relatively small paved areas that he associated with washoff of the most available material.

A corollary to the relationship between imperviousness and catchment size is travel time. Travel time becomes a factor because contaminants are rapidly delivered to the point of discharge within smaller, more impervious catchments relative to larger, less impervious catchments. In our study, the time of travel in the larger ME watersheds like Ballona Creek or Los Angeles River was estimated in hours while travel times in the small LU catchments was minutes. As a result, not all first flush in smaller catchments upstream arrive at a ME site at the same time, effectively diluting short peaks in concentration. Hence, the different times of concentration (i.e., travel times) from various portions of the watershed may obscure first flush patterns at larger mass emission sites.

Spatial and/or temporal differences in rainfall further complicate first flush in large watersheds. Adams and Papa (2000) and Deletic (1998) both concluded that the presence of a first flush depends on numerous site and rainfall characteristics. In smaller catchments, rainfall distribution is more uniform compared to larger watersheds. When rainfall is distributed uniformly, then particles and associated pollutants are potentially washed off at the same time. In larger catchments, rainfall lags between various parts of the watershed may take hours and rainfall quantity and/or duration may not be similar between subwatersheds. Ackerman and Weisberg (2003) quantified rainfall temporal and spatial variability and determined that these factors were an important consideration in hydrologic inputs to the coastal ocean of southern California. Ultimately, the differences in first flush, whether they were due to imperviousness, travel time, or rainfall variability, suggest that management strategies at most moderate to large catchments should focus on more than just the initial portion of the storm if the goal is to capture a majority of metals load.

Urban storm water runoff from this study appeared worthy of management concern because it represented a large mass emission source that frequently exceeded water quality criteria (Table 3-1). Cumulatively, the annual average loading of total copper, lead, and zinc from the Los Angeles River, Ballona Creek, and Dominguez Channel exceeded the mass emissions from industrial point sources such as power generating stations and oil refineries by orders of magnitude. Annual storm water loading from these three watersheds also rivaled, or exceeded, trace metal emissions from point sources such as publicly owned treatment works. One significant difference between these point sources and urban storm water is that southern California has a completely separate sanitary sewer collection system and urban storm water receives no treatment prior to discharge into estuaries or the coastal ocean. Assuming a hardness of 100 mg/L and that 15% of the total metals in storm water occur in the dissolved fraction (Young *et al.* 1980), storm water concentrations of copper and zinc exceeded California Toxic Rule (US EPA 2000) water quality criteria in more than 80% of the wet weather samples collected at mass emission sites. This was partly due to industrial LU sites where 100% and 87% of runoff samples exceeded water quality criteria for zinc and copper, respectively. Commercial LU sites exceeded water quality criteria in 79% and 72% of its runoff samples, respectively. Only 8% to 9% of the runoff samples exceeded the water quality criterion for lead at commercial

or industrial LU sites. Hall and Anderson (1988) concluded that industrial and commercial land use sites were the major source of trace metals most often considered toxic to aquatic invertebrates, with runoff from the commercial sites proving most frequently toxic to the test organism.

The focus on LU sites in this study enabled the comparison of median EMCs with data sets collected from other parts of the nation (Table 3-2). All of the median EMCs for total copper at LU sites from Los Angeles were greater than, or equal to, median EMCs at LU sites reported in the NSQD (Pitt et al. 2004). With the exception of the open LU, all of the median EMCs for zinc were greater at LU sites in Los Angeles than median EMCs at LU sites reported in the NSQD. In contrast, all of the median EMCs for lead were lower at LU sites in Los Angeles than median EMCs at LU sites reported in the NSQD. Of the 15 LU – EMC combinations, all but one of the median EMCs (industrial zinc) were lower in Los Angeles than median EMCs reported by NURP (US EPA 1983; Table 3-2). Unlike the NSQD that was focused on data from the 1990's, NURP data was collected during the 1970's. Therefore, the differences between median EMCs from NURP and median EMCs from Los Angeles were also a function of time. Certainly this factor affected median EMCs for lead, which was phased out of gasoline in the mid-1980s (Marsh and Siccama 1997, Hunt et al. 2005).

Further research is needed to directly assess the relationship between trace metal concentrations and particle-size distributions in storm water runoff from mass emission and land use sites to better understand the fate, transport and treatment of trace metals in urban runoff. Storm water borne trace metals are typically associated with particulates to varying degrees depending on the metal and the size distribution of suspended solids in the storm water runoff. Furthermore, the particle size distribution, and metal partitioning can change over the course of a storm event (Furumai et al. 2002). Understanding the dynamic partitioning of trace metals to various size particles is important to being able to estimate temporal and spatial patterns of trace metal deposition in estuaries and harbors, and should be an area of future investigation. Our understanding of the mechanisms of metal loading from urban land uses could also be improved by estimating the percent of directly connected impervious area (DCIA) in each land use category (i.e., percent rooftop, sidewalks, paved driveways and streets) and its impacts on storm water runoff concentrations and loads. This could allow identification of critical source areas, which in turn could allow for more focused application of best management practices.

Table 3-1. Mean annual (± 95% confidence intervals) trace metal loading from different sources (mt = metric tons).

	Mean Annual Load / Year (mt ± 95% CI)		
	Total Copper	Total Lead	Total Zinc
Point Source Data[1,2] (2000-2005)			
Large Publicly Owned Treatment Plants (POTWs)	10.9 ± 6.8	0.8 ± 0.8	13.9 ± 7.6
Low Volume Waste Power Generating Stations (PGS)	0.01	0.00	0.09
Wet Weather Runoff (2000-2005) [3]			
Los Angeles River	1.6 ± 1.2	1.4 ± 1.5	9.8 ± 9.4

SECTION 4. POLYCYCLIC AROMATIC HYDROCARBONS (PAHS)

Results

PAHs from Developed and Undeveloped Watersheds

In-river total PAH loads, concentrations, and fluxes were higher for developed versus undeveloped watersheds. For the 14 storm events measured, mean PAH load from developed watersheds was 5.6 ± 5.1 kg/storm, while mean load from undeveloped watersheds was 0.03 ± 0.02 kg/storm. Similarly, mean total PAH concentration from developed watersheds exceeded that from undeveloped watersheds (2,655.0 ± 1,768.1 ng/L vs 452.2 ± 444.9 ng/L; Tables 4-1 and 4-2). Flux of PAHs from developed watersheds was 46 times greater than that from undeveloped watersheds (Table 4-1). Mean PAH flux from the developed watersheds was 35.6 ± 69.8 g/km^2 compared to 0.75 ± 0.77 g/km^2 for the undeveloped watersheds. When the anomalously high fluxes from the Dominguez watershed are removed, flux from the developed watersheds was 7.8 ± 8.6 g/km^2, which is still greater than 10 times that of the undeveloped watersheds. Furthermore, the higher fluxes from developed watersheds were generated by substantially less rainfall than the lower fluxes from the undeveloped watersheds (1.85 ± 0.97 cm for storms in developed watersheds vs. 6.11 ± 4.32 cm for storms in undeveloped watersheds).

Annual PAH Loading in Storm water Runoff

The estimated annual output rate of total PAHs in the Los Angeles River watershed during the 2002–2003 water year was around 34.9 kg/year (Table 4-1). During this same period, Ballona Creek had an estimated annual output rate of approximately 20.0 kg/year into Santa Monica Bay. The following water year (2003–2004), the storm-water runoff discharge rate from Ballona Creek increased by a factor of four (72.9 kg/year). For comparative purposes, during the same time period, the Los Angeles River watershed discharged an estimated 150.6 kg/year of total PAHs into Santa Monica Bay. Annual output rates for undeveloped watersheds could not be estimated because those sites are not gauged, and consequently annual storm volumes are not available for estimation of annual PAH loads.

Effect of Rainfall Patterns

Antecedent dry period (expressed as cumulative rainfall) was strongly correlated with total PAH concentration, load, and flux in an exponentially nonlinear manner (r^2 = 0.54–0.81; Figure 4-1). Early-season storms have significantly higher PAH loads than late-season storms both within and between watersheds, even when rainfall quantity is similar. For example, the two early-season storms from Ballona Creek in water years 2002 and 2003 had total PAH loadings that were approximately four times larger (ranging from 7.9–8.3 kg) than the two storms that occurred at the end of the rainy season (1.1–1.8 kg), despite the early- and late-season storms resulting from comparable rainfall. When all watersheds are analyzed together, PAH concentration and load decrease with increasing cumulative rainfall until approximately 10 cm (average annual rainfall is 33 cm), beyond which the effect is markedly less dramatic (Figure 4-1).

PAH Variability Within Storms

The greatest total PAH concentrations occurred during the rising limb of the storm hydrograph for nearly every storm sampled. For example, peak concentrations (2,761 and 2,276 ng/L, respectively) occurred before the peak in flow (757 and 101 cms) in both the Los Angeles River and Ballona Creek (Figure 4-2). In the Los Angeles River example, peak total PAH concentrations occurred almost 8 h before the peak in storm flow. In the Ballona Creek example, a second peak in flow (75 cms) was also preceded by a second peak in total PAH concentration (1,015 ng/L).

Despite a strong and consistent pattern of first flush in concentration, cumulative mass loading plots exhibited only a moderate first flush of PAHs. Between 40% and 60% of the total PAH load was discharged in the first 25% of storm volume for the storms examined in this study. The mass loading plots for Ballona Creek (Figure 4-3) illustrate a consistent pattern of higher mass loading in the early portions of the storm, with a slightly stronger first flush in late-season storms. Land use sites showed a similar pattern of higher mass loading in the early portions of the storm however mid season storms (i.e., January-March) exhibited the strongest first flush.

Potential Sources of PAHs

Sources of PAHs were investigated by comparing concentrations and loads in runoff from homogeneous land uses sites. For all land use sites samples, mean PAH flux was between 0.33 and 140 g/km^2, while FWM concentration was between 4.6E ± 02 and 4.4E ± 03 ng/L (Table 4-3). Despite some apparent differences between land uses (e.g., high-density residential having higher concentrations and industrial having higher flux), no significant differences were observed in either concentration or flux among land use category (p = 0.94 and 0.60, analysis of covariance, with rainfall as a covariate).

The relative proportion of individual PAH compounds can be used to determine the source of PAHs in storm water. The HMW PAHs dominated LMW PAHs in runoff from all storms analyzed, suggesting a pyrogenic source. During the May 2–3, 2003, storm, HMW PAHs in runoff from the Los Angeles River and Ballona Creek accounted for 72% of the total PAH concentrations from these watersheds (Figure 4-4 and Table 4-2). Similarly, HMW PAHs in runoff from the Dominguez channel watershed in Los Angeles County, California, USA, accounted for 74% of the total PAH concentrations from its watershed. Even in the undeveloped Arroyo Sequit watershed, HMW PAHs accounted for 63% of the total PAH concentrations. In all storms and at all sites, the HMW compounds fluoranthene and pyrene were the dominant HMW PAHs. Analysis of the distribution of PAHs within each storm event shows that HMW PAHs are predominant uniformly throughout each storm regardless of land use (Figure 4-5). The exceptions were the industrial oil refinery and the agricultural sites, where the proportions of HMW and LMW PAHs were comparable throughout the storm. In all cases (except the oil refinery and agricultural sites), the relative contribution of LMW PAH compounds averaged 14 to 30% of the total PAH mass. Phenanthrene was the most dominant LMW PAH, comprising 7 to 21% of the total PAH contribution (Table 4-2).

The F/P ratio was between 0.9 and 1.2 for all storms in this study, indicating a strong predominance of pyrogenic PAH sources (Table 4-2). Furthermore, the P/A ratio was nearly always less than 21, once again indicating a strong predominance of pyrogenic PAH sources

(Table 4-2). Only one storm, March 17–18, 2002, at the Dominguez channel site, had a potential petrogenic source; the F/P ratio was 0.9, but the P/A ratio was .74. This result is consistent with the data from the land use sites, as the Dominguez watershed contains four major oil refineries. As with the distribution of HMW versusLMW PAHs, the F/P and P/A ratios indicate a consistent pyrogenic source for all lands use and mass emission sites regardless of the point within the storm (Figure 4-6). Again, the exception was at the industrial oil refinery, where the P/A ratio is low until the peak runoff occurs, at which time it rises to between 17 and 20. For both Ballona Creek and the Los Angeles River, a moderate, transient increase in the P/A ratio occurs coincident with the time of peak flow (Figure 4-4).

Discussion

Anthropogenic sources of total PAHS in storm-water runoff from urbanized coastal watersheds appears to be a significant source of PAHs to the southern California Bight. Estimates from this study based on FWM concentrations and gauged annual discharge volume indicate that during the study period approximately 92.8 and 32.7 kg/year of total PAH were discharged annually from the Los Angeles River and Ballona Creek watersheds, respectively. Over the same time period, the combined treated wastewater discharge from the city and county of Los Angeles (~2.8 x 10^6 m^3/d) discharged an estimated 740 kg of PAHs to the southern California Bight (Steinberger et al. 2003). The main difference between the two types of discharges is the delivery of the load to the coastal oceans; the treated wastewater discharge occurs in small, steady doses that occur daily, while storm-water loading occurs over the 10 to12 precipitation events that this region averages annually. The impact of the total PAHs in storm water discharged from urbanized watersheds is also reflected in receiving waterbody impacts. Regional monitoring of the southern California Bight revealed that the highest concentrations of PAHs were associated within bay and harbor areas that receive inputs from urbanized coastal watersheds (Noble et al. 2003). Bays and harbors only accounted for 5% of the total area of soft-bottom habitat but contained approximately 40% of the total PAH mass residing in southern California Bight surficial sediments. A second concern is the cost of remediating PAH in dredged materials. Total PAH is one of the most commonly occurring contaminants in dredged materials from San Pedro Bay (Steinberger and Schiff 2003). While some of these contaminants likely arise from port and industrial activities, they are colocated at the mouths of the Los Angeles River and Dominguez Channel watersheds, which is likely a contributing source.

The impact of PAH contributions on receiving waters from urbanized watersheds are not constrained to the southern California Bight. The National Status and Trends Program, which samples sediments and tissues in estuaries and coastal areas nationwide, repeatedly finds elevated PAHs near urban centers (Daskalakis and O'Conner 1995). San Pedro Bay (CA, USA) ranked third nationwide in total PAH concentration in mussel tissue during 2002. The top two locations are Elliott Bay (WA, USA) and Puget Sound (WA, USA), both located near urban centers. On the East Coast, Long Island Sound (NY, USA) adjacent to New York City was ranked fourth.

The annual watershed loading of PAHs estimated from this study are lower than those estimated from two studies in the eastern United States. Hoffman et al. (1984) estimated 680 kg/year of PAH loading from the 4,081 km^2 Narragansett Bay watershed in Rhode Island, USA. Similarly, Menzie et al. (2002) estimated 640 kg/year of PAH loading from the 758 km^2

Massachusetts Bay, USA, watershed. This difference may be explained by several factors. First, PAH loading relies on washoff of aerially deposited materials (the process by which airborne toxic contaminants enter coastal waters via aerial fallout). Watersheds in the western United States typically experience less than one-third rainfall and runoff volumes than comparably sized watersheds in the eastern United States. The lower volumes of annual runoff likely translate to lower loads. This may seem counter-intuitive; however, if the primary pollutant source to the land surface is aerial deposition (vs. being generated by activities within the land use), there is a practical limit to the amount of material that can accumulate. Previous studies have shown that physical processes such as wind or turbulence from traffic can limit pollutant accumulation on roads and other impervious surfaces (Pitt and Shawley 1981, Asplund et al. 1982, Kerri et al. 1985). Chemical processes, such as volatilization or oxidation can also limit the accumulation of potential pollutants on impervious surfaces (Hewitt and Rashad 1992). Because of the asymptotic nature of PAH buildup, loading to receiving waters is controlled by the frequency and magnitude of runoff events that "cleanse" impervious surfaces and provide subsequent opportunity for additional material to accumulate. A second reason for higher estimated PAH loading in the eastern United States is that PAHs are generated predominantly from concentrated point sources, such as coal-fired power plants. Southern California does not have coal-fired power plants; rather, PAHs are predominantly from mobile sources (cars, trucks, and trains), which discharge more diffusely across the region.

Concentrations in runoff from land use sites in this study were between 0.03 and 7.84 µg/L; these values are similar to those observed in previous studies by others. For example, Mahler et al. (2004) reported PAH concentrations between 5.1 and 8.6 µg/L in parking lot runoff, and Menzie et al. (2002) reported concentrations between 1 and 14 µg/L from a broad range of land uses.

In contrast to the results of this study, storm-water monitoring by local municipalities in southern California consistently report no detectable PAHs in storm water. This discrepancy is likely attributable to two factors. First, the practical PAH detection limit used by local municipalities is typically between 1 and 5 µg/L, which is acceptable by U.S. EPA regulatory guidelines. However, the mean FWM concentrations in storm water during this study were often lower than this level. The second factor is the sampling design used for regulatory-based monitoring. Most local municipalities are mandated to collect a storm composite sample that do not emphasize (and may completely miss) the first flush of total PAH that was observed. We almost always observed the greatest peaks in total PAH concentrations during initial storm flows, up to 8 h before peak flow. This pronounced first flush suggests that in highly urbanized watersheds, particle-bound PAHs may be rapidly mobilized from impervious land surfaces during the early portions of storms. Similar first-flush patterns in PAH concentrations during storms were observed by Hoffman et al. (1984) and (Smith et al. 2000). Furthermore, (Buffleben et al. 2002; University of California, Los Angeles, Los Angeles, CA, USA, unpublished data) also observed that peak PAH concentrations in Ballona Creek occur up to 14 h before peak flow.

Seasonal flushing at mass emissions sites was one phenomenon not previously reported by others. Seasonal flushing occurred when early-season storms consistently discharged higher PAH loads than storms of a similar size or larger later in the season. This seasonal effect was correlated with the length of antecedent dry condition but not with rainfall quantity. The lack of

a meaningful relationship between rainfall quantity and PAH loading has been reported in several other studies (Eaganhouse et al., Hoffman et al. 1984). Hoffman et al. (1984) suggested that the lack of a clear relationship was due to the complex spatial and temporal dynamics associated with rain patterns, which may affect runoff patterns more than the total amount of rainfall during a given storm. In addition, differential particle wash-off from land surfaces may mask any differences associated with total rainfall. The strong relationship between PAH flux and antecedent dry period suggests that storm-event PAH loads are a function primarily of the amount of time available for PAHs to build up on the land surfaces between subsequent rain events. The PAH loads from land surfaces during later-season storms (i.e., after 10 cm of accumulated rainfall) may reflect contributions from wet deposition or from localized accumulation; however, we currently lack the data to answer this question definitively. Analysis of PAH concentration in wet deposition would help improve our understanding of the sources of PAHs during the latter part of the storm season. Environmental managers can use this knowledge of temporal patterns of PAH loading to focus efforts on storm capture or treatment during the early portions of storms and during the earliest storms of the year.

Sources of PAHs in Storm water

Several lines of evidence implicate aerial deposition and subsequent wash-off of combustion by-products as the main source of PAH loading in storm water. First, the flux of total PAHs among large developed watersheds were similar throughout the urbanized region of Los Angeles, suggesting a similar regional source of PAHs. If urban land use distribution strongly influenced PAH loadings, then flux would have differed by watershed based on differential urban land use practices. In fact, no difference was observed in PAH concentrations in runoff between various urban land uses, which differs from the findings of previous studies from the eastern United States (Ngabe et al. 2000). Menzie et al. (2002) concluded that residential and commercial land uses generated higher PAH concentrations than other land use types because of secondary petrogenic sources that enhanced the regional pyrogenic source of PAHs. Hoffman et al. (1984) found that runoff from industrial and highway sites had higher PAH concentrations than residential runoff but accounted for these differences in runoff dynamics as opposed to unique sources.

Second, the relative abundance of individual PAHs in runoff indicates a strong pyrogenic source indicative of combusted fossil fuels. The typical distribution of PAHs observed from mass emission sites (Figure 4-7) was similar to the distribution of PAHs observed in dry deposition collected in Los Angeles by Sabin et al. (2004). Furthermore, in this study, HMW PAH consistently comprised approximately 73% of the total PAH concentration regardless of land use. Hoffman et al. (1984) reported comparable results in their study of urban runoff in Rhode Island's Narragansett Bay watershed, where HMW PAHs accounted for 71% of the total inputs to Narragansett Bay. A more recent study by Menzie et al. (2002) of PAHs in storm-water runoff in coastal Massachusetts identified similar HMW PAH compounds as observed in this study (chrysene, fluoranthene, phenanthrene, and pyrene) as the primary PAH compounds in storm water. Similarly, (Soclo et al. 2002) found that high PAH loads associated with storm-water runoff to the Cotonou Lagoon in Benin were characterized by HMW PAHs that appear to be derived from atmospheric deposition. The consistent predominance of HMW PAHs throughout all storms, even during the period of first flush, further indicates a consistent regional source, such as aerial deposition. If specific land uses were generating secondary petrogenic

wash-off as suggested by Menzie et al. (2002), the distribution of PAHs would have changed during the storm; however, we did not observe any differences within storms. The exception to this pattern was for the industrial oil refinery site, where the signature of petrogenic PAHs was more pronounced. This makes sense given the obvious petrogenic source associated with this land use type. Nevertheless, the pyrogenic signature was still prevalent at this land use, especially during the latter portions of the storm.

The PAH sources can also be inferred by examining ratios of particular PAHs in runoff samples. We used both the fluoranthene/pyrene (F/P) and phenanthrene/anthracene (P/A) ratios. Small F/P ratios close to 0.9 suggest that individual PAHs are associated with combustion products (Maher and Aislabie 1992); in contrast, large F/P ratios suggest petrogenic sources of PAHs (Colombo et al. 1989;Table 4-4). Both the F/P and the P/A ratios observed in this study indicate that aerial deposition of combustion by-products is likely the dominant source of PAHs in the watersheds that drain to the greater Los Angeles coastal region, and this source is consistent during all portions of storm-water runoff. Several additional ratios have been used to assess the different sources of PAHs. Takada et al. (1990) used methylated/parent PAH ratios as indicators of PAH sources. Results showed that PAHs in runoff from residential streets had a more significant contribution from atmospheric fallout of other combustion products. Zakaria et al. (2002) explained their low ratios of methylphenanthrene to phenanthrene (MP/P; <0.6) to mean that combustion- derived PAHs are transported atmospherically for a long distance and serve as background contamination. The ratios of methylphenanthrene to phenanthrene in our study (0–0.2) also suggest a strong contribution of aged urban aerosols to overall PAH loads (Nielsen 1996, Simo et al. 1997, Hwang et al. 2003). Watersheds in the greater Los Angeles area are heavily urbanized; therefore, ample opportunity exists for combustion-derived aerosols that generate particulate matter to be deposited on land surfaces. The petrogenic signature seen in the Dominguez Channel can be explained by the presence of slightly different sources in this watershed. The Dominguez watershed contains a high density of oil refineries and other industrial land uses that drain directly to the Ports of Los Angeles and Long Beach. The presence of multiple oil refineries discharging to a single stream explains the concentration of petrogenic PAHs in this area.

Conclusions based on ratios of specific PAH compounds should be used with some caution, especially because a relatively limited set of PAHs were analyzed in this study. Furthermore, if reference (or source) samples were not analyzed, it is always a good idea to use these ratios on a relative basis. Nevertheless, the preponderance of evidence from this study, combined with the well-documented fact that atmospheric deposition (both wet and dry) is the major source of contamination in arid and semiarid climates, such as that existing in southern California (Sabin et al. 2004, Gunther et al. 1987), supports the conclusions of this study: The predominant source of PAHs in urban storm water in the greater Los Angeles area is from aerial deposition and subsequent wash-off of PAHs associated with combustion byproducts.

Table 4-4. Selected polycyclic aromatic hydrocarbon ratios and their source signature ranges.

Indicator	Pyrogenic	Petrogenic	Reference
Fluoranthene / Pyrene Ratio	0.9 - ≤1	>1	Maher and Aislabie, 1992
Phenanthrene / Anthracene Ratio	3 - 26	>26	Gschwend and Hites, 1981; Lake et al., 1979
Methylphenanthrene / Phenanthrene Ratio	<1.0	2 - 6	Hwang et al., 2003

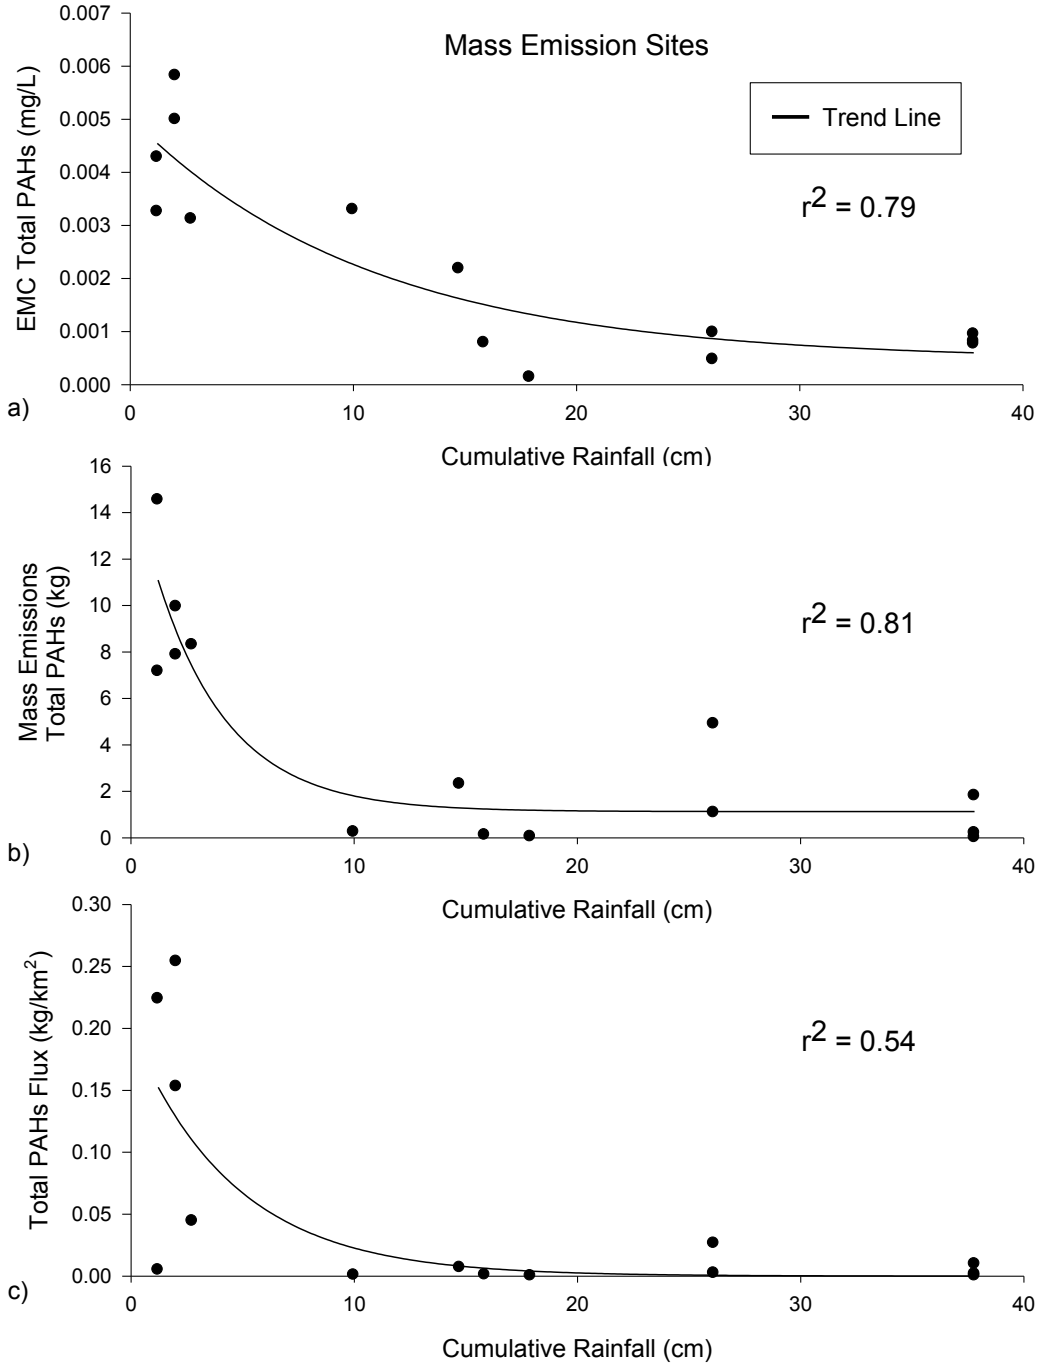

Figure 4-1. Cumulative annual rainfall versus polycyclic aromatic hydrocarbon (PAH) event mean concentration (EMC; a), load (b), and flux (c). Plots show data for mass emission sites only.

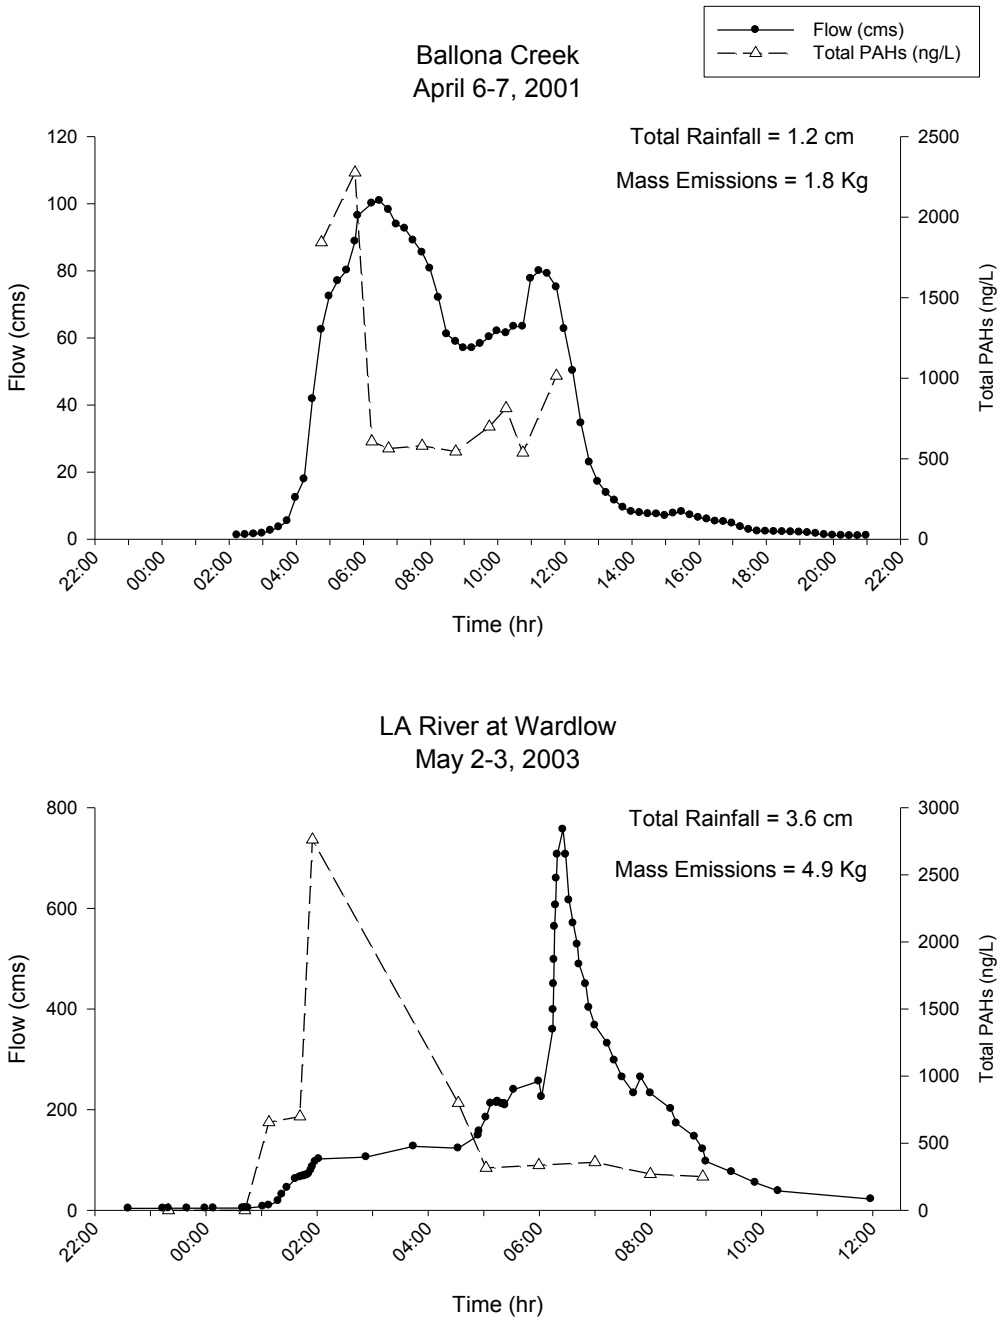

Figure 4-2. Variation in polycyclic aromatic hydrocarbon (PAH) concentrations with time for storm events in Ballona Creek (top) and Los Angeles River (bottom).

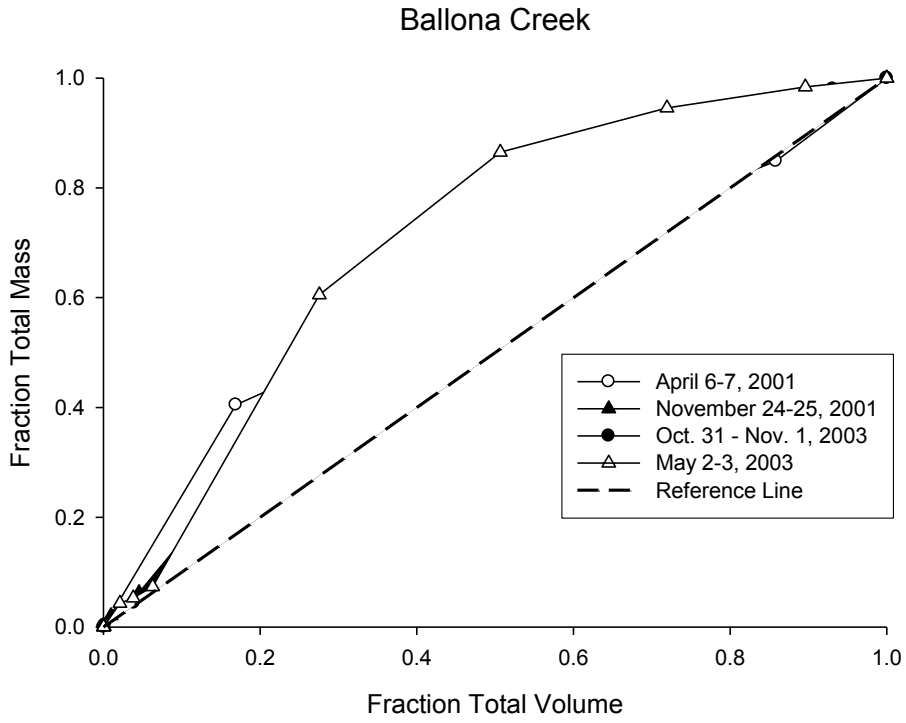

Figure 4-3. Cumulative polycyclic aromatic hydrocarbon mass loading for four storms in Ballona Creek. Plots show percent of mass washed off for a given fraction of the total runoff. Reference line indicates a 1:1 relationship between volume and mass loading. Portions of the curve above the line indicate proportionately higher mass loading per unit volume (i.e., first flush). Portions below the line (if any) indicate the reverse pattern.

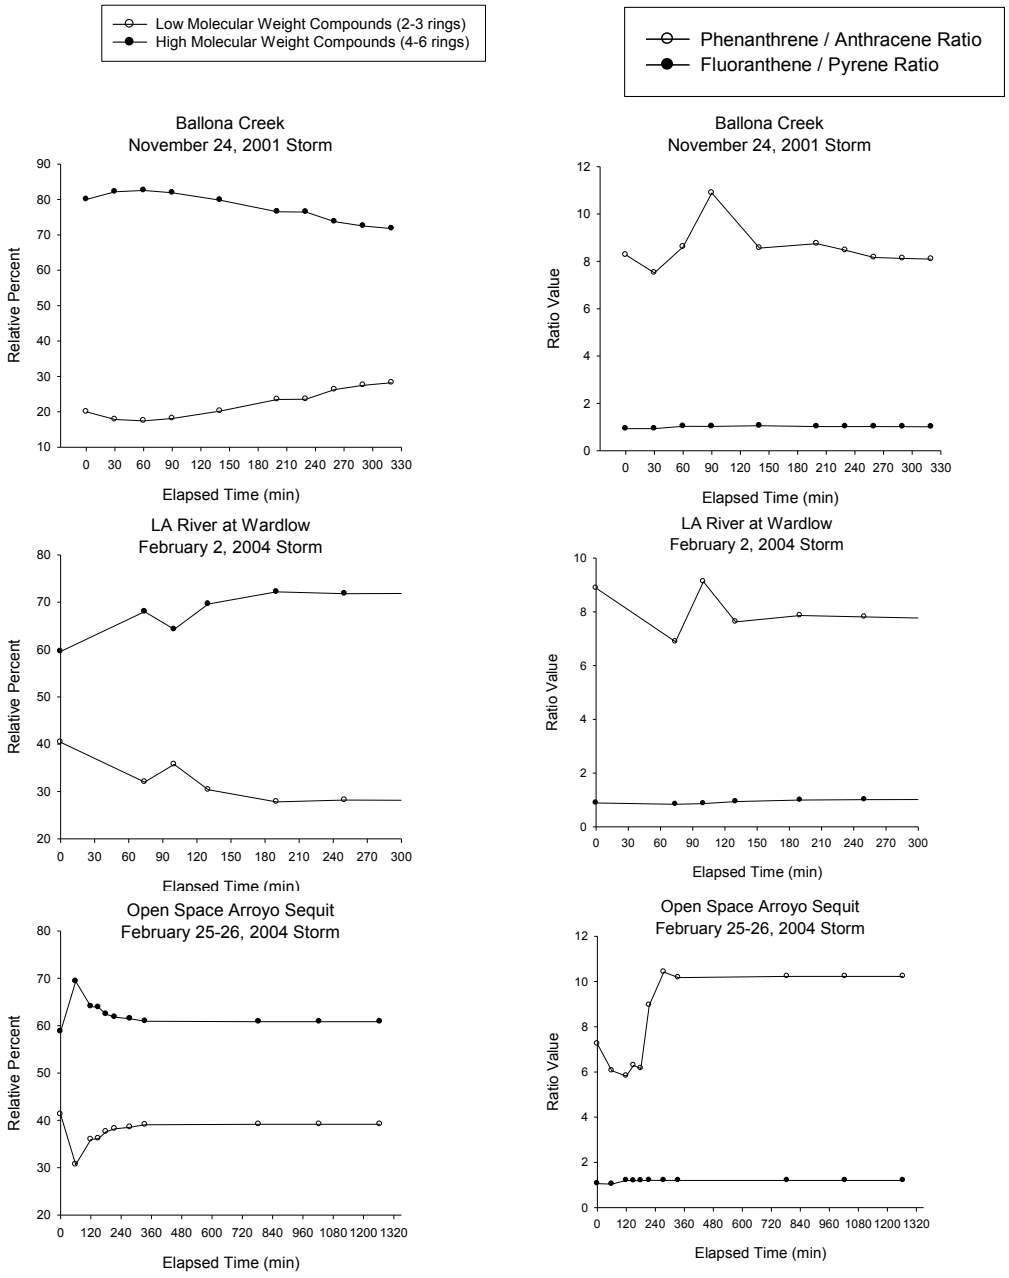

Figure 4-4. Distribution of polycyclic aromatic hydrocarbons (PAHs) within storms for mass emission sites. Plots on the left (a–c) show distribution of high- versus low-molecular-weight PAHs throughout individual storms. Plots on the right (d–f) show phenanthrene/anthracene (P/A) and fluoranthene/pyrene (F/P) ratios throughout individual storms. Peaks in the P/A ratio correspond to peak storm flows.

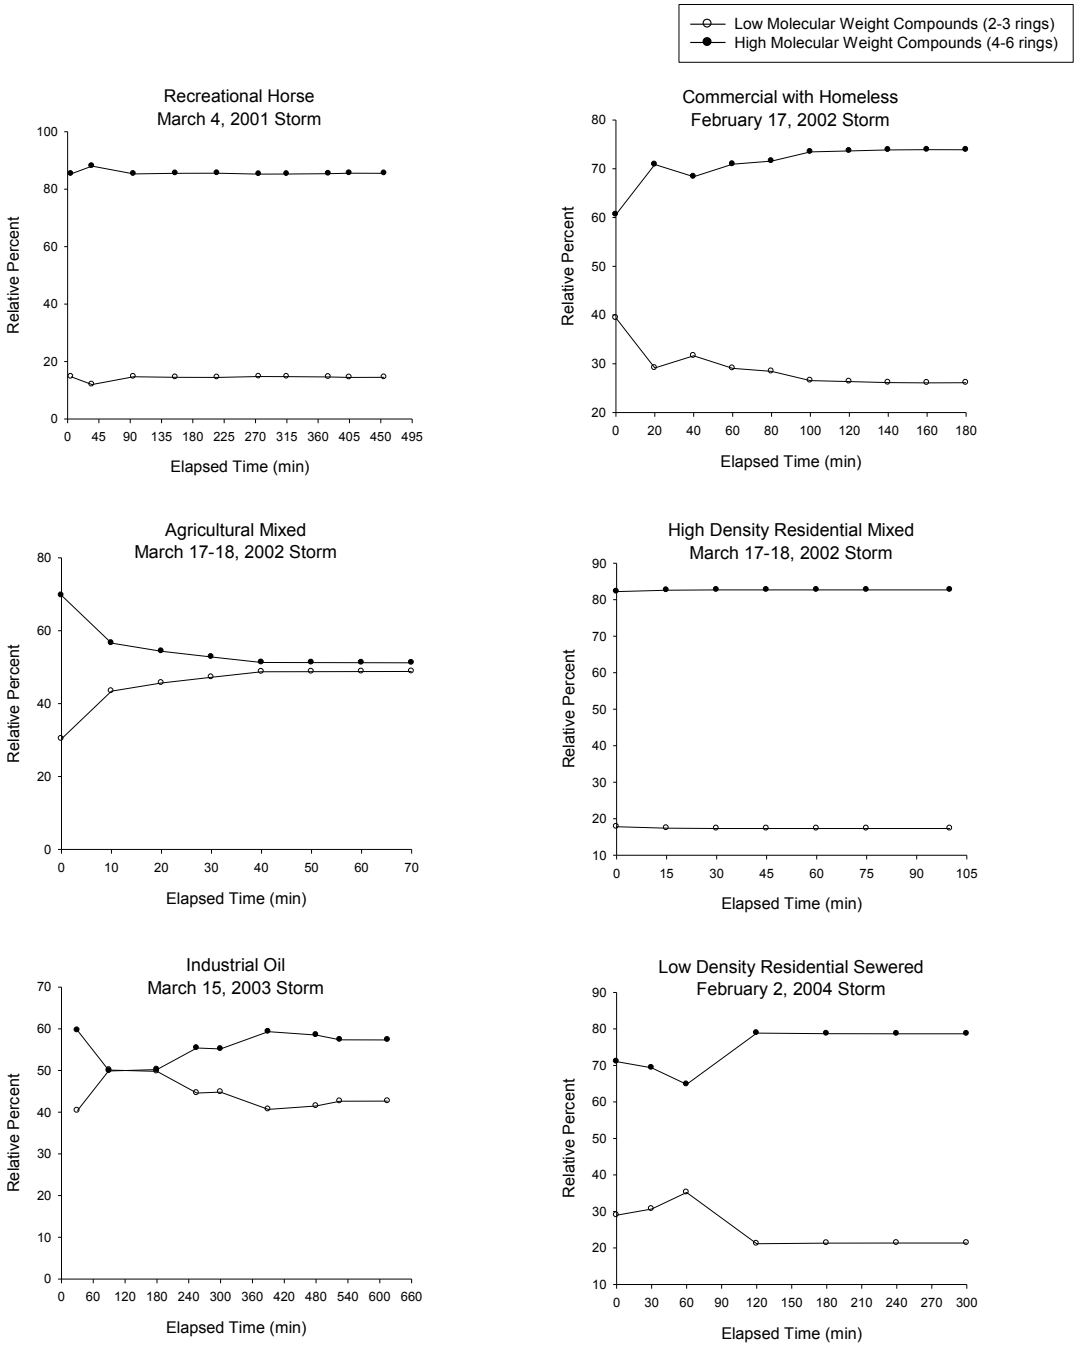

Figure 4-5. Distribution of polycyclic aromatic hydrocarbons (PAHs) within storms for representative land use sites (a–f). Plots show distribution of high- versus low-molecular-weight PAHs throughout individual storms. Data are shown for six sites that represent the results observed for the 15 land use sites where data were collected.

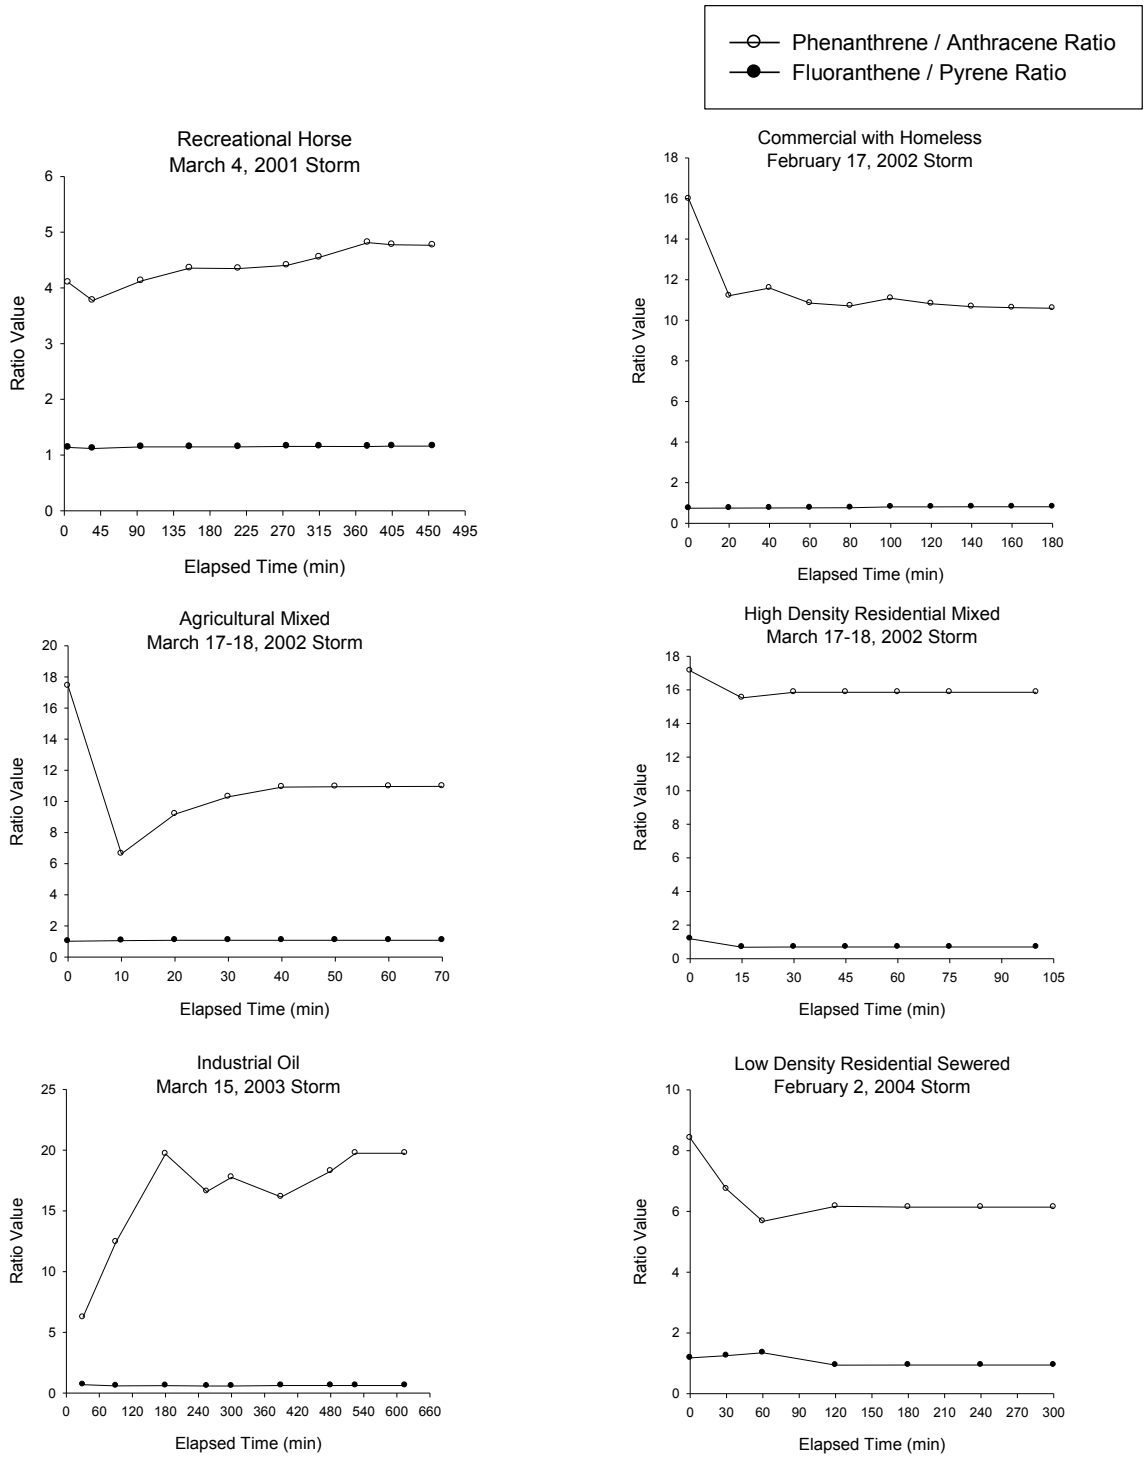

Figure 4-6. Distribution of polycyclic aromatic hydrocarbons within storms for representative land use sites. Plots (a–f) show phenanthrene/anthracene (P/A) and fluoranthene/pyrene (F/P) ratios throughout individual storms. Data are shown for six sites that represent the results observed for the 15 land use sites where data were collected.

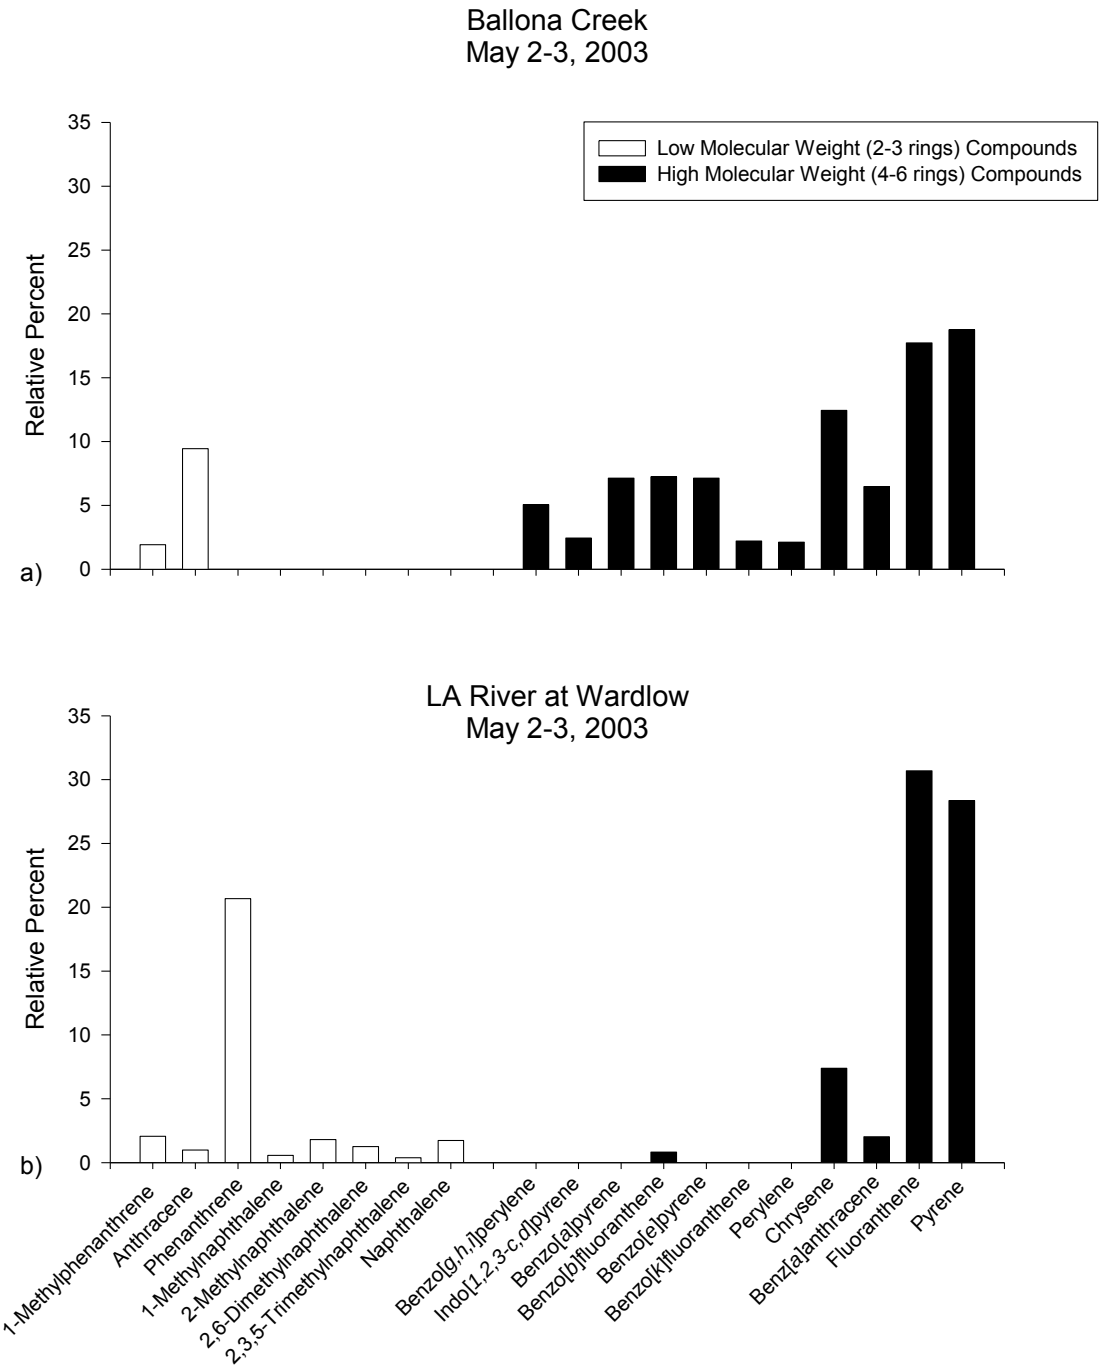

Figure 4-7. Relative distribution of individual polycyclic aromatic hydrocarbon compounds for Ballona Creek (a) and Los Angeles River (b) on May 2–3, 2003.

SECTION 5. FECAL INDICATOR BACTERIA (FIB)

Results

FIB from Developed and Undeveloped Watersheds

E. coli, *Enterococcus* spp. and total coliforms occurred at all ME sites at concentrations that consistently and uniformly exceeded CA water quality standards (Figure 5-1). Mean *E. coli*, *Enterococcus* spp. and total coliforms EMCs and fluxes were significantly greater at ME sites from developed compared to undeveloped watersheds (ANOVA, p = 0.006). For example the mean EMC at the developed Ballona Creek watershed was two orders of magnitude higher than at the undeveloped Open Space Arroyo Sequit watershed (10^4 MPN/100 mL vs. 10^2 MPN/100 mL, respectively; Fig. 5-1a). Bacteria EMCs were typically higher in the Los Angeles River compared to the other watersheds sampled.

Bacterial flux from ME sites exhibited a similar pattern as that observed for the EMCs. For example, *E. coli* fluxes were two orders of magnitude higher at the developed Ballona Creek watershed versus the undeveloped Arroyo Sequit watershed (i.e., 10^{12} colonies/km^2 vs. 10^{10} colonies/km^2, respectively; ANOVA, p = 0.02, Figure 5-1b). Similarly, *Enterococcus* spp., and total coliforms fluxes were substantially higher for the developed watersheds versus the undeveloped watershed, but these differences were not statistically significant. Furthermore, the higher fluxes from developed watersheds were generated by substantially less rainfall than the lower fluxes from the undeveloped watersheds (2.07 ±1.22 cm for storms in developed watersheds vs 6.49 ±3.79 cm for storms in undeveloped watersheds).

FIB Concentration and Flux from Specific Land-use Types

Figure 5-2 shows the median FIB concentrations for the storm events sampled for each LU category. Mean *E. coli,* EMCs from the recreational LU site were significantly higher than the commercial, high density residential, industrial and transportation LU sites (i.e., $5.3\text{x}10^5$ MPN/100mL ± $1.7\text{x}10^5$, p=0.004, Appendix B-15) and were an order of magnitude higher than mean EMCs observed at ME sites. Agricultural LU sites contributed the second highest mean indicator bacteria EMCs but were not statistically different from all other LU sites (i.e., $4.0\text{x}10^4$ MPN/100mL ± $1.4\text{x}10^4$ *E. coli*, $1.2\text{x}10^5$ MPN/100mL ± $9.6\text{x}10^4$ *Enterococcus* spp. and $6.4\text{x}10^5$ MPN/100mL ± $9.6\text{x}10^4$ total coliforms).

Direct comparison of flux showed that storm water from agricultural, recreational and industrial LU sites had the highest mean FIB fluxes. Most of the developed LU types exhibited comparable fluxes of 10^{11} colonies/km^2 (Appendix B-15). In contrast, the agricultural LU contributed substantially higher flux of both *Enterococcus* spp. and total coliforms (e.g. mean *Enterococcus* flux = 10^{14} colonies/km^2 (Appendix B-15). Mean FIB fluxes at the open space LU were comparable to those observed at developed LU sites (e.g. 10^{12} colonies/km^2; Appendix B-15).

Correlation between FIB and TSS Concentration

A simple Spearman's correlation matrix (Table 5-1) of TSS, stream flow and FIB indicates that *E. coli* was significantly positively correlated (p <0.0001) with TSS from agricultural, recreational and open LU sites. *E. coli* concentration from low-density residential

and industrial LU sites were weakly correlated with TSS. *Enterococcus* spp. was significantly correlated (p <0.0001) with total suspended solids from low-density residential, agricultural, recreational and transportation LU sites and all correlations with the exception of the low-density residential site were positive. *Enterococcus* spp. counts from commercial and open LU sites were weakly and positively correlated with TSS. Both *E. coli* and *Enterococcus* spp. had correlation coefficients (Spearman's *rho* or ρ) between 0.5 and 0.8, indicating that similar processes may have controlled the effect of TSS on each of these parameters. FIB concentrations were only significantly correlated (p <0.0001) with stream flow at the commercial, high-density residential and agricultural LU sites.

California Bacterial Water Quality Standards

Bacteria concentrations exceeded the California beach water quality single-sample water quality standard in almost all of the samples collected during this study. Concentrations of FIB at many LU sites were as high as those found in primary wastewater effluent (10^6-10^7 MPN/100ml). Cumulative density frequency plots showed 98%, 94% and 92% of the in-river storm water samples for *Enterococcus* spp., *E. coli* and total coliforms bacteria exceeded CA ambient water quality standards (Figure 5-3). Similar results were observed at LU sites. Approximately 80% of all samples exceeded water quality thresholds at LU sites for at least one indicator (i.e., *E. coli* exceedence = 83%; Figure 5-3). The above comparisons are based on receiving water quality standards. If compared to the proposed freshwater standards, which are approximately 60% lower than the receiving water standards, the exceedances would be slightly higher.

Large-sized watersheds (>100 km^2) exhibited the greatest frequency of water quality threshold exceedences (Figure 5-4). More than any other indicator, concentrations of *Enterococcus* spp. were responsible for the majority of water quality threshold exceedences across all three watershed size categories, exceeding thresholds 98% of the time for both large and medium-sized watersheds (25-100 km^2), and 96% of the time for small-sized watersheds. *E. coli* and total coliform concentrations followed a decreasing frequency of exceedences in terms of watershed size (i.e., large > medium > small).

Temporal Patterns in Indicator Bacteria Loading

Effect of Rainfall Patterns: Indicator bacteria from LU sites showed little variation when evaluated for seasonal differences between early- and late- season storms. In contrast, antecedent dry period (expressed as cumulative annual rainfall) was strongly correlated with FIB concentrations from ME sites in an exponentially non-linear manner (r^2 = 0.67-0.92; Figure 5-5). Early-season storms generally had higher *Enterococcus* spp. and total coliforms EMCs than late-season storms both within and between watersheds with an inflection point at approximately 10 cm, even when rainfall quantity was similar. For example, the early-season storm from Ballona Creek in water year 2004 had an *Enterococcus* spp. EMC two times larger (3.0×10^4 MPN/100mL) than the storm that occurred at the end of the rainy season in water year 2003 (1.6×10^4 MPN/100mL), despite the early- and late-season storms resulting from comparable rainfall (approx. 3.0 cm). The results for *E. coli* EMCs from early- and late- season storms were comparable. When all watersheds are analyzed together *E. coli*, *Enterococcus* spp. and total coliforms concentrations decrease with increasing cumulative annual rainfall until approximately

10 cm (average annual rainfall is 33 cm), beyond which the effect is markedly less dramatic (Figure 5-5).

With-in Storm Variability

FIB concentrations varied with time and as a function of flow over the course of storm events. Figures 5-6 and 5-7 show the pattern of change throughout storm events for *E. coli* and *Enterococcus* spp.. In all cases, bacterial concentrations increased markedly preceding peak flow (compared to base flow level). *Enterococcus* spp. concentrations stayed high for a relatively short period at the developed Ballona Creek site (2.4×10^5 MPN/100mL) and then decreased back to base levels within two hours (Figure 5-6a). In contrast, *E. coli* concentrations were more variable exhibiting two separate peaks around 2.6×10^4 MPN/100mL and an order of magnitude lower than *Enterococcus* spp. concentrations (Figure 5-6b)[1]. Although the pattern of an early peak in concentration was comparable in both undeveloped and developed watersheds, in the undeveloped watersheds the peak concentration tended to occur later in the storm and persist for a longer duration (i.e., three to four hours; Figure 5-7). Furthermore, flow continued above base flow conditions for a longer duration in the undeveloped watersheds however FIB concentrations steadily decreased following the early peak in storm. We cannot make conclusions about the consistency of these patterns given the small number of storms sampled at undeveloped watersheds.

Discussion

The relatively higher bacteria concentrations from recreational and agricultural LU sites may be due to several sources. Sources of bacteria include domestic pet and wildlife wastes that are deposited, stored, or applied to the land, a fact that may account for the high *E. coli* and *Enterococcus* spp. EMCs, and overall mean flux of 1.4×10^{13} and 1.1×10^{14} colonies/km^2, respectively observed at the agricultural sites during this study. In contrast, land use sites, such as industrial areas and built-out residential areas, have proportionately less direct sources of fecal material and have lower sediment concentrations in storm water than do mixed LU and developing areas (i.e., recreational, Mallin 1998, Burnhart 1991). This difference in source material may be a factor that accounts for why these LU sites had lower indicator bacteria EMCs and fluxes.

The association of bacteria with storm water particles may also explain differences in *E. coli* and *Enterococcus* spp. concentrations from different LU sites. Correlations of FIB with TSS from recreational and agricultural LU sites indicate associations with particulate material, but it is unclear if that particulate material resulted from soils transported to the stream from these LU sources or from erosion and resuspension of sediment already in the streambed from upland sources. Other studies have implicated streambed sediment and its resuspension (Matson et al. 1978, Francy et al. 2000, Embrey 2001) as sources and principal transport vectors for bacteria. The higher indicator bacterial concentrations at the recreational and agricultural land use sites indicate that bacteria associated with these areas may be directly associated with sources at those sites. Another possible explanation for the high FIB concentrations at agricultural sites may be

[1] Unfortunately FIB samples were not collected prior to 3:30 AM due to failure to be on site when storm commenced.

due to the regular application of fertilizers, algaecides and fungicides (Niemi 1991, Cook and Baker 2001). Assessing particle size distribution over the entire storm duration at these LU sites may provide a clearer or consistent particle source association. Interestingly, indicator bacteria concentrations were only significantly correlated ($p<0.0001$) with stream flow at the commercial and high-density residential LU sites even though bacteria in streams are commonly associated with suspended particles (Schillinger and Gannon, 1985, Hunter et al. 1999), either because they were transported to the streams attached to the particles, they were bound to streambed sediment (Matson et al.1978) that has been resuspended (Grimes 1975, Matson et al.1978, Hunter et al. 1999) or because of specific bacterial affinities for sediment particles (Scholl and Harvey 1992, Bolster et al. 2001) that may occur in the water column. Although bacterial transport has been correlated with stream stage (Hunter et al. 1992) and stream flow during storms and also tends to be associated with the transport of suspended sediment (Davis et al. 1977), these associations are not always evident (Qureshi and Dutka 1979). In the Los Angeles River watershed the lack of correlations at specific LU sites with stream flow may indicate that contributing sources or processes for bacteria were different from storm to storm.

Comparison of FIB concentrations in runoff from LU sites from this study reveal median *E. coli* EMCs that are comparable to current U.S. averages reported in the National Stormwater Quality Database (NSQD; Maestre et al. 2003), but lower than concentrations reported in the Nationwide Urban Runoff Program (NURP) database (U.S. EPA 1983a; Figure 5-8). The exception is that median total coliform values from all LU sites in Los Angeles, CA are substantially higher than those observed in the rest of the U.S. (Table 5-2). The similarities in median event-mean *E. coli* concentrations from LU sites across the U.S. measured since 1992 (reported by the NSQD) and those observed 13 years later during this study demonstrate that the issue of fecal bacteria contamination in urban watersheds is not improving over time.

Seasonal comparisons of wet weather FIB concentrations to dry weather concentrations from the urbanized Ballona Creek watershed during 2002-03 revealed that contributions from wet weather far exceeded those from dry weather (Table 5-3). Freshwater outlets such as storm drains are found to be especially high contributors of indicator bacteria contamination (Stein and Tiefenthaler 2005, Noble et al. 2000, Bay and Schiff 1998). Nevertheless, the highest mean dry-weather *E. coli* concentrations (7,457 MPN/100 ml) found in samples from Ballona Creek were still an order of magnitude lower than the lowest mean *E. coli* storm EMC from this study (43,305 MPN/100 ml; Table 5-3, $p<0.03$ E. coli; $p<0.04$ *Enterococcus* spp.; $p<0.02$ total coliforms). Wet versus dry sampling events have been compared by other studies in the southern California region (Noble et al. 2006, Schiff et al. 2003, Noble et al. 2003). These studies also found a higher number of exceedences of water quality standards during wet weather for all indicators, especially at storm water outflows and storm drains.

Consistently higher bacteria levels during early season storms likely reflect bacteria buildup during dry periods that "flushes" to rivers during early season storms. Bacteria concentrations in rivers were strongly influenced by the length of antecedent dry condition but not with amount of rainfall. The strong relationship between indicator bacteria EMC and antecedent dry period suggests that the magnitude of bacterial load associated with storm water runoff depends on the amount of time available for build up on land surfaces, and that storm size is a less reliable predictor of the magnitude of bacterial loading. Since indicator bacteria

continue to reproduce in the environment and reproduction is favored in aerobic temperate waters, low flow and high temperature conditions that typically occurs in southern California between May and October likely allows indicator bacteria concentrations to build-up on land surfaces, resulting in proportionally higher bacteria concentrations and loads during the initial storms of the season. A similar seasonal pattern (i.e., 10 cm cumulative annual rainfall threshold) was observed for polycyclic aromatic hydrocarbons (PAHs) and trace metals in the Los Angeles region (Stein et al. 2006, Sabin et al. 2004, Tiefenthaler et al. in press). Han et al. (2006) also reported that antecedent dry period was the best predictor of the magnitude of pollutant runoff from highways. Other researchers (Anderson and Rounds 2003, Ngoye and Machiwa 2004) have reported corresponding temporal trends for other particle-bound contaminants. This seasonal pattern suggests that focusing management actions on early season storms may provide relatively greater efficiency than distributing lower intensity management actions throughout the season.

FIB concentrations in storm water were highly variable, with concentrations often ranging by factors of 10 to 100 during a single storm. The greatest bacteria concentrations occurred at or just before the peak in flow of the storm hydrograph for nearly every storm sampled. This hydrograph/pollutograph pattern was also observed for PAHs (Stein et al. 2006) and trace metals (Tiefenthaler et al. in press) in the greater Los Angeles area. Tiefenthaler et al. (2001) observed similar pollutographs that showed peak suspended-sediment concentrations preceding the peak in discharge for the Santa Ana River. Similar time vs. concentration relationships were observed by Characklis and Wiesner (1997), who reported that the maximum concentrations of zinc, organic carbon and solids coincided with early peak storm water flows. Bacterial counts typically vary by up to five orders of magnitude on daily, seasonal, and inter-annual scales. The extreme variability in FIB makes storm water bacteria concentrations difficult to accurately estimate. Furthermore, as living organisms, many processes that do not influence other constituents, such as re-growth of environmentally adapted strains, die-off, and random fluctuations in population size, may affect bacterial counts (Ferguson et al. 2005). Therefore, more frequent monitoring over longer time periods and for the entire duration of storms is necessary in order to make assessments of "typical" bacterial counts and accurate estimates of EMC and FIB loading.

Further research is needed to directly assess the relationship between indicator bacteria concentrations and particle-size distributions in storm water runoff from mass emission and LU sites to better understand the fate, transport and treatment of indicator bacteria in urban runoff. Storm water borne bacteria are typically associated with particulates to varying degrees depending on the indicator bacteria and the size distribution of suspended solids in the storm water runoff. Furthermore, the particle size distribution, and bacteria partitioning can change over the course of a storm event (Furumai et al. 2002). Understanding the dynamic partitioning of indicator bacteria to various size particles is important to being able to estimate temporal and spatial patterns of bacterial deposition in estuaries and harbors, and should be an area of future investigation. Our understanding of the mechanisms of indicator bacteria loading from urban LU sites could also be improved by estimating the percent watershed impervious surface coverage in each LU category (i.e., percent rooftop, sidewalks, paved driveways and streets) and its impacts on storm water runoff concentrations and loads. This could allow identification of critical source areas and allow for more targeted application of best management practices.

Table 5-1. Correlations between total suspended solids (TSS) and stream flow with respect to fecal indicator bacteria (FIB) during storm condition. Within a table cell, the upper row shows Spearman's correlation coefficient (ρ), the middle row shows probability (p) that the null hypothesis of no correlation is true, and the lower row shows number of samples (n). Numbers in bold indicate correlations that are significant (p <0.04).

Subject: Fwd: DPR Acts to Curb Water Pollution from Pyrethroid Insecticides

Renee:

If DPR's new regulations and the new labeling of pyrethroids will be as effective in cutting the amount of pyrethroids in urban runoff as indicated in this email, do we really need the pyrethroid study specified in the Tentative Order?

>> Subject: DPR Acts to Curb Water Pollution from Pyrethroid Insecticides
>>
>> New California Department of Pesticide Regulation (DPR) requirements that become effective July 19 will modify the way that professional applicators apply pyrethroid insecticides around buildings. In parallel, new pyrethroid product labeling being implemented voluntarily by manufacturers at DPR's request--including special labels for the most persistent pyrethroid, bifenthrin--will provide further water quality protection. Both the regulations and the labeling will reduce treatments of outdoor impervious surfaces, thus reducing the quantity of pyrethroids that can be washed directly into gutters and storm drains when it rains or when water like irrigation overflow runs across treated surfaces. Together, the regulations and the new labeling will reduce the amount of pyrethroid insecticides in urban stormwater runoff by 80-90%.
>>
>> DPR developed the regulations and requested manufacturers modify product labels in response to the finding that pyrethroid insecticides are causing water and sediments in California urban creeks to be toxic to sensitive aquatic organisms. California Water Boards and the California Stormwater Quality Association (CASQA), using information assembled by the government-funded Urban Pesticides Pollution Prevention Project (UP3 Project), worked with DPR toward development of a solution to this water pollution problem.
>>
>> University of California scientific research played a key role in the characterization of the pyrethroid insecticide water pollution problem and in identification of application practices that reduce pyrethroid use while continuing to control pests. California's professional structural pest control applicators provided DPR and other agencies invaluable information about pyrethroid application practices and the practical aspects of controlling insects around buildings.
>>
>> UP3 Project analysis--based on pyrethroid monitoring data, pyrethroid use data, and urban runoff modeling by U.C. Davis-- suggests that the regulations will largely--but not completely--end widespread water and sediment toxicity from pyrethroids in California's urban watersheds. In some watersheds, lower levels of toxicity may continue. In a larger number of watersheds, pyrethroid concentrations will continue to exceed aquatic life protection benchmarks such as the water quality criteria developed by UC Davis with funding from the Central Valley Water Board.
>>
>> In coming months, some professional pest control operators are likely to switch to other insecticides, some of which may create new water pollution problems. A recent CASQA monitoring data summary suggests that one substitute insecticide, fipronil, may already be washing into urban creeks at levels sufficient to harm sensitive aquatic organisms.
>>
>> California government agencies will be monitoring urban creeks and working together toward making further adjustments as necessary to

protect water quality.
>>
>> Businesses and residents can prevent pesticide-related water pollution by employing effective pest control practices that minimize the need to use pesticides. Professional applicators certified by Ecowise or Green Pro provide this type of pest control. Do-it-yourselfers can learn how to implement these practices from Our Water Our World or University of California's Integrated Pest Management Program.
>>
>> DPR's Enforcement Branch will be working with California's Agricultural Commissioners and California professional pest control applicators to implement the new regulations. For implementation questions, DPR recommends contacting George Farnsworth, Chief of DPR's Enforcement Branch at gfarnsworth@cdpr.ca.gov

NOTICE AND DISCLAIMER

This document provides the technical basis for the Test of Significant Toxicity (TST) approach under the National Pollutant Discharge Elimination System (NPDES) for permitting authorities (states and Regions) and persons interested in analyzing valid whole effluent toxicity (WET) test data using the traditional hypothesis testing approach as part of the NPDES Program under the Clean Water Act (CWA). This document describes what the U.S. Environmental Protection Agency (EPA) believes is another statistical option to analyze valid WET test data for NPDES WET reasonable potential and permit compliance determinations. The document does not, however, substitute for the CWA, an NPDES permit, or EPA or state regulations applicable to permits or WET testing; nor is this document a permit or a regulation itself. The TST approach does not result in changes to EPA's WET test methods promulgated at Title 40 of the *Code of Federal Regulations* Part 136. The document does not and cannot impose any legally binding requirements on EPA, states, NPDES permittees, or laboratories conducting or using WET testing for permittees (or for states in evaluating ambient water quality). EPA could revise this document without public notice to reflect changes in EPA policy and guidance. Finally, mention of any trade names, products, or services is not and should not be interpreted as conveying official EPA approval, endorsement, or recommendation.

EXECUTIVE SUMMARY

The U.S. Environmental Protection Agency (EPA or the Agency) has developed a new statistical approach that assesses the whole effluent toxicity (WET) measurement of wastewater effects on specific test organisms' ability to survive, grow, and reproduce. This new approach is called the Test of Significant Toxicity (TST) and is a statistical method that uses hypothesis testing techniques based on research and peer-reviewed publications. The hypothesis test under the TST approach examines whether an effluent, at the critical concentration (e.g., in-stream waste concentration or IWC), as recommended in EPA's Technical Support Document (TSD; USEPA 1991) and implemented under EPA's WET National Pollutant Discharge Elimination System (NPDES) permits program, and the control within a WET test differ by an unacceptable amount (the amount that would have a measured detrimental effect on the ability of aquatic organisms to thrive and survive).

Since the inception of EPA's NPDES WET program in the mid 1980s, the Agency has striven to advance and improve its application and implementation under the NPDES WET Program. The TST approach explicitly incorporates test power, which, using the TST approach, is the ability to correctly classify the effluent as acceptable under the NPDES WET Program (i.e., non-toxic). The TST approach also provides a positive incentive to generate high quality, valid WET data to make informed decisions regarding NPDES WET reasonable potential (RP) and permit compliance determinations. Once the WET test has been conducted (using multiple effluent concentrations and other requirements as specified in the WET test methods), the TST approach can be used to analyze valid WET test results to assess whether the effluent discharge is toxic. The TST approach is designed to be used for a two concentration data analysis of the IWC or a receiving water concentration (RWC) as compared to a control concentration.

Background

In the NPDES WET Program, an effluent sample is declared toxic relative to a permitted WET limit if the no observed effect concentration (NOEC) is less than the permitted IWC using a hypothesis statistical approach. In such an approach, the question being answered is, "Is the mean response of the organisms the same or worse in the control than at the IWC?" The hypothesis testing approach has four possible outcomes: (1) the IWC is truly toxic and is declared toxic, (2) the IWC is truly non-toxic and is declared non-toxic, (3) the IWC is truly toxic but is declared non-toxic, and (4) the IWC is truly non-toxic but is declared toxic. The latter two possible outcomes represent decision errors that can occur with any hypothesis testing approach. In the NPDES WET Program, those two types of errors occur when either test control replication is poor (i.e., the within-test variability is high) so that even large differences in organism response between the IWC and control are incorrectly classified as non-toxic (outcome [3] above) or, test control replication is very good (i.e., the within-test variability is low) so that a very small difference between IWC and control is declared toxic (outcome [4] above). That former outcome stems from the fact that in the NPDES WET Program, the hypothesis approach established and controls the false positive error rate (i.e., Type I or alpha) but not the false negative error rate (i.e., Type II or beta). Establishing the beta error rate determines the power of the test (power = 1-beta), which is the probability of correctly detecting an actual toxic effect using the traditional hypothesis testing approach (i.e., declaring an effluent toxic when, in fact, it is toxic). By not establishing an appropriate beta error rate and test power in the NPDES WET

Program, the permittee has no incentive to generate more precise data within a test using the traditional hypothesis approach, and, in fact, is at a disadvantage for achieving a high level of precision.

What is the Test of Significant Toxicity Approach?

Organism responses to the effluent and control are unlikely to be exactly the same, even if no toxicity is present. They might differ by such a small amount that even if statistically significant, it would be considered negligible biologically. A more useful approach could be to rephrase the null hypothesis, "Is the mean response in the effluent less than a defined biological amount?" the Food and Drug Administration has successfully used that approach for many years to evaluate drugs, as have many researchers in other biological fields. In that approach, the null hypothesis is stated as the organism response in the effluent is less than or equal to a fixed fraction (*b*) of the control response (e.g., 0.75 of the control mean response):

$$\text{Null hypothesis: Treatment mean} \leq b \times \text{Control mean}$$

In the NPDES WET Program, to reject the null hypothesis above means the effluent is considered non-toxic. To accept the null hypothesis means the effluent is toxic. That test has been adapted for the NPDES WET Program and is referred to as the *Test of Significant Toxicity* (TST).

Before the TST null hypothesis expression could be used in the NPDES WET Program, certain decisions were needed, including what effect level in the effluent is considered unacceptably toxic and the desired frequency of declaring a truly negligible effect within a test non-toxic. Such decisions are referred to as Regulatory Management Decisions (RMDs).

What are the RMDs for TST?

In the TST approach, the *b* value in the null hypothesis represents the threshold for unacceptable toxicity. For *chronic* testing in EPA's NPDES WET Program, the *b* value in the TST analysis is set at 0.75, which means that a 25 percent effect (or more) at the IWC is considered evidence of unacceptable *chronic* toxicity. IWC responses substantially less than a 25 percent effect would be interpreted to have a lower risk potential. The RMD for *acute* WET methods is set at 0.80, which means that a 20 percent effect (or more) at the IWC is considered evidence of unacceptable *acute* toxicity. The acute RMD toxicity threshold is higher (i.e., more strict) than that for chronic WET methods because of the severe environmental implications of acute toxicity (lethality or organism death).

EPA's RMDs using the TST approach are intended to identify unacceptable toxicity in WET tests most of the time when it occurs, while also minimizing the probability that the IWC is declared toxic when in fact it is truly acceptable. This objective requires additional RMDs regarding acceptable maximum false positive (**β using a TST approach)** and false negative rates (**α using a TST approach)**. In the TST approach, the RMDs are defined as (1) declare a sample toxic between 75–95 percent of the time ($0.05 \leq \alpha \leq 0.25$) when there is unacceptable toxicity (20 percent effect for acute and 25 percent effect for chronic tests), and (2) declare an effluent non-toxic no more than 5 percent of the time ($\beta \leq 0.05$) when the effluent effect at the critical effluent concentration is 10 percent. Table ES-1 summarizes the difference in Type I and II error

expressions between the TST approach and the traditional hypothesis approach currently used in the NPDES WET Program.

Table ES-1. Definition of the Type I and Type II error under the traditional hypothesis testing approach and the TST approach.

	Traditional hypothesis approach	TST
Type I (alpha)	Set at 0.05	Set at 0.05 to 0.25 given a *b* value of 0.80 or 0.75 depending on whether the WET test method is acute or chronic, respectively
	Effluent is considered safe but declared *toxic*	Effluent is considered toxic, but declared *safe*
	Permittee concern	Regulatory concern
Type II (beta)	Not established	Set at 0.05
	Effluent is considered toxic but declared *safe*	Effluent is considered safe but declared *toxic*
	Regulatory concern	Permittee concern

How was the TST approach developed?

EPA used valid WET data from approximately 2,000 WET tests to develop and evaluate the TST approach. The TST approach was tested using nine different WET test methods comprising twelve biological endpoints (e.g., reproduction, growth, survival) and representing most of the different types of WET test designs in use. More than one million computer simulations were used to select appropriate alpha error rates for each test method that also achieved EPA's other RMDs for the TST approach.

Once the alpha error rates were established, the results of the TST approach were compared to those obtained using the traditional hypothesis testing approach for a range of test results. The alpha values identified in this project build on existing information (such as data sources and analyses examining ability to detect toxic effects) on WET published and peer reviewed by EPA, including *Understanding and Accounting for Method Variability in WET Applications Under the NPDES Program* (USEPA 2000).

This document outlines the recommended TST approach and presents the following:

- How an appropriate alpha value was identified for several common WET test methods on the basis of desired beta error rates, various effect levels, and within-test control variability.

- The degree of protectiveness of TST compared to the traditional hypothesis testing approach. In this report, *as protective as* is defined as an equal ability to declare a sample toxic at or above the regulatory management level.

Because TST is a form of hypothesis testing, analyses in this document focus on comparing results of TST to the traditional hypothesis testing approach and not to point estimate techniques such as linear interpolation (i.e., IC25). Therefore, this document does not discuss point estimate procedures.

Data analysis approach

EPA assembled a comprehensive database to analyze the utility of the TST approach with data obtained from EPA Regions, several states, and private laboratories, which represent a widespread sampling of typical laboratories and test methods for approximately 2,000 tests. Nine commonly tested WET methods were examined. For each test method, control precision (coefficient of variation [CV]) was calculated on the basis of valid WET test data compiled in the project. Cumulative frequency plots were used to identify percentiles of observed method-specific CVs (e.g., 25^{th}, 50^{th}, 75^{th} percentiles). The measures were calculated to update previous EPA analyses (USEPA 2000) using more recent valid WET test data and to characterize typical, achievable test performance in terms of within-test control variability. A similar analysis was performed for the control response for each of the nine test methods (e.g., mean offspring per female in the *Ceriodaphnia dubia* test method) to characterize typical achievable test performance in terms of control response.

Monte Carlo simulation analysis was used to estimate the percentage of WET tests that would be declared toxic using TST as a function of different α levels, within-test control variability, and mean percent effect level. The simulation analysis identified expected beta error rates (i.e., declaring an effluent toxic when in fact it is acceptable under TST) for a broad range of possible test scenarios. Using the RMDs above, an appropriate α level was then identified for a given WET test design that also yielded a β error rate ≤ 0.05 when there was a 10 percent mean effect. By simulating thousands of WET tests for a given scenario (mean percent effect and control CV), the percentage of tests declared toxic could be calculated and compared among scenarios, and between TST and the traditional hypothesis approach.

Results of the analysis

Results of all analyses indicate that TST is a suitable alternative to the traditional hypothesis approach for analyzing two-concentration WET data (i.e., IWC and control) in the NPDES WET Program. A demonstrated benefit of the TST approach is that increasing the precision and power of the test increases the chances of declaring an effluent non-toxic when there is ≤ 10 percent mean effect in the effluent. Increasing test replication (and thereby the power of the test) results in a *lower* rate of tests declared toxic using TST but a *higher* rate of tests declared toxic using the traditional hypothesis approach (see Figure ES-1). Using TST, a permittee has the ability to demonstrate that its effluent is acceptable, by improving the quality of test data (e.g., decreasing within-test variability, and/or increasing replication), if indeed the mean effect at the IWC is less than the regulatory management decision (25 percent [chronic] or 20 percent [acute]).

On the basis of EPA's analyses, the alpha levels shown in Table ES-2 are recommended for the nine EPA WET test methods examined using the TST approach. An important feature of the TST approach is that the TST's alpha is analogous to beta under the traditional hypothesis testing approach, which had not been established by EPA previously for the NPDES WET Program.

Table ES-2. Summary of alpha (α) levels or false negative rates recommended for different EPA WET test methods using the TST approach.

EPA WET test method	*b* value	Probability of declaring a toxic effluent non-toxic False negative (α) error[a]
Chronic Freshwater and East Coast Methods		
Ceriodaphnia dubia (water flea) survival and reproduction	0.75	0.20
Pimephales promelas (fathead minnow) survival and growth	0.75	0.25
Selenastrum capricornutum (green algae) growth	0.75	0.25
Americamysis bahia (mysid shrimp) survival and growth	0.75	0.15
Arbacia punctulata (Echinoderm) fertilization	0.75	0.05
Cyprinodon variegatus (Sheepshead minnow) and *Menidia beryllina* (inland silverside) survival and growth	0.75	0.25
Chronic West Coast Marine Methods		
Dendraster excentricus and *Strongylocentrotus purpuratus* (Echinoderm) fertilization	0.75	0.05
Atherinops affinis (topsmelt) survival and growth	0.75	0.25
Haliotis rufescens (red abalone), *Crassostrea gigas (oyster), Dendraster excentricus, Strongylocentrotus purpuratus* (Echinoderm) and *Mytilus sp* (mussel) larval development methods	0.75	0.05
Macrocystis pyrifera (giant kelp) germination and germ-tube length	0.75	0.05
Acute Methods		
Pimephales promelas (fathead minnow), *Cyprinodon variegatus* (Sheepshead minnow), *Atherinops affinis* (topsmelt), *Menidia beryllina* (inland silverside) acute survival[b]	0.80	0.10
Ceriodaphnia dubia, *Daphnia magna, Daphnia pulex*, *Americamysis bahia* acute survival[b]	0.80	0.10

Notes:
a. α levels shown are the probability of declaring an effluent toxic when the mean effluent effect = 25% for chronic tests or 20% for acute tests and the false positive rate (β) is ≤ 0.05 (5%) when mean effluent effect = 10%.
b. Based on a four replicate test design

Results obtained from the TST analyses using the nine EPA WET test methods should be applicable to other EPA WET methods not examined. For example, results generated under this project for the fish *Pimephales promelas* survival and growth test is extrapolated to other EPA fish survival and growth tests (e.g., *Menidia* sp., *Cyprinus variegatus, Atherinops affinis*) because the test methods use a similar test design (e.g., number of replicates, number of organisms tested) and measure the same endpoints.

Figure ES-1 illustrates that conducting tests with more replicates (a priori) can assist a permittee to demonstrate that the effluent is acceptable. Conversely, increasing the number of replicates in a test does not assist a permittee using the current hypothesis testing approach.

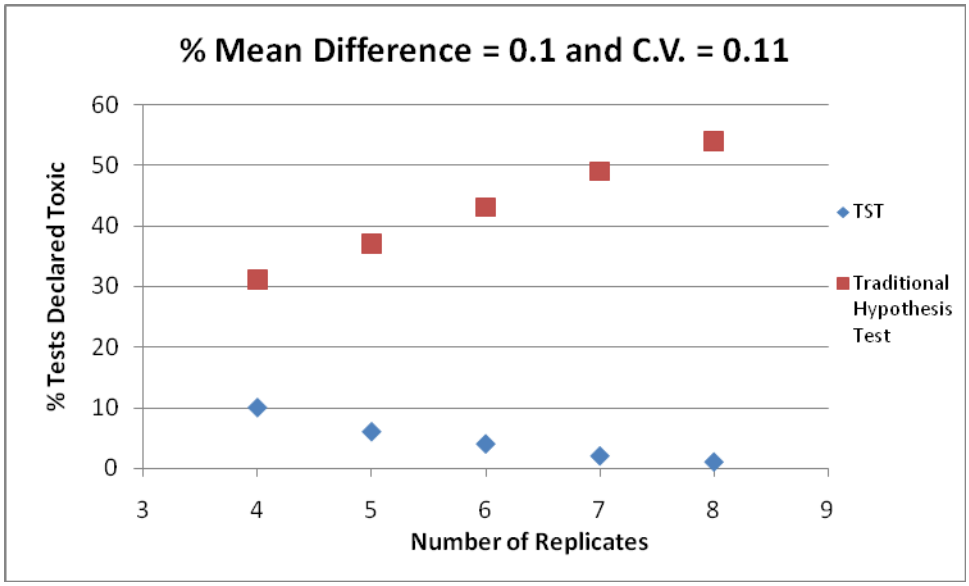

Figure ES-1. Percent of chronic fathead minnow WET tests declared toxic using TST having a mean effluent effect of 10 percent, above average control variability (CV = 0.11 or 11 percent) and an α = 0.25, as a function of the number of within-test replicates. Results using the traditional hypothesis test are shown as well.

Summary

Results of nearly 2,000 valid WET tests and thousands of simulations were conducted to develop the technical basis for the TST approach. That approach builds on the strengths of the traditional hypothesis testing approach, including use of robust statistical analyses, to determine whether an effluent sample is acceptable in WET testing. Specific benefits of using TST in WET analysis include the following:

- Provides transparent RMDs, which are incorporated into the data analysis process
- Incorporates statistical power directly into the statistical process by controlling for both alpha and beta errors, thereby, increasing the confidence in the WET test result
- Provides a positive incentive for the permittee to generate valid, high quality WET data
- Applicable to both NPDES WET permitting and 303(d) watershed assessment programs

Results of this project indicate that the TST is a viable additional statistical approach for analyzing valid acute and chronic WET test data. Using the explicit RMD and test method-specific alpha values, TST provides similar protection as the traditional hypothesis testing approach when there is unacceptable toxicity while also providing a transparent methodology for demonstrating whether an effluent is acceptable under the NPDES WET Program.

In summary, the TST approach provides another option for permitting authorities and permittees to use for analyzing WET test data. The TST approach provides a positive incentive to generate valid, high quality WET data to make informed decisions regarding NPDES WET reasonable

potential (RP) and permit compliance determinations. Using TST, permitting authorities will be better able to identify toxic or acceptable samples.

WET	whole effluent toxicity

GLOSSARY

Acute Toxicity Test is a test to determine the concentration of effluent or ambient waters that causes an adverse effect (usually mortality) on a group of test organisms during a short-term exposure (e.g., 24, 48, or 96 hours). Acute toxicity is determined using statistical procedures (e.g., point estimate techniques or a t-test).

Ambient Toxicity is measured by a toxicity test on a sample collected from a receiving waterbody.

Chronic Toxicity Test is a short-term test in which sublethal effects (e.g., reduced growth or reproduction) are usually measured in addition to lethality.

Coefficient of Variation (CV) is a standard statistical measure of the relative variation of a distribution or set of data, defined as the standard deviation divided by the mean. The CV can be used as a measure of precision within and between laboratories, or among replicates for each treatment concentration.

Effect Concentration (EC) is a point estimate of the toxicant concentration that would cause an observable adverse effect (e.g., mortality, fertilization). EC_{25} is a point estimate of the toxicant concentration that would cause observable 25% adverse effect as compared to the control test organisms.

False Negative is when the in-stream waste concentration is declared non-toxic but in fact is truly toxic. In the traditional hypothesis approach, false negative error rate is denoted by Beta (β). In the TST approach, false negative error rate is denoted as Alpha (α), which applies when the percent effect in the critical effluent concentration is $\geq$ 25% for a given test.

False Positive is when the in-stream waste concentration is declared toxic but in fact is truly non-toxic. In the traditional hypothesis approach, false positive error rate is denoted by Alpha (α). In the TST approach, false positive error rate is denoted as Beta (β), which applies when the percent effect in the critical effluent concentration is $\leq$ 10% for a given test.

Hypothesis Testing is a statistical approach (e.g., Dunnett's procedure) for determining whether a test concentration is statistically different from the control. Endpoints determined from hypothesis testing are no observed effect concentration (NOEC) and lowest observed effect concentration (LOEC). The two hypotheses commonly tested in WET are

- **Null hypothesis (H_o)**: The effluent is non-toxic.
- **Alternative hypothesis (H_a)**: The effluent is toxic.

Inhibition Concentration (IC) is a point estimate of the toxicant concentration that would cause a given, percent reduction in a non-lethal biological measurement (e.g., reproduction or growth), calculated from a continuous model (i.e., Interpolation Method). E.g., IC_{25} is a point estimate of the toxicant concentration that would cause a 25 percent reduction in a non-lethal biological measurement.

In-stream Waste Concentration (IWC) is the concentration of a toxicant or effluent in the receiving water after mixing. The IWC is the inverse of the dilution factor. It is sometimes referred to as the receiving water concentration (RWC).

LC50 (lethal concentration, 50 percent) is the toxicant or effluent concentration that would cause death to 50 percent of the test organisms.

Lowest Observed Effect Concentration (LOEC) is the lowest concentration of an effluent or toxicant that results in statistically significant adverse effects on the test organisms (i.e., where the values for the observed endpoints are statistically different from the control).

Minimum Significant Difference (MSD) is the magnitude of difference from control where the null hypothesis is rejected in a statistical test comparing a treatment with a control. MSD is based on the number of replicates, control performance, and power of the test.

No Observed Effect Concentration (NOEC) is the highest tested concentration of an effluent or toxicant that causes no observable adverse effect on the test organisms (i.e., the highest concentration of toxicant at which the values for the observed responses are not statistically different from the control).

National Pollutant Discharge Elimination System (NPDES) is the national program for issuing, modifying, revoking and reissuing, terminating, monitoring and enforcing permits, and imposing and enforcing pretreatment requirements, under sections 307, 318, 402, and 405 of Clean Water Act.

Power is the probability of correctly rejecting the null hypothesis (i.e., declaring an effluent toxic when, in fact, it is toxic using the traditional hypothesis test approach).

Precision is a measure of reproducibility within a data set. Precision can be measured both within a laboratory (within-laboratory) and between laboratories (between-laboratory) using the same test method and toxicant.

Quality Assurance (QA) is a practice in toxicity testing that addresses all activities affecting the quality of the final effluent toxicity data. QA includes practices such as effluent sampling and handling, source and condition of test organisms, equipment condition, test conditions, instrument calibration, replication, use of reference toxicants, recordkeeping, and data evaluation.

Quality Control (QC) is the set of more focused, routine, day-to-day activities carried out as part of the overall QA program.

Reasonable Potential (RP) is where an effluent is projected or calculated to cause an excursion above a water quality standard on the basis of a number of factors including the four factors listed in Title 40 of the *Code of Federal Regulations* (CFR) 122.44(d)(1)(ii).

Reference Toxicant Test is a check of the sensitivity of the test organisms and the suitability of the test methodology. Reference toxicant data are part of a routine QA/QC program to evaluate the performance of laboratory personnel and the robustness and sensitivity of the test organisms.

Regulatory Management Decision (RMD) is the decision that represents the maximum allowable error rates and thresholds for toxicity and non-toxicity that would result in an acceptable risk to aquatic life.

Replicate is two or more independent organism exposures of the same treatment (i.e., effluent concentration) within a whole effluent toxicity test. Replicates are typically separate test chambers with organisms, each having the same effluent concentration**.**

Sample is a representative portion of a specific environmental matrix that is used in toxicity testing. For this document, environmental matrices could include effluents, surface waters, groundwater, stormwater, and sediment.

Significant Difference is a statistically significant difference (e.g., 95 percent confidence level) in the means of two distributions of sampling results.

Statistic is a computed or estimated quantity such as the mean, standard deviation, or Coefficient of Variation.

Test Acceptability Criteria (TAC) are test method-specific criteria for determining whether toxicity test results are acceptable. The effluent and reference toxicant must meet specific criteria as defined in the test method (e.g., for the *Ceriodaphnia dubia* survival and reproduction test, the criteria are as follows: the test must achieve at least 80 percent survival and an average of 15 young per surviving female in the control and at least 60% of surviving organisms must have three broods).

t-test (formally Student's t-Test) is a statistical analysis comparing two sets of replicate observations, in the case of WET, only two test concentrations (e.g., a control and IWC). The purpose of this test is to determine if the means of the two sets of observations are different (e.g., if the 100-percent effluent or ambient concentration differs from the control [i.e., the test passes or fails]).

Type I Error (alpha α) is the error of rejecting the null hypothesis (H_o) that should have been accepted.

Type II Error (beta β) is the error of accepting the null hypothesis (H_o) that should have been rejected.

Toxicity Test is a procedure to determine the toxicity of a chemical or an effluent using living organisms. A toxicity test measures the degree of effect on exposed test organisms of a specific chemical or effluent.

Welch's t-test is an adaptation of Student's t-test intended for use with two samples having unequal variances.

Whole Effluent Toxicity (WET) is the total toxic effect of an effluent measured directly with a toxicity test.

1.0 INTRODUCTION

1.1 Summary of Current EPA Recommended WET Analysis Approaches

Within the National Pollutant Discharge Elimination System (NPDES) Program, freshwater and marine acute and chronic whole effluent toxicity (WET) tests are used in conjunction with other analyses to evaluate and assess compliance of wastewater and surface waters with water quality standards of the Clean Water Act. In the NPDES WET Program, WET tests examine organism responses to effluent, typically along a dilution series (USEPA 1995, 2002a, 2002b). Acute WET test methods measure the lethal response of test organisms exposed to effluent (USEPA 2002c). The principal response endpoints for such methods are the effluent concentration that is lethal to 50 percent of the test organisms (LC50) or the effluent concentration at which survival is significantly lower than the control (e.g., t-test). Chronic WET test methods often measure both lethal and sublethal responses of test organisms. The statistical endpoints that are used in chronic WET testing in the NPDES WET Program are the no observed effect concentration (NOEC), and the 25 percent inhibition concentration (IC25). The NOEC endpoint is determined using a traditional hypothesis testing approach that identifies the maximum effluent concentration tested at which the response of test organisms is not significantly worse from the control. From a regulatory perspective, an effluent sample is declared toxic relative to a permitted WET limit if the NOEC is less than the permitted in-stream waste concentration (IWC), as recommended in EPA's Technical Support Document (TSD) (USEPA 1991) and implemented under EPA's WET NPDES permits program. The IC25, by contrast, is a point-estimation approach. It identifies the concentration at which the response of test organisms is 25 percent below that observed in the control concentration and interpolates the effluent concentration at which this magnitude of response is expected to occur. From a regulatory perspective, an effluent sample is declared toxic relative to a permitted WET limit if the IC25 is less than the permitted IWC. This document focuses on another statistical option with respect to the traditional hypothesis testing approach for analyzing and interpreting valid WET data.

1.2 Advantages and Disadvantages of Recommended Traditional Hypothesis Testing Approach

The hypotheses traditionally used in WET statistical comparisons of a biological measure (survival, growth, reproduction) in control water versus a particular effluent sample are the following:

$$\begin{aligned} &\textit{Null Hypothesis}: && \mu_T \geq \mu_C \\ &\textit{Alternative Hypothesis}: && \mu_T < \mu_C \end{aligned}$$

where μ_C refers to the true mean for the biological measure in the control water and μ_T refers to the true mean for this measure in the effluent sample. *True mean* here refers to the mean for a theoretical statistical population of results from indefinite repetition of toxicity tests on the same control water and effluent sample. In contrast, the mean for the biological measure for a single toxicity test would be referred to as the *sample mean*, and random variation among organisms might cause a sample mean for an effluent to be less than the control even if the effluent is actually non-toxic. The traditional WET hypothesis thus assumes that the effluent sample is non-toxic. For an individual test, there must be a statistical test to determine if the null hypothesis is

rejected in favor of the alternative hypothesis; i.e., that any apparent toxicity based on the sample means is real and not simply reflective of random variation. Such a statistical test is part of current recommended practice in WET testing.

Table 1-1 summarizes the correctness of results from such statistical testing, contrasting the true condition of whether the effluent sample is toxic to the result of the statistical test. Two types of errors can occur in the statistical test result. A false positive occurs when the effluent is actually non-toxic, but the statistical test infers that it is toxic. For the statistical hypotheses here, that is a Type I error (the null hypothesis is rejected when it is true) and the probability of this error is typically designated by the variable α, so that the correct decision occurs with probability 1 - α. The other type of error, a false negative, occurs when the effluent truly is toxic, but the statistical test infers that it is non-toxic. For the statistical hypotheses here, that is a Type II error (the null hypothesis is accepted when it is false) and the probability of the error is typically designated by the variable β, so that the probability of the correct decision is 1 - β, which is also referred to as the test power.

Table 1-1. Error terminology for traditional WET hypothesis methodology

Statistical test result	**True condition**	
	$\mu_T \geq \mu_C$ (sample is non-toxic)	**$\mu_T < \mu_C$ (sample is toxic)**
$\mu_T \geq \mu_C$ (Sample is non-toxic)	Correct Decision (probability=1–α)	False Negative Type II Error (probability=β)
$\mu_T < \mu_C$ (Sample is toxic)	False Positive Type I Error (probability=α)	Correct decision Test Power (1-β)

It is important to note that β does not have a single value but rather is a function of how toxic the sample actually is (i.e., there is a greater chance of incorrectly saying an effluent is non-toxic if it is only slightly toxic than if it is highly toxic). Similarly, given that the null hypothesis is an inequality, α also does not have a single value, because if effluent characteristics actually improve the biological measure, the probability with which a non-toxic effluent is called toxic will be a function of the extent of this beneficial effect. Although there is a designated single value for α in the statistical test calculations (e.g., 0.05), this error probability applies only when the true condition is exactly at $\mu_T = \mu_C$.

This variation of α and β can be better understood using Figure 1-1, which depicts the probability of declaring an effluent toxic versus the true toxicity of the effluent, expressed as the ratio of the true biological measure in the effluent to the true biological measure in the control (μ_T / μ_C). The curves on this figure are for a hypothetical statistical analysis of hypothetical toxicity tests, but exemplify performance curves that could be drawn for *any* statistical analysis of *any* toxicity test under the traditional WET hypotheses provided above. The solid line is for a toxicity test with large variability so that it is less likely that the statistical test will detect toxicity, and the dashed line is for a toxicity test with low variability. Such curves provide a useful and complete summary of the basic information desired from WET testing. How

effectively will the testing detect toxicity for different levels of true toxicity? How often will non-toxic effluents mistakenly be declared toxic? Although test performance can be appreciated from such curves without addressing specific types of statistical errors, the behavior of those errors can be illustrated using the curves. The portion of the curve with $\mu_T / \mu_C \geq 1$ gives values for α (i.e., the effluent is truly non-toxic so that calling it toxic, a false positive, is a Type I error under the traditional null hypothesis). In accordance with WET hypothesis test procedures, the example curves have $\alpha = 0.05$ when μ_T / μ_C is exactly at 1.0. The portion of the curve with $\mu_T / \mu_C < 1$ is the *power curve* for the test (i.e., 1–β, the probability of calling an effluent toxic when it truly is toxic). This illustrates how test power is very low (approaching 0.05) when the effluent is only slightly toxic, but it increases as the true toxicity increases. The two different curves illustrate how this increase in test power depends on test uncertainty—i.e., higher within-test variability in the toxicity test results in less power for the statistical analysis.

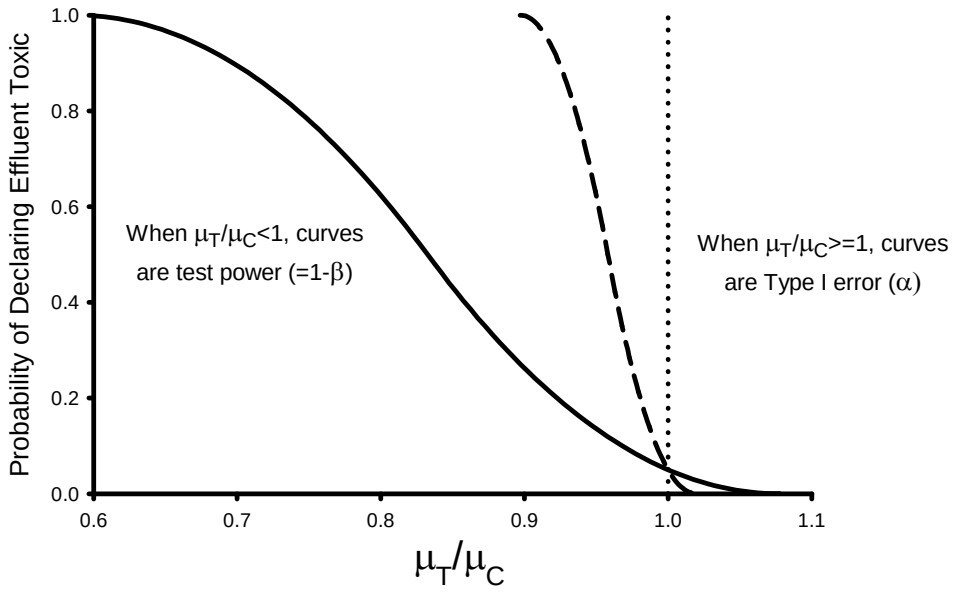

Figure 1-1. Example test performance curves for traditional WET hypothesis tests. The dotted line marks where the true mean biological measure in the effluent equals that in the control. The solid curve is for a high variability test, while the dashed curve is for a low variability test.

Various researchers have reported several advantages and disadvantages of the traditional hypothesis testing approach as currently used in the NPDES WET Program (Grothe et al. 1996). Two common limitations cited are (1) if the test control replication is very good (i.e., test is very precise), an effluent might be considered toxic when in fact its toxicity is low enough to be considered acceptable, and (2) if test control replication is poor (i.e., the test is very imprecise), a highly toxic effluent might be incorrectly classified as non-toxic. For example, the more precise test in Figure 1-1 would declare an effluent with only 5 percent toxicity to be toxic about 60 percent of the time, whereas the less precise test in Figure 1-1 would declare 20 percent toxicity to be non-toxic about 40 percent of the time. The first limitation arises because the null hypothesis is defined around $\mu_T = \mu_C$, so the goal is to call an effluent toxic if $\mu_T < \mu_C$, no matter

how small the difference. The second limitation arises from the fact that the NPDES WET Program hypothesis testing approach does not address the false negative error rate (i.e., Type II error, β) and thus does not address requirements regarding the power of the test to detect substantial levels of toxicity. By not establishing an appropriate β and test power in the NPDES WET Program, the permittee has no incentive to increase the precision of a WET test when using the traditional hypothesis approach. As illustrated in Figure 1-1, greater precision simply results in more samples being declared toxic and can lead to high rejection rates for effluents with low levels of toxicity that might be considered acceptable. Although EPA has made improvements in statistical procedures, such as including a test review step of the percent minimum significant differences (i.e., to minimize within-test variability), it is desirable to further improve the hypothesis testing approach. Such improvement is the focus of this report and a general approach for this, the Test of Significant Toxicity (TST), is discussed next.

1.3 Test of Significant Toxicity

The TST is an alternative statistical approach for analyzing and interpreting valid WET test data that also uses a hypothesis testing approach but in a different way, building on previous work conducted by EPA in the NPDES WET Program (USEPA 2000) as well as other researchers (Erickson and McDonald 1995; Shukla et al. 2000; Berger and Hsu 1996). The TST approach is based on a type of hypothesis testing referred to as *bioequivalence testing*. Bioequivalence is a statistical approach that has long been used in evaluating clinical trials of pharmaceutical products (Anderson and Hauck 1983) and by the Food and Drug Administration (Hatch 1996; Aras 2001; Streiner 2003). The approach has also been used to evaluate the attainment of soil cleanup standards for contaminated sites (USEPA 1988, 1989) and to evaluate effects of pesticides in experimental ponds (Stunkard 1990).

For the NPDES WET Program, the TST approach changes the hypotheses to the following:

$$\textit{Null Hypothesis:} \qquad \mu_T \leq b \times \mu_C$$

$$\textit{Alternative Hypothesis:} \qquad \mu_T > b \times \mu_C$$

The TST hypotheses thus incorporate two important differences from the traditional WET hypotheses. First, a specific value for the ratio μ_T / μ_C, designated *b*, is included to delineate unacceptable and acceptable levels of toxicity, allowing a risk management decision about what level of toxicity should be allowed if the true means were known, other than the absence of any toxicity as specified by the traditional hypothesis. Second, the inequalities are reversed so that it is assumed that the effluent sample has an unacceptable level of toxicity until demonstrated otherwise. As a result of this reversal of the inequalities, the meanings of α and β under the TST hypotheses (Table 1-2) are reversed from those under the traditional hypothesis approach (Table 1-1). Under the TST approach, α is associated with false negatives, β is associated with false positives, and statistical test power using the TST approach in the NPDES WET Program is the ability to correctly conclude that true toxicity levels are acceptable. In addition, an effluent sample would be considered acceptable under the TST approach when the null hypothesis is rejected; in contrast, a sample is considered unacceptable under the traditional hypothesis approach when the null hypothesis is rejected.

Table 1-2. Error terminology for TST WET hypothesis methodology

Statistical test result	**True condition**	
	$\mu T \leq b \times \mu C$ (Toxicity is unacceptable)	**$\mu T > b \times \mu C$ (Toxicity is acceptable)**
$\mu_T \leq b \times \mu_C$ (Toxicity is unacceptable)	Correct Decision (1–α)	False Positive Type II Error (β)
$\mu_T > b \times \mu_C$ (Toxicity is acceptable)	False Negative Type I Error (α)	Correct Decision Test Power (1–β)

Figure 1-2 provides illustrative examples of test performance under the TST approach and illustrates advantages of this approach over the traditional hypotheses. This figure shows the same basic type of performance curve as in Figure 1-1: the probability of calling an effluent unacceptably toxic versus the true toxicity in the effluent. Incorporating *b* in the hypotheses explicitly recognizes that the true mean for the organism response in an effluent can be less than that in the control by a certain amount and still be considered acceptable, and it keeps the false negative rate for this amount of toxicity constant regardless of test variability (Figure 1-2). As mentioned previously, the current NPDES WET Program does not control the false negative rate, which varies markedly at any given level of toxicity as test precision varies (Figure 1-1). By reversing the inequalities and referencing them to *b*, the TST approach also results in more precise tests having lower false positive errors (Figure 1-2); i.e., effluents with true levels of toxicity that are acceptably low are declared toxic with less frequency as precision increases, a desirable attribute for the method. That provides permittees with a clear incentive to improve the precision of test results. Thus, using the TST approach, a permittee has to demonstrate with some confidence that their effluent has toxicity in an acceptable range, but can also improve testing procedures as needed to do so (i.e., increase replicates or decrease within-test variability or both).

1.4 Regulatory Management Decisions for TST

Regulatory management decisions (RMDs) are incorporated into the TST methodology by selecting values for *b*, the dividing point between acceptable and unacceptable toxicity, and α, the false negative error rate when $\mu_T = b \times \mu_C$.

The selection of *b* should reflect what is considered acceptable if the true biological response means for the effluent and control were actually known, especially because precise tests might have performances closely approaching this ideal. For all chronic WET test methods, the RMD is to set *b* to 0.75. This *b* value (25 percent toxic effect) is consistent with EPA's use of the IC25 in point estimation methods for examining chronic WET data. Chronic effects less than 25 percent would be considered to have an acceptably low risk potential. Because of the more severe environmental implications of acute toxicity (organism death), the RMD for acute WET test methods is to set *b* higher than that for chronic WET test methods, at 0.80.

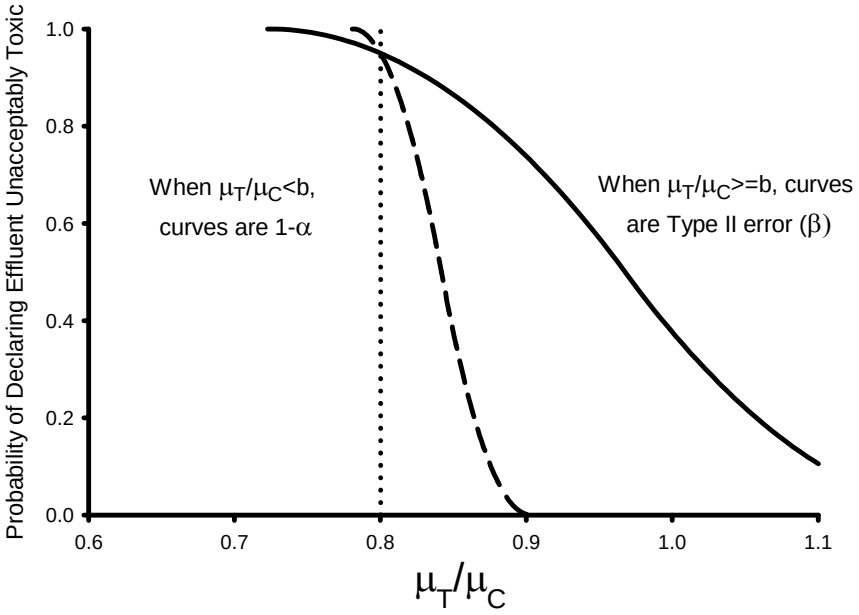

Figure 1-2. Example test performance curves for TST WET hypothesis tests. For this example, *b* is set to 0.8 (denoted by dotted line), with $\alpha = 0.05$. The two curves represent test performance for tests with high (solid line) and low (dashed line) variability.

For a given test precision and value for *b*, selecting a value for α completely determines both false negative and false positive error rates at all toxicity levels, such as the curves in Figure 1-2. However, the value selected for α does not have to be based just on consideration of the desired error rate when $\mu_T = b \times \mu_C$. Rather, α can be selected on the basis of balancing goals regarding this false negative error rate with goals for false positive error rates at lower levels of toxicity. Therefore, a different α can be assigned for different types of WET toxicity tests based on test precision and on specific goals regarding false positive and false negative rates.

With regard to false negative rates, EPA's general goal is to identify unacceptable toxicity in WET tests most of the time when it occurs. It would be preferred to set α at the typical 0.05 level (i.e., if $\mu_T = b \times \mu_C$, the effluent will be declared unacceptable 95 percent of the time). However, for tests with low precision, this could result in a high rate of false positives (declaring effluents unacceptable) when toxicity is low or absent (e.g., Figure 1-2). Therefore, values of α up to 0.25 will be allowed, as needed to meet the goal regarding false positive rates discussed in the next paragraph. Thus, the false negative rate RMD is $0.05 \leq \alpha \leq 0.25$, so that there is at least a 0.75 probability that an effluent with unacceptable toxicity ($\mu_T \leq b \times \mu_C$) will be declared toxic.

With regard to false positive error probabilities, EPA's general goal is that they be low when toxicity is negligible. It is necessary to define *negligible* as a second, smaller level of effect than *acceptable* because the latter includes toxicity as high as that represented by *b*, at which point the false positive error rate always will approach $1 - \alpha$, so cannot be low. With regard to this, EPA defines negligible as 10 percent toxicity or less, and specifies that the false positive error

probability be no higher than 0.05 at 10 percent toxicity. Thus, the false positive RMD is $\beta \leq 0.05$ at $\mu_T/\mu_C=0.90$, provided this is achievable with $\alpha \leq 0.25$ (if α is at this maximum, this false positive RMD no longer applies). It should be emphasized that this RMD relates to only one point in the range of toxicity considered acceptable, and that false positives will vary widely within this range (e.g. Figure 1-2). False positive rates will be lower when toxicity is lower than 10 percent, dropping to near zero when toxicity is absent, and will be higher when toxicity values are greater than negligible but still acceptable, rising to 1-α as the toxicity approaches the unacceptable level.

Therefore, the overall RMD for α (the false negative rate when $\mu_T / \mu_C = b$) is to set it to the lowest value that results in $\beta \leq 0.05$ (the false positive rate) when the true toxicity is at $\mu_T / \mu_C = 0.90$, but that α will be no lower than 0.05 and no higher than 0.25. This selection will be primarily a function of test method within-test variability (e.g., control coefficient of variation or CV), but cannot and should not be done on an individual test basis. Rather, TST alphas are assigned for different types of WET tests on the basis of simulations that address how TST method performance is affected by the test design and types of endpoints measured, and the associated CVs.

1.5 Document Objectives

This document presents TST as a useful alternative data analysis approach for valid WET test data that may be used in addition to the approaches currently recommended in EPA's Technical Support Document (USEPA 1991) and EPA's WET test method manuals. In adapting the TST for use in evaluating WET test data, analyses were conducted to identify an appropriate Type I error rate (α) for several common EPA WET methods given certain RMDs. Once alpha error rates were established, results of the TST approach were compared to those obtained using the traditional hypothesis testing approach and a range of test results.

This document outlines the recommended TST approach and presents the following:

- How an appropriate alpha value was identified for several common EPA WET test methods on the basis of desired alpha and beta error rates using explicit RMDs (i.e., effect levels) and considering a range of within-test control variability observed in valid WET tests.
- The degree of protectiveness of TST compared to the traditional hypothesis testing approach. In this report, *as protective as* is defined as an equal ability to declare a sample toxic at or above the regulatory management decision.

In this project, emphasis was placed on comparing results of TST to traditional hypothesis testing approaches and not to point estimate techniques such as linear interpolation (i.e., IC25). Therefore, this document does not discuss linear interpolation techniques. In addition, this document discusses the TST approach only with regard to comparing individual effluent samples to a control, and does not evaluate extensions of the TST approach to simultaneous multiple comparisons such as in Erickson and McDonald (1995).

The focus of this document is on chronic WET test methods and sublethal endpoints because many different types of alternative analysis procedures have been proposed for these tests.

Applying the TST methodology to the acute fish and *Ceriodaphnia* WET test method is also included. This document provides a summary of the recommended TST method, α values for several common WET methods, and results of comprehensive analyses supporting EPA recommendations.

2.0 METHODS

Methods used to evaluate the TST approach and determine how it should be applied for WET test analysis in the NPDES WET Program proceeded using several general steps as follows:

Step 1: WET test methods and endpoints were selected for analysis in the TST evaluation. A range of the more common EPA WET test methods were identified in this step.

Step 2: WET data were compiled from several state and EPA sources to determine current WET test method performance in terms of control response and within-test control variability.

Step 3: Simulation analyses were conducted using data characteristics obtained from Step 2 to guide the types of simulated data analyzed in this project and to set test method-specific α levels.

The following sections describe in more detail each of the steps.

2.1 Test Methods and Endpoints Evaluated

Table 2-1 summarizes the nine EPA WET test methods evaluated in this project. Preference was given to valid WET data generated using the EPA 1995 WET test methods for the EPA West Coast marine species (USEPA 1995) and for all other species the 2002 EPA WET test methods (USEPA 2002a, 2002b). Examining the inter-laboratory reference toxicant data for *C. dubia* by year indicated significantly more precise data from 1996 on as compared to pre-1995 (Figure 2-1). Similar results were observed for the fathead minnow and chronic mysid test methods as well. This result is not unexpected because the EPA chronic WET test methods were substantially refined as of 1995 and laboratories had more experience with the chronic test methods by this time. Within-test control 90th percentile CVs were not significantly different among years following 1995. Therefore, only post-1995 data were used in analyses for all EPA WET test methods.

All of the WET test methods listed in Table 2-1 are commonly used by regulatory authorities in making regulatory decisions such as determining WET reasonable potential (RP) or to determine compliance with acute and chronic WET limits or monitoring triggers. These nine test methods are representative of the range of EPA WET test methods commonly required of permittees in terms of types of toxicity endpoints written into NPDES permits and test designs followed by permittee's testing laboratories. Results obtained using these nine EPA test methods should be applicable to other EPA WET test methods not examined. For example, results of this project for the fish *Pimephales promelas* survival and growth test is extrapolated to other EPA fish survival and growth tests (e.g., *Menidia sp*., *Cyprinus variegatus*, *Atherinops affinis*) because those test methods use a similar test design (e.g., number of replicates, number of organisms tested) and measure the same endpoints. Previous analyses conducted by EPA (Denton and Norberg-King 1996; Denton et al. 2003) found comparable effect sizes for a given power among similar experimental designs and test endpoints. Similarly, the acute freshwater fish WET test analyzed in this project can be extrapolated to other fish acute test methods because they use a similar test design and measure mortality or immobility. The use of both EPA saltwater and freshwater WET tests ensured that there was adequate representation of different types of discharge situations and laboratories.

Table 2-1. Summary of test condition requirements and test acceptability criteria for each EPA WET test method evaluated in TST analyses

EPA method	Organism with scientific name	Endpoint type	Test type	Minimum # per test chamber	Minimum # of rep per conc.	Minimum # effluent conc.	Test duration	Test acceptance criteria (TAC)
2000.0	Fathead minnow *(Pimephales promelas)*	Survival	Acute	10	2	5	48–96 hours	≥ 90% survival in controls
1000.0	Fathead minnow *(Pimephales promelas)*	Survival and growth (larval)	Chronic	10	4	5	7 days	≥ 80% survival in controls; average dry weight per surviving organism in control chambers equals or exceeds 0.25 mg
1002.0	Water flea *(Ceriodaphnia dubia)*	Survival and reproduction	Chronic	1	10	5	Until 60% of surviving control organisms have 3 broods (6–8 days)	≥ 80% survival and an average of 15 or more young per surviving female in the control solutions. 60% of surviving control organisms must produce three broods
1007.0	Mysid shrimp *(Americamysis bahia)*	Survival and growth	Chronic	5	8	5	7 days	≥ 80% survival; average dry weight ≥ 0.20 mg in controls
1016.0	Purple urchin *(Strongylocentro-tus purpuratus)* or Sand dollar *(Dendraster excentricus)*	Fertilization	Chronic	100	4	4	40 min (20 min plus 20 min)	≥ 70% egg fertilization in controls; %MSD < 25%; and appropriate sperm counts
1017.0	Giant kelp *(Macrocystis pyrifera*	Germination and germ-tube length	Chronic	100 for germination 10 for germ-tube length	5	4	48 hours	≥ 70% germination in controls; ≥ 10 μm germ-tube lengths in controls; %MSD of < 20% for both germination and germ-tube length NOEC must be below 35 μg/L in reference toxicant test
1014.0	Red abalone (*Haliotis rufescens*)	Larval development	Chronic	100	5	4	48 hours	≥ 80% normal larval development in controls Statistical significance @ 56 μg/L zinc % MSD < 20%

Table 2-1. continued.

EPA method	Organism with scientific name	Endpoint type	Test type	Minimum # per test chamber	Minimum # of rep per conc.	Minimum # effluent conc.	Test duration	Test acceptance criteria (TAC)
2002.0	Water flea (*Ceriodaphnia dubia)*	Survival	Acute	5	4	5	24, 48, or 96 hours	≥ 90% survival in controls
1003.0	Green algae (*Selenastrum capricornutum*)	Growth (cell counts, chlorophyll fluorescence, absorbance, or biomass)	Chronic	10,000cells/ mL	4	5	96 hour	Mean cell density of at least 1 X 10^6 cells/mL in the controls; variability (CV%) among control replicates less than or equal to 20%

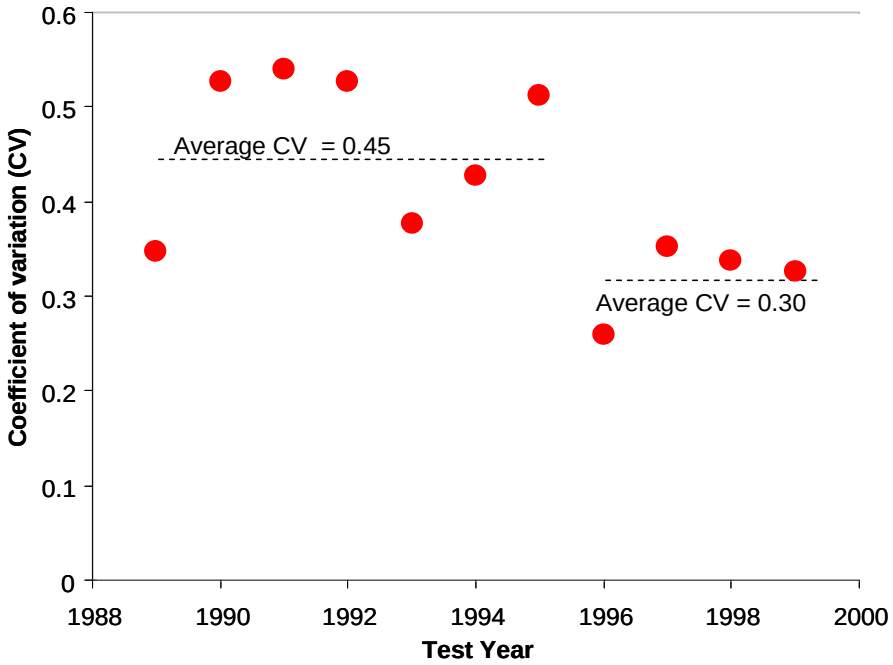

Figure 2-1. Summary of test variability (expressed as the control 90th percentile coefficient of variation or CV) observed between 1989 and 2000 for the chronic *Ceriodaphnia dubia* EPA WET test. This figure illustrates and supports the basis for using test data post 1995, as test precision improved from an average 90th percentile CV of 0.47 to 0.30.

2.2 Data Compilation

Data Sources

WET data were received from several reliable sources to identify baseline test method statistics (e.g., control CV percentiles, mean response percentiles) that were used in simulation analyses (see Section 2.4) and to help identify appropriate α values for each test method. The sources included Washington State Department of Ecology, EPA's Office of Science and Technology, North Carolina Department of the Environment and Natural Resources, California State Water Resources Control Board, and Virginia Department of Environmental Quality. Data acceptance criteria and types of WET test data desired were identified and documented in the Data Management Plan and the Quality Assurance Project Plan for this project. Nearly 2,000 valid WET tests of interest were incorporated, representing many permittees and laboratories (Table 2-2). Only data from WET tests meeting EPA's test acceptability criteria were used in the analyses.

For each set of test data received, additional metadata information was required including the following:

- Permittee name and NPDES permit number (coded for anonymity)
- Laboratory name and location (coded for anonymity)
- Design effluent concentration in the receiving water (expressed as percent effluent upon complete mix) used by the regulatory authority
- EPA test method version used (cited EPA number)
- Information indicating that all EPA test method's test acceptability criteria were met

In addition to the above effluent test data and metadata, two other sources of toxicity data were compiled in this project, which were used to help calculate the range of control organism response by endpoint for each EPA WET test method in Table 2-1. The first source of data was reference toxicant test data previously compiled for the EPA document, *Understanding and Accounting for Method Variability in Whole Effluent Toxicity Application Under the NPDES Program* (USEPA 2000). A second source of additional WET test data used in this project was data generated in ambient toxicity tests by the California State Water Resources Control Board. These data were useful in supplying information on control responses for the freshwater test methods in Table 2-1. Many states routinely conduct ambient toxicity tests as part of 305(b) monitoring; Total Maximum Daily Loads (TMDLs), and other programs (e.g., California's Surface Water Ambient Monitoring program (SWAMP), Washington Department of Ecology's ambient program, Wisconsin Department of Natural Resources' (WDNR) ambient monitoring program).

Table 2-2. Summary of WET test data analyzed

EPA WET test method	Number of tests		Number of laboratories	Number of permittees
	Effluent	Ref Tox		
Ceriodaphnia dubia (water flea) Survival and Reproduction[a]	554	238	44	68
Pimephales promelas (fathead minnow) Acute Survival[b]	347	0	15	101
Pimephales promelas (fathead minnow) Survival and Growth[b]	275	197	28	50
Americamysis bahia (mysid shrimp) Survival and Growth[c]	74	136	20	6
Dendraster excentricus and *Strongylocentrotus purpuratus* (Echinoderm) Fertilization[c]	83	94	11	10
Macrocystis pyrifera (giant kelp) Germination and Germ-tube length[d]	0	135	11	--
Haliotis rufescens (red abalone) Larval Development[c]	0	136	10	--
Ceriodaphnia dubia (water flea) Survival	7	232	27	2
Selenastrum capricomutum (green algae)	139	84	14	44

Notes:
a. Freshwater invertebrate
b. Freshwater vertebrate
c. Saltwater invertebrate
d. Saltwater algae

Representativeness of WET Data

The usefulness of the results obtained in this project depended on having valid, representative WET test data for each of the EPA WET test methods examined. Representativeness was characterized in this project as having data that met the following:

- Cover a range of NPDES permitted facility types, including both industrial and municipal permittees

- Represent many facilities for a given EPA WET test method (i.e., no one facility dominates the data for a given WET test method)
- Cover a range of target (design) effluent dilutions upon which WET RP and compliance are based, ranging from perhaps 10 percent to 100 percent effluent
- Generated by several laboratories for a given EPA WET test method
- Cover a range of observed effluent toxicity for each EPA WET test method (e.g., NOECs range from < 10 percent to 100 percent effluent)

Efforts were made to ensure that no one laboratory or permittee had > 10 percent of the test data for a given test type. The summary information presented in Table 2-2 demonstrates that WET test data were received from numerous laboratories and facilities for all EPA WET test methods analyzed under this project.

Data Processing

Processing of raw WET test data began with identifying the contents of each data package and recording the data source, test type, and related information as described in the previous section. Each valid WET test was assigned a unique code, and each laboratory was uniquely coded. A tracking system was used to help evaluate whether WET test data were needed for certain types of EPA WET test methods and to help increase representativeness of laboratories or types of facilities for a method.

Data were received in a variety of formats and compiled by test type in the database program CETIS® (Comprehensive Environmental Toxicity Information System; Tidepool Software, v. 1.0). The CETIS program is designed to analyze, store, and manage WET test data. WET test data received in either ToxCalc® or CETIS were imported directly into the CETIS database dedicated to this project. WET test data received in Excel or other spreadsheet formats were also directly imported into CETIS. In cases where the source organizations had not yet entered its WET test data electronically, they were supplied with a template so the data could be readily transferred to CETIS to minimize transcription errors. Data in CETIS were checked on 10 percent of the tests received from each source to document proper data transfer.

WET test data received as copies of bench sheets were first checked to ensure that all EPA WET method test acceptance criteria were met, as well as several other requirements discussed in the previous section. Those tests meeting all requirements were input into the CETIS database directly using the double entry mode and a comparison of entries to ensure accuracy of data input. All WET test data used in analyses originated from tests conducted with the minimum number of treatment replicates as required according to the specific EPA WET test methods (e.g., 10 replicates in chronic *Ceriodaphnia* tests). Tests using a different number of replicates per treatment were not used in analyses to generate percentiles of CV or mean response.

2.3 Setting the Test Method-Specific α Level

Monte Carlo simulation analysis was used to estimate the percentage of WET tests that would be declared toxic using TST as a function of different α levels, within-test control variability, and mean percent effect level. This analysis identified probable beta error rates (i.e., declaring an effluent toxic when in fact it is acceptable) as a function of α, mean effect at the IWC, and control CV. Using the RMDs discussed in Section 1.4, the lowest α level (with 0.05 being the

lowest α level used) was then identified for a given WET test design that also resulted in a β = 0.05 at a 10 percent mean effect in the effluent sample.

For each of the nine test methods examined, control CV was calculated on the basis of WET test data compiled as described in Section 2.2. Cumulative frequency plots were used to identify various percentiles of observed method-specific CVs (e.g., 25th, 50th, 75th percentiles). These measures were calculated to characterize typical achievable test performance in terms of control variability. A similar analysis was performed for the control endpoint responses for each of the nine test methods (e.g., mean offspring per female in the chronic *Ceriodaphnia dubia* test method) to characterize typical achievable test performance in terms of control response. The following describes the simulation analysis used to help identify appropriate alpha levels for each WET test method examined.

2.3.1 Simulation Analyses

In simulation analyses, sets of effluent and control WET test data were constructed having known properties with respect to different mean effect percentages and control CV as described below. Control CVs examined were based on CV percentiles observed in actual WET test data for a given WET test method. All simulation analyses were based on normally distributed WET test data and equal variances between the effluent and control for each scenario examined. These data were then analyzed using the one-tailed t-test published by Erickson and McDonald (1995) for bioequivalence testing (and mathematically defended in Erickson 1992 for normally distributed equal variance data) and the one-tailed traditional hypothesis t-test formulation (see Equations 1 and 2 below) to determine whether a given effluent was declared toxic using each approach at a specified α value. By simulating thousands of WET tests for a given scenario (mean percent effect and control CV and α level), the percentage of tests declared toxic could be calculated and compared among scenarios, and between the TST and the traditional hypothesis testing approach.

Equation 1: TST t-test assuming equal variances

$$t = \frac{\overline{Y_t} - b \times \overline{Y_c}}{S_p \sqrt{\frac{1}{n_t} + \frac{b^2}{n_c}}}$$

$$S_p = \sqrt{\frac{S_t{}^2 \times (n_t - 1) + S_c{}^2 \times (n_c - 1)}{(n_t + n_c - 2)}}$$

Equation 2: Traditional t-test assuming equal variances

$$t = \frac{\overline{Y_c} - \overline{Y_t}}{S_p \sqrt{\frac{1}{n_t} + \frac{1}{n_c}}}$$

$$S_p = \sqrt{\frac{S_t{}^2 \times (n_t - 1) + S_c{}^2 \times (n_c - 1)}{(n_t + n_c - 2)}}$$

It is understood that using normally distributed data and equal variances is a simplification for some WET test methods that are prone to non-normally distributed data and heterogeneous variances (e.g., acute fathead minnow test method). Additional analyses suggested that the bioequivalence t-test of Erickson and McDonald (1995) results in a very small (< 0.01) departure of the nominal α error rate using TST with data that have even a nine-fold difference between control and effluent variances (which is greater than most variance ratios observed in nearly 2,000 WET tests) and with data that were non-normally distributed (Appendix A). Thus, results of simulation analyses should be applicable to the types of non-normality and variance heterogeneity encountered in WET tests. This was further supported by additional research showing that WET test data distributions are typically not highly skewed or long-tailed because of the way in which the tests are designed and because there are boundaries on test acceptability criteria that truncate the data within a test and the difference in variance one observes between control and an effluent treatment. A review of the statistical literature as well as additional analyses in developing the TST approach confirmed that Welch's t-test is appropriate for the types of non-normal data distributions encountered in actual effluent WET tests as well as for normally distributed data (see Appendix A).

Probabilities of accepting the null hypothesis for the traditional and TST approaches will differ according to different settings for a number of parameters, including population variances, test sample size, and effect size (i.e., fraction of the control response). Each of these factors was varied in simulation analysis as follows:

Population Variances: Population variances were defined by test method (control CVs in a large number of actual WET tests for a given method). The population mean was set to the median value of observed control mean values from actual effluent tests, and the CV value ranged from approximately the 10^{th} to 90^{th} percentile of the observed control CV range. N samples (representing the minimum number of replicates required in the test method) from the control population were selected for each simulation.

Effect Size: Population mean for the treatment group was defined by a specified effect size. Five different effect sizes (from 10 percent to 30 percent of the control mean) were evaluated for each treatment group. For example, when the control mean = 25 and the effect size = 10 percent, N samples (corresponding to the minimum number of replicates required in the test method) were picked at random from a population with mean = 25 × ([100 – 10] percent).

Sample Size (N): For certain WET test methods, sample size for each test method was increased up to double the minimum number of replicates required for a given test method. For example, number of replicates for the chronic *C. dubia* test ranged from 10 to 20 in simulation analyses. This analysis provided useful information indicating potential benefits to a permittee if they conducted a WET test method with additional replicates, given a specified mean percent effect level and control CV observed, and a specified α level.

Alpha Error: The maximum allowable Type I error (α) in TST was specified at different levels ranging from 0.05 to 0.30 (6 values). Results of these analyses indicated potential β error rates (probability of declaring a sample toxic when it is acceptable) given a specified mean percent effect in the effluent and control CV. These results were also compared with results using the traditional hypothesis testing approach and an $\alpha = 0.05$ (the EPA-recommended α level using the

traditional hypothesis testing approach) to compare β error rates using both approaches. While comparison of results between TST and the traditional approach were not used to set test method α levels, this analysis was useful in documenting whether the TST approach was as protective as the traditional approach using a given α level.

After N samples of control and effluent were randomly selected from specified populations, the traditional hypothesis testing approach and TST were conducted as specified in equations 1 and 2 above. The one tail probabilities of declaring the test toxic using the traditional hypothesis testing approach and the TST approach were calculated and saved. This simulation was repeated 10,000 times for each combination of effect levels, CV, and alpha level. The percent of tests declared toxic was then calculated for each simulation setting.

Once β error rates were identified for a WET method given different α levels, control CVs, and percent mean effect levels, bivariate plots were used to compare the percentage of tests declared toxic as a function of α and the ratio of effluent mean: control mean at various within-test variability percentiles (e.g., 25^{th}, 50^{th}, 75^{th}) and the RMD effect thresholds identified as either toxic (25 percent effect for chronic and 20 percent for acute) or negligible (10 percent mean effect). The results were then used to identify an appropriate α error rate for a test method given the RMDs noted in Section 1.4.

Finally, where there was sufficient effluent test data available, an analysis of actual effluent data was conducted using TST and the α level identified for the test method, and using the traditional hypothesis testing approach. Results of that analysis were used to estimate potential results if TST was used in the NPDES WET Program and to compare those results with those using the traditional hypothesis testing approach.

3.0 RESULTS

3.1 Chronic *Ceriodaphnia dubia* Reproduction Test

On the basis of actual WET data (N = 792 tests), the mean control reproduction ranged from 15.0 to 51.7, with a median mean value of 25.5 (Table 3-1). Control CVs ranged from 0.04 to 1.22 with a median value of 0.15 (Table 3-1). Using these data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), CVs, and percent mean effect in reproduction between the control and effluent concentration.

Table 3-1. Summary of mean control reproduction and control CV derived from analyses of 792 chronic *Ceriodaphnia dubia* WET tests

Percentile	Mean control reproduction	Control CV	Control SD
10th	17.7	0.08	2.07
25th	21.2	0.10	2.64
50th	25.5	0.15	3.79
70th	28.4	0.22	5.27
75th	29.4	0.24	5.82
85th	31.6	0.31	7.24
90th	33.3	0.35	8.41
95th	35.6	0.40	10.25

Identifying Test Method-Specific α

A summary of the simulation results is shown graphically in Figure 3-1. An alpha level of 0.20 satisfies both RMDs of (1) ensuring at least a 75 percent probability of declaring a 25 percent mean effect as toxic regardless of within-test control variability (denoted as effluent mean: control mean value of 0.75 on the x-axis of each graph in Figure 3-1), and (2) ensuring that a negligible effect (10 percent mean effect denoted as effluent mean: control mean value of 0.90) is declared toxic $\leq$ 5 percent of the time. Lower α levels (e.g., $\alpha = 0.10$) resulted in > 5 percent tests declared toxic when there was a 10 percent effect under average within-test CV values (i.e., $\beta > 0.05$). Note that using an $\alpha = 0.20$, a *Ceriodaphnia* test having a 20 percent mean effect at the IWC (effluent mean:control mean = 0.8) and median control variability (control CV = 0.15) will be declared toxic approximately 50 percent of the time using TST (Figure 3-1). Thus, as discussed in Section 1.3 and shown in Figure 1.2, some percentage of tests having an effluent mean effect less than the RMD threshold of 25 percent will be declared toxic using TST, even when the test control responds acceptably. Likewise, at an $\alpha = 0.20$, a *Ceriodaphnia* test exhibiting a 10 percent mean effect in the effluent (0.9 on the x-axis in Figure 3-1) and relatively high control variability (control CV = 0.25, 75th percentile for this WET test method) will have approximately a 25 percent probability of being declared toxic (Figure 3-1), even though a 10 percent mean effect is considered acceptable using TST.

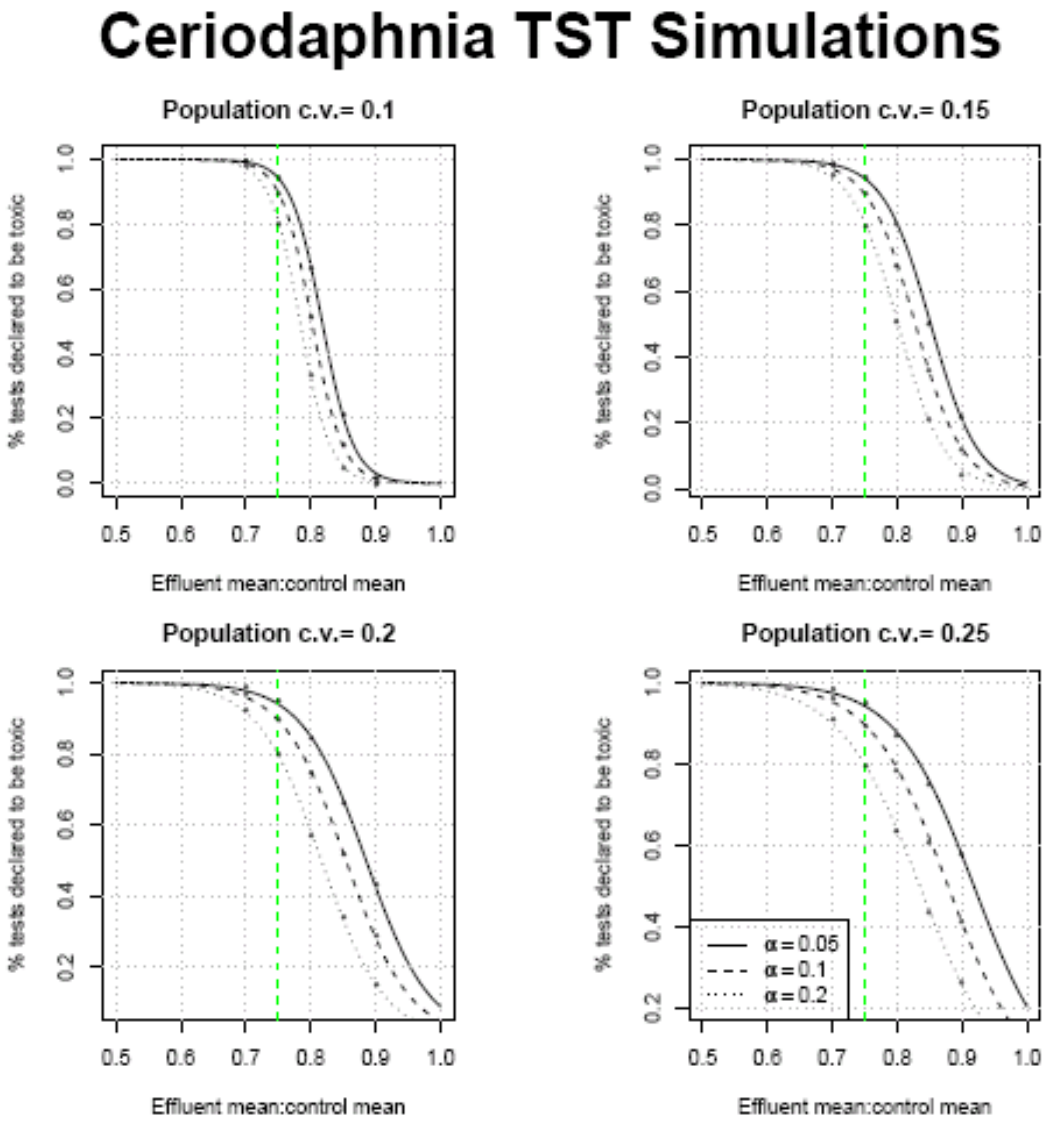

Figure 3-1. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs of 0.1, 0.15, 0.2, and 0.25 correspond to the approximate 25th, 50th, 70th, and 75th percentiles for the chronic *Ceriodaphnia* WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

The above results illustrate two features of the TST approach that should be understood: (1) At mean effect levels < the RMD toxicity threshold, there are differing probabilities of an effluent being declared toxic (i.e., different actual α error rates) depending on within-test variability and the difference in mean responses observed between control and IWC (see Figure 1-2). An effluent with a mean effect substantially lower than the RMD threshold of 25 percent will have some probability of being declared toxic. (2) For this WET test method and some others examined in this project, there is some probability of declaring a test non-toxic when the mean effect in the effluent exceeds the RMD threshold of 25 percent; e.g., at an α = 0.20 and relatively

high within-test variability, a 30 percent mean effect in the effluent might not be declared toxic as much as 10 percent of the time.

The following examples give representative results of the simulation analysis, illustrating the effect of different alpha levels in terms of meeting RMDs for TST.

In the first example, there is a 10 percent mean effect in the effluent and a median level of within-test control precision (50th percentile CV of 0.15). Use of alpha levels ranging from 0.05 to 0.30 resulted in failure to reject the null hypothesis in ~20 percent to ~5 percent of tests, respectively, with α levels $\geq$ 0.20 meeting the RMD of $\beta \leq 0.05$ at a 10 percent mean effect level (Figure 3-2).

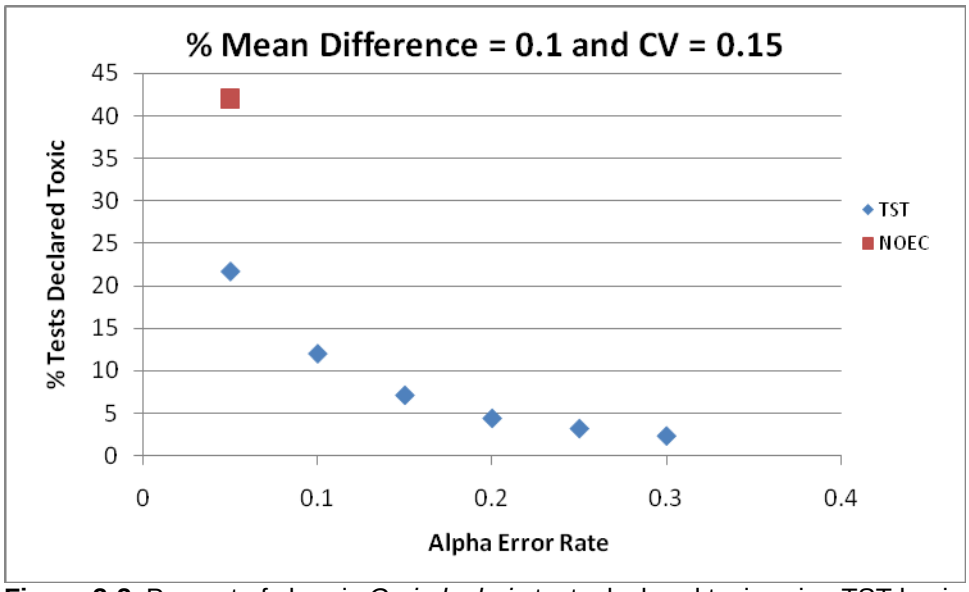

Figure 3-2. Percent of chronic *Ceriodaphnia* tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

In a second example, the effluent has a mean effect of 25 percent and above average control CV (75th percentile). At α levels < 0.25, the percentage of tests declared toxic is $\geq$ 75 percent, meeting the RMD for false negative rate (α).

The rate at which tests were declared toxic was evaluated using both the traditional hypothesis testing approach with an alpha error rate of 0.05 (as recommended in the EPA WET test methods) and the TST approach with different alpha error rates. At a 50th percentile CV (0.15) and a mean effect of 10 percent, use of the TST approach results in fewer declared toxic tests relative to the traditional hypothesis approach at all alpha error rates examined (Figure 3-2). For tests with the same mean effect (10 percent) but higher control variability (CV = 0.25), TST yields a higher rate of tests declared toxic at alpha error rates of 0.05, 0.10, and 0.15 and approximately equivalent percent toxic tests at alpha error rates of 0.20 and 0.25 (Figure 3-2). Those results are in keeping with the RMD that tests with negligible (10 percent) mean effect in

the effluent are declared non-toxic most of the time but are declared to be toxic more frequently as test precision is poorer.

Tests with a mean effect of 25 percent and above average precision (CV = 0.25) result in a higher rate of tests declared toxic using TST than using the traditional hypothesis approach (Figure 3-3). This result is a direct consequence of the RMDs defined for TST but illustrate disincentives to collect more precise data using the traditional hypothesis approach currently used.

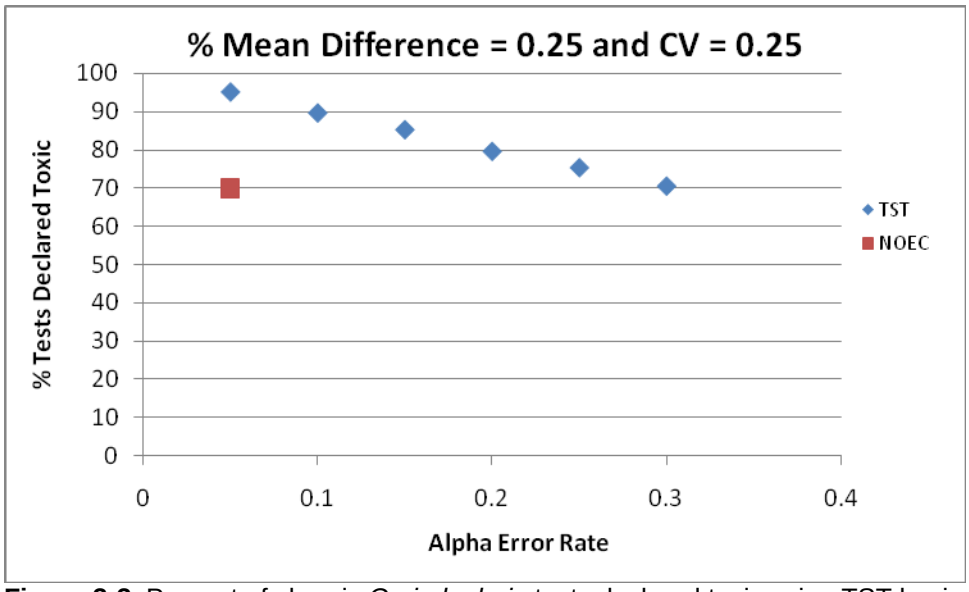

Figure 3-3. Percent of chronic *Ceriodaphnia* tests declared toxic using TST having a mean effluent effect of 25 percent and high control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Effect of Increased Number of Within-Test Replicates

One of the intended benefits of the TST approach is that increasing the precision and power of the test increases the chances of rejecting the null hypothesis and declaring a sample non-toxic when it meets the RMD for acceptability. This increases the ability of the permittee to *prove the negative* that a sample is acceptable. To demonstrate this benefit, the effect of increasing test replication on the TST β error rate (declaring a sample toxic when it is not) was explored using simulated data.

Increasing test replication with this method (and thereby the power of the test) results in a *higher* rate of tests declared toxic using the traditional hypothesis testing approach and a *lower* rate of tests declared toxic using the TST approach (e.g., Figure 3-4). For tests with a mean effect of 10 percent and a control CV of 0.25 (approximately 75th percentile for this method), slightly more tests will be declared toxic using the TST approach as compared to the traditional hypothesis testing approach when the minimum test design of 10 replicates is used for this WET method. If the number of within-test replicates is increased, the TST approach demonstrates an improved ability to declare such a test as acceptable. As the mean effect at the effluent approaches 25 percent, the percentage of tests declared toxic is less affected by increased replication using TST because the *b* value and α value were selected to identify a 25 percent mean effect in the IWC as

toxic ≥ 75 percent of the time. However, the percentage of tests declared toxic continues to increase using the traditional hypothesis approach even when there is a negligible effect (10 percent effect) of the effluent as defined by TST (Figure 3-5). Thus, increasing test replication increases TST's ability to confirm that an effluent is acceptable in tests with mean effect less than 25 percent.

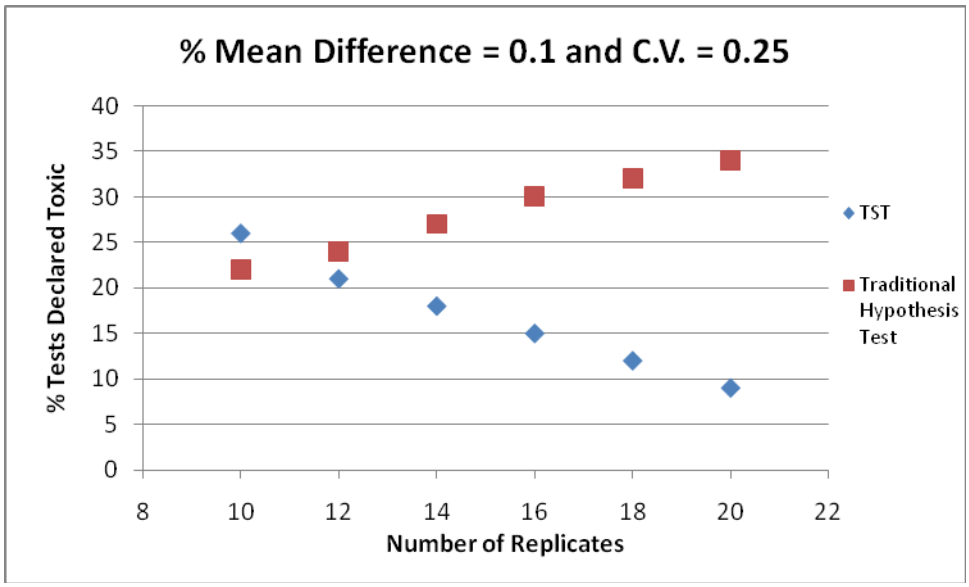

Figure 3-4. Percent of chronic *Ceriodaphnia* tests declared toxic using TST having a mean effluent effect of 10 percent and above average control variability and α = 0.20, as a function of the number of test replicates. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Effluent Data Results

Results from actual effluent tests were compared between TST and the traditional hypothesis testing approach for those tests having control CV between 0.15–0.24 (Table 3-2). At a mean effect of 10–15 percent at the IWC (N = 48), TST declared a lower percentage of tests toxic than the traditional hypothesis testing approach. This result is consistent with the RMD that a 10 percent mean effect should be declared acceptable much (95 percent) of the time. However, when the mean effect was greater than 25 percent (N = 303), TST declared 100 percent of the tests toxic while the traditional hypothesis testing approach did not. This result is also consistent with the TST goal that as the mean effect approaches 25 percent at least 75 percent of the tests should be declared toxic. This result also indicates that given the effluent data available, TST is at least as protective as the traditional hypothesis approach currently used.

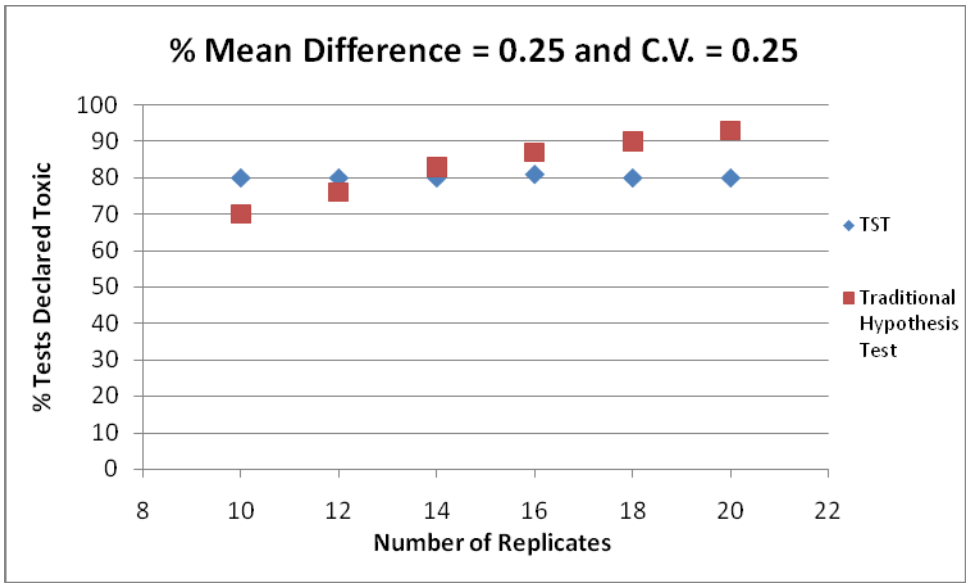

Figure 3-5. Percent of *Ceriodaphnia* tests declared toxic using TST having a mean effluent effect of 25 percent and above average control variability (α = 0.20) as a function of the number of test replicates. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Table 3-2. Comparison of the percentage of chronic effluent *Ceriodaphnia* tests declared toxic using TST versus the traditional hypothesis testing approach

% Mean effect	N	% tests toxic using TST	% Tests toxic using traditional hypothesis testing approach
10–15	48	6.2	18.7
20–30	48	100	87.5
> 25	303	100	95.2

3.2 Chronic *Pimephales promelas* Growth Test

On the basis of actual WET data (N = 472 tests), the mean control growth ranged from 0.31 to 1.30, with a median mean value of 0.62 (Table 3-3). Control CVs ranged from 0.03 to 0.50 with a median value of 0.09 (Table 3-3). Using these data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), CVs, and percent mean effect in growth between the control and effluent concentration.

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-6), an alpha error rate of 0.25 is appropriate for use in applying the TST approach to analysis of two concentration chronic *P. promelas* data because using that alpha error rate satisfies both RMDs of (1) ensuring at least an 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time.

Table 3-3. Summary of mean control growth and control CV derived from analyses of 472 chronic *Pimephales promelas* WET tests

Percentile	Mean control growth	Control CV	Control SD
10th	0.34	0.04	0.02
25th	0.43	0.06	0.03
50th	0.62	0.09	0.05
70th	0.76	0.12	0.07
75th	0.79	0.13	0.08
85th	0.86	0.16	0.10
90th	0.89	0.17	0.11
95th	0.94	0.21	0.13

As noted for the *Ceriodaphnia* chronic test in Section 3.1, the Type I error rate will vary from the RMD Type I error rate of 0.25 depending on the level of toxicity observed in the effluent and control variability within a test. When toxicity is > 25 percent mean effect in the effluent, the Type I error rate is lower. However, as noted in Section 1.3, there is some probability (< 10 percent) that a mean effect > 25 percent in the IWC will be declared non-toxic depending on within-test variability. Likewise, a reasonable percentage (as much as 50 percent) of tests having a mean effect = 15 percent in the effluent will be declared toxic using the TST approach, again depending on within-test variability: the greater the within-test variability the greater the probability of declaring toxicity at mean effect levels below the toxicity decision threshold of 25 percent.

For example, at a 10 percent mean effect in the effluent and above average within-test control variability (between the 50th and 75th percentile, CV of 0.11), use of an alpha level of 0.25 results in failure to reject the null hypothesis ~5 percent of the time (Figure 3-7). Lower alpha levels resulted in a higher percentage of tests declared toxic at that mean effect level and CV range (Figure 3-6). That indicates that using an alpha = 0.25 for this test method, TST achieves the RMD of correctly identifying an acceptable sample (based on the RMD that a 10 percent mean effect is negligible). However, less precise tests (but still well within normal test method performance) result in less ability to reject the null hypothesis that the sample is toxic and the rate of tests declared toxic increases even at a percent mean effect of 10 percent (Figure 3-6). For tests with a mean effect of 25 percent (the RMD toxicity threshold) and alpha error rate of 0.25, 75 percent of the tests are declared toxic as expected (Figure 3-8).

Effect of Increased Number of Within-Test Replicates

As expected, increasing test replication (and thereby the power of the test) results in a *higher* rate of tests declared toxic using the traditional hypothesis testing approach and a *lower* rate of tests declared toxic using the TST approach and chronic *P. promelas* test data (e.g., Figure 3-9). For tests with a mean effect of 10 percent in the effluent and a control CV of 0.15 (slightly greater than the 75th percentile for this method), slightly more tests are declared toxic using the TST approach as compared to the traditional hypothesis testing approach when the minimum test design of four replicates is used for this WET endpoint. If replicates are added to the test design, the TST approach demonstrates an increased ability to declare the results acceptable. As the mean effect approaches 25 percent, the percentage of tests declared toxic is less affected by

increased replication using TST because a 25 percent effect is the RMD used to define *b* and the null hypothesis. However, the percentage of tests declared toxic continues to increase using the traditional hypothesis testing approach even when there is a 10 percent effect of the effluent. Thus, increasing test replication increases TST's ability to confirm an acceptable effluent when the mean effect is less than 25 percent in the effluent.

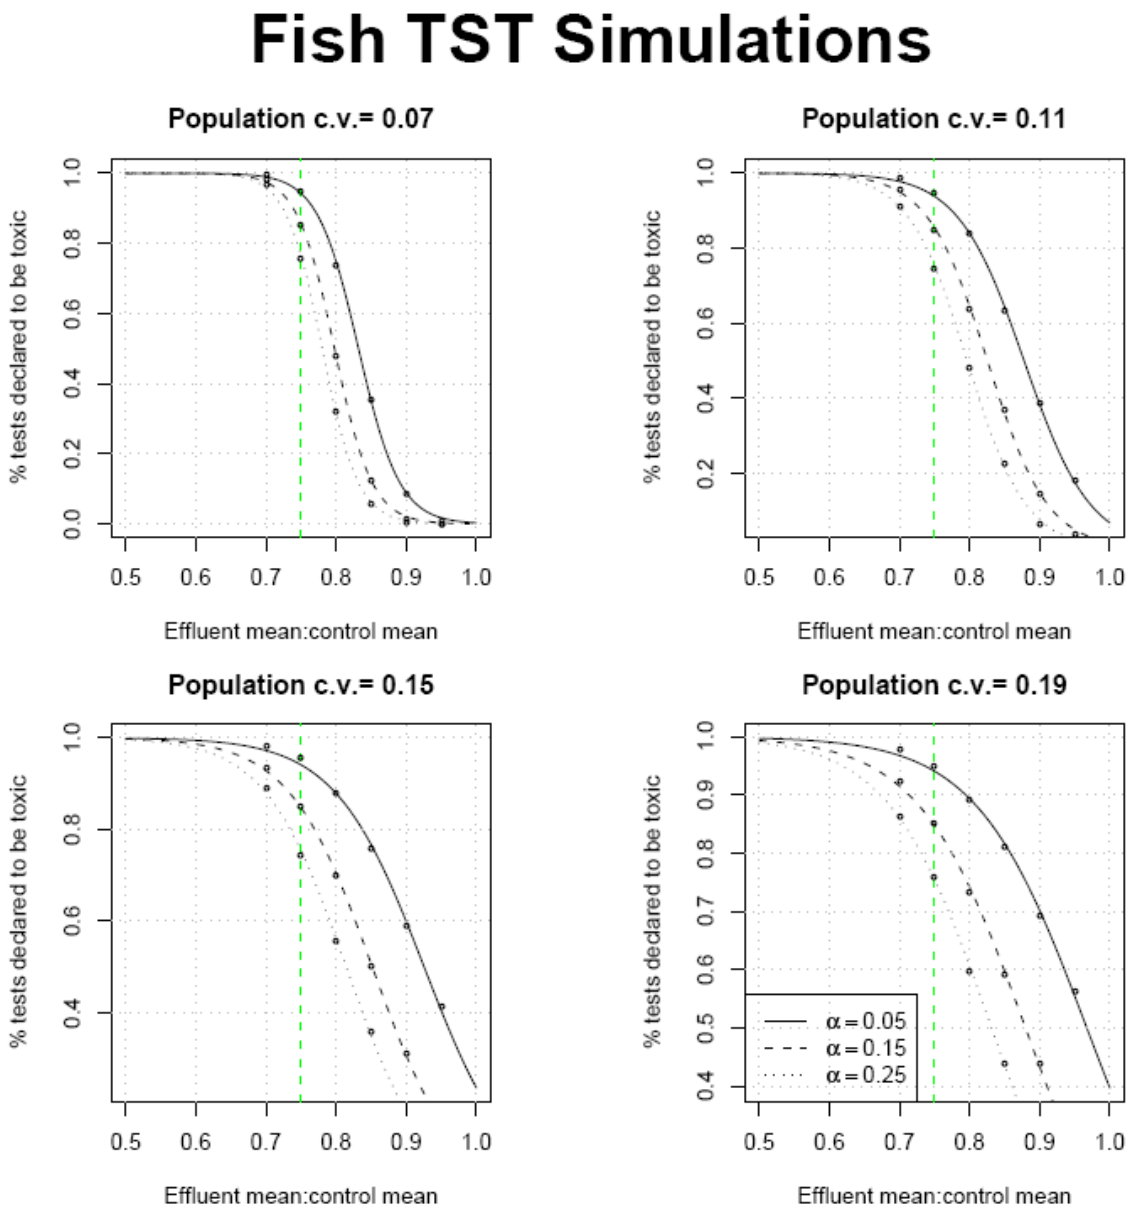

Figure 3-6. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 25th, 50th, 75th, and 90th percentiles for the chronic fathead minnow WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

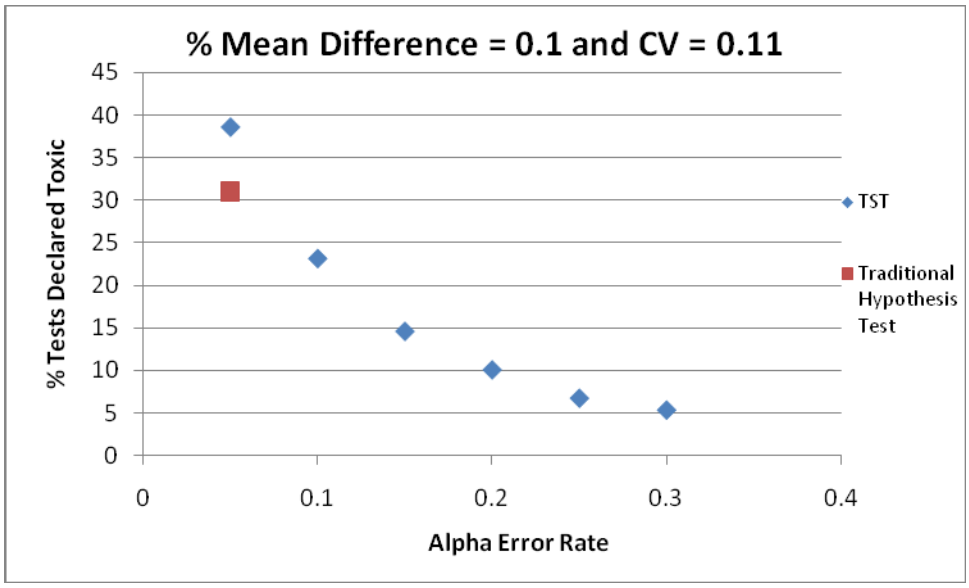

Figure 3-7. Percent of chronic fathead minnow tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of α error rate. Result using the traditional approach (α = 0.05) is shown as well.

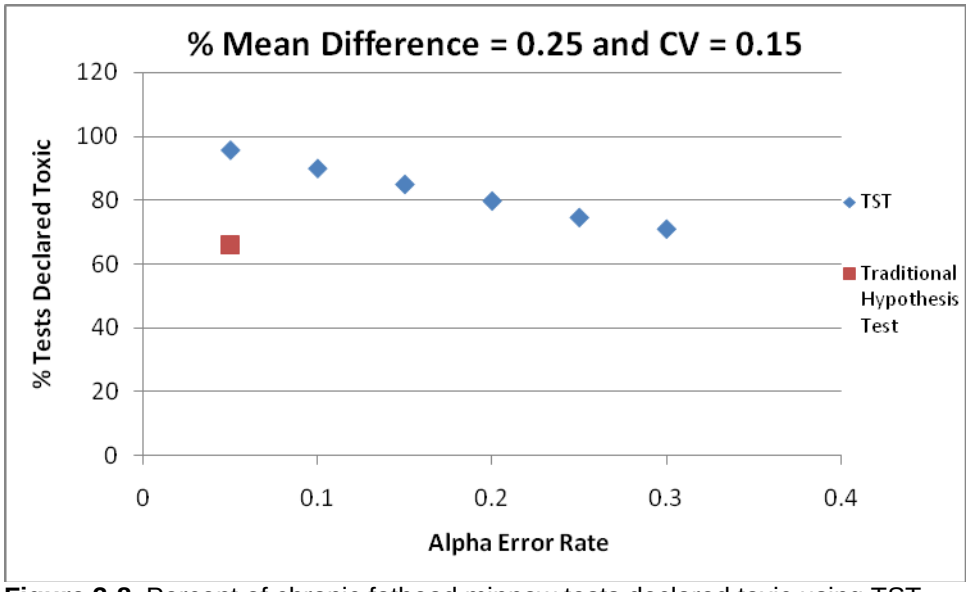

Figure 3-8. Percent of chronic fathead minnow tests declared toxic using TST having a mean effluent effect of 25 percent and above average control variability as a function of α error rate. Result using the traditional approach (α = 0.05) is shown as well.

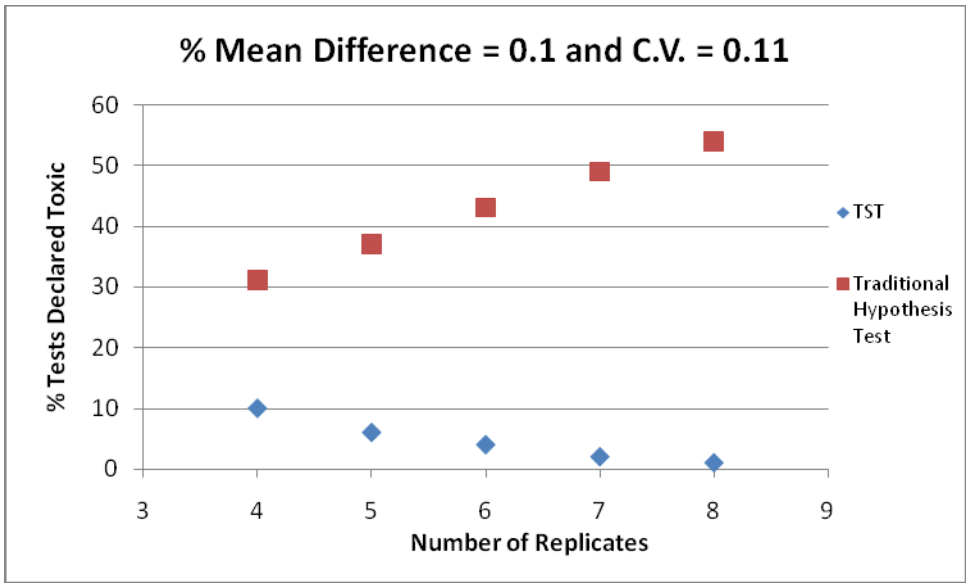

Figure 3-9. Percent of chronic fathead minnow tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability and an α = 0.25, as a function of the number of test replicates. Result using the traditional approach (α = 0.05) is shown as well.

Effluent Data Results

Results from actual effluent tests were compared between TST and the traditional hypothesis testing approach for those tests having control CV between 0.09–0.13 (Table 3-4). At a mean effect of 10–15 percent (N = 58), TST declared none of the tests toxic while the traditional hypothesis testing approach declared nearly all of the tests toxic. However, if the mean effect is greater than 25 percent (N = 136), both approaches declared 100 percent of the tests toxic. Those results indicate that TST is as protective as the current hypothesis testing approach for those tests when the TST RMD threshold for toxicity is exceeded.

Table 3-4. Comparison of the percentage of chronic effluent fathead minnow tests declared toxic using TST versus the traditional hypothesis testing approach

% Mean effect	N	% tests toxic using TST	% tests toxic using traditional hypothesis testing approach
10–15	58	0	98
> 25	136	100	100

3.3 Chronic *Americamysis bahia* Growth Test

On the basis of actual WET data (N = 210 tests), the mean control growth ranged from 0.20 to 0.66, with a median value of 0.30 (Table 3-5). Control CVs ranged from 0.07 to 0.87 with a median value of 0.14 (Table 3-5). Using those data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), CVs, and percent mean effect in growth between the control and effluent concentration.

Table 3-5. Summary of mean control growth and control CV derived from analyses of 210 chronic *Americamysis bahia* WET tests

Percentile	Mean control growth	Control CV	Control SD
10th	0.22	0.08	0.02
25th	0.25	0.10	0.03
50th	0.30	0.14	0.04
70th	0.36	0.17	0.06
75th	0.38	0.18	0.06
85th	0.41	0.22	0.07
90th	0.43	0.27	0.08
95th	0.47	0.35	0.11

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-10), an alpha error rate of 0.15 is appropriate for use in applying the TST approach to analysis of chronic mysid data because using this alpha error rate satisfies both RMDs of (1) ensuring at least an 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time under average or better than average test performance.

For example, at a 10 percent mean effect in effluent and an approximate median level of precision (50^{th} percentile CV of 0.14), an alpha level of 0.15 or greater resulted in failure to reject the null hypothesis in ≤ 5 percent of tests (Figure 3-11). For tests with a mean effect of 25 percent, the rate of tests declared toxic > 75 percent is achieved for alpha values ≤ 0.25 (Figure 3-12).

At a ~50^{th} percentile CV (0.13) and a mean effect of 10 percent, use of the TST approach results in significantly fewer toxic tests relative to the traditional hypothesis testing approach at all alpha error rates (Figure 3-11). For tests with the same mean effect (10 percent) but lower control precision (CV = 0.18), TST yields a higher rate of tests declared toxic at an alpha error rate of 0.05 and approximately equivalent percent toxic tests at a alpha error rate of 0.10.

Tests with a mean effect of 25 percent and above average precision (CV = 0.18) result in a high rate of tests declared toxic (Figure 3-12). The results are in agreement with the RMDs of the TST: As the mean effect approaches 25 percent, a greater proportion of the tests are determined to be toxic. Further, the less precise the test control data, the greater the rate of tests declared toxic (i.e., fail to reject the null hypothesis).

Effect of Increased Number of Within-Test Replicates

As expected, increasing test replication (and thereby the power of the test) results in a *higher* rate of tests declared toxic using the traditional hypothesis testing approach and a *lower* rate of tests declared toxic using the TST approach at a negligible effect of 10 percent, as shown in the example using chronic *A. bahia* test data (e.g., Figure 3-13). If replicates are added to the test design, the TST approach demonstrates an increased ability to declare such a test as non-toxic. As the mean effect approaches 25 percent, the percentage of tests declared toxic is less affected by increased replication using TST because a 25 percent effect is the RMD toxicity threshold identified in TST. However, the percentage of tests declared toxic continues to increase using the

traditional hypothesis testing approach even when there is a negligible effect (10 percent effect as defined by TST) of the effluent. Thus, increasing test replication increases TST's ability to confirm an acceptable level of toxicity in tests with mean effect less than 25 percent.

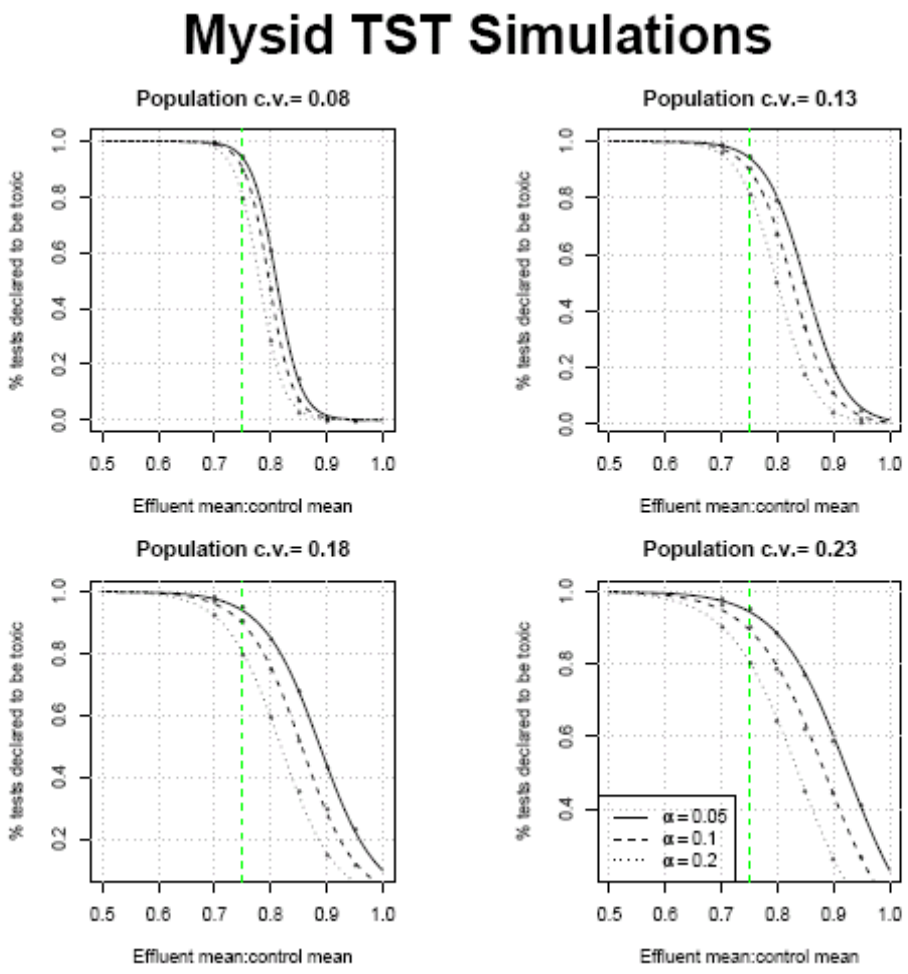

Figure 3-10. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 25th, 50th, 70th, and 90th percentiles for the chronic mysid WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

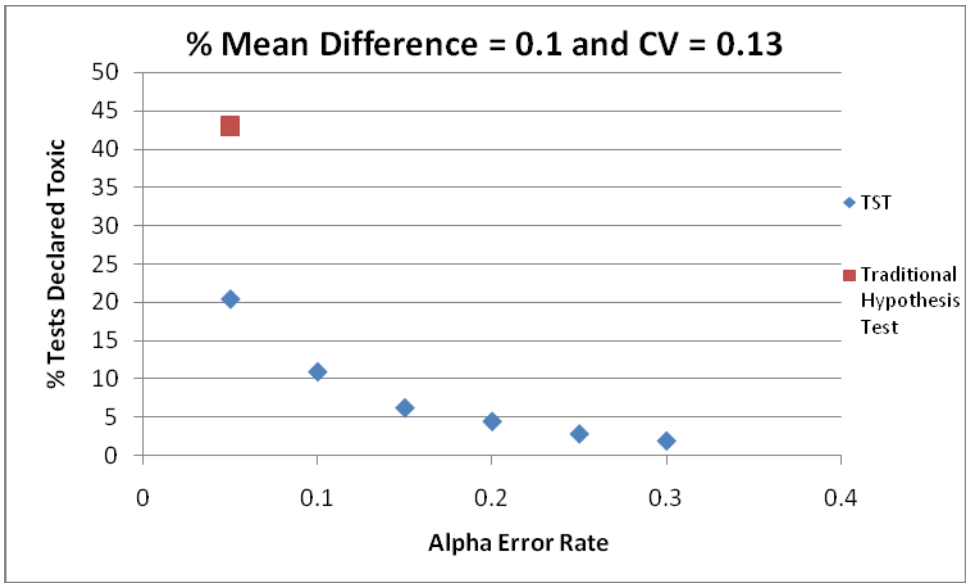

Figure 3-11. Percent of chronic mysid tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

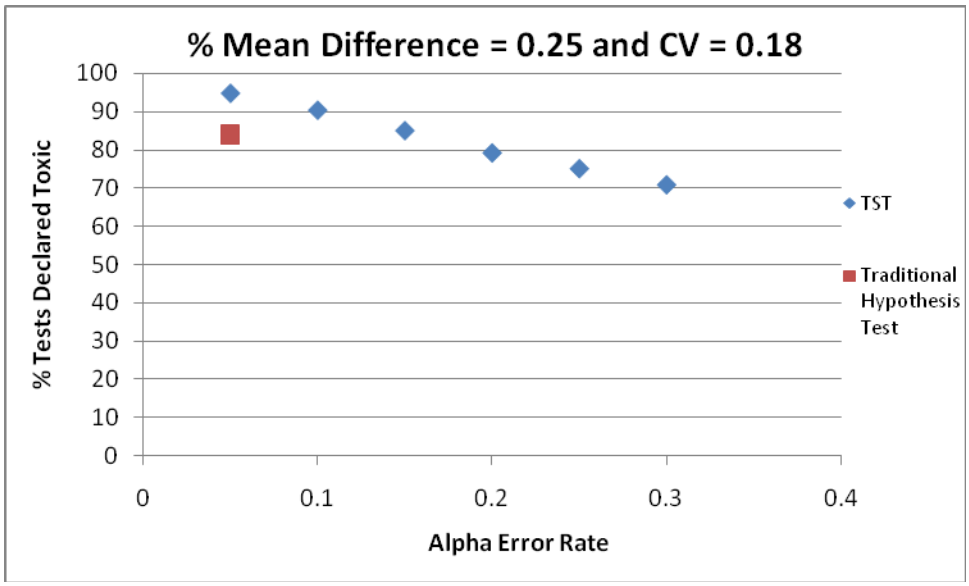

Figure 3-12. Percent of chronic mysid tests declared toxic using TST having a mean effluent effect of 25 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

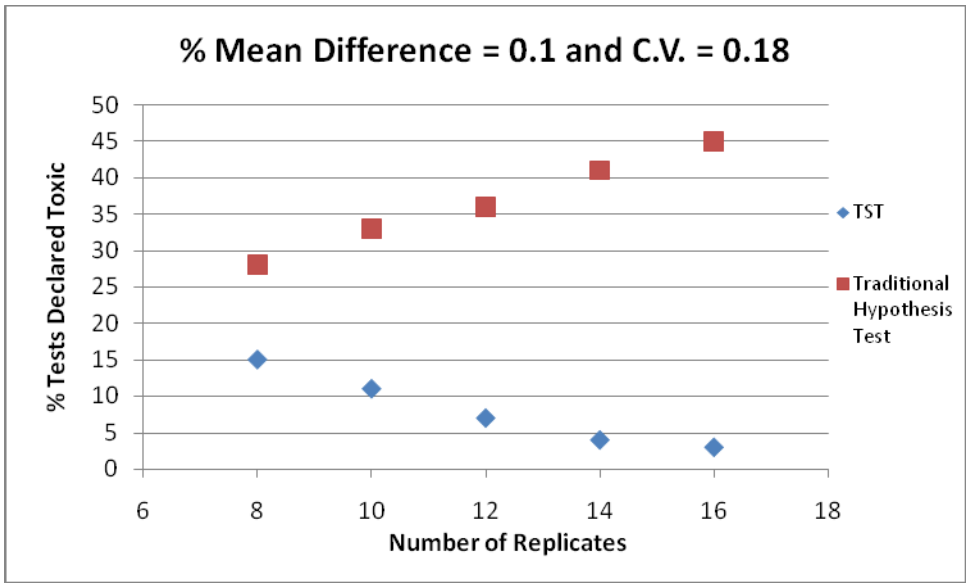

Figure 3-13. Percent of chronic mysid tests having a mean effluent effect of 10 percent and above average control variability declared toxic using TST and an α = 0.15, as a function of the number of test replicates. Results using the traditional hypothesis approach (α = 0.05) are shown as well.

Effluent Data Results

Results from actual effluent tests were compared between TST and the traditional hypothesis testing approach for those tests having control CV between 0.14–0.26 (75^{th} – 90^{th} percentile; Table 3-6). At a mean effect of 5–15 percent (N = 52), TST declared a lower percentage of tests toxic than the traditional hypothesis approach. That is expected because 10 percent mean effect in the effluent is considered negligible. However, when the mean effect in the effluent is greater than 25 percent (N = 95), both approaches declared 100 percent of the tests toxic.

Table 3-6. Comparison of percentage of chronic effluent mysid shrimp tests declared toxic using TST versus the traditional hypothesis testing approach

% Mean effect	N	% tests toxic using TST	% tests toxic using traditional hypothesis testing approach
5-15	52	1.9	11.5
> 25	95	100	100

3.4 Chronic *Haliotis rufescens* Larval Development Test

From actual WET data (N = 136 reference toxicant tests), mean control larval development ranged from 0.800 to 1.000, with a median mean value of 0.938 (Table 3-7). Control CVs ranged from 0.000 to 0.333 with a median value of 0.03 (Table 3-7). Using those data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), CVs, and percent mean effect in larval development between the control and effluent concentration.

Identifying Test Method-Specific α

On the basis of simulation results and power analyses (Figure 3-14), an alpha error rate of 0.05 is appropriate for use in applying the TST approach to analysis of chronic *H. rufescens* data because using this alpha error rate satisfies both RMDs of (1) ensuring at least an 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time (Figure 3-14). Note that higher alpha levels would also satisfy the above RMDs; however, as noted in Section 1.4, the Type I error rate is set as close to 0.05 as practicable given routine control performance.

Table 3-7. Summary of mean control larval development and control CV derived from analyses of 136 chronic red abalone WET tests

Percentile	Mean control larval development	Control CV	Control SD
10th	0.839	0.02	0.01
25th	0.900	0.02	0.02
50th	0.938	0.03	0.03
70th	0.961	0.04	0.04
75th	0.968	0.05	0.04
85th	0.977	0.06	0.05
90th	0.982	0.06	0.06
95th	0.988	0.07	0.07

At a 10 percent mean effect in the effluent, for example, and ~80th percentile CV of 0.05, alpha levels ranging from 0.05 to 0.30 result in failure to reject the null hypothesis in none of the tests (Figure 3-15). The rate of rejection of the null hypothesis using TST decreases only slightly with increasing CV. This result is indicative of the low within-test control variability routinely achieved using this WET test method.

For tests with a mean effect of 25 percent, the rate of tests declared toxic ranges from ~95 to ~70 percent, at approximately the 80th percentile CV value for alpha levels ranging from 0.05 to 0.30, respectively (Figure 3-16). Thus, at an alpha = 0.05, the rate of tests declared toxic at a 25 percent mean effect in the effluent meets the RMD.

At ~80th percentile CV (0.05) and a mean effect of 10 percent, use of the TST approach results in significantly fewer toxic tests relative to the traditional hypothesis approach at all alpha error rates (Figure 3-15). Those results are in keeping with the RMD of the TST approach; tests with a negligible (10 percent) mean effect of the effluent are declared non-toxic 95 percent of the time when test control data have average precision.

Tests with a mean effect of 25 percent and above average precision (CV = 0.05) resulted in an equivalent rate of tests declared toxic as the traditional hypothesis approach when the TST α = 0.05 (Figure 3-16). The results further support the selection of TST α = 0.05 for this test method.

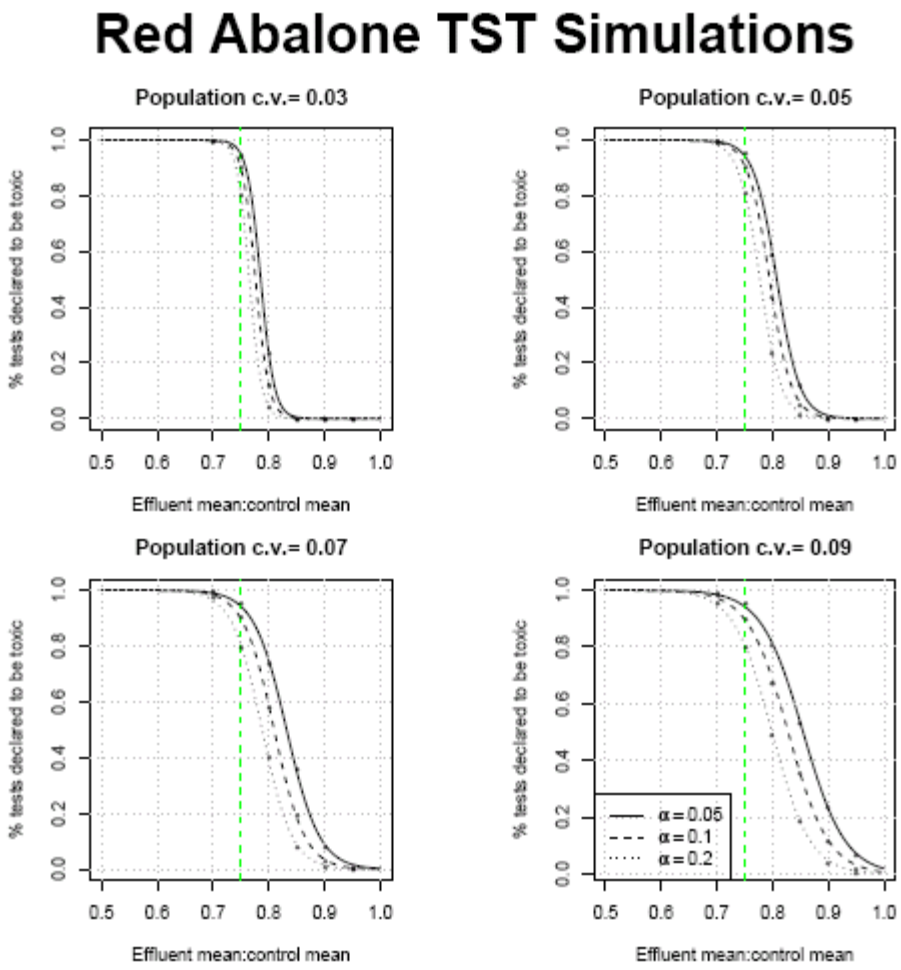

Figure 3-14. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 25th, 50th, 75th, and 98th percentiles for the chronic red abalone WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

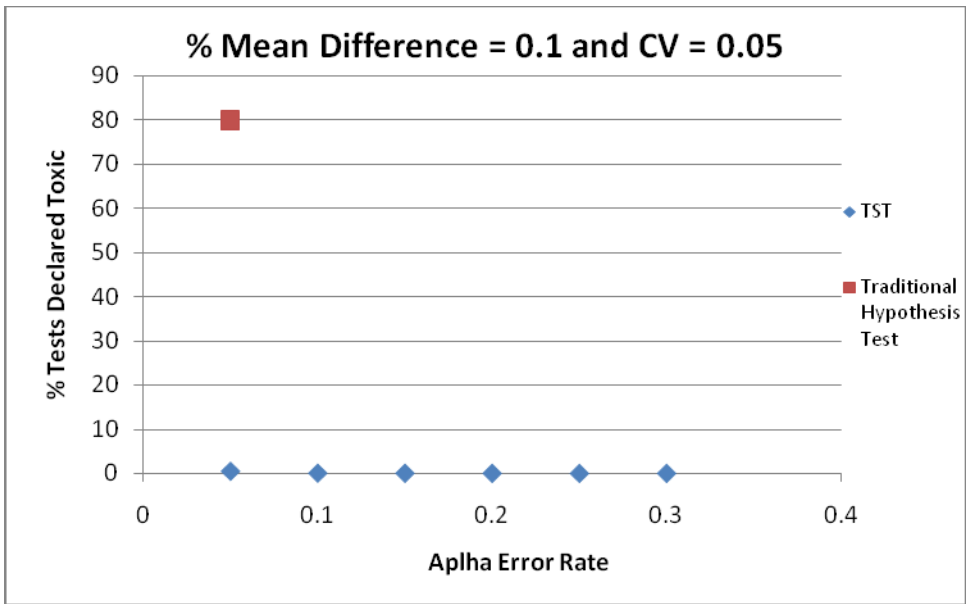

Figure 3-15. Percent of chronic red abalone tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

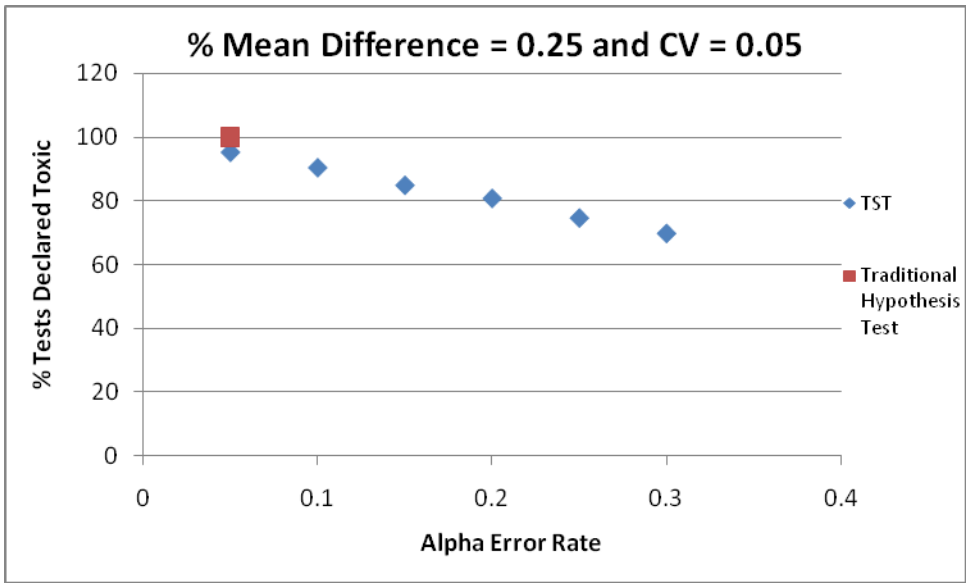

Figure 3-16. Percent of chronic red abalone tests declared toxic using TST having a mean effluent effect of 25 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

3.5 Chronic *Macrocystis pyrifera* Germination Test

On the basis of actual WET data (N = 135 reference toxicant tests), mean control germination ranged from 0.700 to 0.985, with a median mean value of 0.908 (Table 3-8). Control CVs ranged

from 0.006 to 0.560 with a median value of 0.04 (Table 3-8). Using that data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), CVs, and percent mean effect in germination between the control and effluent concentrations.

Table 3-8. Summary of mean control germination and control CV derived from analyses of 135 chronic giant kelp WET tests

Percentile	Mean control germination	Control CV	Control SD
10th	0.783	0.02	0.02
25th	0.859	0.03	0.02
50th	0.908	0.04	0.03
70th	0.936	0.05	0.04
75th	0.940	0.05	0.05
85th	0.958	0.07	0.06
90th	0.965	0.07	0.06
95th	0.973	0.10	0.09

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-17), an alpha error rate of 0.05 is appropriate for use in applying the TST approach to analysis of chronic *M. pyrifera* germination data because using this alpha error rate satisfies both RMDs of (1) ensuring at least an 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time under average test performance. As noted above for the Abalone test method, higher alpha levels also satisfy the above RMDs; however, an alpha level of 0.05 is selected because it is more protective at effect levels > 25 percent.

At a 10 percent mean effect in the effluent for example, and routine, achievable control precision (~75th percentile CV of 0.05), alpha levels ranging from 0.05 to 0.30 resulted in failure to reject the null hypothesis in none of tests (Figure 3-18). Thus, for this test endpoint, low within-test control variability is routinely achieved.

For tests with a mean effect of 25 percent, the rate of tests declared toxic ranges from ~95 percent to ~70 percent, at alpha levels ranging from 0.05 to 0.30, respectively, and approximately the 75th percentile CV level (Figure 3-19). All alpha levels < 0.25 achieved the RMD that a 25 percent mean effect is declared toxic at least 75 percent of the time.

At ~75th percentile CV (0.05) and a mean effect of 10 percent, use of the TST approach results in significantly fewer tests declared toxic relative to the traditional hypothesis approach at all alpha error rates (Figure 3-18). Those results are because the RMD for effluent acceptability (10 percent mean effect) is designed to be met ≥ 95 percent of the time.

Tests with a mean effect of 25 percent and above average precision (CV = 0.05) result in a similar rate of tests declared toxic (Figure 3-19) as the traditional hypothesis approach when the TST $\alpha = 0.05$. The results further support the selection of TST $\alpha = 0.05$ for this test endpoint.

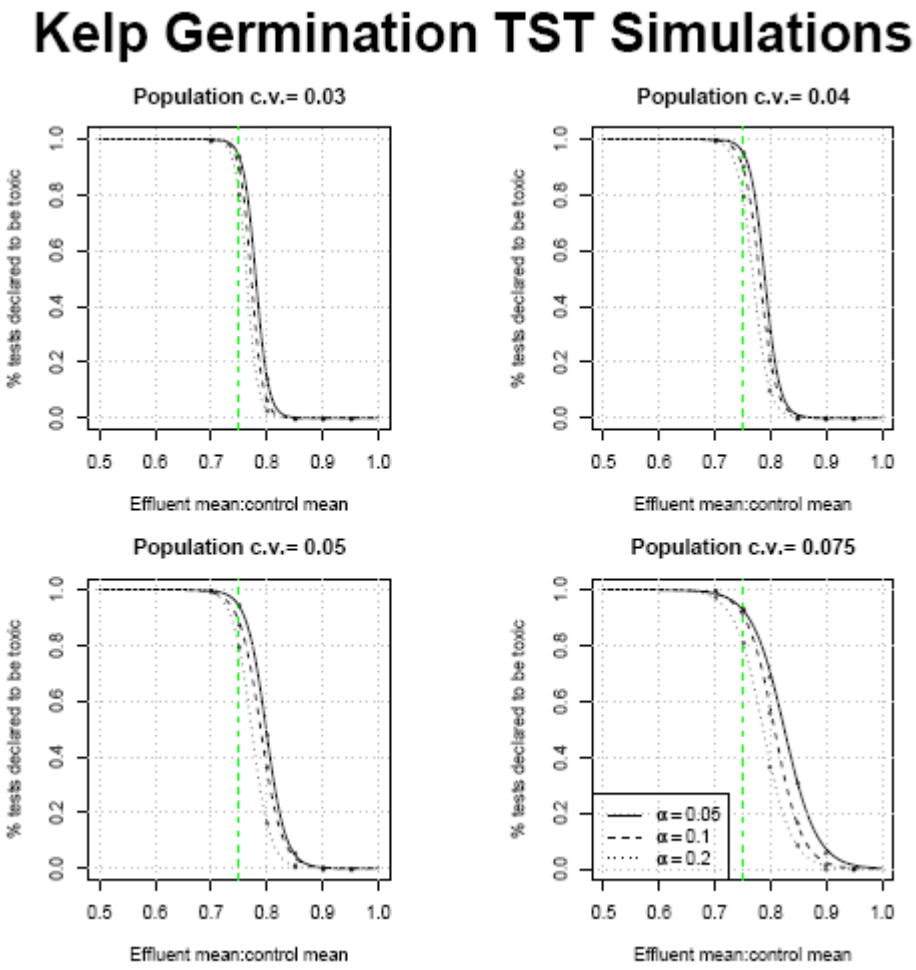

Figure 3-17. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 25th, 50th, 75th, and 95th percentiles for the chronic giant kelp germination WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

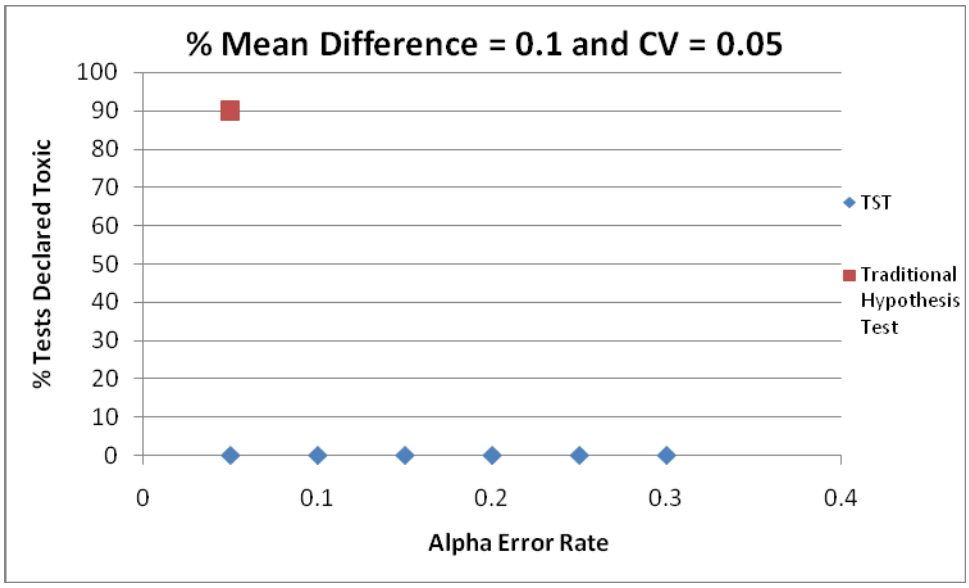

Figure 3-18. Percent of chronic giant kelp germination tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

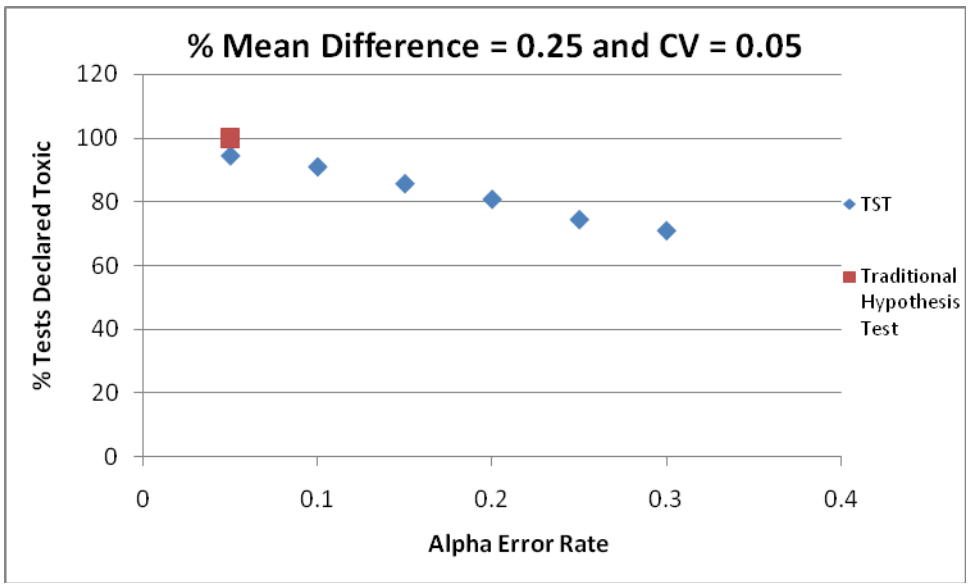

Figure 3-19. Percent of chronic giant kelp germination tests declared toxic using TST having a mean effluent effect of 25 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

3.6 Chronic *Macrocystis pyrifera* Germ-tube Length Test

On the basis of actual WET data (N = 135 reference toxicant tests), the mean control germ-tube length ranged from 10.200 to 20.778, with a median mean value of 14.014 (Table 3-9). Control CVs ranged from 0.009 to 0.189 with a median value of 0.073 (Table 3-9). Using that data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), CVs, and percent mean effect in germ-tube length between the control and effluent concentration.

Table 3-9. Summary of mean control germ-tube length and control CV derived from analyses of 135 chronic *Macrocystis pyrifera* WET tests

Percentile	Mean control germ-tube length	Control CV	Control SD
10th	11.965	0.03	0.46
25th	12.704	0.05	0.71
50th	14.014	0.07	1.04
70th	15.210	0.09	1.22
75th	15.554	0.09	1.29
85th	16.848	0.11	1.54
90th	17.568	0.12	1.74
95th	18.694	0.14	1.89

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-20), an alpha error rate of 0.05 is appropriate for use in applying the TST approach to analysis of chronic *M. pyrifera* tube-length data because using that alpha error rate satisfies both RMDs of (1) ensuring at least a 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time under average test performance. As noted for the germination endpoint of this species above, higher alpha levels would also satisfy these RMDs; however, in such cases, the lowest alpha $\geq$ 0.05 is selected.

At a 10 percent mean effect in the effluent for example and ~50th percentile CV of 0.07, alpha levels ranging from 0.05 to 0.30 resulted in failure to reject the null hypothesis in almost none of the tests (Figure 3-21). For tests with a mean effect of 25 percent, the rate of tests declared toxic ranged from ~95 to ~70 percent, at alpha error rates ranging from 0.05 to 0.30, respectively, and the 75th percentile CV value (Figure 3-22). Thus, alpha levels < 0.25 achieved the RMD that a 25 percent mean effect is declared toxic at least 75 percent of the time.

At ~50th percentile CV (0.07) and a mean effect of 10 percent, use of the TST approach results in significantly fewer tests declared toxic relative to the traditional hypothesis approach at all alpha error rates examined (Figure 3-21). These results are because of the RMDs of the TST approach; tests with a small (10 percent) mean effect of the effluent are declared non-toxic most of the time when test control data are average or better.

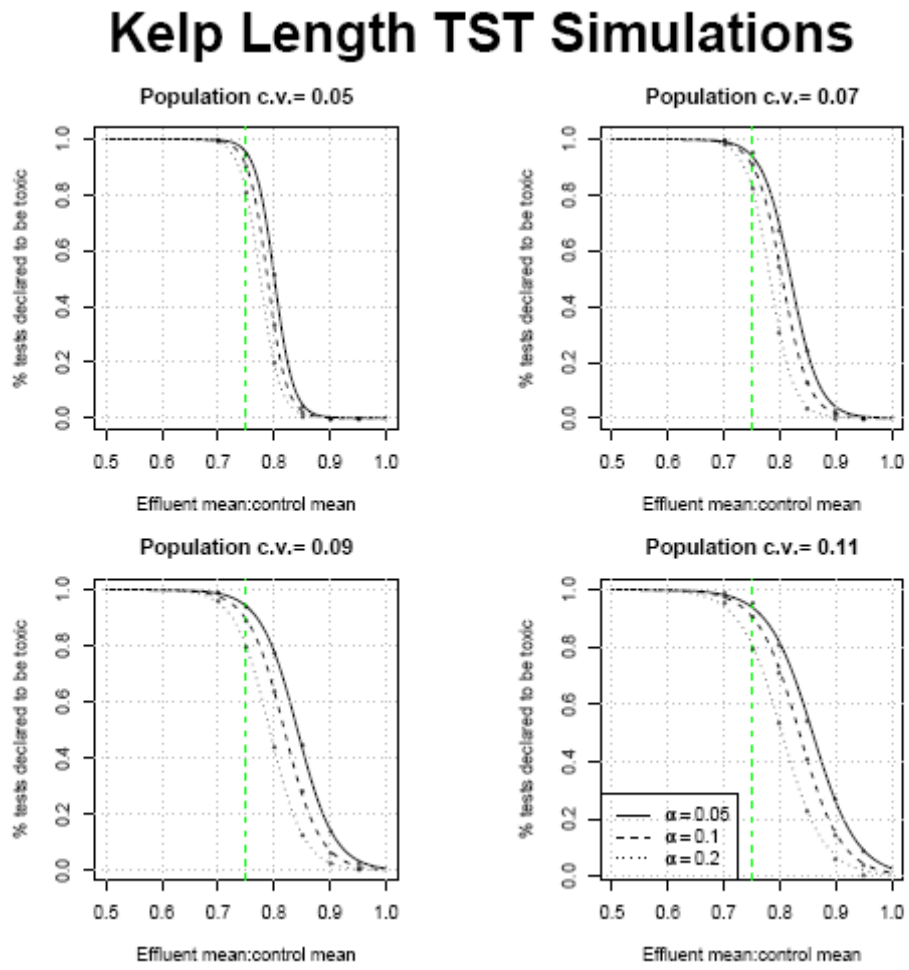

Figure 3-20. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 25th, 50th, 75th, and 90th percentiles for the chronic giant kelp germ-tube length WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

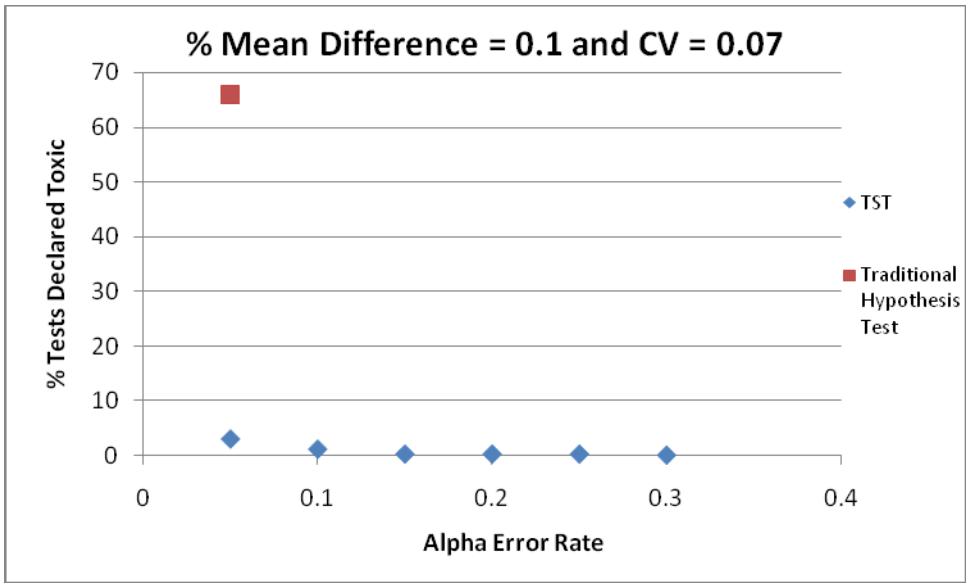

Figure 3-21. Percent of chronic giant kelp germ-tube length tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

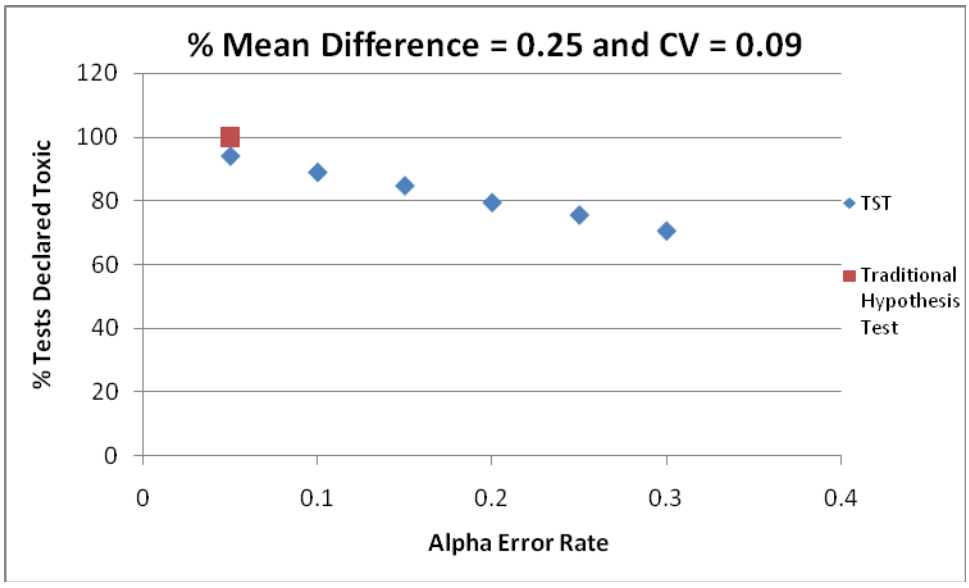

Figure 3-22. Percent of chronic giant kelp germ-tube length tests declared toxic using TST having a mean effluent effect of 25 percent and above average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Tests with a mean effect of 25 percent and above average precision (CV = 0.09) result in a similar rate of tests declared toxic as the traditional approach when alpha = 0.05 (Figure 3-22). These results further support the selection of 0.05 as the alpha value under TST for this WET endpoint.

3.7 Chronic Echinoderm Fertilization Test

On the basis of actual WET data (N = 177 tests), mean control fertilization ranged from 0.538 to 1.000, with a median mean value of 0.953 (Table 3-10). Control CVs ranged from 0.000 to 0.667 with a median value of approximately 0.03 (Table 3-10). Using that data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.3), CVs, and percent mean effect in reproduction between the control and effluent concentration of concern.

Table 3-10. Summary of mean control fertilization and control CV derived from analyses of 177 chronic *Dendraster excentricus and Strongylocentrotus purpuratus* WET tests

Percentile	Mean control fertilization	Control CV	Control SD
10th	0.826	0.01	0.58
25th	0.875	0.01	1.16
50th	0.953	0.03	2.45
70th	0.975	0.05	4.32
75th	0.978	0.07	5.97
85th	0.990	0.09	7.44
90th	0.993	0.11	9.32
95th	0.996	0.14	11.00

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-23), an alpha error rate of 0.05 is appropriate for use in applying the TST approach to analysis of chronic *D. excentricus* and *S. purpuratus* data because using this alpha error rate satisfies both RMDs of (1) ensuring at least an 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time under average test performance. As with the other West Coast chronic WET test methods, higher alpha values also satisfy the above RMDs. In these cases, the alpha value $\geq$ 0.05 that satisfies the RMDs is used.

At a 10 percent mean effect in the effluent for example, and ~50th percentile CV of 0.03, alpha levels ranging from 0.05 to 0.30 result in failure to reject the null hypothesis in none of the tests (Figure 3-24). For tests with a mean effect of 25 percent, the rate of tests declared toxic ranged from ~95 to ~70 percent, at alpha error rates ranging from 0.05 to 0.30, respectively, and approximately the 80th percentile CV value (Figure 3-25). Thus, alpha levels < 0.25 achieved the RMD that a 25 percent mean effect in the effluent is declared toxic at least 75 percent of the time regardless of within-test variability.

At ~50th percentile CV for this test endpoint (0.03) and a mean effect of 10 percent in the effluent, TST resulted in significantly fewer tests declared toxic relative to the traditional hypothesis approach at all alpha error rates (Figure 3-24). This results from the fact that the RMD is that tests with a negligible (10 percent) mean effect in the effluent are declared non-toxic most of the time when test control data are average or better.

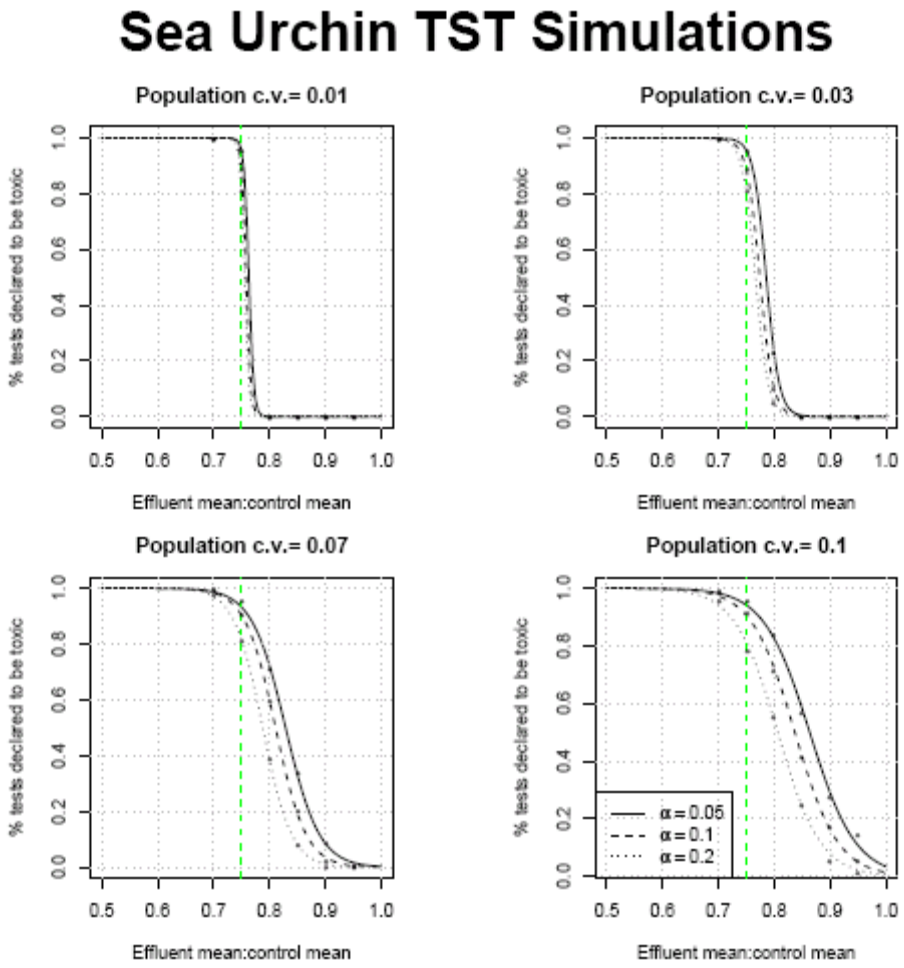

Figure 3-23. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 25th, 50th, 75th, and 90th percentiles for the chronic echinoderm fertilization WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

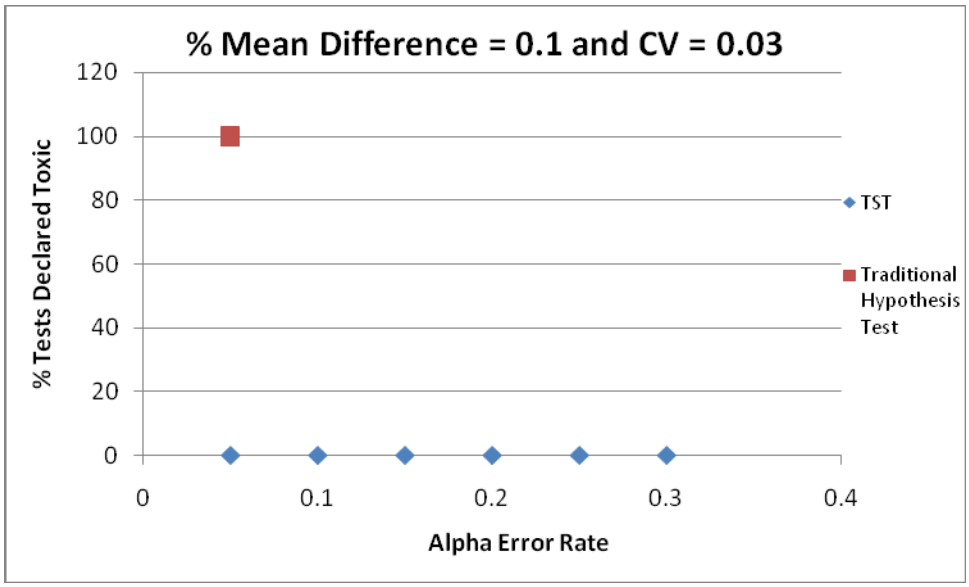

Figure 3-24. Percent of chronic echinoderm tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of the α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

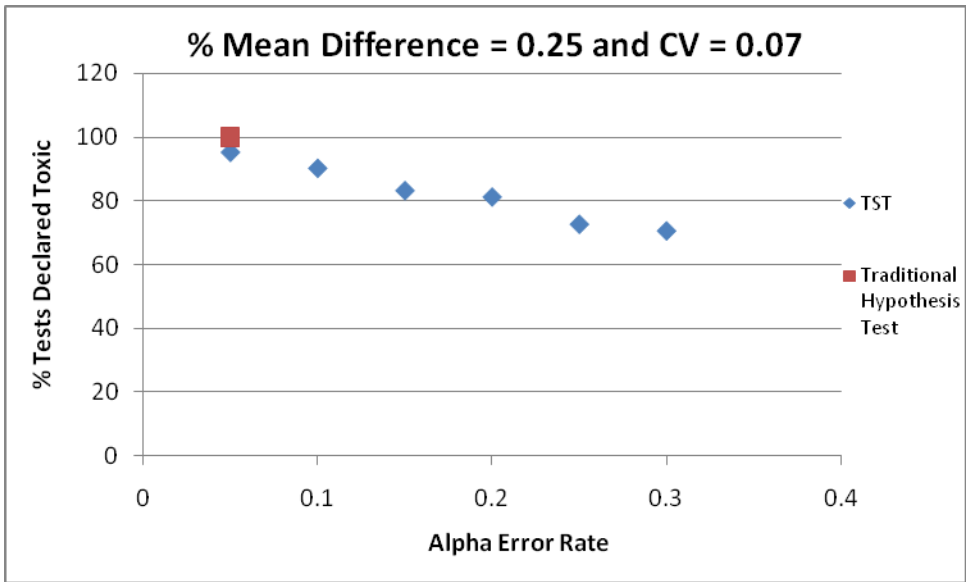

Figure 3-25. Percent of chronic echinoderm tests declared toxic using TST having a mean effluent effect of 25 percent and above average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Tests with a mean effect of 25 percent and above average precision (CV = 0.07) result in a similar rate of tests declared toxic as the traditional hypothesis approach when alpha = 0.05 (Figure 3-25). The results further support the selection of alpha = 0.05 for this WET test endpoint.

3.8 Acute *Pimephales promelas* Survival Test

As noted in the RMD discussion in Section 2.1, acute toxicity (i.e., mortality or immobility of organisms) needs to be tightly controlled because of the potential environmental implications of acute toxicity. Therefore, the RMD toxicity threshold for acute WET methods is set higher than that for the chronic WET methods, with the acute WET method *b* value = 0.80, rather than 0.75 as in the chronic methods. Consequently, the following analyses and results incorporated a *b* value of 0.80.

On the basis of actual WET data (N = 347 tests), mean control survival ranged from 0.900 to 1.000, with a median mean value of 1.000 (Table 3-11). Control CVs ranged from 0.000 to 0.185 with a median value of 0.00 (Table 3-11). The very low control variability observed is expected because of the strength and repeatability of the test endpoint (survival) and the fact that test acceptability criteria for acute WET methods require no less than 90 percent survival in controls. Using that data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.20), a range of CVs corresponding to between the 75th to the 90th percentiles, and percent mean effect in reproduction between the control and effluent concentration.

Table 3-11. Summary of mean control survival and control CV derived from analyses of 347 acute *Pimephales promelas* WET tests

Percentile	Mean control survival	Control CV	Control SD
10th	0.95	0.00	0.00
25th	1.00	0.00	0.00
50th	1.00	0.00	0.00
70th	1.00	0.00	0.00
75th	1.00	0.00	0.00
85th	1.00	0.09	0.15
90th	1.00	0.12	0.18
95th	1.00	0.19	0.23

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-26), an alpha error rate of 0.10 is appropriate for use in applying the TST approach to analysis of acute *P. promelas* data because using this alpha error rate satisfies both RMDs of (1) ensuring at least a 75 percent probability of declaring a 20 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time under average control performance.

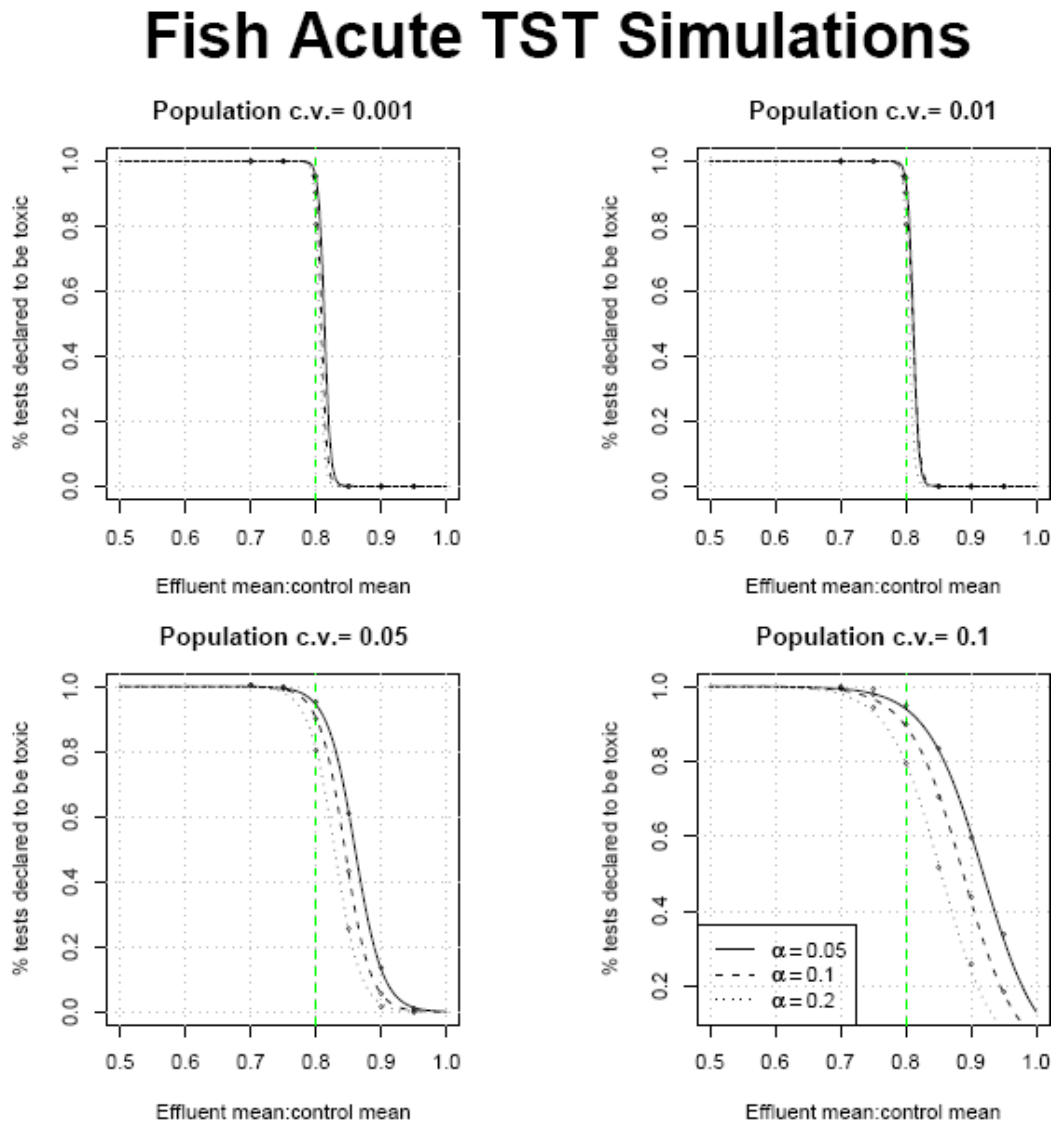

Figure 3-26. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 75th, 80th, 85th, and 88th percentiles for the acute fathead minnow WET method. The dashed line indicates the 80 percent mean effect level, which is the decision threshold for acute tests.

At a 10 percent mean effect in the effluent and a CV of 0.001 (slightly higher than the 75th percentile), alpha levels ranging from 0.05 to 0.20 resulted in failure to reject the null hypothesis in none of the tests (Figure 3-27). At the 88th percentile CV of 0.10 and a mean effect of 10 percent, alpha levels ranging from 0.05 to 0.20 resulted in declaring between 60 and 25 percent of the tests toxic, respectively. At more moderate CVs (85th percentile), an alpha of 0.10 results in 5 percent of the tests declared toxic. A lower alpha has a higher percentage of tests declared toxic.

For tests with a mean effect of 20 percent, the rate of tests declared toxic ranged from ~100 percent to ~80 percent, at alpha levels ranging from 0.05 to 0.20, respectively, and above average

CV values (Figure 3-28). The rates of tests declared toxic are consistent with the RMD that a 20 percent mean effect in the effluent is declared toxic at least 75 percent of the time. With more routine test performance, an alpha = 0.10 results in 95 percent of the tests declared toxic at a mean effect of 20 percent.

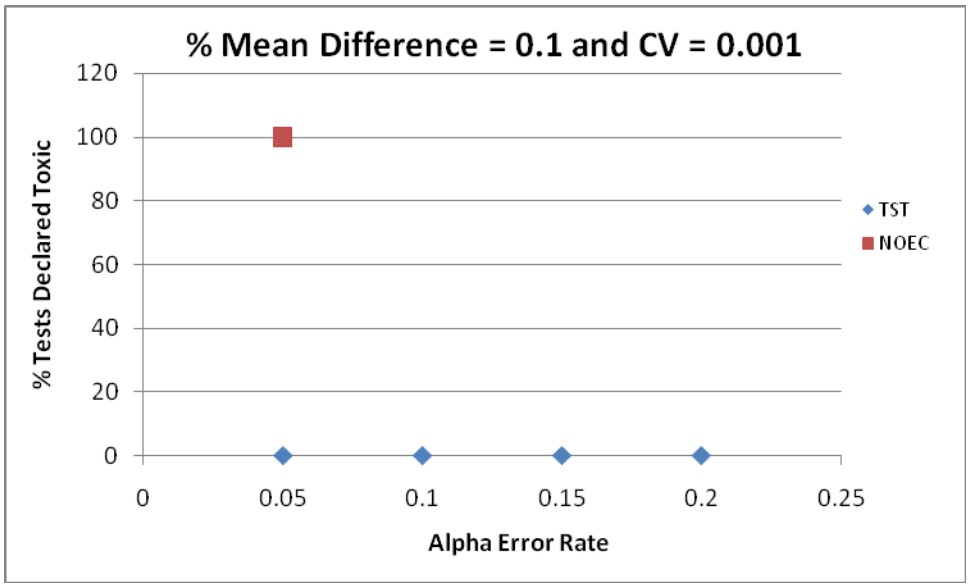

Figure 3-27. Percent of acute fathead minnow tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

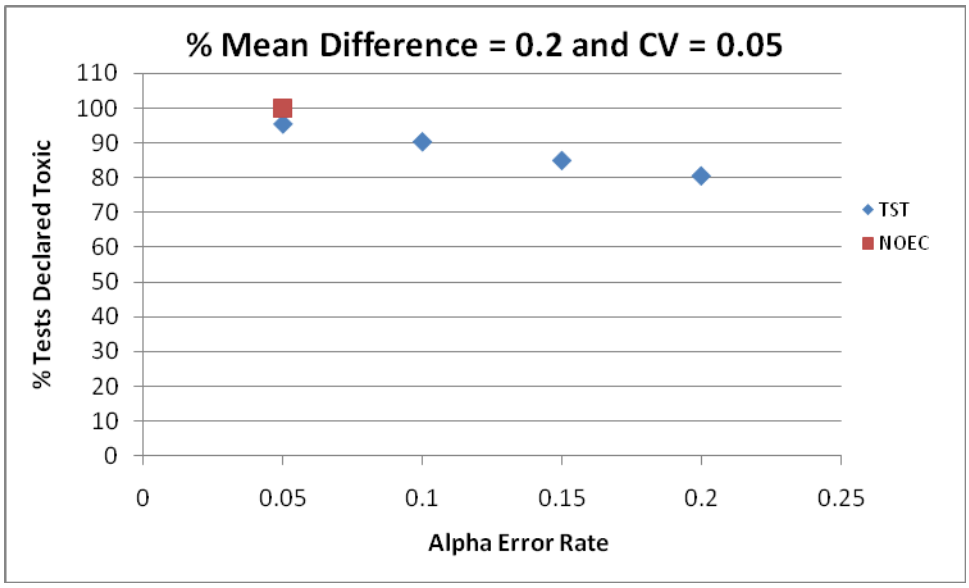

Figure 3-28. Percent of acute fathead minnow tests declared toxic using TST having a mean effluent effect of 20 percent and above average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

At a CV of 0.001 and a mean effect of 10 percent, use of the TST approach results in significantly fewer toxic tests relative to the traditional hypothesis approach at all alpha levels (Figure 3-27). These results are due to the RMD that tests with a 10 percent mean effect at the IWC are declared non-toxic most of the time.

Tests with a mean effect of 20 percent and a CV of 0.05 (85th percentile) result in a similar rate of tests declared toxic at alpha = 0.05 and 10 percent fewer tests declared toxic (90 percent of tests) at alpha = 0.10 (Figure 3-28). Because all the results noted above, an alpha = 0.10 is considered appropriately protective for this WET test method.

Effect of Increased Number of Within-Test Replicates

As expected, increasing test replication from two (the minimum allowed in the EPA WET test methods for acute fish tests) to four replicates results in a *higher* rate of tests declared toxic using the traditional hypothesis testing approach and a *lower* rate of tests declared toxic using the TST approach at a 10 percent effect using *P. promelas* acute test data. For tests with a mean effect of 10 percent and a control CV of 0.05 (corresponding to between the 75th and 90th percentile), if replicates are added to the test design, the TST approach demonstrates an increased ability to declare such a test as non-toxic (Table 3-12). As the mean effect approaches 20 percent, the percentage of tests declared toxic is less affected by increased replication using TST because a 20 percent effect in the effluent is the toxicity threshold using TST. However, the percentage of tests declared toxic continues to increase with increased replication using the traditional hypothesis approach, even when there is a negligible effect (10 percent effect as defined by TST) of the effluent. Thus, increasing test replication increases TST's ability to confirm an acceptable effluent test with mean effect less than 20 percent.

Table 3-12. Percent of fathead minnow acute tests declared toxic using TST and a *b* value = 0.8 as a function of percent mean effect, number of replicates (2 or 4 replicates), and different alpha or Type I error levels

				Alpha			
***B* value**	**CV**	**% effect**	**# reps**	**0.05**	**0.1**	**0.15**	**0.2**
0.8	0.05	0.10	2	57	33	21	13
0.8	0.05	0.20	2	95	91	85	80
0.8	0.05	0.10	4	14	5	3	1
0.8	0.05	0.20	4	95	90	85	80

3.9 Chronic *Selenastrum capricornutum* Growth Test

On the basis of actual WET data (N = 223 tests), the mean control growth ranged from 1,019,250 cells to 14,109,450 cells, with a median value of 3,331,250 cells (Table 3-13). Control CVs ranged from 0.00 to 0.20 with a median value of 0.06 (Table 3-13). Using those data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.25), CVs, and percent mean effect in growth between the control and effluent concentration. In addition, WET

test data (N = 173), in which EDTA was added to the controls, as required in the 2002 *Selenastrum* method, were evaluated independently and compared to the simulation results. For those tests the mean control growth ranged from 1,019,250 cells to 14,109,450 cells, with a median value of 3,430,000 cells (Table 3-13). Control CVs from those tests ranged from 0.00 to 0.20 with a median value of 0.06, similar to the results observed for all 223 tests (Table 3-13).

Table 3-13. Summary of mean control growth, CV and standard deviation derived from the analyses of all chronic *Selenastrum capricornutum* WET test data and compared with the analysis of only the chronic *Selenastrum capricornutum* WET test in which it was assumed that EDTA was added to the controls.

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-29), an alpha error rate of 0.25 is appropriate, for both tests with EDTA addition and tests with no EDTA addition, for use in applying the TST approach to analysis of chronic *Selenastrum* data. Using this alpha error rate addresses both RMDs of (1) ensuring at least a 75 percent probability of declaring a 25 percent mean effect as toxic and (2) ensuring that a negligible effect ($\leq$ 10 percent mean effect) is declared toxic $\leq$ 5 percent of the time under average or better than average test performance.

For example, at a 10 percent mean effect and a low level of precision (~70th percentile for all tests, CV of 0.10), an alpha level of 0.25 resulted in failure to reject the null hypothesis in $\leq$ 5 percent of tests with or without EDTA addition (Figure 3-29). For all tests with a mean effect of 25 percent, and a similar precision, the rate of tests declared toxic is 75 percent at an alpha value of 0.25, consistent with RMDs (Figure 3-29).

At ~70th percentile CV (0.10) and a mean effect of 10 percent, for both tests with and without EDTA addition, use of the TST approach results in fewer toxic tests relative to the traditional hypothesis testing approach at all alpha error rates, including the alpha error rate of 0.25 which declared less than 5 percent of the tests toxic (Figure 3-30).

Tests with a mean effect of 25 percent, regardless of precision (CV = 0.10 or 0.15), result in a 75 percent or greater rate of tests declared toxic, which is significantly more than that using the traditional hypothesis testing approach using any alpha value between 0.05 and 0.25 (Figure 3-31). The percent of tests found to be toxic using the TST approach with a mean effect of 25 percent was not significantly affected by the change in CV values.

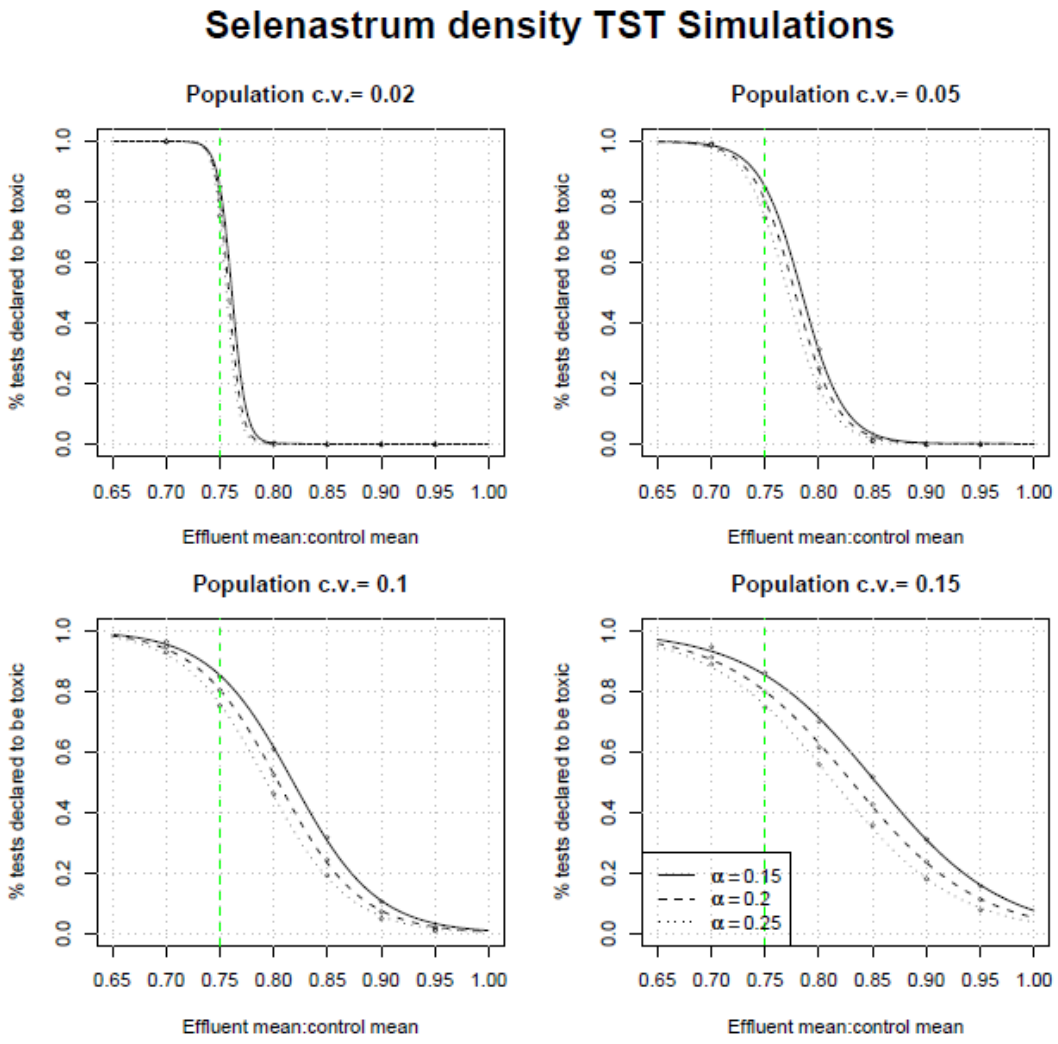

Figure 3-29. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. CVs correspond to the 10th, 40th, 70th, and 85th percentiles for the chronic *Selenastrum* WET method. The dashed line indicates the 75 percent mean effect level, which is the decision threshold for chronic tests.

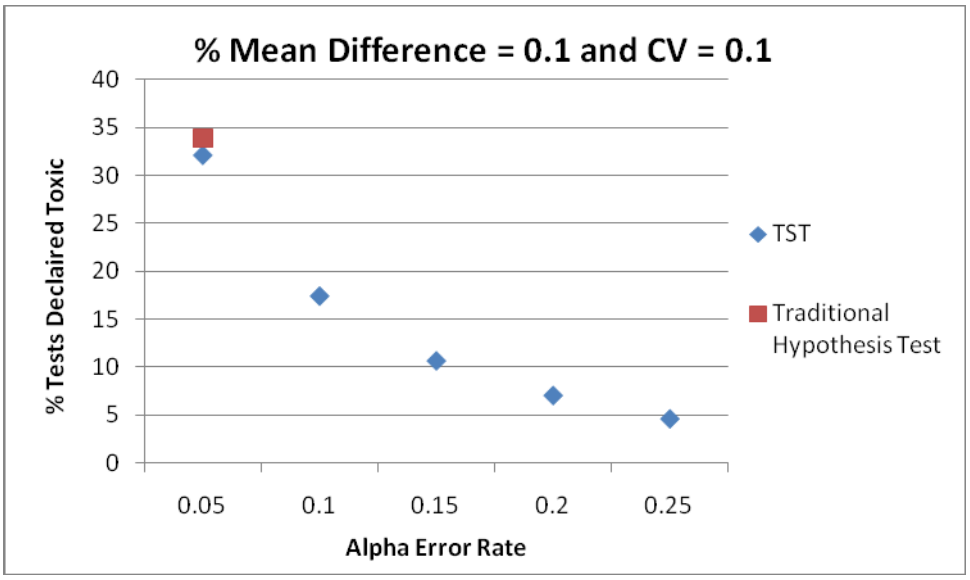

Figure 3-30. Percent of *Selenastrum* tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

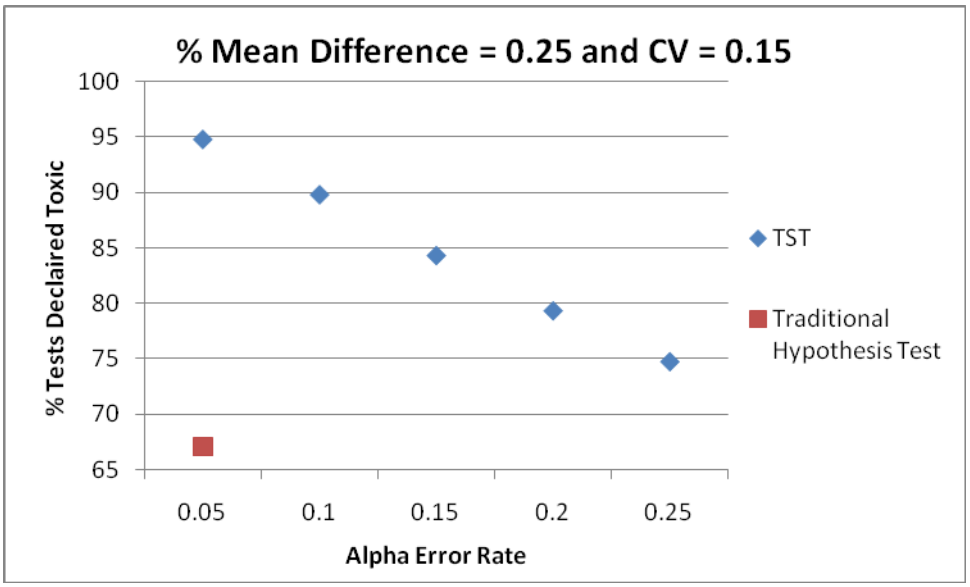

Figure 3-31. Percent of *Selenastrum* tests declared toxic using TST having a mean effluent effect of 25 percent and above average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Effluent Data Results

Results from actual effluent tests were compared between TST and the traditional hypothesis testing approach for all control CV's (Table 3-14). At a mean effect of 10–15 percent (N = 25),

TST declared none of the tests toxic while the traditional hypothesis testing approach declared 67 percent of the tests toxic. However, if the mean effect is greater than 25 percent (N = 97), TST declared 100 percent of the tests toxic, while the traditional hypothesis testing approach declared 98 percent of the tests toxic. These results indicate that TST is as protective as the current hypothesis testing approach for those tests when the TST RMD threshold for toxicity is exceeded.

Table 3-14. Comparison of the percentage of chronic *Selenastrum* tests declared toxic using TST versus the traditional hypothesis testing approach

% Mean effect	N	% tests toxic using TST	% tests toxic using traditional hypothesis testing approach
10–15	25	0	67
> 25	97	100	98

3.10 Acute *Ceriodaphnia dubia* Survival Test

Acute toxicity (i.e., mortality or immobility of organisms) needs to be tightly controlled because of the potential environmental implications of acute toxicity. Therefore, the RMD toxicity threshold for acute WET methods is set higher than that for the chronic WET methods, with the acute WET method *b* value = 0.80, rather than 0.75 as in the chronic methods. Consequently, the following analyses and results incorporated a *b* value of 0.80.

On the basis of actual WET data (N = 239 tests), mean control survival ranged from 0.900 to 1.000, with a median mean value of 1.000 (Table 3-15). Control CVs ranged from 0.00 to 0.22 (the minimum and maximum levels obtainable using the test acceptability criteria) with a median value of 0.00 (Table 3-15). The very low control variability observed is expected because of the strength and repeatability of the test endpoint (survival) and the fact that test acceptability criteria for acute WET methods stipulate no less than 90 percent survival in the controls. Using that data, simulation analyses were conducted to evaluate the percentages of tests declared toxic (i.e., failure to reject the null hypothesis) by TST at various alpha error rates (between 0.05 and 0.30), a range of CVs, and percent mean effect in survival between the control and effluent concentration.

Table 3-15. Summary of mean control growth, CV and standard deviation derived from analyses of 239 acute *Ceriodaphnia dubia* WET tests.

Percentile	Mean Survival (%)	Control CV	Control SD
10th	0.95	0.00	0.00
25th	1.00	0.00	0.00
50th	1.00	0.00	0.00
70th	1.00	0.00	0.00
75th	1.00	0.00	0.00
85th	1.00	0.00	0.00
90th	1.00	0.11	0.10
95th	1.00	0.11	0.10

Identifying Test Method-Specific α

On the basis of all simulation results (Figure 3-32), an alpha error rate of 0.10 is appropriate for use in applying the TST approach to analysis of acute *Ceriodaphnia dubia* data because using this alpha error rate best satisfies both RMDs of (1) ensuring at least a 75 percent probability of declaring a 20 percent mean effect as toxic and (2) ensuring that a negligible effect (≤ 10 percent mean effect) is declared toxic ≤ 5 percent of the time under average control performance.

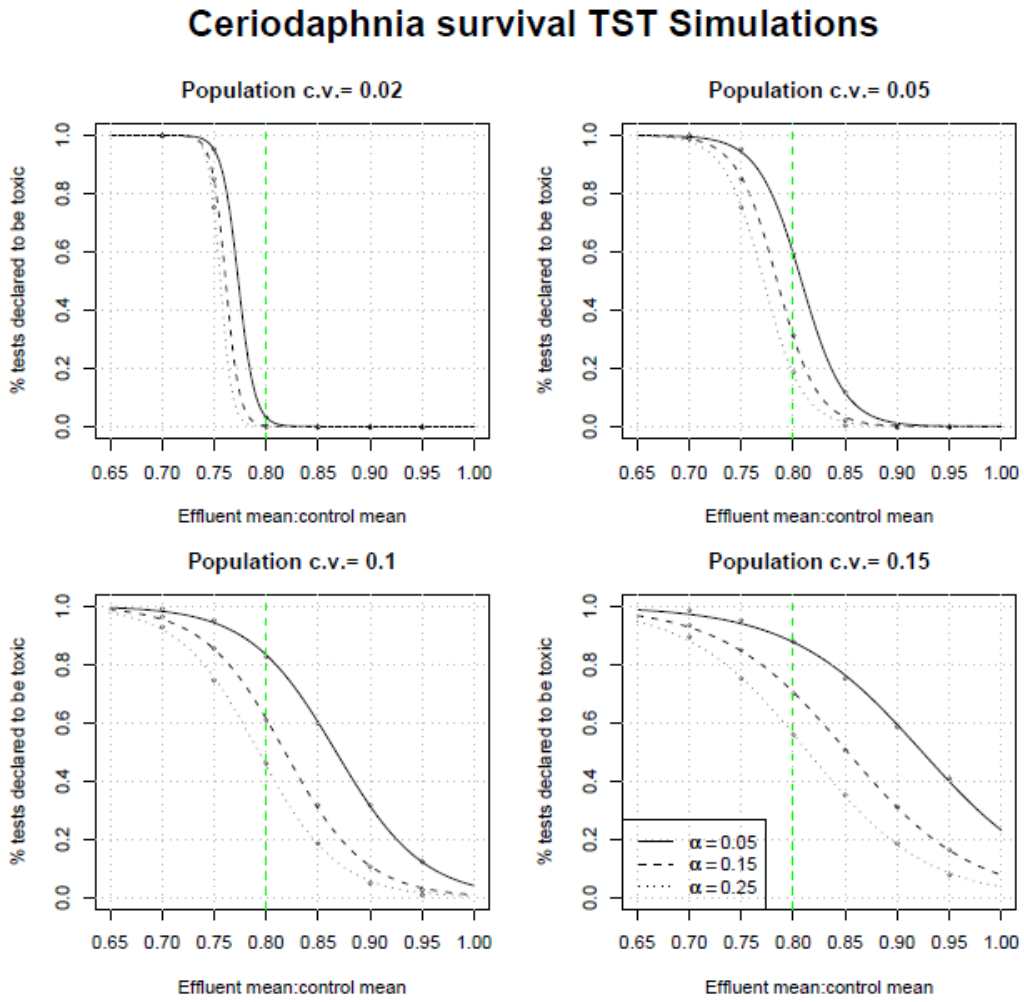

Figure 3-32. Power curves showing the percentage of tests declared toxic as a function of the ratio of effluent mean to control mean response and α level categorized by the level of control within-test variability. The first two CVs correspond to the 85th percentile, and the following two correspond to the 95th and ~98th, respectively for the acute *Ceriodaphnia dubia* WET method. The dashed line indicates the 80 percent mean effect level, which is the decision threshold for acute tests.

For example, at a 10 percent mean effect in the effluent and a CV of 0.02 (slightly higher than the 85th percentile), alpha levels ranging from 0.05 to 0.25 resulted in failure to reject the null hypothesis in ≤ 5 percent of the tests (Figure 3-32). However, at the 90th and 95th percentile CVs of 0.10 and a mean effect of 10 percent, the alpha level of 0.25 resulted in 19 percent of the tests

found toxic. For tests with a mean effect of 20 percent, and ~85th percentile precision (CV of 0.02), 75 percent of the tests are declared toxic, achieving the RMD using an alpha value of 0.25 (Figure 3-32).

For tests with a mean effect of 20 percent, the rate of tests declared toxic ranged from ~95 percent to ~75 percent, at alpha levels ranging from 0.05 to 0.25, respectively, using all CV values that correspond to $\leq$ 95th percentile. (Figure 3-32). The rates of tests declared toxic are consistent with the RMD that a 20 percent mean effect in the effluent is declared toxic at least 75 percent of the time. With more routine test performance, an alpha of 0.10 results in 90 percent of the tests declared toxic at a mean effect of 20 percent.

At a CV of 0.02 (~85th percentile) and a mean effect of 10 percent, use of the TST approach results in no toxic tests, while the traditional hypothesis approach results in 100 percent toxic tests at all alpha levels (Figure 3-33).

Tests with a mean effect of 20 percent and a range of within-test control precision values (CV of 0.02 to 0.15) result in at least 75 percent of the tests declared toxic using an alpha = 0.10 (Figure 3-34). In contrast fewer tests are declared toxic at a 20% effect when using the traditional hypothesis testing approach and any alpha value between 0.05 and 0.25 (Figure 3-34). Thus, the percent of tests found to be toxic using the TST approach with a mean effect of 20 percent was not significantly affected by the change in CV values.

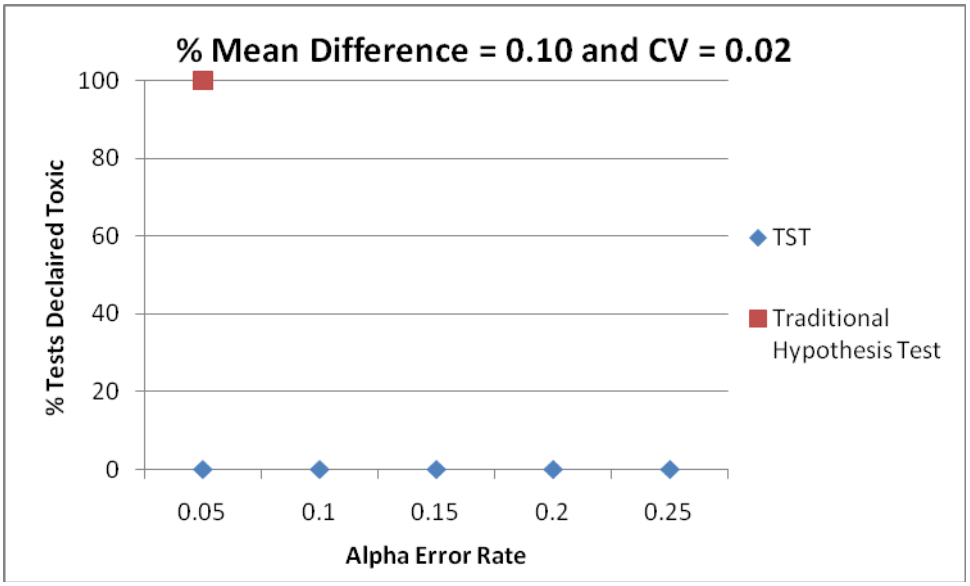

Figure 3-33. Percent of acute *C. dubia* tests declared toxic using TST having a mean effluent effect of 10 percent and average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

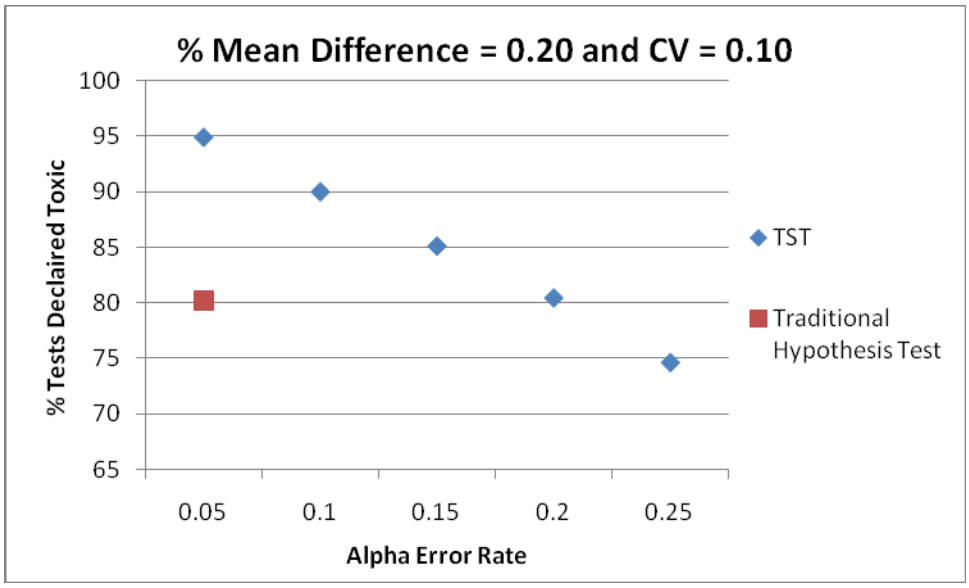

Figure 3-34. Percent of acute *C. dubia* tests declared toxic using TST having a mean effluent effect of 20 percent and above average control variability as a function of α error rate. Result using the traditional hypothesis approach (α = 0.05) is shown as well.

Effect of Increased Number of Within-Test Replicates

As with the fathead minnow acute method, increasing test replication from four (the minimum allowed in the EPA WET test methods for acute *Ceriodaphnia dubia* tests) to six replicates results in a *higher* rate of tests declared toxic using the traditional hypothesis testing approach and a *lower* rate of tests declared toxic using the TST approach at a 10 percent mean effect using *C. dubia* acute test data. For tests with a mean effect of 10 percent and a control CV of 0.06 (corresponding to between the 85th and 90th percentile), if replicates are added to the test design, the TST approach demonstrates an increased ability to declare such a test as non-toxic (Table 3-16). As the mean effect approaches 20 percent, the percentage of tests declared toxic is less affected by increased replication using TST because a 20 percent effect in the effluent is the RMD using TST. However, the percentage of tests declared toxic continues to increase with increased replication using the traditional hypothesis approach, even when there is a negligible effect (10 percent effect as defined by TST) of the effluent. Thus, increasing test replication increases TST's ability to confirm an acceptable effluent test with mean effect less than 20 percent.

Table 3-16. Percent of *Ceriodaphnia dubia* acute tests declared toxic using TST and a *b* value = 0.8 as a function of percent mean effect, number of replicates (4 or 6 replicates), and different alpha or Type I error levels

B value	CV	% effect	# reps	Alpha			
				0.05	0.1	0.15	0.2
0.8	0.06	0.10	4	23	12	7	5
0.8	0.06	0.20	4	95	90	85	80
0.8	0.06	0.10	6	8	4	3	2
0.8	0.06	0.20	6	95	90	85	80

4.0 SUMMARY OF RESULTS AND IMPLEMENTING TST

4.1 Summary of Test Method-Specific Alpha Values

On the basis of all the analyses conducted in this project, the test method-specific alpha levels summarized in Table 4-1 are used with the TST approach. The method-specific alpha values apply to all test endpoints for a given EPA WET test method (e.g., survival and reproduction for the *Ceriodaphnia* chronic WET test method). As noted in Section 2.3.1, alpha values were selected on the basis of simulation analyses using normally distributed data and equal variances in the control and the effluent. While additional analyses indicate that the alpha levels identified are robust to the type of heterogeneous variances and non-normal data observed in WET test data (see Appendix A), this issue is still acknowledged as a potential uncertainty.

The alpha values identified above provide as much protection under most circumstances as the current approved WET test analysis methods when the mean effect at the IWC exceeds the toxicity threshold of the TST approach.

At the chronic toxicity regulatory management threshold of 25 percent mean effect of the effluent and lower within-test control CVs ($< 50^{th}$ percentile), TST declares a greater percentage of tests non-toxic than the traditional hypothesis approach for some of the chronic WET test methods examined (e.g., fathead minnow chronic WET test) because of the higher alpha levels assigned to those test methods. At either higher within-test CVs or higher mean effect levels, results are more similar between the two approaches, as explained in Section 1.4 of this document. With more extreme within-test variability ($\geq 80^{th}$ percentile CV), results tend to be reversed with TST declaring a higher percentage of tests toxic at 25 percent mean effect of the effluent as compared to the traditional hypothesis approach; e.g., for the *Ceriodaphnia* reproduction endpoint, at the 80^{th} percentile CV, TST declares ~20 percent of the tests non-toxic at a 25 percent mean effect, while the traditional approach declares 24 percent of the tests non-toxic. If test data are non-normal (a somewhat frequent condition for some WET endpoints such as acute and chronic survival, or when a high level of toxicity is observed in certain effluent concentrations within a test), additional research has indicated that use of Welch's t-test results in a lower rejection rate (i.e., is more conservative) using the TST approach, resulting in a higher percentage of tests declared toxic when the effluent effect $\geq b \times$ control mean (Appendix A). For the acute fathead minnow test method, at the acute toxicity regulatory management threshold of 20 percent mean effect of the effluent, both approaches had a similarly low percentage of tests declared non-toxic over all within-test CVs. Results of this comparison also demonstrate that for all WET test methods, the TST approach declares a lower percentage of tests as toxic at a 10 percent mean effect in the effluent, for most WET tests (i.e., within-test CV $\leq 75^{th}$ percentile for a given WET test method). If within-test variability is lower (control data has greater precision), the result is further accentuated; i.e., an even greater percentage of tests are declared toxic at a 10 percent effect using the traditional hypothesis approach and an even lower percentage of tests declared toxic using TST.

Table 4-1. Summary of alpha (α) levels or false negative rates recommended for different EPA WET test methods using the TST.

EPA WET test method	*b* value	Probability of declaring a toxic effluent non-toxic: False negative (α) error[a]
Chronic Freshwater and East Coast Methods		
Ceriodaphnia dubia (water flea) survival and reproduction	0.75	0.20
Pimephales promelas (fathead minnow) survival and growth	0.75	0.25
Selenastrum capricornutum (green algae) growth	0.75	0.25
Americamysis bahia (mysid shrimp) survival and growth	0.75	0.15
Arbacia punctulata (Echinoderm) fertilization	0.75	0.05
Cyprinodon variegatus (Sheepshead minnow) and *Menidia beryllina* (inland silverside) survival and growth	0.75	0.25
Chronic West Coast Marine Methods		
Dendraster excentricus and *Strongylocentrotus purpuratus* (Echinoderm) fertilization	0.75	0.05
Atherinops affinis (topsmelt) survival and growth	0.75	0.25
Haliotis rufescens (red abalone), *Crassostrea gigas (oyster), Dendraster excentricus, Strongylocentrotus purpuratus* (Echinoderm) and *Mytilus sp* (mussel) larval development methods	0.75	0.05
Macrocystis pyrifera (giant kelp) germination and germ-tube length	0.75	0.05
Acute Methods		
Pimephales promelas (fathead minnow), *Cyprinodon variegatus* (Sheepshead minnow), *Atherinops affinis* (topsmelt), *Menidia beryllina* (inland silverside) acute survival[b]	0.80	0.10
Ceriodaphnia dubia, *Daphnia magna, Daphnia pulex*, *Americamysis bahia* acute survival[b]	0.80	0.10

Notes:
a α levels shown are the probability of declaring an effluent toxic when the mean effluent effect = 25% for chronic tests or 20% for acute tests and the false positive rate (β) is ≤ 0.05 (5%) when mean effluent effect = 10%.
b. Based on a four replicate test design

4.2 Calculating Statistics for Valid WET Data Using the TST Approach

Appendix B includes a step-by-step guide for using the TST approach to analyze valid WET data. The appendix also includes a statistical flowchart. Note that the WET test method should follow the test condition requirements as specified in EPA's approved WET methods (USEPA 1995, 2002a, 2002b, 2002c).

The TST approach is used to statistically compare organism responses from two treatments of the WET test, the IWC and the control. Percent data (quantal data), such as percent survival or percent germination from a WET test, is first transformed as recommended in the EPA WET test manuals. Other types of WET data (e.g., growth or reproduction data) are not transformed (for

the rationale, see Appendix A). Data are then analyzed using Welch's t-test, a well-known modification of the traditional t-test (Zar 1996), which is appropriate for the TST approach (see Appendix A).

Appendix C lists the critical t values that apply to WET testing using the TST approach given the number of degrees of freedom and the α level that applies for a given WET test method from Table 4-1 of this document. If the calculated t value for the WET test is greater than the critical t value (given in Appendix C), the null hypothesis is rejected, i.e., the test result is a *pass* and **the effluent is declared *non-toxic***. If the calculated t value is less than the critical t value in Appendix C, the null hypothesis is not rejected, i.e., the test result is a *fail* and **the effluent *is* declared toxic**.

4.3 Benefits of Increased Replication Using TST

One of the intended benefits of the TST approach is that increasing the precision and power of the test increases the chances of rejecting the null hypothesis and declaring a truly acceptable sample as non-toxic. This increases the permittee's ability to demonstrate that a sample is acceptable. Results for the *Ceriodaphnia*, fathead minnow, and mysid chronic test methods presented in Section 3 indicate the benefits of increased replication within a test, especially when the mean effect of the sample is below about 20 percent in the case of chronic tests and about 15 percent for acute tests. As expected, increasing test replication (and thereby the power of the test) results in a *higher* rate of tests declared toxic using the traditional hypothesis testing approach but a *lower* rate of tests declared toxic using the TST approach.

Conducting tests with more replicates can help a permittee demonstrate that the effluent is acceptable if the mean effect at the IWC is truly less than the RMDs as defined by TST (25 percent effect for chronic and 20 percent for acute). Conversely, increasing replicates does not assist a permittee using the traditional hypothesis testing approach.

4.4 Applying TST to Ambient Toxicity Programs

In ambient and stormwater toxicity testing, a laboratory control and a single concentration (i.e., 100 percent ambient water or stormwater) are often tested. In those two-concentration WET tests, the objective is to determine if a sample or site water is toxic, as indicated by a significantly worse organism response compared to the control. In this WET testing design, the determination of pass or fail (i.e., toxic or non-toxic) is ascertained using a traditional t-test (USEPA 2002c). EPA WET test methods recommend that the statistical significance (i.e., pass/fail) of a two-sample test design for ambient and stormwater toxicity testing be determined by using only a modified t-test (if homogeneity of variance is not achieved) or a traditional t-test (if homogeneity of variance is achieved).

To demonstrate the value of the TST approach in ambient toxicity programs, ambient toxicity test data from California's SWAMP was used for 409 chronic tests for *Ceriodaphnia dubia* and 256 chronic tests for *Pimephales promelas* using EPA's 2002 WET test methods (USEPA 2002a). WET test data for each WET test method were subjected to the same statistical analyses as described in Section 2 of this document.

Chronic *Ceriodaphnia dubia* Ambient Toxicity Tests

Table 4-2 summarizes results from the 409 *Ceriodaphnia dubia* ambient toxicity tests analyzed and a $\alpha = 0.20$ for this test method. Although the majority of the tests examined resulted in the same decision using either the TST or the traditional t-test approach, approximately 6 percent of the tests (24 tests) would have been declared non-toxic using the traditional t-test approach with mean effect levels > 25 percent. In addition, 2 percent of the tests (7 tests) would have been declared toxic at mean effect levels < 15 percent and as low as 7 percent.

Table 4-2. Comparison of results of chronic *Ceriodaphnia* ambient toxicity tests using the TST approach and the traditional t-test analysis. $\alpha = 0.2$ and *b* value = 0.75 for the TST approach. $\alpha = 0.05$ for the traditional hypothesis testing approach

Both approaches declare toxic	Only TST declares toxic	Only traditional approach declares toxic	Both approaches declare non-toxic
19.8%	5.9%	1.7%	72.6%

Figure 4-1 shows ranges of CV values observed in *Ceriodaphnia dubia* ambient toxicity tests for those samples declared toxic using either the TST approach or the traditional t-test but not both approaches. As expected, within-test variability was relatively high (higher CVs) for those tests found non-toxic using a t-test but toxic using the TST approach. The results again demonstrate a limitation of the traditional hypothesis testing approach when control variability is relatively high. Under those conditions, the t-test did not have the power to detect toxicity when it was present. Figure 4-1 also demonstrates that the TST approach is superior to the traditional t-test when within-test variability is relatively low and the mean percent effect is well below the risk management level of 25 percent. Under such conditions, the traditional t-test declared some samples toxic using this WET test method, even when the mean effect was as little as 7 percent. The TST approach, however, declared all such samples non-toxic using the recommended $\alpha = 0.20$. Thus, the TST approach reduces the number of tests classified as toxic when effects are actually well below risk management levels of concern.

Similar to the *Ceriodaphnia* ambient test data, within-test variability was higher in those chronic fathead minnow ambient tests found non-toxic using a t-test but toxic using the TST approach (Figure 4-2). Similarly, those tests declared non-toxic by the TST approach but toxic using t-test had lower within-test variability and mean effect levels < 25 percent (Figure 4-2). Thus, as with the chronic *Ceriodaphnia* ambient tests, data from chronic fathead minnow ambient tests demonstrate that the TST approach provides better protection than the traditional t-test approach while also identifying those samples that are truly acceptable from a regulatory management perspective.

4.5 Implementing TST in WET Permitting under NPDES

The TST approach is an alternative statistical approach for analyzing and interpreting valid WET data; it is not an alternative approach to developing NPDES permit WET limitations. Using the TST approach does not result in any changes to EPA's WET test methods.

Chronic *Ceriodaphnia* ambient WET tests that are identified as non-toxic (pass) using the traditional hypothesis approach (t-test) generally have poor test sensitivity (high control CVs), masking effects, as compared to using the TST approach.

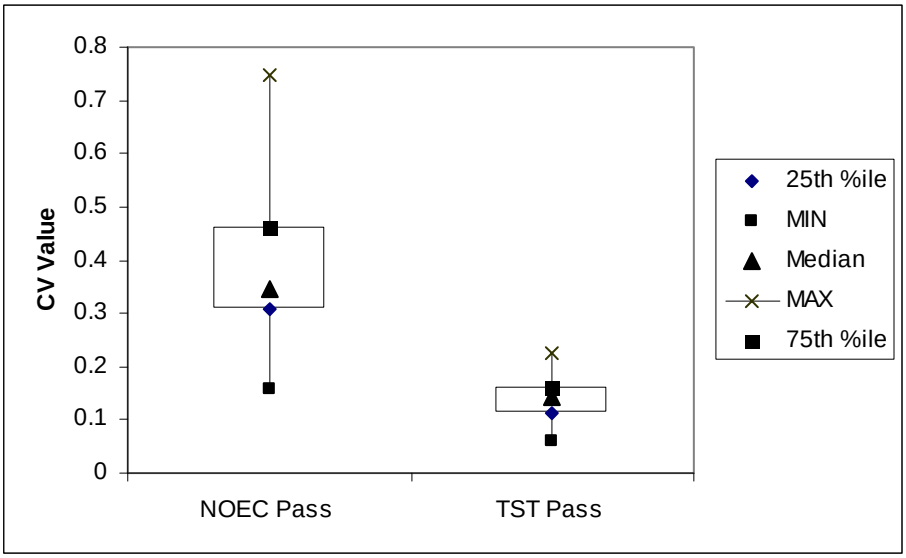

Figure 4-1. Range of CV values observed in chronic *C. dubia* ambient toxicity tests for samples that were found to be non-toxic using the traditional t-test but toxic using the TST approach (*NOEC Pass*) and for those samples declared toxic using t-test but not the TST approach (*TST Pass*). California's SWAMP WET test data.

Fish ambient WET tests that are identified as non-toxic using the traditional hypothesis approach (t-test) generally have poor test sensitivity (high control CVs), masking effects, as compared to using the TST approach.

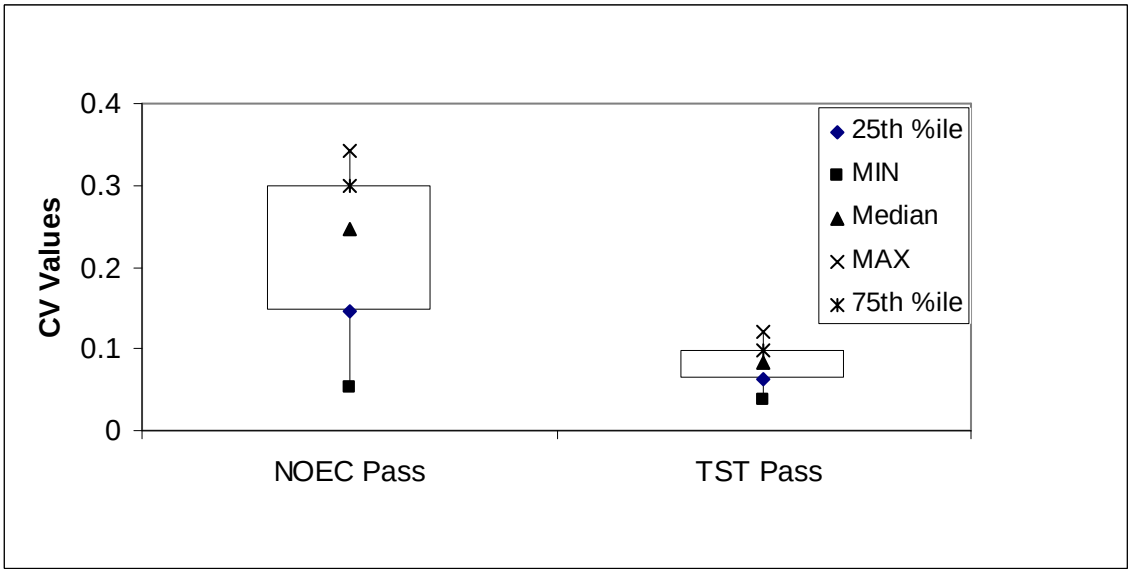

Figure 4-2. Range of CV values observed in chronic *P. promelas* ambient toxicity tests for samples that were declared to be non-toxic using the traditional t-test but toxic using the TST approach (*NOEC Pass*) and for those samples declared toxic using t-test but not the TST approach (*TST Pass*). California's SWAMP WET test data.

4.6 Reasonable Potential (RP) WET Analysis

NPDES permitting authorities conducting an RP analysis must follow 40 CFR 122.44(d)(1) to determine whether a discharge will, "cause, have the reasonable potential to cause, or contribute to" an excursion of a numeric criterion or a narrative WET criterion. Some states have state-specific WET RP approaches in their water quality control plan or other NPDES policy or guidance.

For RP calculations using the TST approach, EPA recommends that permitting authorities use all valid WET test data generated during the current permit term and any additional valid data that are submitted as part of the permit renewal application. The TST RP approach necessitates having at least a minimum of four valid WET tests to address effluent representativeness (see EPA's TSD, Chapter 3, pg. 57, under Step 2 in the section *Steps in Whole Effluent Characterization Process*). EPA also recommends that states request that their permittees provide the actual test endpoint responses for the control (i.e., control mean) and IWC concentration (i.e., IWC mean) for each WET test conducted to make it easier for permit writers to find the necessary WET test results when determining WET RP. WET test data are then analyzed according to the TST approach using the IWC and control test concentrations for all the valid WET test data available. If fewer than four valid WET test data points are available, permitting authorities should follow EPA's TSD RP approach because it addresses small WET data sets by incorporating an RP multiplying factor (see section 3.3.2 of the TSD, pg. 54) to account for effluent variability in small WET data sets. If sufficient, valid WET test data are available and the TST statistical approach indicates that the IWC is toxic in any WET test, RP has been demonstrated (40 CFR 122.44(d)(1)(i)). To address concerns regarding the "potential to cause or contribute to toxicity," an analysis of the mean effect at the IWC is also conducted to determine whether the effluent has RP, even if all test results are declared a *pass* using the TST approach (for more details, see EPA's *TST Implementation Document* EPA 833-R-10-003).

Note that using the TST approach might be to the permittee's advantage. If the permittee decides to incorporate additional test replicates for the control and the IWC when conducting the WET test, above the minimum required in the EPA WET test methods, the test power is increased. More test replicates increases test power, which means a lower probability of a false positive using the TST approach *if the effluent is truly non-toxic based on the RMDs in the TST approach*. Thus, using the TST approach, a permittee has a greater ability to *prove the negative* (i.e., its effluent does not have RP).

In those cases where the WET RP outcome is *yes*, a WET limit is expressed in the permit. In situations where the RP outcome is *no*, WET monitoring requirements should still be incorporated in the permit. A *fail* test result during monitoring could trigger additional steps if described in the permit. In either of those situations, if toxicity is demonstrated, states should specify an approach to address toxicity in the permit. This often includes initially accelerated toxicity tests (i.e., increased frequency of testing) and permit requirements to perform a toxicity reduction evaluation.

4.7 NPDES WET Permit Limits

Using the TST approach, WET NPDES permit limits would be expressed as *no significant toxicity of the effluent at the IWC using the TST analysis approach*. A test result of *Pass* is when

the calculated *t* value is greater than *the critical t value*. A test result of *Fail* is when the calculated *t* value is less than *the critical t value*.

Beyond assessing WET data for the NPDES Program, WET tests are used to assess toxicity of receiving water (watershed assessment for CWA section 303(d) determinations) and stormwater samples. Often as a first assessment of receiving or stormwater toxicity, researchers test a control and a single concentration (e.g., 100 percent receiving water or stormwater). In such cases, the TST approach can be used in the same way a t-test is used. Such analysis is used to determine whether organism response in a specified ambient concentration is significantly different than the control organism response.

5.0 CONCLUSIONS

Results of this project indicate that the TST is a viable additional option for analyzing valid acute and chronic WET test data. Given the RMDs and test-method specific alpha values specified in the TST approach, TST provides a transparent methodology for demonstrating whether an effluent truly is acceptable under the NPDES WET Program. The advantage of the TST approach is that it provides a structure in which it is easier to express, understand, and implement regulatory management goals. The alpha values identified in this project build on existing statistical information (such as data sources and analysis examining ability to detect toxic effects) on WET previously published by EPA, including *Understanding and Accounting for Method Variability in WET Applications Under the NPDES Program* (USEPA 2000).

More than 2,000 valid WET test results and thousands of simulations were conducted to develop the technical basis for the TST approach. This approach builds on the strengths of the traditional hypothesis testing approach, including using robust statistical analyses to determine whether an effluent is toxic (i.e., Welch's t-test), as well as published EPA documents regarding WET analysis and interpretation and the statistical literature. The TST approach yields a rigorous statistical interpretation of valid WET data by incorporating the transparent RMDs, established alpha and beta error rates, and thereby test power. Because this approach incorporates statistical test power, using TST will result in greater confidence in WET regulatory decisions. Additional benefits of using TST in WET analysis include the following:

- It provides a positive incentive for the permittee to generate high quality WET data to the permitting authority.
- It provides the ability to analyze a two-concentration test design (e.g., IWC versus control; stormwater and watershed assessments) using a streamlined statistical analysis flowchart. It is applicable to both NPDES WET permitting and section 303(d) watershed assessment programs.

In summary, the TST approach provides another option for permitting authorities and permittees to use in analyzing valid WET test data. The TST provides a positive incentive to generate high quality WET data to make informed decisions regarding NPDES WET RP and permit compliance determinations. By using TST, permitting authorities will be better able to identify toxic or non-toxic samples.

APPENDIX A

RATIONALE FOR USING WELCH'S T-TEST IN TST ANALYSIS OF WET DATA FOR TWO-SAMPLE COMPARISONS

APPENDIX A

RATIONALE FOR USING WELCH'S T-TEST IN TST ANALYSIS OF WET DATA FOR TWO-SAMPLE COMPARISONS

This appendix demonstrates that the Welch modification of the t-test is suitable for WET test data and applicable to the TST approach. It also provides the evaluation and justification for certain WET test data that do not strictly adhere to the assumptions of the Welch t-test.

The Welch t-test accounts for different variances in two groups and assumes data are normally distributed (Welch 1938, 1947; Moser et al. 1989; Coombs et al. 1996; Zar 1996). For non-normal data that have skewed, long-tailed distributions, the Welch's t-test is known to have poor coverage (Zimmerman 2006). (By poor coverage, EPA means that the realized error rate, alpha, under the null hypothesis, is greater than the intended, nominal value of alpha). It is demonstrated below that WET data to which the TST will be applied typically have moderately unequal variances in the control and the IWC. That fact motivates use of the Welch t-test rather than the t-test (which assumes equal variances). It is also demonstrated that WET test data are typically non-normal but in a way that does not substantially compromise coverage of the Welch test—the data are leptokurtic and typically held within some range by the test design of the EPA WET test methods. Such data are known to have little effect on coverage for the Welch t-test (Zimmerman 2006; Zar 1996).

So as not to rely on previous literature alone, simulations were conducted to demonstrate that the Welch t-test applied to the TST is suitable for WET test data. Simulated data were generated, having variances and non-normal distributions similar to WET test data for control and IWC groups. It is demonstrated that (a) moderately unequal variances (similar to WET data) have little effect on coverage of the t-test or Welch t-test (for normally-distributed data), and (b) for non-normally distributed data (similar in distribution to WET data) representing control and IWC groups, the TST using the Welch t-test has close to nominal coverage, on the basis of simulations with up to a nine-fold difference in variance between IWC and control (a relatively high difference in variances on the basis of observed WET test data).

Therefore, published studies provide ample evidence, the analysis of WET data and simulations described here, that the Welch t-test can be applied with confidence using the TST approach.

Characterization of WET Data

Because various WET test methods have a different experimental design, and thus could represent different distribution functions, a range of WET test methods (six) was examined to determine the frequency and magnitude of unequal variances between control and IWC as well as the frequency and type of non-normality in these methods. In addition, standard data transformations were used for tests when data were non-normal to see whether transformed data would meet assumptions of normality.

Unequal Variances

Standard F-tests ($p = 0.01$) were conducted for each valid WET test (IWC and control) to determine whether variances were unequal. Some WET test methods and endpoints demonstrated a higher frequency of unequal variances than other test methods (Table A-1).

Table A-1. Number (and percent) of tests with non-normal distribution and unequal variances for different types of WET tests, as well as the effect of data transformation on distribution, including skew and kurtosis

Test name	Number of tests	Data transformation	# (%) of non-normal tests ($p < 0.01$)	# (%) tests failing f-test for unequal variances ($p \leq 0.01$)	Range of skewness statistic for non-normal tests	# (%) tests failing D'Agostino test for skewness ($p \leq 0.01$)	Range of kurtosis statistic for non-normal tests	# (%) tests failing Anscombe test for kurtosis ($p \leq 0.01$)
C. dubia reproduction	1,382	Raw	285 (20.6)	390 (28.2)	-1.529 – -0.26	33 (2.4)	3.821 – 6.571	159 (11.5)
		Sqrt trans	418 (30.2)	545 (39.4)	-1.790 – -0.385	89 (6.4)	4.013 – 7.45	268 (19.4)
		Log +1	525 (37.9)	630 (45.6)	-2.058 – -0.564	143 (10.3)	4.06 – 8.43	343 (24.9)
Fish growth	108	Raw	2 (1.9)	18 (16.7)	-1.253 – 1.250	0 (0)	3.261 – 4.213	0 (0)
Mysid growth	907	Raw	10 (1.1)	37 (4.0)	-0.423 – 1.443	1 (0.1)	2.52 – 4.912	7 (0.77)
Kelp growth	100	Raw	9 (9.0)	22 (22)	-1.478 – 1.548	0 (0)	4.025 – 5.456	6 (6)
		Log+1	8 (8.0)	30 (30)	-1.571 – 1.234	0 (0)	4.25 – 6.080	8 (8)
		sqrt	9 (9.0)	29 (29)	-1.625 – 1.381	0 (0)	4.238 – 6.068	8 (8)
Kelp germination	100	Raw	3 (3.0)	15 (15)	-0.9 – 1.281	0 (0)	3.465 – 4.697	3 (3)
		arcsin(sqrt)	1 (1.0)	9 (9)	-0.872 – 1.04	0 (0)	3.465 – 4.698	0 (0)
Fish survival	108	percent	44 (40.7)	61 (56.5)	-1.633 – 0.654	0 (0)	2 – 4.67	3 (2.8)
		arcsin(sqrt)	42 (38.9)	61 (56.5)	-1.633 – 0	0 (0)	2 – 4.67	3 (2.8)

For example, over half of the *P. promelas* (fish) acute survival tests had unequal variances. That result is expected because control acute survival typically has little or no variance (i.e., all control replicates display 100 percent survival). *Ceriodaphnia* reproduction had the next highest frequency of tests with unequal variances (28.2 percent). The giant kelp growth or germination, and *P. promelas* (fish) chronic growth WET endpoints each had a lower frequency of tests with unequal variances (15–22 percent) while the mysid growth endpoint had the lowest frequency of unequal variances of the six test endpoints evaluated (4 percent). Using the *Ceriodaphnia* test method as an example of a WET method having a higher frequency of heterogeneous variances, the variance ratio between IWC and control was generally < 9:1 (95^{th} percentile ratio) with a median variance ratio of 2.5. Examination of data using other growth/reproduction methods indicates that most tests have a variance ratio < 10:1 (95^{th} percentile) and median variance ratio < 3.0. Percent data (germination) are subject to higher variance ratios (20~30:1); however, the fish acute test method has a variance ratio generally < 6.2:1 (95^{th} percentile).

Non-Normality

Shapiro's normality test was used to evaluate if WET test data were normally distributed. A measure of skewness was then used and Pearson's measure of kurtosis (R moments package) to examine if skewness or kurtosis or both are the major sources of non-normality. The critical values of those moments for a normal distribution are shown in Table A-2. A skewness measure significantly less than 0 indicates that the sample comes from a population that is skewed to the left, and a skewness measure significantly larger than 0 indicates that the distribution is skewed to the right. A kurtosis measure significantly larger than the median value (50^{th} percentile) for a given test design in Table A-2 indicates an underlying leptokurtic distribution. EPA also used the D'Agostino test of skewness (D'Agostino 1970) and Anscombe–Glynn test of kurtosis (Anscombe and Glynn 1983) for hypothesis testing.

Table A-2. Distribution of critical skewness and kurtosis ranges for different sample size (N) based on 1,000,000 simulation runs. N = 20 corresponds to *C. dubia* reproduction test (10 replicates in IWC and control); N = 16 corresponds to the Mysid chronic test (8 replicates per treatment); N = 10 corresponds to the two giant kelp chronic test endpoints (5 replicates per treatment); N = 8 corresponds to fathead minnow acute and chronic tests (four replicates per treatment)

N	Statistic	Percentiles						
		1%	5%	10%	50%	90%	95%	99%
20	Skewness	-1.152	-0.771	-0.587	0	0.588	0.772	1.155
	Kurtosis	1.645	1.831	1.951	2.551	3.667	4.151	5.361
16	Skewness	-1.244	-0.834	-0.635	0	0.635	0.833	1.247
	Kurtosis	1.562	1.746	1.866	2.477	3.629	4.126	5.351
10	Skewness	-1.407	-0.956	-0.729	0	0.726	0.953	1.404
	Kurtosis	1.387	1.563	1.679	2.289	3.463	3.940	4.972
8	Skewness	-1.453	-0.998	-0.766	0	0.766	0.997	1.450
	Kurtosis	1.318	1.470	1.583	2.173	3.319	3.731	4.567

The number of tests failing the hypothesis tests at 1 percent probability is reported in Table A-1. About 21 percent of the *Ceriodaphnia* reproduction tests (285 out of 1,382 cases) failed Shapiro's normality test (Table A-1). Both square root transformation and logarithm

transformation did not correct the non-normal distribution problem and instead increased the total number of tests failing the normality test (Table A-1). The D'Agostino test of skewness indicated that 33 tests (< 3 percent) were highly skewed. A test of kurtosis found 11 percent of tests (160) had significantly leptokurtic distribution (Table A-1). Apparently, most of the *Ceriodaphnia* test data failed the normality test because of kurtosis (leptokurtic distribution) and that occasional asymmetric distribution was mostly from outliers (Figure A-1). In general, most WET test growth data (i.e., *Pimephales promelas* growth, mysid growth, or kelp growth) were normally distributed. Both fish and mysid growth data exhibited non-normal distribution in only a very few cases (< 2 percent) and those were generally related to leptokurtic distributions that were short-tailed. Almost half of the acute fish survival tests had non-normally distributed data. Zero variance in many tests for either the control (34 cases) or IWC (26 cases) were the main cause of failing the normality test. Non-normality in acute fish survival data was because of leptokurtic data distribution (Table A-1).

The above analyses indicate that WET data in general do not have the distribution characteristics indicative of when Welch's t-test would be inappropriate (long-tail, highly skewed distribution).

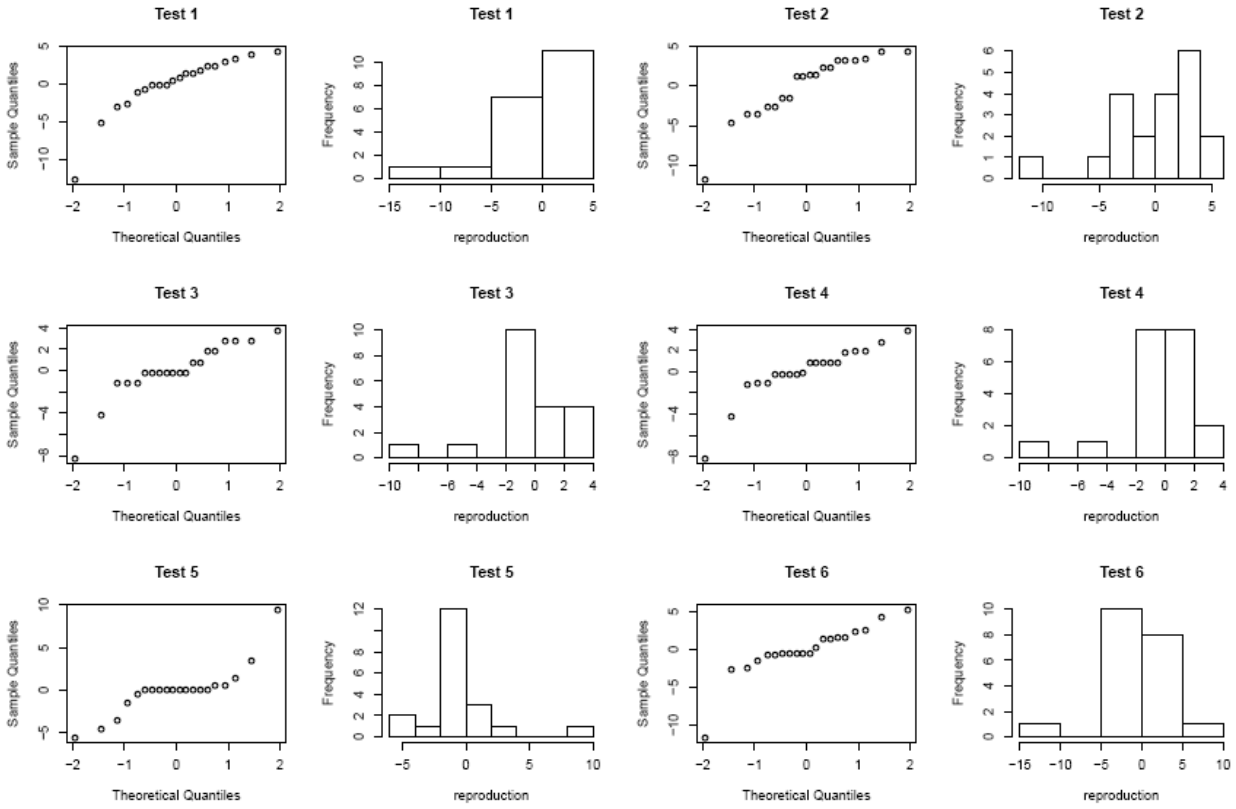

Figure A-1. Probability plots and histograms of examples of *Ceriodaphinia* chronic reproduction test data showing non-normal distribution and especially leptokurtic distribution.

Simulations

Unequal Variances

Various simulations were conducted using the chronic *Ceriodaphnia* test method as an example, to examine alpha error rate using either the traditional hypothesis t-test or Welch's t-test with data having different relationships between control and effluent variance. From analyses of more than 2,000 WET tests presented in Table A-1, a variance ratio (IWC/control) of 9:1 (95th percentile of variance ratio) is a reasonable upper limit. Therefore, simulation scenarios examined included (1) equal variances and no mean difference between control and effluent; (2) IWC with 9 times the control variance and no mean difference; (3) equal variance and a 25 percent mean effect of the IWC; and (4) IWC with 9 times the control variance and a 25 percent mean effect. Equal sample size (N = 10 using *Ceriodaphnia* chronic test method as the example) was assumed for both control and treatment group which is most often the case in WET analyses. Results are shown in Table A-3.

Table A-3. Results of Monte Carlo simulations evaluating alpha error rate using either the traditional t-test or Welch's t-test with data having different relationships between control and effluent variances. S_c^2 = control variance, S_t^2 = IWC variance, μ_c = control mean, and μ_t = IWC mean. Results are based on 1,000,000 simulation runs per scenario.

	0.250	0.2526	0.2499	0.2732	0.2499

When there are equal variances and the true difference is equal to 0, the observed error rates from both the traditional t-test and Welch's t-test are very close to the expected error rates. When control and treatment groups have unequal variance, (effluent variance = 9 times the control variance), the traditional t-test has a slightly higher Type I error rate, but Welch's t-test has a Type I error rate similar to the expected value. When the true response at the IWC is 0.75 × control mean, and both populations have equal variances, alpha error rates are very similar to expected using both the traditional t-test and Welch's t-test. When the true response at the IWC is 0.75 × control mean and population variances are not equal (i.e., effluent variance is 9 times

the control variance), the error rates are about 2–3 percent higher than expected using the traditional t-test but are similar to expected alphas using Welch's t-test.

While the specific results pertain to the *Ceriodaphnia* reproduction endpoint, the general conclusions of this analysis would apply to all WET methods and endpoints. Such results confirm that Welch's t-test has better coverage than the traditional t-test using the TST approach when variances are unequal.

Non-Normality

The objective of the simulations was to confirm that the alpha error rate is relatively stable against deviations from non-normal distribution when variances are unequal as well for both the traditional hypothesis test and Welch's t-test.

EPA examined the distribution of control and effluent reproduction data from 281 *C. dubia* multiple concentration tests (Figure A-2). While most tests indicate that control reproduction follows a normal distribution (mean = 24.5, standard deviation = 5.56), effluent data tend to deviate from a normal distribution: effluents with low toxicity have less skewed data, while effluents with data that have high toxicity are more likely to deviate from normal distribution. To address this observation, two populations were simulated on the basis of the shape of the frequency distribution in the highest effluent concentration in each *C. dubia* test (Figure A-3). The first simulated effluent population had a mean = 25 (equal to the population mean for the control group) and a standard deviation = 7.7, while the second one had a population mean of $b \times 25$ (where $b = 0.75$ for chronic test methods), resulting in an effluent mean of 18.75. The variance of those two effluent populations was the same. Random samples taken from these two populations were used to compare with the control population data (mean = 25, standard deviation = 5.56).

Simulation results (Table A-4) indicate that when the two populations had the same mean but had a different distribution shape as compared to a normal distribution (control population), the alpha error rate using the traditional t-test was about 1 percent higher than expected. Welch's modified t-test slightly corrected the error rate (Table A-4). When the true population mean difference between control and effluent is 25 percent of the control mean and when the effluent population is not normally distributed, the alpha error rate is almost identical to the expected value using traditional t-test (Table A-4). Welch's t-test resulted in a decrease in the nominal alpha error rate by 2–3 percent using the TST approach. That is, when data are extremely non-normal (for WET test data) and variances are heterogeneous between control and effluent, Welch's t-test is less likely to reject the null hypothesis and slightly more likely to declare a sample toxic than expected (i.e., the analysis will be more conservative). As data approach a normal distribution, α error rates using Welch's t-test will be closer to nominal values.

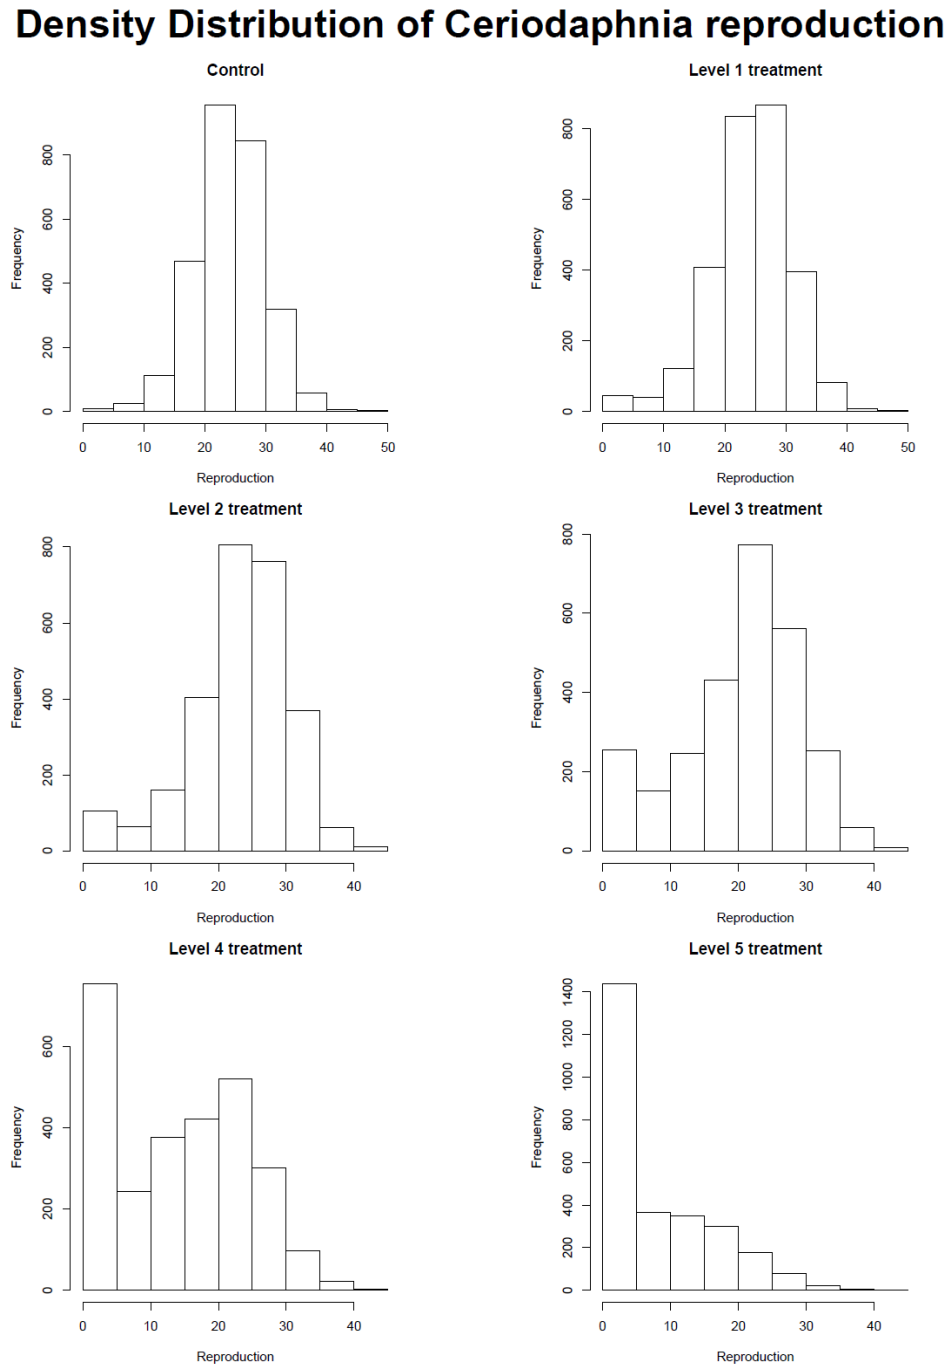

Figure A-2. Histogram of observed *Ceriodaphnia* reproduction at different level of effluent concentrations based on 281 multiple concentration tests.

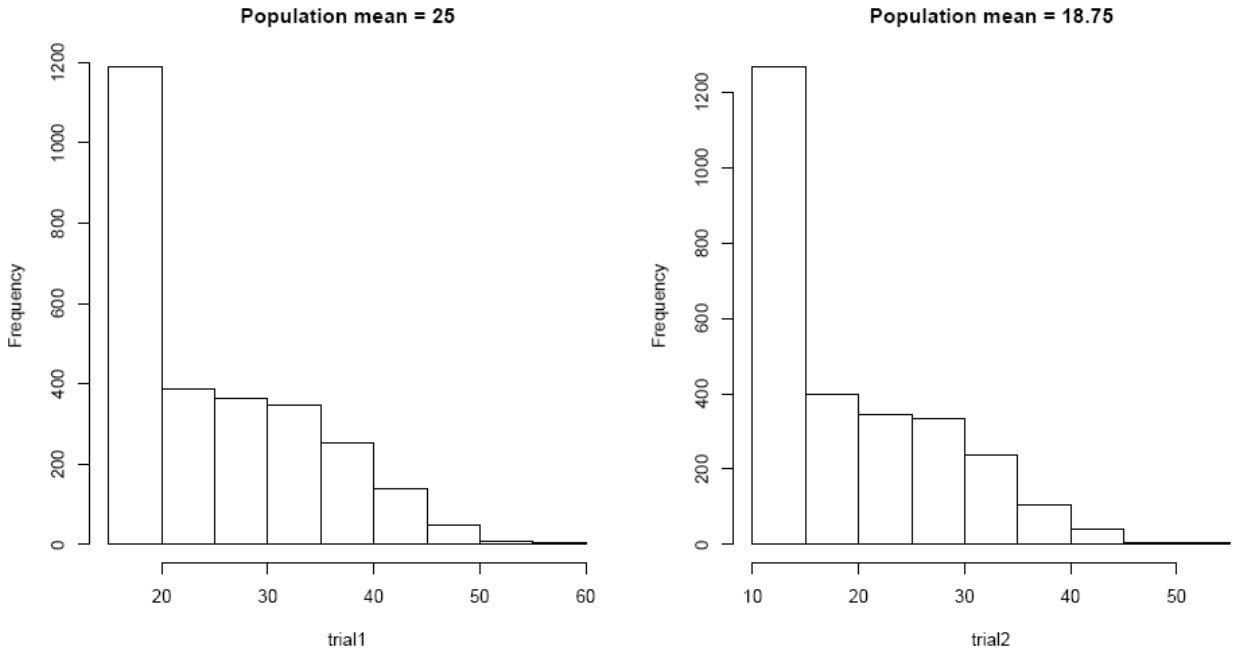

Figure A-3. Simulated frequency distributions of Ceriodaphnia reproduction data with two populations having non-normal data and different means. Both populations have a standard deviation of 7.7.

Table A-4. Results of Monte Carlo simulation analyses (100,000 simulations per scenario) indicating alpha error rates based on comparisons between two non-normally distributed populations and a normal distribution (control population, mean = 25, standard deviation = 5.65). The population means are 25 and 18.75, respectively, and the standard deviation is 7.7 in both populations.

Alpha	Welch's (μ = 25)	Traditional t (μ = 25)	TST t-test (μ = 18.75, b = 0.75)	TST Welch's (μ = 18.75, b = 0.75)
0.05	0.053	0.059	0.043	0.031
0.10	0.104	0.108	0.090	0.074
0.15	0.151	0.155	0.140	0.122
0.20	0.199	0.203	0.191	0.173

Although the simulated population does not necessarily represent the true population of effluent groups, EPA's examination of sample distribution indicates that effluent populations with low toxicity are less likely to deviate from normal distribution. The simulation also indicates that the alpha error rate using Welch's t-test under severely non-normal distributions and heterogeneous variances is less than the expected/critical values. That is, Welch's t-test is more conservative when toxicity is high (a desirable attribute for WET analysis) than when effluent toxicity is low. When effluent toxicity is low, results of analyses using *Ceriodaphnia* reproduction WET test data indicate that the effluent data are less likely to be non-normally distributed, and the observed alpha error rate approaches the expected error rate. On the basis of the foregoing results, the type of non-normal distribution observed in WET tests should not affect the overall performance of simulation analyses used to derive test method alpha values for the TST approach.

Rationale/Conclusions

When population variances are not equal or test samples are non-normally distributed (or both), concerns could be raised in using the two concentration t-test or the bioequivalence t-test (Erickson and McDonald 1995) because statistical assumptions might not be met. EPA WET test methods specify that if the data fail Shapiro-Wilks's normality test or Bartlett's homoscedasticity test (or both), a non-parametric test such as Wilcoxon Rank sum test should be used in such situations. Extension of such nonparametric tests to TST is, however, complicated because the null hypothesis for those tests is that results from control and effluent are from same population. This is stated as the null hypothesis of no difference among treatments. Because an effect size $1–(b \times \mu_0)$ is specified in the TST approach that is related to the control population mean, a non-parametric equivalent to a t-test approach using a bioequivalence formulation (such as with the TST approach), has been difficult to demonstrate (Zimmerman and Zumbo 1993; Manly 2004).

Data compiled from more than 2,000 valid WET tests in this project confirmed that the type of distributions exhibited by most test data do not seriously compromise the use of a t-test. The data can be dealt with appropriately using Welch's t-tests for unequal variances, as shown in simulation analyses. Use of Welch's t-test for TST analysis is supported on the basis of analysis of actual WET test data, which indicate that the majority of WET test data are normally distributed or have a leptokurtic distribution with short tails such that the use of Welch's t-test produces Type I error rates very close to expected error rates. Statistical literature indicates that actual power of the t-test (and by extension Welch's t-test) is *greater* when populations are leptokurtic, especially for small sample sizes (Zar 1996).

WET test data are biologically expected to have short-tailed distributions supporting the use of Welch's t-test because of the test method's required test acceptability criteria and test termination times, which constrain the range of endpoint responses encountered. For example, a chronic *Ceriodaphnia dubia* test must have 80 percent or greater survival and an average of 15 or more young per surviving female in the control for the test to meet the required test acceptability criteria (i.e., a valid test). Additionally, test termination is prescribed in the method as the time at which at least 60 percent or more of the surviving control females generate at least three broods, which can be 6–8 days (maximum is 8 days), also a test requirement. That results in a lower distribution bound (e.g., reproduction responses in controls start at 15). In addition, the upper part of the distribution cannot go to infinity, even if populations were to survive and reproduce beyond the prescribed test requirements because of biological constraints. Similar test method and biological constraints apply to all other WET test endpoints (e.g., growth, survival).

Furthermore, Welch's t-test is robust to non-normal distributions when the underlying distribution is symmetric and skewness is low, especially with sample sizes > 10 (Tiku 1971; Lee and D'Agostino 1976; Tiku and Akkaya 2004). For the West Coast WET methods examined and the *Ceriodaphnia* and Mysid chronic WET method evaluated, those conditions are met. Therefore, at least for those WET methods and others with similarly large sample sizes, Welch's t-test should not result in a substantial underestimation of the Type I error rate.

In addition, the Type I error rate using TST for several WET methods is set ≥ 0.05. The higher α levels include WET test methods that have smaller sample sizes such as the fathead minnow acute test. For those methods, the slight overestimation of the nominal Type I error rate that can occur using Welch's t-test when WET test data are not normally distributed is insignificant given

the higher nominal α levels established. For the West Coast WET test methods that have α levels set at 0.05, effect size examined in those test methods is large and, in many cases, data are normally distributed even without data transformation (e.g., giant kelp germination and tube-length endpoints, Table A-1).

The observed sample distribution from 281 *C. dubia* multiple concentration tests indicates that test populations at low effluent concentrations are less likely to deviate from normal distribution. A similar trend is expected for other WET endpoints such as growth. The simulation based on the distribution shape of the high effluent concentration population also indicates that the alpha error rate using Welch's t-test is less than expected. That is, Welch's t-test is more conservative when toxicity is high. Therefore, the type of non-normal distribution observed in WET tests should not negatively affect the outcome of TST analyses.

Analyses used to develop the TST analysis approach indicate that data transformation (log or square root) does not help the non-normality issue for WET test data (Table A-1). That is usually because of the leptokurtic distribution observed rather than because of skewness of data (Table A-2). Therefore, data transformation before TST analysis is not recommended except for percent data, which should be arcsine square root transformed before TST analysis (consistent with current EPA analysis recommendations). This precaution is suggested because percent data (especially acute percent survival) is most prone to non-normality.

In conclusion, given the leptokurtic and short-tailed distribution of most WET test data, as well as the other factors noted above, Welch's t-test is appropriate to use for one-tailed, two-sample comparisons using TST. Furthermore, because Welch's t-test performs as effectively as the t-test in terms of Type I error when data are normally distributed and variances are equal (Moser et al. 1989; Coombs et al. 1996), Welch's t-test should be used for all WET test data analysis using TST. Furthermore, many researchers have shown that the combination of using a preliminary variance test (e.g., F-test) plus a t-test does not control Type I error rates as well as simply always performing an unequal variance t-test such as Welch's t-test (Gans 1992; Moser and Stevens 1992). That is one reason why it is generally unwise to decide whether to perform one statistical test on the basis of the outcome of another (Smith 1936; Markowski and Markowski 1990; Zimmerman 2004).

STEP-BY-STEP PROCEDURES FOR ANALYZING VALID WET DATA USING THE TST APPROACH

APPENDIX B

STEP-BY-STEP PROCEDURES FOR ANALYZING VALID WET DATA USING THE TST APPROACH

The following is a step-by-step guide for using the TST approach to analyze valid WET data for the NPDES WET Program. This guide is applicable for a two-concentration data analysis of an IWC or a receiving water concentration compared to a control concentration. For further information regarding conducting WET tests and proper quality assurance/quality control needed, see the EPA WET method manuals. As you proceed through this guide, refer to the flowchart shown in Figure B-1 of this appendix.

Step 1: Conduct WET test following procedures in the appropriate EPA WET test method manual. This includes following all test requirements specified in the method (USEPA 1995 for chronic West Coast marine methods, USEPA 2002a for chronic freshwater WET methods, USEPA 2002b for chronic East Coast marine WET methods, and USEPA 2002c for acute freshwater and marine methods).

Step 2: For each test endpoint specified in the WET test method manual (e.g., survival and reproduction for the *Ceriodaphnia* chronic WET test method), follow Steps 3–7 below. Note that the guide refers to an effluent concentration tested, which is assumed to be the IWC as specified in the permit or a receiving water concentration for ambient testing. For example, if no mixing zone is allocated, the IWC is 100 percent effluent.

Note: If there is no variance (i.e., zero variance) in the endpoint in both concentrations being compared (i.e., all replicates in each concentration have the same exact response), then skip the remaining steps in the flowchart and do the following. Compute the percent difference between the control and the other concentration (e.g., IWC) and compare the percent difference against the RMD values of 25% for chronic and 20% for acute endpoints. Percent mean effect is calculated as:

$$\%\ \text{Effect at IWC} = \frac{\text{Mean Control Response} - \text{Mean Response at IWC}}{\text{Mean Control Response}} \times 100$$

If the percent mean response is $\geq$ the RMD, the sample is declared toxic and the test is "*Fail*". If the percent mean response is < the RMD, the sample is declared non-toxic and the test is "*Pass*".

Step 3: For data consisting of proportions from a binomial (response/no response; live/dead) response variable, the variance within the *i*th treatment is proportional to $P_i (1 - P_i)$, where P_i is the expected proportion for the treatment. That clearly violates the homogeneity of variance assumption required by parametric procedures such as the TST procedure because the existence of a treatment effect implies different values of P_i for different treatments, *i*. Also, when the observed proportions are based on small samples, or when P_i is close to zero or one, the normality assumption might be invalid. The arcsine square root (arcsine $\sqrt{P}$) transformation is used for such data to stabilize the variance and satisfy the normality requirement. The square root of percent data (e.g., percent survival, percent fertilization), expressed as a decimal fraction (where 1.00 = 100 percent) for each treatment, is first calculated. The square root value is then

arcsine transformed before analysis in Step 4. Note: Excel and most statistical software packages can calculate arcsine values.

Step 4: Conduct Welch's t-test (Zar 1996) using Equation 1:

Equation 1

$$t = \frac{\overline{Y_t} - b \times \overline{Y_c}}{\sqrt{\frac{S_t^{\,2}}{n_t} + \frac{b^2 S_c^{\,2}}{n_c}}}$$

where

$\overline{Y_c}$ = Mean for the control

$\overline{Y_t}$ = Mean for the IWC

$s_c^{\,2}$ = Estimate of the variance for the control

$s_t^{\,2}$ = Estimate of the variance for the IWC

n_c = Number of replicates for the control

n_t = Number of replicates for the IWC

b = 0.75 for chronic tests; 0.80 for acute tests

Note on the use of Welch's t-test: Welch's t-test is appropriate to use when there are an unequal number of replicates between control and the IWC. When sample sizes of the control and treatment are the same (i.e., $n_t = n_{c)}$, Welch's t-test is equivalent to the usual Student's t-test (Zar 1996).

Step 5: Adjust the degrees of freedom (df) using Equation 2:

Equation 2

$$\upsilon = \frac{\left(\frac{S_t^{\,2}}{n_t} + \frac{b^2 S_c^{\,2}}{n_c}\right)^2}{\frac{\left(\frac{S_t^{\,2}}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^{\,2}}{n_c}\right)^2}{n_c - 1}}$$

Using Welch's t-test, df is the value obtained for *v* in Equation 2 above. Because *v is* most likely a non-integer, round *v* to the next smallest integer, and that number is the df.

Step 6: Using the calculated t value from Step 4, compare that *t* value with the critical *t* value table in Appendix C using the test method-specific alpha values shown in Table 4-1. To obtain the correct *t* value, look across the table for the alpha value that corresponds to the WET test method (for the appropriate alpha value, see Table 4-1 of this document) and then look down the table for the appropriate df.

Step 7: If the calculated *t* value is less than the critical *t* value, the IWC is declared toxic, and the test result is *Fail*. If the calculated *t* value is greater than the critical *t* value, the IWC is not declared toxic and the test result is *Pass*.

NOTICE AND DISCLAIMER

This document provides the basis for implementing the Test of Significant Toxicity (TST) approach under the National Pollutant Discharge Elimination System (NPDES) for permitting authorities (states and Regions) and persons interested in analyzing whole effluent toxicity (WET) test data using the traditional hypothesis testing approach as part of the NPDES Program under the Clean Water Act (CWA). This document describes what the U.S. Environmental Protection Agency (EPA) believes is another statistical option to analyze valid WET test data for NPDES WET reasonable potential and permit compliance determinations. The document does not, however, substitute for the CWA, an NPDES permit, or EPA or state regulations applicable to permits or WET testing; nor is this document a permit or a regulation itself. The TST approach does not result in changes to EPA's WET test methods promulgated at Title 40 of the *Code of Federal Regulations* Part 136. The document does not and cannot impose any legally binding requirements on EPA, states, NPDES permittees, or laboratories conducting or using WET testing for permittees (or for states in evaluating ambient water quality). EPA could revise this document without public notice to reflect changes in EPA policy and guidance. Finally, mention of any trade names, products, or services is not and should not be interpreted as conveying official EPA approval, endorsement, or recommendation.

Table **Page**

EXECUTIVE SUMMARY

The U.S. Environmental Protection Agency (EPA or the Agency) has developed a new statistical approach that assesses the whole effluent toxicity (WET) measurement of wastewater effects on specific test organisms' ability to survive, grow, and reproduce. The new approach is called the Test of Significant Toxicity (TST) and is a statistical method that uses hypothesis testing techniques based on research and peer-reviewed publications. The TST approach examines whether an effluent, at the critical concentration (e.g., in-stream waste concentration or IWC, as recommended in EPA's Technical Support Document (TSD) (USEPA 1991) and implemented under EPA's WET National Pollutant Discharge Elimination System (NPDES) permits program and the control within a WET test differ by an unacceptable amount (the amount that would have a measured detrimental effect on the ability of aquatic organisms to thrive and survive). EPA Regions and their NPDES states can still use EPA's TSD approaches. The TST approach is another statistical option to analyze valid WET test data.

Since the inception of EPA's NPDES WET Program in the mid 1980s, the Agency has striven to advance and improve its application and implementation under the NPDES Program. The TST approach explicitly incorporates test power (the ability to correctly classify the effluent as non-toxic, also see reference in the glossary under power) and provides a positive incentive to generate valid, high quality WET data to make informed decisions regarding NPDES WET reasonable potential (RP) and permit compliance determinations. Once the WET test has been conducted (using multiple effluent concentrations and other requirements as specified in the EPA WET test methods), the TST approach can be used to analyze the WET test results to assess whether the effluent discharge is toxic at the critical concentration. Performing the EPA WET test where the minimum five required test concentrations (pursuant to the EPA WET test methods) can establish a concentration-response curve. The TST approach is designed to be used for a two concentration data analysis of the IWC or a receiving water concentration (RWC) compared to a control concentration. Using the TST approach, permitting authorities will have more confidence when making NPDES determinations as to whether a permittee's effluent discharge is toxic or non-toxic. Use of the TST approach does not result in any changes to EPA's WET test methods; however, a facility might desire to modify its future WET tests by increasing the number of replicates over the minimum required (USEPA 1995, 2002a, 2002b, 2002c) by the approved EPA WET test method to increase test power, which is the probability of declaring an effluent *non-toxic* if the organism response at the IWC is truly acceptable. If WET tests have already been performed, the WET data generated cannot be modified to increase the number of test replicates because the TST analysis is done on valid WET data generated within a WET test.

The TST approach was developed on the basis of extensive analyses and detailed research. EPA used valid WET data from *more than 2,000* WET tests to develop and evaluate the TST approach. The TST approach was tested using *nine different* WET test methods comprising *twelve biological endpoints* (e.g., reproduction, growth, survival) and representing most of the different types of WET test designs currently in use. *More than one million* computer simulations were also used to select error rates achieving EPA's regulatory management decisions for the TST approach.

Background

In the NPDES Program, an effluent sample is declared toxic relative to a permitted WET limit if the no observed effect concentration (NOEC) is less than the permitted IWC using a hypothesis statistical approach. In that traditional hypothesis approach, the question being answered is, ~~"I~~s the mean response of the organisms the same in the control and at the IWC?" The hypothesis testing approach has four possible outcomes: (1) the IWC is truly toxic and is declared toxic, (2) the IWC is truly non-toxic and is declared non-toxic, (3) the IWC is truly toxic but is declared non-toxic, and (4) the IWC is truly non-toxic but is declared toxic. The latter two possible outcomes represent decision errors that can occur with any hypothesis testing approach. In the NPDES WET Program, those two types of errors can occur when test control replication is very good (i.e., test is very precise) so that a very small difference between IWC and control is declared toxic (outcome [4] above), and when test control replication is poor (i.e., the test is very imprecise) so that *even large differences in organism response between the IWC and control cannot be distinguished as statistically different, and the effluent is incorrectly classified as non-toxic (outcome [3] above)*.

Organism responses to the IWC and control are unlikely to be exactly the same. The difference might be so small that even if statistically significant, it would be considered biologically negligible. Another approach for assessing an effluent's toxicity on the basis of collected WET data might be to rephrase the question, ~~"D~~oes the mean WET test response in the control and the IWC differ by a defined biological amount?" That approach is known as the *test of bioequivalence*, which the Food and Drug Administration has successfully used to evaluate drugs, as have many researchers in other biological fields. Using the TST approach, the question is, ~~"I~~s the organism response at the IWC less than or equal to a fixed fraction of the control response (e.g., 75 percent of the control mean response)?" That fixed fraction, expressed as a decimal between 0.00 and 1.00, is termed ~~*"b"*~~ in the TST approach. Thus, the hypothesis being tested is written as follows: mean response [IWC] $\leq b \times$ mean response [control].

The TST approach requires defining what is considered toxic. For *chronic* testing (i.e., for both lethal and sublethal toxicity test endpoints) in EPA's NPDES WET Program, the *b* value in the TST analysis is set at 0.75, which means that a 25 percent effect (or more) is considered evidence of unacceptable *chronic* toxicity. IWC responses substantially less than a 25 percent effect would be interpreted to have a lower risk potential. The regulatory management decision (RMD) for *acute* WET methods is set at 0.80, which means that a 20 percent effect (or more) is considered evidence of unacceptable *acute* toxicity. The acute RMD toxicity threshold is higher than that for chronic WET methods because of the severe environmental implications of acute toxicity (lethality or organism death). For more discussion on the *b* values of 0.75 (chronic toxicity) and 0.80 (acute toxicity), see Section 2.1 of this document.

EPA's RMDs using the TST approach identify true toxicity in WET tests most of the time when it occurs, while also minimizing the probability that the IWC is declared toxic when in fact it is not. That objective requires additional RMDs regarding acceptable maximum false positive *(β or beta using a TST approach) and false negative rates (α or alpha using a TST approach)*. In the TST approach, the RMDs are defined as (1) declare a sample toxic at least 75 percent of the time (alpha, $\alpha \leq 0.25$) when there is unacceptable toxicity (20 percent effect for acute and 25 percent effect for chronic test methods), and (2) declare an effluent non-toxic no more than 5 percent

(beta, $\beta \leq 0.05$) of the time when the mean effect at the critical effluent concentration is ≤ 10 percent for both acute and chronic WET tests (including for sublethal endpoints). For more discussion on the RMDs, see Section 2.1 of this document.

On the basis of EPA's analyses, the alpha levels shown in Table ES-1 are recommended for the nine WET test methods examined using the TST approach. An important feature of the TST approach is that the false negative error rate (rate of declaring a toxic effluent to be non-toxic) is established, which, under the traditional hypothesis testing approach, had not been established by EPA previously. For more discussion on the inclusion of the beta error rate in the TST approach, see Section 1.2 of this document and Section 1.1 on the current approach in EPA's 1991 TSD. A demonstrated benefit of the TST approach is that increasing within-test replication (the test power) results in a *lower* rate of WET tests being declared toxic using the TST approach when the IWC is truly non-toxic.

Results obtained from the TST analyses using the *nine* EPA test methods should be applicable to other EPA WET methods not examined. For example, results generated under this project for the fish *Pimephales promelas* survival and growth test is extrapolated to other EPA fish survival and growth tests (e.g., *Menidia* sp., *Cyprinus variegatus*, *Atherinops affinis*) because those test methods use a similar test design (e.g., number of replicates, number of organisms tested) and measure the same endpoints.

Summary

More than 2,000 WET test results and more than one million simulations were conducted to develop the technical basis for the TST approach. The approach builds on the strengths of the traditional hypothesis testing approach, including use of robust statistical analyses and published EPA documents regarding WET data analysis and interpretation. The TST approach yields a rigorous statistical interpretation of valid WET data by incorporating transparent RMDs and established alpha and beta error rates, which can provide incentives to generate test results having greater test power. Because the approach considers statistical test power, its use will result in greater confidence in WET regulatory decisions. In addition, the TST approach provides a positive incentive for the permittee to generate valid, high quality WET data by either increasing the number of test replicates for the IWC and the control within a test and/or achieving better precision within a test through improved WET test method performance (e.g., a high level of quality assurance and quality control).

Permitting authorities should consider the practical programmatic shift from the traditional hypothesis testing approach to the TST approach by opening a dialogue with their regulated community. In addition, they might want to begin to identify what changes might be needed to assimilate the TST approach into any regulations, policy, guidance, and training in their respective NPDES WET Programs. Again, the traditional hypothesis testing approach under EPA's TSD is still considered valid as applied; however, that approach can now be advanced through the TST approach by providing new incentives to permittees to provide valid, high quality WET data.

Table ES-1. Summary of alpha (α) levels or false negative rates recommended for different WET test methods using the TST approach

EPA WET test method	*b* value	Probability of declaring a toxic effluent non-toxic False negative (α) error[a]
Chronic Freshwater and East Coast Methods		
Ceriodaphnia dubia (water flea) survival and reproduction	0.75	0.20
Pimephales promelas (fathead minnow) survival and growth	0.75	0.25
Selenastrum capricornutum (green algae) growth	0.75	0.25
Americamysis bahia (mysid shrimp) survival and growth	0.75	0.15
Arbacia punctulata (Echinoderm) fertilization	0.75	0.05
Cyprinodon variegatus (Sheepshead minnow) and *Menidia beryllina* (inland silverside) survival and growth	0.75	0.25
Chronic West Coast Marine Methods		
Dendraster excentricus and *Strongylocentrotus purpuratus* (Echinoderm) fertilization	0.75	0.05
Atherinops affinis (topsmelt) survival and growth	0.75	0.25
Haliotis rufescens (red abalone), *Crassostrea gigas (oyster), Dendraster excentricus, Strongylocentrotus purpuratus* (Echinoderm) and *Mytilus sp* (mussel) larval development methods	0.75	0.05
Macrocystis pyrifera (giant kelp) germination and germ-tube length	0.75	0.05
Acute Methods		
Pimephales promelas (fathead minnow), *Cyprinodon variegatus* (Sheepshead minnow), *Atherinops affinis* (topsmelt), *Menidia beryllina* (inland silverside) acute survival[b]	0.80	0.10
Ceriodaphnia dubia, *Daphnia magna, Daphnia pulex*, *Americamysis bahia* acute survival[b]	0.80	0.10

Notes:

a. (1) declare a sample toxic at least 75 percent of the time (alpha ≤ 0.25) when there is unacceptable toxicity (20 percent effect for acute and 25 percent effect for chronic test methods) and (2) declare an effluent non-toxic no more than 5 percent of the time (beta ≤ 0.05) when the mean effect at the critical effluent concentration is 10 percent for both acute and chronic WET tests (including sublethal endpoints). For more discussion on the RMDs, see Section 2.1 of this document.

b. Based on four replicate test design

In addition, EPA recommends the following:

- Permitting authorities should decide up front which approach (the EPA's 1991 TSD approach, the TST approach, or another scientifically defensible approach that is sufficient to meet the statutory and regulatory requirements) they will follow (including for their RP procedures) and use the selected approach consistently in all their state NPDES permits. Permitting authorities should ensure that the most environmentally protective approach is consistently used across all permits when assessing valid WET data (e.g., WET RP) for

NPDES permit requirements (e.g., WET limits, monitoring frequencies, toxicity identification evaluation/toxicity reduction evaluation) and avoid selecting the approach that underestimates the true toxicity of the permitted effluent discharge.

- Where a *small data set* exists (fewer than four valid WET tests performed and reported in the previous 5 years), permitting authorities should use the TSD approach for determining RP. With small WET data sets, the TSD's RP multiplying factor is more conservative for environmental water quality protection purposes than the TST. The TST approach is intended for larger data sets (four or more) because it does not use an RP multiplying factor.
- If WET tests have already been performed, the WET data generated cannot be modified to increase the number of test replicates within a test. The decision to increase the number of within test replicates is a decision that needs to be made before conducting the WET tests.
- Where a permittee has concerns about WET data quality, EPA recommends increasing the number of replicates in tests, even if the permitting authority has not yet adopted the TST approach.

GLOSSARY

Acute Toxicity Test is a test to determine the concentration of effluent or ambient waters that causes an adverse effect (usually mortality) on a group of test organisms during a short-term exposure (e.g., 24, 48, or 96 hours). Acute toxicity is determined using statistical procedures (e.g., point estimate techniques or a t-test).

Ambient Toxicity is measured using a toxicity test on a sample collected from a receiving waterbody.

Chronic Toxicity Test is a short-term test in which sublethal effects (e.g., reduced growth or reproduction) are usually measured in addition to lethality.

Coefficient of Variation (CV) is a standard statistical measure of the relative variation of a distribution or set of data, defined as the standard deviation divided by the mean. The CV can be used as a measure of precision within and between laboratories, or among replicates for each treatment concentration.

Confidence Interval is the numerical interval constructed around a point estimate of a population parameter.

Effect Concentration (EC) is a point estimate of the toxicant concentration that would cause an observable adverse effect (e.g., mortality, fertilization). EC25 is a point estimate of the toxicant concentration that would cause an observable adverse effect in 25 percent of the test organisms.

False Negative is when the in-stream waste concentration is declared non-toxic but in fact is truly toxic. In the traditional hypothesis approach, false negative error rate is denoted by Beta (β). In the TST approach, false negative error rate is denoted as Alpha (α), which applies when the percent effect in the critical effluent concentration is $\geq$ 25% for a given test.

False Positive is when the in-stream waste concentration is declared toxic but in fact is truly non-toxic. In the traditional hypothesis approach, false positive error rate is denoted by Alpha (α). In the TST approach, false positive error rate is denoted as Beta (β), which applies when the percent effect in the critical effluent concentration is $\leq$ 10% for a given test.

Hypothesis Testing is a statistical approach (e.g., Dunnett's procedure) for determining whether a test concentration is statistically different from the control. Endpoints determined from hypothesis testing are no observed effect concentration and lowest observed effect concentration (LOEC). The two hypotheses commonly tested in WET are:

Null hypothesis (Ho): The effluent is non-toxic.

Alternative hypothesis (Ha): The effluent is toxic.

Inhibition Concentration (IC) is a point estimate of the toxicant concentration that would cause a given percent reduction in a nonlethal biological measurement (e.g., reproduction or growth), calculated from a continuous model (i.e., Interpolation Method). IC25 is a point estimate of the toxicant concentration that would cause a 25 percent reduction in a nonlethal biological measurement.

In-stream Waste Concentration (IWC) is the concentration of a toxicant or effluent in the receiving water after mixing. The IWC is the inverse of the dilution factor. It is sometimes referred to as the receiving water concentration (RWC).

Lethal Concentration, 50 percent (LC50) is the toxicant or effluent concentration that would cause death to 50 percent of the test organisms.

Lowest Observed Effect Concentration (LOEC) is the lowest concentration of an effluent or toxicant that results in statistically significant adverse effects on the test organisms (i.e., where the values for the observed endpoints are statistically different from the control).

No Observed Effect Concentration (NOEC) is the highest tested concentration of an effluent or toxicant that causes no observable adverse effect on the test organisms (i.e., the highest concentration of toxicant at which the values for the observed responses are not statistically different from the control).

National Pollutant Discharge Elimination System (NPDES) is the national program for issuing, modifying, revoking and reissuing, terminating, monitoring and enforcing permits, and imposing and enforcing pretreatment requirements, under the Clean Water Act sections 307, 318, 402, and 405.

Power (or test power) in the context of the Test of Significant Toxicity approach, is the probability of correctly declaring an effluent non-toxic when, in fact, it has an acceptably low level of toxicity.

Precision is a measure of reproducibility (which is a statistical term about the ability to reproduce similar results across test replicates with in a test treatment) within a data set. Precision can be measured both within a laboratory (within-laboratory) and between laboratories (between-laboratory) using the same test method and toxicant.

Quality Assurance (QA) is a practice in toxicity testing that addresses all activities affecting the quality of the final effluent toxicity data. QA includes practices such as effluent sampling and handling, source and condition of test organisms, equipment condition, test conditions, instrument calibration, and replication, use of reference toxicants, recordkeeping, and data evaluation.

Quality Control (QC) is the set of more focused, routine, day-to-day activities carried out as part of the overall QA program.

Reasonable Potential (RP) is where an effluent is projected or calculated to cause an excursion above a water quality standard based on a number of factors including the four factors listed in Title 40 of the *Code of Federal Regulations* Part 122.44(d)(1)(ii).

Reference Toxicant Test is a check of the sensitivity of the test organisms and suitability of the test methodology using the reference toxicant required by the EPA WET test methods. Reference toxicant data are part of a routine QA/QC program to evaluate the performance of laboratory personnel and the robustness and sensitivity of the test organisms.

Regulatory Management Decision (RMD) is the decision that represents the maximum allowable error rates and thresholds for toxicity and non-toxicity that would result in an acceptable risk to aquatic life.

Replicate is two or more independent organism exposures of the same treatment (i.e., effluent concentration) within a WET test. Replicates are typically separate test chambers with organisms, each having the same effluent concentration**.**

Sample is defined as a representative portion of a specific environmental matrix that is used in toxicity testing. For this document, environmental matrices could include effluents, surface waters, groundwater, stormwater, and sediment.

Significant Difference is defined as a statistically significant difference (e.g., 95 percent confidence level) in the means of two distributions of sampling results.

Statistic is a computed or estimated quantity such as the mean, standard deviation, or coefficient of variation.

Test Acceptability Criteria (TAC) are test method-specific criteria for determining whether toxicity test results are acceptable. The effluent and reference toxicant must meet specific criteria as defined in the test method (e.g., for the *Ceriodaphnia dubia* survival and reproduction test, the criteria are as follows: the test must achieve at least 80 percent survival and an average of 15 young per surviving female in the control and at least 60% of surviving organisms must have three broods).

t-test (formally Student's t-Test) is a statistical analysis comparing two sets of replicate observations—in the case of WET, only two test concentrations (e.g., a control and IWC). The purpose of this test is to determine if the means of the two sets of observations are different (e.g., if the IWC or ambient concentration differs from the control [i.e., the test result is pass or fail]).

Type I Error (alpha α) is the error of rejecting the null hypothesis (H_o) that should have been accepted.

Type II Error (beta β) is the error of accepting the null hypothesis (H_o) that should have been rejected.

Toxicity Test is a procedure to determine the toxicity of a chemical or an effluent using living organisms. A toxicity test measures the degree of effect on exposed test organisms of a specific chemical or effluent.

Welch's t-test is an adaptation of Student's t-test intended for use with two samples having unequal variances.

Whole Effluent Toxicity (WET) is the total toxic effect of an effluent measured directly with a toxicity test.

1.0 INTRODUCTION

Whole effluent toxicity (WET) test methods are laboratory procedures that measure biological effects (e.g., survival, growth, reproduction) on aquatic organisms exposed to effluents or storm water discharged to receiving waters in implementing the National Pollutant Discharge Elimination System (NPDES) Program under the Clean Water Act (CWA) section 402. Since the publication of EPA's *Technical Support Document for Water Quality-based Toxics Control* (TSD) (USEPA 1991), permitting authorities have requested alternative approaches for analyzing WET test data that would provide increased confidence in the data assessment and simplify the NPDES permit decision-making process with respect to WET. In response to those requests, EPA developed the TST approach as another statistical option to analyze valid WET test data. This document presents the NPDES programmatic features of the TST statistical approach for analyzing valid WET data and how it can be used to support permitting authorities and permittees when analyzing and interpreting WET test data. Use of the TST approach does not result in any changes to EPA's WET test methods, nor does it preclude the use of EPA's TSD approaches for analyzing valid WET data, or another scientifically defensible approach that is sufficient to meet the statutory and regulatory requirements.

1.1 Terminology and Concepts

This section briefly summarizes the major statistical concepts and terminology involved in WET analysis so as to give the reader a context with which to understand the TST approach and how it differs from current statistical approaches used to analyze valid WET data. This TST implementation document is not intended to provide a detailed discussion of WET test methods, data interpretation, or statistics, and it is assumed that the reader will consult EPA's TSD, WET test method documents, and other WET-related documents (e.g., *Understanding and Accounting for Method Variability in Whole Effluent Toxicity Applications*, USEPA 2000).

In the NPDES Program, WET tests examine organism responses to effluent, typically along a dilution series (USEPA 1995, 2002a, 2002b, 2002c). Acute WET methods measure the lethal response of test organisms exposed to effluent (USEPA 2002c). The principal response endpoints for those methods are the effluent concentration that is lethal to 50 percent of the test organisms (LC50) or the effluent concentration at which survival is significantly lower than the control. Chronic WET methods often measure both lethal and sublethal responses of test organisms. The statistical endpoints used in chronic WET testing are the no observed effect concentration (NOEC) and the 25 percent inhibition concentration (IC25). The NOEC endpoint is determined using a hypothesis testing approach that identifies the maximum effluent concentration at which the response of test organisms is not significantly different from the control. From a regulatory perspective, an effluent sample is declared toxic if the NOEC is less than the in-stream waste concentration (IWC) specified through the WET limitations in the permit. The IC25, by contrast, is a point estimation approach. It identifies the concentration at which the response of test organisms is 25 percent below that observed in the control concentration, and it interpolates the effluent concentration at which this magnitude of response is expected to occur. From a regulatory perspective, an effluent sample is declared toxic if the IC25 is less than the IWC specified through the WET limitations in the permit. This document focuses only on the hypothesis testing approach and not on point estimation approaches for analyzing and interpreting WET data.

In any hypothesis testing approach, two hypotheses are stated: the null hypothesis and the alternative hypothesis. The statistical concepts associated with the traditional hypothesis testing approach currently used in WET analysis are summarized in Table 1. Using that approach, the null hypothesis is that the IWC is non-toxic (i.e., the organism response at the IWC is equal to or better than the response in the test control). The alternative hypothesis is that the IWC is toxic (i.e., the organism response is worse in the IWC than in the control). With any hypothesis testing approach, two types of decision errors occur: (1) conclude that the null hypothesis is correct when in fact it is not or (2) conclude that the null hypothesis is incorrect (i.e., reject the null hypothesis) and thereby declare that the alternative hypothesis is correct, when in fact the null hypothesis is correct. In WET testing, the first type of error above is referred to as a *false negative*, meaning that the *IWC is declared non-toxic when in fact it is toxic*. The second type of error above is referred to as a *false positive* in WET testing, meaning that the *IWC is declared toxic when in fact it is not*.

In the traditional hypothesis testing approach summarized in Table 1, statisticians have assigned Greek letters to the two types of errors identified above. Alpha (or α) refers to the false positive error rate. Beta (or β) refers to the rate of false negatives. In the EPA WET test methods supporting the NPDES WET Program (USEPA 1995, 2002a, 2002b), α was established but β was not. Therefore, the application of α from the EPA test methods and implemented under EPA's TSD, recommended that the maximum rate of false positives that should be observed should be low (no more than 5 percent or $\alpha = 0.05$), but the rate of false negatives was not similarly controlled and is not currently evaluated in WET testing. As a result, the rate of false negatives in the NPDES WET Program has not been controlled. Put another way, the statistical power of these tests, the ability to correctly classify the IWC as toxic (where power is defined as $1-\beta$, Table 1) has not been controlled.

As noted previously in this section, a hypothesis testing approach determines whether the organism response at the IWC is significantly worse than that in the control. In practice, this statistical approach relies on two properties of the data: the average values in the control and the IWC (e.g., average fish weight in each test concentration), and the variability observed among replicates (i.e., organisms' responses from multiple replicates) within the IWC and the control. Whether the IWC is considered toxic depends on both of those data properties, which in many cases results in a well-established, statistically rigorous way to evaluate WET data. However, there are two types of situations in which the traditional hypothesis testing approach can yield equivocal results in WET testing: (1) in tests where within-test variability is high and (2) in tests where within-test variability is exceptionally low. In the first case, because within-test variability is high, it will be difficult to determine statistically whether the organism response to the IWC is worse than the control. That could result in more false negatives than would otherwise be the case. In the second case above, because within-test variability is very low, it will be relatively easy to show statistically significant differences in organism response between the IWC and the control. That could result in more false positives (as defined in the TST approach) than would otherwise be the case.

Table 1. Expression of null and alternative hypotheses used in traditional hypothesis testing and relationships between error rates and resulting decisions based on this approach. Entries correspond to the probability decision given in parentheses. The probability of a false positive (i.e., rejecting a null hypothesis that should not have been rejected) is represented by α and the probability a false negative (i.e., failing to reject the null hypothesis when it should have been rejected) is represented by β.

	True condition	
Decision	**Null hypothesis** Treatment mean ≥ Control mean **Sample is non-toxic**	**Alternative hypothesis** Treatment mean < Control mean **Sample is toxic**
Treatment mean ≥ Control mean **Sample is non-toxic**	Correct decision (1-α)	False negative (β)
Treatment mean < Control mean **Sample is toxic**	False positive (α)	Correct decision (1 – β) (power)

1.2 Background on the TST Approach

The TST is an alternative statistical approach for analyzing and interpreting valid WET data that also uses a hypothesis testing approach but in a different way, building on previous work conducted by EPA in the NPDES WET Program (USEPA 2000) and other researchers (Erickson and McDonald 1995; Shukla et al. 2000; Berger and Hsu 1996). The TST approach is based on a type of hypothesis testing referred to as *bioequivalence testing*. Bioequivalence is a statistical approach that has long been used in evaluating clinical trials of pharmaceutical products (Anderson and Hauck 1983) and by the Food and Drug Administration (Hatch 1996; Aras 2001; Streiner 2003). The approach has also been used to evaluate the attainment of soil cleanup standards for contaminated sites (USEPA 1989) and to evaluate effects of pesticides in experimental ponds (Stunkard 1990). In the context of the NPDES WET Program, the TST approach assesses whether the response of test organisms at the IWC (e.g., fish weight or number of neonates per female) is less than a predetermined proportion of the control response that is considered unacceptably toxic. *Once the WET test has been conducted (using multiple effluent concentrations and other requirements have been met as specified in the EPA methods), the TST approach is designed to be used for a two concentration data analysis of the in-stream waste concentration (IWC) or a receiving water concentration (RWC) compared to a control concentration.*

The null hypothesis using the TST approach is that the IWC is significantly more toxic (i.e., results in a worse organism response) compared to the control (see Table 2). The alternative hypothesis using the TST approach is that the IWC is non-toxic. Thus, the null and alternative hypotheses using the TST approach are opposite of what they are under the traditional hypothesis testing approach described in Section 1.1. In addition, the meaning of α and β are also opposite from what they represent in the traditional hypothesis approach. Under the TST approach, α is associated with false negatives, and β is associated with false positives. Statistical power using the TST approach is the ability to correctly classify the IWC as non-toxic (Table 2). The proportion or fraction of the control response that represents the toxicity threshold is denoted as *b* in the equations in Table 2 and is expressed as a decimal between 0.00 and 1.00. For example,

a *b* value set at 0.85 would mean that a response at the IWC that is at least 85 percent of the control response in the test (i.e., no more than a 15 percent effect) would be considered a lower risk for environmental impacts.

Using the TST hypothesis approach in the NPDES WET Program has several benefits. By incorporating *b* in the hypothesis equation, using the TST approach, there is explicit acknowledgement of the fact that the organism response at the IWC can be less than the control organism response by a certain amount and still be considered acceptable (i.e., non-toxic). In that way, truly non-toxic samples (as defined in the TST approach) can be addressed in a clearer manner than is possible with the traditional hypothesis testing approach as practiced in the NPDES WET Program. A low false positive rate in the TST approach is further addressed by having a low β ($\beta \leq 0.05$), which means more statistical power to identify an acceptable effluent (as defined by EPA's regulatory management decisions [RMDs]) as non-toxic in the NPDES WET Program. In addition, because the null hypothesis in the TST approach is opposite to what is used in the traditional hypothesis testing approach, false negatives are explicitly addressed (α in the TST approach addresses the false negative rate). As mentioned previously, the current NPDES WET Program does not control for false negatives. Thus, the TST approach allows permitting authorities to minimize the occurrence of false negatives (i.e., declaring the IWC non-toxic when it is actually exhibiting unacceptable toxicity), while also minimizing the occurrence of false positives (i.e., declaring the IWC toxic when it is actually acceptable). The TST approach has the added advantage of providing permittees with a clear incentive to improve the precision of test results (e.g., decrease within-test variability and/or use more replicates within a WET test than the minimum required in the EPA WET test method) to reach a definitive conclusion as to whether unacceptable toxicity is observed in a test. Thus, using the TST approach, a permittee can in fact *prove a negative*, i.e., that their effluent is acceptable (non-toxic).

Table 2. Expression of null and alternative hypotheses using the TST approach and relationships between error rates and resulting decisions based on this approach. Entries correspond to the probability decision given in parentheses. The probability of a false positive (i.e., rejecting a null hypothesis that should not have been rejected) is represented by α and the probability a false negative (i.e., failing to reject the null hypothesis when it should have been rejected) is represented by β.

	True condition	
Decision	**Null hypothesis** Treatment mean ≤ b × Control mean **Sample is toxic**	**Alternative hypothesis** Treatment mean > b × Control mean **Sample is non-toxic**
Treatment mean ≤ b × Control mean **Sample is toxic**	Correct decision (1-α)	False positive (β)
Treatment mean > b × Control mean **Sample is non-toxic**	False negative (α)	Correct decision (1-β) (power)

2.0 TST METHODOLOGY

2.1 Regulatory Management Decisions for the TST Approach

Toxicity is not an absolute quantity but rather an effect that is determined relative to a control or reference sample using a given WET test method. In the TST approach, what is considered unacceptable or acceptable toxicity are explicit RMDs. For *chronic* testing in EPA's NPDES WET Program, the *b* value in the TST null hypothesis is set at 0.75, which means that a 25 percent effect (or more) is considered a demonstration of unacceptable toxicity in a given WET test. Using a 25 percent effect threshold as the *b* coefficient is consistent with EPA's use of a 25 percent inhibition concentration (IC25) as an acceptable WET endpoint for examining chronic WET data. Responses substantially less than a 25 percent effect would be interpreted as a lower risk potential. The unacceptable toxicity RMD threshold for acute WET methods is set higher than that for chronic WET methods because of the severe environmental implications of acute toxicity (lethality or organism death). Therefore, for *acute* WET tests, the *b* value in the TST approach is set at 0.80 (i.e., ≥ 20 percent effect in the effluent in acute WET tests is considered unacceptable).

For both acute and chronic WET test methods, the low-risk RMD threshold is set at a 10 percent mean effect at the IWC within a WET test. Thus, one can *prove the negative* (i.e., an effluent is *acceptable or considered non-toxic under NPDES*) if that condition is met in a WET test. For mean effect levels greater than 10 percent but less than the unacceptable toxicity RMD threshold (20 percent for acute and 25 percent for chronic WET tests), the TST approach will still declare the IWC non-toxic depending on within-test variability: the lower the variability in the WET test, the more likely the sample will be declared non-toxic on the basis of the mean responses observed under these test conditions.

EPA's RMDs using the TST approach are used to specify unacceptable toxicity in WET tests most of the time when it occurs (i.e., a low false negative rate). As mentioned previously, under the traditional hypothesis testing approach currently used in the NPDES WET Program, the false negative rate was not controlled. Using the TST approach, the false negative rate RMD is $0.05 \leq \alpha \leq 0.25$, which translates to at least 75 percent probability that an effluent causing unacceptable toxicity will be declared toxic. As noted in the previous paragraph, the unacceptable toxicity RMD threshold is defined as ≥ 20 percent effect of the IWC in acute WET tests and ≥ 25 percent effect of the IWC in chronic WET tests.

EPA also desires to minimize the probability that the IWC is declared toxic when in fact it is acceptable (i.e., low false positive rate). Under the traditional hypothesis testing approach currently used in the NPDES WET Program, the false positive rate is set at 0.05 or 5 percent. Therefore, in the TST approach, the desired false positive rate is also set at 0.05 or 5 percent ($\beta \leq 0.05$). A $\beta = 0.05$ in the TST approach means that 95 percent of the time, a truly acceptable effluent (≤ 10 percent mean effect at the IWC) will be declared non-toxic in the NPDES WET Program. Depending on the minimum WET test design required in the EPA methods (e.g., number of replicates and number of organisms per test concentration) and achievable laboratory control precision for a WET test method, α will be set between 0.05 and 0.25 while still

maintaining a $\beta \leq 0.05$. Extensive analyses were used to identify the lowest α for a given WET test method for which $\beta = 0.05$ and all other RMDs are met.

The RMD thresholds above represent boundaries in terms of desired α and β rates. An $\alpha = 0.20$ for a chronic test method, for example, means that the Type I error rate will be approximately 20 percent at a mean effect of 25 percent. At higher levels of effect in the IWC, actual Type I error rates would be lower; at lower mean effect levels in the IWC, Type I error rate would be somewhat higher, depending on the test method. Therefore, at mean effect levels between the 10 percent non-toxic RMD boundary and the unacceptable toxicity RMD boundary (20 percent for acute and 25 percent for chronic WET test methods), there are differing probabilities of an effluent being declared toxic depending on within-test variability and the difference in mean responses observed between control and IWC. As a result, there will be some instances in which TST will declare a test toxic, whereas the traditional hypothesis approach would declare that test non-toxic (particularly when within-test variability is high or the mean effect at the IWC is near 25 percent, as explained in Section 1.1). Similarly, there will be some instances in which TST will declare an effluent non-toxic but the traditional hypothesis approach would declare that test toxic (when within-test variability is low and the mean effect at the IWC is less than the 20 percent toxicity RMD threshold for acute test methods or 25 percent for chronic toxicity test methods, as explained in Section 1.1).

WET test design and the types of WET endpoints measured influence test sensitivity (e.g., control coefficient of variation or CV). Therefore, TST α error rates are identified for different types of test designs. For example, all fish chronic WET test methods that use a similar test design and have the same type of test endpoints (e.g., growth and survival) would have the same α value. Varying α by WET test design is appropriate for the TST approach. Given the way that the hypotheses are formulated in the TST approach (see Table 2), α represents what is considered β in the traditional hypothesis testing approach, and an acceptable β error was not identified in the current EPA TSD's approach to the EPA NPDES WET Program. Setting α as well as β in the TST approach addresses both false positives and false negatives.

2.2 Setting the Test Method-Specific Alpha Level

Several types of analyses were conducted to determine the appropriate α level for each WET test method. First, representative effluent and reference toxicant data meeting EPA WET test method's test acceptability criteria (TAC) were obtained from several state databases, which included multiple laboratories and wastewater effluents. Valid effluent WET data that met the following data selection requirements were considered to be a representative sample.

- Cover a range of NPDES permitted facility types, including both industrial and municipal permittees
- Represent many facilities for a given EPA WET test method (i.e., no one facility dominates the data for a given WET test method)
- Cover a range of target (design) effluent dilutions on which WET reasonable potential (RP) and NPDES permit compliance are based, ranging from 10 percent to 100 percent effluent concentrations
- Generated by several laboratories for a given EPA WET test method

- Cover a range of observed effluent toxicity for each EPA WET test method (e.g., NOECs range from < 10 percent to 100 percent effluent)

For each of the nine EPA WET test methods examined, control precision was calculated on the basis of valid WET data compiled in this project. A similar analysis was performed for the control response for each of the nine test methods (e.g., mean number of offspring per female in the chronic *Ceriodaphnia dubia* test method) to characterize typical achievable test performance in terms of control response.

A Monte Carlo simulation analysis (a statistical method) was used to estimate the percentage of WET tests that would be declared toxic using the TST approach as a function of different α levels, within-test variability (control and effluent variability), and different effect levels. That analysis identified probable false positive error rates (i.e., declaring an effluent toxic when in fact it is not) under all WET test scenarios encountered. Using the RMDs defined above, an appropriate α level was then identified for each WET test design given a desired β error of ≤ 5 percent (0.05) when there is a 10 percent mean effect at the IWC. By simulating thousands of WET tests for a given scenario (mean percent effect and control CV), the percentage of tests declared toxic under a given effluent assessment scenario could be calculated and compared with other scenarios.

3.0 USING THE TST APPROACH IN WET DATA ANALYSES

3.1 Summary of Test Method-Specific Alpha Values

On the basis of all the analyses conducted in this project, EPA recommends the following alpha levels when using the TST approach in a two concentration (i.e., two treatments) data analysis comparison (e.g., IWC and control) (see Table 3).

Table 3. Summary of alpha (α) levels or false negative rates recommended for different WET test methods using the TST approach

EPA WET test method	*b* value	Probability of declaring a toxic effluent non-toxic False negative (α) error[a]
Chronic Freshwater and East Coast Methods		
Ceriodaphnia dubia (water flea) survival and reproduction	0.75	0.20
Pimephales promelas (fathead minnow) survival and growth	0.75	0.25
Selenastrum capricornutum (green algae) growth	0.75	0.25
Americamysis bahia (mysid shrimp) survival and growth	0.75	0.15
Arbacia punctulata (Echinoderm) fertilization	0.75	0.05
Cyprinodon variegatus (Sheepshead minnow) and *Menidia beryllina* (inland silverside) survival and growth	0.75	0.25
Chronic West Coast Marine Methods		
Dendraster excentricus and *Strongylocentrotus purpuratus* (Echinoderm) fertilization	0.75	0.05
Atherinops affinis (topsmelt) survival and growth	0.75	0.25
Haliotis rufescens (red abalone), *Crassostrea gigas (oyster), Dendraster excentricus, Strongylocentrotus purpuratus* (Echinoderm) and *Mytilus sp* (mussel) larval development methods	0.75	0.05
Macrocystis pyrifera (giant kelp) germination and germ-tube length	0.75	0.05
Acute Methods		
Pimephales promelas (fathead minnow), *Cyprinodon variegatus* (Sheepshead minnow), *Atherinops affinis* (topsmelt), *Menidia beryllina* (inland silverside) acute survival[b]	0.80	0.10
Ceriodaphnia dubia, *Daphnia magna, Daphnia pulex*, *Americamysis bahia* acute survival[b]	0.80	0.10

Notes:

a. (1) declare a sample toxic at least 75 percent of the time (alpha $\leq$ 0.25) when there is unacceptable toxicity (20 percent effect for acute and 25 percent effect for chronic test methods) and (2) declare an effluent non-toxic no more than 5 percent of the time (beta $\leq$ 0.05) when the mean effect at the critical effluent concentration is 10 percent for both acute and chronic WET tests (including sublethal endpoints). For more discussion on the RMDs, see Section 2.1 of this document.

b. Based on four replicate test design

3.2 Calculating Statistics for Valid WET Data Using the TST Approach

Appendix A includes a step-by-step guide for using the TST approach to analyzing WET test data. The appendix also includes a statistical flowchart and several examples. Note that the WET test method should follow the test condition requirements as specified in EPA's approved WET methods (USEPA 1995, 2002a, 2002b, 2002c).

The TST approach is used to statistically compare organism responses from two concentrations (i.e., treatments) of the WET test, the IWC and the control. Percent data (quantal data), such as percent survival or percent germination from a WET test, is first transformed as required in the EPA WET test manuals. Other types of WET data (e.g., growth or reproduction data) are not transformed. Data are then analyzed using Welch's t-test, a well-known modification of the standard t-test (Zar 1996), which is appropriate for the TST approach (see Appendix A).

Appendix B lists the critical *t* values that apply to WET testing using the TST approach given the number of degrees of freedom and the α level that applies for a given WET test method from Table 3 of this document. If the calculated *t* value for the WET test is greater than the critical *t* value (see Table B-1), the null hypothesis is rejected, i.e., the test result is *Pass* and **the effluent is declared *non-toxic***. If the calculated *t* value is less than the critical *t* value in Appendix B, the null hypothesis is not rejected, i.e., the test result is *Fail* and **the effluent *is* declared toxic.** Appendix A contains examples that demonstrate the formulae used in the TST approach and are designed to illustrate how the outcome is influenced by within-test variability and the mean effect of the IWC using the TST approach. Four different case examples are presented, three of which have equal variances between control and IWC: (1) *Ceriodaphnia* reproduction data having relatively high within-test variability, (2) *Ceriodaphnia* reproduction data having relatively low within-test variability and the same effect as in Example 1, (3) growth data from two fathead minnow chronic WET tests, both with relatively high within-test variability but small mean effect at the IWC; one test was conducted with the minimum number of replicates required in the EPA WET test method (four replicates) and the other test was conducted a priori with six replicates per concentration; and (4) calculations using the TST approach for an acute fathead minnow WET test.

Case Example #1 in Appendix A: ***Demonstrates a benefit of the TST approach by addressing false negatives***. A WET test that has relatively high within-test variability for a given WET test method and has an effect at the IWC approaching the RMD threshold (25 percent in this case because it is a chronic WET test) *is declared toxic* using the TST approach. Using the traditional hypothesis testing approach as recommended in the TSD, such test data typically lead to a conclusion that the effluent is not toxic (i.e., a false negative).

Case Example #3 in Appendix A: ***Demonstrates the benefits of increased within-test replication using the TST approach***. Increasing the replication before conducting the test, which thereby improves the precision and power of the WET test, increases the chances of rejecting the null hypothesis and declaring a truly acceptable effluent as *non-toxic* using the TST approach. That increases the ability to *prove the negative*, i.e., that an effluent is declared not toxic.

The TST approach can also be used for ambient toxicity (i.e., receiving water) tests and stormwater toxicity testing programs because the TST approach compares two treatments (for application of the TST approach to ambient toxicity testing, see Appendix C).

4.0 IMPLEMENTING THE TST APPROACH IN WET NPDES PERMITS

The TST approach is an alternative approach for analyzing and interpreting valid WET data. Use of the TST approach does not result in any changes to EPA's WET test methods. WET limits are simpler to communicate and understand (for example permit language for acute and chronic WET monitoring using the TST statistical analysis approach, see Appendix D) than the TSD approach. EPA recommends that permitting authorities decide up front which approach (the 1991 TSD approach, the TST approach, or another scientifically defensible approach that is sufficient to meet the statutory and regulatory requirements) they will incorporate and consistently use in their state's NPDES implementation procedures, including their RP procedures. The permitting authority should use the selected WET statistical approach consistently in all of their state NPDES permits.

4.1 Reasonable Potential (RP) WET Analysis

NPDES permitting authorities conducting an RP analysis must follow Title 40 of the *Code of Federal Regulations* (CFR) section 122.44(d)(1) to determine whether a discharge will ~~"c~~ause, have the [RP] to cause, or contribute to" an excursion of a numeric criterion or a narrative WET criterion. Some states have state-specific WET RP approaches in their water quality control plan or other NPDES policy or guidance.

For RP calculations using the TST approach, EPA recommends that permitting authorities use all valid WET test data generated during the current permit term and any additional valid data that are submitted as part of the permit renewal application. The TST RP approach necessitates having at least a minimum of four valid WET tests to address effluent representativeness (see EPA's TSD, Chapter 3, p. 57, under Step 2 in the section *Steps in Whole Effluent Characterization Process*). EPA also recommends that states request that their permittees provide the actual test endpoint responses for the control (i.e., control mean) and IWC concentration (i.e., IWC mean) for each WET test conducted to make it easier for permit writers to find the necessary WET test results when determining WET RP. WET test data are then analyzed according to the TST approach using the IWC and control test concentrations for all the valid WET test data available. For data sets with fewer than four valid WET data points, RP should be assessed using EPA's TSD RP approach because it addresses small WET data sets by incorporating an RP multiplying factor (see Section 3.3.2 of the TSD, p. 54) to account for effluent variability in small WET data sets. If WET test data are available and the TST statistical approach indicates that the IWC is toxic in any WET test, RP has been demonstrated (40 CFR 122.44(d)(1)(i)). Similar to the TSD approach, the TST approach can establish the existence of RP for WET even when no tests have been declared toxic using the TST to address concerns regarding the ~~"p~~otential to cause or contribute to toxicity." Appendix E presents the approach used to determine RP using the TST approach.

Note that using the TST approach might be to the permittee's advantage. If the permittee decides to incorporate additional replicates for the control and the IWC within a WET test, beyond the minimum required in the WET test method, the test power is increased. More test replicates increases test power, which means a higher probability of declaring a sample as non-toxic using the TST approach *if the effluent is truly non-toxic*. A demonstration is provided in Appendix A (Case Example #3), which illustrates that as an intended consequence of the TST approach

methodology. Thus, using the TST approach, a permittee has a greater ability to *prove the negative* (i.e., their effluent does not have RP).

In those cases where the WET RP outcome is *yes*, a WET limit is expressed in the permit. In those situations where the RP outcome is *no*, WET monitoring requirements should still be incorporated in the permit. Also in the permit, a test result of *Fail* (i.e., sample declared toxic) during monitoring, would trigger additional steps in the permit. In either of those situations—either a WET limit or a WET monitoring requirement, if toxicity is demonstrated—states should specify an approach to address toxicity in the permit. Doing so often includes increased frequency of WET testing and additional permit requirements to perform a toxicity reduction evaluation.

4.2 NPDES WET Permit Limits

Using the TST approach, WET NPDES permit limits would be expressed as *no significant toxicity of the effluent at the IWC using the TST analysis approach*. A test result of *Pass* is when the calculated *t* value is greater than *the critical t value*. A test result of *Fail* is when the calculated *t* value is less than *the critical t value*.

Beyond assessing WET data for the NPDES Program, WET tests are used to assess toxicity of receiving water (watershed assessment for CWA section 303(d) determinations) and stormwater samples. Often as a first assessment of receiving or stormwater toxicity, researchers test a control and a single concentration (e.g., 100 percent receiving water or stormwater). In such cases, the TST approach can be used in the same way a t-test is used. Such analysis is used to determine whether organism response in a specified ambient concentration is significantly different than the control organism response (for further information, see Appendix C).

5.0 RECOMMENDATIONS FOR NPDES IMPLEMENTATION OF THE TST APPROACH

5.1 EPA Regions and NPDES States (Permitting Authorities)

Permitting authorities should consider adding the TST approach to their implementation procedures for analyzing valid WET data for their current NPDES WET Program. Permitting authorities should consider the practical programmatic shift from the traditional hypothesis testing approach to the TST approach by opening a dialogue with their regulated community. In addition, they might want to begin to identify what changes might be needed to assimilate the TST approach into any regulations, policy, guidance, and training within their respective NPDES WET Programs. EPA also recommends that permitting authorities decide up front which RP approach (the 1991 TSD approach, the TST approach, or another scientifically defensible approach that is sufficient to meet the statutory and regulatory requirements) the permitting authority will incorporate and consistently use in their state's NPDES implementation procedures. The permitting authority should then use the WET statistical approach (either the TSD approaches or the TST data analysis approach) selected throughout all its state NPDES permits. Again, the traditional hypothesis testing approach recommended in EPA's TSD is still considered valid as applied; however, that approach can now be advanced through the TST approach by providing new incentives to permittees to generate valid, high quality WET data.

The RMDs incorporated into the TST approach were selected on the basis of considerable research and analysis involving several of the EPA WET test methods. Lower *b* values (i.e., for chronic test methods using a 0.70 instead of 0.75 *b* is unacceptable) are not recommended because it would mean that a lower fraction of test control response (i.e., greater effect at the IWC) is considered acceptable. EPA chose the acute and chronic *b* values to minimize effects on aquatic ecosystems. Likewise, the alpha values identified by EPA using the TST approach were determined on the basis of the predetermined *b* values and therefore should *not* be altered.

The permitting authority should consider carefully how the TST approach will be implemented in NPDES permits. Example permit language is shown in Appendix D. In consideration of maintaining NPDES WET Program implementation consistency, the TST approach should be used in place of, *and not in addition to*, the traditional hypothesis testing (NOEC) approach for WET analysis.

5.2 NPDES Permittees

One of the intended benefits of the TST approach is that increasing the precision and power of the WET test increases the chances of declaring a truly *acceptable effluent as non-toxic*. The permittee has greater control over the interpretation of WET test results using the TST approach because the RMDs are transparent, and the level of WET data quality needed to obtain unequivocal results can be determined beforehand. For example, conducting tests with more test replicates improves the power of the WET test, which can then support and provide a defensible basis for a permittee's demonstration that its effluent is *acceptable (i.e., in compliance with the permit*) if the mean effect is truly within the RMDs as defined in the TST approach. Using the TST approach, there is a *lower* rate of WET tests declared toxic for tests that are truly acceptable because of the increased power of the WET test when the permittee increases its number of

replicates in a WET test or achieves better replication within a test through improved test method performance. Thus, the TST approach increases the ability of the permittee to *prove the negative*, that the effluent is *non-toxic* if it is truly *acceptable*. Where a permittee has concerns about WET data quality, EPA recommends increasing the number of replicates in tests, even if the permitting authority has not yet adopted the TST approach.

6.0 SUMMARY OF THE TST APPROACH

EPA's TSD approaches are valid and can still be used by EPA Regions and their NPDES states. The TST approach is another statistical option for analyzing valid WET test data. The TST approach can be applied to acute (survival) and chronic (sublethal) endpoints and is appropriate to use for both freshwater and marine EPA WET test methods. The TST approach requires no more time or expertise than is presently expended when using the TSD hypothesis testing statistical approach and can be used with a well-recognized statistical test. Below is a brief outline of both the TST and TSD hypothesis testing approaches relevant to the information in this document and a short list of the benefits derived when using the TST approach.

TST Approach

- Considered additional guidance only—TST is a statistical approach for analyzing WET test data as an alternative option to the traditional hypothesis testing approach provided in EPA's TSD
- Expresses NPDES WET permit limit ~~as~~ no significant toxicity of the effluent at the in-stream waste concentration" using the TST analysis approach
- Provides a positive incentive to NPDES permittees to generate valid, high quality WET data to the permitting authority by improving test performance or increasing the number of replicates within a WET test (which increases statistical power of WET test)
- Addresses both false negative (declared non-toxic when actually toxic) and false positive (declared toxic when actually non-toxic) error rates in a WET test

Traditional Hypothesis Test (EPA TSD)

- Existing approaches remain valid and can still be used by NPDES permitting authorities
- In existing guidance, WET permit limits are expressed as *no observed effect concentration (NOEC)* at the IWC
- Provides relatively less incentive to permittees to generate high quality valid, WET data or to increase the number of replicates within a WET test to increase statistical power of a WET test
- False negative error rate in a WET test is not addressed

Benefits When Using the TST Approach in WET Data Analysis

- ***The TST approach*** is similar to statistical concepts used in other EPA programs and at other federal agencies
- ***Transparent RMDs.*** RMDs are transparent because they are incorporated into the WET data analysis process, e.g., what effect level is considered toxic and what effect level is considered acceptable.
- ***WET test method-specific alpha and beta error rates.*** Both error rates are directly incorporated into the TST statistical approach, thereby increasing confidence in WET test interpretation.
- ***High quality WET test data incentive.*** Provides a positive incentive for the permittee to generate valid, high quality WET data; better test performance (lower within-test

variability) helps ensure appropriate WET decisions using the TST approach (e.g., a truly acceptable effluent will be declared non-toxic).

- ***Streamlined, simpler statistical analysis.*** Flowchart for analyzing valid WET data under the TST approach is much simpler because fewer statistical tests are needed.
- ***RP analysis is simpler.*** Because the calculation of the individual test result, using the TST statistical approach, incorporates both error rates in the analysis, the RP determinations can rely on a direct calculation of the percent effect at the IWC. Thus, the RP procedures are much simpler to use than the RP statistical procedures recommended in the TSD.

APPENDIX A

STEP-BY-STEP PROCEDURES FOR ANALYZING VALID WHOLE EFFLUENT TOXICITY DATA USING THE TEST OF SIGNIFICANT TOXICITY APPROACH

APPENDIX A: STEP-BY-STEP PROCEDURES FOR ANALYZING VALID WET DATA USING THE TST APPROACH

The following is a step-by-step guide for using the TST approach to analyze valid WET data for the NPDES Program. This guide is applicable for a two-concentration valid WET data analysis of an in-stream waste concentration (IWC) or a receiving water concentration (RWC) compared to a control concentration. For further information regarding conducting WET tests and proper quality assurance/quality control needed, see the EPA WET test method manuals. Refer to the flowchart shown in Figure A-1 in this appendix as you proceed through this guide.

Step 1: Conduct WET test following procedures in the appropriate EPA WET test method manual. That includes following all test requirements specified in the method (USEPA 1995 for chronic west coast marine methods, USEPA 2002a for chronic freshwater test methods, USEPA 2002b for chronic east coast marine test methods, and USEPA 2002c for acute freshwater and marine WET test methods).

Step 2: For each test endpoint specified in the WET test method manual (e.g., survival and reproduction for the *Ceriodaphnia* chronic WET test method), follow Steps 3–7 below. Note that the guide refers to an effluent concentration tested, which is assumed to be the IWC as specified in the permit or a receiving water concentration for ambient testing. For example, if no mixing zone is allocated, the IWC is 100 percent effluent.

Note: If there is no variance (i.e., zero variance) in the endpoint in both concentrations being compared (i.e., all replicates in each concentration have the same exact response), then skip the remaining steps in the flowchart and do the following. Compute the percent difference between the control and the other concentration (e.g., IWC) and compare the percent difference against the RMD values of 25% for chronic and 20% for acute endpoints. Percent mean effect is calculated as:

$$\%\ \text{Effect at IWC} = \frac{\text{Mean Control Response} - \text{Mean Response at IWC}}{\text{Mean Control Response}} \times 100$$

If the percent mean response is $\geq$ the RMD, the sample is declared toxic and the test is "*Fail*". If the percent mean response is < the RMD, the sample is declared non-toxic and the test is "*Pass*".

Step 3: For data consisting of proportions from a binomial (response/no response; live/dead) response variable, the variance within the i^{th} treatment is proportional to $P_i (1 - P_i)$, where P_i is the expected proportion for the treatment. That clearly violates the homogeneity of variance assumption required by parametric procedures such as the TST procedure because the existence of a treatment effect implies different values of P_i for different treatments, i. Also, when the observed proportions are based on small samples, or when P_i is close to zero or one, the normality assumption might be invalid. The arcsine square root (arcsine $\sqrt{P}$) transformation is used for such data to stabilize the variance and satisfy the normality requirement. The square root of percent data (e.g., percent survival, percent fertilization), expressed as a decimal fraction (where 1.00 = 100 percent) for each treatment, is first calculated. The square root value is then

arcsine transformed before analysis in Step 4. Note: Excel and most statistical software packages can calculate arcsine values.

Step 4: Conduct Welch's t-test (Zar 1996) using Equation 1:

Equation 1

$$t = \frac{\overline{Y}_t - b \times \overline{Y}_c}{\sqrt{\frac{S_t^{\,2}}{n_t} + \frac{b^2 S_c^{\,2}}{n_c}}}$$

where

$\overline{Y}_c$ = Mean for the control

$\overline{Y}_t$ = Mean for the IWC

s_c^2 = Estimate of the variance for the control

s_t^2 = Estimate of the variance for the IWC

n_c = Number of replicates for the control

n_t = Number of replicates for the IWC

b = 0.75 for chronic test methods; 0.80 for acute test methods

Note on the use of Welch's t-test: Welch's t-test is appropriate to use when there are an unequal number of replicates between control and the IWC. When sample sizes of the control and treatment are the same (i.e., $n_t = n_{c)}$, Welch's t-test is equivalent to the usual Student's t-test (Zar 1996).

Step 5: Adjust the degrees of freedom (df) using Equation 2:

Equation 2

$$\upsilon = \frac{\left(\frac{S_t^{\,2}}{n_t} + \frac{b^2 S_c^{\,2}}{n_c}\right)^2}{\frac{\left(\frac{S_t^{\,2}}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^{\,2}}{n_c}\right)^2}{n_c - 1}}$$

For tests using Welch's t-test, df is the value obtained for *v* in Equation 2 above. Because *v is* most likely a non-integer, round *v* to the next smallest integer, and that number is the df.

Step 6: Using the calculated *t* value from Step 4, compare that *t* value with the critical *t* value table in Appendix B using the test method-specific alpha values shown in Table A-1. To obtain the correct critical *t* value, look across the table for the alpha value that corresponds to the WET test method (for the alpha value, see Appendix A, Table A-1) and then look down the table for the appropriate df.

Step 7: If the calculated *t* value is less than the critical *t* value, the IWC is declared toxic and the test result is *Fail*. If the calculated *t* value is greater than the critical *t* value, the IWC is not declared toxic and the test result is *Pass*.

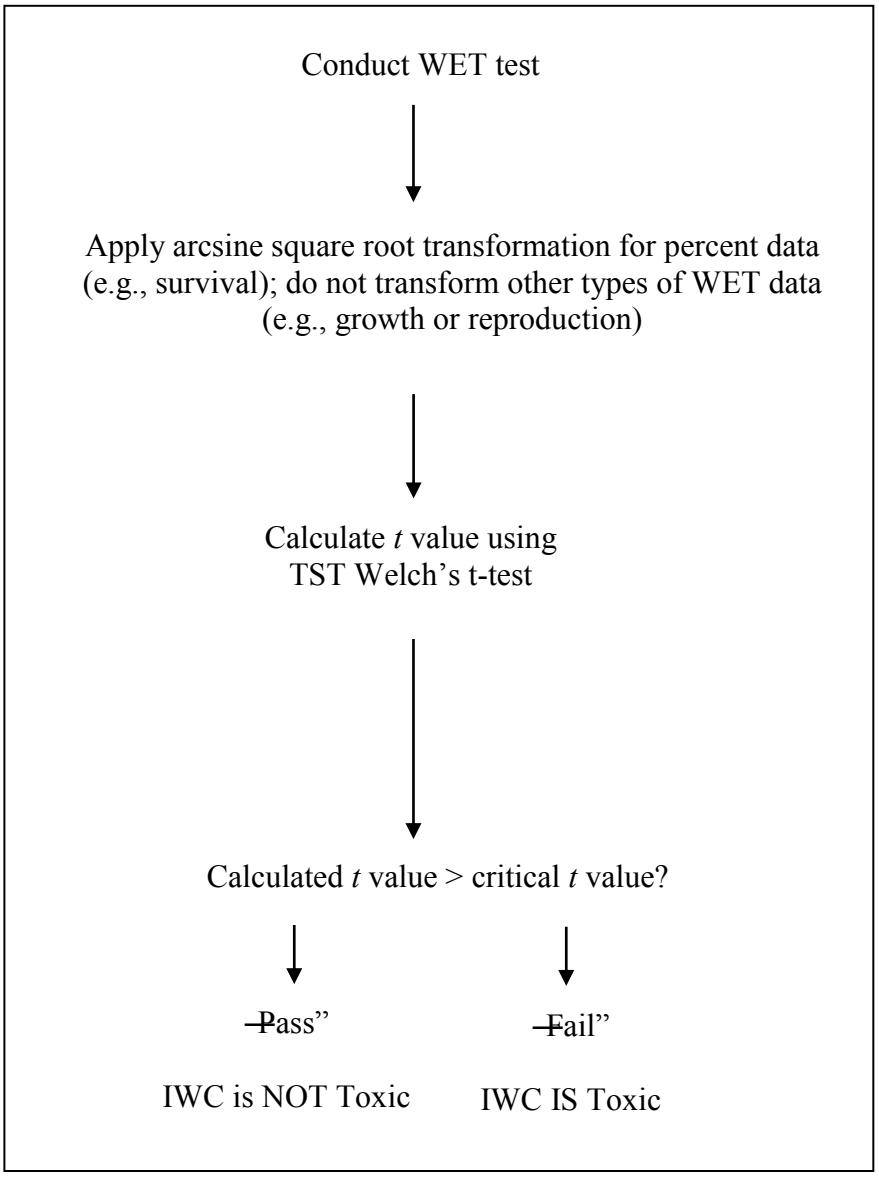

Figure A-1. Statistical flowchart for analyzing valid WET data using the TST approach for control and the IWC, receiving water, or stormwater.

Table A-1. Summary of alpha (α) levels or false negative rates recommended for different WET test methods using the TST approach

EPA WET test method	*b* value	Probability of declaring a toxic effluent non-toxic False negative (α) error[a]
Chronic Freshwater and East Coast Methods		
Ceriodaphnia dubia (water flea) survival and reproduction	0.75	0.20
Pimephales promelas (fathead minnow) survival and growth	0.75	0.25
Selenastrum capricornutum (green algae) growth	0.75	0.25
Americamysis bahia (mysid shrimp) survival and growth	0.75	0.15
Arbacia punctulata (Echinoderm) fertilization	0.75	0.05
Cyprinodon variegatus (Sheepshead minnow) and *Menidia beryllina* (inland silverside) survival and growth	0.75	0.25
Chronic West Coast Marine Methods		
Dendraster excentricus and *Strongylocentrotus purpuratus* (Echinoderm) fertilization	0.75	0.05
Atherinops affinis (topsmelt) survival and growth	0.75	0.25
Haliotis rufescens (red abalone), *Crassostrea gigas (oyster), Dendraster excentricus, Strongylocentrotus purpuratus* (Echinoderm) and *Mytilus sp* (mussel) larval development methods	0.75	0.05
Macrocystis pyrifera (giant kelp) germination and germ-tube length	0.75	0.05
Acute Methods		
Pimephales promelas (fathead minnow), *Cyprinodon variegatus* (Sheepshead minnow), *Atherinops affinis* (topsmelt), *Menidia beryllina* (inland silverside) acute survival[b]	0.80	0.10
Ceriodaphnia dubia, *Daphnia magna, Daphnia pulex*, *Americamysis bahia* acute survival[b]	0.80	0.10

Notes:

a. (1) declare a sample toxic at least 75 percent of the time (alpha $\leq$ 0.25) when there is unacceptable toxicity (20 percent effect for acute and 25 percent effect for chronic test methods) and (2) declare an effluent non-toxic no more than 5 percent of the time (beta $\leq$ 0.05) when the mean effect at the critical effluent concentration is 10 percent for both acute and chronic WET tests (including sublethal endpoints). For more discussion on the RMDs, see Section 2.1 of this document.

b. Based on four replicate test design

Case Example 1: Chronic *Ceriodaphnia* Reproduction Test with High Within-Test Variability

Step 1: Conduct WET test

Replicate/statistic	Control	Treatment
1	27	32
2	38	28
3	27	25
4	34	28
5	37	20
6	35	15
7	30	27
8	31	31
9	36	31
10	39	30
Mean	33.4	26.7
Std. deviation	4.402	5.417
N (# of replicates)	**10**	**10**

Step 2: Follow Steps 3–7 for each endpoint required in the test method

The following example is for chronic *Ceriodaphnia dubia* reproduction endpoint only.

Step 3: Transform data using an arcsine square root transformation, if necessary

Not necessary because reproduction is not percent data.

Step 4: Conduct Welch's t-test

$$t = \frac{\overline{Y}_t - b * \overline{Y}_c}{\sqrt{\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}}} = \frac{26.7 - (0.75 \times 33.4)}{\sqrt{\frac{29.34}{10} + \frac{(0.75)^2 (19.38)}{10}}} = 0.82$$

Step 5: Adjust the df

$$v = \frac{\left(\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}\right)^2}{\frac{\left(\frac{S_t^2}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^2}{n_c}\right)^2}{n_c - 1}} = \frac{\left(\frac{29.34}{10} + \frac{(0.75)^2 (19.38)}{10}\right)^2}{\frac{\left(\frac{29.34}{10}\right)^2}{10 - 1} + \frac{\left(\frac{(0.75)^2 (19.38)}{10}\right)^2}{10 - 1}} = 15$$

Step 6: Calculated *t* value > critical *t* value? 15 df and test method alpha = 0.20 (Table A-1)

Critical *t* value = 0.87

0.82 < 0.87

Step 7: Declare effluent toxic or not

Calculated *t* < critical *t* value. Therefore, ***effluent is declared toxic; test result is FAIL***.

Case Example 2: Chronic *Ceriodaphnia* Reproduction Test with Low Within-Test Variability

Step 1: Conduct WET test

Replicate/statistic	Control	Treatment
1	29	31
2	38	28
3	31	25
4	34	28
5	36	22
6	35	21
7	30	27
8	31	26
9	36	29
10	34	30
Mean	33.4	26.7
Std. deviation	2.989	3.268
N (# of replicates)	10	10

Step 2: Follow Steps 3–7 for each endpoint required in the test method

The following example is for chronic *Ceriodaphnia dubia* reproduction endpoint only.

Step 3: Transform data using an arcsine square root transformation, if necessary

Not necessary because reproduction is not percent data.

Step 4: Conduct Welch's t-test

$$t = \frac{\overline{Y}_t - b \times \overline{Y}_c}{\sqrt{\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}}} = \frac{26.7 - (0.75 \times 33.4)}{\sqrt{\frac{10.68}{10} + \frac{(0.75)^2\ (8.93)}{10}}} = 1.32$$

Step 5: Adjust the df

$$v = \frac{\left(\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}\right)^2}{\frac{\left(\frac{S_t^2}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^2}{n_c}\right)^2}{n_c - 1}} = \frac{\left(\frac{10.68}{10} + \frac{(0.75)^2 (8.93)}{10}\right)^2}{\frac{\left(\frac{10.68}{10}\right)^2}{10 - 1} + \frac{\left(\frac{(0.75)^2\ (8.93)}{10}\right)^2}{10 - 1}} = 16$$

Step 6: Calculated *t* value > critical *t* value? 16 df and test method alpha = 0.20 (Table A-1)

Critical *t* value = 0.86

1.32 > 0.86

Step 7: Declare effluent toxic or not

Calculated *t* > critical *t* value. Therefore, ***effluent is declared Non-Toxic; test result is PASS***.

Case Example 3: Benefit of Increased Replication in Chronic Fish Growth Test with Low Mean Effect and High Within-Test Variability

Step 1: Conduct WET test

Replicate/statistic	Control	Treatment
1	0.366	0.303
2	0.399	0.379
3	0.354	0.311
4	0.422	0.236
Mean	0.385	0.307
Std. deviation	0.031	0.058
N (# of replicates)	**4**	**4**

Step 2: Follow Steps 3–7 for each endpoint required in the test method

Step 3: Transform data using an arcsine square root transformation, if necessary

Not necessary because growth is not percent data.

Step 4: Conduct Welch's t-test

$$t = \frac{\overline{Y}_t - b \times \overline{Y}_c}{\sqrt{\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}}}$$

$$= \frac{0.307 - (0.75 \times 0.385)}{\sqrt{\left(\frac{0.00342}{4} + \frac{(0.75)^2\ (0.00096)}{4}\right)}} = 0.58$$

Step 5: Adjust the df

$$v = \frac{\left(\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}\right)^2}{\frac{\left(\frac{S_t^2}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^2}{n_c}\right)^2}{n_c - 1}}$$

$$= \frac{\left(\frac{0.00342}{4} + \frac{(0.75)^2\ (0.00096)}{4}\right)^2}{\frac{\left(\frac{0.00342}{4}\right)^2}{4-1} + \frac{\left(\frac{(0.75)^2\ (0.00096)}{4}\right)^2}{4-1}} = 4$$

Step 6: Calculated *t* value > critical *t* value? 4 df, alpha = 0.25 (Table A-1); Critical *t* value = 0.74

0.58 < 0.74

Step 7: *Effluent is declared toxic, test result is FAIL.*

Step 1: Conduct WET test

Replicate/statistic	Control	Treatment
1	0.366	0.303
2	0.399	0.379
3	0.354	0.311
4	0.422	0.236
5	0.343	0.364
6	0.407	0.247
Mean	0.382	0.307
Std. deviation	0.032	0.058
N (# of replicates)	**6**	**6**

Step 2: Follow Steps 3–7 for each endpoint required in the test method

Step 3: Transform data using an arcsine square root transformation, if necessary

Not necessary because growth is not percent data.

Step 4: Conduct Welch's t-test

$$t = \frac{\overline{Y}_t - b \times \overline{Y}_c}{\sqrt{\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}}}$$

$$= \frac{0.307 - (0.75 \times 0.382)}{\sqrt{\frac{0.00342}{6} + \frac{(0.75)^2 (0.00101)}{6}}} = 0.79$$

Step 5: Adjust the df

$$v = \frac{\left(\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}\right)^2}{\frac{\left(\frac{S_t^2}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^2}{n_c}\right)^2}{n_c - 1}}$$

$$= \frac{\left(\frac{0.00342}{6} + \frac{(0.75)^2\ (0.00101)}{6}\right)^2}{\frac{\left(\frac{0.00342}{6}\right)^2}{6-1} + \frac{\left(\frac{(0.75)^2\ (0.00101)}{6}\right)^2}{6-1}} = 7$$

Step 6: Calculated *t* value > critical *t* value? 7 df, alpha = 0.25 (Table A-1); Critical *t* value = 0.71

0.79 > 0.71

Step 7: *Effluent is declared Non-Toxic; test result is PASS.*

Case Example 4: Fish Acute Toxicity Test Example

Step 1: Conduct WET test

Replicate/statistic	Control	Treatment
1	10	10
2	10	8
3	10	9
4	10	8
Mean	10	8.75
Variance	0.000	0.917
N (# of replicates)	**4**	**4**

Step 2: Follow Steps 3–7 for each endpoint required in the test method

The following example is for acute *Pimephales promelas* survival endpoint only.

Step 3: Transform data using an arcsine square root transformation

Replicate/statistic	Control	Treatment
1	1.412	1.412
2	1.412	1.107
3	1.412	1.249
4	1.571	1.107
Mean	1.412	1.218
Variance	0.000	0.021
N (# of replicates)	**4**	**4**

Step 4: Conduct Welch's t-test

$$t = \frac{\overline{Y}_t - b \times \overline{Y}_c}{\sqrt{\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}}} = \frac{1.218 - (0.80 \times 1.412)}{\sqrt{\frac{0.021}{4} + \frac{(0.80)^2\ (0.000)}{4}}} = 1.2297$$

Step 5: Adjust the df

$$v = \frac{\left(\frac{S_t^2}{n_t} + \frac{b^2 S_c^2}{n_c}\right)^2}{\frac{\left(\frac{S_t^2}{n_t}\right)^2}{n_t - 1} + \frac{\left(\frac{b^2 S_c^2}{n_c}\right)^2}{n_c - 1}} = \frac{\left(\frac{0.021}{4} + \frac{(0.80)^2\ (0.000)}{4}\right)^2}{\frac{\left(\frac{0.021}{4}\right)^2}{4-1} + \frac{\left(\frac{(0.80)^2\ (0.000)}{4}\right)^2}{4-1}} = 3$$

Step 6: Calculated *t* value > critical *t* value? 3 df, alpha = 0.10 (Table A-1)

Critical *t* value = 1.64

1.229 < 1.64

Step 7: Declare effluent toxic or not

Therefore, ***effluent is declared toxic; test result is FAIL***.

APPENDIX C

APPLICATION OF THE TEST OF SIGNIFICANT TOXICITY APPROACH TO AMBIENT TOXICITY PROGRAMS

APPENDIX C: APPLICATION OF THE TST APPROACH TO AMBIENT TOXICITY PROGRAMS

In ambient and stormwater toxicity testing, a laboratory control and a single concentration (i.e., 100 percent ambient water or stormwater) are often tested. In these two-concentration WET tests, the objective is to determine if a given sample or site water is toxic, as indicated by a significantly different organism response compared to the control. In the WET testing design, the determination of Pass or Fail (i.e., non-toxic or toxic) is ascertained using a traditional t-test (USEPA 2002c). EPA test methods recommend (USEPA 1995, 2002a, 2002b, 2002c) that the statistical significance (i.e., Pass/Fail) of a two-sample test design for ambient and stormwater toxicity testing be determined only using either a modified t-test (if homogeneity of variance is not achieved) or a traditional t-test (if homogeneity of variance is achieved).

To demonstrate the value of the TST approach in ambient toxicity programs, ambient toxicity test data from California's Surface Water Ambient Monitoring Program (SWAMP) was used for 409 chronic tests for *Ceriodaphnia dubia* and 256 chronic tests for *Pimephales promelas* using EPA's 2002 WET test methods (USEPA 2002a). Valid WET data for each EPA WET test method were subjected to the same statistical analyses as described in Section 2 of this document.

Chronic *Ceriodaphnia dubia* Ambient Toxicity Tests

Table C-1 summarizes results of the 409 *Ceriodaphnia dubia* ambient toxicity tests analyzed and an $\alpha = 0.20$ for this test method. Although the majority of the tests examined resulted in the same decision using either the TST or the traditional t-test approach, approximately 6 percent of the tests (24 tests) would have been declared non-toxic using the traditional t-test approach with mean effect levels $\geq$ 25 percent. In addition, 2 percent of the tests (7 tests) would have been declared toxic using the traditional t-test approach at mean effect levels < 15 percent and as low as 7 percent.

Table C-1. Comparison of results of chronic *Ceriodaphnia* ambient toxicity tests using the TST approach and the traditional t-test analysis. $\alpha = 0.20$ and *b* value = 0.75 for the TST approach. $\alpha = 0.05$ for the traditional hypothesis testing approach

Both approaches declare toxic	Only TST declares toxic	Only traditional approach declares toxic	Both approaches declare non-toxic
19.8%	5.9%	1.7%	72.6%

Figure C-1 shows ranges of CV values observed in *Ceriodaphnia dubia* ambient toxicity tests for those samples declared toxic using either the TST approach or the traditional t-test, but not both approaches. As expected, within-test variability was relatively high (higher CVs) for those tests found non-toxic using a t-test but toxic using the TST approach. The results demonstrate the lack of control of false negative rates using the traditional hypothesis testing approach when control variability is relatively high. Under those conditions, the traditional t-test did not have the power to detect toxicity when it was present. Figure C-1 also demonstrates that the TST approach recognizes a negligible effect as non-toxic when within-test variability is relatively low and the

mean percent effect is well below the risk management level of 25 percent. Under such conditions, the traditional t-test declared some samples toxic using this WET test method, even when the mean effect was as little as 7 percent. The TST approach, however, declared all such samples non-toxic using the recommended $\alpha = 0.20$. Thus, the TST approach reduces the number of tests declared as toxic when effects are actually well below the risk management decision.

Chronic *Ceriodaphnia* ambient WET tests that are identified as non-toxic (Pass) using the traditional hypothesis approach (NOEC) generally have high within-test variability (high control CVs) as compared to using the TST approach.

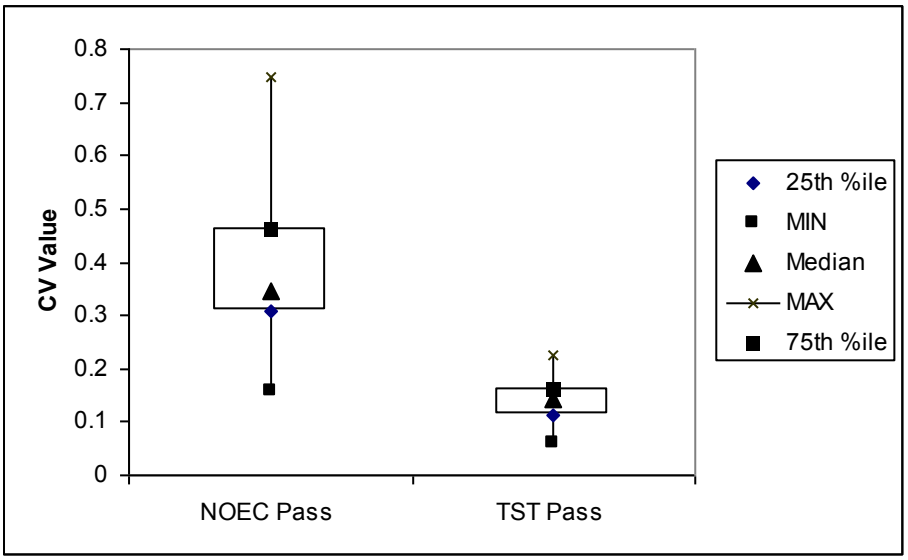

Figure C-1. Range of CV values observed in chronic *C. dubia* ambient toxicity tests for samples that were found to be non-toxic using the standard t-test but toxic using the TST approach (NOEC Pass) and for those samples declared toxic using t-test but not the TST approach (TST Pass). California's SWAMP WET test data.

Similar to the *Ceriodaphnia* ambient test data, within-test variability was higher in those chronic fathead minnow ambient tests found *non-toxic* using a t-test but toxic using the TST approach (Figure C-2). Similarly, those tests declared *non-toxic* by the TST approach but toxic using t-test had lower within-test variability and mean effect levels < 25 percent (Figure C-2). Thus, similar to the chronic *Ceriodaphnia* ambient tests, data from chronic fathead minnow ambient tests demonstrate that the TST approach can provide as much protection as the traditional t-test approach while also identifying those samples that are truly acceptable from a regulatory management decision.

Fish ambient WET tests that are identified as non-toxic using the traditional hypothesis approach (NOEC) generally have high within-test variability (high control CVs) as compared to using the TST approach.

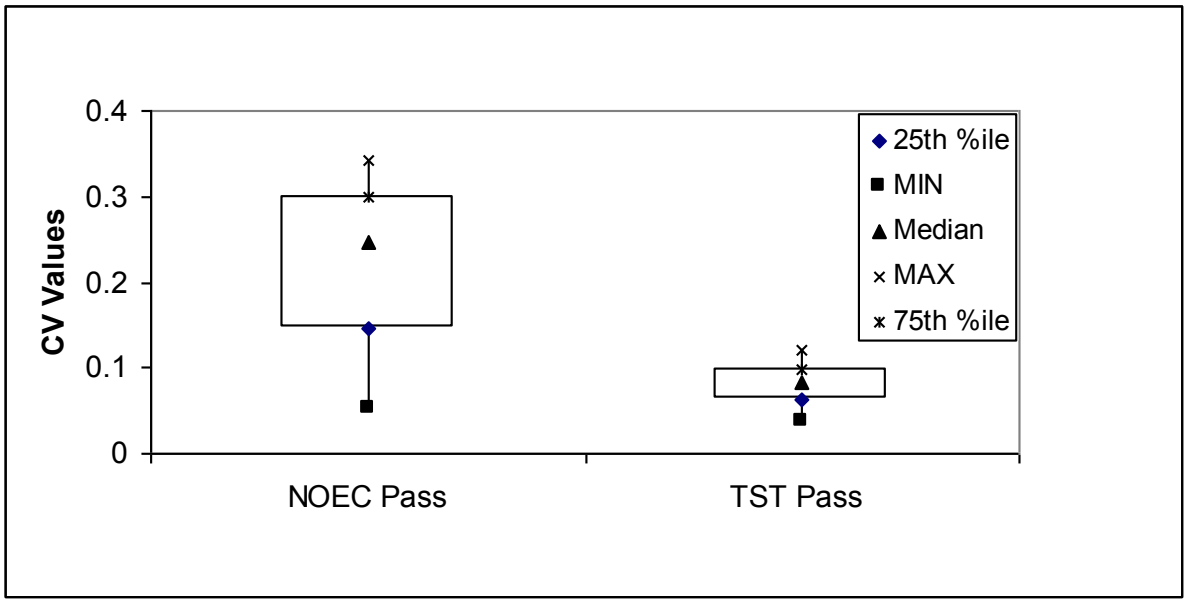

Figure C-2. Range of CV values observed in chronic *P. promelas* ambient toxicity tests for samples that were declared to be non-toxic using the standard t-test but toxic using the TST approach (NOEC Pass) and for those samples declared toxic using t-test but not the TST approach (TST Pass). California's SWAMP WET test data.

APPENDIX D

EXAMPLE NATIONAL POLLUTANT DISCHARGE ELIMINATION SYSTEM PERMIT LANGUAGE USING THE TEST OF SIGNIFICANT TOXICITY APPROACH

APPENDIX D: EXAMPLE NPDES PERMIT LANGUAGE USING THE TST APPROACH

ACUTE WHOLE EFFLUENT TOXICITY (WET) NPDES PERMIT LANGUAGE

xx. <u>Acute Whole Effluent Toxicity (WET) Requirements</u>

1. Monitoring Frequency

The permittee must conduct ***monthly/quarterly/semiannual*** acute toxicity tests on 24-hour composite effluent samples. Once each calendar year, at a different time of year from the previous years, the permittee must split a 24-hour composite effluent sample and concurrently conduct two toxicity tests using a fish and an invertebrate species; the permittee must then continue to conduct routine ***monthly/quarterly/semiannual*** toxicity testing using the single, most sensitive species.

Acute toxicity test samples must be collected for each point of discharge at the designated NPDES sampling station for the effluent (i.e., downstream from the last treatment process and any in-plant return flows where a representative effluent sample can be obtained). During years ***1, 2, 3, 4, and 5*** of the permit, a split of each sample must be analyzed for all other monitored parameters at the minimum frequency of analysis specified by the effluent monitoring program.

2. Freshwater Species and WET Test Methods

Species and short-term WET test methods for estimating the acute toxicity of NPDES effluents are in the fifth edition of *Methods for Measuring the Acute Toxicity of Effluents and Receiving Waters to Freshwater and Marine Organisms* (EPA/821/R-02/012, 2002; Table IA, 40 CFR Part 136). The permittee must conduct 96-hour static renewal toxicity tests with the following vertebrate and invertebrate species, respectively:

- ***Vertebrate:*** The fathead minnow, *Pimephales promelas* (Acute Toxicity Test Method 2000.0)
- ***Invertebrate:*** The daphnid, *Ceriodaphnia dubia* (Acute Toxicity Test Method 2002.0)

3. Acute WET Permit Triggers

a. There are no acute toxicity effluent limits for this discharge. For this permit, the determination of Pass or Fail from a multiple-effluent concentration acute toxicity test at the IWC is determined using the Test of Significant Toxicity (TST) approach that is described in the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document* (EPA/833/R-10-003). The acute WET permit trigger is any one WET test where a test result is *Fail* (during the monthly reporting period) at the acute in-stream waste concentration (IWC). For this discharge, the IWC is **XXX** percent (e.g., either is 100 percent or an effluent at the mixing zone to be determined at the time of permit issuance) effluent. To calculate

either a Pass or Fail of a multiple-effluent concentration acute toxicity test at the IWC, follow the instructions in Appendix A in the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document*. A *Pass* result indicates no toxicity of the multiple-effluent concentration test at the IWC, and a *Fail* result indicates toxicity of the multiple-effluent concentration test at the IWC. The permittee must report either a *Pass* or a *Fail* on the Discharge Monitoring Report (DMR) form. If a result is reported as Fail, the permittee must follow Section 6 (Accelerated Toxicity Testing and TRE/TIE Process) of this permit.

- OR -

3. Acute WET Permit Limit

b. There is an acute toxicity effluent limit for this discharge. For this permit, the determination of Pass or Fail from a multiple-effluent concentration acute toxicity test at the IWC is determined using the Test of Significant Toxicity (TST) approach which is described in the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document* (EPA/833-R-10-003). The acute WET permit trigger is any one WET test where a test result is *Fail* (during the monthly reporting period) at the chronic in-stream waste concentration (IWC). For this discharge, the IWC is **XXX** percent (e.g., either is 100 percent or an effluent at the mixing zone to be determined at time of permit issuance) effluent. To calculate either a Pass or Fail of the multiple-effluent concentration acute toxicity test at the IWC, follow the instructions in Appendix A in the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document*. A Pass result indicates no toxicity of the multiple-effluent concentration at the IWC and a Fail result indicates toxicity of the multiple-effluent concentration test at the IWC. The permittee must report either a *Pass* or a *Fail* on the DMR form. If a result is reported as Fail, the permittee must follow Section 6 (Accelerated Toxicity Testing and TRE/TIE Process) of this permit.

4. Quality Assurance – EPA WET Test Methods

a. Quality assurance measures, instructions, and other recommendations and requirements are in the EPA 2002 WET test methods manual previously referenced.

b. This permit is subject to a determination of Pass or Fail from a multiple-effluent concentration acute toxicity test at the IWC (for statistical flowchart and procedures, see Appendix A, Figure A-1 of the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document*). The acute in-stream waste concentration (IWC) for this discharge is **XXX** percent effluent.

c. Effluent dilution water and control water should be prepared and used as specified in the EPA WET test methods manual *Methods for Measuring the Acute Toxicity of Effluents and Receiving Waters to Freshwater and Marine Organisms* (EPA/821/R-02/012, 2002).

d. If organisms are not cultured in-house, concurrent testing with a reference toxicant must be conducted. If organisms are cultured in-house, monthly reference toxicant testing is sufficient. Reference toxicant tests and effluent toxicity tests must be conducted using the same test conditions (e.g., same test duration).

e. If either the reference toxicant or effluent toxicity tests do not meet all test acceptability criteria in the EPA WET test methods manual, the permittee must resample and retest within 14 days.

f. If the discharged effluent is chlorinated, chlorine must not be removed from the effluent sample before toxicity testing without written approval by the permitting authority.

5. Initial Investigation TRE Work Plan

Within 90 days of the permit effective date, the permittee must prepare and submit to the permitting authority a copy of its Initial Investigation Toxicity Reduction Evaluation (TRE) Work Plan (1–2 pages) for review. That plan must include steps the permittee intends to follow if toxicity is measured above an acute WET permit limit or trigger and should include the following, at minimum:

a. A description of the investigation and evaluation techniques that would be used to identify potential causes and sources of toxicity, effluent variability, and treatment system efficiency.

b. A description of methods for maximizing in-house treatment system efficiency, good housekeeping practices, and a list of all chemicals used in operations at the facility.

c. If a Toxicity Identification Evaluation (TIE) is necessary, an indication of who would conduct the TIEs (i.e., an in-house expert or outside contractor).

6. Accelerated Toxicity Testing and TRE/TIE Process

a. If an acute WET permit limit or trigger is exceeded and the source of toxicity is known (e.g., a temporary plant upset), the permittee must conduct one additional toxicity test using the same species and EPA WET test method. This WET test must begin within 14 days of receipt of WET test results exceeding an acute WET permit limit or trigger. If the additional toxicity test does not exceed an acute WET permit limit or trigger, the permittee may return to the regular testing frequency.

b. If an acute WET permit limit or trigger is exceeded and the source of toxicity is not known, the permittee must conduct six additional toxicity tests using the same species and EPA WET test method, approximately every two weeks, over a 12-week period. This testing must begin within 14 days of receipt of WET test results exceeding an acute WET permit limit or trigger. If none of the additional toxicity tests exceed an acute WET permit limit or trigger, the permittee may return to the regular testing frequency.

c. If one of the additional toxicity tests (in paragraphs 6.a or 6.b) exceeds an acute WET permit limit or trigger, within 14 days of receipt of this WET test result, the permittee must initiate a TRE using, according to the type of treatment facility, EPA WET TRE manual, *Toxicity Reduction Evaluation Guidance for Municipal Wastewater Treatment Plants* (EPA/833/B-99/002, 1999) or EPA WET TRE manual, *Generalized Methodology for Conducting Industrial Toxicity Reduction Evaluations* (EPA/600/2-88/070, 1989). In conjunction, the permittee must develop and implement a Detailed TRE Work Plan that must consist of the following: further actions undertaken by the permittee to investigate, identify, and correct the causes of toxicity; actions the permittee will take to mitigate the effects of the discharge and prevent the recurrence of toxicity; and a schedule for such actions.

d. The permittee may initiate a TIE as part of a TRE to identify the causes of toxicity using the same species and EPA WET test method and, as guidance, EPA WET TIE/TRE method manuals: *Methods for Aquatic Toxicity Identification Evaluations: Phase I Toxicity Characterization Procedures* (EPA/600/6-91/003, 1991); *Methods for Aquatic Toxicity Identification Evaluations, Phase II Toxicity Identification Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA/600/R-92/080, 1993); *Methods for Aquatic Toxicity Identification Evaluations, Phase III Toxicity Confirmation Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA/600/R-92/081, 1993).

7. Reporting of Acute Toxicity Monitoring Results

a. The permittee must submit a full laboratory report for all toxicity testing as an attachment to the Discharge Monitoring Report (DMR) for the month in which the toxicity test was conducted; the laboratory report must contain the following: the toxicity test results, the dates of sample collection and initiation of each toxicity test; all results for effluent parameters monitored concurrently with the toxicity test(s); and progress reports on TRE/TIE investigations.

b. The permittee must provide the actual test endpoint responses for the control (i.e., control mean) and IWC concentration (i.e., IWC mean) for each WET test conducted to make it easier for permit writers to find the necessary WET test results when determining WET RP.

c. The permittee must notify the permitting authority in writing within 14 days of exceedance of an acute WET permit limit or trigger. Such notification must describe actions the permittee has taken or will take to investigate, identify, and correct the causes of toxicity; the status of actions required by this permit; and schedule for actions not yet completed; or reason(s) that no action has been taken.

8. Permit Reopener for Acute Toxicity

In accordance with 40 CFR Parts 122 and 124, this permit may be modified to include effluent limitations or permit conditions to address acute toxicity in the effluent or receiving waterbody, as a result of the discharge; or to implement new, revised, or newly interpreted water quality standards applicable to acute toxicity.

CHRONIC WET NPDES PERMIT LANGUAGE

xx. Chronic Whole Effluent Toxicity (WET) Requirements

1. Monitoring Frequency

The permittee must conduct ***monthly/quarterly/semiannual*** chronic toxicity tests on 24-hour composite effluent samples. Once each calendar year, at a different time of year from the previous years, the permittee must split a 24-hour composite effluent sample and concurrently conduct three toxicity tests using a fish, an invertebrate, and an alga species; the permittee must continue to conduct routine ***monthly/quarterly/semiannual*** toxicity testing using the single, most sensitive species.

Chronic toxicity test samples must be collected for each point of discharge at the designated NPDES sampling station for the effluent (i.e., downstream from the last treatment process and any in-plant return flows where a representative effluent sample can be obtained). During years ***1, 2, 3, 4, and 5*** of the permit, a split of each sample must be analyzed for all other monitored parameters at the minimum frequency of analysis specified by the effluent monitoring program.

2. Freshwater Species and EPA WET Test Methods

Species and short-term EPA WET test methods for estimating the chronic toxicity of NPDES effluents are in the fourth edition of *Short-term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Freshwater Organisms* (EPA/821/R-02/013, 2002; Table IA, 40 CFR Part 136). The permittee must conduct static renewal toxicity tests with the following:

- Fathead minnow, *Pimephales promelas* (Larval Survival and Growth Test Method 1000.0)
- Daphnid, *Ceriodaphnia dubia* (Survival and Reproduction Test Method 1002.0);
- Green alga, *Selenastrum capricornutum* (also named *Raphidocelis subcapitata*) (Growth Test Method 1003.0).

3. Chronic WET Permit Triggers

a. There are no chronic toxicity effluent limits for this discharge. The chronic WET permit trigger is any one WET test (either biological endpoint of survival or sublethal) where a test result is *Fail* (during the monthly reporting period) at the chronic in-stream waste concentration (IWC). For this discharge, the IWC is **XXX** percent (e.g., either is 100 percent or an effluent at the mixing zone to be determined at time of permit issuance) effluent. To calculate either a Pass or Fail of the multiple-effluent concentration chronic toxicity test at the IWC, follow the instructions in Appendix A in the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document* (EPA/833-R-10-003). A Pass result indicates no toxicity at the IWC, and a Fail result indicates toxicity at the IWC. The

permittee must report either a Pass or a Fail on the DMR form. If a result is reported as Fail, the permittee must follow Section 7 (Reporting of Chronic Toxicity Monitoring Results) of this permit.

- OR -

3. Chronic WET Permit Limits

b. There is a chronic toxicity effluent limit for this discharge. The chronic WET permit trigger is any one WET test (either biological endpoint of survival or sublethal) where a test result is *Fail* (during the monthly reporting period) at the chronic in-stream waste concentration (IWC). For this discharge, the IWC is **XXX** percent (e.g., either is 100 percent or an effluent at the mixing zone to be determined at time of permit issuance) effluent. To calculate either a Pass or Fail of the multiple-effluent concentration chronic toxicity test at the IWC, follow the instructions in Appendix A in the *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document* (EPA/833-R-10-003). A Pass result indicates no toxicity at the IWC, and a Fail result indicates toxicity at the IWC. The permittee must report either a Pass or a Fail on the DMR form. If a result is reported as Fail, the permittee must follow Section 7 (Reporting of Chronic Toxicity Monitoring Results) of this permit.

4. Quality Assurance – EPA WET Test Methods

a. Quality assurance measures, instructions, and other recommendations and requirements are in the EPA WET test methods manual previously referenced in this permit.

b. This permit is subject to a determination of Pass or Fail from a multiple-effluent concentration chronic toxicity test at the IWC (for statistical flowchart and procedures, see *National Pollutant Discharge Elimination System Test of Significant Toxicity Implementation Document*, Appendix A, Figure A-1). The chronic in-stream waste concentration (IWC) for this discharge is **XXX** percent (e.g., either is 100 percent or an effluent at the mixing zone to be determined) effluent.

c. Effluent dilution water and control water should be standard synthetic dilution water as described in the EPA WET test methods manual, *Short-term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Freshwater Organisms* (EPA/821/R-02/013, 2002). If the dilution water is different from test organism culture water, a second control using culture water must also be used.

d. If organisms are not cultured in-house, concurrent testing with a reference toxicant must be conducted. If organisms are cultured in-house, monthly reference toxicant testing is sufficient. Reference toxicant tests and effluent toxicity tests must be conducted using the same test conditions (e.g., same test duration).

e. If either the reference toxicant or effluent toxicity tests do not meet all test acceptability criteria in the EPA WET test methods manual, the permittee must resample and retest within 14 days.

f. Following Paragraph 10.2.6.2 of the freshwater EPA WET test methods manual, all chronic toxicity test results from the multi-concentration tests required by this permit must be reviewed and reported according to EPA guidance on the evaluation of concentration-response relationships in *Method Guidance and Recommendations for Whole Effluent Toxicity (WET) Testing (40 CFR Part 136)* (EPA/821/B-00-004, 2000).

g. If the discharged effluent is chlorinated, chlorine must not be removed from the effluent sample before toxicity testing without written approval by the permitting authority.

5. Initial Investigation TRE Work Plan

Within 90 days of the permit effective date, the permittee must prepare and submit to the permitting authority a copy of its Initial Investigation Toxicity Reduction Evaluation (TRE) Work Plan (1–2 pages) for review. That plan must contain steps the permittee intends to follow if toxicity is measured above a chronic WET permit limit or trigger and should include the following, at minimum:

a. A description of the investigation and evaluation techniques that would be used to identify potential causes and sources of toxicity, effluent variability, and treatment system efficiency.

b. A description of methods for maximizing in-house treatment system efficiency, good housekeeping practices, and a list of all chemicals used in operations at the facility.

c. If a Toxicity Identification Evaluation (TIE) is necessary, an indication of who would conduct the TIEs (i.e., an in-house expert or outside contractor).

6. Accelerated Toxicity Testing and TRE/TIE Process

a. If a chronic WET permit limit or trigger is exceeded and the source of toxicity is known (e.g., a temporary plant upset), the permittee must conduct one additional toxicity test using the same species and EPA WET test method. This WET test must begin within 14 days of receipt of WET test results exceeding a chronic WET permit limit or trigger. If the additional toxicity test does not exceed a chronic WET permit limit or trigger, the permittee may return to their regular testing frequency.

b. If a chronic WET permit limit or trigger is exceeded and the source of toxicity is not known, the permittee must conduct six additional toxicity tests using the same species and EPA WET test method, approximately every two weeks, over a 12 week period. This testing must begin within 14 days of receipt of WET test results exceeding a chronic WET permit limit or trigger. If none of the additional toxicity tests exceed a chronic WET permit limit or trigger, the permittee may return to their regular testing frequency.

c. If one of the additional toxicity tests (in paragraphs 6.a or 6.b) exceeds a chronic WET permit limit or trigger, within 14 days of receipt of this WET test result, the permittee must initiate a TRE using as guidance, according to the type of treatment facility, the EPA TRE manual, *Toxicity Reduction Evaluation Guidance for Municipal Wastewater Treatment Plants* (EPA/ 833/B-99/002, 1999) or EPA TRE manual, *Generalized Methodology for Conducting Industrial Toxicity Reduction Evaluations* (EPA/600/2-88/070, 1989). In conjunction, the permittee must develop and implement a Detailed TRE Work Plan that must contain the following: further actions undertaken by the permittee to investigate, identify, and correct the causes of toxicity; actions the permittee will take to mitigate the effects of the discharge and prevent the recurrence of toxicity; and a schedule for such actions.

d. The permittee may initiate a TIE as part of a TRE to identify the causes of toxicity using the same species and EPA WET test method and, as guidance, EPA WET TIE/TRE method manuals: *Toxicity Identification Evaluation: Characterization of Chronically Toxic Effluents, Phase I* (EPA/600/6-91/005F, 1992); *Methods for Aquatic Toxicity Identification Evaluations, Phase II Toxicity Identification Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA/600/R-92/080, 1993); *Methods for Aquatic Toxicity Identification Evaluations, Phase III Toxicity Confirmation Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA/600/R-92/081, 1993).

7. Reporting of Chronic Toxicity Monitoring Results

a. The permittee must submit a full laboratory report as an attachment to the DMR for all toxicity testing for the month in which the toxicity test was conducted; the laboratory report must contain the following: the toxicity test results, the dates of sample collection and initiation of each toxicity test; all results for effluent parameters monitored concurrently with the toxicity test(s); and progress reports on TIE/TRE investigations.

b. The permittee must provide the actual test endpoint responses for the control (i.e., control mean) and IWC concentration (i.e., IWC mean) for each WET test conducted to make it easier for permit writers to find the necessary WET test results when determining WET RP.

c. The permittee must notify the permitting authority in writing within 14 days of exceedance of a chronic WET permit limit or trigger. The notification must describe actions the permittee has taken or will take to investigate, identify, and correct the causes of toxicity; the status of actions required by this permit; and schedule for actions not yet completed; or reason(s) that no action has been taken.

8. Permit Reopener for Chronic Toxicity

In accordance with 40 CFR Parts 122 and 124, this permit may be modified to include effluent limitations or permit conditions to address chronic toxicity in the effluent or receiving waterbody, as a result of the discharge; or to implement new, revised, or newly interpreted water quality standards applicable to chronic toxicity.

APPENDIX E

WHOLE EFFLUENT TOXICITY REASONABLE POTENTIAL ANALYSIS USING THE TEST OF SIGNIFICANT TOXICITY APPROACH

APPENDIX E: WET RP ANALYSIS USING THE TST APPROACH

For reasonable potential (RP) calculations using the TST approach, EPA recommends that permitting authorities use all the valid WET test data generated during the current permit term and any additional valid data that are submitted as part of the permit renewal application. The permitting authority should be using at least a minimum of four valid WET tests to address effluent representativeness using the TST RP approach. WET test data are then analyzed according to the TST approach using the IWC and control test concentrations for all valid WET test data available. For the RP approach, data sets with fewer than four valid WET data points should be assessed using EPA's Technical Support Document (TSD) RP approach because it addresses small WET data sets by incorporating an RP multiplying factor (see Section 3.2.2 of the TSD, p. 54) to account for effluent variability in small WET data sets.

EPA also recommends that states request that their permittees provide the actual test endpoint responses for the control (i.e., mean of control) and IWC concentration (i.e., mean of IWC) for each WET test conducted to make it easier for permit writers to find the necessary data with which to calculate WET RP with this approach. EPA recommends that permitting authorities decide up front which approach (the 1991 TSD approach, the TST approach, or another scientifically defensible approach that is sufficient to meet the statutory and regulatory requirements) they will incorporate and consistently use in their state's NPDES implementation procedures, including for their RP procedures. Permitting authorities should consistently use the selected WET statistical approach in all the state NPDES permits.

All valid WET test data are then analyzed according to the TST approach using the IWC and control test concentrations. If WET test data are available and the TST statistical approach indicates that the IWC is toxic in any WET test (~~"~~effluent **cause(s)** toxicity"), RP has been demonstrated (40 CFR 122.44(d)(1)(i)). For example, if results of five WET tests are available using the TST approach and the results are Pass, Pass, Fail, Pass, Pass, because at least one test was a Fail (i.e., TST declared the effluent toxic in at least one test), RP has been demonstrated.

To address concerns regarding the ~~"~~**potential** to cause or contribute to toxicity," a second assessment is applied to determine whether the effluent has RP even if all test results are *Pass* using the TST approach.

The current TST approach results in four outcomes with respect to RP at the IWC:

1. **Caused (effluent is toxic):** RP is demonstrated if any one test using the TST approach indicates a test result is *Fail* (i.e., using the statistical test (Appendix A) and *t* table (Appendix B), the test result is *Fail*; see Example A below in Table E-1);
2. **Potential to Cause:** Effluent has reasonable potential to cause (RP is demonstrated) if any test exhibits a mean effect at the IWC > 10 percent as compared to the mean control response, even if the test result is *Pass* using TST (see examples B-D, Table E-1); and
3. **No RP (effluent is non-toxic at the IWC):** Effluent does not cause or have reasonable potential to cause if the tests are each a *Pass* using the TST approach and the mean effect at the IWC is always ≤ 10 percent.

4. **Insufficient valid WET data (fewer than 4 tests or no data):** If fewer than four valid WET data are available, follow the TSD RP procedure for WET.

The second outcome is where the determination of RP is critical to demonstrate that the discharge has the reasonable *potential* to cause an excursion above the state toxicity water quality standards. In the TST approach, the regulatory management decision threshold for non-toxicity in WET tests under the NPDES WET Program is 10 percent mean effect at the IWC. At or below that mean effect level, the TST approach is designed to declare a WET test as non-toxic (i.e., *Pass*) most (at least 95 percent) of the time to help control for false positives. For purposes of RP assessment then, a 10 percent mean effect level at the IWC is used as a threshold, above which potential to cause is indicated, and the effluent has demonstrated RP. Any test with a mean effect at the IWC > 10 percent would demonstrate a potential for RP even if the TST test result is *Pass*. Equation E-1 below demonstrates how the effluent effect is calculated at the IWC.

$$\%\ \text{Effect at IWC} = \frac{\text{Mean Control Response} - \text{Mean Response at IWC}}{\text{Mean Control Response}} \times 100 \qquad \textbf{Equation E-1}$$

Table E-1. Examples illustrating the reasonable potential approach using TST and data from *Ceriodaphnia* chronic survival and reproduction WET tests

Example	Pass/Fail based on TST analysis	Mean control response	Mean response @ IWC	% effect at IWC	Reasonable potential?
A	Fail	26.3	17.0	35.4%	Yes
B	Pass	26.3	23.4	11.0%	Yes
C	Pass	28.6	22.0	23.1%	Yes
D	Pass	22.4	20.9	6.7%	No

Foreword

This guidance document has been prepared to assist dischargers and/or their consultant laboratories in conducting chronic aquatic toxicity identification evaluations (TIEs). TIEs may be required by the state or federal agencies as a result of enforcement actions or as a condition of the discharger's National Pollutant Discharge Elimination System (NPDES) permit or may be conducted voluntarily by permittees. This document will assist the state and federal agencies and permittees in overseeing and determining the adequacy of the TIE in toxicity reduction evaluations (TREs).

This document discusses methods to characterize the chemical/physical nature of the constituents in effluents which cause their chronic toxicity. The general approach for toxicity identification evaluations is described in the document *Methods for Aquatic Toxicity Identification Evaluations: Phase I Toxicity Characterization Procedures* (EPA, 1988A; EPA, 1991A), hereafter referred to as the *"acute Phase I manual."* The acute Phase I manual provides much of the basis for the statements and guidance provided in this chronic Phase I characterization document. This chronic TIE manual and the acute Phase I manual should be used as companion documents, because all the guidance of the acute Phase I manual is not repeated here.

The general approach for the chronic characterization is divided into Tier 1 and Tier 2. Tier 1 consists of the EDTA and sodium thiosulfate additions, the graduated pH test, aeration and filtration manipulations, and the use of the C_{18} solid phase extraction (SPE) resin. For Tier 1, the tests are all done using the effluent sample without any pH adjustments (i.e., at the initial pH (pH *i*) of the effluent). Tier 2 manipulations are added when Tier 1 tests are not definitive in characterizing the toxicity. Tier 2 includes the aeration, filtration, and C_{18} SPE steps of Tier 1 performed at pH 3 and pH 10 and returned to pH *i* prior to testing.

The chronic Phase I procedures should provide information on whether the toxicants are volatile, chelatable, filterable, reducible, non-polar, or pH sensitive. These characteristics are indicated by comparing the results of toxicity tests conducted using unaltered and manipulated effluent samples. As with the acute TIE, the characterization results from the chronic TIE can be used for the treatability approach in a TRE (EPA, 1991A).

These chronic TIE methods are not written as rigid, required protocols, but rather as general guidance for conducting TIEs with effluents. These acute and chronic methods should also be applicable to samples from ambient waters, sediment pore and elutriate waters, and leachates. The methods to identify (Phase II; EPA, 1989A) and confirm (Phase III; EPA, 1989B) the cause of toxicity in effluent samples evaluated with the acute Phase I procedure are also applicable to effluent samples evaluated with this chronic Phase I procedure. The identification and confirmation documents are being revised (EPA, 1992A; EPA, 1992B) to reflect additional information from this manual and the revised acute Phase I manual (EPA, 1991A) to discuss the aspects of TIEs for both acute and chronic toxicity.

In September of 1991, we solicited peer-review comments until January 31, 1992 from all persons who obtained the document from any of the following locations: EPA's Office of Water, Washington, D.C., each EPA Regional Water Division Office, EPA's Environmental Research Laboratory-Duluth, MN, or EPA's Center for Environmental Research Information (CERI), Cincinnati, Ohio. Appropriate technical comments were incorporated into this manual.

Abstract

This manual is intended to provide guidance to aid dischargers in characterizing the type of toxicants that are causing chronic toxicity in industrial and municipal effluents. In a regulatory context, a toxicity identification evaluation (TIE) may be required as part of the National Pollutant Discharge Elimination System (NPDES) permit or as an enforcement action. TIEs may also be conducted by permittees on a volunteer basis to characterize their discharge toxicity.

The Phase I chronic toxicity methods are modified from those described in the acute Phase I TIE manual (EPA, 1988A; EPA, 1991A) and additional techniques are incorporated. This chronic Phase I manual describes procedures for characterizing the physical/chemical nature of toxicants in effluents that exhibit chronic toxicity to freshwater species, although many of the principles and procedures are similar for TIEs on marine species. Aliquots of effluent samples are manipulated and the resulting effect on toxicity measured. The objective is to characterize the toxicants so that appropriate analytical methods can be chosen to identify the toxicants.

The general approach to the chronic toxicity characterization is a two tiered approach, where usually Tier 1 is applied before proceeding to Tier 2. Tier 1 consists of filtration, aeration, use of additives to chelate or reduce the toxicants, minor pH adjustments, and use of a separation technique with the C_{18} solid phase extraction (SPE) resin. Each effluent is characterized in Tier 1 by performing the manipulations at the initial pH (pH *i*) of the effluent. Tier 2 consists of the Tier 1 manipulations combined with pH adjustments of additional aliquots of the effluent sample, and the Tier 2 characterization steps include aeration, filtration, and the C_{18} solid phase extraction of effluent samples adjusted to pH 3 and pH 10.

The Phase I characterization methods were developed for the short-term *"chronic"* test methods using two species, *Ceriodaphnia dubia* and the fathead minnow (*Pimephales promelas*) (EPA, 1989C). Chronic threshold levels for the various additives (sodium thiosulfate, EDTA, methanol) used in some of the characterization tests are provided for these species. Although developed for these species, the characterization techniques should be applicable to other species as well, provided threshold levels are established.

The guidance provided in this manual is intended to be supplemental to that given in the acute Phase I manual (EPA, 1991A). Sections of this chronic Phase I TIE manual discuss quality assurance, effluent handling, facilities and equipment, health and safety, dilution water, principles of the chronic TIE testing, and the Phase I characterization tests as a two tiered approach. The use of the whole effluent test as a *baseline test* (in manner similar to the acute Phase I characterization procedure), the appropriate treatment of dilution water for blanks and the toxic levels of the additives for two species are described. Use of short-cuts, reduced test volumes, reduced test duration, and a small number of replicates are discussed. The importance of sample type, frequency of sample collection and renewal, and descriptions of all manipulations are discussed, along with a section on the application of combining several of the characterization tests.

Acknowledgments

Many people at the National Effluent Toxicity Assessment Center (NETAC) at the Environmental Research Laboratory-Duluth (ERL-Duluth) have provided assistance to produce this manual by performing the toxicity tests, chemical analyses, and data analyses as well as providing advice based on experience. This document is the result of the input by the NETAC group which has consisted of both federal and contract staff members, and includes Gary Ankley, Larry Burkhard, Liz Durhan, Don Mount, Shaneen Murphy, and Teresa Norberg-King (federal staff), and Joe Amato, Lara Andersen, Steve Baker, Tim Dawson, Nola Englehorn, Doug Jensen, Correne Jenson, Jim Jenson, Marta Lukasewycz, Liz Makynen, Greg Peterson, Mary Schubauer-Berigan, and Jo Thompson (contract staff). The toxicity test data generated for this document and the biological data upon which this report is based was produced by Doug Jensen, Jo Thompson, Tim Dawson, Greg Peterson, Nola Englehorn, Shaneen Murphy, Mary Schubauer-Berigan, Joe Amato, and Jim Jenson. The skillful assistance and dedication of Debra Williams and Jane Norlander (NETAC) in producing this document are gratefully acknowledged.

Comments were received from the following people and organizations: Charles Carry and LeAnne Hamilton for the County Sanitation Districts of Los Angeles County, Whittier, CA.; David Mount and J. Russell Hockett for ENSR Consulting and Engineering, Fort Collins, CO; Norman LeBlanc for Hampton Roads Sanitation District, Virginia Beach, VA; Charlie Webster, State of Ohio Environmental Protection Agency (EPA), Columbus, OH.; Michael Gallaway, State of Ohio EPA, Columbus, OH; Robert Berger for the Association of Metropolitan Sewerage Agencies (AMSA), Washington, D.C.; and Kerrie Schurr for EPA Region 10, Seattle, WA. We want to thank those individuals or organizations for reviewing the report, and in turn improving the document with their comments.

In the review comments, a suggestion was made to summarize all the effort on TIEs by government, state, academia, contract laboratories, and industries to date. While the TIEs at Duluth can be summarized, data from all the possible sources are difficult if not impossible to obtain. Contract laboratories and industrial data are protected for confidentiality and proprietary reasons, and information about the kinds of toxicants, the types of discharges, the time-frame for the TIE, and the costs are difficult to obtain. Numerous toxicity problems have been resolved as TIEs are initiated because of better plant operation. In fact, during a workshop (Aquatic Habitat Institute, 1992) held March 17 and 18, 1992 in Richmond, CA, these issues were discussed, and presenters of chronic TIE data indicated chronic TIEs have been much more successful than expected.

This work was supported in part by the Office of Water, Permit Division, Washington, D.C., through the backing of Rick Brandes and Jim Pendergast, who have provided strong support for the whole effluent water quality-based approach.

Section 1
Introduction

The United States Federal Water Pollution Control Act Amendments (commonly referred to as the Clean Water Act (CWA); (Public Law 92-500 of 1972) states that the discharge of toxic pollutants in toxic amounts is prohibited. In the CWA, the National Pollutant Discharge Elimination System (NPDES) was established; this system provides a mechanism whereby point source wastewater discharges are permitted. NPDES permits contain effluent limits that require baseline use of treatment technologies (best available technology). The technology-based limits are independent of receiving water impact, and additional water quality-based limits may be needed in order to meet the goal of the CWA of "*no toxics in toxic amounts.*" State narrative and state numerical water quality standards are used in conjunction with EPA's water quality criteria and other toxicity databases to determine the adequacy of the technology-based permit limits and the need for any additional water quality-based controls.

When limits were first written into the permits, they were based primarily on physical factors such as biological oxygen demand (BOD), suspended solids (SS), and color. Additional components were added in subsequent amendments to the CWA; for example, the list of 126 *"priority pollutants"* of which many or most were required to be monitored by the permittees. Water quality criteria were used to develop the water quality-based limits for these pollutants. However, water quality criteria or discharge limits exist for only a few of the thousands of chemicals in use.

An important objective of the NPDES program is the control of toxicity of discharges and to accomplish this objective, EPA uses an integrated water quality-based approach. Published water quality criteria are converted to standards that consist of both chemical-specific numeric criteria for individual toxics and narrative criteria. The states' narrative water quality criterion generally requires that the waters be free from oil, scum, floating debris, materials that will cause odors, materials that are unsightly or deleterious, materials that will cause a nuisance, or substances in concentrations that are toxic to aquatic life, wildlife or human health. Use of toxicity testing and whole effluent toxicity limitations is based on a state's narrative water quality criterion and in some cases, a state numeric criterion for toxicity.

EPA, in 1984, issued a policy statement (Federal Register, 1984) that recommends an *"integrated approach"* for controlling toxic pollutants. This *integrated approach* is referred to as the water quality-based approach and is described in detail in the Technical Support Document (hereafter referred to as the TSD; EPA, 1985A; EPA, 1991B). The control regulations for EPA (Federal Register 23868, 1989) establish specific requirements that the *integrated approach* be used for water quality-based toxics control. This *integrated approach* results in NPDES permit limits to control toxic pollutants through the use of both chemical-specific and whole effluent toxicity limitations as a means to protect both aquatic life and human health. This combination of chemical specific and whole effluent toxicity limitations is essential to the control of toxic pollutants. Once the permit limits are set, compliance is established through routine monitoring of effluent quality. In this manner, water quality-based limits (when following EPA, 1991B) will protect water quality and prevent the state water quality standards from being violated.

The whole effluent toxicity limitation aspect involves using acute and chronic toxicity tests to measure the toxicity of wastewaters. *Acute toxicity* refers to toxicity that occurs in a short period of time, operationally defined as 96 h or less. *Chronic toxicity* occurs as the result of long exposures in which sublethal effects (fertilization, growth, reproduction) are measured in addition to lethality. The chronic test is used to measure the effects of long-term exposure to chemicals, wastewaters, and leachates to aquatic organisms. True chronic toxicity tests include the life-cycle of the organism. For fish, the life-cycle test is infrequently conducted (Norberg-King, 1989A), and abbreviated test methods have been used to estimate chronic toxicity. These tests are the 7-d growth and survival test (EPA, 1989C), or the 32-d embryo-larval early life stage test (Norberg-King, 1989A). These tests rely on the most sensitive life-cycle stages (i.e., embryos and larval fish) to estimate chronic toxicity (McKim, 1977; Woltering 1983; Norberg-King, 1989A). Hereafter, chronic tests refer to the short-term tests that are described in the EPA manuals (EPA, 1992C; EPA, 1992D; EPA, 1989C; EPA, 1985C).

Toxicity is a useful parameter to protect receiving waters from potential impacts on water quality and designated uses caused by the mixture of toxic pollutants in wastewaters. EPA has published manuals which provide test methods for use of freshwater and marine organisms to determine acute and chronic toxicity of effluents. These manuals have been available since 1978 and 1985, respectively (EPA, 1978; EPA,

1985B; EPA, 1985C; EPA, 1988B; EPA, 1989C) and have been recently revised (EPA, 1991C; EPA, 1992C; EPA, 1992D). These methods are used by federal, state and local governments to assess toxicity and determine compliance of permitted point source discharges. Since the late 1970's, toxicity has been measured in wastewaters; permit writers began using toxicity limits in the early 1980's. With the increased use of toxicity testing, substantial numbers of unacceptably toxic effluents have been identified. Now, some permittees are required to perform *toxicity reduction evaluations* (TREs) as a condition of the NPDES permit. The TSD defines a TRE as "*a site specific study conducted in a stepwise process designed to identify the causative agents of effluent toxicity, isolate the sources of toxicity, evaluate the effectiveness of toxicity control options, and then confirm the reduction in effluent toxicity.*" *Toxicity identification evaluations* (TIEs), which are a part of the TRE, consist of methods to characterize (Phase I; EPA, 1988A; EPA, 1991A; EPA, 1991D), identify (Phase II; EPA, 1989A; EPA, 1992A), and confirm (Phase III; EPA, 1989B; EPA, 1992B) the cause of acute and chronic toxicity in effluents.

The TIE approach (EPA, 1988A; EPA, 1991A) relies on the use of organisms to detect the presence of toxicants in the effluent. Information about the physical/chemical characteristics of the effluent's toxicity is gained (by the various manipulations) and if possible the number of constituents in the effluent is reduced before any analyses begin. Using this approach, analytical problems can be simplified and the costs reduced. Toxicity throughout the TIE must be tracked to determine if the toxicity is consistently being caused by the same substance. Once the physical/chemical characteristics of toxicants are known, a better choice of analytical methods can be made. Knowledge of physical/chemical characteristics of any effluent is used for the treatability approach to TRE's (EPA, 1989D; EPA, 1989E).

As with the acute Phase I TIE approach, the chronic Phase I TIE is based on manipulations designed to alter a group of toxicants (such as oxidants, cationic metals, volatiles, or non-polar organics) so that toxicity is changed. Chronic toxicity tests are conducted after each manipulation to indicate the effect on the toxicity of the effluent. Based upon the manipulations that change toxicity, inferences about the chemical/physical characteristics of the toxicants can be made. Using several samples of the effluent for these characterization steps provides information on whether the nature of compounds causing the chronic toxicity remains consistent. The tests do not provide information on the variability of toxicants within a characterization group. From these data the toxicant characteristics can be identified as pH sensitive, filterable, volatile, soluble, degradable, reducible, or EDTA chelatable. Such information indicates how samples must be handled for analyses and which analytical methods should be used.

The recommended procedure is to concentrate on the characterization steps that are most clean-cut and have the major effect of reducing the toxicity in the effluent. If toxicity in every effluent sample is not caused by the same toxicant(s), the characterization tests should indicate if the type of toxicant(s) is the same or different. Once identification is initiated, and suspects identified, the varying causes of toxicity can be evaluated because the concentration of toxicants should be tracking with the toxicity. In the earlier version of this document (EPA, 1991D) we suggested that samples be subjected to Phase I techniques until no additional responses are found (which was suggested to be at least three samples). After conducting several Phase I evaluations for chronic toxicity, we have determined that if the effluents' toxicity is readily characterized after Phase I even with one sample it may be prudent to proceed with Phase II (EPA, 1992C) to measure the toxicant(s). Use of toxicity patterns as the TIE progresses can be helpful if patterns are tracked, beginning with the first samples. Following characterization, a decision is made to proceed with identification (Phase II; EPA, 1989A; EPA, 1992A) and confirmation (Phase III, EPA, 1989B; EPA, 1992B) or to conduct treatability studies where the identification of the specific toxicants (cf., acute treatability procedures (EPA, 1989D; EPA, 1989E)) is not made.

Chronic toxicity must be present frequently enough so that an adequate number of toxic samples can be obtained. Enough routine toxicity testing should be done on each effluent before a TIE is initiated (EPA, 1991B), to ensure that toxicity is consistently present. It is not important that the same amount of toxicity is present in each sample; in fact, variable levels of toxicity can assist in determining the cause of toxicity. If toxicity is not consistently present, when it occurs the toxicity can be pursued and if a toxicant(s) is suspected, the non-toxic samples may be used to eliminate suspects. One cannot assume that if the effluent showed acute toxicity and a TIE was completed, identifying the cause(s) of acute toxicity and action taken to remove the acute toxicant from the effluent, that the sublethal toxicity exhibited is due to the same compound.

Section 2
Quality Assurance, Health, and Safety, and Facilities and Equipment

2.1 Quality Assurance

The quality assurance plan (QAP), as described in *Standard Methods for the Examination of Water and Wastewater* (APHA, 1989) (describes standards to conduct performance evaluations) is primarily for analytical analyses. A QAP for toxicity testing can be developed, but determining the recovery of known additions for toxicity testing is not possible. For TIEs the combination of chemistry and biology requires a level of checks and balances not typically used under other situations. A step-by-step QAP for all steps of a TIE is not always possible due to the unknown toxicant(s) requiring various follow-up testing and analytical procedures; however as a TIE progresses, additional or different tests may be needed and many aspects of the TIE QAP can be addressed as the TIE proceeds. Adhering to the general guidelines of a strong QAP is important however, and should increase the probability of the TIE succeeding. As additional steps are recognized, the details should be added to the QAP.

Specific quality control (QC) procedures for aquatic toxicity tests are different than the specific QC procedures for chemical analytical methods. Both procedures have common goals that are to know that reliable data are generated, to recognize and eliminate unreliable data, and to have methods which assist investigations in resolving problems for future work. The quality assurance (QA/QC) guidance given by EPA (1989C) for the short-term tests lists numerous items of concern for toxicity testing. These are: (a) effluent sampling/handling, (b) test organisms, (c) facilities, equipment and test chambers, (d) analytical methods, (e) calibration and standardization, (f) dilution water, (g) test conditions, (h) test acceptability, (i) test precision, (j) replication and test sensitivity, (k) quality of organisms, (l) quality of food, (m) control charts, and (n) record keeping and data evaluation. Many of these should be closely followed, and the reader is encouraged to review the guidance in relation to QA/QC in both the short-term effluent test manual (EPA, 1989C; EPA, 1992C) and the acute Phase I manual (EPA, 1991A).

2.2 QA/QC Cost Considerations and Testing Requirements

For the chronic TIE, cost considerations are important and concessions in the requirements of the QC may have to be made. In some instances, the data will demand stringent control while in others, the QC can be lessened without impact to the overall endpoint of the TIE.

TIEs can require a great number of toxicity tests. The use of all aspects of the standard test protocols (EPA, 1989C; EPA, 1991C) is not necessary in Phase I. The factors of time requirements, number of tests and the test design (i.e., five replicates versus ten, four dilutions versus five) must be considered and weighed against the type of questions that are posed. For example, the need for water chemistry data are specific for each Phase I test. The testing requirement (EPA, 1989C) according to the permit requirement most likely included pH, daily measurements of DO, temperature, conductivity, alkalinity, and hardness measurements in the low, middle, and high concentrations for the five test dilutions of the effluent. However, hardness measurements are not pertinent for the methanol eluate collected from a solid phase extraction column. The post C_{18} SPE column effluent samples are more similar to the effluent and a concern for low dissolved oxygen (DO) exists, while the test solutions of the methanol eluate are more similar to the dilution water and the possibility of low DOs is not as great a concern. In contrast, frequent pH measurements on all test concentrations are needed to determine the impact of pH sensitive compounds.

As TIEs are reliant on a strong QAP, there are several aspects of a QA/QC program for chronic TIEs that should be delineated. In regard to test organism quality, there are steps for culturing organisms that should help provide the necessary QC verification that is needed to ensure the animals are representative in their sensitivity. These steps are simply routine items such as monitoring and recording the young production (for cladocerans) of the culture brood animals once a month, conducting monthly reference toxicant tests (including maintaining control charts), monitoring the preparation dates for the reconstituted waters used, and monitoring the types and age of the foods fed (Norberg-King, 1989B). For fathead minnows, it is useful to monitor the survival of the breeding stock, and the percent hatchability of the embryos, to verify that new genetic stock is introduced on a regular basis, and to conduct monthly reference toxicant tests (Norberg-King and Denny, 1989; Denny, 1988). Similar parameters for other species that are used are also desirable.

Since toxicity tests in the early part of the chronic Phase I do not generally follow all the effluent testing

requirements (EPA, 1989C), the QC measures are not as strict because the data are primarily informative rather than definitive. When Phases II (identification) and III (confirmation) are initiated, then QC aspects should be reconsidered and the tests modified. Phase I procedures frequently use one species and later stages of the TIE (Phase III) use more than one species to determine whether the cause of toxicity is the same for other species of the aquatic community.

Reference toxicant tests are not conducted with each set of Phase I manipulations because of the amount of labor and large numbers of animals required for testing. In general, the utility of the reference toxicant test is to know that the organisms are responding as expected. Since only relative differences are needed at this stage (Phase I), reference toxicant data are much less useful for the characterization interpretation but are important for the knowledge of the quality of the test organisms and general test procedures. For various manipulations of the TIE, organism responses are compared to either the *baseline test* (see Section 6) or the response of organisms in the dilution water treatments. Monthly reference toxicant tests should provide the necessary information about the quality of the organisms for the laboratory conducting the TIE. When a toxicant has been identified (Phase II) and tests for Phase III confirmation indicate it is the toxicant(s), that chemical should become the reference toxicant with the species used in the TIE.

Using receiving water as the dilution water in Phase III confirmation will help ensure that receiving water effects are properly considered (see Section 3, Dilution Water). The variability of the effluent, by nature of the TIE, is defined during the TIE, and this information will aid in determining the appropriate control option in order that the final effluent is safe upon discharge.

2.3 QA/QC and Chronic Testing Considerations

An inherent problem with effluents is that no effluent test can be repeated to assure that the toxicity is the same and that the toxicants are the same. However, repeated *baseline tests* (Section 6) can be done with the same effluent sample to determine how long that effluent sample can be used. The chemical and toxicological nature of the effluent shifts as an effluent is discharged or as an effluent sample is stored. Effluent constituents degrade (at unknown rates) and each constituent has its own rate of change. Analysis of each sample should be initiated as soon as the sample is received in the testing laboratory (generally <24 h). Until an effluent sample has been tested several times, there is no way to predict how long a sample can be stored before the toxicity changes. Testing of each sample can be done provided the toxicity remains and/or stabilizes; however this cannot be determined at the beginning of the Phase I battery of tests and will be known only through testing several samples a few times. Even though the toxicity remains, it is possible that the toxicant may change with time. The number of samples to evaluate and the number of tests to conduct must be weighed against the cost of the effort and how representative each effluent sample is of the effluent. Effluents that have low and non-persistent toxicity may need to be approached with the Tier 1 and Tier 2 characterization steps applied simultaneously (see Section 6).

In a chronic TIE, information obtained from a test should be maximized. This may mean paying particularly close attention to details such as small differences in the number of neonates the cladocerans are producing or the lack of food in the stomach of the larval fish. These parameters and any other observed characteristics during a test may be subtle indicators and quite informative about small changes in toxicity. For example, if all the animals exposed to the whole effluent die on day 4, and in some characterization test the animals don't reproduce or grow but are alive at day 7 of the exposure, that characterization manipulation reduced the toxicity, but did not remove it completely. Observations such as these may be just as useful as reductions in young production or growth.

While some abbreviations in the test design are made, the general principles for toxicity testing still apply. For example, all animals must be added to test solutions randomly. Animals must be placed in a test chamber one at a time. For the fathead minnows, use of an intermediate vessel to hold all 10 animals is preferable to ensure that animals are assigned randomly and that the volume of water added with the fish is minimized (1-2 ml). Also, transferring animals may require separate pipettes for each concentration or cleaning of the pipettes between concentrations to prevent cross contamination. However, we have observed that *C. dubia* do not have to be placed under the water; they can be added or transferred by dropping the water droplet containing the animal into the test solution. The problem frequently observed with *D. pulex* where animals are caught at the surface of the test solution (called "floaters") does not occur with *C. dubia*. Randomization, careful exposure time readings, use of animals of uniform narrow-age groups (i.e., *Ceriodaphnia* neonates 0-6 h old rather than 0-12 h old) should assist in quality data generation.

Standard operating procedures (SOPs) should be developed for each Phase I test, for preparing the reconstituted waters, preparing the foods for the test organisms, calibration and standardization for all measurements (temperature, DO, pH, conductivity, alkalinity, hardness, ammonia, chlorine), and other general routine practices.

An important aspect of TIEs is accurate and thorough data recording. All observations should be documented. Items that were not thought to be important at first may be useful in later stages of analysis and actually assist in the confirmation of the toxicant(s). These observations can be as simple as large bubbles produced during the aeration and filtration manipulations, large particles present in whole effluent, and low

pH upon arrival. It is best to record data so that any preconceived ideas of the toxicants are avoided. Data records should include records of test organisms (species, source, age, date of receipt, history and health), calibration records, test conditions, results of tests, and summaries of data. Once a control chart is developed using point estimates for reference toxicant tests, 1 out of 20 reference toxicity test results will be predicted to fall outside the acceptable limits if the 95% confidence intervals are used to develop the control chart (EPA, 1991C). If TIEs are conducted during such a period, the TIE data generated must be used with caution, and the investigator must carefully examine the TIE data to determine if the results are usable. The decision may be based on consistency of the concentration response data, *control blank* performance, and the consistency of the TIE results with those obtained with the same effluent sample.

2.4 QA/QC Blanks and Artifactual Toxicity

Throughout the TIE, dilution water samples are subjected to most of the procedures and analyses performed on the effluent sample (see Section 5.6). This is done to detect toxic artifacts (i.e., toxicity due to anything other than the effluent constituents causing toxicity) that are created during the effluent characterization manipulations (see Section 6). These manipulations can make QC/QA verifications difficult, as the use of such *blanks* for interpreting toxicity results is not standard toxicology. For example, typically organism responses from any toxicity test in standard aquatic toxicology are compared to the performance of *control* organisms which were in dilution water only. In the TIE, *controls* are used to judge organism performance (Section 5), and *toxicity controls* and *blanks* are used to evaluate whether a manipulation affected the toxicant(s), therefore the results of all characterization tests are not necessarily compared to the *baseline test*. For instance, post-column effluent samples that are collected and tested following concentration on a resin column have been filtered first. Therefore it is only logical to compare the post-column effluent toxicity (*post C_{18} SPE column test*; Section 6.6) to the toxicity observed in the filtered effluent sample (*filtration test*; Section 6.4) rather than to the unfiltered whole effluent (*baseline test*; Section 6.1) (see Section 5).

Artifactual toxicity can occur in several of the manipulations, particularly from the major pH adjustment manipulation (Tier 2). Toxicity results from tests relying on the addition of the reagents (EDTA, sodium thiosulfate, acids/bases) must be interpretable. Addition of both the acid (HCl) and the base (NaOH) can form a toxic product (e.g., NaCl). The addition of the acid and base may interfere with the growth and reproduction of the test organisms for the short-term chronic test, at lower levels than cause mortality in the acute test. Whether additives act in an additive, synergistic, or independent manner with the compounds in the effluent must be determined during the TIE but this is not likely to be clear during Phase I. Artifactual toxicity can occur in the aeration process, where contaminated air can be introduced. Also, contaminants can be leached from solid phase extraction (SPE) columns, and methanol leaching off the column can cause bacterial growth that will confound the results in the post-column *blank* and *post C_{18} SPE column tests*. Originality and judgement are needed to devise tests that will reveal artifactual toxicity (see Section 6) and some of these methods to deal with artifactual toxicity will be effluent specific.

2.5 Health and Safety Issues

For the toxicity identification work, hazards present in any effluent may not be known until Phase II identification steps have been started. Therefore, safety requirements for working with effluents (or other samples) of unknown composition must follow safety procedures for a wide spectrum of chemical and biological agents. Because all of the hazards in an effluent sample may not be known when a toxicant is identified, effluent samples should be treated as hazards of unknown composition throughout the TIE. Knowledge of the types of wastewater treatment applied to each effluent can provide some insight for the possible hazards. For example, unchlorinated primary treatment plant effluents containing domestic waste may contain pathogens. Chlorinated secondary effluents are less likely to contain such agents. Effluents from activated sludge treatment plants are less likely to contain volatile toxicants.

Because effluent characteristics are unknown, personnel should follow the guidelines for hazardous materials (EPA, 1991A; 1991C). Also, if any sample contains human waste, personnel should be immunized for diseases such as hepatitis B, tetanus, polio, and typhoid fever.

Each laboratory should provide a safe and healthy work place. All laboratories should develop and maintain effective health and safety programs (APHA, 1989; EPA, 1991C). Each program should consist of: (a) designated health and safety officers, (b) formal written health and safety plans, (c) on-going training programs, and (d) periodic inspections of emergency equipment and safety violations. Further guidance on safety practices is provided in other documents (APHA, 1989; EPA, 1991A; 1991C).

2.6 Facilities and Equipment

The laboratory facilities and equipment needed to conduct TIEs are discussed in the acute Phase I manual (EPA, 1988A; EPA, 1991A). Most of the equipment for conducting the short-term tests are delineated elsewhere (EPA, 1989C; EPA, 1992C). The reagents used for the chronic Phase I characterization are identical to those described in the acute Phase I manual (EPA, 1991A). Compressed air systems with oil-free compressors and air filters to provide high purity air are very important (EPA, 1991A). All glassware should be rigorously cleaned, and the glassware used for filtering must be rigorously cleaned to remove residual contaminants from the glass frit(s). Filtering equipment may

need to be made of plastic to avoid leaching of metals or other toxicants from glass when acid washes are used (see Section 6). Use of stainless steel frits can be used provided pH adjustments are not made since metals will rinse off the stainless steel at extreme pH's and cause toxicity. Ultra pure acids and bases (e.g., Suprapur®, E. Merck, Darmstadt, Germany) should be used to prevent impurities in the acids/bases from interfering in the toxicity results.

Section 3
Dilution Water

Dilution water used for chronic TIE's must meet several requirements. Obviously it must support adequate performance of the test animals in regard to growth, survival, and reproduction since these are the effects measured in the tests. Secondly, it must not substantially change the animals' response to the sample toxicants. Because the characteristics of the toxicants are not known, there is no way to be sure which dilution water characteristics are important. Hardness and alkalinity are most often used to select the dilution water but these parameters are generally of little importance for non-polar organics. Rarely is the organic matter content considered and yet for both non-polar organics and metals, organic matter has more effect on toxicity than hardness. Experience in the acute TIE work has shown pH to be the single most important water quality characteristic for characterizing the cause of toxicity.

The most important consideration, in addition to those mentioned above, is that the water be consistent in quality and not contain contaminants that could produce artificial toxicity. For example, if there was a nontoxic concentration of a non-polar organic present in the dilution water, when samples are concentrated, it might be toxic and this can confound the identification of the components causing toxicity in the effluent. The best policy is to use a high purity reconstituted water or a well water of known suitability. Receiving water should not be used until Phase III, when it is the water of choice to evaluate the toxicant in the receiving water system (see Section 2.2).

A reconstituted water of similar pH, hardness and alkalinity to that of the effluent is a first approximation of an appropriate water; however, organic matter is hard to duplicate. Experience has shown that for the *Ceriodaphnia* test, the addition of food[1] to the water has been helpful to provide some organic material. With food added, traces of contaminants can be less toxic. If higher concentrations of effluent are to be used, the choice of the dilution water is less important because the characteristics of the effluent dilution mixture will resemble those of the effluent. As information is gained about the toxicant characteristics, the choice of dilution water can be improved.

The impact of dilution water choice depends on the IC25 (see Section 5.8) of the effluent. If toxicity changes substantially from sample to sample, but the dilution water selected does not match the effluent in water characteristics yet is kept the same throughout several samples for Phase I, then the effect of the effluent in the dilution water can also vary across samples. As the TIE progresses into Phase II, attributing relative toxicity to various constituents must be more refined. For instance, suppose the suspect toxicant is a cationic metal whose toxicity is hardness dependent. Also, suppose that the whole effluent has a hardness of 300 mg/l as $CaCO_3$ (very hard water) but the dilution water has a hardness of 40 mg/l as $CaCO_3$. In this case, the hardness in each of the test dilutions will be different from that of either the whole effluent or the dilution water. Provided the cationic metal concentrations vary over the course of the TIE period, the amount of toxicity (as toxic units[2], TUs) due to a particular metal concentration will also vary depending upon the effect concentration in the effluent. If the first whole effluent sample contains 160 µg/l of zinc (for this example, 160 µg/l is 1.0 TU_c in very hard water) and the test is conducted using a dilution water of 40 mg/l as $CaCO_3$ (soft water), the no effect concentration would be 100% where hardness is 300 mg/l and the effluent would have <1 TU_c. The second whole effluent sample contains 480 µg/l of zinc. One would expect this sample to possess 3 TUs (480 µg/l ÷ 160 µg/l). The toxicity due to the second effluent sample would likely contain more than 3 TUs because the hardness at the effect level (<100%) would be much lower than at 100% effluent (where hardness is 300 mg/l as $CaCO_3$). The effect

[1] Food added for the *C. dubia* tests are the yeast-cerophyll-trout food (YCT) and the algae (*Selenastrum capricornutum*) at a rate of 0.1 ml/15 ml (EPA, 1989C). Although at ERL-Duluth the algae has been added at the rate of 0.05 ml/15ml until May of 1991 when we increased the level (EPA, 1989C).

[2] TUs is a means of normalizing the concentration term (i.e., LC50, NOEC, IC25 as percent effluent; see Section 5.8) to a unit of toxicity. The use of the TUs approach allows effluent toxicity to be compared (provided test species and test duration are the same) to a suspect toxicant's toxicity. The toxicity of an effluent and a chemical are different and different concentrations of each equal one LC50 (1 TU). TUs of an effluent can be calculated for either acute or chronic toxicity endpoints. The number of acute TUs in the effluent is 100% ÷ LC50 = TU_a and the chronic TUs in the effluent is 100% ÷ NOEC = TU_c or 100% ÷ IC25 = TU_c (EPA, 1991B). For specific chemicals the TU_c is equal to the concentration of the compound present in the effluent divided by the acute test LC50 for TU_a or the chronic test NOEC or IC25 for the TU_c. The assignment of TU_c is necessary for the correlation step (Phase III) when effluent toxicity TUs are compared to suspect toxicant(s) TUs.

level would be near 20-25% effluent where hardness would be <100 mg/l as $CaCO_3$ and 1 TU of zinc would be <160 µg/l. In addition, if one were to use receiving water for the diluent, the hardness might change dramatically and confound calculation of TU's in a like manner if the effect concentration was <100% effluent.

Section 4
Effluent Samples

To determine whether an effluent sample is typical of the wastewater discharge may require a number of samples to be tested. Experience has shown that the use of several samples spanning two to three months has been successful in characterizing many effluents. TIE work on atypical samples may be problematic and these TIE procedures were not developed for one-time episodic events. However, the very nature of atypical samples may provide valuable assistance in the TIE effort by identifying the type of toxicant(s) that previously was not suspect. This is probably more likely when an atypical sample has greater toxicity than the other samples. In addition, the atypical toxic sample may aid a discharger in recognizing wastewater treatment plant upsets and assist the discharger in implementing prevention procedures or generally improve and maintain better wastewater plant housekeeping efforts, which in turn may eliminate the episodic toxicity problems.

The acute Phase I manual discusses the quantitative and qualitative changes in effluents (EPA, 1988A; EPA, 1991A) that may affect toxicity. Varying concentrations of toxicants, different toxicants, water quality characteristics, and analytical and toxicological error are all factors in determining the toxicity of an effluent. Although the toxicity of an effluent over time appears unchanged, there may be more than one toxicant involved in each sample, and not necessarily the same ones.

At the same time a sample is collected, information on the facilities treatment system (normal operation; aberrant processes) may be useful. When dealing with industrial discharges, details of the process being used may be helpful. These details and others should be recorded and provided to the laboratory conducting the TIE at the time of sample shipment. When samples are received, temperature, pH, chronic toxicity, hardness, conductivity, total residual chlorine (TRC), total ammonia, alkalinity and DO should be measured. Figure 4-1 provides a typical format to record such information.

Since most TIEs are not performed on-site, the effluent samples must be shipped on ice to the testing location. The samples should be cooled to 4°C or less prior to shipment and they should be shipped in sturdy ice chests to prevent either temperature increases or container breakage during shipment. Primary requirements of the TIE are that toxicity occurs frequently in the effluent samples and that the toxicity of each sample (held at 4°C) remains in the efiluent sample for a sufficient period of time. If samples repeatedly lose their toxicity after shipment, steps should be taken to preserve toxic fractions (Section 6.7) for later testing and analysis. For example, if the initial characterization tests indicate the presence of non-polar organics, one tool to use is to concentrate large volumes (5-10 L) of effluent when the sample arrives (see Section 6). Use of the Phase II (EPA, 1992A) non-polar fractionation procedure is the preferred way to concentrate the non-polar toxicants for subsequent analysis and testing. While efforts must be expended on this procedure, it can be a crucial step to aid in identifying potential toxicants (in instances where toxicity is present and lost in the effluent). The information on when toxicity degrades or is lost may become useful as the toxicant(s) is identified (see Section 9; EPA, 1991A). Filterable toxicants which degrade quickly in the effluent may be recovered from the filters with solvent and stored for future use (cf., *filtration test*; Section 6.4).

For one chronic Phase I TIE, a typical volume of effluent needed to ship is 19 L (5 gal) but of course this will depend on the options chosen for the TIE (Section 6) and 38 L (10 gal) may be more helpful once identification and confirmation begin on any sample. The second edition of the acute Phase I TIE manual (EPA, 1991A) recommends that samples be initially collected and stored in both glass and plastic to determine whether effluent stored in either container affects the toxicity. Some compounds (such as surfactants) are less toxic if water samples containing them are stored in plastic containers. Prior to initiating the characterization it may be useful to collect and test several preliminary samples to determine which containers to use during the TIE to provide samples that are the most representative of the effluent (see Phase I, Section 6 (EPA, 1991A) for more details). Less volume (≤2 L) is needed for these tests.

Composite samples should be used for Phase I. Later, in Phases II and III, where variability is desired, grab samples should be used. Samples that are consistent (i.e., composite samples) give results that are easier to interpret and lead more rapidly to identification (Phase II) and confirmation (Phase III) of the cause of toxicity. Grab samples can provide the maximum effluent toxicity; however, it is more difficult to catch

intermittent peaks of toxicity (such episodic events may not be caused by the same toxicant that causes routine toxicity).

Multiple effluent samples in each test should *not* be used in Phase I as is done for permit testing (EPA, 1989C). We have found that using only *one* composite sample for each set of Phase I characterization tests is adequate. If several effluent samples are used for renewals during the chronic Phase I TIE and the toxicants are different or change in their ratios one to another, the interpretation of Phase I will be nearly impossible. Indeed such variability must be identified but it should be done after at least one or preferably most of the toxicants are known. The use of *one* sample is more important in Phase III, (EPA, 1992B) where toxicity data are correlated to the measured concentrations in the effluent. If multiple samples are used, this correlation can not be readily done because the same toxicant may not be present in each sample, or it is present in varying concentrations and other toxicants may appear.

Existing routine toxicity test data should be examined. If one notes a sudden response such as death in the middle to the end of the test period and especially if it is associated with a new sample, the effect being measured may actually be acute rather than chronic and if so the approach may be switched to an acute TIE approach. The investigative approach should be adjusted to respond to such situations. When the permit test is conducted and the test fails, it may be desirable to try to identify the toxicants in those permit compliance samples. This can be done by collecting the appropriate volume needed for a chronic TIE of either the daily samples or the three samples used for the short-term toxicity test (EPA, 1992C). Additional short-term toxicity tests can be conducted on each

sample prior to any TIE tests on each sample or preferably additional short-term tests would be initiated on each new sample during the 7-d test to evaluate whether it is the cumulative toxicity from all samples or whether one or two samples are driving the toxicity. We have observed in several effluent tests that the toxicity during the short-term chronic test can be caused by one or two samples and these samples cause the chronic test to demonstrate that the effluent is toxic in less than the full 7-d of the *C. dubia* or fathead minnow tests. When the toxicity that occurs in ≤48 h (*C. dubia*) or ≤96 h (fathead minnow) with any one of the samples from the permit compliance samples or any sample collected for the TIE, is observed as >50% mortality, acute TIE procedures can be applied to more quickly characterize the toxicant(s).

Section 5
Toxicity Testing

5.1 Principles

The test organism is used as the detector of chemicals causing chronic toxicity in effluents and other aqueous media. The response to toxic levels of chemicals is a general one; however the organism is the only tool that can be used specifically to measure toxicity. Only when the cause of toxicity is characterized can chemical analytical methods be applied to identify and quantify the toxicants.

Chronic TIE's will usually be triggered by the use of the toxicity test methods as found in the short-term chronic toxicity test manuals (EPA, 1989C; EPA, 1992C). These methods rely on sublethal endpoints as the indicator of chronic toxicity for the Phase I manipulations, therefore conducting the tests strictly as detailed in those manuals is not always necessary and sometimes not possible. Modifications have been developed and these include: (a) reduced test volumes, (b) shorter test duration, (c) smaller number of replicates, (d) reduced number of test concentrations, and (e) reduction in the frequency of the test solution renewal. In addition, the frequency of preparation of manipulated samples for test solution renewal must be established and this issue is discussed in the following section. Any loss of test precision due to these modifications is not as critical during Phase I characterization as it is in Phase II and Phase III (EPA, 1992A; EPA, 1992B). During Phase I the analyst is searching for an obvious alteration in effluent toxicity, which may be obtained using modified chronic test methods. Confirmation testing (Phase III) conducted according to the standard methodologies will confirm whether the toxicant(s) detected in the characterization and identification steps (Phases I and II) is the true toxicant.

5.2 Test Species

In most cases, freshwater effluents will be subjected to this evaluation because they have been found to be chronically toxic to the cladoceran, *C. dubia*, or to the fish, fathead minnow (*P. promelas*), or possibly to the cladocerans, *D. magna* or *D. pulex*. Freshwater effluents discharged into marine environments are evaluated for toxicity using marine species or may be assessed with freshwater species (EPA, 1991D). TIE guidance for the marine species will be forthcoming in the fall of 1992 (George Morrison, personal communication, ERL-Narragansett, RI).

The species which detected the toxicity which in turn triggered the TIE, is the first choice for the TIE species. When an alternative species is chosen one must prove that it is being impacted by the same toxicant(s) as the species which initially detected the toxicity. The species need not have the same sensitivity to the toxicant(s), but each species' threshold must be at or below the toxicant concentration(s) present in the effluent. One method of proving that the species are being affected by the same compound(s) is to test several samples of the effluent over time to both species. If the effluent possesses sufficient variability, and the two species IC25s (see Section 5.8 below for a description of the IC25) change in proportion to one another, the analyst may assume that the organisms are reacting to changing concentrations of the same compound. Further proof that the two species are responding to the same toxicant should surface during Phase III. If the toxicant is the same for both species, then characterization manipulations which alter toxicity to one species should also alter toxicity to the second species. The extent to which toxicity is altered for each will depend upon the efficiency of the manipulation and the organism's sensitivity to the toxicant. Steps applied in Phase III will confirm whether the two species are indeed sensitive to the same toxicant in the effluent. Extensive time and resources may be wasted if one discovers during Phase III that the organism of choice is not responding to the same toxicant as the species which triggered the TIE.

For the above mentioned reasons, we recommend when at all possible to use the organism which prompted the TIE. Our chronic TIE experience has been based on tests with *C. dubia* and/or larval fathead minnows. Obvious constraints on the use of other species are availability, size, age, and adaptability to test conditions. Also, the threshold levels for additives and reagents must be determined for other species.

5.3 Toxicity Test Procedures

Measures to conserve time and resources required to conduct a chronic Phase I must be used in order to make the procedures cost-effective. The application of all aspects of the standard short-term chronic tests to Phase I in terms of replicates, routine water chemistries, test duration, and volume is not practical due to time constraints and expense. Variations of the procedures need to be implemented whenever possible.

As mentioned above, smaller test volumes can be used in all tests with *C. dubia* and in most instances with fathead minnows. For example, 10 ml in a 1 oz

plastic cup (or 30 ml glass beaker) has been adequate for *C. dubia* and 50 ml in a 4 oz plastic cup (10 fish per cup) has been used successfully to test the fathead minnows (or 100 ml in a 400 ml glass beaker). There are two precautions to watch for in the chronic TIE tests—1) evaporation of test solutions and 2) transfer of toxicants while moving the animals. If evaporation reduces test volumes, efforts to reduce the evaporation must be made or larger volumes must be used. The volume of water added with each transfer should be minimized, because the volume used in the test is small, and the resultant test concentration could be diluted, thereby reducing toxicity. Using the same size test chambers and consistent volumes should be maintained in Phase I; when Phases II and III are initiated, tests should be conducted following the test protocol that was used to trigger the TIE. This may be important in Phase I to be as sure that the oxygen requirements for the test species are met and that toxicity is not due to physical restrictions of the test procedure.

If a reduction in the number of replicates per test concentration is used, one must assume that precision is sufficient enough to decipher changes in toxicity that must be measured. For the *C. dubia* test, five animals per concentration (one per cup) and for the fathead minnow test, two replicates per concentration and 10 fish per replicate have been found to be adequate for interpreting the changes in toxicity. However this smaller data set is not amenable to all statistical requirements as described for the short-term tests (EPA, 1989C; see Section 5.8). Use of more organisms and more replicates may be preferable if Phase I data are likely to be used in Phase III confirmation (see Sections 2.2 and 2.3).

A shortened version of the 7-d *C. dubia* test, referred to as the 4-d test, may be useful in the TIE. The 4-d test does not have to be as sensitive as the 7-d test, just sensitive enough that the toxicity changes occurring in Phases I and II of the TIE (using 4-d tests) would be the same as the 7-d tests. The 4-d day test was found to produce similar results for single chemicals (Oris et al., 1991), but in tests in our laboratory with effluents, the 4-d test has not been as sensitive for all effluents tested as the 7-d test in determining the effects on young production and survival. Masters et al. (1991) tested *C. dubia* to one effluent (three times), three surfactants, three metals, and three organic compounds with the 4-d and 7-d exposures. They found that for the most part the effluent toxicity was similar for the 4-d and 7-d test results but for the surfactants the 7-d test was more sensitive. For the metals (cadmium, lead, and zinc), ethylene glycol, and pentachlorophenol, the chronic toxicity values for both tests were very similar while the 4-d test was more sensitive for phenol.

In the 4-d test, when animals are initially exposed at 72 h they are ready to produce their first brood. Therefore, toxicity can be underestimated because these animals are predisposed to produce their first brood, unlike the animals exposed as neonates (24 h old). The exposure during a 4-d test may miss their most sensitive life stage. However for the Phase I where the purpose is to detect differences following various manipulations, this issue is not as important as the ability to rapidly conduct the characterization. Use of the shorter term test will decrease the cost of Phase I TIE's. In the confirmation of toxicity (Phase III), the 7-d test is required because the toxicity as measured in the 7-d test (with more replicates, more dilutions, more volume) was used to detect toxicity for the permit, and should be used to confirm the cause of toxicity.

To conduct a 4-d test with *C. dubia*, neonates (0-12 h old) are placed in the dilution water that will be used to conduct the TIE. At present these animals are held in groups of three, two or individually in test containers (with 15 ml of culture water) and fed daily until they are 72 h (±6 h) old in a similar test fashion (Oris et al., 1991). The animals are then transferred to the *baseline test* solutions or the various characterization test solutions. The test is then continued for 4-d using the endpoint of three broods.

The use of known parentage (EPA, 1989C) for the *C. dubia* test is important when the number of replicates is reduced, and helpful for Phase I, II or III tests and in routine tests as well (EPA, 1992C). For Phase I, this known parentage approach allows the young of one female to be used across one replicate of all dilutions and the control (i.e., 5 animals), the young from another female for the next replicate set of dilutions and control, and so on until all test cups contain one young animal. By this technique, animals from a given female that later appear atypical in appearance or movement or produce no young when others in the same test concentration are producing normally can legitimately be dropped from the data set without statistical bias (Norberg-King et al., 1989). The ability to discard such data without bias improves precision. Precision will be better when $n \geq 7$ per treatment for *C. dubia* or $n \geq 4$ for the fathead minnow test.

5.4 Concentrations to Test

The level of toxicity for any given discharger most likely will have been established with some degree of certainty from previous tests that were conducted on the effluent that triggered the TIE.

Therefore during Phase I of the TIE, we have found that four effluent dilutions and a control are adequate to define the toxicity of the sample while reducing the cost of the tests. Now for the TIE, the key to choosing the concentrations to test is to select those that will assist in the detection of small changes in toxicity, which is essential in the chronic TIE. For example, if the NOEC (from a previous data set) is 12% (or IC25 is 10%), then a concentration series such as 6.3%, 12.5%, 25%, and 50% would be logical; or perhaps closer concentration intervals may be desired. Using 20% as the high concentration and a dilution factor of 0.7, would mean the concentrations to test would be 7%, 10%, 14%, and 20%. If the NOEC (from historical data) is 40-50% (or above 50%), then the concentrations to test should be, for example, 25%, 50%, 75%, and 100% or

40%, 60%, 80%, and 100%. Choice of dilution factor and test concentration range is a matter of judgement and depends on needed precision and practicality.

In nearly all examples in this document, the concentrations of 12.5%, 25%, 50%, and 100% are used. We are assuming that if effluents have ICp (or NOEC) values below 10%, the effluent is likely to show acute toxicity and if so, an acute TIE approach should be used. If chronic work is to be done on a highly toxic effluent, the same recommendations given in the acute manual should be used; that is, use concentrations of 4x, 2x, 1x and 0.5x the IC25 or IC50 value (see Section 5.8 for which value to select). For example, if the IC25 is 5% effluent, we would suggest using a range such as 20%, 10%, 5% and 2.5% for the various tests. It is best to use the same dilution sequence within a series of tests (Tier 1) when tests are to be compared to each other for differences in toxicity.

5.5 Renewals

For *C. dubia*, daily renewals of the test media (as required in the chronic manual, EPA, 1989C) are not necessary in Phase I as long as the toxicity of the effluent can be measured with one or two renewals. Because available sample volume is limiting in some manipulations, fewer renewals are desirable. As with the test duration (4-d vs. 7-d) the acceptability of less frequent renewals must be established by comparison with whichever test duration is selected. However in Phase III, tests must be conducted similarly to the routine biomonitoring test. For the fathead minnow test the frequency of sample replacement must be daily to maintain adequate water quality because the live food organisms (brine shrimp, *Artemia salina*) die 2-8 h after being added to the freshwater test solutions. A *baseline test* (see Section 6) is always conducted when the sample is received. The suitability of reduced renewal frequency can efficiently be evaluated at this time by conducting comparative *baseline tests* simultaneously with different renewal frequencies.

The number and types of chemical measurements taken initially and at the renewal intervals (referred to as finals) should be based on the need for these measurements and their usefulness (see Section 2). Initially, little judgement about the value of these can be made, but as toxicant characteristics are identified, the usefulness of various measurements can be judged. Initially, the usual measurements (hardness, alkalinity, conductivity; EPA, 1989C) should be made but some of these can be dropped as the TIE progresses. For example, if non-polar toxicity is found, then hardness and alkalinity need not be closely monitored. However if a metal is suspected, then these measurements are important. Low levels of dissolved oxygen in the fathead minnow test are a greater concern than in the *C. dubia* test, and the pH between the two tests will be dissimilar after 24 h of exposure. The pH measurement is frequently needed and for toxicants such as ammonia it is extremely important (EPA, 1992A). If an effluent contains greater than 5.0 mg/l of ammonia, the pH should be carefully measured at least daily (or more often) in *all* test concentrations. Since ammonia is a highly pH dependent toxicant, one must be aware of variable pH drift in the Phase I treatments which may lead to erroneous conclusions. One generalization, however, can be made. For characteristics that are unlikely to change, such as conductivity and hardness, both initial and final measurements need not be made-once is enough.

5.6 Toxicity Blanks

A risk of the reliance on a toxicity response in the characterization step of TIEs is the probability that artifactual toxicity is created during sample manipulations (see Section 2.4). While a particular manipulation may cause some degree of artifactual toxicity, if the toxicity is predictable the test may still retain its validity. Since chronic tests are more sensitive to artifactual toxicity, lower concentrations of additives or less severe conditions must be used as compared to the acute test.

The presence of artifactual toxicity caused by contaminated acids, bases, air, filters and columns and by intentional additives are detected by treatment *blanks* and *toxicity controls*. A *blank* is dilution water manipulated the same as the effluent, and then it is toxicity tested to determine if the manipulation added any toxicity. The *toxicity control* is the reference used to judge the impact of a manipulation. Sometimes the *toxicity control* is the *baseline test*, at other times it will be a characterization test. For example, the *toxicity control* for the *EDTA addition test* is the *baseline test* while the *toxicity control* for the *post C_{18} SPE column test* is the *filtration test* (filtered whole effluent). Treatment *blanks* for either the *EDTA addition test* or the *sodium thiosulfate addition test* are not appropriate as the testing of these additives in clean dilution water is not representative of the effluents' characteristics. The *toxicity control* must be distinguished from the *control* treatment (animals in standard culture or dilution water; also described as "performance controls") which is always used. *Controls* provide information on the health of the test organism and the test conditions while the *blanks* provide information on the cleanliness of the acids and bases, the aeration system, the filter apparatus, the C_{18} SPE column, and other apparatus used.

Although artifactual toxicity may appear in the dilution water *blanks*, artifactual toxicity in the effluent matrix may not be observed. One must decide whether the test results from that manipulated sample are meaningful. For example, if the aeration manipulation caused toxicity in the dilution water *blank* but aeration removed the effluents' toxicity then the conclusion that aeration was an effective treatment is valid. However, if the dilution water *blank* was toxic and it appeared aeration did not remove the effluent's toxicity then one cannot conclude that aeration was not effective without further investigation.

5.7 Renewal of Manipulated Samples

One must decide whether a manipulated sample to be used for renewal during the test should be prepared (e.g., aerated or passed over a C_{18} SPE column) as a batch sample for the entire test or prepared separately for each renewal. This choice may be dependent on the persistence of the effluent toxicity, but whether daily samples are prepared or batch samples are prepared and used for renewals of the tests should be decided by the investigator, and the same methods should be performed consistently throughout the TIE. As a general guideline, we have chosen to discuss these Phase I steps as though one aliquot of effluent samples prepared for the characterization tests is used for all renewals. However for either daily or batch samples, the same techniques should be used for all the manipulations. For example, a sample for the *filtration test* (Section 6) may be batch prepared on day 1. Then on day 2, a batch sample for the *aeration test* should be prepared. Yet for the *EDTA and sodium thiosulfate addition tests*, these additives should be added to the effluent dilutions on the day of each renewal as batch solutions for each dilution (e.g., add EDTA to 50 ml of 100% effluent, let sample sit and dispense to test cups). This is true for the methanol addition and the graduated pH manipulations as well. To test the post C_{18} SPE column samples for some effluents, daily samples may need to be prepared because of bacterial growth problems in samples stored for several days.

Since Phase I TIE work is often concerned with the qualitative evaluation of toxicity, rather than quantitative, there is no reason why a test could not be terminated sooner than 7 d, if the answer to the particular question posed has been found. For example, if the *baseline test* with a sample indicates a complete inhibition of *C.dubia* reproduction by day 5 of a 7-d test, and one of the manipulated samples (e.g., aeration) shows normal reproduction, there may be little point in continuing that test, because toxicity was altered. This type of judgmental decision is harder to make in a chronic fathead minnow test based on growth; however, by careful observation of factors such as survival or behavior, the trend of the toxicity response may be discerned earlier than 7 d. Sufficient measurable growth of the fathead minnows may have been achieved by 5-d. Experiments with fish exposed to zinc and selenium for 5-d and 7-d indicated that sufficient growth differences could distinguish the toxic effect even at 5-d (Norberg-King, 1989). However, if this information is needed in Phase III, it is important to correlate the same type of data and terminating the test early may require additional tests later on.

Because the chronic test is longer and requires more laboratory work than the acute test, loss of toxicity of any effluent sample is more troublesome when it occurs. If the presence of toxicity is not measured in the whole effluent before Phase I tests begin, much work will be wasted if the sample is non-toxic initially. On the other hand, to delay by waiting for the test may also result in the loss of toxicity. The best approach is to examine existing data sets for evidence of toxicity loss due to storage of samples. If there are none then start a *baseline test*, and upon the onset of chronic toxicity (e.g., 60% mortality, no reproduction by day 5 in high test concentrations of a 7-d test, absence of food in the gut of the fishes), additional follow-up manipulations of Phase I tests should be started. Toxicity degradation can be a useful tool in identification and confirmation (cf., Section 2). Once it has been determined that the sample toxicity degrades quickly, Tier 1 and Tier 2 steps should be started on the day of arrival. Removal of headspace in effluent storage containers may help minimize the loss of toxicity.

5.8 Test Endpoints and Data Analysis

For evaluating whether any manipulation changed toxicity, the investigator should not rely on statistical evaluations only. Some treatments may have a significant biological effect that was not detected by the statistical analysis. Judgement and experience in toxicology should guide the interpretation.

Endpoints for the most commonly used freshwater short-term chronic tests are growth, reproduction, and survival. Historically, the effect and no effect concentrations have been determined using the statistical approach of hypothesis testing to determine a statistically significant response difference between a control group and a treatment group. The no effect level, called the no observed effect concentration (NOEC), and the effect concentration, called the lowest observed effect concentration (LOEC), are then statistically defined endpoints. The NOEC/LOEC are heavily affected by choice of test concentrations and test design. For example, these effect levels are dependent not only on the concentration intervals (dilution sequence) chosen, but the number of organisms, the number of replicates used, and the choice of the statistical analysis for the data (i.e., parametric or non-parametric). The minimum significant difference detected in hypothesis tests can be quite variable (e.g., 10% or 50%; Stephan and Rogers, 1985) and yet this difference is used to determine the NOEC. In the chronic testing manual (EPA, 1989C), the minimum number of replicates (a relatively large number), organisms, and dilutions for the *C. dubia* and fathead minnow short-term tests are needed to meet the hypothesis testing requirements. When less replicates, fewer numbers of dilutions and fewer test organisms are used (as in the chronic TIE) the hypothesis tests will not be able to detect smaller differences that are needed for chronic TIEs. Therefore, hypothesis testing is not suitable for Phase I purposes and a point estimation method must be used.

The linear interpolation method described in the supplement to the freshwater chronic manual (EPA, 1989C) calculates a point estimate of the effluent concentration that causes a given percent reduction based

on the organisms response. The inhibition concentration (ICp[3]) program (Norberg-King, 1989; DeGraeve et al., 1988; EPA, 1989C) was developed for the purpose of analyzing data from the short-term tests. This method of analysis is not as dependent on the test design as hypothesis analysis and is particularly useful for analyzing the type of data obtained from Phase I testing. When analyzing data for the ICp estimates, only one test endpoint is determined. For *C. dubia* all the data are used. If all animals have died, the data are entered as zeros and if some animals have some young but the adult dies, the partial brood values are used. We have found with some effluents that when the 4-d test is routinely applied during a chronic TIE, often the first brood is produced and then the adult dies. In other cases we have observed no adult mortality in the 4-d or 7-d test, but at the same effluent exposure concentrations the 7-d test animals will not produce any young while the 4-d test animals produce their first brood. The dose response from this 4-d test is not typical in the 7-d test, and the production of young can be problematic in data interpretation and analysis since mortality also occurred. For example, when analyzing the data using the ICp program, the effects of survival and young production are incorporated into one estimate for the IC50 and IC25. Yet there is no doubt that 0-40% survival is a significant reduction in survival that indicates toxicity, and would cause a routine test to fail (EPA, 1989C). Therefore when this occurs, to track toxicity in the TIE, it may require calculating the IC25/IC50 for young production and survival and then recalculating the IC25/IC50 for survival alone. For the fathead minnow test in the routine monitoring test and the TIE tests, the weights are calculated as mean weight per original fish rather than mean weight per surviving fish (EPA, 1992C). Also the program allows direct comparison of results from tests conducted using different concentration intervals. The level of inhibition (p) used as an endpoint (e.g., 25 or 50%) is not critical, although the IC25 is generally suggested as an equivalent for the NOEC (EPA, 1991B). Confidence intervals are calculated using a bootstrap technique, and these confidence intervals can be used to determine the significance of toxicity alterations observed in Phase I. A *"significant reduction"* in toxicity must be determined by each laboratory for each effluent and in combination with the precision of reference toxicant tests that the performing laboratory achieves. The use of the IC50 for Phase I TIEs may be more useful when trying to correlate the characterization test results to the effluent toxicity. However, an IC50 may not be able to be estimated while the IC25 can; use of a consistent endpoint effect level is important for subsequent TIE work (EPA, 1992A: EPA, 1992B). We have observed substantial toxicity reductions in characterization tests, yet it does not always appear to be a significant reduction when only the IC25s are compared. When this happens the sample size should be increased with subsequent testing in order to more clearly differentiate the toxicity and the dose response curve should be studied. Once the toxicant is identified, the number of replicates is increased and more dilutions are used (Phase III; EPA, 1992B), which increases the confidence in the IC25.

---

[3] The ICp program (Release 1.1) calculates confidence intervals which are limiting when the sample size is ≤5 and these confidence intervals are less than 95% in version 1.1 (R. Regal, personal communication, University of Minnesota, Duluth, MN). This is being corrected in the revision of the program now underway (for more information, contact Teresa Norberg-King). The ICp program is available by sending a formatted disk to Teresa Norberg-King, EPA, 6201 Congdon Boulevard, Duluth, MN 55804.

Section 6
Characterization Tests

The chronic Phase I manipulations follow the same approach and employ the same type of manipulations used in the acute TIE (EPA, 1991A). These include aeration, filtration, C_{18} SPE extraction and chromatography, chelation with EDTA, oxidant reduction and/or complexation with sodium thiosulfate, and toxicity testing at different pH values (Figure 6-1). The main differences between the acute and chronic techniques are that the concentrations of additives must be lower and the test conditions must be less severe in a chronic TIE because the chronic test organisms are more sensitive to these conditions. The pH adjustment procedures in Tier 2 are changed from the acute Phase I because we found that consistent, representative blanks with reconstituted water could not be obtained at higher pH's.

The following characterization steps are all based on the use of *Ceriodaphnia* or fathead minnows. Obviously, use of other species will require consideration of appropriate test volumes and additive concentrations. As discussed in the acute manual, if the TIE is done with species different from the species used in the permit, one must demonstrate that both species are sensitive to the same toxicant(s) (see Section 5).

More than one effect is measured in chronic tests (reproduction or growth and survival) and because partial effects are more frequent in short-term chronic tests than in acute tests, a graded response with concentration is often seen. A graded response allows one to better judge small changes in toxicity—an advantage not often available in acute tests. Also, effects (initial mortality, delayed mortality, aborted young, reduced young, poor growth) can be observed and used in interpreting the results as can the time to onset of effect be used. Such effects can be useful in distinguishing the response to different toxicants.

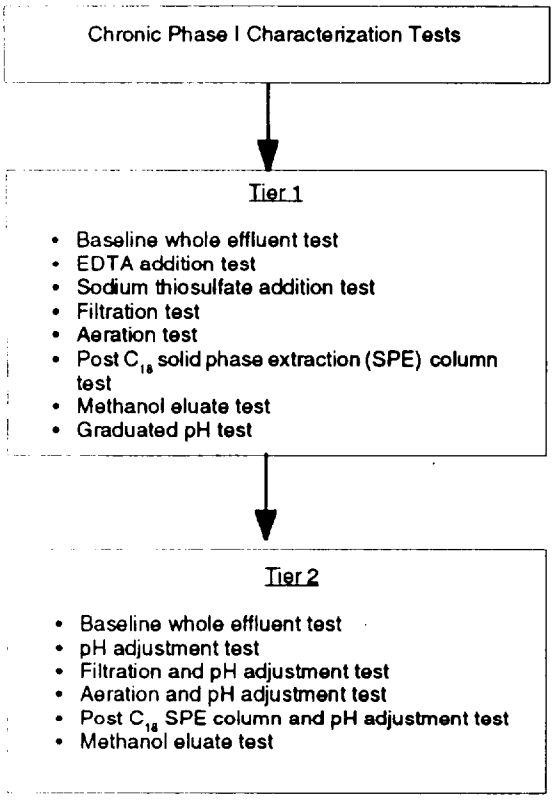
For acute TIEs, tests are quick and relatively inexpensive, so the need to maximize their usefulness is lessened. The chronic test is more work not only because the test is longer and more complex, but also because more sample volume is needed. For example, for tests such as the sublation test (a subsequent step in the *aeration test* (Section 6.4)) sample size can be very restricting. In addition, if an effluent is not always toxic, a decision has to be made as to whether to test for the presence of toxicity first, before manipulations are started. If the effluent is not toxic and all the manipulations are set up, the results may be of no value. On the other hand, if the presence of toxicity is first established, often a week will have passed and by the time manipulations are tested, the toxicity may have degraded. Unfortunately, there is no clear answer to which way to proceed. When there are data for effluent toxicity for preceding months, examination of these data may assist in the decision.

In the acute TIE, the *initial test* (EPA, 1991C) is used to set the range of concentrations to test. However in the chronic TIE, an equivalent of the *initial test* is not practical, therefore historical data must be used to make such judgements. Lacking historical data, a judgement will have to be made to set the test range and guidance for this is given in Section 5.4.

For chronic Phase I characterization, the use of two tiers of characterization tests is suggested (Figure 6-1). Tier 1 is done without major pH adjustments. Experience with acute TIEs has shown that major pH adjustments are usually not needed. Tier 2 is performed only when Tier 1 does not provide sufficient information, and consists of filtration, aeration and the C_{18} separation technique of Tier 1 with an effluent sample adjusted to both pH 3 and pH 10. Therefore when the characterization tests indicate Tier 2 is not required, resources needed to conduct the TIE are significantly reduced.[4] Each characterization test used in the Tier 1 or Tier 2 has as its foundation the information in the acute Phase I manual (EPA, 1988A; EPA, 1991A). The principles, methods, and interpretation of results are based on the acute manual, and the tests for Tier 1 (Figure 6-2) are discussed in Sections 6.1-6.8. All tests within a Tier (1 or 2) should be started on the same day. Starting chronic tests involves more effort than acute tests, and logistics must be planned (for instance, available animals of the appropriate age for the chronic test, sufficient food supply for more chronic tests, adequate supply of dilution water for all test renewals). Tests need to be started on the same day in order to compare results of each manipulation test to others and to the *baseline test* (Section 6.3) results (Table 6-1). Once the Tier 1 data are generated, they are compared, and interpretations are made to see which inferences can be drawn concerning the nature of the toxicants. Usually, multiple manipulations and a retest of selected manipulations will be effective in

[4] A recent estimate of the cost of the Tier 1, Phase I for chronic toxicity was equivalent to the full Phase I acute TIE (Aquatic Habitat Institute, 1992).

Figure 6-1. Overview of characterization tests.



yielding information concerning the nature of toxicants before additional effluent samples are tested (see Sections 6.15, 6.16 and acute Phase I manual, EPA 1991A).

Sample Preparation for the Characterization Tests

As for acute TIE tests, we suggest doing certain chemical measurements and the manipulations on one day and then starting the tests the next day (Table 6-1). This schedule balances the work load more evenly. When the sample is received (day 1), various measurements (Section 4) are taken and some preparatory manipulations for the Tier 1, Phase I are done.

First, the routine chemical measurements are taken as discussed in Section 4. DO, conductivity, and pH should be measured on the 100% effluent to ensure that the values are in the physiologically tolerable range for the test species. If these are at levels that could be toxic (EPA, 1989C), there is little point to test the effluent sample without some sample manipulation. In addition, the water hardness and alkalinity should be measured so that the appropriate dilution water can be selected (see Section 3, Dilution Water). As the TIEs have progressed, we have begun to match both the hardness and the alkalinity of the dilution water to similar values for the effluent.

Figure 6-2. Tier 1 sample preparation and testing overview.

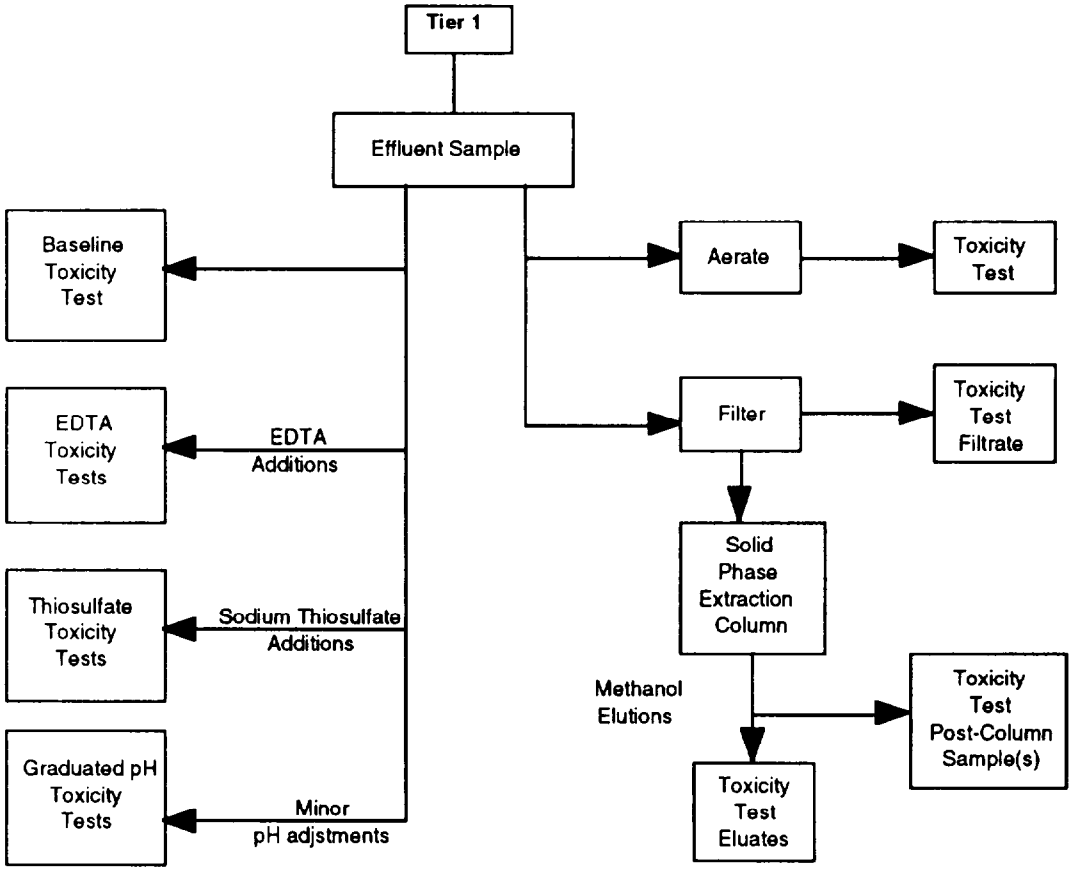


Table 6-1. Outline of Phase I effluent manipulations Tier 1 and Tier 2.

Description	Section
DAY 1 SAMPLE ARRIVAL:	
Measure	4.0
• temperature	
• conductivity	
• pH	
• DO	
• alkalinity	
• hardness	
• total ammonia	
• total residual chlorine	
Perform Sample Manipulations	6.0
• filter effluent	6.4
• perform solid phase extraction (SPE)	
• collect effluent	6.6
• collect methanol eluate	6.7
DAY 2 TOXICITY TESTING:	
Warm aliquot of whole effluent and aliquots of filtered effluent, post C_{18} SPE column effluent, and methanol eluates.	
Initiate Tier 1 Tests	
• *baseline toxicity test*	6.1
• *EDTA addition test*	6.2
• *sodium thiosulfate addition test*	6.3
• *aeration test*	6.4
• *filtration test*	6.5
• *post C_{18} SPE column test*	6.6
• *methanol eluate test*	6.7
• *graduated pH test*[1]	6.8
ADDITIONAL TESTING ON SUBSEQUENT DAYS[2]*:*	
Tier 2 Tests	
• *pH adjustment test*	6.10
• *aeration and pH adjustment test*	6.11
• *filtration and pH adjustment test*	6.12
• *post C_{18} SPE column and pH adjustment test*	6.13
• *methanol eluate test for pH adjusted samples*	6.14

[1] Experimentation may be needed for this test (see text for details).

[2] Tier 2 is primarily for those effluents where the results from Tier 1 did not indicate any clear pattern of toxicity change following manipulation (see text for details).

The initial pH of effluent upon arrival at the testing laboratory is referred to as pH *i*, which is not necessarily the pH of the effluent at air equilibrium[5]. The pH of the sample after being warmed, may be selected as pH *i* rather than the pH upon arrival. The important point is to use the same pH *i* for all subsequent tests. As an effluent warms to 25°C in an open container, CO_2 escapes and the pH may rise from 7.2-7.6 to 8-8.5. In some tests, once the food is added the pH may rise faster or in some cases (e.g., the fathead minnow growth test), once the food has been in the test solution for a period of time, the pH may be lower (e.g., 7.5-7.6). These changes may be important for interpreting the data in a chronic TIE, and pH should be measured in the test dilutions that determine the test endpoint. Of course, since the endpoint may be unknown, pH is typically measured in all test concentrations.

Since samples are cooled for shipping and storage, upon warming to 25°C, some of the samples are apt to be supersaturated. Supersaturation can usually be monitored by measuring DO. If DO is too high, it should be reduced to acceptable levels as described by EPA (1989C) for the routine monitoring test or by maximizing surface-to-volume ratio of the container to facilitate more rapid exchange of equilibrium of the sample and atmospheric oxygen. *Ceriodaphnia* are less sensitive to supersaturation than newly hatched fathead minnows. For chronic Phase I tests, routine water chemistry measurements (such as DO, pH, temperature) are more important than in acute Phase I tests.

The manipulations performed the day the sample arrives are filtering, extraction on the C_{18} SPE column, and collection of the methanol eluates (see Sections 6.5 and 6.7 below). The aliquots of filtered effluent and post-column effluent will be held until the next day (day 2) to start the tests. Of course these samples should be stored in the refrigerator at 4 (± 2°C). This sample preparation schedule is particularly convenient for laboratories who rely on courier services to deliver samples, which typically occurs late in the morning.

On day 2, the EDTA addition test should be prepared first so that compounds that are EDTA chelatable, yet may require an equilibration time for complexation, can be chelated (see Section 6.4). Then the rest of the manipulations (aeration, sodium thiosulfate additions, graduated pH adjustments) should be started. For the laboratory that is experienced in chronic toxicity testing, the amount of time required to conduct the Tier 1 sample manipulations and set up the toxicity tests is about 6-10 h.

6.1 Baseline Test

General Approach: To determine the effects of Phase I manipulations on the toxicity of the effluent, its inherent toxicity must be determined. The toxicity measured in this test is used to gauge toxicity changes caused by some manipulations and to detect changes in the sample's toxicity during storage. *Baseline tests* must be repeated each time additional manipulation tests are started.

Methods: The *baseline test* will be initiated using concentrations based on the historical data for each particular discharger. For the TIE, use of four (and

[5] EPA suggests that toxicity must be prevented under worst case scenarios (EPA, 1991B) which may mean the routine monitoring tests were conducted at high pH's.

three) dilutions have been sufficient for defining toxicity (Section 5.4). If the toxicity is low, in order to draw distinctions between the concentrations used in the test for the various characterization tests, the dilutions may need to be set closer, for example, 40%, 60%, 80%, 100%. In this test, and all subsequent characterization tests, the test concentrations, test volumes and number of replicates should be kept the same as described in Section 5, Toxicity Testing.

On day 2, an aliquot of the effluent is warmed slowly in a warm water bath to test temperature (25°C). The various test concentrations are prepared using the appropriate hardness reconstituted water. Next, routine chemistries are measured (initial pH, temperature, DO). The use of *dilution water controls* is not required for every manipulation but at least two sets of *controls* should be included to estimate reproducibility. In addition, the tests are conducted using one *C. dubia* per one 10 ml test volume in a 1 oz plastic cup (or glass beaker) and five animals per treatment. For the fathead minnow tests, two replicates per treatment, 10 fish in 50 ml in a 4 oz plastic cup, or 100 ml in a 400 ml beaker, are assumed.

Interpretation of Results/Subsequent Tests: The *baseline tests* serve as the basis for determining the effects produced by various characterization tests. This test serves as the *toxicity control* for some of the other tests. If *baseline tests* done on subsequent days with additional manipulations indicate that the toxicity of the effluent is decreasing, either every effort should be expended to characterize the toxicity more quickly (i.e., Phase II identification or Tier 2 tests) or another sample should be obtained. The *"shelf life"* of the toxicity can be determined after a few samples have been evaluated.

Special Considerations/Cautions: The *controls* in this test will provide information on the health of the test organisms, the dilution water, the test glassware and equipment used to prepare the test solutions and the cleanliness of the test chambers. This *baseline test* serves as the *toxicity control* for some subsequent Tier 1 or Tier 2 tests.

6.2 EDTA Addition Test

General Approach: This test is designed to detect effluent toxicity caused by certain cationic metals. The addition of EDTA to water and effluent solutions can produce non-toxic complexes with many cationic metals. Loss of toxicity with EDTA addition(s) suggests that cationic metals are causing toxicity.

EDTA is a strong chelating agent and because of its complexing strength, it will often displace other soluble forms (such as chlorides and oxides) of many metals. The ability of EDTA to chelate any metal is a function of pH, the type and speciation of the metal, other ligands in the solution, and the binding affinity of EDTA for the metal. And the complexation of metals by EDTA may vary according to the sample matrix. The specific form of metal that causes toxicity in the water matrix may be more important than the total concentration of the metal.

Cations strongly chelated by EDTA include aluminum ($^{3+}$), cadmium, copper, iron, lead, manganese ($^{2+}$), nickel, and zinc (Stumm and Morgan, 1981). EDTA weakly chelates barium, calcium, cobalt, magnesium, strontium, and thallium (Flaschka and Barnard, 1967). EDTA can form relatively weak chelates with arsenic and mercury and anionic forms of metals (selenides, chromates and hydrochromates) will not be chelated.

For some cationic metals for which EDTA forms relatively strong complexes, the acute toxicity to *C. dubia* is reduced (Mount, 1991; Hockett and Mount, In Preparation). EDTA was shown to chelate the metal causing the acute toxicity (at 4x the LC50) for copper, cadmium, lead, manganese ($^{2+}$), nickel, and zinc to *C. dubia* in both dilution water and effluents. However, they also found that EDTA did not remove/reduce the acute toxicity of silver, selenium (either as sodium selenite or sodium selenate), aluminum ($Al(OH)_4^-$), chromium (either as chromium chloride or potassium dichromate), or arsenic (either sodium m-arsenite or sodium arsenate) when tested using moderately hard water and *C. dubia* (Hockett and Mount, In Preparation).

In the acute Phase I manual (EPA, 1988A), the recommended amount of EDTA to be added was high because the authors thought calcium and magnesium had to be complexed in order to complex toxic metals (D. Mount, personal communication, NETAC, Duluth, MN). The mass of EDTA required was approximated by the amount needed for the titration of hardness or the measurement of calcium and magnesium when titration was not possible due to interferences. A third choice was to use 0.5x the EDTA LC50 for the test species (EPA, 1991A). Ideally the amount of EDTA to add would be just enough to chelate the toxicant(s) without causing toxicity or otherwise changing the matrix of the effluent. Without knowing how much toxicant must be chelated, the amount of EDTA to add must be estimated. Recently, the role of calcium and magnesium was tested in our laboratory. Acute toxicity tests with *C.dubia* were conducted in moderately hard and very hard reconstituted water using copper, cadmium, and zinc at 4x, 2x, and 1x the LC50 of each. When one metal and EDTA were present at approximately a 1:1 molar basis, all the toxicity was removed regardless of water hardness (J. Thompson, personal communication, NETAC, Duluth, MN). These results indicate that calcium and magnesium concentrations do not affect the levels of EDTA needed to remove the acute cationic metal toxicity. Whether toxicity reduction using the 1:1 molar ratio is true for chronic toxicity has not yet been evaluated in a likewise manner (cf., *Interpretation of Results/Subsequent Tests* below). However, EDTA and nitrotriacetic acid (NTA) were effective in chelating the toxicity of one concentration of either cadmium or copper to *C. dubia* at molar ratios of less than 1:1 (Zuiderveen and Birge, 1991). However, NTA pos-

sesses the characteristic of increasing the toxicity of some metals therefore NTA is limited in its usefulness for the TIE.

The threshold levels for *C. dubia* and fathead minnows to EDTA were determined using 7-d tests in different hardness waters and the results are given in Table 6-2. For *C. dubia*, the chronic toxicity of EDTA is not water hardness dependent, but for fathead minnows the sublethal toxicity appears to be greater in softer waters. This is in contrast to the acute toxicity of EDTA to *Ceriodaphnia* which indicated that EDTA toxicity decreased with increased water hardness (Phase I; EPA, 1991A). Natural waters and effluents have many constituents in addition to those added to reconstituted waters, and the behavior of EDTA in effluents (or receiving waters) could be different than in simple reconstituted water.

Methods: The goal is to add enough EDTA to reduce metal toxicity, without causing EDTA toxicity or substantially changing the water quality. The toxicity of EDTA as determined in clean reconstituted water is likely to be higher than the toxicity of EDTA added to an effluent. Therefore, the EDTA toxicity values contained in Table 6-2 represent maximum toxicity in any effluent. The toxic concentration of EDTA in one effluent will probably not be the same as the concentration causing toxicity in a different effluent or even a different sample of the same effluent. To be safe, the concentrations of EDTA added to any effluent should be less than the expected effect concentration of EDTA in clean water. For either species, two EDTA concentrations are added to two sets of two effluent dilutions. EDTA stock solution is added after the effluent dilutions are prepared so that the EDTA concentrations for each addition are constant across each set of effluent dilutions. A stock solution of EDTA (ethylene–diaminetetraacetic acid, disodium salt dihydrate) is prepared in distilled water. This EDTA stock solution should be prepared so that only microliter amounts of the stock are needed to minimize effluent dilution. No more than 5% dilution of the effluent aliquot by EDTA stock should occur.

To perform the effluent dilution test, two sets of effluent dilution concentrations are prepared (e.g, 100%, 50%, 25%,) and each set receives one of two addition levels of EDTA (Table 6-3). By using non-toxic concentrations of EDTA, there is less chance for artifactual toxicity; since the total amount of metal to be chelated is probably low for most chronically toxic effluents, there is no reason to add high levels of EDTA. The additive levels are based on the assumption that the calcium and magnesium need not be chelated in order to chelate the toxic metals, although the amount of EDTA added is most likely still an excess.

An EDTA stock solution of 2500 mg/l can be prepared. For the *C. dubia* tests, 0.06 ml is added to three separate 50 ml aliquots in the first effluent dilution set (i.e., 25%, 50%, 100%) to obtain a 3.0 mg/l final EDTA concentration. In the second dilution set, 0.16 ml is added to the other set of 50 ml effluent aliquots for a final concentration of 8.0 mg/l. For the fathead minnow tests, the same concentration of an EDTA stock solution can be used but the volume of stock additions must be doubled for the 100 ml test volume/concentration.

Table 6-2. Chronic toxicity of EDTA (mg/l) to *C. dubia* and *P. promelas* in various hardness waters using the 7-d tests.

Species	Water Type	IC50 95% C.I.	IC25 95% C.I.	NOEC	LOEC
C. dubia	VSRW	4.5 3.6-6.0	3.0 2.1-3.9	2.5	5.0
	SRW	7.5 6.2-8.3	4.9 3.7-5.7	3.1	6.3
	MHRW	8.8 4.7-13	5.9 3.4-10	5.0	10
	HRW	7.5 6.2-9.8	5.5 0.98-6.9	5.0	10
	VHRW	7.8 6.7-8.6	6.1 4.0-6.8	5.0	10
	VHRW	12 10-14	8.3 4.2-10	7.5	15
P. promelas	SRW	136 130-139	103 94-110	100	200
	MHRW	163 150-188	132 123-144	100	200
	HRW	236 227-248	—[1]	200	400
	VHRW	287 269-300	230 203-247	200	400

[1] Value could not be determined, value would be less than lowest test concentration.

Note: C.I. = confidence interval; VSRW = very soft reconstituted water; SRW = soft reconstituted water; MHRW = moderately hard reconstituted water; HRW = hard reconstituted water; VHRW = very hard reconstituted water.

Table 6-3. Concentrations of EDTA to add for chronic TIEs. Values given are the final exposure concentration in mg/l.

Species	Water Type[1]	Concentrations (mg/l)	
C. dubia and *P. promelas*	SRW, MHRW, HRW, VHRW	3.0	8.0

[1] In very soft water, the final concentrations of EDTA must be lower in order to not have EDTA induced toxicity, for example 1.0 mg/l and 5.0 mg/l.

Note: SRW = soft reconstituted water; MHRW = moderately hard reconstituted water; HRW = hard reconstituted water; VHRW = very hard reconstituted water.

To allow the EDTA time to complex the metals, solutions should be set up on day 2 and all solutions containing EDTA are allowed to equilibrate while other manipulations are being prepared before test organisms are introduced. A minimum of 2 h equilibration time should elapse before organisms are added.

Since EDTA is an acid, the pH of the effluent after addition of EDTA should be checked, although additions at these low levels should not lower the pH of the effluent. The amount of change in solution pH will depend upon the buffering capacity of the effluent and the amount of reagent added. If the pH of the effluent has changed, readjustment of the test solution pH to pH *i* should be performed.

The EDTA is not added to one batch of effluent on day 2; rather at each renewal EDTA is added to the renewal test solutions prior to dispensing into the test chambers in the identical way that the test solution was first made (allowing equilibration time).

Interpretation of Results/Subsequent Tests: Toxicity may be removed at all exposures provided the addition of EDTA does not cause toxicity. If the effluent is less toxic (i.e., EDTA addition IC50 (or IC25) shows less toxicity than *baseline test* IC50 (or IC25)) in either of the EDTA addition dilution tests, then EDTA removed or reduced the toxicity and cationic metal toxicity is probably present. If, in either test, the effluent is more toxic than in the *baseline test*, EDTA itself may be causing toxicity and the test should be repeated using lower EDTA concentrations. If toxicity is not reduced below the *baseline test*, the probability of cationic metals causing toxicity in the effluent is low and higher concentrations of EDTA can be tried, although this may or may not be useful.

Table 6-4 shows the results of a chronic zinc test and the reduction of the toxicity by the addition of EDTA. When *C. dubia* were tested in very hard reconstituted water, zinc was chronically toxic at 55 µg/l and EDTA was chronically toxic at 15 mg/l. When EDTA was added to solutions of 55 µg/l zinc at 2.5, 5.0, and 7.5 mg/l EDTA respectively, the toxicity of the zinc was removed but at 15 mg/l EDTA, EDTA itself was toxic. Such trends may be similar to the toxicity reduction observed in effluents. If toxicity is reduced in a systematic manner, such as in the example, proceed to Phase II methods for identification of those metal(s) which are chelated by EDTA. Additions of EDTA at 3 mg/l and 8 mg/l removed the toxicity of copper to *C. dubia* in a 7-d two-renewal test with hard reconstituted water at levels of 210 µg/l and 105 µg/l of copper. In addition to removing toxicity due to metals, EDTA reduces the acute toxicity of some cationic surfactants. This reduction of toxicity may also occur in chronically toxic effluents, and the toxicity reduced by EDTA should not be assumed to be due only to cationic metals. See Section 6.4 *Aeration Test* for subsequent tests to conduct if cationic metals are not present in the effluent at chronically toxic levels but EDTA reduced toxicity.

Table 6-4. The chronic toxicity of zinc (µg/l) to *C. dubia* in very hard reconstituted water and the toxicity of zinc when EDTA is added.

Zinc[1] Conc.	Mean Young per Female				
	EDTA Additions (mg/l)				
µg/l	0	2.5	5.0	7.5	15
0	19.2	18.6	17.5	17.6	6.8
3.4	19.4	—[2]	—	—	—
14	17.8	22.0	23.2	20.8	1.8
55	8.2	20.8	19.0	16.6	5.3

[1] Measured values.
[2] EDTA not added to this zinc concentration.

Special Considerations/Cautions: If pH in the EDTA tests is greatly different from that in the *baseline test*, the test might need to be redone. There is no way to distinguish the effect of pH change on the toxicity of a pH sensitive toxicant (e.g., ammonia) from toxicity changes caused by EDTA. A change of 0.1 pH unit can cause substantial errors if ammonia is involved. Before the test is reinitiated, data from the *graduated pH test* should be examined to evaluate whether the toxicity is pH dependent. This test data may be useful in deciding whether the *EDTA addition test* should be redone. EDTA additions to dilution water are not relevant *controls* for the EDTA additions to effluent; therefore, the *toxicity control* is the *baseline test*. The *control* of the *baseline test* serves as the QC for the health of the test organisms, the quality of the dilution water, and general test conditions.

If all dilutions where EDTA is added should cause mortality, one possibility is that the stock solution of EDTA is contaminated and the stock solution should be checked by conducting another test with a new EDTA stock.

6.3 Sodium Thiosulfate Addition Test

General Approach: Oxidative compounds (such as chlorine) and other compounds (such as copper and manganese) can be made less toxic or non-toxic by additions of sodium thiosulfate ($Na_2S_2O_3$). Toxicity from bromine, iodine, ozone, and chlorine dioxide is also reduced. Sodium thiosulfate has been routinely used to reduce the toxicity of substances such as chlorine (EPA, 1989C).

Reductions in effluent toxicity observed with sodium thiosulfate additions may also be due to the formation of metal complexes with the thiosulfate anion (Giles and Danell, 1983). The ability of sodium thiosulfate to form a metal complex is rate dependent and metal dependent (Smith and Martell, 1981) and sodium thiosulfate is not a particularly strong ligand for metal complexation. Cationic metals that appear to have this potential for complexation, based upon their equilibrium

stability constants, include cadmium, copper, silver, and mercury ($^{2+}$) (Smith and Martell, 1981). The rate of complexation is specific for various metals and some cationic metals may remain toxic in the 24-h or 48-h renewal period of the chronic toxicity test due to the slow rate of complexation or the stability of the complex. The thiosulfate anion is not very stable, and the ability of sodium thiosulfate to complex the compound(s) causing chronic toxicity without daily renewals has not been tested completely.

Recent findings have shown that the acute toxicity of certain cationic metals may be reduced by levels of sodium thiosulfate added in the acute Phase I tests (EPA, 1988A; EPA, 1991A). The acute toxicity of several cationic metals was shown to be removed by sodium thiosulfate in standard laboratory water. The acute toxicity at 4x the LC50s of copper, cadmium, mercury, silver, and selenium (as selenate) to *C.dubia* was removed by sodium thiosulfate additions at levels suggested in the acute Phase I manual. However, for zinc, manganese, lead, and nickel, the acute toxicity was not removed by the sodium thiosulfate additions (Mount, 1991; Hockett and Mount, In Preparation). The toxicity of mercury with the addition of sodium thiosulfate was reduced for 24 h but not 48 h which indicates it may not have been completely complexed by the thiosulfate. If the acute toxicity of metals can be reduced or complexed by sodium thiosulfate, the same may be true for chronic toxicity. However, for *C. dubia* 7-d tests with hard reconstituted water, sodium thiosulfate levels of 5 mg/l and 10 mg/l did not remove or reduce the chronic toxicity of copper at the same concentrations where EDTA complexed the toxicity (cf., Section 6.2).

The test animals will probably tolerate more sodium thiosulfate than would ever be needed to render oxidants or metals non-toxic in effluent samples, especially the fathead minnows in comparison to the *C. dubia* (Table 6-5). The presence of oxidants or complexable metals will reduce the concentrations of sodium thiosulfate below the nominal concentrations added.

Table 6-5 gives the toxicity values in various reconstituted waters. The effect concentrations for *C. dubia* and fathead minnows were measured in waters of different hardnesses (soft, moderately hard, hard, and very hard water (EPA, 1989C)). For *Ceriodaphnia*, the results indicate that the sublethal toxicity is unchanged regardless of the water type (Table 6-5). The toxicity tests with sodium thiosulfate and fathead minnows (7-d growth test) indicate that the toxicity due to sodium thiosulfate is greater in softer waters.

Methods: Two sets of effluent dilutions (such as 25%, 50%, 100%) each set with a different level of thiosulfate concentration (Table 6-6) are prepared regardless of whether *C. dubia* or fathead minnows are used as the TIE test organism. The concentration of thiosulfate remains constant across one set of effluent concentrations within a series (identical to *EDTA addition test*). Small volumes (microliter) of the sodium thiosulfate stock solution should be added to minimize the dilution (5% of total volume). Non-toxic concentrations of sodium thiosulfate are used to reduce the pro–

Table 6-5. Chronic toxicity of sodium thiosulfate (mg/l) to *C. dubia* and *P. promelas* in various hardness waters using the 7-d tests.

Species	Water Type	IC50 95% C.I.	IC25 95% C.I.	NOEC	LOEC
C. dubia	SRW	39 30-42	26 15-33	30	60
	HRW	38 26-44	27 20-36	30	60
	VHRW	43 37-44	34 21-37	30	60
P. promelas	SRW	1,070 1,041-1,1005	820 785-859	750	1,500
	MHRW	2,001 1,891-2,161	720 550-1,528	750	1,500
	HRW	4,871 4,633-5,051	3,590 3,226-3,800	3,000	6,000
	VHRW	8,522 8,053-8,704	6,780 6,065-7,073	6,000	12,000

Note: C.I. = confidence interval; SRW = soft reconstituted water; MHRW = moderately hard reconstituted water; HRW = hard reconstituted water; VHRW = very hard reconstituted water.

Table 6-6. Concentrations of sodium thiosulfate to add for chronic TIEs. Values given are the final exposure concentration in mg/l.

Species	Water Type[1]	Concentrations (mg/l)	
C. dubia and *P. promelas*	SRW, MHRW, HRW, VHRW	10	25

[1] In very soft water, the final concentrations of sodium thiosulfate must be lower in order to not have sodium thiosulfate induced toxicity, for example 1.0 mg/l and 5.0 mg/l.

Note: SRW = soft reconstituted water; MHRW = moderately hard reconstituted water; HRW = hard reconstituted water; VHRW = very hard reconstituted water.

bability of artifactual toxicity, yet sufficient concentrations are needed to remove/reduce oxidants.

For a *C. dubia* test, to the first effluent dilution set (i.e., 25%, 50%, 100%), 0.20 ml of sodium thiosulfate stock (2500 mg/l) is added to each 50 ml dilution to obtain final concentrations of sodium thiosulfate of 10 mg/l. To the second effluent dilution set, 0.50 ml of the same stock solution is added to 50 ml of each test dilution to obtain final concentrations of 25 mg/l (Table 6-6).

The fathead minnow test is similar except that twice the volume of the same thiosulfate stock is needed (because of 100 ml test volumes) to achieve the same final concentrations (Table 6-6).

The sodium thiosulfate is not added to a batch of the effluent on day 2; rather, at each renewal, sodium thiosulfate is added to the renewal test solutions in a manner identical to the way they were first prepared.

Interpretation of Results/Subsequent Tests: The results of the *sodium thiosulfate addition tests* are compared to one another and to the *baseline test* results to determine whether or not toxicity reduction occurred. Toxicity may be completely reduced, partially reduced, or not reduced. If toxicity appears to be reduced and/or removed, then more tests to determine whether the toxicity is due to an oxidant or to some metal should be performed. When chlorine concentrations are ± 0.1 mg/l total residual chlorine (TRC), there may be a toxicity problem for *C. dubia*. A significant drop in the chlorine level in the whole effluent may occur in the first 24-h period after sample collection and testing. Therefore, tests repeated on an aged sample may give different results if an oxidant is involved but may give the *same* results if a metal is involved.

For cases where oxidants account for only part of the toxicity, sodium thiosulfate may only reduce, not eliminate, the toxicity. Yet the *sodium thiosulfate addition test* is useful even when chlorine appears to be absent in the effluent. Oxidants other than chlorine occur in effluents, and even if the effluent is not chlorinated this test should not be omitted. Both thiosulfate and EDTA reduce the toxicity of some metals and this information can be helpful in identifying the toxicant. (However, this effect of thiosulfate/metal complexation has not been demonstrated for chronic toxicity.) In cases where both the *sodium thiosulfate addition test* and the *EDTA addition test* reduce the toxicity in the effluent sample, there is a possibility that the toxicant(s) may be a cationic metal(s). Many oxidants are reduced by aeration but if aeration does not reduce toxicity, Phase II methods for identification of cationic metal(s) toxicants should be investigated. No change in toxicity suggests either no oxidants or certain metals.

Special Considerations/Cautions: The general test conditions, quality of the dilution water, and health of the test organisms are tracked by the *controls* in the *baseline test*. Additions of sodium thiosulfate to dilution water are not relevant *controls* for thiosulfate additions to effluent to determine if the thiosulfate was toxic. Therefore the *toxicity control* is the *baseline test*.

If all dilutions where sodium thiosulfate is added should exhibit mortality, one possibility is that the stock solution of sodium thiosulfate is contaminated and this phenomena should be checked by conducting another test.

6.4 Aeration Test

General Approach: Changes in toxicity due to aeration at pH *i* may be caused by substances that are oxidizable, spargeable, or sublatable. The chemical/physical conditions of the aeration process will also affect whether or not the toxicity is reduced or removed.

Sparging of samples is done using air which includes oxidation as a means of toxicity removal. In our experience, typically volatile compounds that are highly water soluble (such as ammonia) will not be air-stripped at pH *i* by this method. If aeration is one of the mechanisms that removes the toxicity, then additional tests must be performed to identify which mechanism is removing the toxicity. Subsequent tests with nitrogen can be used to determine if toxicity reduction was due to oxidation. Also, air or nitrogen sparging can cause surface active agents to sublate. As bubbles break at the surface, sublatable compounds will be deposited on the sides of the aeration vessel. Sublatable toxicity identification requires special sample removal and rinsing (see below). A visible deposit does not indicate the presence or absence of such toxicants.

Methods: For the aeration process, the volume of effluent and dilution water aerated is kept the same even though all of the dilution water volume is not needed for the *aeration blank*. The flow rate, bubble size, geometry of apparatus and time of aeration should be consistent among treatments. Taller water columns and smaller bubbles should ensure better stripping; therefore, the aeration vessel should be half-full or greater for this process. Each aliquot (effluent and dilution water) should be moderately aerated for a standard length of time (60 min). Use of gas washing bottles (Kontes Glass Co., Vineland, NJ) fitted with

glass frit diffusers located at the bottom of the vessel for aeration is suggested because they sparge the sample effectively. During aeration, the pH of the effluent is not maintained at "pH *i*."

The volume of effluent aerated should be the same for either a 4-d *C. dubia* test or a 7-d *C. dubia* two renewal test (four dilutions, five replicates for each dilution; see Section 5), although there is excess of solutions for the 4-d test. Use of 300 ml of effluent (or dilution water) in a 500 ml gas washing bottle or 500 ml in a 1 L bottle and a flow-rate of 500ml/min is suggested. Any loss of volume and any formation of precipitates should also be recorded.

Interpretation of Results/Subsequent Tests: If the aerated effluent has less toxicity than the *baseline test*, and the *aeration blank* is not toxic, aeration was effective in reducing toxicity. If the toxicity of the aerated effluent is less than the *baseline test*, even though the *aeration blank* is toxic, the results indicate that aeration is an effective removal technique. If the effluent toxicity is not reduced or it is more toxic after aeration than in the *baseline test* (and the *aeration blank* was non-toxic, then either toxicity was concentrated during the aeration process or toxicity was added or created during the aeration process (see *Special Considerations/Cautions* below).

Typically, using this aeration technique, ammonia is not air-stripped from the sample at pH *i*. However, if total ammonia is at least 10 mg/l or higher and the pH is above 8.0, ammonia measurements in the aerated sample may be useful if the aeration manipulation resulted in a toxicity reduction.

If a substantial reduction in toxicity is observed, then the mechanism for the toxicity removal must be determined. To determine if the reduction is due to oxidation, sparging, or sublation, the air should be replaced by nitrogen. The flow of nitrogen through the sample must be the same as for air. If nitrogen sparging as well as air sparging removes or reduces the toxicity, then oxidation as the removal process is eliminated. If aeration only succeeds in reducing toxicity, then oxidation may be involved. It is possible that a toxicant can be removed through sparging *and* oxidation in which case air should reduce toxicity more than nitrogen.

The presence of sublatable substances can be determined (whether air or nitrogen is used) by removing the aerated sample from the aeration vessel by siphoning or pipetting without contact with the sides of the aeration vessel. The geometry of the aeration vessel (i.e., at least a half-full cylinder) must remain the same as in the initial aeration experiment but the recovery of sublated compounds can be difficult. Dilution water added to the aeration vessel is used as a rinse to remove the sublate residue on the walls. To attempt this recovery, use of graduated cylinders with ground glass stoppers has been successful for acute testing (EPA, 1991A) because the water can be shaken vigorously to contact all surface areas to recover the sublatables. This sublation procedure is effective for dissolved surfactants, and while sewage particles adsorb surface active particles tightly, the actual sublation process may take some time (i.e., >1 h) (AHPA, 1989). If toxicity is not recovered from the vessel walls, the presence of such compounds cannot be ruled out. Specific procedures, for the larger volumes needed in the chronic tests, have not yet been developed.

In some instances, sublatable toxicants may not be removed by dilution water, and the use of solvents (e.g., methanol) may be needed for better recovery. However, the solvent will have to be reduced in volume (aired down) in order to have an adequate concentration factor in the test solution and a sufficiently low concentration of solvent for the subsequent toxicity tests (see Sections 6.7 and 6.8 for methanol toxicity information). Of course, dilution water *blanks* must also be subjected to all steps to check for artifactual toxicity.

Special Considerations/Cautions: Removal of compounds by precipitation can occur through oxidation. However, the *filtration test* should not change toxicity of the effluent if oxidation is involved but filtration might also remove the toxicity of some sublatable compounds absorbed to particles and therefore the results of the *aeration test* can be compared to the *filtration test*.

Use of nitrogen to sparge the sample is likely to drastically reduce the DO. For instance, 1 h of nitrogen sparging has caused the DO to drop below 4 mg/l. To increase the DO before initiating the test after a sample has been sparged with nitrogen, transfer the sample to a container with a large surface area to water volume ratio. The DO should rise to >5 mg/l without additional aeration.

The *baseline test* serves as the *toxicity control* and the aeration of the dilution water (*aeration blank*) provides information on the system apparatus. The general test conditions, quality of the dilution water, and health of the test organisms are tracked by the *controls* in the *baseline test*. No significant toxicity should occur in the *aeration blank*. Toxicity in the *aeration blank* implies toxic artifacts from the aeration process, the glassware, or a dilution water problem. If the *aeration blank* is toxic, check the results of the test of the *filtration blank*. If both *blanks* are toxic, then most likely there is a problem with the dilution water but if only the *aeration blank* is toxic, artifactual toxicity arose during that manipulation.

6.5 Filtration Test

General Approach: Filtration of the effluent sample provides information on whether the toxicity is filterable yet provides relatively little specific information about which class of toxicant may be causing the toxicity. Reductions in the toxicity caused by filtering alone may imply toxicity associated with suspended solids or removal of particle-bound toxicants. Whether compounds in the effluent are in solution or sorbed to particles is

dependent on particle surface charge, surface area, compound polarity and charge, solubility, and the matrix of the effluent. If particles are removed, other compounds may be bound to them and are not available to cause toxicity. The way the toxicant is bound to the particulates is probably more important when using filter feeders as the toxicity test organism in short-term chronic tests. This is primarily a route of exposure for filter feeders as compared to the fathead minnow. Toxicity can also be reduced by filtering if a toxicant(s) is not particle-associated; we have observed that some chemicals in a dilution water stock are removed by filtering (e.g., DDT).

The filtration step also serves an important purpose for another Phase I manipulation, the solid phase extraction (SPE) (Section 6.6), where aliquots of the effluent typically must be filtered before application to the SPE sorbent (see *Interpretation of Results/Subsequent Tests* below). If many particles are present in the sample, the sorbent may act as a filter itself or the column will become plugged.

Methods: The use of a positive pressure filtration system is superior to the use of a vacuum filter because volatile compounds may be removed by vacuum filtering and hence confuse the effect of filtering (see *Interpretation of Results/Subsequent Tests*).

As in the acute Phase I, prepare the filters (typically 1 µm glass fiber filters without organic binder) by passing an appropriate volume (approximately one-fourth of effluent volume to be filtered) of high purity water over the filter(s) in the filter housing. This water is discarded, a small aliquot of the dilution water is filtered (prepare excess, at least 500 ml for the *C. dubia* 7-d test and 800 ml for the fathead minnow 7-d test) and discarded (100 ml) and the rest collected. A portion of the filtered dilution water is collected and used for testing and a portion reserved for the *post C_{18} SPE column test blank* (Section 6.6). For example, the last 400 ml of the filtrate is collected for the *C. dubia* 7-d *filtration blank* and *post C_{18} SPE column blank* tests.

Next the effluent sample is filtered using the same filter, and a portion of the filtrate is collected for toxicity testing and a portion set aside that will be concentrated on the C_{18} column. When filtering the effluent, filter enough sample for this test and enough sample (>1 L) to use for the SPE step described below. For some effluents, one filter will not suffice. A technique we use is to prepare several filters at once by stacking 5-8 filters together followed by rinses of high purity water and dilution water using the same rinse volumes as above. Then the filters are separated, and set aside, using one at a time for the effluent sample. If the samples measure quite high in total suspended solids, pre-filtering using a larger pore size filter may help. Again, appropriate *blanks* must be obtained for any pre-filtering. Low levels of metals on the glassware or the filters could cause interferences in toxicity interpretation. Pre-rinsing the filters and glassware with high purity water adjusted to pH 3 may provide consistently clean *blanks* and possibly less contamination in effluent samples. If the sample cannot be effectively/easily filtered due to many fine particles, centrifuging may be better (again *blanks* must be prepared).

The filter housing should be thoroughly cleaned between effluent samples to prevent any particle build-up or toxicity carryover. We have found large filter apparatus (1 L), removable glass frits, or plastic filtering apparatus (Millipore®) to be useful. The glassware cleaning procedure that is described in the acute Phase I TIE manual should be sufficient for chronic TIE work (EPA, 1991A). The glass frits may require rigorous cleaning (i.e., soak in strong acid (10% v/v) for 20-40 min) to remove residuals that may remain after filtering, since the glass frit may itself act as a filter.

Interpretation of Results/Subsequent Tests: If toxicity in the whole effluent is reduced by filtration, a method for separating the toxicants from other constituents in the effluent has been achieved. This should advance the characterization considerably because any subsequent analysis will be less confused by non-toxic constituents. If appropriate, one should determine if toxicity loss was due to volatilization. Comparisons of pressure filtering and vacuum filtering should indicate if volatilization is involved. For further characterization, the mechanism of removal should be determined (precipitation, sorption, changes in equilibrium or volatilization).

Identification efforts should be focused on the residue on the filter after testing indicates that the toxicant(s) is not volatile. To recover the toxicity from the filter(s), use of acidic and basic water as well as various organic solvents can be tried. The recovery achieved by these various methods provides information about pK_a and water solubility of the toxicants. Filtration has reduced the quantity of total cationic metals present in some effluents. The recovery of the metal and acute toxicity was successful when dilution water adjusted to pH 3 was used to extract the filter (EPA, 1991A). Filter extraction into smaller volumes than that of the effluent sample filtered will give a higher concentration of toxicant, perhaps allowing the use of acute test endpoints. However, evidence then must be gathered to be sure the toxicants causing acute toxicity are the same as those causing chronic toxicity. Use of solvents will require solvent reduction or solvent removal (exchange) before testing (see Phase II; EPA, 1992A). Sonication of filters is another approach but the manipulation must be accompanied by proper *blanks* in similar fashion to those needed for the pH 3 extraction of the filter extraction step described above.

If large volumes of an effluent (~2 L over one 1 µm filter) can be readily filtered, the effluent should be filtered for the *filtration test* and unfiltered effluent can be passed over the C_{18} SPE column (see Section 6.6; *Post C_{18} SPE column test*). Once it has been demonstrated that filtration does not reduce toxicity in the effluent, and the toxicity is recovered in the *methanol eluate test* the routine filtering can be eliminated. By

this approach the amount of testing to be done is decreased, yet the tracking of toxicity is possible. We have infrequently experienced any effluents that have low amounts of filterable solids where the effluent could be concentrated without filtering. If any effluent sample has reduced toxicity in the *filtration test* and toxicity is not observed in the *methanol eluate test*, characteristics of the toxicant(s) will be described as filterable and not C_{18} recoverable.

If the toxicity cannot be recovered from the filter, was not volatile (see Section 6.4 *aeration test*) and no other manipulations changed toxicity, use of Tier 2 is a good subsequent step. Toxicity could have been removed by the glass frit, and use of a plastic filter apparatus or stainless steel frits may assist in identifying that the toxicant(s) removed is on the frit or filter. Filter-removable toxicity in Tier 2 is more difficult to identify (because of the radical pH adjustments) because of irreversible reactions and potential for artifactual toxicity (see Section 6.12 below).

Special Considerations/Cautions: The filtered dilution water and filtered effluent sample also serve as the *toxicity blank* and *toxicity control* respectively for the *post C_{18} SPE column test* (see Section 6.6). The results of the effluent *filtration test* should be compared with the *filtration blanks* and no major change in the trend of young production, growth or survival should occur in the *filtration blanks* in comparison to the *controls* in the *baseline test*. If the *filtration blanks* are acceptable, then the results of the *filtration test* and the *baseline test* should be compared.

As a *toxicity blank* for the SPE tests, if the *filtration blank* is either slightly or completely toxic, but the post C_{18} SPE column effluent is not toxic (and effluent toxicity was unchanged after filtration), the *filtration blank* toxicity can be ignored since the effluent toxicity was removed. However, as work proceeds to identification, the *blank* toxicity will have to be eliminated or else it could introduce an artifact and lead to a misidentification of the cause of toxicity.

6.6 Post C_{18} Solid Phase Extraction Column Test

General Approach: The C_{18} SPE column is used to determine the extent of the effluent's toxicity that is due to compounds that are removed or sorbed onto the column at pH *i* (cf., *post C_{18} SPE column and pH adjustment test*; Section 6.13 below). By passing effluent through a SPE column, non-polar organics, some metals, and some surfactants are removed from the sample. In addition, these columns may also behave as a filter (see *filtration test* above).

Compounds in effluent samples interact with the C_{18} and depending upon the polarity and solubility of the compounds, the sorbent may extract the chemicals from the water solution/effluent onto the column. Extraction occurs when the compounds have a higher affinity for sorbent than for the aqueous phase. Non-polar organic chemicals are extracted because the C_{18} sorbent is very non-polar in comparison to the polar water phase; this extraction process is referred to as reverse phase chromatography.

The effluent that passes over the column is collected and the post-column effluent is toxicity tested in order to determine if the column removed toxicity. If the toxicity of the post-column sample is decreased, removal of toxicant(s) by the column is probable but if it is not, artifactual toxicity may be obscuring the removal. Steps to deal with this are given below in *Interpretation of Results/Subsequent Tests*. If the post-column sample is highly toxic, the capacity of the column to extract the toxicants may be exceeded or the column may have been inadequately conditioned.

Because toxicity may be retained by the C_{18} column, efforts to recover the toxicity are necessary. After a sample is passed over the C_{18} column, many of the compounds extracted by the sorbent at a neutral pH should be soluble in less polar solvents than water (i.e., hexane, methylene chloride, methanol, chloroform). However, most of the non-polar solvents are highly toxic to aquatic organisms. Sorbed non-polar organics are eluted from the column because they have higher affinity for the non-polar solvent than the C_{18} sorbent. The *methanol eluate test* (Section 6.7) is designed to determine if toxicants are non-polar.

Methods: The toxicity of the effluent, the type of test to be conducted, and the frequency of the solution renewal affect how much effluent must be filtered and passed over the C_{18} SPE column. First, the concentrations and the volume of the eluate needed for the *methanol eluate test* (Section 6.7) to test at 2x or 4x the whole effluent concentrations should be determined (keeping in mind that the methanol test level must be below the chronic threshold level for the species used; Section 6.7). However, limiting factors of the maximum volume to apply to a column, the minimum elution volume required, and the concentration that can be obtained within these confines must be calculated (Tables 6-7 and 6-8).

For example, our procedure has been to pass 1000 ml of 100% effluent over a 1 g (6 ml) column and elute with 3 ml of methanol which results in a theoretical 333x concentrate. The 1000 ml is the limit of sample volume over a 1 g (6 ml) column and the 3 ml methanol elution is slightly more than the minimum elution volume required (Table 6-7). However to test *C. dubia* at 4x, and to have the methanol concentration at a non-toxic chronic level (Table 6-9), the 3 ml must be further concentrated to 1.5 ml (now 666x whole effluent concentration). At present 3 ml of the eluate is concentrated in graduated centrifuge tubes to 666x by using a gentle stream of nitrogen gas over the surface of the methanol eluate in a warm water bath (25-30°C) to concentrate the 333x eluate to a final volume of 1.5 ml. For five replicates of 10 ml each, 0.30 ml of the eluate can be added to 50 ml of dilution water and the resultant effluent concentration is 4x and the methanol concentration is 0.6%. However the 1.5 ml eluate from the

Table 6-7. Factors to consider for the size of available pre-packed C_{18} SPE columns. Appropriate volumes of sample to apply to each column with respect to maximum volumes of sample and minimum elution volumes, and elution volumes frequently used in the TIE process.

Columns Available[1]		Conditioning Volume (ml)	Maximum Volume (ml) of Effluent	Minimum Elution Volume[2]	Methanol Elution Used (ml)[3]	No. Methanol Fractions[4]	Eluate Concentration
Size (ml)	g of Sorbent						
6	1	10	1,000	2.0, 2.4	3[5], 2.4	3	333x[5], 417x
12	2	24	2,000	4.8	3	3	417x
20	5	40	5,000	12	6	3	417x
60	10	120	10,000	24	12	3	417x

[1] 1 g columns are available from J.T. Baker Chemical Company, Phillipsburg N.J. (1 g, 6 ml columns have been extensively used at ERL-Duluth). 1 g, 2 g, 5 g, and 10 g columns are available from Analytichem International, Mega Bond Elut™, Harbor City, CA. Pumping rates for each column are proportional to volume based on 1 L at 5 ml/min; therefore 2 L at 10 ml/min, 5 L at 25 ml/min, and 10 L at 50 ml/min. We are currently evaluating the minimum elution volumes to determine if less eluting solvent can be used. Pumping rates for 5 L and 10 L may need to be slower when eluting each column. Yet how much the pump should be slowed will be a function of the toxicants. The contact time of the elution solvent with C_{18} sorbent may need to be increased if toxicity is not recovered in the methanol eluates.

[2] Minimum elution volume as recommended by the manufacturers. For the 1 g column, J.T. Baker recommends 2.0 ml and Mega Bond Elut™ recommends 2.4 ml, but 2.0 ml is probably adequate.

[3] Elution of two one-half volume aliquots is better for optimizing the elution efficacy

[4] For each fractionation of any size column, collect three separate 100% methanol fractions to use in *methanol eluate test* to attempt recovery of the non-polar toxicants (see text for more details).

[5] This procedure has been routinely used for acute TIEs. To maximize concentration and minimize methanol levels in concentration and minimize methanol levels in toxicity tests it is best to use the minimum elution volumes recommended by the manufacturer.

1 L fractionation will allow testing of 4x, 2x, 1x only if two solution renewals are used (Table 6-8). Daily renewals for a 7-d *C. dubia* test require a total of 3.7 ml at a water concentration of 0.6% methanol (which means 3 L of effluent must be fractionated to obtain 9 ml of 333x eluate which is concentrated to 4.5 ml to test at 4x) (Table 6-8).

To test at 2x using a 417x eluate from a 2.4 ml elution, 0.048 ml in 10 ml will result in the 2x test concentration. For a 7-d, daily renewal test at 2x, 1x, 0.5x, 3.0 ml is needed (5 replicates of 10 ml each) which will require 1 L of effluent to be concentrated (Table 6-8). By this procedure the final methanol concentration is 0.48%. The 417x concentrate can also be concentrated to 834x and use 0.048 ml/10 ml to test the eluate at 4x.

For the 7-d fathead minnow test using 50 ml per replicate and two replicates, a total of 7.4 ml of a methanol eluate is needed for test initiation and six renewals, which requires fractionation of 3 L of effluent. This assumes the methanol test concentration between species are kept the same. Actually the fathead minnows could probably be tested at methanol concentrations of ~1%, and using 0.96 ml of the 417x eluate per 100 ml will result in 4x effluent test concentration and a 1% methanol concentration (Table 6-9).

The methods below assume one effluent volume (usually the 100%) is concentrated and the post column effluent sample collected and used for all solution renewals during the test (Table 6-8). The procedure described below is an overview of the steps needed to prepare the column, collect methanol *blanks*, recondition the column, collect post-column effluent, and collect methanol eluate (steps needed for this test and the next test—Section 6.7). All steps are detailed in the acute Phase I manual (EPA, 1991A), and the major difference for the chronic Phase I is that fewer post-column samples (one or two versus three) are collected.

The general technique for conditioning and using the prepackaged SPE columns is as follows. Using a pump system with a reservoir for the effluent sample and teflon tubing, first pump 10-120 ml of HPLC grade methanol over the column to condition the sorbent (Table 6-7). This methanol is discarded. Without letting the column go to dryness, 10-120 ml of high purity water is passed over the column and discarded. Next, before the methanol *blank* is collected, the column is allowed to go to dryness. For 1 L of sample and a 1 g (6 ml) column, two 1.5 ml aliquots of 100% methanol are collected, combined, and tested as the *blank*. The elution is more efficient when two aliquots of 1.5 ml are collected in contrast to one elution of 3 ml. The collection of three 100% methanol eluates (2.4 or 3 ml each) has been more helpful for tracking toxicity than only one 100% methanol eluate sample. The use of three 100% methanol elutions is replaced when the Phase II fractionation procedures are applied. These 100% methanol eluates may need to be concentrated prior to testing (see Section 6.7). The containers to collect the methanol should be acid leached, hexane and acetone rinsed, and allowed to dry before use. After the methanol *blank* is collected, the column must

Table 6-8. Test volume of eluate needed for *methanol eluate test* with *C. dubia* or *P. promelas*. Volumes described are based on minimum elution volumes recommended (Table 6-7) and the highest test concentration possible with the methanol level at an acceptable concentration.

Test Species	Test Duration	No. Renewals & Original Sample	High Test Conc.	No. Rep.	Volume of Eluate Needed for Testing at: 333x[1]	417x[2]	Test Concentrations	Minimum Volume (L) of Effluent[3]
C. dubia	4-d	2	2x	5	1.05	0.84	2x, 1x, 0.5x	1
C. dubia	4-d	4	2x	5	2.10	1.68	2x, 1x, 0.5x	1
C. dubia	7-d	3	2x	5	1.58	1.26	2x, 1x, 0.5x	1
C. dubia	7-d	7	2x	5	3.68	2.94	2x, 1x, 0.5x	2
C. dubia	4-d	2	2x	10	2.10	1.68	2x, 1x, 0.5x	1
C. dubia	4-d	4	2x	10	4.10	3.36	2x, 1x, 0.5x	2
C. dubia	7-d	3	2x	10	3.16	2.52	2x, 1x, 0.5x	2

P. promelas	7-d	7	2x	4	14.70	11.76	2x, 1x, 0.5x	5
P. promelas	7-d	7	4x	2	14.70	11.76	4x, 2x, 0.5x	5
P. promelas	7-d	7	4x	4	29.40	23.52	4x, 2x, 0.5x	10

[1] For the 333x eluate concentration, this volume is based on the assumption that the *C. dubia* test solutions are prepared as 300 µl of 333x into 50 ml for 2x, 150 µl into 50ml for 1x, and 75 µl into 50 ml for 0.5x. More volume will be needed if serial dilutions are prepared (600 µl vs 525 µl). For the fathead minnow tests this assumes test solutions are prepared as 600 µl into 100 mL for 2x, 300 µl into 100 mL for 1x, and 150 µl into 100 mL for 0.5x. More volume will be needed if serial dilutions are prepared (1200 µl vs 1050 µl).

[2] For the 417x eluate concentration, this volume is based on the assumption that the *C. dubia* test solutions are prepared as 240 µl of 333x into 50 ml for 2x, 120 µl into 50ml for 1x, and 60 µl into 50 ml for 0.5x. More volume will be needed if serial dilutions are prepared. For the fathead minnow tests this assumes test solutions are prepared as 480 µl into 100 ml for 2x, 240 µl into 100 mL for 1x, and 120 µl into 100 ml for 0.5x. More volume will be needed if serial dilutions are prepared. For the 4x fathead minnow test, 960 µl per 100 ml must be prepared for the 4x solution.

[3] Volume is based on high test concentration (2x or 4x) tested without concentration to obtain eluate twice as concentrated. If further concentration is needed, twice as much effluent will be needed.

Table 6-9. Chronic toxicity of methanol (%) to *C. dubia* and *P. promelas* using the 7-d tests.

Species	Water Type	Test Renewal	IC50 95% C.I.	IC25 95% C.I.	NOEC	LOEC
C. dubia	SRW	daily	1.2 1.1-1.2	0.45[1] 0.35-1.0	<0.5	—
	SRW[2]	twice	1.4 —	0.45[1] 0.36-0.70	<0.5	—
	SRW[2]	twice	1.2 0.69-1.7	0.59 0.29-0.95	0.75	1.5
	SRW[2]	twice	1.3 —	0.83 0.34-1.0	0.75	1.5
P. promelas	SRW	daily	2.1 2.0-2.2	1.34 0.27-1.5	1.3	2.5

[1] Value is extrapolated.
[2] Tests all conducted independently.

Note: C.I. = confidence interval; SRW = soft water

be reconditioned with 10-120 ml of methanol (which is discarded). Without allowing the column to go to dryness, follow the methanol with an aliquot (10-120 ml) of high purity water, immediately followed by an aliquot of filtered dilution water. The amount of filtered dilution water needed will be dependent on the species and type of test to be conducted. The initial aliquot of the post-column water should be discarded (~200 ml) and the remainder of the post column dilution water should be collected. This post-column dilution water sample will serve as the dilution water *blank* for the *post C_{18} SPE column test.*

In order to optimize concentration of an effluent sample and not exceed the specifications of the sorbent capacity, when the maximum volume (Table 6-7) of a sample is passed over a column, the sorbent must be reconditioned following the collection of the post column dilution water. For example if 1.2 L of dilution water is needed and 5 L of effluent is to be concentrated on a 5 g column, without reconditioning the column between the dilution water and the effluent, the sorbent's capacity is likely to be exceeded. Toxicity might be observed in the *post C_{18} SPE column test* because of the excessive volume of dilution water and 5 L of effluent. The procedures for conditioning the column are similar to those above. The appropriate amount of methanol (Table 6-7) is used to condition the sorbent and the methanol is discarded. Before the column goes to dryness, follow the methanol with an aliquot (10-120 ml) of high purity water, immediately followed by the volume of filtered effluent to be concentrated. Again, collect about 200 ml of the post-column effluent and discard it. This is discarded to reduce the possibility of higher background concentrations of methanol in the post-column sample which might contribute to artifactual toxicity. Collect remainder of post-column effluent as a batch or in aliquots. If small quantities (<500 ml) of post-column effluent are needed for toxicity testing, separate post-column effluent samples may help determine if toxicity breakthrough occurred, and concentration factors will be different for the lower volumes.

Interpretation of Results/Subsequent Tests: The extraction efficiency of the column is evaluated by comparing the toxicity in the *post C_{18} SPE column test* to the *filtration test* data. This *post C_{18} SPE column test* is most useful when there is no post-column toxicity, and filtration did not reduce toxicity.

When toxicity in the post-column effluent is reduced or removed, then the next step is to compare the results with the *methanol eluate test.* If toxicity was recovered in the methanol eluates (see Section 6.7 below), then efforts to identify the toxicants (Phase II) should be initiated immediately.

If the post-column effluent toxicity was removed or reduced, but toxicity was not recovered in the methanol eluates (see below), it is possible that the toxicant is not eluted into 100% methanol and the C_{18} SPE column contains the toxicant. Use of the gradient of methanol and water fractions should be tried as well as testing the eluate at higher concentrations than 2x (i.e., 4x or 8x). If those tests do not indicate toxicity present in the eluates (see below) alternate elution schemes (EPA, 1992A) must be tried to recover the toxicant. It is important to recognize that the toxicity removed by the C_{18} SPE column is not necessarily due to non-polar compounds. Metals can be removed from some effluents via the C_{18} SPE sorbent. However, metals are not efficiently eluted in methanol or other organic solvents. Acid adjusted (pH 3) dilution water may be needed to elute toxicant(s) from the column. If this is done, the pumping rate of the pH-adjusted water should be slowed (perhaps by one-fourth of original pumping rate) to allow adequate contact time to elute the compound from the sorbent. In addition, compounds such as polymers or surfactants may be sorbed onto the column and some will elute with methanol while others do not.

The column can act as a filter itself and the various solvents used do not elute the toxicant. To check whether the C_{18} column is acting as a filter, unfiltered effluent can be passed over the C_{18} column and toxicity test results compared to those from the filtered effluent sample simultaneously. When effluent samples are readily filtered (e.g., ≥1.5 L for one 1 µm filter) filter the effluent to conduct the *filtration test* and use unfiltered effluent for the *post C_{18} SPE column test* and *the methanol eluate test.* When toxicity can be recovered in the methanol eluate, the toxicant(s) is most likely to be non-polar and since filtration can be eliminated for subsequent identification steps the amount of testing is subsequently reduced.

If the post-column toxicity was reduced and/or removed but not recovered in the *methanol eluate test*, the possibility exists that the toxicant has degraded or decomposed during the manipulation and the toxicant(s) was not concentratable.

As mentioned above, when no toxicity occurs in the post-column effluent (or the toxicity is reduced), and yet the *methanol eluate test* did not exhibit toxicity, metals may be involved or a non-polar that was not recovered in the solvent may be involved (discussed above). To check for cationic metal toxicity, the *post C_{18} SPE column test* should be combined with the *EDTA addition test* and the *sodium thiosulfate addition test* to characterize the post-column toxicity (see Section 6.16, *multiple characterization tests*).

For effluents that have shown that the toxicant is C_{18} recoverable, but the degradation of toxicity occurs fairly rapidly (i.e., the effluent sample is non-toxic in 1-2 weeks), it may be prudent to concentrate additional volumes of effluent immediately after the effluent arrives at the testing laboratory. Non-polar toxicants may not degrade in the methanol fractions as quickly in the effluent samples. Collect the methanol fractions (three 100% fractions) or the various methanol/water fractions as described in Phase II (EPA, 1992A) and hold them at 4°C for analysis as the TIE proceeds. Similarly,

once the cause of toxicity has been determined to be non-polar (C_{18} extractable) it might be more appropriate to immediately concentrate 10 to 20 L of effluent and for the elution step, replace the three 100% methanol elutions with the methanol/water procedures (EPA, 1992A). For chronic work, we have been using seven water/methanol fractions (50%, 75%, 80%, 85%, 90%, 95%, and 100%) rather than the eight used in acute TIEs because the toxicity has never recovered in the 25% fraction and by eliminating it the testing workload is reduced. It may be prudent to try two additional 100% methanol fractions following the seven fractions as well or follow it with alternate elution schemes (cf., Phase II; EPA, 1992A). By immediately concentrating the effluent, it is possible to optimize the amount of methanol available for testing and subsequent concentration for analysis and the post-column samples can be tested at one time. This eliminates duplication of effort that is required when additional methanol eluate is needed for subsequent work in Phase II.

Artifactual toxicity in the test containers may appear as a biological growth in the 100% post-column effluent and the effluent dilutions during the test. Effluents from biological treatment plants may develop this characteristic more readily than physical-chemical treatment plant effluents. This growth can negate actual toxicant removal by the column. While this growth does not occur in all effluents, when it does occur with one post-column effluent sample, the growth often occurs in each subsequent post-column effluent sample. The growth appears as a filamentous growth and gives a milky appearance in the test vessel. This growth has been linked to methanol stimulation of bacterial growth. Methanol is present in the post-column samples because methanol is constantly released from the sorbent during the sample extraction. Additional filtering of the post-column effluent sample through a 0.2 µm filter before testing to remove bacteria and eliminate the growth, has not been particularly successful. Artifactual toxicity from the post-column effluent may be avoided if the tests with the post-column samples are initiated on the same day the effluent is concentrated. To date, when we have collected the post-column samples and tested them on the same day, we have not experienced less artifactual toxicity than we found in those effluents where artifactual toxicity consistently has been a problem. However, less time elapses before animals are exposed to the test solution, therefore less time is available for bacteria to cause problems in the post-column sample matrix. Another option is to perform daily concentration of the effluent and extraction of the column during the 7-d test, as fresh post-column samples may minimize the artifactual toxicity.

When post-column artifactual growth is not readily eliminated, then a different solvent (acetonitrile) to prepare the column (but not for eluting) may be useful in reducing the post-column artifactual bacterial growth. Acetonitrile causes narcotic effects in toxicity tests, and is recommended only to condition the columns to avoid toxic concentrations. This technique has been successful on a limited number of effluents.

Special Considerations/Cautions: Careful observations and judgement must be exercised in detecting problems in the *post C_{18} SPE column test.* Low DO levels can occur in these samples. Through testing experience, the investigator will know whether toxicity appears as artifactual (i.e., growth, low DO) as opposed to the presence of the sample toxicity. If artifactual toxicity is not recognized, then a conclusion that the C_{18} SPE column did not remove toxicity can erroneously be made. For this reason if the post-column effluent is toxic, the methanol eluate must be tested (Section 6.7). This avoids the artifactual toxicity issue and the error can be avoided by determining the toxicity of the eluate.

The methanol elution process does not always produce predictable results with the same effluent sample. When toxicity is removed by the column but no toxicity occurs in the 100% methanol eluates, it does not indicate that the toxicity is *not* due to a non-polar toxicant(s). To check this possibility, immediately test the series of methanol/water fractions at concentrations of 4x or 8x. Not all non-polar organic compounds elute into 100% methanol as well as they do into lower methanol/water concentrations. Also toxicants may smear across the fractions and when <100% recovery of toxicity from the column is not 100%, toxicity may not be observed at 2x or 1x.

General test conditions will be tracked (dilution water, health of test animals) by the *controls* in the *baseline test.* The post-column dilution water *blanks* should be compared to those *controls* to determine if the column imparted toxicity. If the post-column dilution water *blank* was toxic, but no toxicity or artifactual toxicity occurred in the post-column effluent sample, the toxic *blank* can be ignored.

Results of the *post C_{18} SPE column effluent test(s)* must be compared to the results of the *filtration test* to determine if the manipulations effectively reduced toxicity. When the *post C_{18} SPE column test* is plagued by artifactual toxicity, the importance of the *methanol eluate test* increases. The results of the *post C_{18} SPE column test* must also be compared to the *baseline test* to determine if toxicity was removed by the C_{18} SPE column.

6.7 Methanol Eluate Test

General Approach: In order to elute toxicants from the C_{18} SPE sorbent, a relatively non-polar solvent is used. Hexane, one of the most non-polar solvents, can be used to remove highly non-polar compounds from the C_{18} SPE column. Yet hexane is one of the most toxic solvents to aquatic organisms and has a low miscibility with water. Methanol is more polar than hexane, but is much less toxic and will elute many

compounds. The use of methanol has been adopted as the eluant for the acute TIE (EPA, 1991A; EPA, 1989A) and the chronic TIE because of its low toxicity (Table 6-9) and its usually adequate ability to elute chemicals from the C_{18} SPE column.

Methods: The conditioning and elution steps are described in detail in the *post C_{18} SPE column test* above (see Section 6.6). For this test, we assume that the column extraction efficiency and elution efficiency are 100%.

If a 1 g (6 ml) SPE column was used with 1 L of 100% effluent, and a 3 ml methanol eluate was collected, the methanol eluate is a 333x concentrate of the original effluent (Table 6-7). Depending on the amount of effluent toxicity, this eluate may have to be concentrated further in order to test at a sufficient concentration (i.e., 4x) and have methanol concentrations in the test lower than the methanol effect concentration. In Table 6-9 the toxicity data for methanol toxicity to *C. dubia* and fathead minnows are given. The toxicity of methanol is slightly greater for *C. dubia* when the test solutions were renewed daily but not significantly for this characterization stage of the TIE. From these data, one can decide how much methanol can be added and how concentrated the eluant must be to achieve 2x or 4x the original effluent concentration. The choice of test concentration depends on the toxicity of the effluent; for example, if the effluent is toxic at ~25%, one may not need to achieve a 4x concentration. Some methanol toxicity can be present, as long as sufficient toxicity from the effluent is present to be measurable. As discussed in the *post C_{18} SPE column test*, the fathead minnows can be tested at 4x using only 0.96 ml of a 417x methanol eluate but the methanol concentration is about 1%, which cannot be tolerated by *C. dubia*.

Interpretation of Results/Subsequent Tests: If toxicity occurs in the *methanol eluate test* at any concentration tested, Phase II should be initiated. This step would include the use of a gradient of methanol/water eluant solutions to elute additional columns and conduct the toxicity tests on each fraction (Phase II; EPA 1989A; EPA, 1992A). Toxicants other than non-polar compounds may be retained by the SPE column but they are less likely to be eluted sharply or eluted at all (see Section 6.6). Non-polar toxicity can in some instances be distinguished from post-column artifactual toxicity if the eluate is checked for toxicity. Some toxicants (such as some surfactants) may not elute from the SPE column with methanol, but if toxicity is not recovered in the eluate, it does not exclude the possibility of a non-polar toxicant or metal (see Section 6.6 for additional discussion). Dilution water adjusted to pH 3 or pH 9 may be useful in eluting a toxicant(s) from the column. Some experimentation will be needed to determine the volumes of water to pump over the column. The pumping rate should be slowed considerably to allow sufficient contact time on the column (see details in Section 6.6 and Table 6-8).

At this time, we have not been successful in tracking chronic non-polar toxicity using the acute test endpoint with the methanol eluates, rather chronic tests have been needed to track the chronic toxicity.

A subsequent test that may be useful is to assess whether the toxicant must be metabolically-activated by the test organism before exhibiting toxicity. These activation reactions consist of oxidative metabolism by a family of enzymes collectively known as cytochrome P-450. Some toxicants require cytochrome P-450 activation before expressing toxicity. Piperonyl butoxide (PBO) is a synthetic methylenedioxyphenyl compound that effectively binds to, and blocks the catalytic activity of cytochrome P-450. When a non-toxic amount of PBO is added to an effluent test solution which contains a toxicant(s) that requires metabolic activation, the toxicity of the effluent can be reduced or completely blocked (EPA, 1991A). The relative specificity of PBO for blocking the toxicity of metabolically-activated organic compounds makes this test a useful part of the subsequent testing in the TIE. For example in the acute Phase I (EPA, 1991A) as a subsequent test, we suggest that PBO may be added directly to the effluent before adding the organisms. The 48 h LC50 of PBO is 1 mg/l for *C. dubia* and we have used 0.250 to 0.500 mg/l to effectively block the acute toxicity of metabolically-activated compounds for *C. dubia* in the effluent and the methanol eluate. The NOEC and the IC25 for PBO and *C. dubia* was determined as 63 µg/l and 89 µg/l, respectively. Low concentrations of PBO have reduced the chronic toxicity in the methanol eluate test and levels of 100 or 50 µg/l have been useful in chronic tests with *C. dubia*. The PBO should be added using a minimal amount of methanol as a carrier solvent since the level of methanol present in conjunction with the methanol eluate is present. Since PBO is not readily soluble in water, a superstock of 20 g/l is prepared by dissolving PBO in reagent grade methanol. An aliquot of the superstock is mixed in the standard laboratory dilution water to produce a stock solution at a concentration of 25 mg/l and aliquots of this stock solution are added to the test cups after addition of the methanol eluate, and the solution thoroughly mixed. This test should be conducted in similar fashion to the *EDTA addition test*. Appropriate *blanks* must be used, for example both the *methanol blank* and the *methanol eluate* must be tested with and without PBO. If toxicity occurs in the *methanol blank* fraction with the PBO additions, either PBO was present at toxic concentrations or the methanol concentration in the test was too high. If toxicity is observed in the *methanol eluate* with the PBO addition, but not in the *methanol eluate* without the PBO or either of the *blank eluates* (with PBO and without PBO), this result is not very informative. It is possible that the PBO has interacted in a synergistic fashion with another compound present in the test effluent that normally would not be toxic.

Compounds that are sparingly soluble in water may not be eluted from the column with methanol. If this

occurs, less polar solvents will have to be tried, but this technique will require solvent exchanges to avoid toxic solvent concentrations and other solvents may recover chemicals not toxic in the effluent due to solubility problems. At this time, we have not used solvent exchanges for chronic toxicity tests, but are exploring the use of methylene chloride. The 48 h LC50 of methylene chloride to *C. dubia* is 0.13% and the chronic toxicity to *C. dubia* is ≤0.03%. Therefore it cannot readily be used as the primary solvent, but rather as the exchange solvent and may be of limited use for this effort. Additional work on the appropriate solvent exchange for chronic TIEs is on-going (EPA, 1992A).

Special Considerations/Cautions: The *baseline test* serves as the *toxicity control*, and the *methanol blank* serves as a comparison of the effects of methanol alone in water. The health of the test animals, the viability of the dilution water and general test conditions are evaluated by the *baseline controls*. If the effluent *methanol eluate* is *non-toxic* at 2x or 4x but the *methanol blank* is toxic, the *blank* toxicity can be ignored since no non-polar toxicity is recovered.

If effluent dilutions are set at 100%, 80%, 60%, and 40%, it might be useful to test the eluate at a multiple of these concentrations, i.e., 2x, 1.6x, 1.2x, 0.8x or concentrate them to 4x, 3.2x, 2.4x, or 1.6x to compare the *baseline toxicity* with the toxicity in the *methanol eluate tests*. The artifactual growth observed in the *post* C_{18} *SPE column test* from the methanol has not occurred in our *methanol eluate tests*. This is most likely due to the differences in how the methanol degrades/behaves in dilution waters which are low in methanol-oxidizing bacteria and other organic matter in contrast to effluent samples (even post-column effluents).

6.8 Graduated pH Test

General Approach: This test will determine whether effluent toxicity can be attributed to compounds whose toxicity is pH dependent. The pH dependent compounds of concern are those with a pK_a that allows sufficient differences in dissociation to occur in a physiologically tolerable pH range (pH 6-9). The toxicity depends on the form that is toxic (ionized versus un-ionized). Metal toxicity can be affected by pH differences through changes in solubility and speciation. pH dependent toxicity is likely to be affected by temperature, DO and CO_2 concentrations, and total dissolved solids (TDS). The graduated pH test is most effective in differentiating substantial toxicity related to ammonia from other causes of toxicity.

Ammonia is an example of a chemical that exhibits different ionization states and subsequently pH dependent toxicity. Ammonia is also frequently present in effluents at concentrations of 5 mg/l to 200 mg/l (or higher). Measuring the total ammonia in the sample upon its arrival will be helpful to assess the potential for ammonia toxicity. pH has a great effect on ammonia toxicity. For many effluents (especially with municipal effluents) the pH of a sample rises upon contact with air, typically the pH of effluents at air equilibrium ranges from 8.0 to 8.5. Literature data on ammonia toxicity (EPA, 1985D) can be used only as a general guide because the pH values for most ammonia toxicity tests as reported in the literature are usually not measured or reported fully enough to be useful in TIE tests. Additional data on ammonia toxicity for *C. dubia* and *P. promelas* is provided in the revised Phase II (EPA, 1992A). The acute Phase I manual has a lengthy description of the toxicity behavior of ammonia (EPA, 1991A) and Phase II provides additional information (EPA, 1992A).

One might expect ammonia to be removed during the Tier 2 *aeration and pH adjustment test* at basic pH (described in Section 6.11). Based on our experience, however, ammonia is not substantially removed by the methods used to aerate the sample described in this manual. (If a larger surface to volume ratio is used, this manipulation can reduce ammonia levels; see *Interpretation of Results/Subsequent Tests* below and Phase II; EPA, 1992A.) Other techniques which can be used to remove ammonia may also displace metals or other toxicants with completely different physical and chemical characteristics. For example, ion exchange resins (e.g., zeolite) remove ammonia, cationic metals, and possibly organic compounds through adsorption.

Toxicity related to metals may also be detected by the *graduated pH test*, although these effects are less well documented in effluents (and for chronic toxicity) than those associated with ammonia toxicity. The toxicity may change for both pH increases and decreases from neutral pH (pH 7). Such behavior is characteristic of aluminum and cadmium. Acute toxicity test experiments with *C. dubia* in clean dilution waters indicate lead and copper were more acutely toxic at pH 6.5 than at pH 8.0 or 8.5 (in very hard reconstituted water), while nickel and zinc were more toxic at pH 8.5 than at 6.5 (EPA, 1991A). In recent experiments during a chronic TIE, we have found that chromium is pH dependent on an acute basis for *C. dubia*, but not water hardness dependent. The pH dependence was not observed in acute tests unless food (YCT) (EPA, 1992C) was added during the 48 h acute test at test initiation. Therefore, caution must be exercised in interpreting the chronic toxicity results with effluents, because the toxicant(s) may behave in certain ways that are not documented in the literature.

By conducting tests at different pHs, the effluent toxicity may be enhanced, reduced or eliminated. For example (at 25°C) where ammonia is the primary toxicant, when the pH is 6.5, 0.180% of the total ammonia in solution is present in the toxic form (NH_3). At pH 7.5, 1.77% of the total ammonia is present as NH_3 and at pH 8.5, 15.2% is present as NH_3. This difference in the percentages of un-ionized ammonia is enough to make the same amount of total ammonia about three times more toxic at pH 8.5 as at pH 6.5. Whether or not toxicity will be eliminated at pH 6.5 and the extent to which toxicity will increase at pH 8.5 will depend on the total ammonia concentration. If the graduated pH test is done at two pHs using the same dilutions, one

should see toxicity differences between pH 6.5 and 8.5. The effluent effect level (expressed as percent effluent) should be lower at pH 8.5 than pH 6.5 if ammonia is the dominant toxicant.

The most desirable pH values to choose to test for the *graduated pH test* will depend upon the characteristics of the effluent being tested. The graduation scheme that includes the air equilibrium (the pH the effluent naturally drifts to) will allow a comparison of treatments to unaltered effluent (i.e., *baseline test*). For example, if the air equilibrium pH of the effluent is pH 8.0, it may be more appropriate to use pHs 6.5, 7.3 and 8.0. The pHs of many municipal effluents rise to 8.2 to 8.5 (or higher), so pHs such as 6.5, 7.5 and 8.5 may be more appropriate. In any case, it will be necessary to conduct the test at more than one effluent concentration (e.g., 100%, 50%, 25%) to determine what role, if any, the pH dependent compounds play in toxicity.

The challenge of the graduated pH test is to maintain a constant pH in the test solution. This is a necessity if the ratio of ionized to the un-ionized form of a pH sensitive toxicant is to remain constant and the test results are to be valid. However, in conducting either acute or chronic toxicity tests on effluents, it is not unusual to see the pH of the test solutions change 1 to 2 pH units over a 24-h period.

Methods: To lower the pH of the samples, either CO_2/air mixtures or HCl additions (or the combination of both) are used. The pH should be maintained throughout the 4-d or 7-d test with little variation (±0.2 pH units).

When CO_2/air (without any acid addition) is used to control the pH, the pH of the effluent samples is adjusted by varying the CO_2/air content of the gas phase over the water or effluent samples. By using closed headspace test chambers, the CO_2 content of the gas phase can be controlled. The amount of CO_2/air needed to adjust the pH of the solution is dependent upon sample volume, the test container volume, the desired pH, the temperature, and the effluent characteristics (e.g., dissolved solids). The exact amount of CO_2/air to inject for a desired pH must be determined through experimentation (on day 1) with each effluent sample *before* the *graduated pH test* begins. Therefore, the test may have to be set up later than the other Phase I tests (e.g., day 3) unless experimentation was initiated on day 1. The amount of CO_2 added to the chamber assumes that the liquid volume to gas volume ratio remains the same. Generally, as the alkalinity increases, the concentration of CO_2 that is needed to maintain the pH also increases. For adjusting pH's downward from pH 8.5 to 6, 0.5-5% CO_2 has been used. If more than 5% CO_2 is needed, adjust the solutions with acids (HCl) and then flush the headspace with no more than 5% CO_2/air. With appropriate volumes of effluent, experiments with variable amounts of CO_2/air and equilibrated for about 2 h, are used to select the needed CO_2 concentration. More than 5% CO_2 is not recommended as CO_2 toxicity is likely to be observed. When dilutions of an effluent have the same hardness (or alkalinity) and initial pH as the effluent, the same amount of CO_2 is usually needed for each dilution, but sometimes different amounts are needed in the higher effluent concentrations. Use of a dilution water of similar hardness (or alkalinity) as the effluent makes the CO_2 volume adjustments easier. When tests are conducted in these CO_2 controlled environments, dilution water *controls* for each pH should be included.

Acid is used first to adjust pH's when the amount of CO_2/air needed to adjust to the desired pH is greater than 5% CO_2/air. Again experimentation is needed to determine how much CO_2/air is needed. Techniques for acid adjustment are described in Section 6.10 below and also in the acute Phase I manual (EPA, 1991A).

For adding a mixture of CO_2/air to the headspace of the test compartments, a 1 L gas syringe (Hamilton Model S-1000, Reno, NV) is used. In most instances, the amount of CO_2 produced by the invertebrates has not caused further pH shifts, but with larval fathead minnows, the pH may drop from the additional amount of CO_2 respired by the fish bacterial metabolic CO_2 released.

For the pH controlled tests, the pH should be measured at least two to three times for each 24 h period when readings of survival and/or young production are made. If samples are not renewed daily (as may be the case for the *C. dubia* tests), then the headspace should be re-flushed with CO_2/air after the animals are fed. Again, some experimentation may be needed to determine the amount of CO_2/air needed for this step. In all *graduated pH tests*, the pH should be measured in all the chambers. If the pH drifts as much as 0.2 pH units, the results may not be usable and better pH control must be achieved. However, if pH fluctuates more than 0.2 pH units and toxicity is gone at one pH and not another, the toxicity results may be useful (see *Interpretation of Results/Subsequent Tests* below).

Measurements of pH must be made rapidly to minimize the CO_2 exchange between the sample and the atmosphere. Avoid vigorous stirring of unsealed samples because at lower pH values, the CO_2 loss during the measurement can cause a substantial pH rise. In addition, measure the DO because toxicants such as ammonia have different toxicities when DO is decreased (EPA, 1985D). Keep in mind that if the test animals have been dead for awhile, the pH and/or DO of the test water most likely will have changed. Therefore, pH measurements should be made as soon as possible if animals die rapidly.

Methods that use continuous flow of a CO_2/air mixture, such as tissue cell incubators, may be preferable and give better pH control. A pH feedback system can be used to control the CO_2-mix to the incubators. At this time we have not attempted to use a continuous flow of CO_2 and cannot recommend a system to use.

Maintaining pH above the air equilibrium pH (generally above pH 8.3) is difficult to achieve because the

concentration of CO_2 must be very low, and microbial respiration can increase the CO_2 levels in the test chamber. Frequently we use a dilution water that has a higher pH (i.e., very hard reconstituted water) to prevent pH drift downward.

Interpretation of Results/Subsequent Tests: For the *graduated pH test*, the pHs selected must be within the physiological tolerance range for the test species used (which generally is a pH range of 6 to 9). In this pH range, the amount of acid or base added is negligible, and therefore the likelihood of toxicity due to increased salinity levels is low.

When ammonia is the dominant toxicant, the toxicity at pH 6.5, should be less than in the pH 8 test. However, ammonia is not the only possible cause of toxicity. Using the pH of the *baseline test*, the relative toxicity of each pH adjusted solution can be predicted if ammonia is the sole cause of toxicity (EPA, 1989A; EPA, 1992A).

However, if ammonia is only one of several toxicants in an effluent, this procedure will be hard to interpret. For this reason, if total ammonia concentrations in the 100% effluent are greater than 20 mg/l, include a pH 6 (rather than 6.5) and pH 7.3 (±0.2) effluent treatment interfaced with other Phase I tests. Complicating effects of metal toxicity may be reduced by adding EDTA to the test solutions. However, the ability of EDTA to detoxify metals may also change with pH, although we have not experienced this effect yet.

Other metals may exhibit some degree of pH dependence, but these are not as well defined. Whether the metal toxicity can be discerned will depend in large part on the concentration of other toxicants in the sample. In order to detect metal toxicity, one must be cautious when selecting a dilution water if the test solutions are low effluent concentrations. Artifactual toxicity due to metals may be created if the hardness of the dilution water is much different from that of the effluent (see Section 3). This effect may be magnified for metals when coupled with the pH change. A dilution water similar in hardness to that of the effluent must be used for this test to reveal metal-caused toxicity. If more than one pH dependent toxicant is present, the pH effects may either cancel or enhance one another.

In the acute TIEs, we have suggested the use of hydrogen ion buffers to maintain the pH of effluent test solutions and to compare these test results to those from CO_2 adjusted samples. Three hydrogen ion buffers were used by Neilson et al. (1990) to control pH in toxicity tests in concentrations ranging from 2.5 to 4.0 mM. These buffers were chosen based on the work done by Ferguson et al. (1980). These buffers are: 2-(N-morpholino) ethane-sulfonic acid (Mes) (pK_a = 6.15), 3-(N-morpholino) propane-sulfonic acid (Mops) (pK_a=7.15), and piperazine-N,N'-bis (2-hydroxypropane) sulfonic acid (Popso) (pK_a=7.8). We have replaced the Popso buffer with another buffer which is more readily soluble in order to achieve better pH control around the pH 8.0 range. This buffer is N-tris(hydroxymethyl) methyl-3-amino propanesulfonic acid (Taps) (pK_a = 8.4) and has been used primarily for the chronic *C. dubia* tests at this time.

The acute toxicity of these Mes, Mops, and Popso buffers is low to both *C. dubia* and fathead minnows (Phase I; EPA, 1991A) (48-h and 96-h LC50s for all buffers are ≤25 mM for both species). Sublethal levels of the buffer are added to hold the pH of test solutions for the acute Phase I tests (see EPA, 1991A). Chronic toxicity results using these three buffers indicated that 16 mM did not cause reduced survival or growth for the fathead minnow 7-d test. For *C. dubia*, 4mM of all four buffers has not caused reduced survival or reproduction in either the 4-d or 7-d tests. Use of the buffers is preliminary and the effects due to interferences from the buffers themselves have not been studied. It is possible that the buffers may reduce the toxicity of some toxicants.

The buffers must be weighed and then added to aliquots of the effluent dilutions and control water as batches. Then adjust to desired pH with acid and base to the selected values and add the test organisms. Solutions should be left for several hours to equilibrate, especially for the Popso buffer which has low solubility in water (in contrast to other buffers). While our experience with the buffers is limited, we have found the amount of any buffer needed to hold a pH is effluent specific. Once the pH is adjusted to the desired pH, the test solutions need not be covered tightly to maintain pH; however pH should be measured at each survival reading at all dilutions. The test results with the buffers should mimic those of the earlier *graduated pH test* if ammonia is the suspect toxicant.

The methods described in Phase II can be used to add identify ammonia as the pH sensitive toxicant. Use of the air-stripping method to remove ammonia from the sample at high pH's should help evaluate whether toxicant(s) other than ammonia are present (Phase II, 1992A). The results of this air-stripping test should be compared with the *aeration test* results of Phase I, the *baseline effluent test* and the *graduated pH test*. If the ammonia concentration is decreased and the toxicity is reduced or absent, more evidence that ammonia is playing a role in the toxicity of the effluent has been generated. Other compounds could precipitate with the pH adjustment and concentration during air-stripping and when water is added back into the solution, they may not be available.

Special Considerations/Cautions: The *controls* in the CO_2 controlled chambers for each pH and the *baseline test* act as checks on the general health of the test organisms, the dilution water and most test conditions. If the effluent pH in the *baseline test* is close to that of the pH adjusted test solutions, the toxicity expressed in the two tests should be similar. Significantly greater toxicity may suggest interference from other factors such as the ionic strength related toxicity (if the

pH was adjusted with HCl) or CO_2 toxicity. Dilution water tested at the various pH's does not serve as *blanks*, as the effluent matrix may differ from that of the dilution water. However, if acids and bases are added (with or without CO_2 additions) then *toxicity blanks* with the same amounts of acid/base added need to be tested to determine the cleanliness and effects of the acids and bases. Other compounds with toxicities that increase directly with pH may lead to confounding results or may give results similar to ammonia. Monitoring the conductivity of the effluent solutions after the addition of the acids and bases may also be helpful in determining artifactual toxicity.

6.9 Tier 2 Characterization Tests

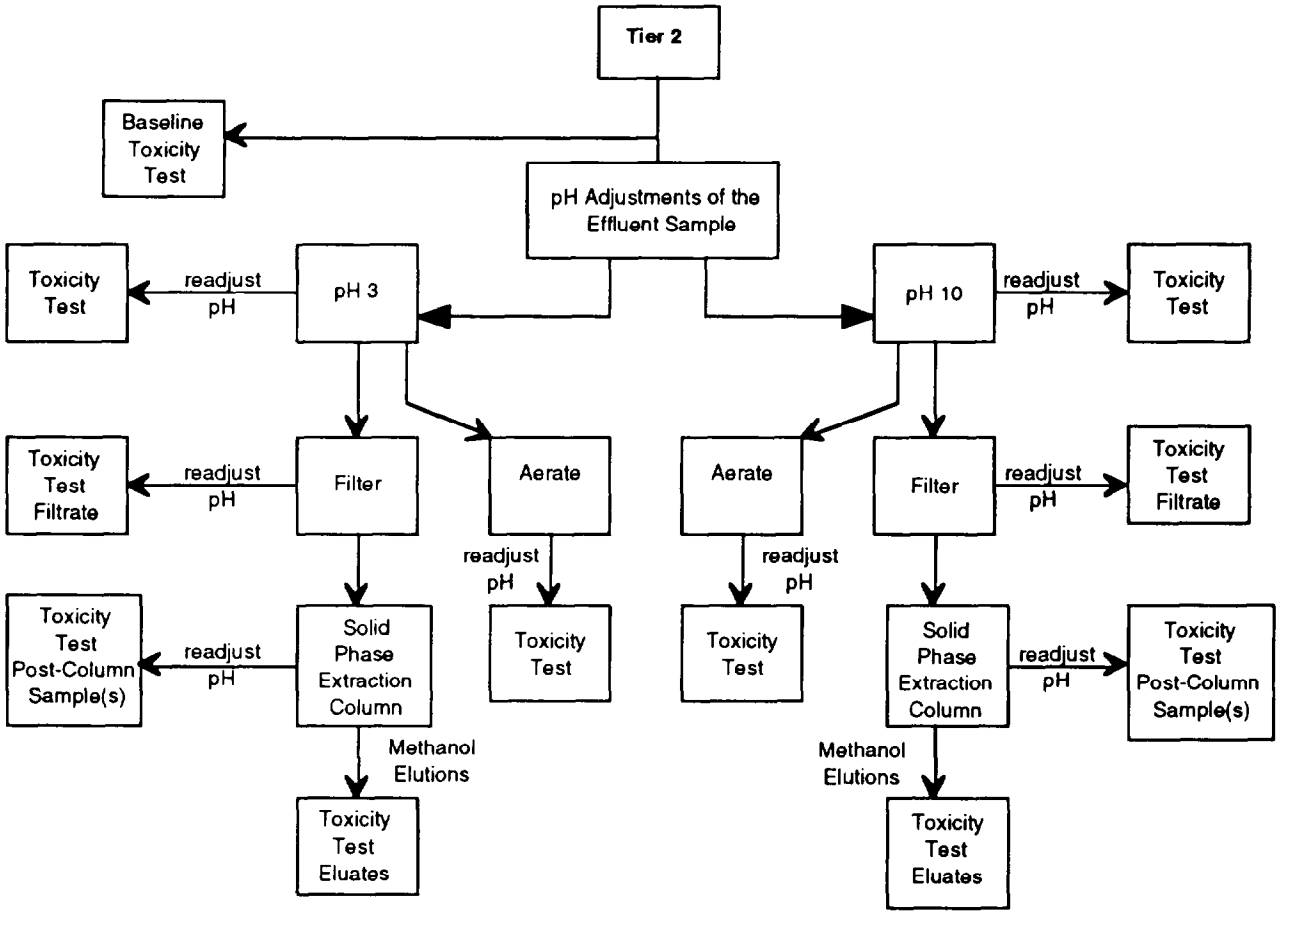
Two tiers are used in the chronic TIE approach primarily because in our experience, radical pH adjustment often is not needed. Only when the manipulations in Tier 1 do not indicate clear patterns is Tier 2 conducted. Tier 1 manipulations do not involve the use of drastic pH manipulations to characterize the toxicity of the sample. The pH adjustments are used to affect toxicity when the Tier 1 tests are not adequate or to assist in providing more information on the nature of the toxicants (Figure 6-3).

Changes in pH can affect the solubility, polarity, volatility, stability, and speciation of a compound. These can change the bioavailability of the compounds, and also their toxicity. The Phase I acute manual (EPA, 1991A; EPA, 1988A) discusses the effect of pH on groups of compounds at length, therefore only an abbreviated discussion of pH effects will be covered in this document.

Un-ionized forms of chemicals are generally less polar than the ionized form, and the ionized forms interact with water molecules to a greater extent. Compounds may be more toxic in the un-ionized form, as was discussed above in Section 6.8 *graduated pH test*. Un-ionized forms may be easily stripped from water using aeration, or extracted with SPE techniques and subsequent elution with non-polar solvents. Also, changes in solubility with pH change may cause compounds to be removed by filtration. The form of metals can be altered by pH and organic compounds can be degraded at extreme pH values.

Even if the chemical species are unchanged, changes in the pH of the solution may affect the toxicity of a given compound. The cell membrane permeability and the chemistry of the toxicant may be affected.

Figure 6-3. Tier 2 sample preparation and testing overview.



Changing pH and returning it to pH *i* after a short time (~1 h) will not always change the toxicity. However, this adjustment may result in a reduction, loss or increase in the toxicity. Sometimes only the pH adjustment in combination with a manipulation (e.g., filtering, solid phase extraction) changes toxicity when the same pH unadjusted manipulation test did not.

6.10 pH Adjustment Test

General Approach: For this Tier 2 test, the effluent is adjusted to either pH 3 or pH 10, and left at those pHs until other manipulations (aeration, filtration, and C_{18} SPE post-column effluent samples) are ready to be readjusted to pH *i*. The pH adjustment alone may not change toxicity, if equilibrium is slow. Satisfactory *blanks* in chronic tests with various reconstituted waters adjusted to pH 11 have not been consistently produced, but acceptable *blanks* have been obtained at pH 10 (and pH 3), while pH 11 adjustments have not been problematic in some effluent matrices. Since pH 11 was subjectively chosen, we recommend adjustment to pH 10 for chronic TIE's. The *pH adjustment test* serves as a *toxicity control* for the pH adjustments combined with aeration, filtration and the C_{18} SPE column manipulation. As described in Tier 1 and the acute Phase I manual, pH may drift very differently during the toxicity tests following these more severe pH manipulations. Therefore, monitoring and control of test pH is necessary.

Methods: An aliquot of effluent is pH adjusted to pH 3 and another aliquot is adjusted to pH 10, along with dilution water samples which will serve as *blanks*. Enough sample and dilution water are pH adjusted to provide the necessary volumes for the *aeration and pH adjustment test*, the *filtration and pH adjustment test*, and the *post C_{18} SPE column and pH adjustment test*. Minimal dilution of the effluent should occur, and the use of 0.01 N, 0.1 N, and/or 1.0 N solutions of acids/bases (Suprapur®, E. Merck, Darmstadt, Germany) to adjust pH are suggested. The volumes and strengths of the acid/base additions should be recorded as this information may be useful in determining if artifactual toxicity should be expected. This information can be helpful when subsequent testing is conducted and knowledge of the volumes of acid/base added to the previous samples assists in making the pH adjustments more rapidly.

Interpretation of Results/Subsequent Tests: A decrease in toxicity compared to the *baseline test* should be pursued to detect the mechanism of toxicity reduction. Often precipitation occurs after drastic pH change. If precipitation does occur, then the *filtration and pH adjustment test* will likely remove the toxicant and efforts should be focused on recovery and identification from the filter. Similarly, if the C_{18} SPE column or aeration changes toxicity, these manipulations should be pursued. If toxicity is only reduced by pH change, (which is not common) not much can be made of the information, and clustering of several manipulations as well as adding additional techniques such as ion exchange should be explored. Dilution from the acid and base additions should also be checked. Degradation of toxicity is a possibility also, but is nearly impossible to detect at this stage.

The adjustment of pH (to pH 3 or pH 10 and back to pH *i*) may cause toxicity problems. Just the addition of the NaOH or HCl may be the cause of the toxicity and may also occur in the dilution water *blanks* or only in the effluent sample. The effect on effluent toxicity of the Na^+ and Cl^- additions, depends on the TDS concentration of the effluent. The acid/base additions are typically more toxic in dilution water than in effluent, unless the effluent TDS concentration is high, and the additional concentrations of acid/base result in toxic TDS concentrations. These effects are of more concern in chronic TIE's. The effect of NaCl additions on TDS can be tracked by measuring conductivity. Appreciable increases in conductivity should be a warning to evaluate TDS toxicity caused by acid and base addition.

Increases in toxicity compared to the *baseline test* may be a result of either an increase in TDS or toxicant changes. TDS as a toxicant may be eliminated by calculating the TDS at the ICp value. Effluents that have high toxicity require high dilution to determine the ICp, and at such great dilution the TDS is subsequently diluted sufficiently to remove TDS as a candidate. If this is not the case, NaCl can be added to an aliquot of effluent to see if the acid/base additions could have caused the increased toxicity. Table 6-10 provides chronic toxicity information for NaCl in various hardness waters for *C. dubia* and fathead minnows.

Precipitates can remove toxicity through sorption of such chemicals as non-polar organics. In this case the precipitate is only the mechanism of removal, not the toxicant itself. The C_{18} SPE column is likely to remove the toxicity in such cases; however, in Tier 2 a pH change can also desorb toxicants from particles and make them bioavailable and therefore toxic.

Different pH drift during the *baseline toxicity test* and those after manipulations has been discussed (EPA, 1991A). For a valid test, the pH during the test must be known and maintained the same as in the pH *i* test. If the drift of the pH varies considerably, confusion in interpreting the results can arise if a compound whose toxicity is pH dependent is present in the sample. If good pH control is not maintained incorrect conclusions are likely to be made and mislead the TIE process.

Special Considerations/Cautions: The addition of acids and bases to the effluent does not give comparable results of acids and bases added to the dilution water. The amount of acid and base added to each sample will more than likely be dissimilar. However, dilution water toxicity *blanks* to assess the additions of the acid and base are needed to determine whether toxic concentrations of ions have been reached and to determine the cleanliness of the acid and base solutions that are used in this manipulation and subsequent pH manipulation tests. The *controls* from the *baseline test* provide information on the health of the test organ-

Table 6-10. Chronic toxicity of sodium chloride (g/l) to *C. dubia* and *P. promelas* in various hardness waters using the 7-d tests.

Species	Water Type	IC50 95% C.I.	IC25 95% C.I.	NOEC	LOEC
C. dubia	SRW	1.3 1.2-1.5	0.93 0.76-0.96	0.63	1.3

The *pH adjustment test* serves as the *toxicity control* (or perhaps the "*worst case*" *toxicity control*) for the subsequent pH adjustment/characterization tests.

isms, dilution water, and laboratory test conditions. The pH adjustment test serves as the toxicity control (or perhaps the "worst case" toxicity control) for the subsequent pH adjustment/characterization tests.

6.11 Aeration and pH Adjustment Test

General Approach: Aeration at pH 3 or pH 10 may make toxicants oxidizable, spargeable or sublatable, that are not so at pH *i*. If this does occur, avenues are then available to characterize and identify, similar to the procedures described for aeration at pH *i* in Tier 1. For this test, two effluent aliquots which were adjusted to pH 3 and pH 10 in the *pH adjustment test* are each aerated for a period of time, for example, 1 h. The aeration process can concentrate compounds due to loss of volume, and caution should be exercised in this aeration process and lost water may need to be replaced with dilution water.

Methods: The steps for this procedure should be identical to those used in the non-pH adjusted sample aeration (Section 6.4). The pH of the effluent may drift during the aeration, and it should be checked at 30 min intervals and readjusted to the original pH (pH 3 or 10) if it has drifted more than 1 pH unit. The amount of NaCl added from the acid/base additions may be different in aerated samples than for *pH adjustment test* and proper compensation for this difference must be made as described above. The volume of effluent aerated should be compared to the amount of original sample volume prepared.

After aeration is completed, adjustments back to pH *i* should be made on all samples at the same time. The formation of any precipitates should be noted, but the importance of precipitates (if any) will not be known at this point in the characterization.

Interpretation of Results/Subsequent Tests: If aeration with either pH adjustment removes or reduces the toxicity, additional tests must be performed to identify whether sparging, sublation, or oxidation removed the toxicity, as described in Tier 1 (Section 6.4). If toxicity is reduced because of precipitation, the results for this test and the *filtration and pH adjustment test* should be similar, but if oxidation is a problem, pH adjustment and filtration will not affect the toxicity of the effluent. At pH 10 the total ammonia levels can be reduced by aeration. However, the geometry of the aeration technique (i.e., small surface area) for this *pH adjustment and aeration test* described here is not particularly conducive to ammonia removal. However, if aeration at pH (10) reduces toxicity compared to the toxicity in the *aeration test* at pH *i* and the *baseline test*, measure the total ammonia level in the sample to determine if it was stripped from the effluent.

Special Considerations/Cautions: The results of this test should be compared to the *toxicity control* (*pH*

adjustment test) and the *baseline test*. The *aeration and pH adjustment blank* should be compared to the pH adjustment *blank*. If the effluent toxicity is reduced in the effluent following pH adjustment/aeration, and the *blank* is toxic, the *blank* can be ignored and the results indicate toxicity removal. However, if toxicity is the same or greater, artifactual toxicity cannot be ruled out and further tests must be conducted. Compare the results of the *aeration and pH adjustment blank* to the *filtration and pH adjustment blank* and the *pH adjustment blank* (Sections 6.10 and 6.12). If all have toxicity, then artifactual toxicity occurred from the pH adjustment, while if only the *aeration and pH adjustment blank* has toxicity, then the artifactual toxicity crept in during the aeration manipulation and the test should be repeated.

6.12 Filtration and pH Adjustment Test

General Approach: Since a pH change can cause toxicants to precipitate or cause solubilized toxicants to sorb on particles, filtration at altered pH values can be used as a tool in characterizing the effluent. Therefore, by filtering pH adjusted effluent, compounds that were in solution without a pH adjustment may no longer be in solution or any toxicants associated with particles may be removed by the filtration process. Differences in the toxicity caused by filtering (at pH *i*) compared to the *pH adjustment test* (Section 6.10) may imply toxicity associated with suspended solids. If pH affects the filterability of the toxicants, solubility changes are implied at those pH values. Once the toxicants are filtered, the particles may be recoverable from the filter if toxicity has not degraded.

Methods: Details of preparing filters are generally the same as described in Tier 1 (Section 6.5), except the high purity water used to rinse the filters must be pH adjusted to the appropriate pH, as should the dilution water for the *blank*.

Effluent samples adjusted to pH 3 or pH 10 (Section 6.10) are filtered, readjusted to pH *i*, and the filtrate toxicity tested. Stainless steel filter housings are not to be used for this step, because stainless steel will frequently bleed metals when a pH 3 solution being filtered is in contact with the stainless steel. An inert plastic or properly cleaned glass housing should be used.

Interpretation of Results/Subsequent Tests: The results of the *filtration and pH adjustment test* are compared to the *toxicity controls*—the *baseline test* and the *pH adjustment test*. If the effluent is more toxic after filtration and contamination is not the cause, the breaking of an emulsion might be involved. If the toxicity is removed or reduced by the filtration step and dilution is not the cause, then toxicants have been separated from the whole effluent and efforts should focus on identifying the compounds filtered out. The next step is to recover the toxicity as described in Tier 1 *filtration test*. This may be accomplished using a pH adjusted sample of water, perhaps using the pH opposite of that used in the filtration process.

Special Considerations/Cautions: The pH adjusted and filtered dilution water serves as a *blank* and the pH adjusted and filtered effluent sample serves as a *toxicity control* for the solid phase extraction step (Section 6.13). The results of the *filtration and pH adjustment test* should be compared to the effluent *pH adjustment test* and the *baseline test*. The *filtration blank* should be compared to the *baseline control*, the *aeration blank*, and *pH adjustment blank*. Toxicity in the *filtration blank* implies toxic artifacts from the filtration process, the glassware, the pH adjustment or a dilution water problem. If the *baseline control* performance is acceptable, the *blank* toxicity was most likely created during the pH adjustment or filtration. If the *aeration and pH adjustment blank* is non-toxic, and if the *filtration blank* is toxic, and the filtered effluent sample is still toxic or more toxic, artifactual toxicity cannot be ruled out. To check if it occurred during the manipulation, the experiment must be repeated. If the *filtration blank* is toxic, yet the filtered pH adjusted effluent indicates that toxicity is reduced/eliminated, the toxicity in the *blank* can be ignored.

6.13 Post C_{18} Solid Phase Extraction (SPE) Column and pH Adjustment Test (pH 3 and pH 9)

General Approach: Shifting the ionization equilibria at high and low pHs may cause the C_{18} SPE column to extract different compounds than at pH *i*. pH adjusted and filtered effluent is passed over a prepared C_{18} SPE column to remove non-polar organic compounds (cf., *post C_{18} SPE column test*, Section 6.6 above). Organic acids and bases may be made less polar by shifting their equilibrium to the un-ionized species. By adjusting the effluent samples to a low pH and a high pH, some compounds that are in the un-ionized form should sorb onto the column. However, the C_{18} packing degrades at high pH, so pH 9 (rather than pH 10 or pH 11) is used in this manipulation. Specific manufacturer's data should be checked for acceptable pH range. We have had no experience in eluting toxicants off the C_{18} SPE column that would be sorbed only at an altered pH, and therefore we can only provide general rules to follow in these cases except those inferred from how ionizable compounds behave in regard to pH change.

Methods: All of the procedures for this manipulation and the use of the C_{18} SPE column are the same as is described in Tier 1 for the SPE extraction at pH *i* (Section 6.6) with one exception. All water passed through the column (rinse, *blank* and effluent) should be acidified or rendered basic depending on which pH is under investigation (see Section 6.12). The potential for bacterial growth and artifactual toxicity in the post-column samples remain the same as for pH *i*.

Interpretation of Results/Subsequent Tests: The extraction efficiency of the column is assessed by comparing the results of the *post C_{18} SPE column and pH adjustment test* (pH 3 and pH 10) to the *filtration and pH adjustment test*, and the *pH adjustment test*. Again post-column test results are the most interpretable when there is no artifactual toxicity and toxicity was removed.

When the toxicity is removed, compare the results of the test with the *methanol eluate test* below (Section 6.14). If toxicity is removed that was not removed under pH *i* and recovered in the methanol eluate, efforts to identify the toxicants should be started. If methanol does not recover toxicity, a pH adjusted water should be tried. For further discussions of the interpretation of the results, see Section 6.6 above.

Special Considerations/Cautions: Careful observations and judgement must be exercised in detecting problems in the *post C_{18} SPE column and pH adjustment test*. Low DO levels can occur in these samples (cf., Section 6.6). Through testing experience, the investigator will know whether toxicity appears as artifactual (i.e., growth, low DO) or as lack of toxicity removal. If artifactual toxicity is not recognized, then an erroneous conclusion that the C_{18} SPE column did not remove toxicity can be made.

General test conditions (dilution water, health of test animals) will be tracked by the *controls* in the *baseline test*. The post-column dilution water *blanks* should be compared to those *controls* to determine if the column imparted toxicity. If the post-column dilution water *blank* was toxic, but no toxicity or artifactual toxicity occurred in the post-column effluent sample the toxic *blank* can be ignored.

Results of the *post-column effluent test(s)* must be compared to the results of the *filtration and pH adjustment test* to determine if the manipulations effectively reduced toxicity. When the *post C_{18} SPE column test* data is plagued by artifactual toxicity, the importance of the *methanol eluate test* increases.

6.14 Methanol Eluate Test for pH Adjusted Samples

General Approach: This test is essentially the same as the *methanol eluate test* in Section 6.7, except that the columns were prepared with pH adjusted waters/effluents (see Section 6.13).

Methods: These are identical to those in Section 6.7, except the pH of the rinse water, blank and effluent sample has to be adjusted to pH 3 or pH 9 (lowered from pH 10).

Interpretation of Results/Subsequent Tests: If the toxicity is recovered in the eluate, identification should be initiated. Refer to Sections 6.6, 6.7, and 6.13 for more information.

Special Considerations/Cautions: The *baseline test* serves as the *toxicity control*, and the *methanol blank* (for *pH adjusted samples*) serves as the *toxicity control* for the effects of methanol in water. The health of the test animals, the viability of the dilution water and general test conditions are evaluated by the *controls*.

The artifactual growth observed in the *post C_{18} SPE column test* (with and without pH adjustments) from the methanol has not occurred in *methanol eluate tests*. This is most likely due to the differences in how the methanol degrades/behaves in dilution waters which are low in bacteria and other organic matter in contrast to effluent samples (even post-column effluents).

6.15 Toxicity Characterization Summary

Phase I will not usually provide information on the specific toxicants. If effluent toxicity is consistently reduced, for example, through the use of the C_{18} SPE column, this does not prove the existence of a single toxicant because several non-polar organic compounds may be causing the toxicity in the effluent over time, but use of the C_{18} SPE technique in Phase I detects the presence of these compounds as a group. This lack of specificity is very important to understand for subsequent Phase II toxicant identification. Efforts should concentrate on those manipulations affecting toxicity in which the toxicant is isolated from other effluent constituents, such as the SPE column, filtration and aeration.

After the Tier 1 group of Phase I tests has been completed, the results will usually show that some manipulations increased toxicity, some decreased it, and others effected no change. In some instances, Tier 1 results allow the researcher to proceed immediately into the Phase II identification, and sometimes Phase I (Tier 1 and/or Tier 2) and Phase II combinations are needed to determine the cause of toxicity (cf., EPA, 1992A). Of course, new approaches are frequently devised as more Phase I TIEs are completed.

Toxicity may be changed by two or more tests, and if so, then more conclusive inferences might be possible than when only one manipulation changed the toxicity.

If all of the toxicity is not removed, it is possible that other toxicants could be present in the effluent so that only partial removal was obtained. Frequently more than one manipulation affects toxicity but only infrequently is there no effect from any manipulation. Even if toxicity is affected by only one manipulation, one still does not know whether or not there are multiple toxicants. When several manipulations affect toxicity, it still does not ensure that there are multiple toxicants. There is also no way to tell at this stage if there are multiple toxicants, whether or not they are additive, partially additive or independent. In our experience with acutely toxic effluents, we have not found synergism, but independent action has commonly been found. Some toxicants identified in effluents have been additive, but more often these have been only partially additive.

The two objectives which usually move the TIE along more rapidly are to separate and concentrate the toxicant(s). Therefore, the first step in Phase II (EPA, 1989A) will often be to reduce the number of constituents accompanying the toxicants. These efforts may reveal more toxicants than are suggested by Phase I testing. In Phase II one may discover that toxicants of quite a different nature are also present but were not in evidence in Phase I and if this is the case, different Phase I characterizations may then be needed. Once the analytical methods to identify one or more of the toxicants is found, efforts to confirm the cause should be initiated immediately (EPA, 1989B; EPA, 1992B).

As discussed earlier, the amount of time necessary to adequately characterize the physical/chemical nature and variability of the toxicity will be discharge specific. For a given discharge, the factors that will affect the length of time it takes to move through Phase I is the appropriateness of Phase I tests to the toxicants, the existence of long- or short-term periodicity in individual toxicants and the variability in the magnitude of toxicity. An effluent which consistently contains toxic levels of a single compound that can be neutralized by more than one characterization test should be identified and moved into Phase II more quickly than an ephemerally toxic effluent with highly variable constituents, few of which or none of which are impacted by any of the Phase I tests. Several samples should be subjected to the Phase I characterization tests but not all manipulations have to be done on all subsequent samples. The decision to do subsequent tests on these samples to confirm or further delineate initial results is a judgement call and will depend on whether or not the results of Phase I are clear-cut. Sometimes it may be reasonable to start Phase II and Phase III on the first sample.

If the Phase I characterization tests that remove or neutralize effluent toxicity vary by the sample, the number of tested samples must be increased and the frequency of testing should be sufficient to include all major variability. The differences seen among samples can be used to decide when further differences are not being found. Phase I characterization testing should continue until there is reasonable certainty that new types of toxicants are not appearing. No guidance can be given as to how long this may take—each problem for every discharger is unique. While the toxicity of samples can be very different, the same characterization tests must be successful in removing and/or neutralizing effluent toxicity.

Often the next step of the TIE is obvious; at other times the outcome of Phase I will be confusing and the next step will not be obvious. In our experience with acutely and chronically toxic effluents, once one toxicant is identified, identification of subsequent toxicants becomes easier because: (a) the toxicity contribution of the identified toxicant can be established for each sample; (b) the number of Phase I manipulations that will affect the toxicity of the known toxicant can be determined; (c) one can determine whether the identified and the unidentified toxicant(s) are additive; (d) if some manipulations affect the toxicity due only to the unidentified toxicants, some of their characteristics can be inferred; and (e) one can determine if the relative toxicity contributions of identified and unidentified toxicants varies by sample. Such information can be used to design tests to elucidate additional physical/chemical characteristics of the toxicants that cause chronic toxicity.

6.16 Use of Multiple Characterization Tests

Type and amount of testing is dependent on the toxicity persistence in the effluent, the nature of the toxicity, and reassessment of previous Phase I results (observed trends in the characteristics can be very important). Several tests could each partially remove the effluent toxicity because several compounds are causing the toxicity, or that one toxicant can be removed by several Phase I steps. For example, if several toxicants are acting to cause the toxicity, then the *graduated pH test* and the *post C_{18} SPE column test* both might result in a partial toxicity reduction. If sodium thiosulfate and EDTA both reduce toxicity, cationic metals might be suspect.

In the acute Phase I (EPA, 1991A), the use of multiple manipulations (combining two of the Phase I tests) was advocated and this same concept is also useful for the chronic TIE as well. For effluents with multiple toxicants, especially if they are not additive, multiple manipulations are helpful. Especially when no single manipulation removes all the toxicity, multiple manipulations should be tried.

When the C_{18} SPE column only partially removes toxicity, Phase I manipulations with the post-column sample should be tried. For this multiple manipulation, the post C_{18} SPE column effluent can be treated as whole effluent, and several of the Phase I steps can be conducted on the post-column effluent such as the *EDTA addition test*, the *thiosulfate addition test*, and the *graduated pH test*. However, these combinations are useful only with the post-column effluent provided that no artifactual toxicity is present.

If the C_{18} SPE column partially removes toxicity, pass an aliquot of the post-column effluent over an ion exchange column to determine the characteristics of the remaining toxicity. If a non-polar toxicant and ammonia are suspected, then passing the sample over the C_{18} SPE column and then over zeolite may assist in accounting for all of the toxicity. Likewise, passing the effluent over zeolite and then over the C_{18} SPE column may provide additional insight. To gain this knowledge toxicity tests must be performed after each manipulation and not just on the multiple manipulated sample.

Effluent characterization must be approached without any preconceived notion or bias about the cause of

toxicity because many constituents are present in effluents and their chemistry is often unknown, resulting in circumstantial evidence that is frequently misleading. Certainly all available information and experience should be used to guide the investigative effort but temptations to reach conclusions too soon must be resisted. Sometimes the answer being sought is only whether or not a specific substance is causing toxicity. Obviously in such cases testing is specifically selected to answer that question and therefore not all manipulations need to be performed.

Section 7
Interpreting Phase I Results

After Phase I on one sample or several samples is completed, the investigator must carefully evaluate the data, draw conclusions, and make decisions about the next steps that are needed. Sometimes the next step is obvious, at other times the outcome will be confusing and the next step will not be obvious. Several general suggestions, based on our experience to date, may provide some help.

In this section, various examples of Phase I results are given with interpretation suggestions. This discussion is repeated from the acute Phase I characterization manual (EPA, 1991A), and not all aspects have been evaluated for chronic TIEs yet. These examples should be used only as guides to thinking and not as *definitive* diagnostic characteristics. Since almost any toxicant can be present in effluents, clear-cut logic is not totally dependable in interpreting results. Rather, one must use the weight of evidence to proceed, and be aware that artifacts cannot at this point always be identified.

One should avoid making categorical assumptions to every extent possible. For example, to assume that the toxicity is due to a non-polar toxicant(s) because the toxicity in the post C_{18} SPE column effluent was removed, often is an error. Metals may also be the toxicant adsorbed by the SPE column; we have observed zinc, nickel, and aluminum concentrations remaining on the C_{18} SPE column. However, if the toxicity can be recovered in the methanol fraction, then the theory that a non-polar toxicant(s) is causing the toxicity is better substantiated, because metals do not elute with methanol and therefore do not produce toxicity in the methanol fraction toxicity test (cf., Phase II).

Example 1. Non-polar toxicant(s). The Phase I results implicating non-polar toxicants are:

- Toxicity in the *post C_{18} SPE column test* was absent or reduced.
- Toxicity was recovered in the *methanol eluate test.*

Toxicants other than non-polar compounds may be retained by the SPE column but they are less likely to be eluted sharply. Also, artifactual post-column toxicity can occur, but non-polar toxicity is typically distinguished from the artifactual toxicity when the eluate is checked for toxicity. Some toxicants (metals, some surfactants) may not elute from the SPE column with methanol and so failure to recover the toxicity in the eluate does not exclude the possibility of a non-polar toxicant. Recovery of toxicity in the eluate at pH *i* is less likely to be an artifact than recovery only at pH 3 or pH 9. For those instances where methanol does not recover C_{18}-removable toxicity, other solvents may be needed to elute the toxicants (see Phase II; EPA, 1992A).

Example 2. Cationic Metals. This group of metals has varied chemical/physical behaviors which result in less definitive Phase I results. The following characteristics can be used only in a general way to point to metals as the cause of the toxicity:

- The toxicity is removed or reduced in the *EDTA addition test.*
- The toxicity is removed or reduced in the *post C_{18} SPE column test.*
- The toxicity is removed or reduced in the *filtration test*, especially when pH adjustments and filtration are combined.
- The toxicity is removed or reduced in the *sodium thiosulfate addition test.*
- Erratic dose response curve observed.

No single characteristic is definitive, with the possible exception of EDTA. In addition, toxicity may be pH sensitive in the range at which the graduated pH test is performed but may become more or less toxic at low or high pH depending on the particular metals involved. This characteristic for chronic toxicity has not yet been demonstrated to the extent it was for the acute toxicity of several metals (EPA, 1991A).

Example 3. Total dissolved solids (TDS). TDS consists of a group of common cations and anions (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, SO_4^{-}, NO_3^{-}, Cl^{-}, CO_3^{-}) and in parts of the United States, this group is called "salinity." TDS is usually measured by conductivity, density or refraction, none of which measure specific compounds or ions. The toxicity of any given amount of TDS will depend on the specific composition. TDS behaves as a mixture of toxicants, which do not cause toxicity through osmotic stress. Evidence of this is that the LC50s of the individual salts expressed in moles, are quite different. If osmotic stress were the mode of action, the concentration in moles at the LC50s would be similar (EPA, 1991A). One cannot use marine organisms to circumvent TDS unless NaCl is by far the

dominant TDS. Marine organisms regulate Na^+ and Cl^- but like freshwater organisms, they too are sensitive to non-NaCl TDS.

For these reasons, only very general relationships exist between toxicity and TDS. Because of their varied nature, they do not sort out clearly in Phase I. Rather, unless conductivity is very high (e.g., 10,000 µmhos/cm), one might suspect TDS when nothing else is indicated. For example, if high TDS were present and caused by calcium sulfate ($CaSO_4$), toxicity is likely to be removed in the *pH adjustment test* at pH 10 or in the *filtration and pH adjustment test* at pH 10, whereas if the TDS were due to NaCl, toxicity would likely not be affected.

As a general guide, when conductivity exceeds 1,000 and 3,000 µmhos/cm at the effect concentration for *Ceriodaphnia* and fathead minnows, respectively, TDS toxicity might be suspect. The conductivity of 100% effluent is not the relevant reading, but rather the conductivity at the concentrations bracketing the effluent no effect and effect concentrations.

Following are some Phase I general indicators that TDS might be a suspect:

- No pH adjustments changed the toxicity, unless a visible precipitate occurs upon pH adjustment, pH adjustment and filtration, and pH adjustment and aeration.
- No loss of toxicity in the *post C_{18} SPE column test*, or a partial loss of toxicity but no change in conductivity measurements.
- No change in toxicity with the *EDTA addition test*, *sodium thiosulfate addition test* or in the *graduated pH test*.

In addition, there are two tests that can be used that are not included in Phase I but may help to characterize the toxicity:

- Use acid/base ion exchange resins (EPA, 1992A). When toxicity is removed or reduced, the toxicity could be due to TDS.
- Use of activated carbon to remove toxicity (EPA, 1992A). When no toxicity is removed by passing the effluent over carbon, TDS could be responsible for toxicity.

An additional caution is that where TDS is marginally high, the addition of NaCl from pH manipulations can increase TDS enough to produce artifactual TDS toxicity. The conductivity of the solutions before and after the pH adjustments should be monitored closely to avoid this.

Example 4. Surfactants. There are three main groups of surfactants and/or flocculants (anionic, cationic and nonionic) that may occur in effluents. The Phase I behavior of these types of compounds may vary depending on which particular groups are present.

The general Phase I results implicating a surfactant(s) as the toxicant(s) are:

- Toxicity is reduced or removed in the *filtration test*.
- Toxicity is reduced or removed by the *aeration test*. In some cases, the toxicity is recoverable from the walls of the aeration vessel after removing the aerated effluent sample.
- Toxicity is reduced or removed in the *post C_{18} SPE column test*. The toxicity may or may not be recovered in the *methanol eluate test*.
- Toxicity is reduced or removed in the *post C_{18} SPE column test* using unfiltered effluent. Toxicity reduction/removal is similar to that observed in the *filtration test* and toxicity may or may not be recovered in *methanol eluate test* or the extraction of the glass fiber filter.
- Toxicity degrades over time as the effluent sample is kept in cold storage (4°C). Degradation is slower when effluent is stored in glass containers rather than plastic containers.

Example 5. Ammonia. Ammonia concentrations can be measured easily, and because it is such a common effluent constituent, determining the total ammonia concentration in the whole effluent is a good first step (see Section 4). If more than 5 mg/L of total ammonia is present, additional evaluations should be done. Sole dependence on analyses is not advisable because the chronic effects of ammonia and some other toxicants (e.g., such as surfactants) is not well known. Even though the ammonia concentration is sufficient to cause toxicity, other chemicals may be present to cause toxicity if the ammonia is removed. Three indicators of ammonia toxicity are:

- The concentration of total ammonia is 5 mg/L or greater.
- In the *graduated pH test* the toxicity increases as the pH increases.
- The effluent is more toxic to fathead minnows than to *Ceriodaphnia*.

Example 6. Oxidants. In effluents, oxidants other than chlorine may be present. Measurement of a chlorine residual (TRC) is not enough to conclude that the toxicity is due to an oxidant. In general, oxidants are indicated by the following:

- The toxicity is reduced or removed in the *sodium thiosulfate addition test*.
- Toxicity is removed or reduced in the *aeration test*.

- The sample is less toxic over time when held at 4°C (and the type of container does not affect toxicity).
- *Ceriodaphnia* are more sensitive than fathead minnows.

Of course, TRC greater than 0.1 mg/L in 100% effluent might indicate chlorine as the oxidant causing the toxicity. In addition, the dechlorination with SO_2 provides evidence of chlorine toxicity in the same manner as the sodium thiosulfate addition test.

Foreword

This document is one in a series of guidance documents intended to assist dischargers and their consultants in conducting acute or chronic aquatic toxicity identification evaluations (TIEs). TIEs might be required by state or federal agencies resulting from an enforcement action or as a condition of a National Pollutant Discharge Elimination System (NPDES) permit. The methods described in this document will also help to determine the adequacy of effluent TIEs when they are conducted as part of a toxicity reduction evaluation (TRE).

This Phase II document is the second of a three phase series of documents that provide methods to characterize and identify the cause of toxicity in effluents. The first phase of the series, Phase I (EPA, 1991A; EPA, 1992), characterizes the physical/chemical nature of the acute and chronic toxicant(thereby simplifying the analytical work needed to identify the toxicant(Phase II provides guidance to identify the suspect toxicants, and the last phase, Phase III (EPA, 1993A) provides methods to confirm that the suspect toxicants are indeed the cause of toxicity. The recent TIE documents (EPA, 1991 A; EPA, 1992; EPA, 1993A; and this document) have been produced or revised to include chronic toxicity recommendations and additional information or experiences we have gained since the original methods were printed (EPA, 1988A; EPA, 1989A; EPA, 19898).

This Phase II document provides identification schemes for non-polar organic chemicals, ammonia, metals, chlorine, and surfactants that cause either acute or chronic toxicity. The document is still incomplete in that it does not provide methods to identify all toxicants, such as polar organic compounds. This Phase II manual also incorporates chronic and acute toxicity identification techniques into one document.

While the TIE approach was originally developed for effluents, the methods and techniques directly apply to other types of aqueous samples, such as ambient waters, sediment pore waters, sediment elutriates, and hazardous waste leachates. These methods are not mandatory protocols but should be used as general guidance for conducting TIEs.

The sections of both Phase I documents (EPA, 1991A; EPA, 1992) which address health and safety, quality assurance/quality control (QA/QC), facilities and equipment, dilution water, testing, sampling, and parts of the introduction are applicable to Phase II. These sections, however, are not repeated in their entirety in this document.

Abstract

This manual and its companion guidance documents describe a three phase approach for dischargers to identify the causes of toxicity in municipal and industrial effluents (Phase I, EPA, 1991A; EPA, 1992; and Phase III, EPA, 1993A). In 1989, the document titled Methods for Aquatic Toxicity Identification Evaluations: Phase II Toxicity Identification Procedures was published as a guidance document for identifying the cause of toxicity in acutely toxic effluents (EPA, 1989A). This new Phase II document provides details for more types of samples, tests and test procedures that can be used to identify the specific chemical(s) responsible for acute or chronic effluent toxicity when the cause of toxicity is related to non-polar organic compounds, ammonia, surfactants, chlorine, or metals. Phase I characterization and Phase III confirmation manuals, the other guidance documents in the three phase TIE approach, have also been produced or updated to include both chronic toxicity information and new developments made since the first set of documents were printed. The TIE approach is applicable to effluents, ambient waters, sediment pore waters or elutriates, and hazardous waste leachates.

Acknowledgments

This document presents additional methods and improvements made to the procedures of Methods *for* Aquatic Toxicity *Identification Evaluations: Phase II Toxicity Identification Procedures* (EPA-600/3-88/035) by Donald Mount and Linda Anderson-Carnahan. This manual reflects new information, techniques, and test procedures developed by the National Effluent Toxicity Assessment Center (NETAC) since the previous Phase II document was printed in 1989. This Phase II document is based on the efforts of both federal and contract staff of the NETAC group. We gratefully acknowledge the following individuals' contributions to the research and development of the methods for this document: Penny Juenemann and Shaneen Schmitt (federal staff); Joe Amato, Lara Andersen, Steve Baker, Tim Dawson, Joe Dierkes, Nola Englehorn, Doug Jensen, Correne Jenson, Jim Jenson, Liz Makynen, Phil Monson, Don Mount, and Greg Peterson (contract staff).

Through the support of Rick Brandes and Jim Pendergast (EPA, Permits Division) and Nelson Thomas (ERL-D), the NETAC staff members developed and revised the TIE series of documents.

Section 1
Introduction

1.1 General Overview

The major objective of Phase II is to identify the suspected toxicant(s) in effluent samples using toxicity identification evaluation (TIE) procedures. Some general guidance to achieve this goal might be furnished by the results of acute or chronic Phase I tests (EPA, 1991 A; EPA, 1992), but for many effluents, such as those that contain non-polar organic toxicants, both separation and concentration steps will be needed to achieve the stated objective. If metals are the suspect toxicants, atomic absorption (AA) spectrometry should be sensitive enough to measure toxic concentrations directly in the sample, and the number of metals is small enough that toxicity can be attributed without separating one from another. The same principle applies to toxicants such as ammonia and chlorine; measurements can be made without separating or concentrating the effluent. However, if non-polar organic chemicals are suspected, separation is usually necessary for analytical and toxicological reasons.

Because there are often many constituents within the classes of chemicals (e.g., non-polar organics) identified in Phase I, initial efforts are most productively directed towards separating the toxic from the non-toxic constituents. With the need to identify the toxicant(s) quickly, comes the temptation to analyze too soon. Using methods such as gas chromatography/mass spectrometry (GC/MS) one can identify many non-polar organics that are present in the whole effluent mixture, but the association of toxicity with compound identification is very difficult to make for several reasons:

- There can be hundreds of compounds present in the mixture, and to investigate all of them would be very time consuming.
- Toxicity data for many of the chemicals identified are usually not available; chronic data are especially scarce.
- Separate constituents are often not commercially available; therefore, their toxicities cannot be measured and compared to effluent toxicity.
- Interactions (additivity, synergism, antagonism) are not known for the given mixtures and one must know interactions to apportion toxicity.

Therefore, it is suggested that the search for a separation technique to simplify the mixture into toxic and non-toxic 'subsamples be the first priority, rather than spending time investigating non-toxic components. If there is a single suspect toxicant such as ammonia, then separation needs are limited largely by the analytical requirements. If the toxicity is caused by one constituent, the number of other non-toxic constituents is irrelevant when attributing toxicity. However, Phase I results do not usually lead to a single suspect toxicant and, therefore, separation may be necessary.

When a method for separating the toxicant(s) is found, concentration might be an inherent part of the procedure (as in solvent extraction) which will simplify the problem of finding a method to concentrate the toxicity. At each stage of the separation and concentration process, measurement of toxicity is the best way to evaluate the success or failure of the manipulations.

The interpretation of TIE results can be different than in the classical research approach, where experiments are designed to either accept or reject a hypothesis. In TIE work, an experiment usually permits acceptance but not rejection of the hypothesis. For example., if ammonia is the suspect toxicant, it can be removed using zeolite resin. If the post-zeolite effluent is still toxic, you can conclude that there are additional toxicants present. If the post-zeolite effluent is not toxic, you cannot conclude that there are no additional toxicants because the zeolite might have removed other toxicants in addition to the ammonia.

The always present question of whether or not there is more than one toxicant immensely complicates data interpretation. Phase I results might not give an indication of multiple toxicants unless the toxicant classes change over time or from sample to sample. Phase II results are often such that one cannot tell whether the situation is one of partial removal of a single toxicant or

toxicity resulting from multiple toxicants. The issue might be resolved when one toxicant is identified and measured analytically. Experience shows that the best choice is to try to focus on the toxicant that appears easiest to identify. Usually that will be a toxicant that can be separated from the sample (e.g., extracted or recovered from a sorbent that reduces the toxicity) and for which there is a broad spectrum analytical identification method. Above all, data should always be interpreted under all probable scenarios, i.e., one toxicant, multiple toxicants, and even different toxicants from sample to sample.

Experience gained since the first Phase II (EPA, 1989A) document was printed has shown that effluent toxicants are not always strictly additive. When they are not additive, the toxicant present in the largest number of toxic units (TUs)[1] will determine the toxic units of the effluent. Non-additive toxicity will not be reduced by manipulations that remove toxicants present in fewer TUs than the major toxicant. Two or more toxicants might be present in approximately equal TUs, however, the ratio of TUs might change over different sampling times so that different chemicals determine the toxicity of the effluent. These important problems can be dealt with in Phase III (EPA, 1993A). In Phase II, the objective is to find which toxicants are present in toxic concentrations. However, failure of additivity may confuse Phase II results. Minor toxicants might not be noticed until the major one has been removed. In addition, additivity cannot be determined until at least one toxicant has been identified. Usually Phase II and Phase III merge and overlap, therefore such concerns regarding non-additivity must be incorporated in Phase II, at least in the latter stages.

As effluent constituents are identified, a sorting process begins in which a decision must be made as to whether or not each one identified contributes to the toxicity of the effluent. Usually, this is based on the estimated concentration and the constituents' toxicities. Analytical error in quantitation might be large (1 O-fold or more) because recoveries and instrument response factors probably will not yet have been determined on a particular chemical. Uncertainty about toxicological data is caused by differences in species sensitivity and water quality effects, when literature values are available. Confidence in an acute toxicity value (LC50) will vary depending on the quality of the test, the number of times it was repeated, and the completeness by which the results and conditions were described. Data on chronic effect levels are often scarce and rarely have tests been repeated. Species sensitivity frequently varies from 1 OO-fold to 1,000-fold; an error will likely be introduced when the published toxicity data for species other than the test species are used. When the uncertainty of the toxicity data is high, a maximum of 100-fold difference between measured concentrations and literature effect would be acceptable to classify a chemical as a suspect. If one has good data for the test species being used, then this difference might be reduced (e.g., to IO-fold). Since these decisions are always subjective, they will sometimes be wrong no matter how carefully they are made. Perhaps most important is use of an iterative process to make these decisions. First evaluate candidates that have concentrations higher than or closest to their chronic or acute effect levels and if these prove to be negative, then examine those that have concentrations below their effect levels. Remember that the suspected toxicant concentrations at the dilution equal to the effect level concentration are the important concentrations to compare. At some point, a decision must be made whether the true toxicants have not yet been identified or measured and that different sample preparation or analyses must be used.

For some effluents, Phase I results might not have provided any guidance for selecting the appropriate Phase II procedures to follow. Other characterization steps that might be helpful are solvent extraction (acidic or basic), sample evaporation, size exclusion chromatography, lyophilization, and vacuum or steam distillation (Jop et al., 1991; Walsh et al., 1983). We have little experience upon which to recommend procedures in these cases. It is most important to realize that the more severe the effluent treatment, the more likely it is that toxic artifacts will be created. These toxic artifacts could then be confused with effluent toxicity; therefore, artifactual toxicity must be monitored for each technique by using blanks.

Phase II efforts should develop into Phase III confirmation (EPA, 1989B; EPA, 1993A) as soon as good evidence is obtained that one or more candidates are probable toxicants. The primary product of Phase II is the chemical identification of the suspected toxicants to furnish the basis for Phase III testing. The techniques described in this document are useful for TIE work with effluents as well as ambient waters (Norberg-King et al., 1991) and sediment pore water or elutriates (EPA, 1991 B).

1.2 Biological Testing Considerations

The Phase I characterization documents (EPA, 1991 A; EPA, 1992) provide detailed discussions of various issues that are important in decision making throughout the TIE. The guidance covers use of various species, test concentrations, effluent sample types, testing requirements for quality assurance (QA), test endpoints, frequency of changing the test solutions, and more. All of these issues will not be discussed at length here and the user is encouraged to refer to the acute Phase I or the chronic Phase I as companion documents for the TIE process. As the Phase II identification and Phase III confirmation steps are initiated, QA requirements should

[1] TU calculations are described in EPA, 1992. The TUs of whole effluent equals 100% divided by the LC50, NOEC, or ICp (IC25, IC50) of the effluent. The TU of a specific chemical equals the concentration of the compounded divided by the effect level of the compound.

be revisited and the types of tests modified as needed. Several of these testing concerns are addressed below.

During Phase I, the analyst is searching for an obvious alteration in effluent toxicity, which might be obtained by using modified acute or chronic test methods. Confirmation testing (Phase III) conducted according to the standard methodologies will confirm whether the suspect toxicant(s) detected in the characterization and identification steps (Phases I and II) is the true toxicant.

In characterizing the toxicity in Phase I, factors such as time requirements, number of tests and the test design had to be considered and weighed against the type of questions that are posed. EPA has published manuals that describe the acute or chronic test methods to determine the toxicity of effluent or receiving waters to freshwater and marine organisms (EPA, 1991 C; EPA, 1993B; EPA, 1993C), and these tests are typically those that indicated the presence of toxicity which the TIE initiated. Deviations from these standard effluent testing protocols were discussed in both the acute Phase I (EPA, 1991A) and the chronic Phase I (EPA, 1992) manuals. For either the acute or the chronic Phase I procedures, the test volumes, number of test concentrations, and number of replicates were all reduced from the standard test methods (EPA, 1991 C; EPA, 19938). Additional modifications for the short-term chronic tests (EPA, 19938) including shorter test duration and a reduction in the frequency of the test solution renewal are suggested.

Throughout this document the TIE procedures for acutely toxic samples are based on the following species: *Ceriodaphnia dubia, Pimephales promelas, Daphnia magna, Daphnia pulex, Hyalella azfeca,* and *Chironomus tentans.* Almost all acute tests have been conducted using 10 ml of test solution in a 1oz plastic cup (or 30 ml glass beaker). TIE procedures with chronically toxic effluents are based on tests using either C. *dubia* or larval fathead minnows *(P. promelas).* In our laboratory, the chronic tests with C. *dubia* generally are conducted using 10 ml of test solution in 1 oz cups and the chronic tests with fathead minnows are conducted using 50 ml of test solution in a 4 oz plastic cup (10 fish per cup). Use of other species is constrained only by availability, size, age, and adaptability to test conditions, and the threshold levels for additives and reagents for the other organisms must be determined.

As soon as good evidence is obtained to implicate a suspect toxicant(the procedures for performing the toxicity tests can be changed. Therefore in Phase II, the time to modify the tests from the way they were conducted in Phase I may depend on when the toxicant is identified, and generally there is more flexibility for this in Phase II than in Phase III. The quality control (QC) measures in Phase I were not very strict because the data are primarily informative rather than definitive. The identity of the suspect toxicant(s) furnishes the basis upon which Phase III testing will be conducted, which will require stricter QC measures.

Initially, the use of modified protocols in Phase II may continue; however, once specific toxicant(s) identification has been made, Phase II (and Phase III) testing conditions should be similar to the methods described in the protocol that was used to trigger the TIE. Although a shortened version of the 7-d C. *dubia* test (which is referred to as the 4d test) may have been used in Phase I, the use of this test changes in Phase II (and Phase III). In order to use the 4d test in Phases I and II of the TIE, the 4d test must detect similar trends of toxicity as the 7-d test does. However, in Phase III the 7-d test is required because the toxicity as measured in the 7-d test (with additional replicates, more test concentrations, additional volume) was used to detect toxicity for the permit, and should be used to confirm the cause of toxicity. In the early Phase II chronic toxicity evaluation steps, the qualitative evaluation of toxicii might be useful and there is no reason why a toxicity test could not be terminated sooner than day seven, if the answer to a particular question has been found.

Information obtained from all toxicity tests should be maximized. For instance, in acute toxicity tests, monitoring time to mortality might be useful. In chronic toxicity tests, time to young production of the cladocerans or the lack of food in the stomach of the larval fish might be useful parameters. Observations such as these made during a test might be subtle indications and quite informative of small changes in toxicity. For example, if there is complete mortality on day four of the baseline effluent test, and in the EDTA addition test (Section 4) the animals either do not reproduce or grow yet they are alive at day seven of the exposure, the indication is that the toxicity was reduced. These results suggest that either an additional toxicant is present or the EDTA concentration was not sufficient to remove all cationic metal toxicity. These types of observations in the short-term tests might be just as useful as reductions in young production or growth. For evaluating whether any manipulation changed toxicity, the investigator should not rely only on statistical evaluations of test endpoints (see below and Phase I; EPA, 1992). Some treatments may have a significant biological effect that was not detected by the statistical analysis. Judgement and experience in toxicology should guide the interpretation.

In addition, for acute or chronic toxicity tests, randomization, careful exposure time readings, use of animals of uniform narrow-age groups (i.e., *C. dubia* neonates O-6 h old rather than O-12 h old) might assist in detecting smaller differences in tests. For example, in the chronic *C. dubia* tests, it is important to use organisms of known parentage (EPA, 19938) when the number of, replicates is reduced from ten to five. For C. *dubia,* daily renewals of the test media (as required in the chronic manual; EPA, 1993B) might not be necessary in Phase I or early Phase II testing as long as the toxicity of the

using 20% effluent as the high concentration and a dilution factor of 0.7, the concentrations to test would be 7%, 10%, 14%, and 20%. If the NOEC (from historical data) is 4050% (or above 50%), then the concentration series to test might be either 25%, 50%, 75%, and 100% or 40%, 60%, 80%, and 100%. Choice of dilution factor and test concentration range is a matter of judgement and depends on precision required and practicality.

After conducting Phase I procedures on an effluent sample, the amount of effluent available for subsequent identification work can be sufficiently reduced so that it may be impractical to try to conduct each step as described in this manual. This is most likely to be a concern for the non-polar organic identification techniques and other methods that require large volumes of effluent to identify the toxicant. Therefore, when the volume of an effluent sample is limited, it might be possible to track toxicity through the non-polar identification steps without quantifying the amount of toxicity that is being tracked. Essentially, this means that the toxicity tests are done without dilutions and the results would indicate only that toxicity was present or absent; the degree of toxicity present would not be measured. Once a suspect toxicant is identified, it is important that the amount of toxicity removal is known (through the use of dilutions) because this information can be used to correlate a suspect toxicant to the effluent toxicity in the Phase III confirmation.

If the number of replicates per test concentration is reduced, one must assume that precision is sufficient to decipher changes in toxicity that must be measured. One problem in using reduced replicates and low numbers of test concentrations in chronic tests is that this smaller data set is not amenable to all statistical requirements as recommended for the short-term tests (EPA, 1989C; see Section 5.8). Use of more organisms and more replicates than in the Phase I modified tests might be preferable if Phase I and/or Phase II data are likely to be used in Phase III confirmation (See Sections 2.2 and 2.3).

For acute toxicity tests, usually the LC50 or EC50 is reported for the toxicity data (calculated as recommended in EPA, 1991C). Endpoints for the most commonly used freshwater short-term chronic tests are growth, reproduction, and survival. The no effect level (the NOEC), and the effect concentration (the lowest observed effect concentration (LOEC)) are determined using the statistical approach of hypothesis testing to determine a statistically significant response difference between a control group and a treatment group. The NOEC/LOEC are heavily affected by choice of test concentrations and test design (see Phase I; EPA, 1992). The linear interpolation method (EPA, 1993B) provides a point estimate of the effluent concentration that causes a given percent reduction based on organism response. To calculate the inhibition concentration percentage (ICp), a computer program (Norberg-King, 1993; DeGraeve et al., 1988; EPA, 1989C) is available and the assumptions for the method are not the same as the test design requirements for hypothesis-based analyses. This point estimation method is particularly useful for analyzing the type of data obtained from chronic TIE tests using dilutions (see Phase I; EPA, 1992). Confidence intervals are calculated using a bootstrap technique and might be useful in determining if significant toxicity alterations have been observed. A significant reduction in toxicity and the precision of reference toxicant tests must be determined by each laboratory for each effluent. The use of the IC50 for Phase I TIEs might be more useful in correlating the characterization test results to the effluent toxicity than an IC25. However, there are situations when an IC50 may not be able to be estimated while the IC25 can. Above all, it is most important to use a consistent effect level for TIE toxicity testing (EPA, 1992A; EPA, 1992B). When substantial toxicity reductions occur in the toxicity tests, it may not always appear to be a significant reduction when the IC25s are compared. In order to further evaluate whether toxicity reductions occurred, the sample size (number of replicates, number of concentrations) should be increased in subsequent testing in an effort to differentiate toxicity responses from the sample size limitations. The dose response curves should then be compared to see if responses are similar. Once the toxicant is identified, the number of replicates should be increased, the dilution sequence might be modified and more dilutions used (see Phase III; EPA, 1993A). This should increase the confidence in the IC25 (or any other ICp value chosen) estimate.

Section 2
Non-Polar Organic Compounds

2.1 General Overview

The procedures described in this section presume that the results of Phase I tests have implicated non-polar organic compounds as the cause of acute or chronic toxicity. Results of Phase I tests that clearly implicate a non-polar organic toxicant typically are (1) all toxicity is removed by the C_{18} Solid Phase Extraction (SPE) column and (2) toxicity was observed in the methanol eluate test (see Section 8.6, EPA, 1991 A; and Section 6.7, EPA, 1992). In some instances, toxicity might not be removed completely by the SPE column, but sufficient toxicity is recovered in the methanol eluate to suggest a non-polar organic toxicant is present. While toxicants other than non-polar organic compounds might be removed by the column (e.g., metals), the elution for such toxicants is unlikely to be similar to that of the non-polar organic compounds. However, there is also the possibility that non-polar toxicants such as surfactants will be removed by the column and not recovered in the methanol eluate. The goal in this section is to separate the non-polar organic toxicants from the many non-toxic components of the sample to simplify the analytical work needed to identify the toxicant.

This section provides the general background information on non-polar organic compounds along with methods for concentrating and separating the toxicants for samples with acute and/or chronic toxicity. While the method provides a stepwise procedure, there are instances where the investigator may have to modify the approach to achieve the best results.

Also provided in this section are procedures that might prove helpful in less common situations. Metabolic blockers can be used to reduce or eliminate certain organophosphate compounds from exhibiting their toxicity (Section 2.5.1). In the instance when toxicity is not recovered in the methanol eluate and toxicity is not evident in the post-column effluent, alternate SPE elution procedures might be needed (Section 2.6).

A flow diagram of the general procedures followed in identifying non-polar organic toxicants is shown in Figure 2-I. In this procedure, the C_{18} SPE column is used to extract non-polar organic compounds from effluent samples. These compounds are then selectively

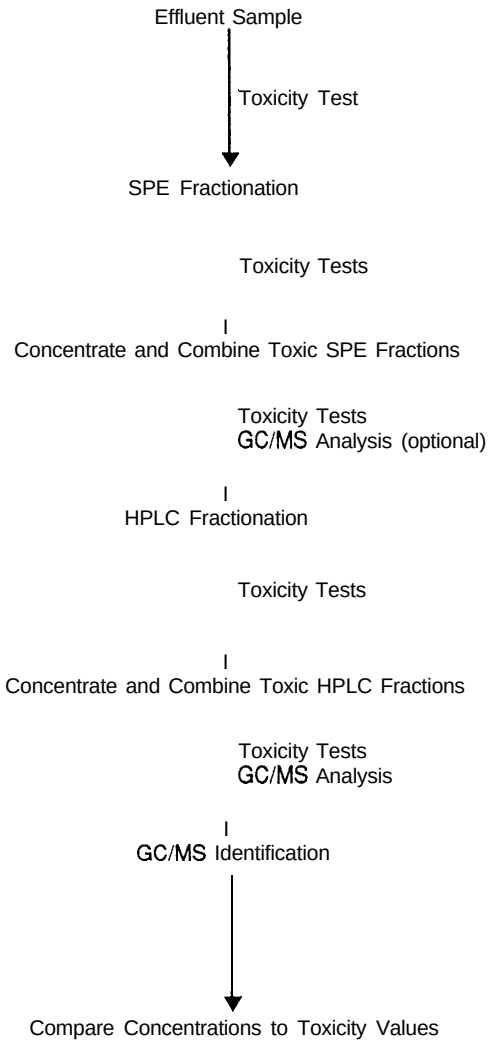

Figure 2-1. Phase II schematic for the identification of non-polar organic toxicants.

stripped off the column by eluting the C_{18} sorbent with solvent/water mixtures that are increasingly less polar. As a series, the 'fractions" resulting from column elutidn contain analytes that are decreasingly polar and decreasingly water soluble. Each fraction is then tested for toxicity. The fractions that exhibit toxicity are concentrated, and chromatographed using reversed phase High Performance Liquid Chromatography (HPLC). The resulting HPLC fractions are collected and tested for toxicity. The toxic HPLC fractions are concentrated into methanol by using another C_{18} SPE column. The concentrates are toxicity tested as before and analyzed using gas chromatography/mass spectrometry (GC/MS). Those constituents that are identified by GC/MS are roughly quantitated, by assuming that the identified constituents and the internal standard have the same response factor, and the estimated concentrations are compared to available toxicity values for each chemical. If this process reveals strong suspect toxicants, mass balance testing (Phase III; EPA, 1993A) could be started to determine whether additional toxicants are present. If no suspect toxicants are identified by GC/MS, a longer analysis time on the HPLC might help the identification by increasing the separation between toxic and non-toxic components, especially if there are many constituents present. Also, additional constituents might be identified by increasing the concentration factor by using larger effluent samples. At some point, the probability that the toxicants are not chromatographing on the gaschromatograph or the mass spectrometer is not detecting the toxicants must be considered if no suspect toxicants are identified. Use of other types of mass spectrometry, such as liquid chromatography/mass spectrometry (LC/MS) or direct probe mass spectrometry may be useful. Some effluents might require the SPE fractionation of several different samples befoie good suspect toxicants are found (Burkhard et al., 1991: Lukasewycz and Durhan, 1992).

The sorbents that we recommend for use in SPE and HPLC columns are chemically identical. The column packing is composed of silica gel which has been reacted with octadecyl silane to produce a covalent bonded phase one layer thick. The mechanism of extraction with C_{18} sorbents is relatively simple. Extraction of effluent compounds occurs because the C_{18} sorbent competes for the non-polar compounds more strongly than the surrounding water molecules of the effluent. Sorption of non-polar organics is also influenced by ionic strength, pH, and total organic carbon (TOC) levels. The same compounds will partition on both SPE and HPLC columns and the order of elution of chemicals will be approximately the same. The major difference between the SPE and HPLC columns is the amount of resolution achieved. The particle size employed in HPLC columns is smaller, providing a greater surface area and better component resolution. Despite less resolution, SPE columns have the advantage of possessing a higher loading capacity in general than HPLC columns. The SPE column could be considered as a preparatory column for sample cleanup while the HPLC column gives far more refined and controlled separation of sample constituents.

To elute non-polar organic toxicants extracted by the C_{18} SPE column, the sorbed compounds must have a higher affinity for the eluting solvent than for the octadecyl functional group (C_{18}). Choosing a solvent for elution is complicated because the toxicants' identities are not known. In general, the solvent should be less polar than water and more polar than the C_{18} functional group. The degree of solvent strength required to elute the toxicants is also unknown. Since methanol is less polar than water, has a very low toxicity (EPA, 1991A; EPA, 1992) and elutes chemicals from C_{18} sorbents, it has been a good solvent choice for most TIE purposes to date.

During sequential column elutions with successively increasing methanol in water concentrations, the relatively hydrophilic, polar compounds are eluted first, and the more hydrophobic non-polar compounds are eluted last. Given the strength of methanol as a solvent for non-polar compounds, it is possible that very hydrophobic (octanol water partition coefficient (log K_{ow}) ≥ 4) effluent compounds will not be eluted from the C_{18} sorbent. If toxicity caused by a very hydrophobic compound is extracted by the SPE column but not eluted by methanol, less polar solvents might be used to elute the SPE column (Section 2.6.1).

Once toxicity is found in one or more C_{18} SPE effluent fractions, the toxic fractions can be concentrated, then fractionated using HPLC. HPLC separation is used to reduce the number of non-polar organic chemicals associated with the toxicant(s) and to simplify analytical identification. The toxic HPLC fractions are concentrated and then analyzed by GC/MS. The estimated concentrations of constituents in the final concentrate (based on an internal standard) are then compared to their toxicity values to decide which may be sufficiently high in concentration to cause toxicity. If none are found, higher concentration factors, other analytical methods (e.g., LC/MS), and better separation are recommended.

Fractionation and toxicity testing procedures for non-polar organic toxicants causing either acute or chronic toxicity are presented in different sections of this chapter. The acute toxicity (Section 2.2) and chronic toxicity (Section 2.3) sections, have similar outlines and were written so either section could be used independently. As a result, some details that apply to both acute and chronic toxicity are repeated. After using Section 2.2 or Section 2.3 the investigator should then follow the identification techniques described in Sections 2.4 and 2.5. Additional identification techniques are included in Sections 2.5.1 and 2.5.2, and alternate fractionation methods are found in Section 2.6.

2.2 Acute Toxicity: Fractionation and Toxicity Testing Procedures

In the initial stages of Phase II, toxicity tests may be conducted on C_{18} SPE effluent fractions and blank fractions to detect the presence of toxicants and not to quantify the magnitude of the toxicity in each. As in the **toxicity** tests conducted during Phase I, careful measure-

ment of test solution water chemistry parameters is not required, and duplicate exposures are not needed during initial stages of Phase II. The major purpose of this step is to assess whether or not acute toxicity is present in the effluent fractions and the blank fractions. However, as suspect toxicants are identified, quantitative toxicity measurements will be needed to compare with the analytical measurements. If Phase II data will be used to correlate effluent toxicity to toxicant concentrations (Phase III), then more replicates per concentration, randomization of test concentrations, careful observation of organism exposure times, and organisms of approximately the same age should be used (Section 1.2). Also, the amount of eluate that is collected from the SPE fractionation, SPE concentration, and the amount of eluate used for testing and GC/MS analysis should be measured at all steps. The volume of eluate must be measured to determine the actual toxicity concentration in each step of the procedure. If it is expected that the Phase II data will be needed later, it is prudent to measure the degree of toxicity in the eight SPE effluent fractions at the onset of testing. We rarely see blank fraction toxicity; therefore, there is little need to evaluate the toxicity of the blank fractions with dilutions.

2.2.1 *Sample Volume*

The volume of effluent needed depends on its toxicity, the toxicity of the chemicals causing effluent toxicity, and the sensitivity of the analytical method. Since only the first of these will usually be known when Phase II begins, trial and error will dictate volume size. For acutely toxic effluents with LC50 values in the range of 25-100%, 2,000 ml have usually been adequate to perform one complete Phase II procedure, i.e., C_{18} SPE and HPLC fractionations, and GC/MS identification. Examples of the variables that should be considered when deciding what volume of effluent to fractionate are provided in Appendix A, Tables A-l and A-2.

2.2.2 *Filtration*

For acute tests, glass fiber filter(s) (1 µm nominal pore size) should be prepared as described in Section 8 of Phase I (EPA, 1991A). Both 45 mm and 90 mm diameter filters have been used routinely, the 90 mm filter allows about four times more effluent to be passed over the filter than one 45 mm filter. All filters and glassware should first be pre-rinsed with pH 3 high purity water (e.g., Milli-Q® Water System, Millipore Co., Bedford, MA) to remove any metal residues followed by a high purity water rinse which is discarded. The filter should then be rinsed with 200 ml of dilution water (rather than with high purity water) and a sample collected after most of the volume has been filtered, to provide the filter toxicity blank. In subsequent steps, a dilution water column blank will be collected after passing the filtered dilution water through the SPE column. The same type of dilution water should be used for the filter blank as for the column blank (Section 2.2.4). Usually, a reconstituted water is used for these procedures (EPA, 1991C).

The volume of effluent that can be passed through a single filter is sample specific. If more than one filter is needed (as is often the case) a single filter blank can be prepared by stacking three to eight pre-rinsed filters in one filter holder, followed by a dilution water rinse. The filters are then separated and used one at a time to filter the effluent sample. If samples are high in suspended solids additional pre-filtration may be needed. Centrifugation may also be useful for reducing solids in the sample. The decision to use a vacuum or a pressure system for filtering should have been made during the filtration tests of Phase I. If a volatile chemical is indicated in Phase I, pressure filtration should be used.

Filtration equipment should be thoroughly cleaned before use to prevent any toxicity carry-over or particle buildup from previous samples. We have found that glass vacuum filtering apparatus with stainless steel filter supports (for samples without pH adjustments), or plastic pressure filtering devices are the most useful. We have also found that if removable glass frits are used, they can be rigorously cleaned with aqua regia for 20-40 min followed by rinsing with copious amounts of water to remove residual effluent particles, since glass frits may act as a filter. The removable stainless steel filter supports do not require as rigorous cleaning as fritted glassware, and therefore are a good substitute.

A portion of the filtered sample must be reserved for toxicity testing while the rest is used for C_{18} extraction. If the filtration toxicity blank exhibits slight or complete toxicity, but the post C_{18} SPE column effluent is not toxic (and effluent toxicity was unchanged after filtration), the blank toxicity can be ignored since the effluent toxicity was removed (see Phase I). However, as the identification process continues, the blank toxicity will have to be eliminated, or it could lead to a misidentification of the cause of toxicity.

When effluent samples are readily filtered (-2,000 ml for one 90 mm 1µm filter) it may be possible to filter the effluent for the filtration test of Phase I but then use unfiltered effluent with the C_{18} SPE column test and the methanol eluate test (Phase I). Once it has been demonstrated that filtration does not reduce toxicity, routine filtering of these effluents (before passing the effluent through the SPE column) can be eliminated. This will reduce the amount of toxicity testing required.

2.2.3 *Column Size*

Various sizes of C_{18} SPE columns are available ranging from 100 mg to 10,000 mg packing material. We routinely have used Baker® 1,000 mg columns for 1,000 ml of effluent (J.T. Baker Chemical Co, Phillipsburg, NJ). Volumes for a 1,000 mg C_{18} SPE column are used in the following description, since this is the size most often used for acutely toxic effluents. Other available column sizes and the appropriate volumes to be used in their preparation are listed in Table 2-I. Positive pressure pumps (EPA, 1991 A) are convenient for the large volume

effluent samples because flow rate can be controlled. Vacuum manifolds can be used for drawing the small samples and solvents through the column. Whichever system is used, it must be made of materials that dilute acid and solvents do not destroy, or from which chemicals are not leached that are toxic or that interfere with analytical measurements. Teflon, glass, and stainless steel are all acceptable choices.

2.2.4 C,, SPE Column Conditioning

The 1,000 mg C_{18} SPE columns are conditioned by pumping 10 ml of 100% methanol through the column at a rate of 5 ml/min. The pumping rate can be increased to 40-50 ml/min when using the larger C_{18} SPE columns (e.g., 5 g or 10 g). The volumes of conditioning solvent recommended for other size columns are shown in Table 2-1. We most commonly use methanol as the conditioning solvent but other water miscible solvents such as acetonitrile, ethanol, or isopropanol may be substituted. Before *the packing goes dry,* 10 ml of high purity water must be added. As the last of the high purity water is passing through the column, 25 ml of filtered dilution water is added. The last 10 ml of dilution water is collected for a dilution water column blank. After the dilution water has been collected, pumping is continued until no dilution water emerges from the column.

2.2.5 *Elution Blanks*

To generate elution blanks from a 1,000 mg column, two successive 1.5 ml volumes of 25% methanol/water (%v/v) are pumped sequentially through the conditioned column and collected in one analytically clean, labeled glass vial to produce a 3 ml sample. This procedure is repeated with two successive 1.5 ml volumes of 50%, 75%, 80%, 85%, 90%, 95% and 100% methanol/water. The column should be allowed to dry for a few seconds between each elution with the different 3 ml volumes of methanol/water solutions. This will result in eight 3 ml SPE fraction blanks (Figure 2-2). The volume of methanol solutions used for elution will vary depending on column size as shown in Table 2-1.

2.2.6 Column Loading with Effluent

The same column is then reconditioned with 10 ml of 100% methanol and 10 ml of high purity water, as described in Section 2.2.4. *Without allowing the column to dry,* 1,000 ml of filtered effluent is pumped through the column at a rate of 5 ml/min (Figure 2-3). The pumping rate can be increased to 40-50 ml/min when using the larger C_{18} SPE columns (e.g., 5 g or 10 g). Three samples (-25 ml) of the post-C,, SPE column effluent are collected after 25 ml, 500 ml and 950 ml of the sample has passed through the column. Each post-column aliquot is toxicity tested to determine the presence of acute toxicity in the post-column effluent. This information can be used to determine whether the toxicant is removed from the eff luent by the column. As Phase II progresses, the recommendation is to increase the volume of post-column effluent collected to 50-60 ml so that dilutions can be made and LC50 values obtained. Pumping is continued until no effluent emerges from the column.

The efficiency of the C_{18} SPE column is determined by the extraction efficiency (i.e., how well the column sorbent removes the effluent components) and the elution efficiency (i.e., how well sorbed effluent compounds are removed from the column by the solvent elution). For purposes of the TIE, "efficiency" applies only to recovery of those compounds causing or affecting effluent toxicity. Since most acute effluent tests do not require large volumes of post-column effluent, the question of extraction efficiency can be determined by measuring the toxicity of the post-C,, column effluent sample. The toxicity of each aliquot collected after different vol-

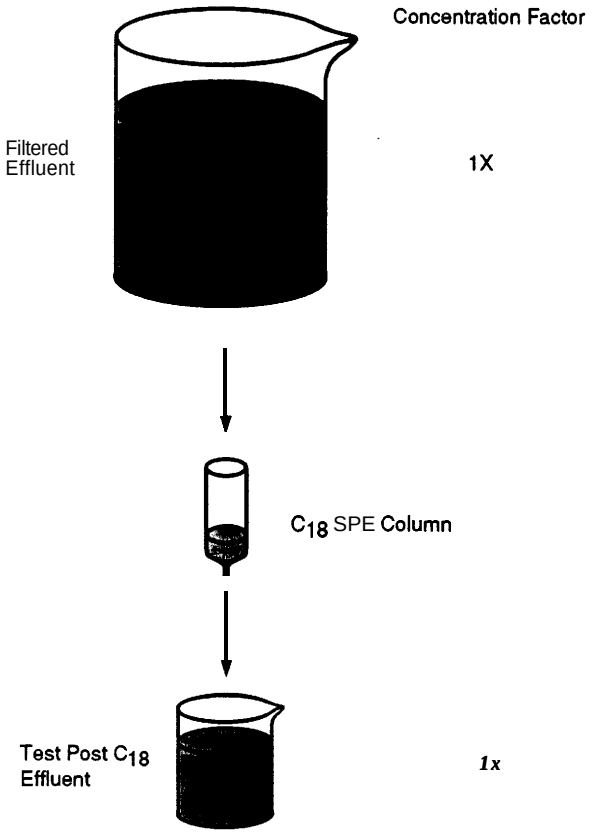

Figure 2-3. Concentrating effluent on the C_{18} SPE column.

umes of effluent have passed through the column can be compared. If there is toxicity in these aliquots, but it is independent of the volume of effluent previously passed through the column, then the post-column effluent toxicity is probably caused by toxicants that are not extracted by the column. If toxicity increases as the volume of post-column effluent passed through the column increases, the capacity of the column to sorb the toxicants was probably exceeded.

In some post-column effluent, a biological growth may occur during toxicity testing which may result in artifactual toxicity. Such growth can make it appear as if the toxicant is not removed by the column. While this growth does not occur in all effluents, when it does occur with one post-column effluent sample, the growth often occurs in each subsequent post-column effluent sample from the same preparation. The growth may appear to be filamentous and give a milky appearance in the test vessel. This effect has been linked to methanol stimulation of bacterial growth. Methanol is present in the post-column samples because a small amount of methanol is constantly released from the column during the sample extraction. Effluents from biological treatment plants may develop this characteristic more readily than industrial effluents.

Additional filtering of the post-column effluent sample through a 0.2 µm filter before testing to remove bacteria and eliminate the growth has been helpful. To avoid artifactual toxicity as much as possible in the post-column effluent, initiate the tests with the post-column samples on the same day the effluent is extracted even if fractions are not tested simultaneously. For those few effluents where we have not eliminated this type of artifactual toxicity, holding the post-column effluent is problematic in that more time is available for bacteria to cause problems in the post-column sample matrix. When post-column artifactual growth is not readily eliminated, a different solvent (e.g., acetonitrile) to condition the column (but not for eluting) may be useful in reducing the post-column artifactual bacterial growth. This artifactual growth has not occurred in the toxicity tests with methanol SPE fractions (Section 2.2.8).

2.2.7 C_{18} SPE Column Elution

Once the effluent sample has been loaded onto the column, elution can begin. To elute a 1,000 mg column, two successive 1.5 ml volumes of the 25% methanol/water mixture are pumped through the column and collected in one labelled, analytically clean vial to make a 3 ml sample. Subsequently, two successive 1.5 ml volumes of each of the 50%, 75%, 80%, 85%, 90%, 95% and 100% methanol/water are pumped through the column and collected in separate vials (Figure 2-2). The next elution volume should be added when no more of the preceding one is emerging from the column.

This entire procedure (conditioning through elution) is repeated using a second 1,000 mg C_{18} SPE column for the second 1,000 ml of filtered effluent. The dilution water column blank samples should be kept separate. The corresponding fractions from the blank and the sample from each 1,000 ml fractionation can be combined. For example, the 3 ml 100% methanol sample fraction from the first column and the 3 ml 100% methanol sample fraction from the second column are combined to produce a total of 6 ml. There will be eight 6 ml blank fractions and eight 6 ml effluent fractions.

The vials containing the methanol/water fractions are tested immediately or sealed with perfluorocarbon or foil-lined caps and stored under refrigeration. These fractions represent a 'first cut" separation of effluent components. Elution volumes will vary if columns of different sizes are used or if the particular effluent under study or the research question being posed dictates method modification.

2.2.8 *Blank and Effluent Fraction Toxicity Tests*

The next step is to determine the toxicity of the blank and effluent fractions. While the choice of test concentration depends on the toxicity of the effluent in most instances, we have used a high test concentration of 2x or 4x (the LC50 or 100% effluent) for acutely toxic effluents. The methanol content in the fractions limits the concentration that can be tested, and at this point the amount of methanol is assumed to be 100% in all the fractions for dilution calculations; however, this is not assumed for add-back tests (described below). Usually 120 µl of each blank and sample fraction (333x) is injected into separate 10 ml aliquots of dilution water to test at 4x the 100% effluent[2]. This will give a 1.2% methanol concentration which is below the methanol LC50 for both C. *dubia* and fathead minnows in the 100% methanol fraction. The resulting methanol concentration must be adjusted for the species tested (see Section 8 of EPA, 1991 A). During the initial stages, five animals in each 10 ml aliquot are used without duplicates. Using the above volumes, the tested solution is more concentrated (i.e., 4x) than 100% effluent, assuming 100% extraction and 100% elution in one fraction. These test solutions can be diluted to provide an LC50 for each sample fraction. Blank fractions need not be diluted, since hopefully they are nontoxic.

Individual chemicals in the fractions could be toxic even when they are not toxic in the whole effluent, since the concentration tested may be as high as 4x whole effluent. Therefore, to be toxic at whole effluent concentrations, an individual fraction must have an LC50 of 25% or less. Since there is no way to know whether the toxicant(s) eluted over more than one fraction or what the percent extraction and elution efficiency are, fraction tox-

[2] In the Phase II document published in 1989, testing at 5x was recommended, the methanol level was 1.5% at this concentration. In order to lower the methanol level, this was changed to 4x in this document.

icity up to 100% (4x whole effluent) should not be disregarded.

If toxicity occurs in any of the fraction blank tests and it is small relative to the toxicity in the corresponding sample fraction (e.g., 20% mortality versus 80%), the sample fraction results should not be dismissed. If all organisms die in the blanks and the effluent fractions, dilutions should be tested to make sure the sample fraction is substantially more toxic than the blank. In general, blanks should not have measurable toxicity.

If the SPE fractions are toxic at effluent concentrations of lx or 2x and toxicity is reduced in two of the three post-column effluent samples, the toxicant could still be a non-polar organic compound. If the effluent fractions are not toxic individually and the post-column samples are non-toxic, it is possible that the toxicity has been spread across several fractions or has not been recovered from the column. Combining and concentrating fractions may be useful or other elution procedures may be necessary. If toxicity is observed in the fractions at lx, 2x, or 4x and in the post-column effluent samples, it is possible that not all the toxicity is caused by non-polar compounds, that break-through of the toxicant has occurred, or that the toxicity is artifactual.

In addition to concentrating column artifacts to toxic levels, effluent constituents present at nonlethal levels may be concentrated to toxic levels in this test if they have a relatively high recovery value. Actual effluent toxicants with poor recovery may not be present in these test solutions at toxic levels. Spurious results of this nature will be identified in the later stages of Phase II and/or in Phase III.

Elution efficiency may be approximated by summing the amount of toxicity (i.e., TUs) in the toxic fractions (provided dilutions are tested) and comparing this value to whole effluent toxicity expressed as TUs. When summing acute toxicity, it is important that all values are for comparable endpoints (i.e., LC50s). Adding of TUs may be somewhat imprecise for several reasons. A single toxicant may occur in more than one adjacent fraction, in which case a small amount of the toxicant in one fraction may not be detectable because it is present below the effect concentration. For acute toxicity, this problem may be solved by combining a portion of each effluent fraction (and separately testing the corresponding blank fractions) and measuring total toxicity at ix. If more than one toxicant is present, the effluent fraction toxicity may not be strictly additive in their toxicities, and when separated into different fractions the sum of the fraction toxicities may be low even if extraction and elution efficiencies were 100%. Table 2-2 illustrates a hypothetical example. The toxicity test results from the test with a portion of all fractions or a few of the fractions may show somewhat greater toxicities than those of the whole effluent. This may be caused by enhanced toxicity due to matrix effects. When this occurs, it may be possible to compensate for toxicity enhancement by methanol, by adding methanol to the whole effluent and evaluating the toxicity. This methanol addition may in turn stimulate

Table 2-2. Comparison of Toxic Units (TUs) in Each Toxic Fraction to TUs of All Fractions Combined and Whole Effluent

Toxic Fraction (% Methanol)	TUs
75	0.5

Combined Fractions	2.7
Whole Effluent	2.5

biological growth, and if this happens, the test is negated. We have rarely used this approach since the fractions have seldom caused more toxicity than the effluent itself. At this point in Phase II, the effluent fractions should also be tested in water with TOC and suspended solids which mimics the effluent to lessen matrix effects on toxicity. As the identification step moves into Phase III, it is better to use dilution water that mimics effluent or receiving water characteristics.

*2.2.9 SPE Fractions: Concentration and Subsequent Toxicity **Testing***

The SPE fractionation provides a general separation of non-polar organics and except in relatively uncomplicated effluents, GC/MS analysis of the concentrates of toxic C_{18} SPE fractions will result in very complicated chromatograms from which the toxicant(s) cannot be distinguished from other effluent components. A secondary fractionation using HPLC is often needed to further simplify toxic effluent fractions prior to component identification by GC/MS analysis.

In order to maximize the chromatographic separation capability of the HPLC, the volume of the sample injected onto an analytical size HPLC column should be as small as possible (i.e., <0.5 ml); therefore, the toxic SPE fractions (usually >1 ml) must be concentrated prior to injection onto the HPLC column. This concentration step will provide the added benefit of an increase in concentrations of constituents in the HPLC fractions as well as rid the SPE fractions of water. The latter issue is important if GC/MS analysis will be performed on the concentrated SPE fraction prior to injection on the HPLC (Durhan et al., 1990).

The volume of the fractions from the initial SPE fractionation procedure and the number of fractions to be combined will determine the size of the SPE column to use for the concentration procedure. Table 2-3 contains information on the column sizes we have found to be most useful. In the procedure outlined below (Figure 2-4), we have used a 100 mg column which is the most commonly used size for concentrating SPE fractions of acutely toxic effluents. Most often the toxic effluent SPE

Table 2-3. Information for Concentrating SPE and HPLC Fractions'

C_{18} SPE Sorbent Amount (mg)	Volume Conditioning Solvent (ml)	High Purity Water Volume (ml)	Maximum Toxic Fraction Volume (ml)	Maximum Diluted Fraction Volume (ml)	Minimum Elution Volume[2] (ml)	Approximate Eluate Volume (ml)
100	1	1	20	100	3 x0.1	0.22
200	2	2	40	200	3 x 0.2	0.44
500	5	5	100	500	3 x 0.5	1.10

[2]Elution with three successive aliquots of the volume listed.

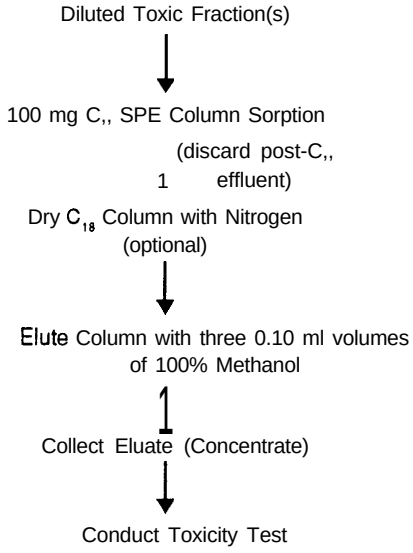

Figure 2-4. Procedure to concentrate toxic SPE fractions.

fractions are combined and diluted with high purity water and the corresponding blank fractions are treated similarly. In cases where there are multiple non-polar toxicants, and when toxicity occurs in several fractions, it may be more useful to concentrate each fraction separately for subsequent HPLC separation. The percent methanol in the diluted fraction sample should be ≤20% and the volume to which the fractions can be diluted is dependent on the amount of column packing. For example, the total volume of the diluted fractions should not exceed 100 ml for the 100 mg C_{18} SPE column (Table 2-3). No more than three toxic fractions of 6 ml each can be combined and concentrated on the 100 mg column. When the total volume of combined fractions or the individual fraction volume is above 20 ml, larger columns should be used; consult Table 2-3 for column size and elution volume information. The effluent and blank concentrates and the column blank are tested for toxicity to ensure that the toxicant is still in the concentrate and that artifactual toxicity was not introduced by the procedure. If there is not measurable toxicity in the concentrate, it is possible that the percentage of methanol in the diluted fraction was too high. The concentration procedure should then be repeated with a new set of toxicity tested fractions diluted to a lower methanol concentration, e.g., 10%.

Below is an example of how to prepare effluent and blank fraction concentrates. First, a 100 mg C_{18} SPE column is conditioned with 1 ml of methanol and 1 ml of high purity water similar to the procedures described in the SPE Column Conditioning Section (2.2.4). Column blanks for toxicity testing are obtained by rinsing the column with at least 20 ml of dilution water. After collecting the column blank, recondition the column with 1 ml of methanol and rinse with 1 ml of high purity water. The diluted blank fractions (for dilution guidance see Table 2-3) are then drawn through the 100 mg C_{18} SPE column under a pressure of 380 mm Hg using a vacuum manifold. Unlike the first fractionation step (Section 2.2.6) the post-column sample cannot be tested for toxicity because of its high methanol concentration (i.e., IO-20%). The column is then dried for 10 min using a gentle flow of nitrogen (1 0-20 ml/sec). Drying the column usually increases the recovery of toxicity, but sometimes toxicity is not recovered from the column, possibly as a result of volatilization. If this occurs the concentration procedure can be repeated without the nitrogen drying step.

After drying the sorbent, the luer tip of the column is fitted with a luer-lock needle and 100 µl of 100% methanol is placed into the column using a microliter syringe. Nitrogen is then applied to the column at a rate of -4 ml/sec to force the methanol through the sorbent. The luer-lock needle is needed to ensure the collection of small volumes; when using larger column sizes (e.g., ≥500 mg) this is not necessary. The first 100 µl aliquot of methanol applied to the column will yield approximately 25 µl of eluate. Two more 100 µl aliquots of 100% methanol are also forced through the column. The final volume of eluate collected will be approximately 220 µl. If desired, measure the exact volume collected (using a µl syringe) to calculate concentration factors (Table 2-3). As in most chromatographic separations and extractions, three separate smaller elutions of methanol are more efficient than one large one.

The 100 mg C_{18} SPE column is reconditioned with 1 ml of methanol and rinsed with 1 ml of high purity water. It is then used to concentrate the diluted toxic SPE column fractions, using the same procedure used for the blank fractions (Figure 2-4). In lieu of reconditioning the same column, two columns can be conditioned, one used for the diluted blank fractions and the other used for concentrating the diluted toxic SPE fractions. The resulting column blanks should be toxicity tested separately.

The original effluent volume of 2,000 ml is now concentrated into a 220 µl sample or a nominal concentration of 9,091x (ignoring the amount used for testing). As work progresses and more quantitative results are needed, the eluate volume must be measured to provide the correct concentration factor. If 9 µl of concentrate is diluted to 10 ml in dilution water, the resulting test concentration will be 8x whole effluent. Additional test concentrations (e.g., 4x, 2x, lx) can be prepared to determine an LC50 of the concentrate, and toxicity recovery can be calculated by comparing this LC50 to the LC50 of the effluent. The concentrate toxicity might be higher than the sum of the individual toxic fractions because some of the toxicant may have been in adjacent fractions that were concentrated in the first step (Section 2.2.7) but not detectable by the toxicity test of the single fraction. The concentrate toxicity may also be lower than expected because of low extraction and elution efficiencies. Where greater concentration factors are desirable, SPE fractionation should be repeated with additional volumes of effluent, followed by combining the toxic fractions before concentration. The size of the column used for concentrating may have to be increased, along with the appropriate changes in dilution and elution volumes (Table 2-3).

The important concern here is not 100% recovery of toxicants but enough recovery for GC/MS analyses and to obtain measurable toxicity in the HPLC fractions. If recovery is too low, changing or eliminating the column drying time may help. Sometimes recovery appears to increase with drying time while other compounds are volatilized from the column during the drying process. For concentrates analyzed using GC/MS, column drying to remove water is critical to GC column performance.

2.2.10 HPLC Separation

The same column packing functionality should be used in the HPLC column as the SPE column. At later stages, when more is known about the toxicants, other sorbent types may be used.

The HPLC conditions presented in this section are general. As more information on the effluent is gathered, HPLC conditions should be modified to achieve better separation and higher concentration factors. We use a flow rate of 1 ml/min on an instrument equipped with a 5 µm C_{18} reverse phase column (250 mm x 4.6 mm i.d.). The HPLC elution conditions will change depending on which SPE fractions have been concentrated. The HPLC conditions for the four most commonly toxic SPE fractions are listed in Table 2-4. Depending on the size of the HPLC injector and column, more than one HPLC fractionation run may be required to fractionate the entire blank concentrate. When multiple HPLC fractionations are conducted, collect all the corresponding HPLC fractions in the same set of vials. For example, if two HPLC fractionations were performed for the blank concentrate, 25-2 ml HPLC fractions would be obtained.

Table 2-4. Example HPLC Elution Gradients for Four Commonly Toxic SPE Fractions

75% or 85% SPE Fractions		85% or 90% SPE Fractions	
Time (min)	% Methanol/Water	Time (min)	% Methanol/Water
0	50	0	60
1	60	1	70
13	90	13	90
20	100	20	100
25	100	25	100

Using the HPLC equipment described above, all of the blank concentrate remaining after toxicity testing is injected (≤500 µl) and 25-1 ml fractions are collected in analytically clean glass vials (Figure 2-5). The same procedure is followed using the effluent sample concentrate. The vials should be sealed (e.g., with foil lined caps) and stored at 4°C after use. As soon as toxicant identification is obtained by GC/MS, then HPLC conditions (gradient, fraction size, and number of fractions) can be optimized for further fractionations.

2.2.11 HPLC Fraction Toxicity Tests

Before specific toxicants are identified, toxicity tests on each HPLC blank fraction and sample fraction are conducted using non-replicated exposures of five animals each. The amount of methanol in the HPLC fractions limits the concentration that can be tested. Assume that each fraction is 100% methanol to calculate the necessary dilution. A methanol concentration of 1.2% should not be exceeded for *C. dubia* and fathead minnow acute toxicity tests.

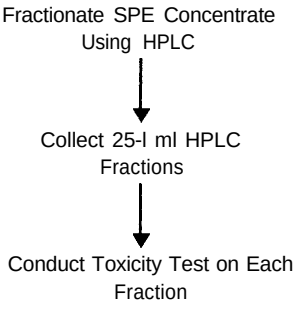

Figure 2-5. Procedure to fractionate acutely toxic SPE concentrates using HPLC.

For acute studies, when all of the SPE fraction concentrate remaining after toxicity testing is injected (one injection) on the HPLC (Figure 2-5), each resulting 1 ml HPLC fraction equals 2,000 ml of effluent (assuming no loss and toxicant elution in only one fraction) or a 2,000-fold concentration. If each HPLC fraction is then diluted for testing (80 µl to 10 ml) the resultant concentration is 16x the original effluent concentration. In preliminary Phase II testing the HPLC fractions are tested without dilutions. Only the toxic HPLC fractions are tested again with dilutions to generate an LC50. Some loss of toxicant tends to occur in each concentration step and the resulting toxicity may be decreased relative to the original effluent.

The blank fractions should not be toxic. If they are, then additional tests with dilutions must be conducted on both blanks and toxic fractions to find out whether there is enough additional toxicity in the sample fractions to warrant analysis

The toxicity of the HPLC fractions should be tested at twice (at least) the concentration at which the original SPE column fractions were tested because recovery of toxicity and analytical measurements indicate that up to 50% of the initial concentration of toxic compounds may be lost in this step (Durhan et al., 1990). The amount of methanol should not exceed the amount used in the SPE fraction tests described above (Section 2.2.8).

*2.2.12 HPLC **Fractions:** Concentration and Subsequent Toxicity Testing*

The HPLC fractions that exhibit toxicity and their corresponding blank fractions must be concentrated in a solvent suitable for GC/MS or other analytical techniques. The procedure is identical to that described in Section 2.2.9 and is depicted in Figure 2-6. Judgement must be used to decide whether to concentrate each toxic fraction separately or to combine various toxic and adjacent fractions prior to concentration. If, for example, three successive fractions exhibit toxicity, there is a good chance that the same toxicant is in all three. If there are other fractions that show toxicity but they are separated from the first set by several non-toxic fractions, there is high probability that the second set contains a toxicant different from the first three. There is also a good chance that at least one non-toxic fraction on either side of the toxic fractions contains some of the toxicant(The advantage of combining fractions is to reduce the work load and increase concentration in the final concentrate. The disadvantage is that more constituents that are not the toxicant(s) will also be concentrated. This decision is not always straightforward and must be based on trial and error, and experience. Blank fractions corresponding to the toxic fractions are concentrated the same way.

The HPLC fraction and blank concentrates should be finally checked for toxicity before GC/MS analysis. This concentrate is now nominally 9,091x more concentrated than the effluent. If 18 µl is diluted to 10 ml, the resultant test concentration will be 16x the original sample

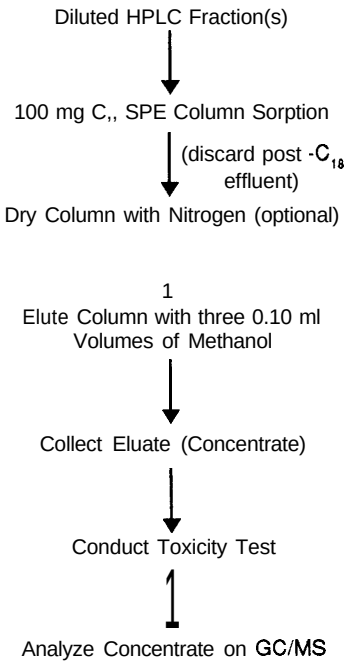

Figure 2-6. Procedure to concentrate toxic HPLC factions.

concentration. To quantitate toxicity and use the Phase II data later, additional lower concentrations should be tested (e.g., 8x, 4x, 2x); TUs of this concentrate can then be compared to previous toxicity test results. The HPLC concentrate should be tested at one to two times the test concentration of the HPLC fraction tests (i.e., 16x or 32x). This is the last opportunity to assure that the toxicant is still present in the concentrate before it is subjected to GC/MS analysis. Whether the toxicant is detected by the analytical detector (mass spectrometry in our laboratory) is always a question. Since GC/MS detects only about 20% of organic chemicals (EPA, 1989B), even such a broad spectrum method is not certain to identify the toxicant. As work progresses with more samples of the effluent and quantitative results are needed, the amount of eluate collected should be carefully measured and recorded to accurately calculate the concentration factors. In addition, the volume of concentrate removed for toxicity testing and analytical analyses should also be recorded.

2.3 Chronic Toxicity: Fractionation and Toxicity Testing Procedures

The chronic Phase II non-polar organic toxicity identification follows the same general approach and employs manipulations similar to those described for the acutely toxic non-polar organic compounds (Section 2.2). One major difference is that the concentration of the eluting solvent (e.g., methanol) must be lower in the chronic toxicity tests than in acute tests. In the initial stages of Phase II, toxicity tests may be conducted on C_{18} SPE effluent fractions and blank fractions to detect the presence of toxicants, and not to quantify the magnitude

of the toxicity in each. However, as suspect toxicants are identified, quantitative toxicity measurements will be needed to compare with the analytical measurements. If Phase II data will be used to correlate effluent toxicity to toxicant concentrations (Phase III), then more replicates per concentration, randomization of test concentrations, careful observation of organism exposure times, and organisms of approximately the same age should be used (Section 1.2). Also the amount of eluate that is collected from the SPE fractionation, SPE concentration, and the amount of eluate used for testing and GC/MS analysis should be measured at all steps. If it is expected that the Phase II data will be needed later, it is prudent to measure the degree of toxicity in the SPE effluent fractions (Section 23.5) at the onset of testing. We rarely see blank fraction toxicity, therefore, there is little need to evaluate the blank fraction toxicity with dilutions. Also, the volume of eluate must be measured to determine the actual toxicity concentration in each step of the procedure.

The following discussion is based on our experiences with C. dubia and fathead minnows (see Section 1.2). The use of other species will require reconsideration of the appropriate test volumes and methanol concentration for each step. Chronic testing is more labor intensive and generally requires more effluent sample volume than acute testing. For the most part, in the descriptions below, for *C. dubia* there are five replicates containing 10 ml of test solution and one animal per cup. For the fathead minnow tests, two replicates of 10 animals per 50 ml and the control are usually used (Section 1.2). Typically we use four concentrations and a control.

As soon as the cause of toxicity has been determined to be a non-polar organic compound (e.g., methanol eluate test; EPA, 1992) it is prudent to concentrate large volumes of effluent for the subsequent analyses. By concentrating large amounts of the effluent it is possible to plan the optimal usage of the amount of column eluate available for toxicity testing.

2.3.1 Sample Volume

The volume of effluent needed depends on its toxicity, the toxicity of the chemicals causing effluent toxicity, and the sensitivity of the analytical method. Since only the first of these will usually be known when Phase II begins, the volume of effluent to process should be considered at the beginning of the identification process to minimize the amount of re-fractionating and re-testing of effluent and fractions. Ideally, fractionation should provide enough volume of post-column effluent (Section 2.3.6), C_{18} SPE fractions (Section 2.3.8), SPE fraction concentrates (Section 2.3.9), HPLC fractions (Section 2.3.1 I), and HPLC fraction concentrates (Section 2.3.12) to conduct all chronic toxicity testing and chemical analyses, Because of the many factors affecting the amount of effluent needed, a significant amount of thought should be put into the volume of effluent to obtain and process at one time. It is prudent for the investigator to anticipate how many identification procedures will be done, and then calculate the volume of effluent needed using the particular test parameters desired, before extracting any effluent to ensure that sufficient volume of fractions, concentrates, and post-column effluent is available for the planned procedures. It may be best to perform these calculations with several different effluent volumes and test conditions to ascertain the optimal volume of effluent to fractionate. A worksheet to assist with these calculations and an example are provided in Appendix A.

The volumes of eluate needed for chronic toxicity testing at 2x, lx, and 0.5x are provided in Table 2-5 for the C. *dubia* and fathead minnow short-term tests based on the methanol concentration that can safely be used for the chronic tests. The amount of SPE fractionation eluate needed for toxicity testing is presented for the range of tests that are commonly performed with C. *dubia* or fathead minnows, these volumes can be used in the calculation worksheets found in Appendix A (Table A-l). The approximate volume of effluent that will be needed for testing with *C.* dubia and fathead minnows is listed in Table 2-6 for various fractionation schemes and toxicity testing parameters. When only a portion of the TIE procedures will be used, obviously less effluent volume will be needed. In Table A-2, the example calculations are based upon the use of minimum elution volume for the SPE columns (Table 2-1), concentrating only one SPE fraction (Section 2.3.9), and taking into account the toxicity testing (Sections 2.3.8, 2.3.9, 2.3.11, and 2.3.12) and GC/MS analysis volumes (Section 2.5). These parameters are discussed in detail below. If additional eluate is needed, the chronic tests must be repeated for each fractionation. In Phase II and Phase III more confidence in the toxicity estimates is needed than in Phase I, therefore tests may require more replicates. The volumes needed for those tests are also presented in Table 2-5. When only limited amounts of effluent are available, one must be creative and plan its usage very carefully to obtain meaningful results.

2.3.2 *Filtra tion*

For filtration of chronically toxic effluents, the use of glass fiber filters (1 µm nominal pore size) is recommended. Both 45 mm and 90 mm diameter filters have been used routinely, but the 90 mm diameter filter allows about four times more effluent to be passed over one filter than the 45 mm filter. All filters and glassware should first be pre-rinsed with pH 3 high purity water to remove any residual metals followed by a high purity water (e.g., Milli-Q® Water System) rinse which is discarded. Low levels of metals (e.g., µg/l) from the filters may cause toxicity interferences and pre-rinsing the filters may provide cleaner blanks and less contamination in effluent samples. To collect the dilution water filter blank, first pass a volume (-200 ml) of dilution water over the filter and discard it. Next, collect the volume of dilution water needed to conduct the filtration blank test. It is a good idea to prepare excess volume, at least 500 ml for the *C. dubia* 7-d test and 800 ml for the fathead minnow 7d test. A portion of the filtered dilution water is collected for testing and a portion is reserved for the solid phase extraction test blank (Section 6.6; EPA, 1992).

Table 2-5. Eluate Volumes Needed for Chronic SPE Fraction Toxicity Tests with *Ceriodaphnia* dubia and *Pimephales promelas*

Test Species	Test Duration	Original Sample& No. Renewals	High Test Conc. of SPE Fraction	No. Rep	Volume (ml) of 500x Eluate Needed for Testing'	Test Concentrations
C. dubia	4-d	2	2x	5	0.70	2x, lx, 0.5x
C. dubia	4-d	4	2x	5	1.40	2x, lx, 0.5x
C. dubia	7-d	3	2x	5	1.05	2x, lx, 0.5x
C. dubia	7-d	7	2x	5	2.45	2x, lx, 0.5x
C. dubia	4-d	2	2x	10	1.40	2x, lx, 0.5x
C. dubia	4-d	4	2x	10	2.80	2x, lx, 0.5x
C. dubia	7-d	3	2x	10	2.10	2x, lx, 0.5x
C. dubia	7-d	7	2x	10	4.90	2x, lx, 0.5x
P. promelas	7-d	7	2x	2	4.90	2x, lx, 0.5x
P. promelas	7-d	7	2x	4	9.80	2x, lx, 0.5x
P. promelas	7-d	7	4x	2	9.80	4x, 2x, lx
P. promelas	7-d	7	4x	4	19.60	4x, 2x, lx

[1]Test volumes per replicate are 10 ml/cup for C. *dubia* and 50 ml/cup for *P. promelas. The* fraction test solutions are prepared as one solution and divided into aliquots for the replicates. For the 500x eluate concentration, this volume is based on the assumption that the C. *dubia* test solutions are prepared as 200 µl of 500x into 50 ml for 2x, 100 µl into 50 ml for lx, and 50 µl into 50 ml for 0.5x. More volume will be needed if serial dilutions are prepared (400 µl vs 350 µl). For the fathead minnow tests this assumes test solutions are prepared as 400 µl into 100 ml for 2x, 200 ml into 100 ml for lx, and 100 µl into 100 ml for 0.5x. More volume will be needed if serial dilutions are prepared (800 µl vs 700 µl). For the 4x fathead minnow test, 800 µl per 100 ml can be prepared in a similar manner.

Table 2-6. Approximate Effluent Volumes Needed for the Chronic Non-Polar Organic Identification Procedures'

Test Species	Test Duration	Original Sample & Number of Renewals	High Test Conc. in SPE Fraction Test	No. Rep.	Are Dilutions Used ?	Volume Effluent (ml) Needed to Conduct SPE & GC/MS[2] Analyses	Volume Effluent (ml) Needed to Conduct SPE & HPLC & GC/MS[3] Analyses
C. dubia	4-d	4	2x	5	Yes	3,000	15,000
C. dubia	7-d	3	2x	5	Yes	2,000	15,000
C. dubia	7-d	7	2x	5	Yes	5,000	20,000
P. promelas	7-d	7	2x	2	Yes	10,000	50,000
P. promelas	7-d	7	2x	4	No	5,000	40,000

'Calculation of toxicity testing volumes assumes that: 4x high concentration for SPE concentrate test (Section 2.3.9), 8x high concentration for HPLC fraction test (Section 2.3.1 1), 16x high concentration for HPLC concentrate test (Section 2.3.12), concentration of only one toxic fraction (SPE and HPLC), the maximum amount of sample is concentrated on the SPE columns and all SPE columns are eluted with the minimum elution volume.

[2]TIE procedures used: SPE fractionation and GC/MS of SPE concentrate,

[3]TIE procedures used: SPE fractionation, GC/MS of SPE concentrate, HPLC fractionation, and GC/MS of HPLC concentrates.

After the filtration blank has been obtained, the effluent sample is filtered using the same filter, a portion of the filtrate is collected for toxicity testing, and a portion is set aside for concentrating on the C_{18} SPE column. For some effluents, one filter will often not suffice. A technique we use to prepare several filters at once is stacking three to eight filters together in one filter holder, followed by sequential rinses with pH 3 high purity water, high purity water and dilution water (using the same rinse volumes as above). Finally, the filters are separated and set aside, using one at a time for the effluent sample. If the samples have high suspended solids concentration, pre-filtering using a larger pore size filter may help, and the appropriate blanks should be used. If the sample cannot be effectively filtered due to the presence of many fine particles, centrifugation may be used (of course, blanks must be prepared).

The filter housing should be thoroughly cleaned before use to prevent any particle build-up or toxicity carry-over from previous samples. We have found large filtration apparatus (1,000 ml), removable glass frits, or plastic filtering apparatus (e.g., Millipore®) to be useful. The glassware cleaning procedure that is described in the acute Phase I TIE manual (EPA, 1991A) is sufficient for chronic TIE work. The glass frits may require rigorous cleaning (i.e., soak in aqua regia for 20-40 min) to remove residuals that may remain after filtering, since the glass frit may itself act as a filter. Also available are removable stainless steel filter supports in a glass vacuum filter apparatus (available from Millipore®). These filter supports do not require as rigorous cleaning as fritted glassware, and therefore are a good substitute.

When effluent samples are readily filtered (-2,000 ml for one 90 mm 1 µm filter) it may be possible to filter the effluent for the filtration test of Phase I but then use unfiltered effluent with the C_{18} SPE column test and the methanol eluate test (Phase I). Once it has been demonstrated that filtration does not reduce toxicity, routine filtering of these effluents (before passing the effluent through the SPE column) can be eliminated, which will reduce the amount of toxicity testing required.

2.3.3 Column Size

Available C_{18} SPE column sizes and the appropriate water and solvent volumes used in their preparation are listed in Table 2-1. Positive pressure pumps are the most convenient to use for the large volume effluent samples because the flow rate can be controlled. Pumps and vacuum manifolds can both be used for eluting C_{18} SPE columns. Whichever system is used, it should be made of materials that dilute acid and solvents do not destroy, or from which chemicals are not leached that are toxic or interfere with analytical measurements. Teflon, glass, and stainless steel are all acceptable.

When SPE is used for isolating non-polar organic toxicants, use the maximum volume of effluent and the minimum elution volume for the column size selected to optimize the concentration of toxicants in the methanol eluates. For example, if 6,000 ml is processed, it is best to use one 5,000 mg column with 5,000 ml and one ***1,000*** mg column with 1000 ml of effluent and elute both columns with the minimum elution volumes (Table 2-1) and combine eluates. It is always best to process the maximum volume of effluent on each column to achieve the highest concentration of toxicants in the eluate.

2.3.4 C_{18} SPE Column Conditioning

The 10,000 mg C, SPE columns (Analytichem International, Harbor City, CA) are conditioned by pumping 100 ml of methanol through the column at a rate of 40-50 ml/min. This size column can process 10,000 ml of effluent and is the largest commercially pre-packed SPE column available at this time. The example presented in this section will be for 10,000 ml effluent using a 10,000 mg SPE column. The volumes of conditioning solvent will change when other size columns are used, as shown in Table 2-1. We most commonly use' methanol as the conditioning solvent but other water miscible solvents such as acetonitrile, ethanol, or isopropanol may also be used to condition columns. ***Before*** *the* ***packing goes*** *dry*, 100 ml of high purity distilled water must be added. As the last of that water is passing through, filtered dilution water is added. The volume of dilution water needed may vary from 250 ml to 1,200 ml depending on the species tested. The first ***100*** ml is discarded and the remainder is collected for the dilution water column blank. After the dilution water has been collected, pumping is continued until no water emerges from the column.

Low dissolved oxygen (DO) in the post-column dilution water blanks (even in reconstituted waters) has occurred during some chronic tests; therefore, we discard the first 100-200 ml and collect the remainder of the post-column dilution water. Low DO has been a problem, particularly in the fathead minnow growth test, and is attributed to the small amount of methanol that bleeds into the post-column sample. This may be alleviated by discarding the first post-column aliquots.

2.3.5 ***Elution*** Blanks

For chronic work, we have been using seven methanol/water fractions (50%, 75%, 80%, 85%, 90%, 95%, and 100%) rather than the eight used in acute TIEs. By eliminating 25% methanol/water fraction used in acute work the toxicity testing workload is reduced, in turn a reduction in separation of toxic and non-toxic components can occur.

To collect the fraction blanks from the 10,000 mg column, two successive 10 ml volumes of 50% methanol in water are pumped through the conditioned column and collected in one analytically clean labeled vial, to make a 20 ml sample. This procedure is repeated six more times with two successive 10 ml volumes of 75%, 80%, 85%, 90%, 95% and 100% methanol/water solutions. The column should be allowed to dry for a **few seconds between** each elution with the different 20 ml volumes of methanol/water mixtures. This will result in seven 20 ml blank SPE

fractions. The volume of methanol solutions used for elution will vary depending on column size as shown in Table 2-1.

2.3.6 Column Loading with Effluent

The same 10,000 mg column is reconditioned with 100 ml of 100% methanol and 100 ml of high purity water, as described in Section 2.3.4. The sorbent must be reconditioned when the maximum volume of dilution water has been passed over the column, otherwise the sorbents' capacity will be exceeded. After the high purity water rinse and *without a//owing the column to dry,* 10,000 ml of filtered effluent sample is pumped through the column at a rate of about 40 - 50 ml/min.

Discard the first 100-200 ml of post-column effluent, to reduce the possibility of higher concentrations of methanol in post-column samples, which may contribute to artifactual toxicity. To evaluate the post-C_{18} SPE column effluent for toxicity, collect at least two aliquots (e.g., beginning and end) separately. If only small quantities (<500 ml) of post-column effluent are needed for toxicity testing (e.g., C. *dubia* test), several separate post-column effluent samples may be more helpful in determining if the toxicants are retained by the column. About 800 ml of post-column effluent is needed for the fathead minnow test if only one concentration (100%) of post-column effluent is tested for toxicity. If two concentrations (100% and 50%) are used, then the required volume for that species increases to 1,200 ml for each post-column aliquot. As Phase II progresses, the recommendation is to collect enough post-column effluent to conduct toxicity tests with dilutions.

2.3.7 C,, SPE Column Elution

To elute the C_{18} SPE column, two successive 10 ml volumes of the 50% methanol/water mixture are pumped through the column and collected in one labelled, analytically clean vial. Subsequently, two successive 10 ml total volumes of each of the 75%, 80%, 85%, 90%, 95% and 100% methanol/water solutions are pumped through the column and collected in separate vials. The next elution volume should not be added until no more of the preceding one is emerging from the column. This results in seven 20 ml SPE fractions. If one 5 g column and two 1 g columns are used to concentrate 7,000 ml of effluent, the corresponding fractions can be combined. For example, the 10 ml eluate of the 80% fraction from the 5 g column can be combined with the two 2 ml 80% fractions from the two 1 g columns. This applies to both sample and blank fractions for a total of 14 ml.

This entire procedure (conditioning through elution) is repeated using a second 10,000 mg C_{18} SPE column for a second 10,000 ml of filtered effluent. The dilution water column blank samples should be kept separate. The corresponding fractions from both the blanks and the sample from each 10,000 ml fractionation can be combined as described above. There will be seven 40 ml blank fractions and seven 40 ml effluent fractions, representing 20,000 ml effluent.

The vials containing the methanol/water fractions are sealed with perfluorocarbon or foil-lined caps, and stored at 4°C if not tested immediately. These fractions represent a 'first cut" separation of effluent components. Volumes will vary if columns of different sizes are used or if the particular effluent under study or the research question posed dictates method modification.

2.3.8 Blank and Effluent Fraction Toxicity Tests

While the choice of test concentration depends on the toxicity of the effluent (Section 1.2), in most instances we have used a concentration of 4x or 2x as the high test concentration for testing SPE fractions. The high test concentration of the SPE fraction is in part controlled by the tolerance of the organisms to methanol. For chronic testing the concentration of methanol should be less than 0.6% for *C. dubia,* and less than or equal to1% for fathead minnows (see Phase I; EPA, 1992).

If the minimum elution volumes are used, typically SPE eluates are 500x effluent concentration. For fathead minnow testing, eluates can be toxicity tested at 4x effluent concentration by diluting 80 µl to 10 ml, which results in a 0.8% methanol concentration. For *C. dubia,* eluates can be toxicity tested at 2x the 100% effluent concentration by diluting 40 µl to 10 ml which results in a methanol concentration of 0.4%. If there is the need to toxicity test the 500x eluate with C. *dubia* at 4x then the SPE eluates can be concentrated by gently airing the eluate down (using nitrogen) to half its original volume. However, by using this procedure you risk losing the toxicant because of evaporation or insolubility. Also realize that when a water and methanol mixture is aired down, the percent methanol composition changes, because methanol will evaporate faster than water.

If toxicity occurs in any of the fraction blank tests and it is small relative to the toxicity in the corresponding sample fraction, the sample fraction results should not be dismissed. If all organisms die in the blanks and effluent fractions, dilutions of each should be tested to make sure the sample fraction is substantially more toxic than the blank. In general, blanks should not have measurable toxicity.

When the post-column effluent sample is toxic and the fractions are toxic at effluent concentrations of lx or 2x, the toxicant could still be a non-polar organic compound. If the fractions are not toxic individually and the post-column sample is non-toxic, it is possible that the toxicity is spread out among the fractions. Combining and concentrating these fractions may be useful or other elution procedures may be necessary (Section 2.6). If the fractions are toxic and the post-column effluent is toxic, it is possible that the toxicant(s) is in the fractions, and that either an additional toxicant(s) is present in the post-

column effluent, that break-through of the toxicant(s) occurred, or that the toxicity is artifactual. If toxicity is recovered at lx, 2x, or 4x and in one of the post-column effluent samples, it is possible that not all the toxicity is caused by non-polar organic compounds or the possibility exists of break-through in the post-column sample.

For the chronic TIE, the question of extraction efficiency cannot be as readily addressed as it is for the acute TIE (Section 2.2.8). Measuring the chronic toxicity of the post-column effluent will be limited by the species tested, the test volumes required for the test and the frequency of sample replacement. Without a measure of the toxicity in the post-column effluent, conclusions regarding extraction efficiency are difficult to make. The limitations created by this concern are addressed in Phase III (EPA, 1993A). Artifactual toxicity in the post-column effluent has been a problem in chronically toxic effluents as it was in some acutely toxic effluents. For a detailed discussion of this artifactual toxicity that appears as a biological growth and suggestions to avoid it please refer to Sections 2.2.6 and 2.3.4., and EPA, 1992.

At this point in Phase II, the effluent fractions should also be tested in water with TOC and suspended solids that mimic the effluent to lessen matrix effects on toxicity. As the identification step moves into Phase Ill, it is better to use dilution water that mimics effluent or receiving water characteristics.

2.3.9 SPE Fractions: Concentration and Subsequent Toxicity Testing

The SPE fractionation provides a general separation of non-polar organics and except in relatively uncomplicated effluents, GC/MS analysis of the concentrates of toxic C_{18} SPE fractions will result in very complicated chromatograms from which the toxicant(s) cannot be distinguished from other effluent components. A secondary fractionation using HPLC is often needed to further simplify toxic effluent fractions prior to component identification by GC/MS analysis.

In order to maximize the chromatographic separation capability of the HPLC, the volume of the sample injected onto an analytical size HPLC column should be as small as possible (i.e., ≤0.5 ml); therefore the toxic SPE fractions (usually >1 ml) must be concentrated prior to injection onto the HPLC column. This concentration step will provide the added benefit of an increase in concentrations of constituents in the HPLC fractions as well as rid the SPE fractions of water. The latter issue is important if GUMS analysis will be performed on the concentrated SPE fraction prior to injection on the HPLC.

The volume of the SPE fraction and the number of toxic fractions to be combined will determine which size SPE column will be used for the concentration procedure. Table 2-3 contains information on column sizes and the appropriate volume of conditioning and eluting solvents we have found to be most useful. In the procedures outlined below we have used a 200 mg SPE column to concentrate one 40 ml toxic fraction from two 10,000 mg SPE columns. Often the toxic effluent SPE fractions are combined and diluted with high purity water. If enough toxicity occurs in each fraction it may be more useful to concentrate each fraction separately for subsequent HPLC separation. The corresponding blank fractions are similarly treated. The percent methanol in the diluted fraction sample should be ≤20% and the volume to which the fractions can be diluted is dependent on the amount of column packing. For example, the total volume of the diluted fraction(s) should not exceed 200 ml for the 200 mg C_{18} column (Table 2-3).

A 200 mg C_{18} column is conditioned with 2 ml of methanol and rinsed with 2 ml of water similar to the procedures described in the SPE Column Conditioning Section (2.3.4). The diluted blank fractions are then drawn through the 200 mg C_{18} SPE column under a pressure of 380 mm Hg using a vacuum manifold. When processing larger volumes, or using larger columns, positive pressure can be used. The solution passing through the column cannot be tested for toxicity because of its high methanol concentration (e.g., 1 0-20% methanol). The column is then dried for 10 min using a gentle flow of nitrogen (1 O-20 ml/sec). Drying ?he column usually increases the recovery of toxicity, but sometimes toxicity is not recovered from the column possibly because of volatilization. If this occurs, the concentration procedure can be repeated without the nitrogen drying step.

After drying the sorbent, the luer tip of the column is fitted with a luer-lock needle (to ease collection of small volumes) and 200 µl of 100% methanol is placed into the column using a microliter syringe. Nitrogen is then applied to the column at a rate of -4 ml/sec to force the methanol through the sorbent, which is then collected in a small glass vial. The first 200 µl aliquot of methanol applied to the column will yield approximately 125 µl of eluate. Two more 200 µl aliquots (applied separately) of 100% methanol are also forced through the column. The final volume of eluate collected will be approximately 440 µL. Measure the exact volume collected using a µl syringe or pipet. As in most chromatographic separations and extractions, three separate smaller elutions of methanol are more efficient than one large one.

The 200 mg C_{18} SPE column is reconditioned following the directions given above in Section 2.3.4. It is then used to concentrate the diluted toxic SPE fractions, using the same sequence used for the blank fractions (Figure 2-4). The concentrated blank fractions will serve as the dilution water column blank because it cannot be obtained for chronic toxicity testing as it can for acute testing.

When the total volume of fractions is above 40 ml, larger columns should be used; consult Table 2-3 for column size and elution volume information. The size of the column used for concentrating should be chosen to maximize concentration in the eluate. Therefore, choose the smallest column appropriate for the diluted fraction volume.

If there is a large toxicity loss after the concentration step, it is possible that the percentage of methanol in the diluted fraction was too high. The concentration procedure should then be repeated with a new set of toxicity tested SPE fractions diluted to a lower methanol concentration (e.g., 10%). Both the effluent and blank concentrates are toxicity tested at each step to track toxicity. Generally we suggest that this toxicity test be at least at two times higher than the concentration used in the first SPE fraction test. The tests are conducted exactly as the SPE fraction tests.

If an original effluent volume of 20,000 ml (using two 10,000 mg SPE columns) is now represented by a 440 µl concentrate, then the sample is 42,670x more concentrated than the effluent (accounting for volume removed for toxicity testing, see Table A-2 example). If 1 µl of concentrate is diluted to 10 ml in dilution water, the resulting test concentration will be about 4x whole effluent. However, the 4x test solution should be prepared as one sample before solutions are split among replicates. For example, 5 µl is diluted to 50 ml for five replicates with the C. *dubia* test described above (Table A-2). Additional test concentrations (e.g., 2x, Ix, 0.5x) can then be prepared to determine an IC25 or IC50 of the concentrate, and toxicity recovery can be calculated by comparing this value to the toxicity of the effluent. The concentrate toxicity might be higher than the sum of the individual toxic fractions because some of the toxicant may have been in adjacent fractions that were concentrated in the first step (Section 2.3.7) but not detectable by the toxicity test of the single fraction. The concentrate toxicity may also be lower than expected because of low extraction and elution efficiencies.

The important concern here is not 100% recovery of toxicants but enough recovery for GC/MS analyses to be successful and to obtain measurable toxicity in the HPLC fractions. If recovery is too low, changing or eliminating the column drying time may help. Sometimes recovery appears to increase with drying time while other compounds are volatilized from the column during the drying process. For concentrates analyzed using GC/MS, column drying to remove water is critical to GC column performance.

2.3. IO *HPLC Separation*

The same column packing functionality should be used in the HPLC column as is used in the SPE column, such as C,,. At later stages, when more is known about the toxicants, other sorbents might be more appropriate.

The HPLC conditions presented in this section are general. An important consideration of HPLC fractionation is the number of HPLC fractions to collect. Since chronic toxicity testing is very time consuming, deciding the appropriate number of fractions to collect is an important step. **However,** when choosing which collection scheme to use, keep in mind the trade-off between separation and toxicity testing load. When the fraction volume is increased (toxicity testing load decreases) the separation of the toxicants from the non-toxic components decreases. We have used a 20 min separation gradient with the collection of 20-1 ml fractions. There are many other collection options that could be used, such as 10-2 ml fractions or 4-5 ml fractions using the same separation gradient. As information on the effluent is gained, HPLC conditions should be modified from the general conditions described below, to achieve better separation and higher concentration factors.

We use a flow rate of 1ml/min on an instrument equipped with a 5 µm C_{18} reverse phase column (250 mm x 4.6 mm i.d.). The HPLC elution conditions will change depending on which SPE fractions have been concentrated. An example of HPLC conditions for commonly toxic SPE fractions is listed in Table 2-f. First, the blank concentrate is injected (≤500 µl) and 20-1 ml fractions are collected in analytically clean glass vials. Depending on the size of the HPLC injector and column, more than one HPLC fractionation run may be required to fractionate the entire blank concentrate. When multiple HPLC fractionations are conducted, collect and combine all the corresponding HPLC fractions in the same set of vials. For example, if two HPLC fractionations were performed for the blank concentrate, 20-2 ml HPLC blank fractions would be obtained. The same procedure is followed using the effluent sample concentrate. The vials should be sealed (e.g., with foil lined caps) and stored at 4°C if not tested immediately. As soon as toxicant identification is obtained by GC/MS (Section 2.5), then HPLC conditions (gradient, fraction size, and number of fractions) can be optimized.

Table 2-7. Example HPLC Elution Gradient for SPE Fractions from Chronically Toxic Effluent Samples

80 or 85% SPE Fractions	
Time (min)	% Methanol/Water
0	80
10	90
12	100
20	100

2.3.11 HPLC Fraction Toxicity Tests

In the HPLC fraction toxicity tests for chronically toxic effluents, the methanol in the HPLC fractions is one of the limiting factors of the concentration of the fractions that can be tested. Each fraction is assumed to be 100% methanol to calculate the necessary dilution. A 0.6% methanol concentration or less can be tested with C. *dubia*, while a 1% or less methanol concentration can be tested with fathead minnows.

In a chronic TIE with *C. dubia*, when all of the SPE concentrate remaining after toxicity testing from 20,000 ml effluent is injected on the HPLC (one injection),

each resulting 1 ml HPLC fraction equals 15,575 ml of effluent (assuming the toxicant elutes in only one fraction, see Table A-2). If 11 µl of each HPLC fraction is then diluted to 10 ml, the test concentration is 16x the original effluent concentration. However, the 16x solution should be prepared as one sample before aliquots are split to provide replicates. For instance, in the example used above, 55 µl should be diluted to 50 ml, which is then equally distributed into five test cups. Additional concentrations are prepared in a similar fashion to estimate the IC25 or IC50 and to compare toxicity recovery to the toxicity of the sample. Of course, some loss of toxicant will occur in each step and the toxicity may be less.

The blank fractions should not be toxic. If they are, then additional tests with dilutions must be conducted on both blanks and toxic fractions to find out whether there is enough additional toxicity in the sample fractions to warrant analysis.

The toxicity of the HPLC fractions should be tested at twice (at least) the concentration at which the SPE fraction concentrates were tested because recovery of toxicity and analytical measurements indicates that up to 50% of the initial concentration of toxic compounds may be lost in this step (Durhan et al., 1990). The concentration of methanol should not exceed the amount used in the SPE fraction tests described above (Section 2.3.8).

2.3.12 *HPLC Fractions: Concentration and Subseguen t Toxicity Testing*

The toxic HPLC fractions and their corresponding blanks must be concentrated in a solvent suitable for GC/MS or other analytical techniques. Use the procedure described in Section 2.3.9, Concentration of Fractions (Figure 2-6). Judgement must be used to decide whether to concentrate each toxic fraction separately or to combine various toxic fractions prior to concentration. if, for example, two successive fractions are toxic, there is a good probability that the same toxicant is present in both. If one toxic fraction is separated from the other by several nontoxic fractions, there is a high probability that they contain different toxicants. There is also a good probability that at least one nontoxic fraction on either side of the toxic fractions contains some of the toxicant. The advantage of combining fractions is to reduce the workload and to increase the amount of toxicant in the concentrate. The disadvantage is that more constituents that are not the toxicant will be included. The decision has to be based on trial and error and experience. Blanks corresponding to the toxic fractions are concentrated the same way.

The HPLC fraction and blank concentrates should also be checked for toxicity before analysis on the GC/MS. Generally, we suggest that these toxicity tests be done at concentrations at least 2x higher than the concentration used in the previous HPLC fraction tests. Hopefully, the amount of concentrate available will be enough to conduct the toxicity test and perform a GC/MS analysis. Dilutions of the concentrate may be useful to compare toxicity of this concentrate to each previous toxicity test result. The HPLC concentrate (of 20,000 ml effluent) is now 48,495x more concentrated than the effluent (see Table A-2). If 3 µl is diluted to 10 ml the resultant test concentration will be about 16x the original sample concentration. This 16x solution should be prepared as one solution before aliquots are removed for the replicates. For instance, 15 µl is diluted to 50 ml for use in the example given above, then split into five 10 ml test cups. It is prudent to verify toxicity in the HPLC concentrate before it is subjected to GC/MS analysis. Whether the toxicant is detected by the analytical detector is always a question. Since GC/MS detects only about 20% of organic chemicals (EPA, 1989B), even such a broad spectrum method is no guarantee that the toxicant will be identified.

2.4 GC/MS Analyses

Procedures and methods provided in this section are based upon our experience in performing GC/MS analyses on fractions from numerous effluents and are applicable to both acute and chronic toxicity identification. In general, these procedures should be used.

A GC/MS system equipped to perform standard chemical residue analyses is suggested; i.e., a 30 m capillary column, electron impact ionization, scan range of 50-500 amu, scan rate of 1 or 2 scans/sec, a GC temperature program of 50 to 300°C at 5°C/min, and a data system with library searching capability.

Prior to GC/MS analysis, the prepared blank and toxic fraction concentrates should be tested for toxicity (Figure 2-6). After verification of the toxicity in the methanol concentrate, inject 1 or 2 µl of the concentrate (to which an internal standard has been added) and collect the mass spectral data. Note, methanol is not a typical solvent for GC analysis and the injection of methanol on a capillary column will shorten the column's life. Therefore, routine GC/MS QA/QC procedures should be followed closely to monitor the performance of the column.

The mass spectral data should be collected, the chromatogram integrated, and all detected peaks library searched. Reverse search is preferred. Concentration estimates for all chromatographic peaks can be obtained by using the response factor of the internal standard. Usually the internal standard is added to a small aliquot (10-20 µl) of the concentrate prior to GC/MS analysis. The selection of internal standard to use is an individual choice, and many different standards are available. An external standard method could also be used for deriving concentration estimates.

The NIST (National Institute of Standards and Technology, Gaithersburg, MD) mass spectral library has been used in ERL-D for performing library searches. Other mass spectral libraries are available, but some of the larger libraries contain multiple spectra for some of the compounds in the database. Library searching results that contain multiple identifications of the same com-

pound are not as useful as those obtained using the NIST library.

Once the library search results are available, the search report for each peak must be examined to decide whether the identification by the search is valid and reasonable. The help of a trained GC/MS chemist is required to do this evaluation. Questions we consider in our laboratory when performing this process include: A) are all major ions present in the correct proportions?, B) is this identification consistent with other information about the fraction?, C) do forward and reverse searching provide similar fits? and 0) are the library searching fits greater than 70%? Factor A *must* be met! Consistency, factor B, considers circumstances such as "has the identified chemical been found in vastly different fractions," or "has the same identification been given to numerous peaks in the same chromatogram?" Both factors C and 0 are somewhat relative and depend a great deal on the sample and its matrix. In addition, the toxicants are often very minor components in the GC/MS total ion chromatogram and thus, the quality of the mass spectral data even after background subtraction can lead to poor results for factors C and 0.

After examination of the library search results, a list of identified chemicals is assembled and evaluated using the methods in the following section. For the confirmation analyses we suggest EPA method 625 (EPA, 1982).

2.5 Identifying Suspect Toxicants

If one toxicant is identified, then the goal of the rest of Phase II is to determine if there are any other toxicants contributing to effluent toxicity. Two parallel lines of investigation should be pursued to achieve that goal. The first is to determine whether or not the concentration of the suspect toxicant is sufficient to cause toxicity (EPA, 1993A). The second is to estimate the proportion of the effluent toxicity that is caused by the suspected toxicants, so that a decision can be made as to whether other toxicants are present in the effluent.

The first line of investigation should begin by comparing the estimated concentrations of identified chemicals in the SPE or HPLC concentrate to their known toxicity values. Recovery of 100% of each effluent toxicant in the C_{18} SPE fractions may not be crucial, because at this stage, only the estimated concentration of compounds in the fraction and the toxicity of the fraction are compared. Assumptions about the concentration of toxicant(s) in the whole effluent are not made at this point, nor is any statement made regarding recovery of whole effluent toxicity in C_{18} SPE column fractions. In later stages of Phase II, inferences regarding the relationship between the concentration of the suspected toxicant(s) in whole effluent and the observed toxicity in the SPE fractions are made. At this step, the compound quantification will have been performed using an internal or external standard response and since the compound's recovery is unknown, considerable error may be involved in the concentration estimate. Secondly, the toxicity data, if available, may be for a different species than that used in the TIE. Species differences are usually as large as 100-fold and often 1,OOO-fold. Given these two sources of uncertainty and the chance that they may reinforce one another, certainly if the estimated concentration of a chemical accounts for the toxicity within a factor of 100, the chemical should remain a suspect. To the extent that data for either quantitation or toxicity values of the compound are known to be better, concentration differences of smaller magnitude may be used to eliminate suspects.

Once a list of suspects is available, the measurements for both concentration and toxicity should be refined. This will usually require obtaining pure compound to make better analytical measurements and to establish acute or chronic toxicity estimates for the species of concern. This step requires as much separation as practical before analysis so that the list of suspects is small.

At this stage, only the concentration of the suspected toxicant(s) in the concentrate is known; until recovery through all the fractionation and concentration steps is complete, suspect compound concentrations in whole effluent are not known. Since the concentrate is virtually devoid of suspended solids and much of the effluent TOC, both of which may dramatically affect toxicity of non-polar organics, the toxicity of non-polar chemicals may be quite different in the fraction tests than in the effluent test. Therefore, the toxicity of suspects in the fraction test should be compared to the suspect's toxicity in a relatively pure water, such as reconstituted water.

During this same stage, the steps leading to the final concentrate should be checked for toxicity recovery. The objective is to place a good estimate on how much of the whole effluent toxicity is contained in the final concentrate. This is best done by testing the toxicity of the concentrate at concentrations near those of whole effluent, correcting for volume losses due to toxicity testing SPE column fractions (which was previously ignored). If the toxicity of the final concentrate is similar to that of whole effluent, allowing for losses, and if the concentration of the suspect(s) is sufficient to account for the concentrate's toxicity, it is time to begin Phase III (EPA, 1993A). If multiple toxicants occur, the toxic units of each are compared to the whole effluent toxic units.

If the concentrations from quantitation and toxicity measurements are close to one another, Phase III procedure should be started, recognizing that other toxicants may yet be identified. If no suspects are found, more concentration, more separation, and possibly different or more sophisticated analytical methods must be used. In some of the effluents we have tested, finding other candidates has taken months and concentration factors of >100,000 have been required. Since few laboratories will have all the needed analytical equipment, instrumentation from other sources should be considered.

Because artifactual toxicity that equals toxicity due to lost or unidentified toxicants can be created, as one progresses to Phase III the suspect toxicant should be identified. One purpose of Phase III is to identify such errors. Should this error occur, one must start again at the beginning of Phase II, or even return to Phase I. If several different effluent samples were evaluated during Phase II, redoing Phase I on additional samples may be time well spent since the effluent may have changed in the interim.

In practice there is no sharp boundary between Phases II and III. In general, as soon as a probable suspect is identified, confirmation procedures of Phase III should begin. If a toxicant has been assumed to have been identified when it has not, the identification of other suspected toxicants can be hampered.

A final suggestion is to investigate the additivity of toxicity for several constituents, if all toxicity is not accounted for. Enhancement of toxicity by methanol should also be checked.

2.5. *I Identifying Organophosphate Pesticides*

Certain compounds must be metabolically activated by the test organism before they become toxic. These activation reactions consist of oxidative metabolism by a family of enzymes collectively known as cytochrome P-450. Compounds such as piperonyl butoxide (PBO) can block the toxicity of metabolically activated toxicants making it a useful tool in the TIE. PBO is a synthetic methylenedioxyphenyl compound that effectively binds to and blocks the catalytic activity of cytochrome P-450. Thus, when a nontoxic amount of PBO is coadministered with the effluent or the effluent fractions that exhibited toxicity, the toxicity of the compound requiring metabolic activation is greatly reduced or completely blocked (Ankley et al., 1991).

Phosphorothioates are organophosphates known to require cytochrome P-450 activation before expressing toxicity and include common insecticides such as diazinon, malathion, parathion, methyl parathion and fenthion. There also are a number of organophosphates that are toxic in the absence of metabolic activation; these include insecticides such as dichlorvos, mevinphos and chlorfenvinphos.

We have found organophosphate insecticides present in effluents and ambient waters at acute and chronic toxicity levels (Amato et al., 1992; Norberg-King et al., 1991). The toxicity of most organophosphates will be removed from the sample by the C, SPE column, and they are typically recovered in the methanol eluates (see EPA, 1991A; EPA, 1992). The addition of PBO to the effluent before addition of the test organisms was used as a subsequent test in Phase I (EPA, 1991A; EPA, 1992). In addition to the C_{18} SPE column removing the toxicity, a reduction in toxicity with the addition of PBO would suggest the presence of metabolically activated compounds such as organophosphates. PBO has similar utility in Phase II of the TIE in that either SPE fractions (Sections 22.8 and 2.3.8) or HPLC fractions (Sections 2.2.11 and 2.3.11) can be tested for toxicity both in the presence and absence of PBO. A reduction in toxicity of the test fraction would suggest the presence of a metabolically activated chemical, and together with chemical analyses, can provide powerful evidence along with GC/MS data, for specific organophosphates as the toxicant(While PBO should be useful for both acute and chronic TIE work, most of our experience has been in the area of acute toxicity. Thus, guidance presented below is based mainly on acute tests.

Toxicity values for PBO are presented in Phase I (EPA, 1991A; EPA, 1992). In acute toxicity tests, concentrations of PBO ranging from 250-500 µg/l have effectively blocked the acute toxicity of relatively large concentrations of metabolically activated organophosphates to cladocerans (Ankley et al., 1991). In chronic toxicity tests with C. *dubia,* PBO concentrations of 50 µg/l have been effective in blocking toxicity in the SPE fractions. Detailed information on stock solution preparation is presented in the Phase I documents and is not repeated here.

When toxicity tests are conducted on SPE fractions or HPLC fractions, aliquots of the PBO solution are added to the test solutions and mixed well before the test organisms are added. As for any TIE manipulation, the successful use of PBO is dependent upon the use of appropriate controls and blanks. Effluent fractions and blank fractions with and without the addition of PBO must be tested simultaneously. A reduction in toxicity of the effluent fraction occurring with the PBO added, and no toxicity exhibited in either of the blanks, indicates that the toxicant requires metabolic activation to exhibit toxicity. If toxicity associated with the PBO addition is observed in the blank fraction, either PBO was present at toxic concentrations or the methanol concentration (from fraction and/or PBO stock addition) in the test was too high. If toxicity is observed in the effluent fraction with PBO added, but not in the effluent fraction without the PBO or in either of the blank fractions, this result is essentially meaningless. In the latter situation it is possible that the PBO has interacted in a synergistic fashion with another compound present in the test effluent that normally would not be toxic.

2.5.2 *Identifying Surfactants*

The goal in this section of Phase II is to identify the toxicants when surfactants are implicated by Phase I and Phase II results. The Phase I procedures of filtration, aeration, and C_{18} SPE all affect surfactant toxicity, and effluent samples that exhibit several or all of these behaviors may contain toxic concentrations of surfactants (EPA, 1991A).

Surfactants are surface active agents that have a molecular structure that includes a polar, hydrophilic segment (either ionic or nonionic) and a relatively large nonpolar, hydrophobic, hydrocarbon segment. Surfactants are used for a variety of household and industrial purposes and therefore are ubiquitous in effluents, particu-

larly in untreated wastewater, and potentially could be present at toxic concentrations in effluents (Ankley and Burkhard, 1992). Some examples of surfactants are soaps, detergents, charged stabilization polymers, and coagulation polymers used in chemical manufacturing processes. The molecular structure of surfactants causes them to congregate at interfaces between water and other phases such as air, oily liquids and particulate matter. This congregative characteristic is responsible for the cleansing and dispersive properties of surfactants.

There are many different kinds of surfactants and they are classified by the nature of their polar segment. When in aqueous solution, the polar segment of a surfactant molecule can be either nonionic (not charged) or ionic (charged). The ionic polar segment can be either negatively charged (anionic), positively charged (cationic), or both negatively and positively charged (amphoteric). Based on this, surfactants are classified into the following major classes: nonionic, anionic, cationic, and amphoteric.

Surfactants physical/chemical properties set them apart from both strictly polar or non-polar organic compounds and these properties uniquely influence the results of Phases I and II procedures for surfactants.

Experiments were conducted with a small sample of surfactants from nonionic, anionic, and cationic categories with the Phase I procedures of filtration, aeration, and C_{18} SPE (Ankley et al., 1990A). In these experiments, filtration removed the toxicity of most of the surfactants tested to some degree, and the degree of removal is most probably dependent on sample matrix, especially solids concentration. Aeration removed the toxicity of all the surfactants tested to some degree while the C_{18} SPE column removed the toxicity completely for all surfactants regardless of class. Surfactants behave unpredictably with regard to eiution from C_{18} SPE columns. For example, toxicity from surfactants of the nonionic and anionic classes, eluted in all fractions 80% to 100% methanol/water (Ankley et al., 1990A). Elution in several fractions rather than eluting in one or two fractions may be caused by the polar/non-polar nature inherent in surfactants. The toxicities from the cationic surfactants were either not recovered in any of the fractions or were recovered to only a small degree in the 100% methanol fraction.

Important indicators of surfactant toxicity are the toxicity test results from aeration experiments. If volatility can be eliminated and toxicity is reduced by aeration, this is strong evidence that a surfactant might be contributing to effluent toxicity (EPA, 1991 A). During aeration, surfactants are most probably removed from solution by the process of sublation. Sublation occurs because surfactant molecules tend to congregate at the interface between the aqueous sample and the aerating nitrogen or air bubbles and are brought to the surface of the liquid sample by the bubbles. At the liquid surface the bubbles break releasing the surfactant, which then adheres to the aeration vessel walls. A compound that can be removed by sublation is by definition a surfactant. It might be possible to recover surfactants from glassware after the sublation process. The glassware can be rinsed with a solvent such as methanol, which can then be toxicity tested and analyzed in the same manner as methanol SPE fractions (Sections 2.2.8 and 2.3.8).

Overall, most surfactants exhibit some of the behavior that is common to non-polar organic compounds such as removal from the effluent by the C_{18} resin and recovery in the methanol/water SPE fractions. While surfactants in general can be considered to be non-polar organics, GC/MS analysis will probably not provide successful sutfactant identification. Most surfactants are not readily chromatographed because of the polar segment of the surfactant molecule. One exception is a class of surfactants in common use that can be analyzed directly by GC/MS, the alkylphenol ethoxyiates. Gieger et al. (1981), provides mass spectral data for the nonylphenol mono-, di- and tri-ethoxylates, which can be used to help identify these compounds. Techniques such as derivatization can make some other specific surfactants compatible with GC and GC/MS, but it is necessary to know the specific identity of the surfactant.

It is difficult to positively identify an unknown surfactant. Although there are many analytical methods available for accurately quantifying specific surfactants, these methods are useful only if the identity of the surfactant is known, or at least suspected. It is not reasonable or practical to analyze a sample using numerous intricate methods, in the hope that one of these methods will detect the surfactant in the sample. Unfortunately, there is no analytical technique available that can readily provide the identity and quantity of an unknown surfactant. Environmental samples (such as municipal and industrial effluents) contain numerous substances that can interfere with available analytical methods. Also, pure surfactants are actually mixtures of homologous and oligomers with varying chain lengths and, in the case of many nonionic surfactants, varying degrees of ethoxylation. The composition and therefore the toxicity of such a mixture might vary. In the course of a TIE, it might become necessary not only to identify the surfactant causing toxicity, but also to learn which particular homologue or oligomer is the most toxic.

One approach to reducing the complexity of identifying an unknown sutfactant is to determine whether the unknown surfactant falls into the anionic or nonionic class. APHA (1989) describes a method for determining anionic surfactants as methylene blue active substances (MBAS). MBAS method can successfully measure the concentration of anionic surfactants of the sulfonate type, the sulfate ester type, and sulfated nonionics type. Unless the identity of the anionic surfactant is known, the analytical measurement is calculated and expressed in terms of the anionic surfactant linear alkylbenzene sulfonate (LAS). APHA (1989) also describes a method for determining nonionic surfactants as cobalt thiocyanate active substances (CTAS). This method is applicable to a wide

range of polyether nonionic surfactants, which includes the widely used alkyl and alkylphenol ethoxylated alcohols.

With these methods the relative amount of anionic or nonionic surfactant can be estimated, but the exact nature or molecular composition of the unknown surfactant will not be determined. These analyses can be conducted on the SPE fractions, HPLC fractions, fraction concentrates, and the whole effluent. Determining the class can be significant progress toward identifying the unknown surfactant. With the class known, specific analyses for the more common surfactants in that class can be performed as a subsequent effort. Unless the identity of the nonionic surfactant is known, the analytical measurement is expressed in terms of an arbitrarily chosen reference nonionic surfactant.

The type of discharge being processed by the wastewater treatment plant might provide information that would enable one to target specific surfactants for analysis. For example, industries feeding into the treatment plant might be discharging certain surfactants or a particular kind of surfactant that is being used in the manufacturing or housekeeping processes. An analytical method suitable for that particular surfactant could then be used to determine whether toxic concentrations can be found in the toxic effluent, fractions, or concentrates.

2.6 Alternate Fractionation Procedures

If toxicity is not recovered in the methanol procedures described above (Sections 2.2 and 2.3), and toxicity is not observed in the post-column effluent, alternative elution procedures can be used. These procedures are not as widely used as the methanol/water elutions discussed above but are effective for highly hydrophobic compounds.

2.6.7 *Modified Elution Method*

The current Phase II method for fractionating non-polar organic toxicants in aqueous samples does not effectively fractionate compounds that are highly hydrophobic. Modifications made to the method have been successful in overcoming this limitation (Schubauer-Berigan and Ankley, 1991; Durhan et al., 1993). Hydrophobic compounds probably are more prevalent in sediment pore waters than in treated effluents. Tracking toxicity caused by these kinds of compounds will be more difficult because of the potential for artifactual toxicity from the solvents required to elute them. An elution scheme incorporating water, methanol, and methylene chloride has been designed that effectively fractionates compounds over a log K_{ow} range from 2.5 to 6.9. The higher log K_{ow} compounds, however, elute in the same set of fractions. Further fractionation by HPLC might be necessary to achieve better resolution of these kinds of compounds. Substituting other sorbents for the currently 'used C SPE resin have also produced encouraging results. 'Both the C_8 SPE and XAD-7 (Rhom and Haas, Philadelphia, PA) sorbents might have utility with particular kinds of toxicants.

The modified elution scheme eliminates the 100% methanol fraction used in the original method, and replaces it with one 50% methylene chloride/methanol, and three 100% methylene chloride fractions (v/v). The composition of the resulting eleven 3 ml (when using a 1,000 mg C_{18} SPE column) fractions is shown in Table 2-8. The methylene chloride containing fractions are combined, then solvent exchange is conducted as described below. The modified elution scheme would be used when the original methanol/water elutions did not effectively elute toxicity in the SPE fractions. In addition, if the suspect toxicants were known to be highly hydrophobic, as in sediment pore water, then the modified elution scheme would be indicated. Blank toxicity should provide insight concerning artifactual methylene chloride toxicity; however, slight reductions in young production might occur in both the blanks and sample fractions. Development of this alternate procedure for chronic toxicity is underway for the C. *dubia* and should be used with caution at this time. If this procedure is used, it is important to accompany the solvent exchanged methanol blank with a methanol only blank.

When toxicity testing SPE fractions, it is always a concern that the matrix of the effluent has been changed and that chemicals might become bioavailable, whereas they were not in the original sample. If this were to happen, the fractions might be more toxic than expected and chemicals might be added to the suspect toxicant list erroneously. This kind of mistake should be caught by obtaining a good toxicity value for the suspect toxicant in an appropriate matrix. For instance, if the suspect toxicant is highly insoluble in water, then when tested in an effluent matrix it should have low toxicity because it is unavailable to the organism. The alternate solvent elution might enhance this problem because the solvent is more likely to solubilize the more hydrophobic compounds than

Table 2-8. Composition of 11 Recommended Fractions in Modified Eiution Scheme

Fraction	Composition of Eluting Solutions (% v/v)		
	Water	Methanol	Methylene Chloride
	75	25	0
2	50	50	0

10	0	0	100
11	0	0	100

methanol. Therefore, additional confirmation steps might be needed to eliminate the false suspects.

2.6.2 Solvent Exchange

Since methylene chloride is quite toxic to aquatic organisms, even at very low concentrations (NOEC for *C. dubia* is 0.03%), it must be removed from SPE fractions before the fractions can be tested for toxicity. The exchange of the methylene chloride fraction into methanol is a relatively easy process because of methylene chloride's volatility. The combined fractions to be exchanged (e.g., 15 ml) are placed in a centrifuge tube with a teflon stir bar and an additional 15 ml of methanol. The tube is placed in a 30°C water bath and stirred while a gentle stream of nitrogen is passed over the solution surface. When the volume of the solution reaches 3 ml, the sides of the tube are carefully rinsed with an additional 3 ml of methanol, and the solution is reduced again to a final 3 ml volume. Adjust the volume of methanol used in this procedure to reflect the total volume of combined fractions. The final volume of methanol may then be tested as suggested previously in Sections 2.2.8. and 2.3.8. It is important to obtain and toxicity test a methanol-only blank in addition to the solvent exchanged methanol blank.

2.6.3 Alternative SPE Sorbents and Techniques

In the SPE method described above, C_{18} bonded silica is used as the solid phase for fractionating and isolating non-polar organic toxicants. C_{18} bonded silica was selected because, with proper conditioning, it does not usually contribute artifactual toxicity to sample or sample fractions, it often achieves the required degree of separation and isolation of non-polar organic compounds, and it is commercially available in inexpensive, easy to use, disposable columns. There is, however, no restriction on the solid phase that is used in the TIE procedure, as long as it results in the isolation and separation of non-polar organic toxicants and at the same time does not contribute artifactual toxicity. We have evaluated several sorbents other than C, bonded silica to use for this purpose (Durhan et al., 6993).

We evaluated two prepurified XAD sorbents, XAD-4 and XAD-7 (Rohm and Haas, Philadelphia PA) and a C_8 bonded silica sorbent. Of these sorbents, only XAD-4, a non-polar styrene-divinyl benzene copolymer performed as well as C_{18} bonded silica in the fractionation of non-polar organic compounds. One disadvantage of using an XAD sorbent such as XAD-4 is that it is not commercially available in prepacked disposable columns. In addition, it is important to obtain prepurified XAD-4 sorbent that is free of toxic artifacts, otherwise extensive, time consuming cleanup procedures are required before the sorbent can be used in a toxicity based fractionation. We found that on XAD-7, an acrylic ester copolymer, non-polar organic compounds were inadequately fractionated because of resolution and co-elution problems. The C_8 bonded silica yielded results that were similar but significantly inferior to those obtained with C_{18} bonded silica.

Traditionally, SPE is carried out with the solid phase particles packed in a cylindrical column or cartridge. An alternative form of SPE has been developed, the Empore™ Extraction Disk, in which C_{18} bonded silica particles are enmeshed in an inert PTFE matrix which is then formed into a disk. The manufacturer (3M, St. Paul, MN) claims good recovery of non-polar organics with flow rates as high as 100 ml/min, which would make this an attractive alternative form of SPE. We have evaluated this technique to a limited degree with acutely toxic effluents and sediment pore waters and feel it has great potential in a toxicity based fractionation scheme. Especially attractive is the high flow rate which would allow for large volumes of sample to be processed quickly. However, a procedure for eluting non-polar organics from the disk into several fractions has not yet been developed and could prove to be a challenge.

Section 3
Ammonia

3.1 General Overview

Unlike Phase II procedures for non-polar organic compounds or metals, the toxicant identification methods described in this section are specific for ammonia. The procedures used in this phase of the study assume that Phase I tests and ammonia measurements (see below) have implicated the pH sensitive toxicant, ammonia as causing the acute or chronic toxicity (see Phase I; EPA, 1991A; EPA, 1992). Other compounds with toxicities that increase directly with pH may lead to confounding results or may give results similar to ammonia. For instance, experiments at our laboratory have shown that C. *dubia* are more acutely sensitive to cadmium, nickel, and zinc in acute tests at high pH levels (Section 4). The testing in Phase II should help to discern the toxicity caused by ammonia from that caused by other compounds that might also become more toxic as pH increases. The methods described below can be used to identify ammonia as the toxicant and these data could also be used in Phase III confirmation.

Ammonia is relatively unique in its behavior as pH changes. When ammonia (NH_3) dissolves in water, some of the molecules react to form the ammonium ion NH_4^+, and the equilibrium between these two species is affected by both pH and temperature (EPA, 1985A). The term "total ammonia" refers to the sum of the un-ionized (NH_3) and the ionized (NH_4^+) forms and is referred to as N^+. The toxicity of ammonia to some aquatic species appears to be primarily caused by the un-ionized form. The equilibrium shifts to increase the un-ionized ammonia concentration with increasing pH and increasing temperature. In a constant temperature situation, Table 3-1 shows that as pH increases by one unit, there is nearly a lo-fold increase in the percent of un-ionized ammonia NH_3 present in aqueous solutions at pH 6.0-8.5. The data in Table 3-I are calculated using the dissociation constants for ammonia (EPA, 1979). There are two effects to consider for ammonia as the pH increases; first, the concentration of NH_3 increases (Table 3-1) and second, the toxicity of NH_3 decreases (Tables 3-2 and 3-3). One possible explanation for the second effect is that NH_4^+ is contributing to the toxicity (EPA, 1985A). Measuring and maintaining the pH of the test solution and understanding the effect of pH on the toxicity of ammonia are very important.

As discussed in EPA's ammonia water quality criteria document (EPA, 1985A), the slope of the LC50-pH curve for acute toxicity is similar for different aquatic species (i.e., an average slope can be used for many species). A model was developed to describe the pH dependence of ammonia toxicity, primarily with data for fishes and cladocerans (i.e., daphnids, fathead minnows, rainbow trout, and coho salmon, see EPA, 1985A). This model has been used with acute toxicity data generated at a pH of 8 and a temperature of 25°C for both C. *dubia* and fathead minnows, to predict the LC50 of NH_3 at other pH values (Tables 3-2 and 3-3). It is apparent that the toxicity of NH_3 is about seven times less at pH 7.0 than at pH 6.0, but the amount of NH_3 is ten times greater at pH 7.0 than at pH 6.0. Similarly, at pH 8.0, NH_3 is three times less toxic than at pH 7.0 but ten times more is available at pH 8.0. Ammonia can be implicated as the cause of toxicity if the effluent toxicity and the suspect toxicant exhibit both of these pH effects. Acute toxicity test data generated at ERL-D indicate that this model is not appropriate for all species. For example, the trend of pH-dependence has not been observed in acute tests conducted with the amphipod, *Hyalella azteca,* over a range of pH values in reconstituted waters (EPA, 1991 B) until the hardness is greater than 160 mg/l. In hard or very hard waters, *H. azteca* is more sensitive to NH_3 at higher pHs (P. Monson, personal communication, University of Wisconsin, Superior, WI). We recommend that the effect of pH on the toxicity of ammonia be characterized for the TIE organism, if it has not been done, so that accurate predictions can be made for the organism.

It has not yet been determined whether the pH dependence of ammonia toxicity described for acute toxicity is appropriate for chronic toxicity. The chronic toxicity of ammonia to species typically used in effluent tests, at temperatures similar to those used in TIEs and a variety of pHs is presented in Table 3-4. If chronic ammonia toxicity has not been characterized with respect to pH for the TIE species, it is prudent for the investigator to generate the ammonia toxicity data for at least three distinct pH levels.

Generally, three procedures are used to implicate ammonia in addition to measuring the ammonia in the effluent. These are 1) the graduated pH test (in place of

the equitoxic solution test as described in the first Phase II document; EPA, 1989A); 2) use of the zeolite resin to remove the ammonia; and 3) air-stripping the ammonia from the sample at a high pH (i.e., pH 11). For both the zeolite resin method and the air-stripping method, subsequent toxicity tests and ammonia measurements are performed on whole effluent and the post-treatment samples.

Depending on the presence of other toxicants in the effluent, additional sample manipulations may be needed before proceeding with the three basic tests. For example, if toxic oxidants such as chlorine are also present in the effluent, sodium thiosulfate must be added to the sample before conducting the Phase II ammonia tests. To date we have not seen ammonia and chlorine as co-occurring toxicants in chronic tests, probably because chlorine degrades rapidly in a test system at 25°C, while ammonia does not. If the additional toxicant(s) can be removed by the C_{18} SPE column, it may be possible to conduct Phase II tests for ammonia on post-C,, SPE column effluent sample. However, the problem of artifactual toxicity associated with the post-C,, SPE column effluent may prevent the use of the graduated pH test (EPA, 1992) and/or the air-stripping test (see Section 8 of EPA, 1991A) on post-column samples.

The results of the graduated pH test, the post-zeolite column test, and the air-stripping test, all will be important in identifying ammonia as a toxicant in acutely or chronically toxic samples. Use of pH changes where graded responses are observed are particularly useful for data evaluation in Phase III correlation steps. Some of the Phase II tests for ammonia are the same steps that are used for Phase III confirmation procedures; therefore, tests such as spiking the effluent with ammonia and then performing the graduated pH test or spiking the post-zeolite effluent samples and then testing the samples simultaneously with the Phase II tests will support the confirmation steps in Phase III.

3.2 Toxicity Testing Concerns

A key issue in interpreting acute or chronic test results for a pH dependent toxicant such as ammonia is monitoring pH changes during the test period. Toxicity differences in Phase I manipulations may be misinterpreted simply because differences in NH, toxicity can occur with only a slight pH change. To illustrate, the change in pH from 8.0 to 7.9 lowers the concentration of NH, 20%, as does a change in pH from 6.1 to 6.0, but a 20% difference is much more important to the toxicity

Table 3-2. Calculated Un-ionized Ammonia LC50s (mg/l) Based on 24-h and 48-h Results of a *Ceriodaphnia dubia* Toxicity Test Conducted at pH 8.0 and 25°C[1]

[1]LC50s for each pH interval were calculated using EPA's water quality criteria document formula (EPA, 1985A) shown below.

$$\text{Formula } LC50 = \frac{(LC50[pH = 8.0])(1.25)}{1 + 10^{7.4 - pH}}$$

[2]The 24 h and 48 h LC50s to C. *dubia* are 1.93 mg/l and 1.49 mg/l, respectively, at pH 8.0. The formula was used to generated expected LC50s for pH values above 8, though the model is not recommended above pH 8, because generally we have found C. *dubia* data to track with these predictions.

expressed by the ammonia at pH 8.0 than at pH 6.0. For this reason frequent pH monitoring (at least daily) must be performed on tests conducted to determine the trend of ammonia toxicity. Ideally, continuous monitoring of pH is desired. The pH should be measured on each test concentration and each replicate. Experience has shown that the choice of pH meters and probes is critical to produce reliable results. The pH meter used must read accurately to two decimal places and should lock-on the stabilized reading after the rate of change has diminished to a specified rate. Routine cleaning of the probe and a standardized calibration procedure should be established. The pH values can also be recorded after an elapsed time of 60-90 sec. The pH readings should be made using a constant and reproducible stirring rate. The stirring should not result in excessive loss (or gain) of CO_2 which will of course change the pH. The choice of the pH electrode is important. We have found that the glass-bodied combination electrodes provide the most consistent pH readings. However, these should not be left in the test solutions for longer than is needed to obtain constant readings of pH because ions from the electrode reference solution can leak into the test solution, potentially causing artifactual toxicity.

For the Phase II ammonia toxicity tests more replicates (at least double that used in Phase I) must be used and tighter QA/QC procedures must be adhered to than those described in the acute or chronic Phase I manuals (see Section 1.2). For example, a control and at least four effluent dilutions using concentrations that more closely bracket the effect and no effect concentrations (that were determined in Phase I) are used. While parameters such as time to mortality or onset of symptoms in the acute and chronic tests are not an integral part of the tests described below, these observations may be very

useful in describing the identification steps used in confirming ammonia as the cause of toxicity.

3.3 Measuring Ammonia Concentration

We have found that the ammonia-selective electrode method has been satisfactory for measuring the ammonia concentrations in most samples, (EPA, 1983; APHA, 1992). Other methods for measuring ammonia are available (such as distillation, nesslerization, and titration) and can be used successfully for determining ammonia concentrations in effluents (EPA, 1983; APHA, 1992). The level of detection for total ammonia generally need not be below 0.5-1.0 mg/l, since concentrations of ≤1.0 mg/l of total ammonia have not been found to be toxic to fathead minnows and C. *dubia.* If ammonia measurements are below 1 mg/l and the sample is toxic, it is likely that the toxicant is not ammonia and other identification procedures should be pursued.

The most reliable ammonia measurements are obtained on fresh samples. However, samples can be preserved by adding concentrated sulfuric acid and storing the samples at 4°C. The pH of the preserved samples should be in the range of 1.5 to 2.0 (EPA, 1983; APHA, 1992). In recent experiments, we have used samples that were stored without acidification at 10°C or refrigerated at 4°C for short periods with good success.

During several effluent tests, the amount of ammonia in the test solutions (see test details below) has decreased over the duration of the test. When levels are in the range of O-30 mg/l, it is prudent to measure the initial concentration of ammonia in the test solution and again after animals were exposed.

3.4 Graduated pH Test

The purpose of the Phase II graduated pH test is to provide more definitive toxicity test data to implicate ammonia as the toxicant in Phase II. In turn, this data may be used in Phase III to confirm the role of ammonia in the toxicity of the effluent. More stringent pH control and pH monitoring will be needed to interpret test results and more precise toxicity estimates (i.e., more replicates, more dilutions, larger number of organisms; see Section 1.2; EPA, 1991A; EPA, 1992) are needed in Phase II than in Phase I. When it is important to predict the impact of the toxicant in the receiving water, the pH of the dilution water should be maintained at receiving water pH. The test procedures discussed below provide good pH control for the graduated pH test. Greater detail is provided for some of the procedures in Phase I (EPA, 1991A; EPA, 1992).

The test chamber size, number of dilutions, species to be tested, type of test (acute or chronic), and the degree of toxicity of the effluent will dictate the volume of effluent needed for the graduated pH test. As a general guide for acute toxicity tests, 300 ml of effluent should suffice for any of three pH adjustment tests described below. The volume for chronic tests will vary based on the type of chronic test performed, the species used, the number of concentrations tested, and number of solution renewals in addition to the items discussed above (Section 1.2 and EPA, 1992).

The procedure for conducting the graduated pH test is to evaluate and determine the toxicity of the effluent at three different pHs (e.g., 6.0, 7.0, and 8.0). The pH should be measured in all of the chambers. If the pH drifts 0.2 pH units or more, the results may not be usable and better pH control must be achieved. However, if pH fluctuates more than 0.2 pH units and toxicity is present only at one pH, the toxicity results may still be useful. The pH levels selected must be within the physiological tolerance of the test species used (which generally is a pH range of 6 to 9). We recommend use of two methods of pH control and comparison of these results to determine that the pH adjustment itself did not introduce an artifact of toxicity. This type of testing may be critical to explaining effects in Phase III (EPA, 1993A).

Regardless of the pH control method chosen, the selection of the appropriate blank is difficult. The change in pH of the dilution water or surface water is not comparable to that of the effluent because the composition of the solutions are different. For some effluents, the addition of either acid or base can be used to adjust and hold the pH within 0.1 pH unit. If this is possible, this technique can be used to compare the results with either the CO_2-pH controlled test or the buffer-pH controlled test. Test results should be similar and these comparisons can be used as a basis for identifying ammonia as a toxicant.

3.4. I *pH Control: Acid/Base Adjustments*

The first method of pH adjustment is the acid/base adjustment described in Phase I (EPA, 1991A; EPA, 1992). For this manipulation, the adjustment of pH is relatively easy and quick, and the loss of volatile compounds is minimized. However, the drawbacks are that: toxicity enhancement from the additives may occur (especially in a chronic TIE), the addition of strong acid or base disrupts the carbonate system equilibrium, the effects of the pH change in the blanks may not serve as a toxicity control for the effluent, the pH stabilization time is lengthy, and pH tends to drift in longer term tests. In the pH range 6 to 9, the amount of high quality acid or base added is usually negligible, and the likelihood of toxicity caused by increased salinity levels is low.

The pH of each concentration and replicate must be frequently monitored because a constant pH during the toxicity test must be maintained. Larger test volumes may be useful to prevent rapid pH fluctuations. The amount of acid and/or base added should be recorded for each pH adjustment to track the additive amount in the effluent samples and the blanks. If toxicity increases dramatically, the concentrations of salts should be calculated to be sure the salinity has not increased above the tolerance level for the TIE species.

3.4.2 *pH Control: CO, Adjustments*

The second method uses CO, to adjust and control test solution pH. The pH is adjusted by varying and controlling the CO, concentration of the gas phase over the water or effluent sample in closed headspace test chambers. It is necessary to maintain a constant pH throughout the test period. The pH of most natural waters and some effluents is controlled by the bicarbonate buffering system and surface waters normally contain <10 mg/l of CO,. Therefore, the amount of CO, to add depends on the desired pH and the chemistry of each test solution. The CO, adjustment has the advantages that the pH is controlled without placing additives directly into the effluent test solutions, the pH change is easy to make, and the pH is generally stable for at least 24 h if the gas-tight container is not opened. Frequent pH measurements are still possible because the headspace can be reflushed with a predetermined concentration of CO_2/air. The disadvantages are that toxicity can occur from the CO,, the concentration of CO_2/air varies for each dilution and effluent (which requires sample specific experimentation) and the manipulations for chronic tests can be time-consuming relative to the acid/base adjustment method. We have not observed any increased toxicity from the addition of CO, unless the concentration in the chamber is over 10%.

Adjustments of the pH to 6.0 or 7.0 can be made by using CO, with or without first adding HCl to the test concentrations. The CO, is purchased in pure form through local commercial gas suppliers, and if particular concentrations of CO_2/air are frequently used, a cylinder of gas of the desired concentration may prove to be resource-efficient. The amount of CO, needed to adjust the pH of the solution is dependent upon sample volume, the test container volume, the desired pH, the temperature, and the effluent constituents (e.g., dissolved solids). Some preliminary work is needed to determine the concentration of CO, to add to achieve the desired pH. When dilutions of an effluent have the same hardness and initial pH as the effluent, about the same amount of CO_2 will usually be needed for each dilution. Sometimes, higher concentrations of CO, are needed for the higher test concentrations. Use of a dilution water of similar hardness as the effluent may make the CO, volume adjustments easier. A different dilution water may only be used in these tests if the toxicity has not been shown to be dependent on water hardness at any pH.

In our laboratory, we have found that glass canning jars with rubber seals and metal balers work well as a gas-tight testing chamber. The testing chamber should be large enough to hold the desired number of test cups, with sufficient headspace to ensure proper DO levels. For example, a 2-quart glass canning jar lying on its side will easily hold 6-l oz cups. We simultaneously test *C. dubia* and fathead minnows in the same chamber using the test solution volumes described in Section 1.2. Since many plastics are permeable to CO,, glass containers are recommended. When CO_2/air is flushed into the headspace of the test chamber, the pH of the test solutions will usually reach equilibrium in about 1 h and a reliable pH can be achieved. Generally, as the alkalinity increases, the concentration of CO, that is needed to maintain the pH also increases. After 1 h, check the pH of the solutions and flush the chambers again. Check the pH again after 2-3 h and from these data determine the concentration of CO, to add for initial pH adjustment for the actual toxicity test and the amount needed for reflushing after the chamber is opened for feeding or pH measurements. In most instances, the amount of CO, produced by the test organisms will not cause further pH shifts. When testing with fish, which usually increase in size during the test, a pH fluctuation may occur that would require flushing with different (e.g., slightly lower) concentrations of CO,.

When the concentration of CO, to inject for the target pH values has been determined, prepare test solutions, add test organisms (and food if necessary) and inject the appropriate concentration of CO, in air using a l-liter gas tight syringe, and quickly close the test chamber. The chambers should be flushed with the CO_2/air mixture several times to ensure the displacement of air currently in the chambers. Place the chamber out of direct laboratory light, as temperatures tend to rise out of the desirable test range in the closed chambers.

For effluents that have initial pH values from 7.8 to 8.5, O-l 0% CO, concentration in the chamber has been used to lower the pH to 6.0. Experiments in hard reconstituted water have shown that up to 8% CO, can be tolerated by C. *dubia* and fathead minnows in acute tests, but 8% has been toxic to C. *dubia* and fathead minnows in the 7-d tests. About 2-3.5% usually will lower the pH of most effluents to 6.5-7.0. If more than 10% CO, for acute tests or 5% CO, for chronic tests is needed to lower the pH of the test solutions, before adding test animals adjust the pH with high quality acid (EPA, 1991 A; EPA, 1992) and then flush the headspace with CO_2/air. The necessary concentration of CO, to use must first be determined experimentally with effluent test solutions adjusted to the appropriate pH with acid solutions. Sometimes >5% CO_2 cannot be used for the dilution water pH adjustment test without the CO, causing toxicity.

The use of a single enclosed test chamber for controlling the pH at all test concentrations may allow the transfer of volatile compounds among treatments. We have experienced volatilization of ammonia in tests and therefore, individual test chambers for each effluent concentration are preferable. Methods that use continuous flow of a CO_2/air mixture, such as tissue cell incubators, may be preferable and give better pH control provided that volatilization or cross contamination is not a problem. At this time we have not attempted to use a continuous flow of CO_2/air mixture and therefore cannot recommend a system to use.

Maintaining pH above the air equilibrium pH (generally above pH 8.3) is difficult without buffers (Section 3.4.3). The pH control in this high range is much more difficult because the concentration of CO, must be very low and microbial respiration can increase the CO, levels in the test chamber. Use of CO,-free air in the headspace may work or flushing a mixture of CO,-free air and normal air through the headspace or test solution may be successful. Because such small CO_2 concentrations are needed and because CO, evolution by microorganisms or test organisms can significantly alter the CO, concentration, frequently flushing (two to four times a day) of the headspace in static tests will probably be required to adequately control pH. For the chronic tests, we have not attempted to use the CO,-free air bubbled through the test solution, because more CO, evolution tends to occur during the chronic tests and the need for reflushing makes the test labor intensive.

For the CO_2-pH controlled tests, the pH should be measured at least every 24 h for both acute and chronic tests and ideally, continuously during pH controlled tests. At each reading, flush the headspace with the CO_2/air mixture. A small amount of experimentation will confirm whether the concentration of CO, previously determined is adequate, or whether the amount required for flushing will be less than that used for the initial pH adjustment.

For chronic tests, daily renewal solutions should be prepared, pH adjusted with HCI if necessary, dispensed into test cups, and placed into a second glass jar chamber and flushed with appropriate concentration of CO,. These should be left to equilibrate at least 1-2 h. Measure the pH quickly and transfer the animals to new test cups and place them into the glass jar. Flush the headspace again with the appropriate CO_2/air mixture.

Table 3-5. Percent Un-Ionized Ammonia in Aqueous Solutions at 25°C and Various TDS Levels'

3000	0.0443	0.441	4.24	30.7

[1]Data from Skarheim (1973).

For the 7-d tests with fathead minnows, the chambers must be opened once more each day to accommodate the feeding schedule. The experimenter can take advantage of this by making a pH reading prior to placing food into the test cups. CO_2/air must again be flushed into the chamber. It is important to note that in the fathead minnow test, the pH most likely will be lower after 24 h than in the *C. dubia* test because of the food added and the respiration of the fish which is considerably greater than that of C. *dubia.*

Measurements of pH must be made rapidly to minimize the CO, exchange between the sample and the atmosphere. Avoid vigorously stirring unsealed samples because at lower pH values, the CO, lost during the measurement can cause a substantial pH rise. If possible, measure the DO at the same time because ammonia may have different toxicities when DO is decreased (EPA, 1985A). Keep in mind that if the test animals have been dead for awhile, the pH and/or DO of the test water most likely will have changed.

The controls in the CO, chamber and the baseline test act as checks on the general health of the test organisms, the dilution water and most test conditions. If the effluent pH in the baseline test is close to the pH of the adjusted test solutions (at their respective LC50s, IC25s or IC50s), the toxicity expressed in the two tests should be similar. Significantly greater toxicity in the pH-adjusted test may suggest interference from other factors such as the ionic strength related toxicity if the pH was adjusted with either HCI or NaOH, or possibly CO, toxicity. Dilution water blanks at the various pH levels may or may not be appropriate since the effluent matrix may differ from that of the dilution water. The dilution water blank will be useful in checking the acids and bases that are added for artifactual toxicity. Monitoring the acid and base additions may be useful in determining if artifactual toxicity resulted from the increase in salt content. Monitoring conductivity of the effluent solutions after the addition of the acids and bases may also be helpful in determining artifactual toxicity. The ionic strength of hardwaters or saline waters results in a decreased level of un-ionized ammonia (Table 3-5). For values of TDS from O-500 mg/l, the dissociation constants are expected to be more accurate than values above 500 mg/l that were based on somewhat tenuous assumptions (Skarheim, 1973; see Table 3-5).

3.4.3 *pH Control: Buffer pH Aa'justments*

The third method of pH control uses the addition of standard buffers to the effluent and dilution water to adjust the pH. This method has the advantage in that pH is stable with the buffer addition, the pH change during a test is slow, frequent pH measurements are possible because test vessels are not in air-tight chambers, and the test method set-up is rapid. The disadvantages are that toxicity enhancement or interference from buffers may occur, not all buffers can be used without additional

acid/base adjustments, and the pH stabilization time may be lengthy.

Hydrogen ion buffers are used to maintain the pH level in the graduated pH test (EPA, 1991A; EPA, 1992). Three hydrogen ion buffers were used by Neilson et al. (1990) to control pH in toxicity tests in concentrations ranging from 2.5 to 4.0 mM. These three buffers were chosen based on the work done by Ferguson et al. (1980). These buffers are: 2-(N-morpholino) ethane-sulfonic acid (Mes) (pK_a = 6.15), 3-(N-morpholino) propane-sulfonic acid (Mops) (pK_a = 7.15), and piperazine-N,N'-bis (2-hydroxypropane) sulfonic acid (Popso) (pK_a = 7.8). We have also used two additional buffers: N-(2-hydroxyethyl) piperazine-N'-2-hydroxypropanesulfonic acid (Heppso) (pK_a = 7.8) and N-tris-(hydroxymethyl) methyl-3-amrnopropanesulfonic acid (Taps) (pK_a = 8.4). The Taps buffer is more frequently used than the Heppso buffer. We have experienced problems of having to add an excessive amount of base to obtain the desired pH with the Popso buffer. The Taps buffer effectively maintains the pH above 7.8. Keep in mind that pH is best maintained at or near the pK_a of the buffer.

The acute toxicity of these buffers is low to both C. *dubia* and fathead minnows (EPA, 1991A) and 4 mM concentration or less of all five buffers has not caused chronic toxicity to *C. dubia* or the fathead minnow. The buffers are added at sublethal (e.g., NOEC) levels to maintain the pH of test solutions. While these buffers serve to prevent the pH from drifting during the test, pH adjustment to the desired level is required in the preparation of the solution. A portion of the buffer compound is weighed out and added to the aliquots of whole effluent and dilution water, and both are then pH adjusted with acid or base solutions to the desired pH values. Serial dilutions are made, replicates prepared, and test organisms are added. Care should be taken to ensure equilibrium of buff ered solutions, which may take at least l-2 h. Dilutions should also be left to equilibrate and minor pH adjustments should be made. In certain situations, it may be desirable to prepare the solutions the day before tests begin. At present, we have found we can use batch solutions prepared ahead of time for solution renewals. Our experience also indicates that the amount of any buffer needed to hold any pH is effluent specific. Experimentation with effluents will be required to determine the lowest concentration of buffer needed to maintain the desired pH. The test solutions need not be covered tightly to maintain pH; however, pH should be measured at each test reading at all dilutions.

Use of the buffers is still being developed and the effects caused by interferences from the buffers themselves have not been fully studied. It is possible that the buffers may reduce the toxicity of some toxicants, but this has not generally been seen.

3.5 Zeolite Resin Method

Zeolite is composed of naturally occurring or synthetically created crystalline, hydrated alkali-aluminum silicates. The general formula is $M^{n+}O{\cdot}Al_2O_3{\cdot}ySiO_2{\cdot}zH_2O$; M = group IA or IIA element, n = +2 for group IA, +1 for group IIA, y>2, and z = the number of water molecules contained in the interconnected voids or channels within the zeolite (Windholz, et al., 1983). When zeolite is placed in aqueous solutions, the positively charged group IA or IIA elements (M^{n+}) of the zeolite are mobile and can undergo exchange with other cations in the water. As such, zeolite has frequently been employed as ion exchange resins to remove the ammonium ion (NH,+) from aqueous solutions in TIE work (Ankley et al., 19906; Burkhard and Jensen, 1993). Because of its ability to exchange other cations such as heavy metals, and its use as molecular sieves, filter adsorbents and catalysts, zeolite was not suggested for use in Phase I, except as a subsequent test (EPA, 1991 A). Zeolite can be effective in Phase II, if Phase I results implicate ammonia as the toxicant and establish that other types of toxicants (such as non-polar organics and metals) play no role in the effluent toxicity.

For the acute TIE procedure, zeolite particles should be screened to be in the range of 32 to 95 mm, to ensure efficient ion exchange while preventing channeling or excessive resistance to flow. Extremely large or small particles can be removed by screening the zeolite with sieves or mesh screens. The zeolite column can be prepared by taking 30 g of aquarium zeolite (Argent Chemical Laboratories, Redmond, WA) and adding it to 60 ml of high-purity water. The zeolite slurry is poured into a chromatography column (11 mm i.d. x 15 cm) and three bed volumes of dilution water are passed through the column. The last 10 ml of dilution water is collected for use as a zeolite blank and should not be toxic. Next, 200 ml of 100% effluent is passed through the column at a rate of 2 ml/min. The post-column effluent that is collected will be toxicity tested and its ammonia concentration measured. Temperature and pH should be recorded at test initiation to provide the means to calculate both total and un-ionized ammonia in the sample.

For chronic toxicity tests larger amounts of zeolite should be used. This can be scaled up proportionally from the amounts used in the acute zeolite work. The amounts of solution needed for testing and ammonia measurements will dictate the amount of sample to prepare. Typically a slurry of 60 g of zeolite and 120 ml of high purity water is sufficient for levels of ammonia in the range of 5-50 mg/l and for processing 2,000 ml of effluent. The post-zeolite effluent is collected in aliquots, then each is toxicity tested. In this manner, break-through of ammonia can be measured and toxicity of the various samples with different ammonia levels can be estimated.

Toxicity tests and ammonia measurements are conducted on the effluent and post-zeolite column effluent. Removal of toxicity by the zeolite column and removal of the ammonia concentration will add to the evidence implicating ammonia as the toxicant. An aliquot of the effluent sample (not having passed through the zeolite column) is used for ammonia analysis and the baseline toxicity test. These data will be compared with the same data for the post-zeolite column effluent to determine if the post-column reduction in effluent toxicity is consistent with ammonia removal by the zeolite. The control for test organism survival, dilution water quality and other test conditions will be provided through toxicity tests on dilution water. Dilution water (at the same hardness as the effluent) should be passed through the zeolite column, and will act as a blank for toxic artifacts leached from the zeolite. Increased toxicity in the post-zeolite effluent, relative to the whole effluent, indicates the presence of toxic artifacts. Since many cations will be exchanged, adding solids in the acute tests, such as the YCT food (yeast-Cerophyl®-trout food) fed to C. *dubia*, might improve control survival. Additional clean-up techniques for the zeolite (such as Soxhlet extraction) or alternate uncontaminated sources of zeolite might be needed. Column packing, effluent pH, ammonia levels, and flow rate through the column can all affect the efficiency of the cation exchange process. Lowering effluent pH prior to zeolite treatment and/or lowering flow rate through the column might also result in greater removal of ammonia. Occluded gas between zeolite particles might also impair the column's capacity to remove ammonia. If this appears to be a problem, the zeolite slurry should be degassed by using a vacuum prior to pouring it into the column.

Zeolite columns can be regenerated, but fresh zeolite should be used to pack columns the first time. If the graduated pH test and the zeolite test results are consistent with ammonia toxicity, Phase III confirmation procedures should be started.

Once ammonia is identified and confirmation is initiated, the post-zeolite samples can be spiked with ammonia at the same concentrations as are present in the effluent. These tests are an integral part of the Phase III confirmation process (EPA, 1993A).

3.6 Air-Stripping of Ammonia

This method of ammonia removal takes advantage of the fact that the relatively volatile un-ionized ammonia (NH_3) predominates in a solution with a pH above 9.3. For this reason, one might expect that ammonia would be removed during the Phase I pH 11 adjustment/aeration test (acute testing) or the pH 10 adjustment and aeration test (chronic testing). Based on our experience ammonia is not removed by this method, most likely because the Phase I aeration manipulation is done in a graduated cylinder, which has a low surface-to-volume ratio. By stirring the sample for a longer period of time (>1 h) at a high pH (pH 9.0 or higher) in a container that allows a large surface area to volume ratio, most of the ammonia can be removed from aqueous samples.

A measured amount of effluent for subsequent analysis and testing is pH adjusted to 10 or 11 and placed into a large shallow glass container (e.g., 1000 ml crystallizing dish). The solutions are then agitated (stirred) continuously. The length of time the sample must be stirred is dependent on the concentration of total ammonia in the sample. We have found that for most samples of 10-100 mg/l of total ammonia, 1-6 h is adequate to remove most of the ammonia. After air-stripping is completed, the volume of effluent should be measured and any appreciable loss replaced with high purity water or toxicity might be caused by the concentration of other components in the effluent. The ammonia concentration should be measured immediately after air-stripping and after volume adjustment is complete to ensure ammonia levels are reduced before toxicity tests are initiated. Toxicity tests on the air-stripped solution can then be conducted for both acute and chronic TIE work. Dilution water blanks at the various pHs may or may not be appropriate since the effluent matrix will probably differ from that of the dilution water. Monitoring the acid and base additions may be useful to determine if artifactual toxicity resulted from the increase in salt content and subsequent evaporation that occurred during the air-stripping process. Monitoring conductivity of the effluent solutions after the addition of the acids and bases may also be helpful in determining artifactual toxicity. The dilution water blank should be treated in the same manner as the effluent although it may not serve as a true toxicity control for the effluent.

If the ammonia is decreased and the toxicity is reduced or absent after air-stripping, ammonia is strongly implicated as a contributing factor to the toxicity of the effluent. The results of this test should be compared with the aeration test results of Phase I, the baseline effluent test and the other graduated pH tests. Other compounds could precipitate as a result of the pH adjustment and during the air-stripping procedure. Precipitates may form during the air-stripping process and not dissolve after the volume is readjusted, leaving these compounds unavailable.

Section 4
Metals

4.1 General Overview

This section contains procedures that can be used to identify suspect metal toxicants. The initial evidence used to implicate metallic toxicants is obtained from the Phase I characterization tests, with the results of the EDTA (ethylenediamine tetraacetic acid) addition test providing the best indication of the presence of a metal toxicant. When certain cationic metal toxicants are present, a reduction in sample toxicity with the addition of EDTA should be observed. Other Phase I manipulations that remove or reduce sample toxicity and suggest the presence of a cationic metal include the sodium thiosulfate addition test, the use of a C_{18} SPE column, and filtering the sample when combined with minor pH adjustments. One additional indication of metal toxicity may be when the organisms' response in the toxicity test is atypical of the expected dose response relationship (i.e., partial mortalities in several test concentrations, Schubauer-Berigan et al., 1993B).

Subsequent Phase I tests such as using ion exchange resins might also lead one to the conclusion that a metal is the toxicant. Toxicity removal or reduction after a sample. is treated with an anion exchange resin might implicate toxicants that exist as anionic oxides in water, such as arsenic, chromium, and/or selenium. These anionic oxides will not be specifically removed or rendered biologically unavailable by the routine Phase I tests. Therefore, when the Phase I tests do not seem to show any toxicity reduction, toxicants such as these might be suspected and subsequent tests as discussed above could be useful (see Phase I, EPA, 1991A; EPA, 1992). These situations should be approached on an individual basis since other classes of toxicants might demonstrate the same behavior in Phase I (e.g., total dissolved solids (TDS)).

Further discussion and interpretation of the Phase I results which would lead to the conclusion that a cationic metal toxicant was present in a sample are provided in the Phase ! TIE documents (EPA, 1991A; EPA, 1992).

Other information, such as process details from the discharger and infcrmation from past TREs and/or TIEs, might also help to implicate cationic metals as the toxicants. However, this type of information should be interpreted and used with caution as it might bias the TIE efforts.

If the EDTA addition test in Phase I showed that toxicity was removed or reduced one should proceed to the metal analysis section (Section 4.2). This section provides guidance and recommendations for analyzing samples for metals so that a list of suspect metal toxicants can be obtained. This section also discusses clean metal techniques, detection limits, a prioritization process for analyzing for specific metals, dissolved vs biologically available metals, and provides the rationale for assembling the list of suspect metal toxicants. Prioritizing metals to analyze from Phase I results is strongly recommended in order to save money and time in the TIE process.

If other Phase I tests implicate a metal but EDTA does not, it may be helpful to acquire additional test information through the use of EDTA addition tests, sodium thiosulfate addition tests, graduated pH tests, and ion-exchange resins. This additional toxicity testing (Section 4.3) may be useful in certain situations before analyzing for metals, even when EDTA additions reduced toxicity. These situations include: when the addition tests of EDTA and sodium thiosulfate in Phase I were performed using a single sample concentration (i.e., no dilutions), when the time it takes to obtain results of metal analyses is lengthy, or when Phase I results indicate another type of toxicant (non-metal) is present. The data obtained from the additional testing can then be included in the prioritization process for metals analysis. Professional judgement is required to decide when you have sufficient and appropriate toxicity testing data to proceed to metals analysis.

After processing one sample, a list of suspects may be generated. As future samples are evaluated, the correlation between toxicity of a sample and the concentration(s) of metal(s) over time may also be used to narrow the list of suspect toxicant(In Phase III, the suspect metal toxicant is implicated based upon the correlation of effluent toxicity and metal concentrations, reference suspect metal toxicity data, the use of additives that chelate metal toxicants, and changes in toxicity observed during manipulations of water quality characteristics.

The procedures in this chapter are generally applicable for both acute and chronic toxicity. The main differences between the acute and chronic procedures are the concentrations of additives used in the EDTA and sodium thiosulfate addition tests, lower analytical detection limits, and generating non-toxic blanks for the ion exchange resins for chronic toxicity testing. The use of species other than *C. dubia* or fathead minnows will require consideration of appropriate test volumes and additive concentrations.

4.2 Analysis of Metals

4.2.1 Prioritizing Metals for Analysis

Many cationic metals can be analyzed in a specific sample, but to simplify the amount of analytical effort needed for metals analysis, we suggest a prioritizing process be performed before analyzing any samples. The prioritization process is more valuable when the metal analyses are performed by AA instrumentation since each metal requires an individual analysis. Conversely, with ICP (inductively coupled plasma) instrumentation, numerous metals can be analyzed at once, and the prioritization process is less valuable in this instance. With both ICP and AA methods, a list of metals and required levels of detection will be needed before the samples are analyzed.

This prioritization is based primarily upon acute toxicity data with C. *dubia.* Its applicability to chronic toxicity and other species is expected to be similar but has not yet been determined. The toxicity test results from the EDTA additions, sodium thiosulfate additions, and graduated pH tests performed in Phase I form the basis for prioritization. When available, Phase II results from using the procedures in Section 4.3, should be included in this evaluation. Because we do not have a complete understanding of the effects of these procedures for each metal, the following should be taken as a starting point for metals analysis.

Information regarding historical discharge monitoring data, past or current TRE and/or TIE information, or process information may be useful in prioritizing metals for analysis. For example, if a discharger uses zinc in their manufacturing process and EDTA removed the toxicity, it would be logical to analyze for zinc first. If zinc was present at nontoxic concentrations or at concentrations too low to cause the observed toxicity, analysis for additional metals would be performed. If zinc was present at concentrations high enough to cause the observed toxicity, Phase III procedures (EPA, 1993A) should then be started to confirm zinc as the identified suspect toxicant.

When EDTA additions reduce or remove the toxicity of the sample, initially copper, lead, cadmium, nickel, and zinc should be measured. When sodium thiosulfate additions reduce or remove the toxicity of the sample, copper, cadmium, and silver should be measured.

Phase I results would not normally lead to the conclusion that an anionic toxicant was present (i.e., cationic metals that exist in aqueous samples as anionic oxides). If additional Phase I tests had been performed which characterized anionic toxicants or other specific discharger information was available, measurements of arsenic, chromium, and selenium should be made.

As stated above, these metals should be a starting point for metals analysis. Further interpretation of the Phase I results could be done by including the results of the graduated pH test and by jointly examining the results of the EDTA addition, thiosulfate addition, and graduated pH tests.

When multiple toxicants of different classes are present, Phase I data are often difficult to interpret. One should try to identify and confirm as soon as possible the role of one toxicant when multiple toxicants are present. By defining the role of one toxicant, efforts can be better focused on the remaining unidentified toxicants.

4.2.2 Metal Analysis Methods

There are three types of chemical instrumentation available for the analysis of cationic elements; these are AA, inductively-coupled plasma-atomic emission spectroscopy (ICP-AES), and inductively-coupled plasma-mass spectrometry (ICP-MS).

EPA methods using ICP-AES, ICP-MS, and AA (EPA, 1983; EPA, 19910) are available for quantifying cationic metals in aqueous samples. Tables 4-l and 4-2 summarize method detection limits for the analysis of cationic metals in aqueous samples using AA with direct aspiration, AA with the furnace procedure, ICP-AES, and ICP-MS.

The detection limits required in Phase II for the identification of suspect cationic metal toxicants will be determined by the toxicity of metals for the TIE species. In some cases, especially for chronic toxicity, the effect level might be lower than the detection limits listed in Tables 4-1 and 4-2. Detection limits should be improved to obtain optimal levels of detection (i.e., at least two times lower than the effect level).

Toxicity data for some species and test types for many metals have not been determined, especially for 7-d chronic toxicity tests. Therefore, to determine the needed levels of detection, effect levels for specific metals may have to be determined.

The required level of detection will often dictate the method needed for performing the metal measurement. It will be beneficial for laboratories to compile a database containing method detection limits and toxic effect levels for cationic metals using data from their organisms, analytical methods, and toxicity testing conditions. These data are not necessary in advance but this

Table 4-1. Atomic Absorption Detection Limits and Concentration Ranges'

Metal	Direct Aspiration		Furnace Method[2]	
	Detection Limit (mg/l)	Optimum Concentration Range(mg/l)	Detection Limit (µg/l)	Optimum Concentration Range (µg/l)

Zinc	0.2	2

[1] The estimated instrumental detection limits are taken from EPA, 1991 D. They are given as a guide for instrumental limits, the actual detection limits are sample dependent and may vary as the sample matrix vanes.
[2]The estimated instrumental detection limits as shown are taken from EPA, 1983. They are given as a guide for an instrumental limit. The actual method detection limits are sample dependent and may vary as the sample matrix varies.
[3]Highly dependent on operating conditions and plasma.

type of information will be very useful for future TIE efforts.

When toxicity effect levels appear to be below the detection limits of current analytical methods, the use of "clean" analytical techniques may be required through all steps in the analysis of the sample because background contamination is the major cause of inadequate levels of detection. Some general principles of clean metal techniques include the use of contamination free reagents, acid cleaned plastic labware, acid cleaned membrane filters (not glass fiber), class 100 benches for sample preparation, proper sample collection, preservation, and storage procedures; and proper QA/QC procedures using blanks, spiked matrixes, and replicate analyses. A summary of clean metal techniques and procedures for lowering the levels of detection can be found in Nriagu et al., 1993; Patterson and Settle, 1976; and Zief and Mitchell, 1976.

Some cationic metals, such as arsenic, selenium, and chromium, have different stable oxidation states in aqueous samples and more importantly the different oxidation states may have different toxicities. In Section 4.23, procedures to determine the concentration of the different oxidation states are provided.

In some TIEs, a measurement of the metals associated with the suspended solids may be needed

(Section 4.2.4). Procedures for preparing suspended solids removed by filtration for metals analysis are available; see EPA method 200 (EPA, 1983) and EPA method 200.2 (EPA, 19910).

4.2.3 *Metal Speciation*

The procedures suggested above (Section 4.2.2) are used to determine the total concentration of a metal in an effluent. Many metals exist in water in different forms due to the various stable oxidation states of the metal. Arsenic (As^{3+}, As^{5+}), chromium (Cr^{3+}, Cr^{6+}), and selenium (Se^{4+}, Se^{6+}) are important metals that exist in different forms in water. Determining the speciation for these metals may be important in the TIE since the toxicities are different for the various forms of each metal. For example, Cr^{6+} is the form that is of toxicological concern while Cr^{3+} is generally not toxic (EPA, 1985D).

For chromium, methods for measuring the hexavalent form (Cr^{6+}) such as method 218.5 (EPA, 1983) are available. The amount of the trivalent form of chromium (less toxic form) is determined by taking the difference between the concentrations for total and hexavalent chromium.

For arsenic, the method of Ficklin (1983) is suggested for speciation measurements. This method uses an anion-exchange resin to separate the arsenite (As^{3+}) and arsenate (As^{5+}, more toxic form) species. Graphite furnace atomic-absorption spectroscopy is then used to measure the concentrations of each form.

For selenium, the method of Oyamada and lshizaki (1986) is recommended for speciation. This method (like that for arsenic) uses column chromatography with an anion-exchange resin to separate the selenite (Se^{4+}) and selenate Se^{6+} (more toxic form) and graphite furnace atomic-absorption spectroscopy to measure each form.

Ion chromatography can also be used to determine the different forms of the above metals (EPA, 1991 D), but we have not used this technique to date.

4.2.4 *Identification of Suspect Metal Toxicants*

Initial implication of suspect metals based on a comparison of total metal analyses data and effluent toxicity test results should be made. Then analysis for dissolved and suspended metals can be made if necessary. These metal values should be compared to available toxicity values, but tests on reference metals might have to be conducted with matching effluent conditions, such as pH and hardness to obtain comparable toxicity values. Side-by-side tests with individual reference metal standards and effluent samples might prevent being mislead by different test designs and are worth the effort. Literature summaries of metal toxicity data are also available (EPA, 1980; EPA, 19858; EPA, 1985D; EPA, 1985E; EPA, 1985F; EPA, EPA, 1986; EPA, 1987; EPA, 19888; and AQUIRE, 1992). In addition to matching the hardness and pH of the dilution water to the effluent sample by the addition of the appropriate ratios of magnesium carbonate and calcium carbonate, it might be possible in some cases to mimic the wastewater total suspended solids (SS) and total organic carbon (TOC) in the water used to test the metal. For example, TOC and SS from the addition of the YCT food can be at levels such that the total SS level in the dilution water might be similar to that found in the effluent. TOC may also be modified by the addition of humic acid. If the dilution water does not closely match the effluent, nonstandard dose-response relationships are observed in the toxicity test, i.e., several test concentrations exhibit partial mortality. In addition, a trend is noticed that as metal concentrations decrease at the effluent LC50s or IC25s, toxicity of the effluent increases.

If a sample is to be filtered, a membrane filter(s), such as a 0.45 µm polycarbonate filter should be prepared by rinsing with high purity water, followed by an appropriate volume of dilution water needed for blank toxicity tests and analysis. The toxicity test guidance is described in Section 1.2 and in the Phase I documents (EPA, 1991 A; EPA, 1992). An appropriate quantity (<50 ml) of the last portion of the high purity water passing through the filter should be collected as an analytical blank to check for metals contamination from the filter and the filtration apparatus. An aliquot of the effluent is then filtered through the 0.45 µm membrane filter(s). If more than one filter is required for the effluent, a portion of each can be combined for testing.

The filtered and unfiltered effluent samples and the filtration blank should be tested for toxicity to measure the effect of filtration on sample toxicity. The toxicity test techniques are described in the non-polar organic section (Sections 2.2.3 and 2.3.3) unless data are needed for Phase III confirmation and then, greater replication and randomization will be needed (see Section 1.2). The toxicity tests should be performed for the test species using a dilution water (e.g., reconstituted water) of a similar hardness and pH to that of the effluent. If toxicity is reduced or removed upon filtration (and effluent toxicity has not previously been affected by C_{18} SPE or filtration through a glass fiber filter), it is possible that metals were retained by the 0.45 µm filter. Analysis for metals retained by the filter may help in interpreting sample data.

Metals analyses should be performed on the analytical blank collected from the filter and on the filtered and unfiltered effluent samples. The choice of metals to measure will be determined by the prioritization process described above. As stated previously, the level of detection for the metal of interest should be lower than the effect concentration for the metal.

Biologically Available Metals: Traditionally, dissolved metals for aqueous samples have been defined as those that pass through a 0.45 µm membrane filter, i.e.,

polycarbonate filter. The dissolved metals are in no way synonymous with the *biologically available metals.* Other than the use of an aquatic organism there is no technique to determine the biologically available fraction of the total metal. Furthermore, only rudimentary techniques are available to specifically identify the individual species of a metal (e.g., free charged metal ions [M^{n+}], inorganic ion pairs or complexes such as aquoions, [$M(H_2O)^{n+m}$], hydroxoions [$M(OH)_p^{n-p+}$], oxoions [MO_q^{n-2q+}], organic complexes and chelates [M x EDTA], metal species bound to high molecular weight organic material [M x lipid] or metal species in the form of highly dispersed colloids or sorbed on colloids [M x clay]). Stumm and Morgan (1981) have listed some general methods for assisting in identification of individual species. In some cases, binding of metals to inorganic and organic ligands in effluents will reduce the bioavailability of the metals and cause the metal concentration at the effluent LC50, IC50, or IC25 to be larger than the metal concentration determined in the metal dilution water toxicity test. For a set of effluent samples with a wide range of toxicities, better agreement should occur between the effect concentration of the metal in a dilution water toxicity test and the more toxic effluent samples (where the toxicity testing matrix of the effluent more closely matches that of the dilution water). Methods for determining the bioavailable fraction of the total metal are limited.

Some indication of the binding of metals to organics in the effluent may be arrived at through hexane extraction of an aliquot of the sample (Stary, 1964). Theoretically, metals bound to organic materials that are soluble in hexane should be extracted from the effluent. The hexane can then be evaporated and the residue reconstituted and analyzed for metals. Additionally, the loss of metals can be estimated by repeating the metal analysis on the extracted effluent and comparing this result to the hexane extract results. The toxicity attributed to metals associated with organics might be estimated by performing a toxicity test on the solvent extracted effluent. Traces of hexane must be removed from the extracted effluent by aeration prior to toxicity testing. The effects of aeration on sample toxicity must also be considered in this analysis. In any case, metals strongly suspected of causing or contributing to sample toxicity should be tested in dilution water as described above with the TIE test species.

The effects of variable water quality characteristics on metal toxicity must be evaluated over the effluent sampling period. One way to assess this is to collect several samples over a short time span. As an example, for an acutely toxic effluent, collect six grab samples in 24 h, and calculate the correlation coefficient for sample metal concentration (or summed toxic units of metals) versus sample toxicity for each sample. The set of correlation coefficients for multiple sampling events might give results less affected by hardness, SS, and TOC, assuming that water quality characteristics affecting metal toxicity will vary less during short time periods. For chronic toxicity, it might be useful to measure concentrations of metals in several daily samples and conduct separate chronic tests on each sample. Obviously, metal concentrations must vary enough to provide a sufficient range for correlation. When one reaches this stage, Phase III work should start using Phase III methods. Symptoms, species sensitivity, spiking, water quality adjustments and correlation are all applicable Phase III approaches to confirm the cause of toxicity.

4.3 Additional Toxicity Testing Methods

Guidance on EDTA addition tests, sodium thiosulfate addition tests, graduated pH tests, and the use of ion-exchange resins for use in Phase II are presented in this section. These procedures might be used before performing analyses for cationic metals, but most often they will be used to refine a list of suspect metal toxicants and to provide data to support the identified suspect in Phase III.

In the acute Phase I, EDTA and sodium thiosulfate addition tests can be conducted by adding incremental amounts of EDTA or sodium thiosulfate to a, single effluent concentration. To provide further evidence in Phase II, these two tests should be conducted with effluent dilutions to assess the toxicity reduction (see EPA, 1992). The data generated from these procedures provide a powerful tool for identifying the cause of toxicity in samples containing mixtures of cationic metals. For example, toxicity caused by either copper or zinc could be determined by using the following test information: toxicity of both metals would be removed by EDTA addition (Section 4.3.1), sodium thiosulfate can remove toxicity caused by copper but not zinc (Section 4.3.2), and copper is more toxic at higher pH levels while zinc is not (Section 4.3.3). Depending on how the toxicity of the sample changes with these tests, one could eliminate one of these metals from the list of suspect metal toxicants.

Results of this type of testing will be used to develop evidence implicating the identified suspect metal. These tests would be performed on a number of samples over time to demonstrate the consistency of the cause of toxicity. In addition, when a mixture of toxicants is present, additions of EDTA or thiosulfate could be used to remove the cationic metal toxicity after performing other Phase II manipulations, e.g., C_{18} SPE.

4.3.1 *EDTA Addition Test*

Any reduction in effluent toxicity effected by the addition of EDTA suggests that certain cationic metals might be present in the effluent at toxic levels. Background information and discussion of the behavior of EDTA and cationic metals can be found in Phase I (EPA, 1991A; EPA, 1992).

Ideally, the amount of EDTA added would be just enough to chelate the toxicant(s) without causing EDTA

toxicity or substantially changing the water quality. For either C. *dubia* or fathead minnows, we have found it useful to add two different EDTA concentrations to two separate effluent tests (with dilutions). Controls without EDTA must be included. The EDTA stock solution is added after the effluent dilutions are prepared so that the EDTA concentration is the same at each effluent dilution (see Phase I, EPA, 1991A; EPA, 1992).

In Phase II, conducting simultaneous EDTA addition tests on effluent and the suspect metal in matching test water can provide evidence supporting the suspect metal as the toxicant if the results of these two tests are similar. If the metal is chelated by EDTA in the dilution water test but not in the effluent test then either there is a strong matrix effect from the effluent or it is the incorrect suspect metal. It is important to use the same pH in both tests in case there is any pH effect on the metal's toxicity.

In addition to removing toxicity caused by metals, EDTA reduces the acute toxicity of some cationic surfactants. This reduction of toxicity might also occur in chronically toxic effluents, and the toxicity reduced by EDTA should not be assumed to be due only to cationic metals.

4.3.2 *Sodium **Thiosulfate** Addition Test*

The acute Phase I oxidant reduction test (EPA, 1991A) or the chronic sodium thiosulfate addition test (EPA, 1992) is used to determine to what extent constituents reduced by the addition of sodium thiosulfate ($Na_2S_2O_3$) are responsible for the effluent toxicity. Although the use of the sodium thiosulfate test was designed to determine if oxidative compounds (such as chlorine) were responsible for effluent toxicity, experience has also shown that thiosulfate can also form a stable non-toxic complex with some metals. Since the complexing ability of thiosulfate is more metal specific than EDTA, this reagent can be used to determine if a specific metal is responsible for the effluent toxicity. Recent work by Mount (1991) has shown that in acute toxicity tests with C. *dubia* in moderately hard water that Cu^{2+}, Cd^{2+}, Hg^{2+}, Ag+, and Se^{6+} can be complexed using sodium thiosulfate (see EPA, 1991 A for more details). This complexing ability might not be applicable to chronic toxicity. For example, in a C. *dubia* 7-d test with copper, the toxicity was not reduced with sodium thiosulfate addition but was reduced with EDTA addition.

Table 4-3. Metal LC50s with Respect to Test pH[1]

Metal	Species	LC50 (µg/l) pH 6.2	pH 7.2	pH 8.2
Zn	C. dubia	>530	360	95
	P. promelas	830	333	502
Ni	C. dubia	>200	137	13
	P. promelas	>4000	3360	3080
Pb	C. *dubia*	*280*	>2700	>2700
	P. promelas	*810*	>5400	>540
cu	*C. dubia*	10	*28*	*201*
	P. promelas	*15*	*44*	>200
Cd	C. *dubia*	*563*	*350*	*121*
	P. promelas	*54*	*74*	<5

[1]LC50 values were determined at 48-h for *C. dubia* and 96-h for *P. promelas.* Data taken from Schubauer-Berigan et al., 1993A.

If the addition of sodium thiosulfate does not reduce the effluent toxicity thought to be related to metals, the use of SO, (EPA, 1991A) additions followed by the addition of sodium thiosulfate is recommended. In some situations, the thiosulfate concentration may be reduced by non-toxic oxidants and thus, not be available for complexing the toxic metal. The addition of SO should preferentially reduce these non-toxic oxidants which will allow the now available thiosulfate to complex the toxic metals. Depending upon the complexation ability of sodium thiosulfate for a specific metal, it might or might not complex the toxic metal. If the suspected metal toxicant can be complexed (e.g., cadmium, copper, selenium (as selenate), mercury; see EPA, 1991A; EPA, 1992), then a reduction in sample toxicity should occur with the addition of sodium thiosulfate. If the suspected metal cannot be complexed (e.g., zinc, lead, manganese, and nickel), then no reduction in sample toxicity should occur with the addition of the sodium thiosulfate.

As with the EDTA addition test, sodium thiosulfate additions should be conducted concurrently on the effluent and on dilution water spiked with the suspect metal toxicant. Care must be used to conduct these tests at similar pH levels. When toxicity test results are consistent with the expected behavior, strong evidence relating the suspected metal toxicant to the cause of the effluent toxicity has been obtained. These results in conjunction with the ion exchange test, analytical measurements for toxic metals, and the EDTA addition test provide evidence sufficient for one to proceed to toxicant confirmation, Phase III, of the TIE.

Both sodium thiosulfate and EDTA can reduce the toxicity of some metals and this information can be helpful in identifying the toxicant. However to date, this effect of thiosulfate/metal complexation has not been demonstrated for chronic toxicity. Knowing which metals are bound by both sodium thiosulfate and EDTA and which metals are complexed with only one or the other additive can be very helpful in narrowing down the possible toxicant.

*4.3.3 Metal Toxicity Changes with **pH***

In Phase I, the graduated pH test is performed to evaluate the presence of compounds whose toxicity varies with pH. For ammonia, toxicity is greatest at pH 8.5 and least at pH 6.5 for some species. Therefore, as suggested in the first Phase II document, that for samples in which toxicity is enhanced at elevated pH, the identification effort should focus on ammonia. However, some

effluent and sediment pore water TIEs have indicated that some toxicity caused by metals can be affected by pH within the range of pH 6 to 9 (Schubauer-Berigan et al., 1993A). Some metals, notably zinc, nickel and cadmium, exhibit greater toxicity at elevated pH, which could confuse their characterization with that of ammonia (Table 4-3), while copper and lead show elevated toxicity at pH 6.2. These pH-dependent toxicities can be used as a tool for the identification (and confirmation) of toxicity caused by these metals. For example, toxicity to *C. dubia* in a sediment pore water sample was completely removed by additions of EDTA. The sample also exhibited greater toxicity at pH 6.5 than at 8.5, and metal concentrations indicated that only copper was present at toxicologically significant concentrations. The pH dependent toxicity of the sample along with the EDTA addition results and metal analysis supported the identification of copper as the toxicant.

4.3.4 *Ion-Exchange Test*

Ion-exchange resins have been used in TIEs for generating supporting evidence for identifying the cause of toxicity in effluents (Doi and Grothe, 1989; Phase II zeolite test). For cation exchange resins, removal of toxic cations such as NH,+, Cd*+, and Pb^{2+} from the effluent occurs with the corresponding release of cations (i.e., counter ions) such as H^+ and Na^+ into solution. Similarly, for anion exchange resins, removal of toxic anions such as $Cr_2O_7^{2-}$ and AsO_4^{2-} from the effluent occurs with the corresponding release of anions such as OH- and Cl- into solution. For both cation and anion exchange resins, charge neutrality exists between the resin and aqueous phase and therefore, if the resins remove 5 µmoles of Cd^{2+} from solution, 10 µmoles of H^+ would be released into solution. The exchange process is concentration dependent and is reversible. Cations removed from the solution may then be recovered from the exchange resin by passing an acidic solution over the resins (e.g., 1 N HCl for analysis of metals).

We have had limited experience with ion exchange resins but the following general guidance can be provided. First, ion exchange resins are not chemical specific but rather remove a wide range of cations or anions, metallic and non-metallic. We have observed that anion exchange resins can remove cations (e.g., Zn^{2+}) from solution quite efficiently. The reasoning that only cationic materials are removed by cation ion exchange resins is not always reliable. Experimental verification of which materials were removed by the resin will be necessary on a case-by-case basis. Second, wide changes in the pH of the post-column effluent can occur depending upon the type of cation or anion released by the resin. These changes in pH will cause problems in interpreting toxicity tests if the pH is not adjusted prior to the toxicity test. Third, many of the ion exchange resins are based upon a styrene or acrylic divinylbenzene backbone and this material can remove other types of toxicants such as non-polar organics. Consequently, because of its non-specificity the removal of toxicity by an ion exchange column should not be used as the only piece of evidence to implicate a metal as the toxicant.

Resins under evaluation and/or those which have been used include IRA-35, IRA-68, IRA-94, IRA-900, IRC-718, and GT-73 (Rohm and Haas, Philadelphia PA) and aquarium zeolite (Argent Chemical Laboratories, Redmond WA). The key to obtaining useable data from an ion exchange test is to obtain non-toxic blanks. Since numerous ion exchange resins exist, guidance for preparing all resins for TIE work cannot be provided. A variety of procedures have been used in our laboratory to condition the columns and to obtain non-toxic blanks.

Effluent volumes ranging from 1,000 to 10,000 ml have been used, and the volume is dependent on the hardness of the dilution water, bed volume of the column, strength and type of the ion change resin, which ions were being exchanged, the toxicity of the effluent, and the species being tested. For example, for acutely toxic effluents, glass chromatography columns (11 mm i.d.) are packed with about 10 cm of resin and the solutions are pumped up through the column at a flow rate of 4 to 5 ml/min. First, a small volume of high purity water (e.g., 200 ml) is passed through the column, and discarded. Next, the dilution water (volumes are variable, i.e., 1 ,000-5,000 ml) is passed through the column until the pH of the post-column dilution water is above 7.0.

Following this procedure, the necessary volume of dilution water to use for toxicity testing is passed through the column and collected. The type of dilution water to use is effluent specific and in general, should be the same as the dilution water used in the toxicity test for the effluent. The pH of the post-column dilution water should be monitored and the pH adjusted to return the water solution to its original pH. Toxicity tests are then performed on the post-column dilution water sample (column blank). After obtaining non-toxic blanks for a particular batch of resin, the conditioning process can be used on other aliquots of the resin with a similar procedure; however, column toxicity blanks must always be tested.

To identify acute toxicity, we generally begin by using 200 ml of effluent (filtered or unfiltered) and collect the post-column effluent. The pH of the post-column effluent is checked and if necessary the pH is adjusted to that of the baseline test, and tested for toxicity. For chronic toxicity, the volume of effluent needed for the toxicity test will dictate the amount of resin and the size of the column. When evaluating a new resin, use proportions of water, effluent, and resin, similar to those described above for acutely toxic effluents. New aliquots of resins should be prepared and used for each ion exchange test. By doing so, artifactual toxicity problems

from other effluents and sample manipulations can be avoided.

We have had limited success in the elution of the ion exchange resin to recover the exchanged toxicant(therefore, we cannot provide specific guidance. in theory, cations and anions can be eluted **from ion exchange** resins using a strong acidic (HCI) or basic (NaOH) solution. Performing successful toxicity testing on these solutions is extremely difficult because of artifactual toxicity problems.

When toxicity is removed by the ion exchange test, useful information about the toxicant(s) may be obtained. However, as discussed above, the removal of a toxicant by the column may not be as straightforward as first perceived. The use of other manipulations and analytical measurements on the pre- and post-column effluents will be required to establish the significance of the results of the manipulation.

When toxicity is not removed by the ion exchange test and non-toxic blanks are obtained, the conclusion that the toxicant is not a cation or anion can be made. However, the slight possibility exists that the resin may not be able to exchange the toxicant because of steric and size considerations.

Section 5
Chlorine

5.1 General Overview

One of the first analytical measurements recommended in the Phase I documents (EPA, 1991A; EPA, 1992) upon arrival at the laboratory is for total residual chlorine (TRC) in each effluent sample. Chlorine is a commonly used biocide and oxidant and is frequently found at acutely toxic concentrations in municipal effluents (EPA, 19856). Sublethal chronic toxicity from chlorine in effluent samples is not as likely to occur due to the degradation of chlorine (see below) with holding of the sample. Chlorine is unstable in aqueous solutions and decomposition is more rapid in solutions when chlorine is present at low concentrations. From the TRC measurement and the Phase I tests (sodium thiosulfate addition and aeration tests), further steps to identify the effects that might be due to chlorine can be taken. Oxidants other than chlorine occur in effluents and the removal of toxicity by the addition of sodium thiosulfate does not prove that chlorine was the cause of effluent sample toxicity.

Molecular chlorine or hypochlorite dissociates into free aqueous chlorine, hypochlorous acid, and hypochlorite ion when added to effluents. Chlorine can also combine with ammonia to form chloramines, i.e., mono- , di-, and tri-chloramines and with organic compounds, especially organic nitrogen (APHA, 1992). The measured total residual chlorine (TRC) of an effluent is the concentration of free and combined forms (mentioned above) added together. The portion of the TRC associated with an individual form is matrix dependent. Chlorinated industrial and wastewater effluents normally contain only the combined form of chlorine (APHA, 1992).

These various forms of combined chlorine may have different effect concentrations for toxicity, and the toxicities of these individual forms are not all known for acute or chronic toxicity to *C. dubia* or fathead minnows. However, while the TRC level in the effluent samples may be the same, the concentration of the various forms may be different because of the matrix inherent to the effluent. This matrix of TRC may also be variable from sample to sample for the same discharger.

Another complication is that current analytical methods for measuring TRC are not chlorine specific. Other oxidizing compounds, e.g., bromine, iodine, hydrogen peroxide, ozone, and manganese, will be quantified as chlorine by the analytical methods for measuring TRC and may provide the analyst with a false positive for chlorine.

5.2 Tracking Toxicity and TRC Levels

Several methods are available for measuring total TRC (EPA methods 330.1, 330.2, 330.3, 330.4, and 330.5 (EPA, 1983)). Measurements of TRC in the effluent upon arrival of the sample at the laboratory should always be made. If TRC is not detected, chlorine should not be considered a suspect toxicant since the analytical methods do not yield false negatives.

For acutely toxic effluents, grab samples both before and after the chlorination process should be collected simultaneously (i.e., within minutes of each other). Upon arrival of these samples at the laboratory, a baseline toxicity test should be initiated and at pre-determined intervals after day 1 (e.g., day 2, day 3, day 5, day 8) to evaluate whether the toxicity is degrading. TRC determinations should be performed in conjunction with each toxicity test.

Generally the TRC in most effluent samples stored at 4°C degrades in 2 to 5 d after collection. Therefore, if residual chlorine is a toxicant the toxicity of the post-chlorination sample should decrease as TRC levels decrease, and pre- and post-chlorination samples should have the same toxicity after the decay of TRC.

The toxicity of chlorine in an effluent sample will be dependent on the matrix of the effluent and the species tested. If chlorine toxicity data does not exist for the species being used, it will be necessary to measure the LC50 or IC25 of chlorine using the TIE organisms and dilution water. Using those LC50 and/or IC25 values, the comparison of TUs of the effluent to the TUs of residual chlorine is useful to evaluate the effects of the TRC. When the TU comparison data and pre- and post-chlorination toxicity data indicate TRC as a suspect toxicant Phase III procedures should be initiated.

With the measurable levels of TRC at sample collection, the loss of toxicity with the corresponding decreasing levels of TRC, and the pre- and post-chlorina-

tion samples exhibiting similar toxicity with the decrease in TRC, Phase III confirmation should begin (EPA, 1989.6; EPA, 1993A). However, these steps will not insure that the toxicant is chlorine since other oxidants will be detected by the TRC measurement techniques.

Section 6
Identifying Toxicants Removed by Filtration

6.1 General Overview

If the results of Phase I tests indicate that the filtration manipulation removed or reduced toxicity, the investigator should carefully compare these results to those of the other manipulations before trying to identify the toxicants that might be on the filter. We have observed that metals, non-polar organic compounds and volatile compounds can all be removed under certain filtering conditions, but these observations have been dependent on the individual effluent or the sediment pore water samples. Other Phase I manipulations (e.g., EDTA, C_{18} SPE extraction) can lead to subsequent Phase II identification steps. However, for toxicity reductions effected by filtration, more intermediate steps of Phase I type manipulations must be done before analytical procedures are used to identify the toxicant(In addition, some other manipulations may provide specific information regarding the identity of toxicants that may have been removed by filtration; these include additions of PBO (Section 2.5.1), the graduated pH test (Phase I tests for determining toxicity caused by ammonia, metals and ionizable organic compounds), and the sodium thiosulfate test (Phase I test for detecting toxicity caused by volatile oxidants such as chlorine or metals). If one or more of these manipulations removes toxicity, then identification work should proceed as described in the previous sections to identify the cause of toxicity.

It is important to consider that all toxicity removed by filtration may not be actually removed by the process of filtering. For example, when the pH of the sample is altered, the mechanism(s) for removal by filtration can change. While ammonia is predominantly ionized at a sample pH of 8.3, the ammonia would not tend to be removed through volatilization if a vacuum was applied for filtration purposes. Yet by adjusting the sample pH to 11, the ionized ammonia concentration decreases to 1.7% at 25°C. When a sample is adjusted to a pH of 11, volatilization of a toxicologically significant amount of the un-ionized ammonia could occur and the toxicity results would indicate that filtration removed toxicity. Also, changes in speciation at elevated pH render many metals insoluble, which could result in their removal by the filter at pH 11 (Schubauer-Berigan et al., 1993B).

If the toxicant is thought to be a non-polar organic toxicant, and filtration partially removes toxicity, it may be useful and save toxicity testing time to eliminate the filtration step altogether before applying the sample to the C_{18} SPE column (discussion in Section 2.2.2 and Section 2.3.2).

6.2 Filter Extraction

When filtration has been the only manipulation to affect the toxicity, then extraction of the filters and tracking the toxicity of the extracts should be attempted. In addition, the use of other types of filters should be evaluated (i.e., nylon, teflon, and polycarbonate) to see if toxicity removal is a function of the filter type. In using the extraction procedures, the idea is to separate the toxic compounds associated with the filter by extracting them into a solvent. Next, efforts are made to concentrate the toxic compounds in the filter extract and test them at a concentration that can be related to the original sample and evaluate the efficiency of the extraction. Identifying the filter-removable contaminants without additional information can be difficult because of the lack of specificity of the filtration process. But once a suspect candidate has been discovered, then measurements can be made to determine whether a toxicologically significant concentration of the suspect toxicant(s) had indeed been removed by filtration. If this is the case, then it may not be necessary to consider further extractions of the filters. If, however, the concentrations of the suspect toxicant(s) are not decreased after filtration then it may be useful to attempt additional identifications by solvent extraction of the filters as described below.

One technique we have used with filterable toxicity is to extract the filters with either polar or non-polar solvents. To remove toxicants from the filter we have used either organic solvents (methanol, methylene chloride) or pH 3 high purity water as the extraction solvent. The solvent is then toxicity tested to track toxicity (methylene chloride must first be exchanged into methanol), additional Phase I tests are performed to characterize the filter extract, and then chemically analyzed using Phase II procedures. It is important to remove all of the methylene chloride before toxicity testing a filter extract and these procedures are described in detail in Section 2.6.2. To date, methanol has been used to extract toxicity from filters used with effluent samples and methylene chloride/ methanol solutions have been used to extract filters from

sediment pore water. The experiences described below are based on acute toxicity experiments, and efforts to recover filterable toxicity for chronically toxic effluent have not yet been needed.

To isolate a toxicant removed through filtration, several filters can be combined and extracted simultaneously if necessary. **The volume of sample passed** through the filters is important for calculating concentration factors, and should be recorded. The filtrate should also be reserved **for toxicity comparisons and analytical** testing. Sufficient sample should be passed through the filter to allow for both toxicity testing and chemical analysis on both the filtered sample and the filter-extract solution (generally >200 ml). Carefully move the filters to a glass (acid leached) or plastic beaker, then soak the filters (l-5) in 20 ml of solvent for 1 h. Cool water sonication is optional to attempt to recover particle-associated compounds. Carefully remove the filters and save (store at 4°C) in case additional extractions are necessary. If pH 3 high purity water is used as the extraction solvent, the extract should be readjusted to the initial pH of the sample, then toxicity tested. If methanol is used, it is evaporated to -2 ml under a stream of nitrogen. Be careful to rinse the sides of the containers with methanol to ensure complete solubilization of organic compounds. This methanol solution can then be toxicity tested using SPE fraction testing procedures (Section 2.2.8). Alternatively, if a methylene chloride/methanol solvent is used, the solvent should first be exchanged into pure methanol (Section 2.6.2), then treated as the methanol extract described above. The concentration of the solvent extract will depend on the volume originally passed through the filters, which depends on the desired high test concentration, and the volume of extract and filtered sample required for analytical purposes. Blank filters (through which has been passed a volume of dilution water) should be extracted and tested identically to the sample filters to ensure that the solvents do not introduce artifactual toxicity.

For any of the extraction techniques, the solutions should be tested at the same time as the baseline test (unfiltered) and filtered sample test to compare the toxicity recovered by the filter extraction with that removed from the sample.

Another option for toxicants removed by filtration is to try other techniques to remove the toxicants which avoid filtration. For example, sediment **pore water samples have been centrifuged at relatively high speeds** (10,000-20,000 g) for 30 min prior to passing the sample over the C_{18} SPE column and filtration could thus be eliminated.

Filter extractions (EPA, 1991 A) have been **used** in several sediment TIE studies, with procedures suggested for both non-polar organics and metals (Schubauer-Berigan et al., 1990; Schubauer-Berigan and Ankley, 1991). In some effluent and pore water samples, toxicity thought to be caused by non-polar organic compounds (e.g., PAHs and polymers) has also been removed by filtration. These compounds may be associated with particulate material, and be physically filtered from the sample, or removed by association with oil and grease that sorbs to the filter.

In some cases, binding of metals or organic compounds to inorganic and organic ligands in effluents or sediment pore waters will reduce their bioavailability and when toxicity testing filter extracts, it is always a concern that the matrix of the sample has been removed and that chemicals might become available when they were not in the original sample. If this were to happen, the extracts might be more toxic than expected and chemicals might be added to the suspect toxicant list erroneously. This kind of mistake should be caught by obtaining a good toxicity value for the suspect in an appropriate matrix (more detailed discussion in Section 26.1). Therefore, additional confirmation steps might be needed to eliminate the false suspects.

Foreword

This Phase III document is the last in a series of guidance documents intended to aid dischargers and their consultants in conducting aquatic organism toxicity identification evaluations (TIEs). TIEs might be required by state or federal agencies as the result of an enforcement action or as a condition of a National Pollutant Discharge Elimination System (NPDES) permit. These documents should aid individuals in overseeing and determining the adequacy of effluent TIEs as a part of toxicity reduction evaluations (TREs).

There are two major reasons to require the confirmation procedures. First the effluent manipulations used in Phase I characterizations (EPA, 1988; EPA, 1991 A; EPA, 1992) and Phase II identifications (EPA, 1989A; EPA, 1993A) might (with some effluents) create artifacts that might lead to erroneous conclusions about the cause of toxicity. Therefore in Phase III confirmation steps, manipulations of the effluent are avoided and/or are minimized, therefore artifacts are far less likely to occur. Sometimes, toxicants will be suspected through other approaches (such as the treatability route) which on their own are not definitive and in these instances, confirmation is necessary. Secondly, there is the probability that the substances causing toxicity might change from sample to sample, from season to season or some other periodicity. As toxicity is a generic measurement, measuring toxicity cannot reveal variability of the suspect toxicant whereas the Phase III confirmation procedures are designed to indicate the presence of variable toxicants. Obviously, this crucial information is essential so that remedial action may be taken to remove toxicity.

Confirmation, whether using the procedures described in this document or others, should always be completed because the risk is too great to avoid or eliminate this step. Especially for discharges where there is little control over the influent or for discharge operations that are very large or complex, the probability that different constituents will cause toxicity over time is great. Most of the approaches in Phase III are applicable to chronically toxic effluents and acutely toxic effluents.

In this confirmation document, guidance is included when the treatability approach (EPA, 19898; EPA, 1989C) is taken. Use of the treatability approach requires confirmation as much as or more than the toxicant identification approach (Phase II). The reader is encouraged to use both the acute Phase I characterization (EPA, 1991 A) and the chronic Phase I characterization (EPA, 1992) documents for details of quality assurance/quality control (QA/QC), health and safety, facilities and equipment, dilution water, sampling and testing. The TIE methods are written as general guidance rather than rigid protocols for conducting TIEs and these methods should be applicable to other aqueous samples, such as ambient waters, sediment elutriate or pore waters, and leachates

Abstract

In 1989, the guidance document for acutely toxic effluents entitled *Methods for Aquatic Toxicity Identification Evaluations: Phase III Toxicity Confirmation Procedures* was published (EPA, 19890). This new Phase Ill manual and its companion documents (EPA, 1991 A; EPA, 1992; EPA, 1993A) are intended to provide guidance to aid dischargers in confirming the cause of toxicity in industrial and municipal effluents. The toxicity identification evaluation (TIE) starts with a characterization of the effluent toxicity using aquatic organisms to track toxicity; this step is followed by identifying a suspect toxicant(s) and then confirming the suspect toxicant as the cause of toxicity.

This Phase III confirmation document provides greater detail and more insight into the procedures described in the acute Phase III confirmation document (EPA, 1989D). Procedures to confirm that all toxicants have been correctly identified are given and specific changes for methods applicable to chronic toxicity are included. Adifficult aspect of confirmation occurs when toxicants are not additive, and therefore the effects of effluent matrix affecting the toxicants are discussed. The same basic techniques (correlation, symptoms, relative species sensitivity, spiking, and mass balance) are still used to confirm toxicants and case examples are provided to illustrate some of the Phase III procedures. Procedures that describe the techniques to characterize the acute or chronic toxicity (EPA, 1988) and to identify (EPA, 1989A) toxicants have also been rewritten (EPA, 1991 A; EPA, 1992; EPA, 1993A).

Acknowledgments

This document presents additional information acquired since the document entitled *Methods for Aquatic Toxicity Identification Evaluations: Phase III Toxicity Confirmation Procedures* (EPA-60013-88-036; EPA, 1989D) was prepared by Donald Mount and published in 1989. This manual reflects new information, techniques, and suggestions made since the Phase III confirmation methods for acute toxicity were developed. The suggestions, techniques and cautions contained in this document are based on a large database generated by the staff of the National Effluent Toxicity Assessment Center (NETAC) at the U.S. Environmental Protection Agency (EPA), Environmental Research Laboratory, Duluth (ERL-D), MN. NETAC staff that provided technical support consisted of Penny Juenemann and Shaneen Schmidt (ERL-D staff), Joe Amato, Lara Anderson, Steve Baker, Tim Dawson, Nola Englehorn, Doug Jensen, Correne Jenson, Jim Jenson, Elizabeth Makynen, Phil Monson, Greg Peterson, and Jo Thompson (contract staff). Their collective experience has made this document possible and the contributions are gratefully acknowledged. The support through EPA's Office of Research and Development (ORD) and Office of Water made this research possible at ERL-D.

Section 1
Introduction

The final confirmation phase of a toxicity identification evaluation (TIE) consists of a group of steps intended to confirm that the suspect cause(s) of toxicity is correctly identified and that all the toxicity is accounted for. Typically this confirmation step follows experiments from the toxicity characterization step (Phase I) and analysis and additional experiments conducted in toxicity identification (Phase II) (EPA, 1991A; EPA, 1992; EPA, 1993A). However, there often may be no identifiable boundary between phases. In fact, all three phases might be underway concurrently with each effluent sample and depending on the results of Phase I characterization, the Phase II identification, and Phase III confirmation activities might begin with the first sample evaluated. Phase III confirmation procedures should also follow after toxicants have been identified by other means or when treatability approaches are used. Rarely does one step or one test conclusively prove the cause of toxicity in Phase III. Rather, all practical approaches are used to provide the weight of evidence that the cause of toxicity has been identified. The various approaches that are often useful in providing that weight of evidence consist of correlation, observation of symptoms, relative species sensitivity, spiking, mass balance estimates and various adjustments of water quality.

The approaches described in this document have been useful in TIEs at ERL-D. While the guidance provided in this manual is based largely on experience with wastewater effluents, in general the methods discussed are applicable to ambient waters (Norberg-King et al., 1991) and sediment pore or elutriate water samples as well (EPA, 1991B). However, specific modifications of the TIE techniques might be needed (e.g., sample volume) when evaluating these other types of samples.

Confirmation is important to provide data to prove that the suspect toxicant(s) is the cause of toxicity in a series of samples and to assure that all other toxicants are identified that might occur in any sample over time. There may be a tendency to assume that toxicity is always caused by the same constituents, and if this assumption carries over into the data interpretation but the assumption is false, erroneous conclusions might be reached. That is why the correlation step (Section 2) is accompanied by other approaches (i.e., Sections 3-9) because each approach aids in revealing any changes in the toxicant(s) in the confirmation phase of the TIE.

Seasonal trends in toxicants have been observed in publicly owned treatment works (POTW) effluents and some sediment samples. For example, organophosphate pesticides have been observed to increase in concentrations in wastewaters during the late winter and spring months (Norberg-King et al., 1989). Therefore, the confirmation steps of Phase III might need to include seasonal samples. This effort cannot always be pre-determined. The presence of a different toxicant(s) must be considered throughout the TIE, and when samples are collected over several months the seasonality of a suspect toxicant should be carefully considered and studied. When remedial action requires treatment changes, one must be certain that toxicity from specific toxicant(s) is consistently present and that the suspect toxicant(s) accounts for all the toxicity. Treatment modifications will not necessarily result in removal of all toxicants to acceptable concentrations. If toxicity is caused by a variety of toxicants present at varying intervals, the remedial actions that are practical might differ from the remedial action required when toxicity is caused by the same constituents consistently.

TIEs conducted at ERL-D have shown that toxicants often are not additive or toxicants are present in ratios such that the toxicity contribution by one might be diluted out in the range of the effluent effect concentration (e.g., LC50 or ICp value). Thus, the toxicant present at lower yet toxic concentrations may not be readily discerned. The frequency of occurrence and impact on data interpretation of either of the above cases was not addressed previously (EPA, 1989D) but are now discussed in Section 2. Toxicants that do not express their toxicity because of the presence of other toxicants (either the toxicants are non-additive or the toxicants occur in disparate ratios) are referred to as hidden toxicants (Section 9). Detection of hidden toxicants is one of the most difficult aspects of confirmation. It is a mistake to search for a concentration of any chemical present in the effluent at a toxic concentration and to declare any found as the cause

of toxicity. Matrix effects of the effluent samples make conclusions such as these subject to error without further work as either the hidden toxicant(s) or the principal toxicant(s) are likely to be missed using such an approach.

There is a strong tendency to shorten or eliminate the confirmation steps because by the time Phase III confirmation has been reached, the investigators might be convinced of the cause of toxicity and the confirmation steps seem redundant. However, one cannot expect to concentrate the effluent on a C_{18} solid phase extraction (SPE) column and not change a complex mixture such as effluents, and arrive at some false conclusions about the toxicants in the earlier phases.

Not all approaches discussed in the following sections will be applicable to every effluent, and additional approaches might need to be developed during the TIE. The various approaches need not be performed in any particular sequence, and the list of possible approaches will get larger as experience is gained. To effectively evaluate effluent samples from one particular discharger to obtain a correlation, substantial calendar time could be required and any steps for correlation should be initiated at the beginning stages of Phase III. Judgement must be made as to how many of the approaches described in Phase III confirmation should be used and how many samples for each should he completed. How completely Phase III confirmation is done will determine the authenticity of the outcome. The amount of confidence in the results of the TIE that is required is dependent at least in part on the significance of the decision that will be based on the results. For example, if a suspect toxicant can be removed by pretreatment or by a process substitution, a higher degree of uncertainty may be acceptable than if an expensive treatment plant is to be built. Such considerations are subjective and cannot be reduced to a single recommended decision making process with a specified number of samples.

Time and resources might be conserved if identification (Phase II) and confirmation (Phase III) can be started on the very first effluent sample used in the Phase I characterization. However, this is only possible when the results from the Phase I characterization are definitive enough to allow the investigators to proceed to identification and confirmation. In the acute Phase III confirmation document (EPA, 1989D), although perhaps not explicitly stated, performing Phase I characterizations on several samples before attempting Phases II and III was implied. Initiating the Phase III confirmation steps earlier in the TIE is often particularly useful. In addition, many regulatory agencies have adopted a policy that requires that the previous TIE approach be modified. For some dischargers, action might be required after the first exceedence in toxicity, which means that each effluent sample collected for toxicity testing is of equal regulatory concern when the toxicity is greater than the permit allows. This regulatory practice was not in place in 1989 when the earlier TIE guidance was available (EPA, 1989D) and at that time we did not expect that the cause of toxicity in one sample could be sufficiently deduced as we have been able to do. The importance of confirmation on several samples is not reduced by the importance of conducting confirmation steps on single samples; rather, the cause of toxicity for each sample must be confirmed.

In addition to the importance of each sample with toxicity greater than the allowable amount specified in a permit, a sample that is quite different from the previous samples must be evaluated to determine if the data point must be included in the Phase III correlation final data analyses. For each effluent sample, the data points must be explainable. If one sample is quite different than other samples it can cause the correlation to be less useful; however, if it can be shown to have a different toxicant the data point for that sample can be eliminated from the correlation. For example, suppose five consecutive samples during a Phase III evaluation exhibited toxicity that correlated well with a suspect toxicant. Then a sixth sample exhibits greater toxicity than previous samples while the measured concentration of the suspect toxicant is much lower than measurements on previous samples. In this sixth sample, the greater toxicity is thought to be caused by a different toxicant. Now in plotting the data for the correlation (Section 2), the datum point for the sixth sample will not be similar to the points for the existing regression and could render the correlation non-significant. If however, when the sixth sample is then subjected to intensive study using Phase I characterization and Phase II identification techniques, and if another toxicant is identified (or even if Phase I only shows that the toxicity has very different characteristics), datum for the sixth sample can legitimately be excluded from the correlation. This preserves the worth of the data for the previous five samples. In confirmation, every effort should be made to determine why a particular sample shows different responses in the various TIE steps from other samples.

This is not to imply that multiple effluent samples need not be subjected to Phase I manipulations, even if Phase II and/or Phase III are initiated on the first sample. Most effluent samples tend to be representative of the routine effluent discharge. However, determining what is the characteristic discharge for each effluent is important to the final success and completeness of the TIE.

When Phase III is completed, all results that were obtained during the TIE should be explainable. Unless the results make sense for all samples (aside from an occasional aberrant data point) something has been missed or is wrong. If so, the confirmation is not complete. Many techniques used in Phase III require keen observations and extensive or broad knowledge of both chemistry and toxicology but above all the ability to synthesize small bits of evidence in a logical sequence is essential. This TIE work is most effective when scientists interact daily.

A note of caution. If data obtained on early samples during Phase I are to be used for Phase III purposes, quality control will have to be suitable to provide defensible data (cf., EPA, 1991A; EPA, 1992; EPA, 1993A). In Phases I and II, the permissibility of using small numbers of animals and replicates, and omitting measurements such as pH, DO, and temperature that are required for routine monitoring tests or single chemical tests was discussed (EPA, 1989E; EPA, 1991 A; EPA, 1992; EPA, 1993A). These modifications were made to reduce cost and allow more testing, but at this point shortcuts must be avoided because definitive data that constitute the basis for important decisions are generated in Phase III. For Phase III testing, the effluent test protocols that triggered the TIE (EPA, 1991C; EPA, 1993B) should be followed, paying careful attention to test conditions, replicates, quality of test animals, representativeness of the effluent samples tested, and strict QA/QC analytical procedures including blanks and recovery measurements. Analytical work must be selective for the identity of the toxicant and its concentration measurement. When small differences in toxicity must be detected, concentration intervals should be smaller to obtain partial effects (e.g., use dilution factors of 0.60 or 0.65 versus 0.5). Remember, all of the data from Phases I and II (for either acute or chronic toxicity) are considered preliminary relative to Phase III data. However, if a suspect toxicant is identified and Phases I and II data may be necessary for confirmation, stricter QA/QC can be applied for each of the subsequent Phases I and II techniques so that the data can be used in Phase III.

For samples exhibiting chronic toxicity, modifications or 'changes to some of the TIE procedures are required for confirming the cause of chronic toxicity. Remember that for confirmation (as well as for Phases I and II), only a single sample of effluent should be used for each renewal in any chronic test (cf., EPA, 1992; EPA, 1993A). This is important because one cannot correlate a measured concentration of a toxicant with the toxicity measured in a test if multiple samples are used for each renewal and the toxicant is not present in some samples but other toxicants appear. Even more likely, the ratios of the toxicants, when more than one is present, might change from sample to sample. In these instances, there is no valid way to calculate the toxicity of a given toxicant. Overall, considerations for chronic toxicity tests in Phase III are not much different than acute toxicity tests in Phase III. At present, permit requirements specify the 7-d test and unless data are gathered to show that the 4-d and 7-d tests yield the same results and that the same toxicants are involved, the 7-d test should be used for confirmation (cf., EPA, 1993A). If the 4-d *Ceriodaphnia dubia* test has been used instead of the 7-d *C. dubia* test (see EPA, 1992) during Phases I and II, serious consideration should be given to returning to the 7-d test for Phase III.

When identification of the toxicant(s) causing chronic toxicity is desired, and the effluent also exhibits acute toxicity, it might be possible to use acute toxicity as a surrogate measure to characterize the toxicity in Phase I and assist in an identification in Phase II. It must be demonstrated that the cause of the acute toxicity is the same toxicant(s) as the toxicant(s) causing the chronic toxicity. Yet for confirmation, use of chronic toxicity endpoints to confirm the cause of the chronic toxicity is strongly recommended to avoid misleading the TIE results when using acute toxicity as a surrogate for chronic toxicity. As discussed in the chronic Phase I manual (Section 5.8; EPA, 1992), effect levels for chronic tests should be calculated using the linear interpolation method rather than the hypothesis test (EPA, 1992). In order to get more precise estimates of endpoints, test concentration intervals might have to be narrowed (see above). However, when point estimation techniques for other than survival endpoints (such as the inhibition concentration (ICp); EPA, 1993B) are used, a point estimate effect concentration can be estimated. The effect concentration estimates will also be more accurate when intermediate concentrations are used (i.e., use dilution factors of 0.6 or 0.65).

Section 2
Correlation Approach

2.1 Correlation

The purpose of the correlation approach is to show whether or not there is a consistent relationship between the concentration of suspect toxicant(s) and effluent toxicity. For the correlation approach to be useful, the toxicity test results with the effluent must demonstrate a wide range of toxicity with several effluent samples to provide an adequate range of effect concentrations for the regression analysis. For sediment samples, spatial variability might be used to perform correlation analyses (EPA, 19916).

The effluent effect concentration (i.e., LC50 or ICp) data and the measured toxicant concentration data must be transformed to toxic units (TUs) for the regression analysis to evaluate whether or not a linear relationship exists. Effluent TUs are obtained by dividing 100% by the effect concentration expressed in percent of the effluent (cf., EPA, 1991A; EPA, 1992). The suspect toxicant concentration is converted to TUs by dividing the measured toxicant concentration by the LC50 or ICp for that toxicant (data to make this comparison might have to be generated; EPA, 1993A). If more than one toxicant is present, the concentration of each one is divided by the respective LC50 or ICp value and the TUs can then be summed (cf., discussion below for non-additive toxicants).

Most of the effluents we have tested have exhibited a wide range of toxicity with several different samples and therefore the data can be used in the correlation approach. Typically for the correlations that we have conducted, the data used are from toxicity tests without any manipulations and from chemical measurements on the effluent samples for the concentrations of the suspect toxicant. However for effluents where ammonia was the cause of the toxicity, the effluent toxicity. results have not varied in toxicity enough, nor have the ammonia concentrations fluctuated enough to use the data in a correlation. Also, when the effect concentration is greater than 1 00%, this information is not useful since the data point cannot be included in the regression analysis. However, when samples are marginally toxic or when the suspect toxicant concentrations do not vary enough from sample to sample (i.e., ammonia is cause of toxicity), changes in toxicity can be induced by sample manipulation (cf., EPA, 1993A) and this toxicity data can be used to develop a different type of correlation. For example, the toxicity of a given amount of total ammonia can be changed by over an order of magnitude by altering the pH of aliquots of the effluent within an acceptable physiological range (e.g, pH 6 to 9). For some metals and some species, the toxicity can also be changed by adjusting the pH and using dilution waters of varying hardness. This type of data is useful in the correlation step as providing additional weight of evidence. Therefore, the idea of minimal manipulation(s) and any risk of creating artifactual toxicity are off set by the utility of the data.

An example of the regression from an effluent from a POTW in which the suspect toxicant was diazinon is given in Figure 2-l. The independent variable (x-axis) is the TUs of diazinon and the dependent variable (y-axis) is the effluent TUs. The solid line is the observed regression line obtained from the data points, and the dashed line is the expected or theoretical regression line. If there is 1 .O TU of the toxicant in 100% effluent, then the effluent should have 1 .0 TU (i.e., the LC50 =100%). Likewise for 2.0 TUs of suspect toxicant, the effluent TUs should be 2.0, et cetera. Thus, the expected line has a slope of one and an intercept of zero. In Figure 2-1, the intercept (0.19) is not significantly different from zero and the slope is very close to 1 (1.05). The r^2 value is 0.63 which, while not high, indicates that the majority of the effluent toxicity is explained by the concentration of the toxicant. As the r^2 becomes lower, less confidence can be placed on slope and intercept. In a small data set such as this, one datum point that had 5.0 TUs for the effluent toxicity lowered the r^2 value substantially. As discussed in Section 1, if an intensive effort had been expended on that sixth sample and another toxicant(s) had been found, this particular datum point could have been excluded and the r^2 value would have been higher.

In another POTW effluent, diazinon was also the suspect toxicant. For these data (Figure 2-2), the slope is 1.38, the intercept is 1.24 and the r^2 value is only 0.15, which all indicate poor fit for diazinon as the only toxicant. The low r^2 value indicates a large amount of scatter, therefore little can be inferred from the slope and the intercept. Based on this correlation, we returned to Phase II analytical procedures and identified two other organophosphates (chlorfenvinphos (CVP) and malathion). Toxicity data indicated that CVP was present at toxic

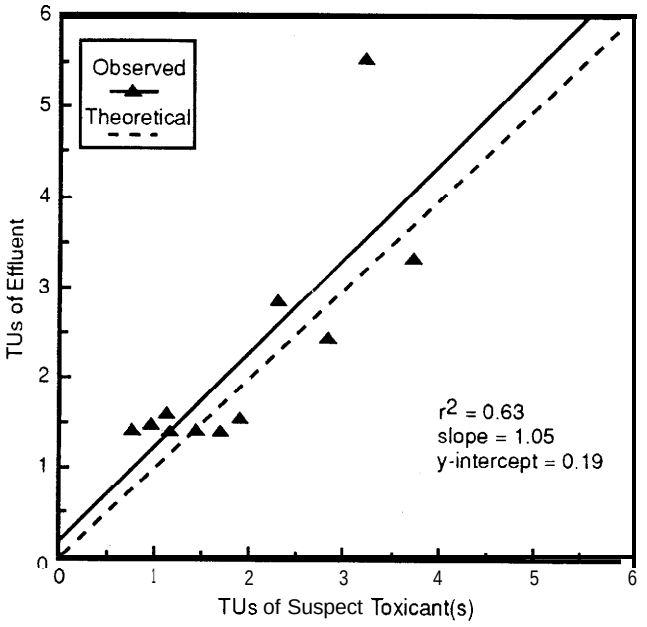

Figure 2-1. Correlation of toxic units (TUs) for an effluent and one suspect toxicant in POTW effluent.

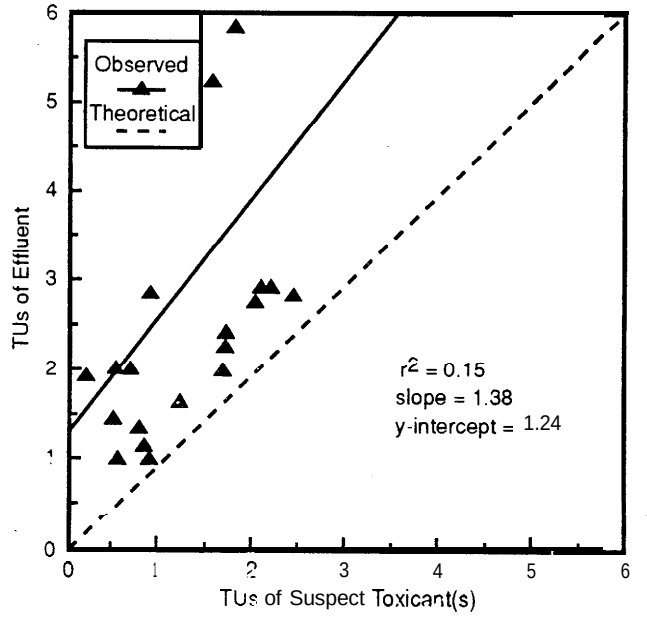

Figure 2-2. Correlation of toxic units (TUs) for an effluent and cne suspect toxicanr in a POTW effluent when two toxicants are the cause of toxicity.

concentrations while malathion was no?. After testing each compound both separately and as a mixture, the toxicity from all three chemicals was determined to be additive, so a new correlation was begun with analytical measurements made for all three chemicals. CVP and diazinon have nearly identical LC50 values for the species (C. *dubia*) used in this TIE. Malathion is about one-fourth as toxic as CVP or diazinon. Since the measured concentrations of malathion were lower than its toxicity, it was not included in the regression analysis. In a new correlation with data for the TUs summed for CVP and diazinon versus the effluent TUs, the data show a much better fit to the expected slope and intercept and a high r^2 value (Figure Z-3). Malathion TUs could also have been included in the regression (although its contribution to toxicity was minimal) because it was additive with other toxicants. This type of situation is discussed below.

In addition to slope and intercept, some judgement of the scatter about the regression line must be made. This can be done statistically, but when the sample size is large, the scatter can be very large and yet not negate the relationship. A-suggested approach to avoid the effect of sample size on the significance of scatter is to set a lower limit on r^2. This value (often expressed as percent) provides the measure of how much of the observed effluent toxicity is correlated to the measured toxicant. It is not dependent on choosing the correct effect concentration of the toxicant. The specific choice of the minimum value of r^2 should be made based upon the consequences of the decision. It is important to recognize that experimental error makes an r^2 value greater than 0.80 or 0.85 difficult to obtain. Therefore, where minimal chance of an incorrect decision is required, an r^2 value of nearly 0.80 may be used. Where an increased risk of an incorrect decision (i.e., a lesser amount of the toxicity accounted for) is acceptable, a lower value such as 0.60 may be used.

Since <1.O TU cannot be directly measured in the effluent, such values are, of necessity, excluded from the regression. (This comment is exclusive of the use of concentrates such as the C_{18} SPE fractions' where TUs of <1.O are possible.} However in some instances, when the TUs based on chemical analyses are <1.O TU and effluent effect values are <1.0 TU, the data support the validity of the regression provided a suspect toxicant has been found in several previous samples. In the correlation for the effluent toxicity depicted in Figure 2-2, toxicity was present in a different fraction (Phase II non-polar organic identification) than where the pesticides were identified. A specific toxicant was not identified in that fraction and toxicity was not always measurable in that fraction. However, this additional toxicity may have decreased the r^2 value.

Correlation might be more definitive when two or more toxicants are present. For example, suppose three toxicants are involved. If each toxicant has the same LC50 and each is strictly additive with the ratio of their concentrations remaining the same, the slope will be the expected but the intercept will be positive if all toxicants

[1]TUs can be calculated from toxicity tests with the fractions, the concentrate or the HPLC fractions as described in Phase II (EPA,' 1993A).

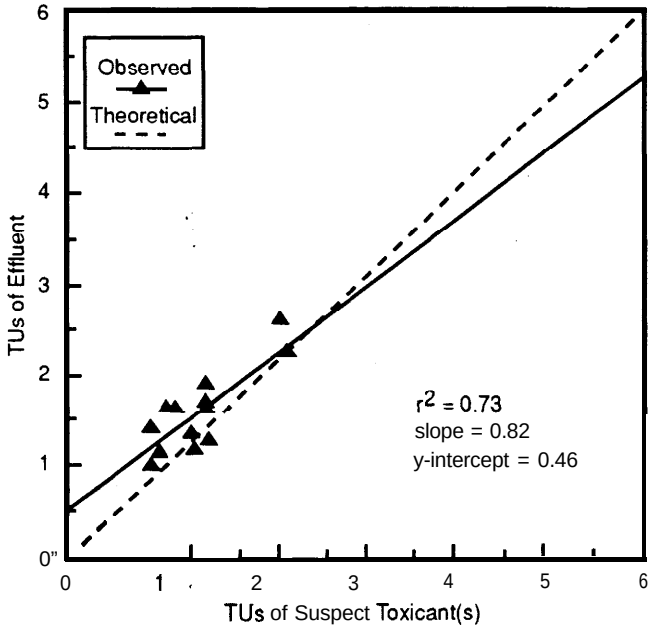

Figure 2-3. Correlation of toxic units (TUs) for an effluent and two toxicants in a POTW effluent.

are not identified. If the relative amounts (ratios) of each toxicant vary from sample to sample, the slope, intercept and r^2 will be different from the expected if only one toxicant is identified. If the toxicity of one of the toxicants is substantially different, and if the ratios of the three toxicants vary from sample to sample, then the slope, intercept, and r^2 value will all be different from expected if all are not identified. Much can be learned from studying the interrelationship of slope, intercept and the r^2 value. For example, a high r^2 value and an intercept near zero with a slope larger than 1 can be caused by using an effect concentration for the toxicant that is not appropriate for the toxicant in the effluent matrix (e.g., suspect toxicant is more toxic in effluent matrix than in single chemical test). This error causes the toxicant TUs to be too few relative to the effluent TUs (Figure 2-4) (cf., discussion below on non-additive toxicants). If toxicant concentrations and effluent toxicity show a wide distribution, a significant correlation will be easier to demonstrate than for a narrow range.

Great care must be taken to understand whether or not toxicants are additive or if the TUs for each toxicant are so different that only one toxicant determines the effect level. For either situation, the resulting data will have to be interpreted as though the toxicants are non-additive. For example, suppose the ratio of TUs is so disparate that at the effluent effect concentration, the toxicant with fewer TUs is always present at a fraction of a TU (e.g., 0.25 of a TU). Whether the two toxicants are additive or not is irrelevant because the major toxicant will set the effluent effect concentration. While 0.25 TUs of the minor toxicant appear to be relatively unimportant in view of experimental variability, this affects the regression. If in one sample the effect concentration is 25% and the 4 to 1 ratio of toxicants occurs, there are 4 TUs of the major toxicant and 1 TU of the minor toxicant. If the toxicant concentrations are summed, 5 TUs will be plotted against 4 effluent TUs, and this results in a 25% error. When secondary toxicants are present in concentrations that will not contribute to the effect concentration of the effluent, they should not be included in the correlation data set. Obviously if an effluent had several toxicants in dissimilar ratios, the error of including the minor TUs in a correlation plot could be large and may negate the correlation significance. The investigator should evaluate the data in regression plots to consider the significance of the contribution of the secondary toxicant especially if the toxicants appear to be additive.

Unfortunately the minimum fraction of a TU that is detectable will depend on the precision of the laboratory performing the testing. And of course the precision of the testing is not only dependent on the quality of the work, but the inherent precision of measuring specific toxicant TUs. That is, the toxicity measurement for some chemicals is more precise than for some other chemicals. In general, a chemical such as NaCl whose toxicity is generally not affected by pH, alkalinity, hardness, total organic carbon (TOC), suspended solids or solubility, can be measured more precisely than a chemical whose toxicity is affected by these factors, such as lead or copper. Therefore, each laboratory must determine which fractional value of a TU at the effect concentration is unmeasurable, thus indicating which TUs contributed by the minor toxicant should be deleted from the correlation data set.

Clearly, if two or more toxicants are strictly non-additive, then only the major one (the one present in the most TUs) should be included in the correlation data set. Since additivity might be easier to measure than the minimum measurable contribution of a fraction of a TU, it may be preferable to first determine if additivity occurs. If substances appear to be partially additive, then very careful work is required to properly add TUs.

Some very unusual decisions are required in accepting data into the correlation database when toxicants are strictly non-additive. For example, consider zinc and ammonia in the same effluent sample; we have found them to be strictly non-additive. Also consider that in some samples zinc and ammonia occur in TU ratios of 3 to 1 and in other samples the ratio is 1 to 2. In the regression for the 3 to 1 ratio samples, only zinc TUs should be plotted. In the regression for the 1 to 2 ratio samples, only ammonia TUs should be plotted. For this particular example, 3 TUs for the first sample and 2 TUs for the second sample would be used if the data is interpreted correctly (i.e., plotting total TUs) or 4 and 3 TUs would be used respectively, if the data is interpreted

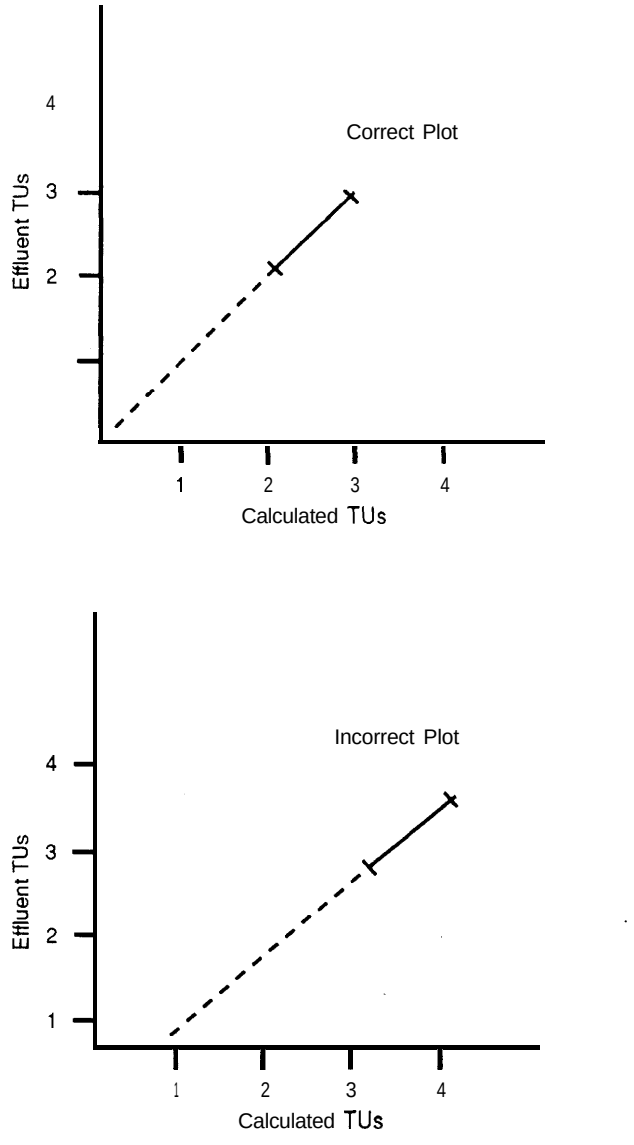

Figure 2-4. Correct (top) and incorrect (bottom) plots of toxic units (TUs) for non-additive toxicants.

incorrectly. The slopes for both plots would be 1 but a negative intercept instead of an intercept of 0 would be obtained for the incorrect plot. The more similar the TUs of each toxicant are to each other, the greater the error in the correlation will be.

2.2 Correlation Problems Caused by Matrix Effects

Correlation becomes much more difficult when the toxicants interact with the other effluent constituents in ways that change their toxicity and we refer to these changes as matrix *effects*. There are numerous matrix effects and all of them will not be discussed here; instead a framework is provided to aid in designing tests or test conditions to validly incorporate matrix effects in such a manner that useable correlation data can be obtained.

Matrix effects generally fit into one of two categories. One category is when the toxicants change form in some manner which exhibit a different toxicity. A very common example is ammonia which changes from NH_3 to NH_4^+ as pH decreases. NH_4^+ is so much less toxic than NH_3 that it is often considered nontoxic? Another example is HCN whose most toxic form is as un-dissociated HCN, a form predominating at low pH values. As pH increases the equilibrium shifts to more H^+ and CN^-. If metals are present, metal-cyanide complexes form which are often less toxic than HCN but metal-cyanide complexes might vary in toxicity depending on the metal. For example, iron-cyanide complexes are much less toxic than some of the other metal complexes. Metal-cyanide complexes might also photodecompose in sunlight releasing HCN or H^+ and CN^-, depending on pH.

A second category of matrix effects involves such physical changes as sorption or binding in some manner so as to make the toxicant unavailable to the organism. For example, non-polar organics sorb onto suspended solids, and some metals, such as copper, also sorb onto suspended solids. The presence of organic matter on suspended solids might increase the sorbtive capacity. Predictably, changes in water chemistry often change the sorption/solution equilibrium and thereby, change the portion of total toxicant that is available to the organism.

To further complicate matters, biological characteristics of the test organisms might change the availability of the same toxicant form. For example a non-polar organic sorbed on suspended solids such as bacterial cells, might be unavailable to a fish but readily available to daphnids because cells might be ingested and digested by daphnids. The uptake route then is through the digestive tract but the toxicant has entered the body none-the-less.

From the above discussion, it is obvious that one method of correlation will not be applicable for all toxicants. A temptation may be to remove the toxicant from the effluent and then use the effluent as a diluent to measure toxicity. However, because effluents are so complex and undefined, there is virtually no way to remove one or a few constituents and still be certain other characteristics have not been changed. For example, zeolite removes ammonia but it also removes some metals and non-polar organics; the C_{18} resin removes metals as well as non-polar organics; ion exchange columns remove ionized constituents, but non-polar organics also are retained by the columns. Toxicant removal procedures have utility but require very complicated simultaneous testing of the effluent and proper blanks (cf., EPA, 1992; EPA,

[2]See specific discussion in Section 3, Phase II (EPA, 1993A).

1993A) is necessary to properly interpret results (cf., Section 9 on hidden toxicants).

In Phase III, quantitative comparisons are being made between toxicity and concentrations of toxicants rather than qualitative comparisons as in Phases I and II (EPA, 1991A; EPA, 1992; EPA, 1993A). In the correlation approach, such comparisons are the essence of the technique. Therefore even small changes in form or availability might be unacceptable. This means that manipulations and changes must be minimized when effluent toxicity and toxicant concentrations are to be compared.

Solvent extraction, so commonly used for organic analyses, is likely to extract biologically unavailable organics as well as soluble forms. The total measured concentration may be larger than the true exposure concentration. Use of the C_8 SPE column also is not free from problems as the C_{18} SPE column is a finer filter than the glass fiber filters commonly used for pre-column filtration. Therefore solids are likely to be physically retained on the upper part of the column. When the column is eluted with methanol, the methanol extracts toxicant(s) from the solids (which might not be biologically available) as well as elutes the C_{18} sorbent itself. For Phases I and II, this might be unimportant, but for the Phase III correlation step where careful quantitative comparison is necessary, the effect might be unacceptable. Such problems probably reach a maximum when working with samples such as highly organic sediment pore water (with high organic characteristics) where much of the chemical might be biologically unavailable.

The central problem for either type of matrix effect is the difficulty of analytically measuring the biologically available portion of the specific toxic form. A correlation for a POTW effluent where for nickel was suspected of causing the toxicity is shown in Figure 2-5. During Phase I, the acute toxicity was removed with EDTA additions, and in Phase II the nickel was measured at toxic concentrations to C. *dubia.* The toxicity correlated very well with total nickel concentration (r^2 = 0.89 and a slope of 1 .17) and it appeared that only nickel seems to be involved. But the intercept of -12.34 is quite different from the expected zero. Such an intercept would be expected if there were a relatively fixed amount of nickel which was not biologically available in all samples. In this example, because all other confirmation data corroborated nickel as the toxicant, a constant concentration of nontoxic nickel was thought to provide the explanation for the unexpected intercept value. However, there is no obvious reason to think that the quantity, or even the percentage of total toxicant, is the same across samples for other toxicants, or for nickel in other matrices.

For the effluent samples that lose their toxicity in a short time, the nontoxic effluent can be used for the suspect toxicant(s) tests as a diluent in parallel tests using a standard dilution water to elucidate matrix effects on toxicity. Toxicity test results with quite different toxicity would reflect matrix effects. If toxicity is persistent, developing two separate correlations using pure chemical additions on two different effluent samples, each with substantially different toxicant concentrations, might be useful. If the toxicity test results indicate that the biologically unavailable portion changes with measured concentrations, the slope should be different than one. This approach requires careful work and the investigator must consider incorporating equilibrium time experiments (cf., EPA, 1993A).

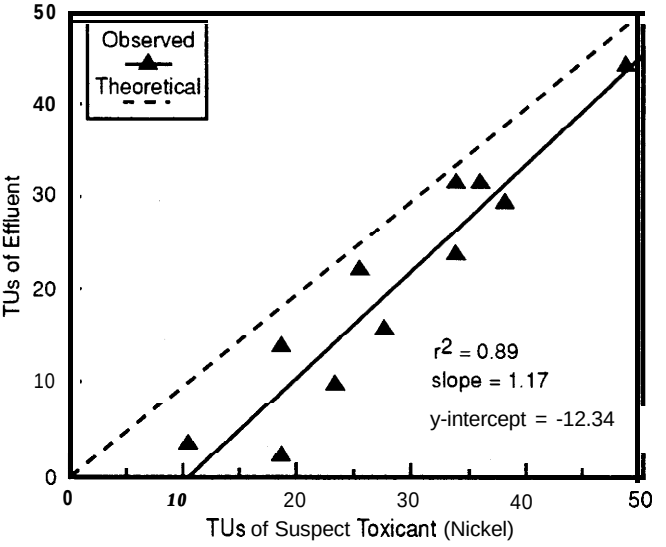

Figure 2-5. Correlation of toxic units (TUs) for a POTW effluent and the suspect toxicant, nickel.

Metals can be especially difficult toxicants to implicate using correlation because the toxicity of metals is typically very matrix dependent. When the knowledge of these characteristics is extensive for a chemical, as it is with ammonia (see Phase II), testing can be tailored to the chemical and a very powerful correlation obtained. The large amount of available information on ammonia does not exist for most metals. In these instances, the logic pattern should to be reversed where the approach has to become: if x *is the toxicant, what are the matrix effects?.* These can be found by pure chemical testing combined with Phases I or II manipulations. Once an adequate understanding of matrix effects is obtained, the information can be used to answer the question: Is the *effluent toxicant behavior consistent with the matrix effects for the suspect toxicant?*

Matrix effects will have varying impacts on toxicant behavior that also depends on the effluent effect concentration. For effluents which have effect concentrations in the <10% range, the test solutions will more closely resemble the diluent water matrix than the effluent. If the effluent has effect concentrations in the 50% to 100% range, the matrix effects of the test solution will most likely resemble those of the effluent, not of the dilution water. Since effluent TUs are calculated from

responses occurring in the dilution near the effect concentration, the matrix characteristics of that concentration are of the most concern for correlation. Thus the importance of the effluent matrix effects diminishes as the toxicity of the effluent is greater (i.e., matrix at effect level is more like dilution water).

One can safely say that the difficulty of simulating the matrix effects with a simulated effluent is quite large so that the choice is clearly to use the actual effluent when possible. An important reason for this choice is that so few matrix effects have been studied extensively, and beyond pH and hardness little data exists. Even then the interrelationship between pH, alkalinity and hardness were often ignored.

The above discussion does not provide all of the options on how to handle matrix effects. However, it should provide convincing evidence that more than the correlation step alone is necessary to provide adequate confirmation!

In summary, the TIE research experience has revealed two major areas of potential problems in using the correlation approach. The lack of additivity for toxicants found in effluents requires careful analysis when calculating TUs for regression purposes. Secondly, when there are matrix effects, correlation becomes difficult because the effluent matrix might change from sample to sample and because there are no analyses specific for the toxic forms. For such effluents, other confirmation techniques should be used more extensively to better support the overall confirmatory efforts.

Section 3
Symptom Approach

Different chemicals may produce similar or very different symptoms in a test species. Probably no symptom of intoxication is unique to only one chemical. Therefore, while similar symptoms observed between two samples means the toxicant(s) could be the same or different, different symptoms means the toxicant(s) is definitely different, or there are multiple toxicants in the two samples. By observing the symptoms displayed by the test organisms in the effluent and comparing them to the symptoms displayed by test organisms exposed to the suspect toxicants, failure to display the same symptoms means the suspect toxicant(s) is probably not the true one or the only one.

Behavior of most test species is difficult to put into words so that a clear image of behavior is obtained. Behavioral and morphological changes of 30-d old fathead minnows (*Pimephales promelas*) were used as diagnostic endpoints in 96 h flow-through single chemical tests. Organic chemicals of various modes of action were tested and video recordings were used to monitor the behavioral response (Drummond et al., 1986; Drummond and Russom, 1990). Substances within a single chemical classification did not necessarily cause the same type of response (Drummond and Russom, 1990). Therefore, it is difficult to predict chemical classification using behavioral monitoring alone.

This type of behavioral monitoring data does not exist for the cladocerans or the newly hatched fathead minnows or other species that are most frequently used in the TIE process. However, noting various symptoms is useful in the TIE. This is done by simply exposing the test species to the suspect toxicant(s) and observing how they react. By the time confirmation is initiated, toxicity tests with the suspect toxicants will have been conducted using pure compounds and symptoms may have been observed. It is important to note the symptoms observed during all testing because such characteristics can be very helpful in confirmatory work.

The intensity of exposure concentrations might change the symptoms observed with the suspect toxicant in the effluent. Therefore, it is important to compare symptoms at concentrations that require about the same period of onset. This can be done by comparing symptoms at exposure concentrations that have similar TUs. In this way both the unknown (sample) and the known toxicants (pure compound) can be set at the same toxicity level.

Observations of the organisms should not be delayed until the normal length of the test has elapsed. With some toxicants, the test organisms will show distinctive symptoms soon after the exposure begins, whereas later, symptoms are often more generalized and less helpful. For some other toxicants, a sequence of different symptom types are displayed by the test organism over the exposure period and the sequence may be more definitive for a given chemical than the individual symptoms. In few cases will the symptoms be unique enough to specifically identify the toxicant, but symptoms different from those caused by the pure suspect toxicant are convincing evidence that the suspect toxicant is not the true or only one.

A second caution is needed regarding mixtures of toxicants. Mixtures of toxicants can produce symptoms in test animals different from the symptoms of the individual toxicants comprising the mixture. When more than one toxicant is involved, the investigator must not only include all the toxicants, but include them in the same ratio as measured in the effluent. Often the toxicant of the mixture at the highest concentration relative to its effect concentration will cause most of the symptoms. As for single toxicants, the mixture concentration causing the same endpoint in a similar exposure period should be compared. Spiking effluent with the suspect toxicants and comparing the results of the spiked effluent sample and the unspiked effluent sample toxicity tests, both near their effect concentrations, is a good approach to take (Section 5).

Symptoms caused by the toxicant(s) might be quite different among different species of organisms; therefore the use of two or more species provides increased definitiveness of the observations. For both species, the researcher must compare symptoms at concentrations that are equitoxic. The greater the difference in sensitivity, the more important this becomes, The chemical concentration is unimportant; the important consideration is that equitoxic concentrations are compared.

Suppose, for example, species A and B have LC50 values for a suspect toxicant of 1 and 80 mg/l. Then concentrations of 2 and 160 mg/l may be used to compare symptoms of species A and B, respectively. If the onset of symptoms is rapid, then perhaps 1.25 and 100 mg/l (1.25xLC50) should be tried. Since symptoms vary with the exposure intensity, using various multiples of the LC50 (i.e., 0.5, 1, 2x) can add additional confirmation data, if the same set of symptoms are seen in both series. If more than one toxicant is involved, and the ratio of the two species' LC50 values for toxicant A is markedly different than for toxicant B, C, D, ... then the definitiveness of using symptoms is even greater.

For acute toxicity, time-to-mortality at equitoxic concentrations can be used as a symptom type of test. Some chemicals cause mortality quickly and some cause mortality slowly. If for two effluent samples, toxicity is expressed quickly for one and for the other very slowly, the toxicants are probably not the same.

In chronic testing, use of symptoms is also applicable. For example, adult mortality, number of young/female, death of young at birth, growth retardation, abortion, or time to onset of symptoms, all can also be monitored and such observations may be useful. The shape of the dose response curve may also be a determinant in assisting in confirmation. Some chemicals show an all or none type of response (diazinon) while others (i.e.. NaCl) display a relatively flat concentration-response slope for chronic toxicity.

Section 4
Species Sensitivity Approach

The effect concentrations can be compared for the effluent of concern and the suspect toxicants, using species of different sensitivities. If the suspect toxicant(s) is the true one(s), the effect levels of effluent samples with different toxicity to one species will have the same ratio as for a second species of different sensitivity. Also the ratio for each species should be the same as for known concentrations of the pure toxicant. The same ratio of effect values for two species implies the same toxicant in both samples of effluent. Obtaining the same effluent toxicity ratio among various effluent samples for each species as is obtained by exposure to comparable concentrations of known toxicants, implies that the suspect toxicants are the actual ones present. However, if other effluent characteristics affect toxicity and if they vary, the ratios could also be affected.

The common notion that goldfish are resistant to most toxicants and trout are sensitive to most toxicants is not readily substantiated (AQUIRE, 1992). Many species are more sensitive to certain groups of toxicants than trout. Of course, there are generalizations that can be made. For example, sunfish (Centrarchids), frequently are much more resistant to metals than goldfish, minnows, and daphnids (AQUIRE, 1992). Daphnids tend to be more resistant to chlorinated hydrocarbon insecticides than many fish species and more sensitive to organophosphate insecticides (AQUIRE, 1992). These differences must always be verified for the suspect toxicants; generalities can only be used as an initial guide to species selection. Sensitivity differences of 1 O-i 00x may occur in some chemical groups and not in others. If several toxicants are involved, interpreting the results and designing the ancillary experiments is more difficult. If successful, the power of the result for multiple toxicants is much greater than for a single toxicant. The difference in sensitivity between *Ceriodaphnia* and fathead minnows has, on several occasions, revealed either a change in the suspect toxicants present in a series of effluent samples, or the presence of other toxicants in addition to those suspected.

Comparison of sensitivity among species has another very important use. Some species may evidence toxicity from an effluent constituent that the TIE test species did not. If this happens, then the above comparison will be confused, but at least there will be a warning that the suspect toxicant may not be the cause of toxicity. In order to determine what is happening, the investigator should step back to Phase II, and possibly step back to Phase I to characterize the additional toxicant and then identify the toxicant using the new species. A second Phase III effort might be necessary for this toxicant and species. It is important not to assume that the resident species have the same sensitivity as the TIE test species. Especially for freshwater discharges into saltwater this concern is critical when a saltwater organism triggered the TIE, because at present the techniques and procedures described in Phases I and II are most likely to be done using freshwater organisms especially since the effluent is freshwater. If the concern is for marine organisms and their protection cannot be assumed (cf., Section 8, Phase I; EPA, 1991A), confirmation must be conducted with marine organisms.

In chronic testing, chemical and physical conditions might differ more among tests on different species because food must be provided during the test period and different foods are used for each species. For example, the final pH of fathead minnow 7-d tests might be lower than in acute fathead minnow tests and both are likely to be lower than in *Ceriodaphnia* chronic tests due to greater respiration rates for fish than cladocerans and food in fish tests. If the investigation was to confirm ammonia toxicity, this pH difference could result in confusing results by showing the *Ceriodaphnia* to be more sensitive than the fathead minnows when the reverse should be true (cf., EPA, 1993A; Phase II). The above example illustrates reasons to maintain careful quality control in Phase III work.

Section 5
Spiking Approach

In spiking experiments, the concentration of the suspect toxicant(s) is increased in the effluent sample and then toxicity is measured to see whether toxicity is increased in proportion to the increase in concentration. While not conclusive, if toxicity increases proportionally to an increase in concentration, considerable confidence is gained about the true toxicant(Two principles form the basis for this added confidence. To get a proportional increase in toxicity from the addition of the suspect toxicant when it is in fact not the true toxicant, both the true and suspect toxicants would to have 1) very similar toxicity and 2) to be strictly additive. The probability of both of these coinciding by chance is small.

Removing the suspect toxicants from the effluent without removing other constituents or in some way altering the effluent is usually not possible. The inability to do this makes the task of establishing the true toxicity of the suspect toxicants in the effluent difficult. For many toxicants, effluent characteristics, such as TOC, suspended solids, or hardness, affect the toxicity of a given concentration, Some characteristics, such as hardness, can be duplicated in a dilution water, but certainly not TOC or suspended solids because there are many types of TOC and suspended solids, and generic measurements do not distinguish among the different types. For example, effluent TOC occurs as both dissolved and suspended solids. In POTW effluents, the source of the TOC is likely to be largely from biological sources, both plant and animal (e.g., bacteria) and bacteria are likely to make up a large component of suspended solids. If there have been recent storms, oily materials from stormwater runoff might be high. Simulating TOCs from such variable sources is next to impossible because TOC is not solely the result of man-made organic chemicals. For suspended solids, shape, porosity, surface-to-volume ratio, charge and organic content (all or any), will impact sorption characteristics. None of these qualities are measured by the standard methods for measuring suspended solids nor can they be reproduced in a simulated effluent.

In a simple system, such as reconstituted soft water, it is reasonable to expect that for most chemicals a doubling of the chemical concentration will double the toxicity, at least in the effect concentration range. If the solubility of the toxicant is being approached or there are effects from water characteristics such as suspended solids, then the toxicity might not double or conceivably could more than double. For example, if a chemical with a large n-octanol/water partition coefficient (log P) is largely sorbed on solids, doubling the total concentration might more than double the toxicity because the added chemical might remain in solution. Another important issue is that equilibrium might not be established during the entire test period and is probably unlikely to occur before the test organisms are added. For example, in our TIE research, we found various surfactants sorb to solids and can be removed by filtration (Ankley et al., 1990). In these experiments, however, filtration failed to remove surfactants immediately after they were spiked in an effluent but surfactants were removed after a few days equilibrium time. Other chemicals are likely to show similar behavior in regard to equilibrium time.

If several toxicants are involved, then their interaction (additivity, independent action, synergism) must be measured or otherwise included in the confirmation process (cf., Section 2). Since ratios might be as important as concentration, the best way to spike when multiple toxicants are involved is to increase each toxicant by the same number of TUs (e.g., by doubling each). In this way the ratios of the toxicities remain constant.

The fact that two or more toxicants fail to show additivity is useful evidence in confirmation. Interpreting spiking data might require a very high level of competence in both toxicology and chemistry; otherwise the data could be very misleading. Using more than one species of differing sensitivity is effective in adding confidence to the results. When matrix effects are complicated, other types of spiking can be done to reduce the effects of the effluent matrix characteristics. If a method exists for removing the toxicants from the effluent, such as the C_{18} SPE procedures (EPA, 1993A), the extracts or methanol fractions can be spiked with pure chemicals in addition to spiking effluent, using the same principles as described for effluents. The advantage in this approach is that matrix characteristics such as suspended solids and TOC will be absent or much reduced and will not affect spiking experiments as much. The disadvantage is that proof that the extracts or fractions contain the true toxicants must be generated. Some approaches for doing

this are given in Section 6. The use of the spiking approach is especially applicable to fractions from the C_{18} SPE column or the high performance liquid chromatography (HPLC) column used for the isolation of non-polar organics. In these procedures, the constituents are separated from much of the TOC, suspended solids and hardness, so that spiked additions might be strictly additive where they might not be in the effluent. Suggestions and precautions about ratios and all other previously discussed concerns apply here too. In addition, concerns about the methanol percentages in the toxicity tests, the amount of SPE or HPLC eluate required for the toxicity tests and the issue of toxicity enhancement by methanol must be considered in order to generate the appropriate toxicity data. Spiking the methanol fractions with suspect toxicants, however, does not provide the same confidence about the cause of toxicity in the effluent as spiking the effluent directly. The mass balance approach described in Section 6 could be coupled with spiking the effluent with a portion of the fractions to make the data more relevant to whole effluent toxicity.

For chronic testing spiking a portion of the methanol fractions, such as C_{18} SPE methanol fractions into dilution water to mimic the effluent, requires some special considerations as discussed in the chronic Phase I (EPA, 1992) and the new Phase II (EPA, 1993A). For any test species, the effects of the methanol at the effluent spiking concentration for the test species must either be essentially non-existent or clearly established so that proper interpretation is applied. The use of spiking for chronic toxicants of the methanol fractions is not as easy as the spiking for acute toxicants due to the limitations in the quantity of methanol that would be added with each fraction for the toxicity test. If the chronic toxicity effect level is around or <25% effluent and the highest fraction tested is 4x higher than the chronic effect level, add-back tests can be conducted similar to the acute add-backs but the quantity of methanol required for the testing and analysis must be considered (cf., Section 2; EPA, 1993A). As discussed in Phase II, once a suspect toxicant has been tentatively identified, the steps of confirmation should be started although sample volumes of methanol eluates might limit the amount of testing (see Phase II, Section 2; EPA, 1993A) with chronically toxic samples. Spiking of appropriate levels for chronic toxicity for single chemicals (or mixtures) is limited as sublethal data are not as plentiful as acute data. The acute toxicity of some chemicals might be altered by methanol (i.e., surfactants). The possibility that this is occurring must be checked and a correction applied if warranted. Spiking fractions also has applicability for hidden toxicants; refer to Section 9 for further details.

Spiking can also be done effectively when the suspect toxicant(s) of concern can be removed. However, since other toxicants might also be removed, the data must be carefully interpreted. Ammonia is a good example (cf., Phase II; EPA, 1993A) to use with this technique where one toxicant can be removed. Ammonia can be removed from the effluent by passing samples over the zeolite resin, after which the concentration can be restored in the post-zeolite effluent by the addition of ammonia. If toxicity is also restored, then it is likely that there is sufficient ammonia to cause the toxicity observed. However, it cannot be concluded from these data alone, that ammonia is the cause of toxicity because the zeolite can also remove substances other than ammonia. Another substance which is non-additive with ammonia yet present at a lesser or the same number of TUs could cause the initial effluent toxicity but not be discernable by this removal technique. This is an example of a hidden toxicant (see Section 9). For acute toxicity, zinc could behave exactly this way because it is non-additive with ammonia yet zinc is also removed by zeolite. Using other ammonia removal methods, such as high pH stripping, followed by spiking to the initial ammonia concentration will enhance confidence that a hidden toxicant is not present. Other examples involving the C_{18} SPE column and various ion exchange resins would be approached and interpreted similarly.

Section 6
Mass Balance Approach

This approach is applicable only to those situations in which the toxicant(s) can be removed from the effluent and recovered in subsequent manipulation steps. The objective is to account for all toxicity to assure that small amounts of toxicity are not being lost. This concern is partly covered by the correlation approach (Section 2); however, a totally different toxicant present at a small concentration could appear as experimental variability in the correlation and go unnoticed.

The mass balance concept is best described by illustration for acutely toxic effluents and the C_{18} SPE fractions. As described in Phase II (Section 2.2.7; EPA, 1993A) for acutely toxic effluents, the effluent has been passed over a C_{18} SPE column which is then eluted with the methanol/water fractions. After the toxicity tests on the individual fractions are completed, add-back tests can be initiated to determine whether all of the toxicity in the original sample was accounted for in the SPE fractions. For this step, there are three separate tests (with dilutions and replicates to calculate effect endpoints) that must be conducted which consist of the all-fraction test, the toxic-fraction test, and the nontoxic-fraction test. Assuming a complete recovery of all non-polar organics from the SPE column, this should yield a solution of non-polar organic compounds equal to the original sample concentrations, In the mass balance approach, these add-back tests are conducted using an aliquot of the effluent that has passed through the C_{18} SPE column (post-SPE column nontoxic effluent) or an aliquot of dilution water. Each toxic fraction is added back to the post-SPE column effluent, so that each is present at original effluent concentrations (i.e., lx effluent concentration). For example for acutely toxic effluents, the toxic-fraction test solution is prepared using methanol concentrations as described in Phase II (i.e., Section 2.2.7; EPA, 1993A) and for each fraction where toxicity was observed in the fraction toxicity test, 30 µl of each is added to the same 10 ml of nontoxic post-C_{18} SPE column effluent (or dilution water). A portion of each of the remaining fractions where toxicity was not demonstrated are now added to a second post-SPE column aliquot at effluent concentrations for the nontoxic-fraction test. Finally portions of all the fractions (e.g., n= 8 for acutely toxic effluents) are added to a third post-SPE column aliquot at effluent concentrations for the all-fraction test. If all the toxicity is exhibited in the toxic-fraction test, then the all-fraction test results and the toxic-fraction test results should be the same as in the unaltered effluent. Results from the nontoxic-fraction test should indicate that no toxicity is present. This mass balance (or add-back) approach allows the researcher to ascertain whether or not the toxicity in the toxic-fraction test equals the effluent toxicity. Small amounts of toxicity can be undetectable in the toxic-fractions when tested separately or the toxicant(s) might not have been eluted from the C_{18} SPE columns. Unless mass balance experiments are conducted, such loss of toxicity might not be detected. In the effluent example discussed in Section 2, the toxicity was contained usually in the 75%, 80%, and 85% fractions and occasionally in the 70% fraction! The r^2-value, slope, and intercept were all close to the expected values if two toxicants (diazinon and CVP) were causing the effluent toxicity (Figure 2-3). However, in Table 6-l the results of mass balance tests indicate that toxicity from the all-fraction test was greater than the toxicity of the toxic-fraction test. While this difference is small, it did seem to be real and was attributed to a small amount of another toxicant in the 70% fraction. In 11 of 12 samples, the results from the all-fraction tests indicate there was greater toxicity than was found in the toxic-fraction tests. On the few occasions when the 70% fraction was toxic, it did not contain any of the three suspect toxicants. Without the mass balance data, consistent presence of the additional toxicant would not have been discovered.

At the stage where the toxic-fractions have been identified, the test of the fractions in a mass-balance test is highly desirable. For chronic toxicity testing, the amount of eluate available might be limited following the fraction toxicity tests. Using eluate for the add-back tests might be a trade-off between tracking toxicity and having sufficient eluate to concentrate for further analysis. This limits the add-back tests broad applicability for chronic toxicity TI Es unless the effluent is toxic enough that at 4x the chronic effect level, the methanol concentrations do not exceed

[3]During development of the non-polar organic procedures, various elution profiles were used that included the 70% methanol/water fraction.

Table 6-1. Comparison of Effluent Toxicity and Toxicity Measured in Effluent Fraction Add-back Tests

Sample	Toxic Units (TUs)		
	Effluent	All-fractions	Toxic-fractions
12/03/87	1.18	1.64	1.43
01/12/88	2.00	2.94	3.13
01/13/88	1.93	2.86	2.53
02/03/88-I[a]	cl .oo	1.15	<1.oo
02/03/88-II	2.00	1.75	1.64
03/03/88-I[a]	1.15	1.06	<1.00
03/03/88-II	1.33	1.52	1.13
03/23/88-I	3.70	3.03	2.86
03/23/88-II	2.86	2.86	2.44
04/28/88	2.27	1.72	1.64
05/17/88	2.27	2.04	2.00
05/17/88	2.27	1.67	1.59
Mean	2.13	2.18	2.00

[a]Values excluded from mean calculations due to less than values.

the organisms tolerance. For chronically toxic samples, the all-fraction add-back test with C. *dubia* is not possible due to high methanol concentrations in test cups unless chronic toxicity is below 25% and add-backs are done using 25% effluent as the high test concentration (cf., Phase II; EPA, 1993A). The data from the individual methanol/water tests may be summed; however this approach must be considered more tentative than add-back tests (see below).

A deficiency in the above approach to mass balance is that there can be some toxicity in the post-SPE column effluent which has not been removed by the C_{18} SPE but which is not present in concentrations high enough to detect. The above mass balance approach alone will not identify this. However, if the add-back tests described above are repeated using a standard dilution water, residual toxicity in the post-SPE column effluent should cause the toxic-fraction test and all-fraction test to show more toxicity when added to the post-SPE column effluent than when added to dilution water. A confounding effect of this approach is that if the toxicity is changed by matrix effects (suspended solids or TOC), then the toxicity will be different in the clean water test. Matrix effects can be discerned, in part, by a third spiking experiment where a portion of all of the fractions and a portion of each toxic-fraction test are spiked into whole filtered effluent (which has not passed through the C_{18} SPE column). If the addback tests in dilution water indicates greater toxicity than the addback tests with the post-SPE column effluent, and the same type of addback test experiment with filtered effluent (i.e., 1 µm filter) indicate that the fractions are exactly additive, then matrix effects are indicated.

Some post-SPE column effluent samples develop fungal or bacterial growth or perhaps a precipitate forms after the effluent passes through the column. For the fungal type of growth, this is thought to occur when some methanol bleeds into the effluent as it passes through the column and more rinsing will not eliminate this problem. Some effluents consistently develop this type of growth in the post-column effluent while others exhibit this pattern in only an occasional sample. To alleviate this problem, conditioning the column with acetonitrile has helped (cf., the acute Phase I (EPA, 1991A) and chronic Phase I (EPA, 1992) for details). When methanol fractions are spiked into the effluent this problem might or might not be enhanced; we have found this to be an effluent-specific occurrence.

Caution is warranted in situations where toxicity is contained in more than one SPE fraction. The researcher should not necessarily expect the toxicity expressed by each individual fraction that is tested separately to add up to the total effluent toxicity. First, toxicants may not be additive and second, some toxicity which cannot be detected in individual fractions may add to the whole toxicity. For example, any one C_{18} SPE fraction may not show toxicity but may contain some of the toxicant that is in the adjacent toxic-fraction. In this case, the toxicity of the toxic-fraction test would be less than expected. If this happens in more than one pair of fractions, the sum of the toxicity from the toxic-fraction test will be less than the effluent toxicity or all-fraction test. These concerns are especially important when several toxicants are involved and one or more occur in more than one fraction.

For effluents where the C_{18} SPE column is not used, but where the toxicants can be removed from the sample, the same objectives should be achievable, but the methods will be different. For example, if an effluent appears to contain a volatile toxicant, the mass balance could be done on the trap and on the purged sample. Since we have not yet done mass balance on samples such as these we have no experience from which to offer additional guidance or advice.

Some of the mass balance process begins in Phase II, and there is a subtle difference in the purpose of mass balances in Phases II and III. In Phase II, usually only a few samples are used and mass balances are necessary to determine the need for more identification in those few samples. The mass balance is useful in early stages of Phase II as well before toxicants are identified at all, because it allows the investigator to decide if the toxicants present at 2x or 4x whole effluent concentrations are also expressing toxicity at lower concentrations.

In Phase III as many samples are tested, the mass balance approach can provide information over time with many samples whether or not the suspect toxicants consistently account for all or the majority of the toxicity. As illustrated above, the power of the mass

balance approach to detect small degrees of toxicity is better than for the correlation approach.

When a portion of the toxicant is not biologically available and therefore does not contribute to toxicity, care must be taken to assure that removal of the toxicant from the sample does not remove biologically non-available portions. An example of this situation may be the alternative solvent extraction procedures which may remove a bound toxicant(s) sorbed on suspended solids with the solvent and is now toxic, yet it was not toxic in the unaltered sample.

Section 7
Deletion Approach

In some situations, particularly for industrial discharges, keeping the suspect toxicants out of the waste stream influent or effluent for short periods of time and also conducting toxicity tests on the wastewater simultaneously may be practical. When this approach can be used, it offers the most convincing evidence obtainable that the suspect toxicants are the true ones. Care must be taken however, that other substances are not deleted or that some characteristic such as pH does not change also. If a researcher can be certain that all changes are known, then this approach is definitive. Changes in the toxicants with time are as much of a concern here as in any other approach. These can be handled by the approaches outlined in earlier sections and the deletion approach need not be done repeatedly; however, if it were practical to do so, it would certainly be effective. If some samples do not contain one or more suspect toxicants, these effluent samples can be used to the advantage in confirmation in much the same way as intentional deletions described in this section can be used to confirm toxicity.

Section 8
Additional Approaches

This section mentions only a few of many steps that can be used to further confirm the cause of toxicity. The steps mentioned are mostly those that we have used and found helpful and practical.

The pH is one of the most important effluent characteristics that changes toxicity. The pH of POTW effluents, sediment pore or elutriate waters, and ambient waters will almost always rise when they are exposed to air, especially in the small test volumes used in TIE work. Commonly, pH in an effluent sample at 25°C will rise from 7.1-7.3 to 8.3-8.5 during a 24 h period. That pH change is enough to increase ammonia toxicity (based on total ammonia) about three fold. Such pH changes can destroy work for some purposes, but by regulating these pH changes, the pH fluctuations can be used to great advantage for other purposes.

Phase II (EPA, 1993A) describes the use of pH change to identify ammonia toxicity. The toxicity of some metals, hydrogen cyanide and hydrogen sulfide among others, is altered by pH change. Other characteristics, such as hardness, can also be varied to see if the changes in toxicity follow a predictable pattern. The toxicity of some metals could be approached in this way. Not all equilibria are as rapid as the ammonia equilibrium, so the amount of time for equilibria to occur should be controlled and standardized (cf., Phase II; EPA, 1993A). Various time . periods may have to elapse before the expected changes occur and this may differ with each effluent. With the improved methods of pH control described in the Phase I documents (EPA, 1991; EPA, 1992), much more use can be made of pH manipulation.

Often chemicals in effluent samples may not be biologically available, and if they are not, then they are not likely to cause toxicity. They may be made biologically available through some manipulation in Phase I and subsequently identified in Phase II. Through confirmation, the toxicity due to such a toxicant will become apparent when the correlation indicates a poor fit (cf., Section 2). For many toxicants, biological availability can be demonstrated by measuring body uptake. If the constituent of concern enters the body from the effluent, it is certainly biologically available. Exposure to pure compounds may be necessary to establish which particular organ should be evaluated for the toxicant. In acute metal exposures using fish, most metals concentrate first in the gills while non-polar organics concentrate in fatty tissues such as the liver. When a chemical is metabolized by the organism, a residue measurement for that compound is not a valid measure of the lethal body burden because it is unknown whether the metabolite is more of less toxic than the parent compound. If the suspect toxicant has a known mode of action, such as the acetylcholinesterase inhibition produced by organophosphate pesticides, this exposure effect can be measured to assess if toxic effects conform with the predicted effect. The use of enzyme blockers such as piperonyl butoxide (PBO) is also an aid in confirming toxicity caused by specific classes of toxicants (cf., Phase II; EPA, 1993A).

As additional steps are needed for confirming the cause of toxicity, combinations of various Phase I and Phase II procedures should always be used whenever practical. When several results are combined and all results are indicating the same type of toxicant, the data are more conclusive than when only one procedure yields predicted results.

Total dissolved solids (TDS) are a common problem in certain areas of the country and for certain industries. TDS will not cause toxicity from osmotic stress (this can easily be shown because their toxicity is not related to osmotic pressure) but rather TDS acts as a set of specific toxicants. For toxicity caused by TDS, the ratios and concentrations of the major cations and anions can be measured analytically. A similar mix of these major ions can be added to a dilution water to see if the expected toxicity is present. By testing various mixtures, the researcher can ascertain which of the TDS components contribute most to the toxicity.

Section 9
Hidden Toxicants

In the previous section, references were made to the problem of hidden toxicants. Essentially there are two situations which may produce the problem of hidden toxicants. The first situation occurs when disparate ratios of TUs of two toxicants are present in the effluent sample. Since the effect concentration is measured by diluting the effluent, when disparate ratios occur, the TUs of the toxicant present in fewer TUs in 100% effluent are so low at the effect diluent, that its contribution if any, is not measurable. This problem exists whether the toxicants are additive or non-additive. This situation generally will not be encountered in effluents that have very slight toxicity (i.e., effect concentration 75% to 100%) because little or no dilution is required to achieve the effect concentration. For those toxicants present in disparate ratios in effluents with marginal toxicity, the chemical present at the low levels may be nontoxic even in 100% effluent.

The second situation where hidden toxicant(s) occurs is when the toxicants are non-additive or partially additive in the effluent sample. These toxicants may occur at approximately equal TUs or at disparate ratios of TUs, as long as those present at lesser TUs are present at 1 TU in the 100% effluent (cf., discussion of performing correlation on these types of toxicants, contained in Section 2).

If confirmation is being conducted for both acute and chronic toxicity or if acute toxicity is being used as a surrogate for chronic toxicity, the acute to chronic ratio must also be considered. For example, consider an effluent with toxicants A and B for which the acute-to-chronic ratios are 3 and 12, respectively and the TUs for acute toxicity are 2 and 1 in an effluent sample for A and B, respectively. By definition, 1 acute TU (TU,) for toxicant A equals 3 chronic TUs (TU_c) and for B, 1 TU, = 12 TU,. In this example, the acute toxicity of the effluent will be determined by A and the chronic toxicity will be determined by B. If in another situation, the acute-to-chronic ratios for two compounds were similar, then one of the toxicants would determine the effect concentration for both acute and chronic toxicity. These examples illustrate the importance of acute-to-chronic ratios for non-additive toxicants. Acute-to-chronic ratios have special importance for additive toxicants when acute toxicity is being used as a surrogate measure for chronic toxicity. If acute toxicity is being used as a surrogate it must be demonstrated that the cause of the acute toxicity is the same as the chronic toxicity. When acute toxicity is used as a surrogate for chronic toxicity in Phases I and II, interpretation of the results can easily be biased and these considerations are important.

When a toxicant can be removed from the effluent and recovered, the identification of the presence of a hidden toxicant is more readily known. For example, the use of the C_{18} SPE column may remove hidden toxicants. The toxicant(s) is recovered in the eluate a&measured both analytically and toxicologically. This type of hidden toxicant may be observed if ammonia is present at concentrations that could cause toxicity. For example, in an effluent sample ammonia is present at 3 TUs. Ammonia will not be removed by the C_{18} SPE column and yet an additional 1.5 TU of a non-polar organic toxicant is evident when the C_{18} SPE eluate test is conducted. If the discharger applied remedial treatment they would be able to remove the ammonia toxicity yet the effluent would still be toxic. The same concept of hidden toxicants can be found when toxicants are removed by sublation which is followed by recovery and concentration of toxicity (cf., Phase I; EPA, 1991 A; EPA, 1992). For example, sublation can separate some surfactants, resin or fatty acids, and polymers from such constituents as metals and ammonia. Hydrogen sulfide can be removed by a purge and trap method, thereby separating it from other effluent constituents.

Specific blockers of toxicity such as EDTA for metals and PBO for organophosphates are also useful in establishing the cause of toxicity. The more specific the blocker, the more definitive are the results, However, present knowledge does not allow us to be certain that compounds such as EDTA do not also affect the toxicity of other chemicals. Use of two specific blockers such as EDTA and sodium thiosulfate for copper, allows more definitive conclusions (cf., Phase I; EPA, 1992).

Manipulating characteristics such as pH is useful but can easily mislead thinking. For example, if the effluent has ammonia toxicity, the toxicity due to ammonia should disappear if the pH is lowered appropriately. These results do not allow a conclusion that there are no hidden

toxicants. If, however, the pH is lowered so as to eliminate ammonia toxicity but the effluent toxicity exists or even increases, then the likelihood of a hidden toxicant is high. Unfortunately a complication to this rationale is that the toxicity expressed at the lower pH may be totally artifactual due to mechanisms of pH adjustments.

The best approach to find hidden toxicants is to first use, those methods that alter the effluent the least, can remove and recover removed hidden toxicants, and are most specific for a few toxicants. This advice is most applicable where the effort is to try to find out if some specified type of toxicant is a hidden one, e.g., is there a non-polar organic as a hidden toxicant.

If, however, the search is for any type of hidden toxicant then every conceivable technique should be used that would help to distinguish a hidden toxicant from the suspect toxicant(Hidden toxicants are very hard to find when ammonia is the primary toxicant. Various tests used to identify ammonia as the toxicant, i.e., use of the zeolite resin, graduated pH tests and air-stripping (EPA, 1993A), all have a reasonable probability of changing the toxicity of many other potential toxicants. For instance, it is known that zeolite removes some non-polar organics and metals. Air-stripping (at pH 11) could also remove or destroy many other chemicals as it often must be done for a extended period of time to achieve good ammonia removal. The graduated pH test results might also implicate a metal as a toxicant (EPA, 1993A). If these tests were conducted in Phase II (EPA, 1993A) and the results consistently indicated ammonia toxicity, these data indicate that there are no hidden toxicants. The required characteristics for a hidden toxicant to behave exactly as ammonia are very specific and obtaining results like those described above for a toxicant other than ammonia is unlikely.

If the hidden toxicant is additive with the suspect toxicant but occurs in a disparate ratio, the confirmation effort must first emphasize confirming the cause of toxicity (or remove the toxicity) of the primary toxicant. Then toxicity from the hidden toxicant should be measurable. The probability a hidden toxicant that has additive toxicity will not express its toxicity using several Phase I or Phase II techniques is less than the probability that a non-additive toxicant will express its toxicity using several of the same techniques.

If the remedial action for a primary toxicant is specific and easy, such as a product substitution, the search for hidden toxicants perhaps should be done after the remedial action has reduced or eliminated the primary toxicant from the effluent. The remedial action (especially if it is treatment) may also eliminate the hidden toxicant(What must be avoided if at all possible, is to carry out expensive remedial action only to find that the effluent is still toxic.

The problem of hidden toxicants is a major reason a researcher should not accept the presence of toxic concentrations of suspect toxicant as sufficient confirmation (cf., Section 1). The presence of biologically unavailable forms (cf., Section 8) is a compelling reason not to do so.

A thorough confirmation is resources well spent in most instances. Non-additivity and disparate ratios complicated by non-availability occur too frequently to bypass confirmation. Seasonal changes or changes without a pattern, in effluent toxicants are further reasons to perform the confirmation over a period of time to assure that the entire suite of toxicants has been found.

Section 10
Conclusions

Often the most laborious and difficult part of the TIE is developing data to adequately establish the cause of toxicity. In our experience, frequently the suspect cause of toxicity is found without difficulty but developing a convincing case to prove that the suspect cause is the true toxicant is the challenge.

Especially for POTW plants, this confirmation phase must be performed over a considerable period of time to be certain that the cause of toxicity is not changing. TIEs on POTWs and some industrial categories are not likely to be a one time event but will have to be repeated as long as the inputs to the plant change. Our current wastewater treatment plants were not designed to remove specific chemicals, so there is no reason to expect that they will remove everything which they receive. Especially where the control over the influent is not complete, as is the case with POTW plants, a solid case must be developed to assure that the cause of toxicity is not changing.

Section 11
When the Treatability Approach Has Been Used

As discussed in Phase I, two main approaches may be used to remove a toxicity problem--toxicant identification and source control or treatability. Phases I and II involve the first approach while treatability procedures accompanied by toxicity testing are used in the second (EPA, 19898; EPA 1989C).

In the second approach, treatment methods are varied to determine which will remove toxicity without identifying the specific toxicants. The treatability approach requires as much confirmation as the toxicant identification approach. Since the treatability approach should remove toxicity, the confirmation procedures are somewhat different.

Repeat samples should be tested to ensure that toxicity has been successfully removed. This should be done over a sufficient length of time to assure that the range of conditions are included during the confirmation phase. Such events as seasonal changes, production changes, storms, and intermittent operations all should be included during the confirmation phase. Toxicity should be consistently removed or appropriately reduced, as required. Either acute or chronic toxicity removal can be confirmed this way.

One must be absolutely sure that the toxicity to resident species has been successfully removed. As has been pointed out in Phases I and II, the effluent constituents producing toxicity to one species may not be the same for other species. Toxicity by a given treatment method may remove all toxicity for one species but not for another. The species of concern must be tested in the effluent from the treatment method selected. If chronic toxicity is the concern, this testing may be more difficult because chronic testing methods may not be available for resident species. In selected cases, symptoms may be substituted for the usual endpoints of chronic tests but their use would be case specific.

Abstract

During the last ten years Toxicity Identification Evaluation (TIE) methods have been used extensively with freshwater effluents, receiving waters, and sediments. TIEs may be required by state or federal agencies as a result of enforcement actions, as a condition of the discharger's National Pollutant Discharge Elimination System (NPDES) permit, or may be conducted voluntarily by permittees. This guidance document, using the freshwater TIE approach as a model, has been developed to aid in conducting acute and chronic marine TIEs. It focuses on Phase I of the TIE: Toxicity Characterization. Phase I of a TIE characterizes the classes of toxicants causing adverse biological effects. These classes may include metals, organics, pH dependent toxicants, volatile toxicants, filterable toxicants, and oxidants. In this document, information is provided for: (1) salinity adjustment of freshwater effluents with brine, (2) general guidance for the performance of small volume marine toxicity tests with Atlantic, Gulf, and Pacific Coast species used in NPDES permit or as a NPDES permit testing requirement, (3) tolerances to the chemicals added during a TIE, and (4) the conduct of TIE manipulations. These acute/chronic TIE procedures have been developed for a number of specific macroalgas, echinoids, mysids, bivalves, an amphipod, gastropods, and fishes. Recommended manipulations described in this document include filtration, aeration, EDTA chelation, oxidant reduction, graduated pH, C_{18} solid phase extraction (SPE), cation exchange SPE, and sea lettuce *Ulva lactuca* addition.

Foreword

The Marine Toxicity Identification Evaluation (TIE): Phase I Guidance Document focuses on methods for characterizing toxicity associated with discharges to marine waters including effluents and receiving waters. Its purpose is to provide guidance to dischargers, testing laboratory staff, and local, state, and regional personnel in conducting Phase I of a marine TIE. Methods for conducting freshwater toxicity tests and TIEs have been produced (EPA 1991a, 1991b, 1993a, 1993b, 1993c); however, these methods were not directly applicable to marine samples. As stated in EPA 1993c:

> These methods are not mandatory but are intended to aid those who need to characterize, identify or confirm the cause of toxicity in effluents or other aqueous samples such as ambient waters, sediments, and leachates. Where we lack experience, we have indicated this and have suggested avenues to follow. All tests need not be done on every sample; the tests are, in general, independent. However, experience has taught us that skipping tests may result in wasted time, especially in the early stages of Phase I. An exception to this is when one wants to know only if a specific substance, for example ammonia, is causing the toxicity or if toxicants other than ammonia are involved. Otherwise, we urge the whole battery of tests.

We assume the reader is familiar with the following documents describing (1) TIE methods: *Toxicity Identification Evaluation: Characterization of Chronically Toxic Effluents, Phase I* (EPA 1991a), *Methods for Aquatic Toxicity Identification Evaluations: Phase I Toxicity Characterization Procedures*, Second Edition (EPA 1991b), *Methods for Aquatic Toxicity Identification Evaluations: Phase II Toxicity Identification Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA 1993b), *Methods for Aquatic Toxicity Identification Evaluations: Phase III Toxicity Confirmation Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA 1993c); 2) toxicity testing methods: *Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Marine and Estuarine Organisms* (EPA 1994), *Methods for Measuring the Acute Toxicity of Effluents and Receiving Waters to Freshwater and Marine Organisms* (EPA 1993a), *Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to West Coast Marine and Estuarine Organisms* (EPA 1995); and 3) Toxicity Reduction Evaluations (TREs): *Toxicity Reduction Evaluation Protocol for Municipal Wastewater Treatment Plants* (EPA 1989a), and *Generalized Methodology for Conducting Industrial Toxicity Reduction Evaluations (TREs)* (EPA 1989b). Methodologies for both acute and sublethal (chronic) toxicity testing have been included in this manual. We invite comments on this document in order to improve future editions.

Acknowledgments

This document is the result of the hard work and dedication of several individuals. In the area of adapting existing toxicity test methods for TIE application the following persons are acknowledged: Pamela Comeleo (formerly of Science Application International Corporation (SAIC), Narragansett, RI), Randy Comeleo (Signal Corporation), Anne Kuhn, (EPA-AED), Glen Modica (formerly SAIC, Narragansett, RI), Mark Tagliabue (EPA-AED), Diane Griffin and Paul Krause (MEC Analytical Systems, Inc., Tiburon, CA), Bryn Phillips, John Hunt, and Brian Anderson (University of California-Santa Cruz). The insightful internal technical reviews of Anne Kuhn (EPA-AED), Rick McKinney (EPA-AED), Peg Pelletier (EPA-AED), Sherry Poucher (SAIC, Narragansett, RI), Richard Steele (EPA-AED), and Richard Voyer (EPA-AED) are appreciated. The data furnished by Bob Berger of the East Bay Municipal Utility District (Oakland, CA) on Pacific coast species is much appreciated. Further, the financial support of EPA Regions IX and X for developing other Pacific coast species tolerance data is noted. The input of Anne Dailey (EPA, Region X, Seattle, WA) is also acknowledged. We also thank the personnel at the EPA Mid-Continent Ecology Division (MED) in Duluth, MN for their hospitality during our visits, willingness to answer our various questions, and sections of their TIE documents; specifically we thank: Teresa Norberg-King, Gary Ankley, Marta Lukasewycz, and Elizabeth Durhan of the EPA-MED, Mary Schubauer-Berigan (University of South Carolina, Georgetown, SC), Tim Dawson (Integrated Laboratory Systems, Duluth, MN), Don Mount and Joe Amato (Asci, Duluth, MN), and Doug Jensen (Sea Grant, Duluth, MN). We also wish to thank the reviewers of the draft and current editions of this document for their comments: Teresa Norberg-King (EPA-MED) , David Hutton (D.G. Hutton, Inc. Newark, DE), Stephen Bainter, Allen Chang, Phillip Jennings, Michael Morton, and Wren Stenger (EPA, Region VI, Dallas, TX), and Patti Tenbrook (East Bay Municipal Utility District, Oakland, CA). Further, we thank the multitude of individuals we have discussed TIE related issues with at scientific meetings and during phone conversations. Finally, the excellent services of Edward Shear (Department of English, University of Rhode Island), our technical writer, are also acknowledged.

Section 1
Introduction

1.1 Background

The Clean Water Act (CWA 1972), in its original and all subsequent versions, established a "national policy that the discharge of toxic pollutants in toxic amounts be prohibited." The goal of the CWA is to eliminate the discharge of pollutants into waters in the U.S.; however, this goal is not immediately attainable. Consequently, the CWA allows for National Pollutant Discharge Elimination System (NPDES) permits for wastewater discharges. In order to insure that the CWA's prohibition on toxic discharges are met, an integrated system of testing procedures has been developed. This document presents additional methods for the conduct of Toxicity Identification Evaluation (TIE) which are part of this testing system.

During the last several years, TIE methods were developed and applied to freshwater effluents and receiving waters (Parkhurst et al. 1979; Walsh and Garnas 1983; Gasith et al. 1988; EPA 1991a, 1991b, 1993b, 1993c; Burkhard and Ankley 1989; Norberg-King et al. 1991). Methods for freshwater sediment TIEs have also been drafted (Ankley et al. 1992a). Implementation of these methods has demonstrated the regulatory and scientific utility of the TIE approach. For example, TIEs have identified specific 'problem toxicants' in effluents (Schimmel et al. 1988; Goodfellow et al. 1989; Ankley et al. 1990a; Jop et al. 1991a; Norberg-King et al. 1991; Amato et al. 1992; McCulloch et al. 1993; Ankley and Burkhard 1992; Burkhard and Jenson 1993; Schubauer-Berigan et al. 1993) receiving waters (Galassi et al. 1988; Schimmel et al. 1988; Norberg-King et al. 1991; Kszos et al. 1992), and freshwater sediments (Ankley et al. 1990b; Schubauer-Berigan and Ankley 1991; Ankley et al. 1992b; Hoke et al. 1992; Krantzberg and Boyd 1992; Schubauer-Berigan et al. 1993; Wenholz and Crunkilton 1995; Gupta and Karuppiah 1996). Furthermore, improvements have been incorporated as methods were applied (Doi and Grothe 1989; Ankley et al. 1990b; Durhan et al. 1990; Burkhard et al. 1991; Jop et al. 1991b; Mount and Mount 1992; Wong et al. 1996; Bailey et al. 1996; Hewitt et al. 1996).

1.2 Related Documents

As stated in the forward, this report assumes that the reader is familiar with several related documents. The report, *Methods for Aquatic TIEs: Phase I Toxicity Characterization Procedures, Second Edition* (EPA 1991b), contains essential background information on Phase I TIE procedures that is not duplicated in this report; and in addition, that report describes the related freshwater TIE procedures. Also, this report assumes that the reader is familiar with the following related documents: *Methods for Aquatic Toxicity Identification Evaluations: Phase II Toxicity Identification Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA 1993b), *Methods for Aquatic Toxicity Identification Evaluations: Phase III Toxicity Confirmation Procedures for Samples Exhibiting Acute and Chronic Toxicity* (EPA 1993c), *Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to Marine and Estuarine Organisms* (EPA 1994), *Methods for Measuring the Acute Toxicity of Effluents and Receiving Waters to Freshwater and Marine Organisms* (EPA 1993a), *Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Waters to West Coast Marine and Estuarine Organisms* (EPA 1995), *Toxicity Reduction Evaluation Protocol for Municipal Wastewater Treatment Plants* (EPA 1989a), and *Generalized Methodology for Conducting Industrial Toxicity Reduction Evaluations (TREs)* (EPA 1989b), and that this report will be used in conjunction with these related documents. Methodologies for both acute and sublethal toxicity testing have been included in this manual.

1.3 Development of Marine TIE Methods

Research conducted at the U.S. Environmental Protection Agency's (EPA) Atlantic Ecology Division (AED) in Narragansett, RI has focused on the development of marine TIEs for saline samples using freshwater TIE methods as models. In addition, two new TIE manipulations are described: a cation exchange manipulation and macroalga *Ulva lactuca* addition (Burgess et al. submitted; Ho et al. in prep.). Marine TIEs are performed using marine species on waters discharging into or from marine environments. The marine TIE methods described in this document are designed specifically for use with the marine species listed in Table 1-1. Other TIE or toxicity testing directed fractionation studies performed in marine waters and sediments used mutagenic (Grifoll et al.1988; Grifoll et al.1990; Grifoll et al. 1992; Samiloff et al. 1983; Ho and Quinn 1993a; Ho and Quinn 1993b) and whole organism assays (Walsh and Garnas 1983; Quilliam and Wright 1989; Higashi et al. 1992; Svenson et

al. 1992; Weis et al. 1992; Burgess et al. 1993; Bailey et al., 1995; Burgess et al., 1995; Ho et al., 1995).

Table 1-1. Marine Species Discussed in This Document.

Region	Organism Type	Species
Atlantic and Gulf Coast	Macroalga	*Champia parvula*
	Echinoid	*Arbacia punctulata*
	Bivalve	*Mulinia lateralis*
	Mysid	*Mysidopsis bahia*
	Amphipod	*Ampelisca abdita*
	Fishes	*Menidia beryllina*
		Cyprinodon variegatus
Pacific Coast	Macroalga	*Macrocystis pyrifera*
	Echinoids	*Strongylocentrotus purpuratus*
		Dendraster excentricus
	Bivalves	*Crassostrea gigas*
		Mytilus californianus
		Mytilus galloprovincialis
	Gastropod	*Haliotis rufescens*
	Fish	*Atherinops affinis*

Two fundamental questions addressed during the development of this manual were: (1) can marine species tolerate the chemicals used in TIE manipulations and (2) are freshwater TIE chemical manipulations directly applicable to saline effluent samples? The tolerance of marine species was addressed with most of the species in Table 1-1 using TIE additives (e.g., ethylenediaminetetraacetic acid (EDTA), sodium thiosulfate ($Na_2S_2O_3$), and methanol). A series of Phase I TIEs, conducted with several marine species on four industrial (electrical equipment) and municipal effluents and several mock effluents and single chemicals, were used to address whether the freshwater manipulations were compatible with saline samples (Burgess et al. 1995; Ho et al. 1995; Ho et al. in prep.). It should be noted that the Atlantic and Gulf coast species in Table 1-1 have undergone fairly extensive TIE research with "real" effluents for the preparation of this document. The Pacific coast species have not undergone similar research; however, they have been used in the private sector for the past few years.

Results of tolerance tests for EDTA and $Na_2S_2O_3$ readily demonstrated that these marine species can tolerate TIE manipulations at concentrations sufficient to alter toxicant effects. Generally, the effect concentrations for various additives by these marine species were similar to those for freshwater species (EPA 1991b).

The feasibility of using TIE chemicals and manipulations, such as EDTA, cation exchange solid phase extraction (SPE), and C_{18}, to characterize toxicity in a seawater matrix has been illustrated through several studies. For example, experiments with the chelator EDTA investigated the toxicity of metals in seawater (Sunda and Guillard 1976; Anderson and Morel 1978). Cation exchange has been used extensively for isolating divalent metals from seawater (e.g., McLaren et al 1985; Pai and Fang 1990). Similarly, C_{18} reverse-phase chromatography has been applied to measure the marine partitioning behavior of chemicals between dissolved organic carbon and aqueous phases (Mills et al. 1982; Hanson et al. 1988).

As the procedures in this manual illustrate, the majority of the freshwater methods (EPA 1991a, 1991b) functioned acceptably when used with marine samples. Two primary exceptions were the graduated pH procedures designed to characterize pH dependent toxicants and the conduct of each manipulation at pHs 9 and 11 (EPA 1991b). Seawater has a strong carbonate buffering system that makes any long-term pH adjustments difficult to maintain. Alteration of seawater pH with acids, bases, or organic buffers, while often initially successful, does not permanently repress the natural carbonate buffering and prevent the return to initial seawater pH. We found the most effective way to successfully adjust and maintain the pH of seawater samples (for the durations required for toxicity testing) was to conduct exposures in controlled atmospheric chambers. Unlike the variety of procedures used in the chronic and acute freshwater TIE methods(EPA 1991a, 1991b, 1993b, 1993c), we found that controlling pH in atmospheric chambers was the least intrusive, and only efficient, method of those we tested.

The use of 'closed chambers' was also investigated. In this approach, exposure chambers were completely filled with the sample, adjusted to the desired pH with acid or base, and the test organisms added. Tight-fitting lids sealed the chambers from the atmosphere. Closed chambers, while useful in some applications (i.e., where dissolved oxygen was not low) were not as universally applicable as the controlled atmospheric chambers.

Unlike the freshwater graduated pH procedure which is conducted at three distinctly different pHs (e.g., 6.0, 7.0 and 8.0 (EPA 1991b)), exposures on saline waters are performed at pHs 7, ambient seawater (8.2-8.4), and 9. These pH values were adopted because: (1) some marine test species demonstrated unacceptable control survival at pHs less than 7 and (2) maintaining sample pHs at levels two pH units above or below ambient pH levels was difficult and often ineffective. Additionally, shifting sample pHs to 11 resulted in the precipitation of some seawater hydroxides (Stumm and Morgan 1981) and severely altered seawater composition.

Section 2
Health and Safety

The following section has been reprinted, with minor modifications from *Methods for Aquatic Toxicity Identification Evaluations: Phase I Toxicity Characterization Procedures,* Second Edition (EPA 1991b).

Since TIEs involve, by definition, working with effluents of unknown composition, the accompanying safety measures must be adequate for a wide spectrum of chemical and biological agents. Often, one may be able to judge probable concerns from the type of treatment used. For example, extended aeration is likely to minimize the presence of volatile chemicals and chlorinated effluents are less likely to contain viable pathogens.

Exposure to water samples during collection and its use in the laboratory should be kept at a minimum. Inhalation and dermal absorption can be reduced by using laboratory hoods and wearing rubber gloves, laboratory aprons or coats, safety glasses, and respirators. Further guidance on health and safety for toxicity testing is described in Walters and Jameson (1984).

In addition to taking precautions with effluent samples, a number of the reagents that might be used during the tests described in this manual are known or suspected to be toxic to humans. Analysts should familiarize themselves with safe handling procedures for these chemicals (DHEW, 1977; OSHA 1976), as well as the manufacturer's Materials Safety Data Sheets (MSDS). Use of the compounds may also necessitate specific waste disposal practices.

Section 3
Quality Assurance

The following section has been reprinted, with minor modifications from *Methods for Aquatic Toxicity Identification Evaluations: Phase I Toxicity Characterization Procedures,* Second Edition (EPA 1991b).

Quality assurance is composed of two aspects, quality verification and quality control. Quality verification entails a demonstration that the proposed study plan was followed as detailed and that work carried out was properly documented. Some of the aspects of quality verification include chain of custody procedures, statements on the objective of the study and what is known about the problem at its outset, instrumental log books, and work assignments. This aspect of quality assurance ensures that a "paper trail" is created to prove that the work plan has been covered completely. The quality control aspect of quality assurance involves the procedures which take place such as the number of samples to be taken and the mode of collection, standard operating procedures for analyses, and spiking protocols.

No set quality assurance program can be dictated for a TIE; the formula to a successful study will be unique to each situation. However, adherence to some general guidelines in formulating a Quality Assurance Plan (QAP) may increase the probability of success.

In preparing a QAP, enough detail should be included so that any investigator with an appropriate background could take over the study at any time. Cross checking of results and procedures should be built into the program to the extent possible. Records should be of a quality that can be offered as evidence in court. Generally, the QAP should be provided in a narrative form that encourages the user to think about quality assurance. To be effective, the QAP must be more than a paper exercise simply restating standard operating procedures (SOPs). It must increase communication between clients, program planners, field and laboratory personnel and data analysts. The QAP must make clear the specific responsibilities of each individual. The larger the staff, the more important this becomes. While QAPs may seem to be an inconvenience, the amount of effort they require is commensurate with the benefits derived.

3.1 TIE Quality Control Plans

A successful TIE is dependent upon a strong quality control program. Obtaining quality TIE data is difficult because the constituents are unknown in contrast to quality control procedures for a standard analytical method for a specific chemical. In such an analysis, one knows the characteristics of the analyte and the implications of the analytical procedure being used. Without knowledge of the physical/chemical characteristics of the analyte, however, the impact of various analytical procedures on the compound in question is not known. Further, quality control procedures are specific to each compound; quality control procedures appropriate to one analyte may be completely inappropriate to another.

The problem of quality control is further aggravated because quality control procedures for aquatic toxicity test may be radically different from those required for individual chemical analyses. This additional dimension to quality control requires a unique framework of checks and controls to be successful. The impacts of chemical analytical procedures on sample toxicity must be included. Likewise, procedures used to insure quality toxicity test results should not impact chemical analyses. For example, in performing a standard aquatic toxicity test, samples with low dissolved oxygen (DO) are usually aerated. This practice may, however, result in a loss of toxicity if the toxicant is volatile or subject to oxidation.

3.2 Cost Considerations/Concessions

The quality control practices required in any given experiment must be weighed against the importance of the data and decisions to be based upon that data. The crucial nature of certain data will demand stringent controls, while quality control can be lessened in other experiments having less impact on the overall outcome.

Effluent toxicant identification evaluations require a large number of aquatic toxicity tests. The decision to use the standard toxicity test methods described in EPA 1993a, 1994, 1995 (involving a relatively high degree of quality control), must be weighed against the degree of complexity involved, the time required and number of tests performed; all of these affect the cost of testing. For this reason, toxicity tests used in the early phases of the evaluation generally do not follow these protocols, nor do they require exacting quality controls because the data are only

preliminary. Phase I, and to a lesser extent, Phase II results are more tentative in nature as compared to tests performed for confirmation of effluent toxicant(s) in Phase III.

The progressions towards increasing definitive results is also reflected in the use of only a few species in the initial evaluation studies and multiple species in the later stages. The use of several species of aquatic organisms to assure that the effluent toxicity has been reduced to acceptable levels is necessary because species may have different sensitivities to the same pollutant. Quality control must relate to the ultimate goal of attaining and maintaining the designated uses of the receiving water. For this reason, final effluent test results must be of sufficient quality to ensure ecosystem protection. The use of dilution water for the toxicity tests that mimics receiving water characteristics (i.e., salinity) will help to ensure that the effluent will remain non-toxic after being discharged into the environment. In the instances where the effluent dominates the receiving water, the dilution water should mimic the characteristics of the effluent. In addition, it is essential that variability in the cause of effluent toxicity be defined during the course of the TIE so that appropriate control actions provide a final effluent safe for discharge.

3.3 Variability

The opportunities to retest any effluent to confirm the quality of initial TIE results will be limited at best. In addition to the shifting chemical and toxicological nature of the discharge over time, individual effluent samples stored in the laboratory change. Effluent constituents degrade at unknown rates, as each toxicant has its own rate of change. The change in a sample's toxicity over time represents the cumulative change in all of the constituents, plus that variation resulting from experimental error. Some guidelines for assessing and minimizing changes in sample chemistry and toxicity are discussed in later sections. Regardless of the precautions taken to minimize sample changes, a sample cannot be retested with certainty that it has not changed.

3.4 Intra-Laboratory Communication

Quality control procedures in chemistry and biology can be quite different. For example, phthalates are a frequent analytical contaminant requiring special precautions that are not of toxicological concern. The toxicological problem presented by zinc levels typically associated with new glassware are of no concern to those performing organic analyses. The difference in glassware cleanup procedures is an example of one of many differences that must be resolved. Cleaning procedures must be established to cover the requirements of both. Time schedules for analyses must be detailed in advance. One cannot assume toxicant stability; therefore, time delays between the biological and chemical analysis of a sample cannot be tolerated.

3.5 Record Keeping

Throughout the TIE, record keeping is an important aspect of quality verification. All observations, including organism symptoms, should be documented. Details that may seem unimportant during testing may be crucial in later stages of the evaluation. Investigators must record test results in a manner such that preconceived notions about the effluent toxicants are not unintentionally reflected in the data. TIEs required by state or federal pollution control agencies may require that some or all records be reviewed.

3.6 Phase I Considerations

Effluent toxicity is "tracked" through Phases I, II, and III using aquatic organisms. Such tracking is the only way to detect where the toxicants are until their identity in known. The organism's response must be considered as the foundation and therefore, the toxicity test results must be dependable. System blanks (blank sampled carried through procedures and analyses identical to those performed on effluent sample) are used extensively throughout the TIE to detect toxic artifacts added during the effluent characterization manipulations. With the exception of tests intended to make the effluent more toxic, or situations in which a known amount of toxicity has been intentionally added, sample manipulation should not cause the effluent toxicity to change.

There are many sources of toxicity artifacts in Phase I. These include: excessive ionic strength resulting from the addition of acid and base during pH adjustment, formation of toxic products by acids and bases, contaminated air or carbon dioxide sources, inadequate mixing of test solutions, contaminants leached from filters, pH probes, solid phase extraction (SPE) columns, and the reagents added and their contaminants. The appropriate toxicity data for the reagent chemicals used in Phase I and common aquatic test organisms are provided as needed in subsequent sections of this document.

Frequently, toxic artifacts are unknowingly introduced. For example, some pH meters with refillable electrodes can act as a source of silver which can reach toxic levels in the solutions being measured for pH. This is especially a problem where there is a need to carefully maintain or track solution pH. Using pH electrodes without membranes avoids the silver problem (which can only be detected by the profuse use of blanks).

Oil in air lines or from compressors is a source of contamination. Simple aeration devices, such as those sold for use with aquaria are better as long as caution is taken to prevent contamination of the laboratory air which is taken in by the pump.

Worst case blanks should be used to better ensure that toxicity artifacts will be recognized. Test chambers should be covered to prevent contamination by dust and to minimize evaporation. Since small volumes are often used, evaporation must be controlled. For some manipulations, plastic disposable test chambers are recommended to avoid problems related to the reuse of test chambers. Cups from the same lot should be spot-checked for toxicity.

Glassware used in various tests and analyses must be cleaned not only for the chemical analyses but so that toxicity is not introduced either by other contaminants or by residues of cleaning agents. Since the organisms are sensitive to all chemicals at some concentrations, all toxic concentrations must be removed and not just those for which analyses are being made.

Randomization techniques, careful observance of organism exposure times and the use of organisms of approximately the same age ensure quality data. Standard reference toxicant tests should be performed with the aquatic test species on a regular basis and control charts should be developed (EPA 1993a, 1994, 1995). During Phase I it will not be known how much the toxicity of the reference toxicants varies over time compared to the toxicant(s). When the toxicants are known, they should be used as the reference toxicant. Reference toxicant tests should be performed to coincide with the TIE testing schedule.

3.7 Phase II Considerations

In Phase II, a more detailed quality control program is required. Interferences in toxicant analysis are for the most part unknown initially but as toxicant identifications are made, interferences can be determined. Likewise instrumental response, degree of toxicant separation, and detector sensitivity can be determined as identifications proceed.

3.8 Phase III Considerations

In Phase III of a TIE, the detail paid to quality control and verification is at the maximum. This phase of the study responds to the compromises made to data quality in Phases I and II. For this reason, confidence intervals for toxicity and chemical measurements must be calculated. These measurements allow the correlation between the concentration of the toxicants and effluent toxicity to be checked for significance based on test variability. Effluent manipulations prior to chemical analyses and toxicity testing are minimized in this phase in an effort to decrease the chance for production of artifacts. Field replicates to validate the precision of the sampling techniques and laboratory replicates to validate the precision of analyses must be included in the Phase III quality control program. System blanks must be provided. Calibration standards and spiked samples must also be included in the laboratory quality control program. Because an attempt will be made to correlate effluent toxicity to toxicant concentration, spiking experiments are important in determining recovery for the toxicant(s). These procedures are feasible because the identities of the substances being measured are known.

The toxicants being analyzed can be tested for using pure compounds, thereby alleviating the need for a general reference toxicant. Because the test organism also acts as an analytical detector in the correlation of effluent toxicity with toxicant(s) concentration, changes in the sensitivity of the test organism must be known. This is best achieved by using the same chemicals identified for the reference toxicants.

Section 4
Equipment, Supplies, and Facilities

Equipment necessary to perform each of the Phase I procedures is listed in Section 9 under each manipulation. In addition, basic analytical laboratory equipment such as pH meters, pumps (vacuum and fluid), pipettors, and the capacity for maintaining compressed gas cylinders and regulators are required.

A reliable source for large numbers (hundreds) of test organisms is essential for TIE work. It is recommended that on-site culturing facilities be used to prevent TIE activity from being subject to seasonal availability of field collected organisms or delays in shipping from suppliers.

A supply of "clean" saline water is necessary as a diluent, a natural seawater control, a performance control for reference toxicant testing (EPA 1994), and as a source of hypersaline brine. Large supplies of brine solutions (100‰) can be prepared, stored, diluted with deionized water (DI) to desired salinities, and used in batches to insure seawater consistency and to avoid seasonal fluctuations in water quality. At AED, saline water has been prepared from both natural seawater and GP2 synthetic seawater (e.g., EPA 1994). In addition, water used for test organism culturing should come from the same source (EPA 1994). For a discussion of acceptable source waters and their quality control, one should consult the reports: *Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Water to Marine and Estuarine Organisms*, Second Edition (EPA 1994) and *Short-Term Methods for Estimating the Chronic Toxicity of Effluents and Receiving Water to West Coast Marine and Estuarine Organisms* (EPA 1995). Further discussion will be found in Section 5.4: Salinity Adjustments and Dilution Water.

Section 5
Sample Collection, Handling, Salinity Adjustment, and Dilution

5.1 General Collection

Effluents should be collected in clean plastic or glass containers. Generally, the collection site should be the same as the monitoring site specified in the NPDES permit unless a specific concern suggests otherwise (cf. EPA 1994). Examples of when it would be appropriate to use alternate or additional collection sites include: (1) better access to a sampling point between the final discharge and the discharge outfall; (2) if the processed waste is chlorinated prior to discharge and it is desired to obtain a sample prior to chlorination; or (3) there is a desire to evaluate the toxicity of the influent to municipal waste treatment plants prior to their being combined with other wastewater streams or non-contact cooling water. It may be possible to collect enough additional sample at the time of compliance sampling if a TIE is to be done. EPA (1991b) provides further guidance on sample handling and includes a discussion of the choice between plastic and glass containers that is useful, since certain types of toxicants may absorb to certain surfaces. Additionally, the documents (EPA 1994, 1995) should be consulted for collection requirements.

The time, date, location, duration and procedures used should be recorded for effluent sample collection. During collection, aeration and transfer of effluents should be minimized to reduce the loss of volatile chemicals. Any additional observations such as color, turbidity, chlorine odor, or unusual sampling conditions (i.e., heavy rain) should be noted. If an industrial effluent is to be tested, it may be useful to record any available information on the current production levels and types of operating processes. The condition of the facilities treatment system should also be determined by the individual collecting the sample. In addition, it is recommended that total ammonia, total residual chlorine (TRC), pH, dissolved oxygen (DO), salinity/conductivity, and temperature be recorded upon arrival of the sample. At AED, salinity is usually measured using a refractometer for marine samples. Figure 5-1 provides a sample log book page for recording of sampling data.

Stored or shipped samples should be kept at 4°C and tested for toxicity within 36 hours. Limited observations on a single industrial effluent suggest that the timing of salinity adjustment (i.e., at time of collection or immediately before testing) was not critical. Parallel tests showed no toxicity differences over a 16 day period (Ho et al. 1995). However, this observation is not universal and it is suggested that an initial toxicity test be conducted on the day that the sample arrives.

The volume requirements for performing Phase I of a TIE will vary according to the toxicity of the sample. The more toxic the sample, the less effluent sample will be needed. To a certain extent, the choice of tests to be performed may also affect the desired sample volume. Table 5-1 provides estimates of the volumes of sample needed for the Phase I marine TIE tests.

5.2 Composite versus Grab Samples

There are several factors to consider when designing a sample collection scheme (EPA 1994). A 24-hour composite sample is more representative of total effluent toxicity and is more likely to collect the toxic fraction if it is intermittent (i.e., timed with an industrial process). However, a composite sample may make the toxic fraction more difficult to detect because of dilution. In addition, compositing is expensive and time consuming. The simpler and less expensive grab sample is a "snap shot" of effluent toxicity at the time of collection. A grab sample, however, has the disadvantage that it may miss intermittent toxicity altogether, or conversely, collections synchronized to a suspected manufacturing process or seasonal discharge can result in a very toxic sample. The choice of sampling method consequently will depend on the goals of a given TIE and the nature of the plant from which it is being collected. For example, if the sample is being taken from a wastewater treatment plant with a two-day detention time, there is little need for the use of composite samples. Please consult EPA 1991b,1993a for further discussion of this issue.

5.3 Pre- or Post- Chlorinated Samples

The decision to sample a municipal effluent before or after the addition of chlorine will depend on the objectives of the study. While addition of sodium thiosulfate helps determine how much of the toxicity is due to chlorine, it may also remove other oxidants and some metals, thus complicating the interpretation of results. Further, the presence of chlorine will often mask the effects of other less abundant toxicants. It is recommended to test both pre- and post- chlorinated samples to determine what portion of toxicity is attributable to chlorine.

Sample Log No.:_____

Figure 5-1. Example Data Sheet for Logging in Samples.

Table 5-1. Estimated Volumes for Phase I Marine TIE Tests.*

Characterization Step	Volume Needed (ml)†	Total (ml)
Chemistry	~ 500 ‡	
Initial	~ 100	
Baseline	~ 120	
Filtration	~ 100	
Aeration	~ 100	
EDTA Addition	~ 100	
$Na_2S_2O_3$ Addition	~ 100	
Ulva lactuca Addition	~ 200	
C_{18} Solid Phase Extraction	~ 100	
Cation Solid Phase Extraction	~ 100	
Graduated pH	~ 100	
pH 7	~ 100	
Ambient pH	~ 100	
pH 9	~ 100	
		~2000

* Values are for three replicates for initial and baseline tests and two replicates in the manipulations. Test volumes are assumed to be 20 ml/replicate. Values are directly applicable to Atlantic and Gulf Coast species, Pacific Coast species may require greater volumes.

† Assumed sample tested at 100% and diluted by 50% splits. Initial and baseline include five treatments, and manipulations include three treatments.

‡ Includes physical measures (e.g., temperature, salinity), pH, ammonia, chlorine, and dissolved oxygen.

5.4 Salinity Adjustments and Dilution Water

Dilution water for marine TIEs is hypersaline brine (100‰) adjusted to the desired salinity with DI water. Brine is made by slowly evaporating filtered natural seawater until the salinity reaches 100‰ (do not exceed this level), filtering it through a one micron filter, and storing it in 20 liter cubitainers® or polycarbonate water cooler jugs (EPA 1994). The seawater should be of high quality and collected on an incoming tide to minimize the possibility of contamination. The brine and DI mixture is a very consistent dilution water as any given "batch" of brine can be used for a year or more.

Directions for the use of hypersaline brine for salinity adjustment is also described in EPA 1993a. Basically, for freshwater salinity adjustment (0‰), the volume of brine (V_{brine}) added is described by the relationship: $V_{brine}=(S_{test} \times V_{test})/S_{brine}$, where S_{test} is the desired test salinity, V_{test} is the test sample volume, and S_{brine} is the brine salinity.

Using hypersaline brine for effluent salinity adjustment causes a degree of sample dilution that is dependent upon the initial sample salinity and the desired test salinity. For example, the greatest concentration of a freshwater effluent (i.e., 0‰) adjusted to 30‰ with 100‰ hypersaline brine is 70%. For purposes of continuity and simplicity, all further discussion of effluent concentration in this document refers to salinity adjusted samples. Therefore, 100% salinity adjusted sample means the effluent concentration is between 70% and 100%.

An alternative approach to adjust effluent salinity is the addition of artificial seawater salts like GP2. Although this method has not been tested at AED with Phase I Marine TIEs, this method has the advantage that it does not dilute the effluent sample, and consequently may be useful in certain circumstances. It is not recommended that the artificial seawater be substituted for brine as dilution water, as brine contains the necessary trace metals, biogenic colloids, and some of the microbial components necessary for the adequate growth, survival, and/or reproduction of marine and estuarine organisms (EPA 1994). Consequently, the use of artificial seawater salts may be problematic in some cases. Conversely, for a very weakly toxic samples, where brine dilution would be problematic, the addition of sea salts may be required. Finally, if a sample is hypersaline (i.e., >34‰), dilution with DI water may be needed. In general, a TIE should be performed using dilution waters similar to that used in the toxicity test(s) which triggered the TIE.

Concentrations selected for testing should be bracketed around known or estimated LC_{50} and EC_{50} values. Determining test concentrations for initial testing requires some estimations, unless the effluent has been previously tested. Starting at the highest possible concentration and using logarithmic splits results in a wide distribution of concentrations. Concentrations for the baseline and the manipulations testing should be established by bracketing the LC_{50} or EC_{50} values generated in the initial test.

Section 6
Toxicity Testing

6.1 Test Species

The toxicity testing species described in this document are listed in Table 6-1. The table indicates species recommended for use in Pacific, Atlantic, and Gulf Coast testing. The reader may note small changes to these methods compared to methods reported elsewhere (EPA 1993a, 1994, 1995). Changes were made to adapt methods for TIE use.

Both acute and chronic (i.e., sublethal) endpoints are presented. In the table, endpoints are labeled as "mortality" for acute toxicity tests while short-term chronic tests specify an endpoint other than mortality. The chronic tests include the macroalga sexual reproduction and germination and growth test using *Champia parvula* and *Macrocystis pyrifera*, and the echinoid sperm cell test using sea urchins *Strongylocentrotus purpuratus* and *Arbacia punctulata*, and the echinoid fertilization test with the sand dollar *Dendraster excentricus*. Bivalve and gastropod development tests with *Mulinia lateralis*, *Crassostrea gigas*, *Mytilus californianus*, *Mytilus galloprovincialis*, and *Haliotis rufescens* are used. The acute tests include those for fishes: *Menidia beryllina*, *Cyprinodon variegatus*, and *Atherinops affinis*, the mysid *Mysidopsis bahia*, and the amphipod *Ampelisca abdita*.

Table 6-1. Marine Species Recommended for Use in Marine TIEs

Organism	Species	Region	Endpoint*	Exposure (hr.)
Macroalga	*Champia parvula*	Atlantic and Gulf Coasts	sexual reproduction	48
	Macrocystis pyrifera	Pacific Coast	germination/growth	48
Echinoid	*Arbacia punctulata*	Atlantic and Gulf Coasts	fertilization	1
	Strongylocentrotus purpuratus	Pacific Coast	fertilization	~1
			or development	72
	Dendraster excentricus	Pacific Coast	fertilization	~1
			or development	72
Bivalve	*Mulinia lateralis*	Atlantic and Gulf Coasts	mortality/development	24
	Crassostrea gigas	Pacific Coast	development	48
	Mytilus californianus	Pacific Coast	development	48
	Mytilus galloprovincialis	Pacific Coast	development	48
Gastropod	*Haliotis rufescens*	Pacific Coast	development	48
Mysid	*Mysidopsis bahia*	Atlantic and Gulf Coasts	mortality	48
Amphipod	*Ampelisca abdita*	Atlantic and Gulf Coasts	mortality	48
Fish	*Menidia beryllina*	Atlantic and Gulf Coasts	mortality	48
	Cyprinodon variegatus	Atlantic and Gulf Coasts	mortality	48
	Atherinops affinis	Pacific Coast	mortality/growth	48-168

* Acute tests are indicated by an endpoint of mortality, chronic tests by an endpoint other than mortality.

6.2 Test Methods

This section provides brief descriptions of the marine Phase I TIE toxicity tests. The TIE toxicity testing methods are very similar to conventional methods described in EPA 1993a, 1994, and 1995 except for minor changes to account for exposure volume reductions and feeding protocols. The Appendix provides test parameters of the methods.

In addition to the noted tests, we have conducted sediment interstitial water TIEs with the marine amphipod *Ampelisca abdita* and bivalve *Mulinia lateralis*. Further, we have used conventional NPDES toxicity tests, using the mysid *Mysidopsis bahia* and sea urchin *Arbacia punctulata*, in sediment interstitial water TIEs.

6.2.1 Macroalga Sexual Reproduction or Germination/Growth Tests

These methods use sexual reproduction of the macroalga *Champia parvula* and the germination and growth of the kelp *Macrocystis pyrifera* to measure toxicity. The *Champia parvula* procedure involves measuring the development of cystocarps on female plants. The *Macrocystis pyrifera* procedure quantifies the germination of settled zoospores and length of the germination tube.

Changes to the *Champia parvula* method (EPA 1994) for TIE purposes include a reduction in test solution volume from 100 mL to 20 mL and use of 50 mL petri dishes as the exposure chambers. Further, when conducting the Graduated pH Procedure, photosynthesis will increase pH by approximately 0.1 - 0.4 units. This is to be expected but should not exceed 0.5 pH units. Test parameters of these methods are presented in the Appendix.

6.2.2 Echinoid Sperm Cell Tests

The echinoid sperm cell tests have reduced fertilization of exposed gametes as an indication of toxicity. Dilute sperm solutions are exposed to test samples for 20 to 60 minutes. Following this exposure eggs are added to the samples and fertilization is allowed to occur. Twenty minutes after egg addition the test is terminated by the addition of a fixative. Fertilization is determined by microscopic examination of an aliquot from each treatment, and is shown by the presence of a membrane surrounding the egg.

Little has been changed in the sperm cell test methods to accommodate TIE applications. The existing method (EPA 1994, 1995) is extremely useful for TIE applications due to its use of very small exposure volumes (i.e., 5 mL), demonstrated sensitivity, and relatively rapid exposure. For conducting the Graduated pH Procedure, we have found it useful to keep the test scintillation vials in the atmosphere controlled chambers during the 20-60 minute sperm exposure to maintain desired pH values (cf. Section 9.9). Test parameters are presented in the Appendix.

6.2.3 Echinoid, Bivalve, and Gastropod Development Tests

The development tests involve several marine species and developmental endpoints (EPA 1994, 1995). Echinoid procedures assess the formation of the larval test. Bivalve and gastropod tests evaluate the growth of the larval shell. Microscopic analysis is used to determine test and shell condition. All tests are performed in small volumes (5-10 mL) and are amenable for TIEs. Test parameters of the methods are found in the Appendix.

6.2.4 Acute Mysid and Fish Tests

For TIEs, three Atlantic and Gulf Coast test methods are conducted similarly and use a mortality endpoint. Experimental designs consist of static 48-hour exposures with five organisms in 10 to 20 mL of test solution (i.e., 30 mL exposure cups). Mysid (*Mysidopsis bahia*) toxicity tests use 1-5 day animals. For fish testing, 9 to 14 day old *Menidia beryllina*, and 1-14 day old *Cyprinodon variegatus* are used. A TIE method for using 9-15 day old fish *Atherinops affinis* with small test volumes has not been fully developed. Test parameters are given in the Appendix.

Noteworthy changes to the standard marine acute methods (EPA 1993a) are the reduction in sample volume from approximately 100 mL to 10 or 20 mL and reduction in exposure period from 96 hours to 48 hours. When conducting the Graduated pH Procedure the organisms will add CO_2 to the exposure chambers resulting in decreases in sample pHs. Also, feeding test organisms *Artemia* will further reduce chamber pHs. To avoid drastic reductions in sample pH, especially in the pH 9.0 treatment, feed test organisms small rations. The Appendix details these and other changes to the standard methods.

6.2.5 Other Marine Species

Included in various sections of this document are references to other marine species, besides some of the common marine NPDES toxicity testing species, which can be incorporated into the marine TIE. Currently, these species are the amphipod *Ampelisca abdita* and the bivalve *Mulinia lateralis*. At AED, they have proven valuable in developing marine sediment TIE methods, but they can also be used to assess effluent toxicity. At the time this document was prepared, insufficient information was available to include the West Coast survival and growth method using the mysid *Holmesimysis costata.*

As with the other marine toxicity tests that use "whole organisms," major changes to the current methods with *Ampelisca abdita* (Scott and Redmond 1989) include reducing exposure volumes to approximately 10 mL and exposure duration to 48 hours. An evaluation of a 24-hour embryo-larval development test using the bivalve *Mulinia lateralis* is continuing.

Section 7
Statistical Methods

Test results are used to calculate point estimates (e.g., LC_{50}s and EC_{50}s). EPA recommends probit, Spearman-Karber, trimmed Spearman-Karber, and Inhibition Concentration (IC_p; p is the percent effect, e.g., mortality, reduced growth, etc.) as means to calculate point estimates (EPA 1993a, 1994, 1995).

Conversion of point estimates to toxic units (e.g., Toxic Units = $100/LC_{50}$ or $100/IC_p$) eliminates the inverse relationship between toxicity and LC_{50} or EC_{50} values making TIE interpretation easier. Furthermore, if the concentration of toxicants are known for a given sample, the toxic units for the individual toxicants can be compared to the total sample toxic units. The sum of the toxic units of the individual toxicants should be similar to the total toxic units of the sample, assuming they are all measured, bioavailable, and that their toxicities are additive.

Section 8
Ion Imbalance

The methods in this document do not directly address toxicity caused by ion imbalance as recorded in some types of effluents (e.g., McCulloch et al. 1993). If an ion imbalance is suspected in a sample, several studies are available that discuss how to characterize and identify such toxicity (McCulloch et al. 1993; Mount et al. in press; Douglas and Horne in press; Douglas et al. in press; Tietge et al. in press). It should be noted that although an ion imbalance may impart an apparent 'salinity' to a sample, in most cases the sample is not truly marine. Marine salinity has a specific composition of ions at relatively consistent proportions to one another. Effluents with ion imbalances seldom will have truly marine composition.

An approach for determining if an ion imbalance may be present in a given sample is to perform an anion and cation analysis for major elements (e.g., sodium, calcium, potassium, magnesium, chloride, sulfate, and bromide). Measured values can be compared to toxicity information (Douglas et al. in press), marine Water Quality Criteria (WQC), and known marine background levels (Millero and Sohn 1992) to assess if an imbalance may occur.

Section 9
Toxicity Identification Evaluation Procedures

A Phase I marine TIE characterization consists of the following recommended components (see also Figure 9-1):

- Initial Toxicity Test (§9.1, §6, Appendix)
- Baseline Toxicity Test (§9.2, §6, Appendix)
- Filtration Procedure (§9.3)
- Aeration Procedure (§9.4)
- EDTA Procedure (§9.5)
- $Na_2S_2O_3$ Procedure (§9.6)
- C_{18} Solid Phase Extraction (SPE) Procedure (§9.7)
- C_{18} SPE Methanol Elution Test (§9.8)
- Graduated pH Procedure (§9.9)
- Cation Exchange SPE Procedure (§9.10)
- Cation Exchange SPE Acid Elution Test (§9.11)
- *Ulva lactuca* Procedure (§9.12)

Figures 9-1 and 9-2 give an overview of the design of a typical marine Phase I TIE. One should note, however, that because of the varying durations of the toxicity tests used in a marine Phase I TIE that the indications of 'DAY 1' and 'DAY 2' may not always be appropriate.

While the Initial and Baseline Toxicity Tests are based on routine toxicity testing exposures, the other procedures (e.g., EDTA and $Na_2S_2O_3$) are specialized and require some knowledge of the sensitivity of the testing organisms to specific chemicals. The following sections describe the objectives and general procedures for conducting the TIE manipulations. Familiarity with the freshwater TIE procedures (EPA 1991a, 1991b) is recommended.

Specific information concerning numbers of treatments, types of species to test, volumes of effluent to prepare, and duration of exposures are only recommendations and may require modification depending upon each application. Blanks are described for each procedure and involve using the control seawater (often brine and DI) in the manipulations before the sample.

9.1 Initial Toxicity Test

9.1.1 General Approach

The objective of an Initial Toxicity Test for a TIE is to determine the toxicity of a given sample. The Initial Toxicity Test is performed on DAY 1 of the marine TIE process, while the Baseline Toxicity Test and procedures are generally conducted on DAY 2 (Figure 9-1 and Figure 9-2).

9.1.2 Materials

- Materials, organisms and apparatus necessary to conduct toxicity test (See Section 6 and Appendix).

9.1.3 Procedural Overview

Design of Initial Toxicity Test

Initial Toxicity Tests have a serial dilution design. We recommend five concentrations (post-salinity adjusted): 100%, 50%, 25%, 12.5%, 6.25% and a control (i.e., 0%) with one to three replicates (three preferred) per concentration (Figure 9-2). However, if a sample is very toxic, this range of concentrations will be too high and a set of lower concentrations will be needed. Therefore, if data from compliance testing suggests high toxicity, one should adopt a different set of concentration ranges including the necessary lower non-toxic concentrations.

Results of Initial Toxicity Test

Initial Toxicity Test results are used to judge how toxic the sample is toxic and if a TIE on the given sample is warranted. If so, Initial Toxicity Test results will be used to establish effluent test concentrations for subsequent TIE manipulations.

From our experience, it may be difficult, but not impossible, to conduct a TIE when the toxic units of a sample from the Initial Toxicity Test using the most sensitive species are <2 (i.e., LC_{50} > 50%). It is critical, however, to insure that the toxic units are <2 by repeating toxicity tests and using smaller concentration intervals (i.e., bracketing the effect concentrations more closely). Table 9-1 provides some other criteria as to when decisions can be made about proceeding with the Baseline Toxicity Test and TIE procedures.

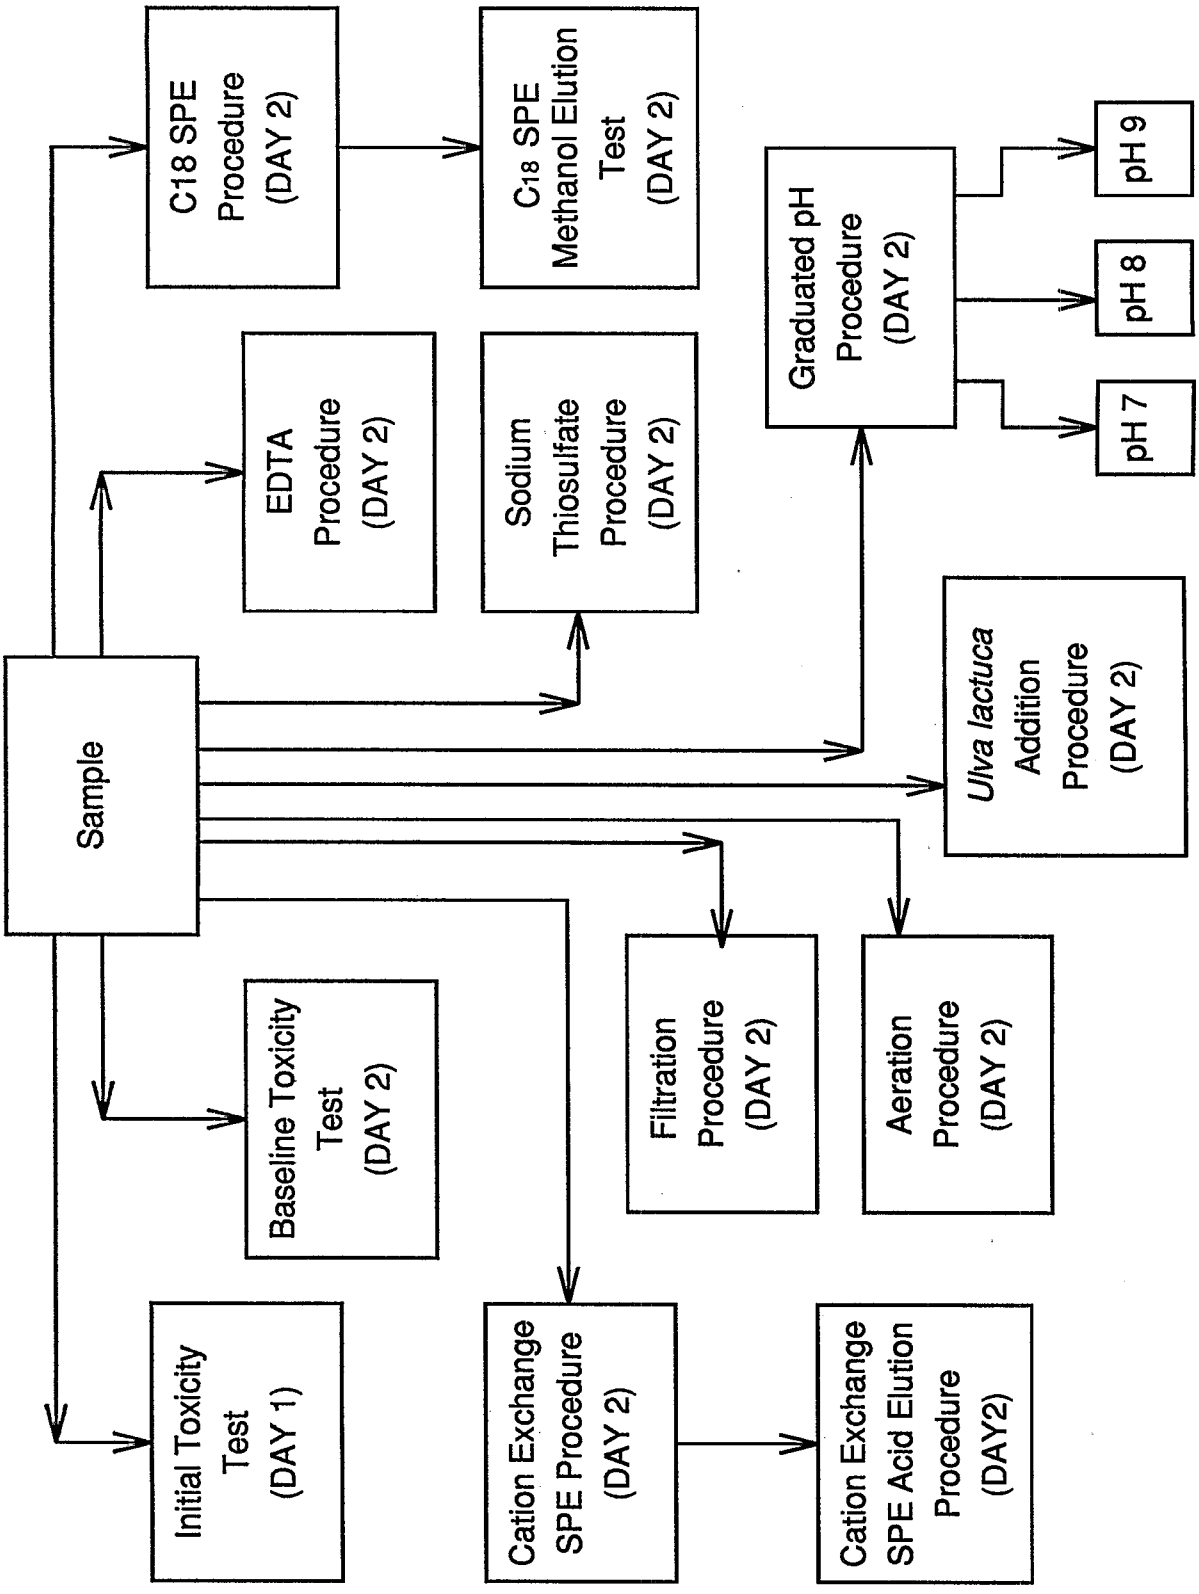

Figure 9-1. Overview Flowchart of a Typical Complete Phase I Marine TIE Characterization.
(NOTE: As a result of toxicity test durations, DAY 2 manipulations may occur later than the true DAY 2)

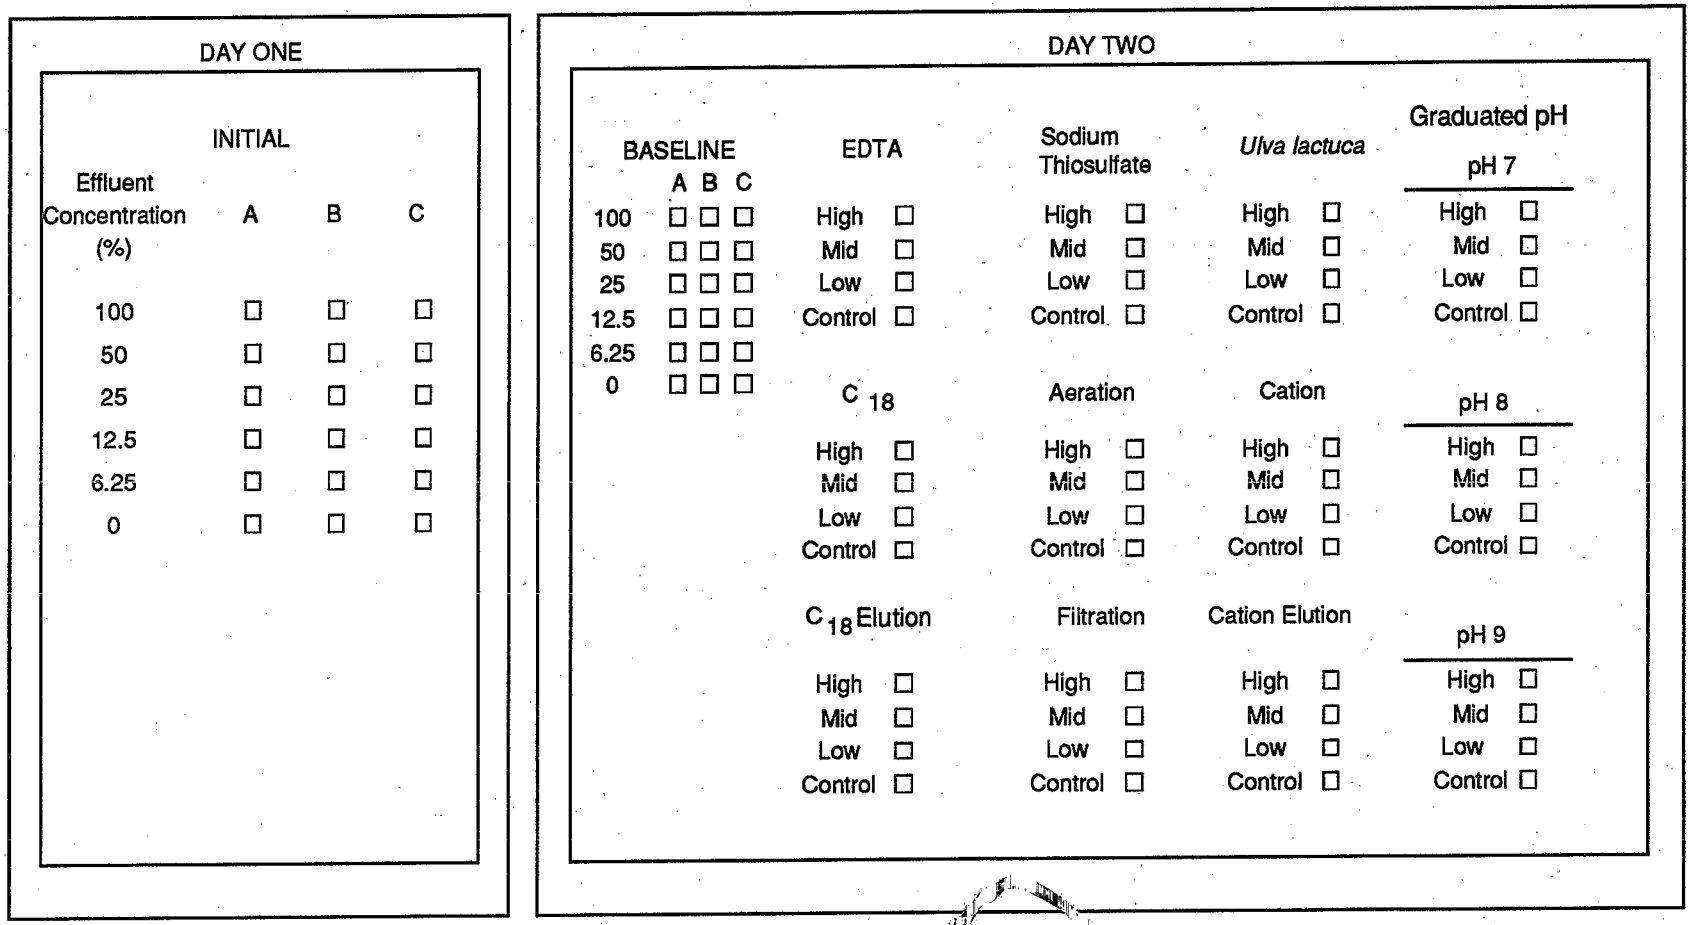

Figure 9-2. Schematic of Marine TIE Experimental Design. (NOTE: Squares represent replicates; Effluent concentrations a[illegible]ample

Table 9-1. Guidance on Conduct of Baseline Toxicity Test and TIE Procedures

Toxicity Test Species	Guidelines to Make Decision to Proceed
Champia parvula	Due to duration of exposure, one may have to use results of other tests or delay initiation of TIE
Arbacia punctulata	Results of initial toxicity test (Day 1)
Mulinia lateralis	48 hr. results
Mysidopsis bahia	24 hr. results; if no toxicity, use 48 hr. results
Ampelisca abdita	24 hr. results; if no toxicity, use 48 hr. results
Menidia beryllina	24 hr. results; if no toxicity, use 48 hr. results
Cyprinodon variegatus	24 hr. results; if no toxicity, use 48 hr. results
Macrocystis pyrifera	48 hr. results
Strongylocentrotus purpuratus	**fertilization:** Day 1 results; **development:** 72 hr. results
Dendraster excentricus	**fertilization:** Day 1 results; **development:** 72 hr. results
Crassostrea gigas	48 hr. results
Mytilus californianus	48 hr. results
Mytilus galloprovincialis	48 hr. results
Haliotis rufenscens	48 hr. results
Atherinops affinis	24 hr. results; if no mortality, use 48 hr. results, up to 168 hr.

Because of the long duration of the algal *Champia parvula* reproduction test, it is difficult to follow the standard TIE format. Therefore, it is necessary to use test results from other species to predict *Champia parvula*'s response or perform the initial test five to seven days earlier than the other species (assuming no alterations in toxicity due to storage). *Champia parvula* is often the most sensitive NPDES toxicity testing species when tested with municipal and industrial effluents (Schimmel et al. 1989) and therefore, a prediction of high toxicity is warranted. Conversely, because of the short duration of the sea urchin *Arbacia punctulata* sperm cell test, an entire TIE can often be conducted in two days, or even one day, if prior information about the toxicity of the sample is available and appropriate dilutions can be prepared. The fertilization endpoints of toxicity test using *Strongylocentrotus purpuratus* and *Dendraster excentricus* can be used similarly.

9.2 Baseline Toxicity Test

9.2.1 General Approach

Results of the Baseline Toxicity Test are used for comparison with the Initial Toxicity Test and TIE manipulations. Objectives are to: (1) determine if sample toxicity has changed relative to Initial Toxicity Test and (2) provide a baseline for comparison with results of TIE procedures. A Baseline Toxicity Test is performed following the Initial Toxicity Test, in conjunction with the TIE Manipulations (Figures 9-1 and 9-2). In Figure 9-2, we indictate the use of one replicate per test concentration and three concentrations per procedure. These values for the study design are not recommendations but must be determined according to study objectives, logistics and economic constraints.

9.2.2 Materials

- Materials, Organisms and Apparatus necessary to conduct toxicity test (See Section 6 and Appendix).

9.2.3 Procedural Overview

Design of Baseline Test

Baseline Toxicity Tests have a serial dilution design. Usually five concentrations: 100%, 50%, 25%, 12.5%, 6.25% and a control (0%) with three replicates/concentration are used. However, if the Initial Toxicity Test demonstrates greater toxicity, lower dilutions may be justified.

Results of Baseline Toxicity Test

Because of the variety of species potentially being tested, Baseline Toxicity Test results will be dependent on the toxicity test being used. However, regardless of species, the questions being answered are the same for each toxicity test, "Did sample toxicity change relative to the Initial Toxicity Test and did the TIE procedures decrease or increase toxicity compared to the Baseline Toxicity Test?" Quantitatively, these questions are answered by comparing toxic units between the various procedures. Sources of toxicity are implied from the magnitude of difference between the baseline and TIE procedures results. However, statistical evaluations of significance may be precluded, for most TIE tests, because of insufficient replication within TIE experimental designs. See Section 10 for further discussion of the interpretation of TIE results.

9.3 Filtration Procedure

9.3.1 General Approach

Filtration is used to determine whether toxicants pass through a filter or are associated with particles. Note for effluents, samples can be filtered before being passed through the C_{18} column (See Section 9.7). However, filtration may create artifacts (e.g., toxicant sorption to filter) that may need to be addressed in evaluating results. Filtrates are the substances that pass through the filter.

9.3.2 Materials

- Oil-free air pump and tubing—to force sample through filtration apparatus.
- 0.45 µm (or similar size) glass fiber filters and filtration apparatus—to separate particles from sample. For samples that are suspected to contain toxic metals, organic membrane filters may be used instead of glass filters. However, a comparison of filter types may be necessary.

9.3.3 Procedural Overview

(1) Filter brine and DI blank; remove brine and DI blank filtrate for testing (Figure 9-3).
(2) Without changing filters, filter the effluent. Change filters as often as necessary to prevent clogging, repeating step 1 as needed. Save all filters for possible later analysis (i.e., wrap in aluminum foil or Parafilm® and store at 4°C). Remove filtrate for testing.
(3) Use filtered brine and DI blank as diluent.

9.4 Aeration Procedure

9.4.1 General Approach

Samples are aerated to determine if toxicity is due to volatile toxicants (e.g., H_2S or volatile hydrocarbons).

9.4.2 Materials

- Oil-free air pump and tubing—to aerate sample.
- Graduated cylinders—to hold sample while aerating.
- 1-10 mL pipettes—attached to tubing and placed in sample during aeration. Fritted end on pipettor tubing will improve aeration.

9.4.3 Procedural Overview

(1) Samples should be aerated in a hood.
(2) Separately pour sample, and brine and DI blank into graduated cylinders (Figure 9-4).
(3) Connect 1-10 mL pipettes to air pump tubing and place pipettes into graduated cylinders.
(4) Turn pump on, adjust air flow to establish many small bubbles, and let sample aerate for 1 hour.
(5) Test aerated sample using aerated brine and DI as diluent.

9.5 EDTA Procedure

9.5.1 General Approach

EDTA (ethylenediaminetetraacetic acid) is an organic chelating agent that preferentially binds with divalent cationic metals, such as copper, nickel, lead, zinc, cadmium, mercury, and other transition metals (Garvan 1964). Studies have demonstrated that when a metal is bound to the EDTA molecule, the toxicity of the metal is greatly reduced (e.g., Sunda and Guilliard 1976). In this procedure, EDTA is added to samples to evaluate metal toxicity. Table 9-2 provides recommended exposure concentrations and Tables 9-3 and 9-4 report results of tolerance testing with Atlantic, Gulf, and Pacific Coast species.

9.5.2 Materials

- EDTA stock solution (25 g EDTA/L DI (74.4 mmols EDTA/L) refrigerated)
- Glass Erlenmeyer flask (100-250 mL), microbalance, weighing pan, and Teflon®-coated stirbar—for preparing EDTA stock solution.
- Adjustable microvolume pipetter (10-1000 µL range) and tips—for dispensing EDTA stock solution to exposure chambers.

Table 9-2. Volumes of EDTA Stock Solution for Additions (25g EDTA/L stock solution)

Replicate Volume (mL)	Volume (µL) EDTA Solution/Replicate	Volume (µL) EDTA Solution/Replicate for *M. pyrifera*
5	12	10
10	24	20
20	48	40
40	96	80
100	240	200
200	480	400

9.5.3 Procedural Overview

(1) Prepare EDTA stock solution: weigh-out 2.78 g of $EDTA \circ 2H_2O$ reagent (sodium salt) and add to 100 mL of DI. Mix with a Teflon®-coated stirbar until EDTA is completely in solution. This stock solution is stable and can be stored refrigerated (Figure 9-5).
(2) Set-up dilution series with sample. Generally, a TIE dilution series consists of three effluent concentrations and a blank (brine and DI), however, the statistical design of the TIE should be based on the objectives of the study, logistics, and economic constraints. The concentrations tested should bracket observed toxicity, based on the Initial Toxicity Test. **Do not add the organisms yet!**
(3) Tolerance testing of several Atlantic, Gulf, and Pacific Coast species indicates that most organisms can tolerate 60 mg EDTA/L (0.22 mmols EDTA/L) (Table 9-3, 9-4). Given the EC_{50} of 100 mg/L for *M. pyrifera*, it is advisable to use 50 mg/L (0.14 mmol/L) for the EDTA Procedure with that species. This concentration of EDTA is sufficient to chelate about 22 mg Total M^{2+}/L (equal molarity of metals). Use Table 9-2 to determine the volume of EDTA stock (25 g EDTA/L) to add to test containers:
(4) Add specified volume, mix thoroughly and allow EDTA and sample to interact for about 3 hours. **Do not add the organisms yet!**
(5) After 3 hours, add test organisms to dilution series.

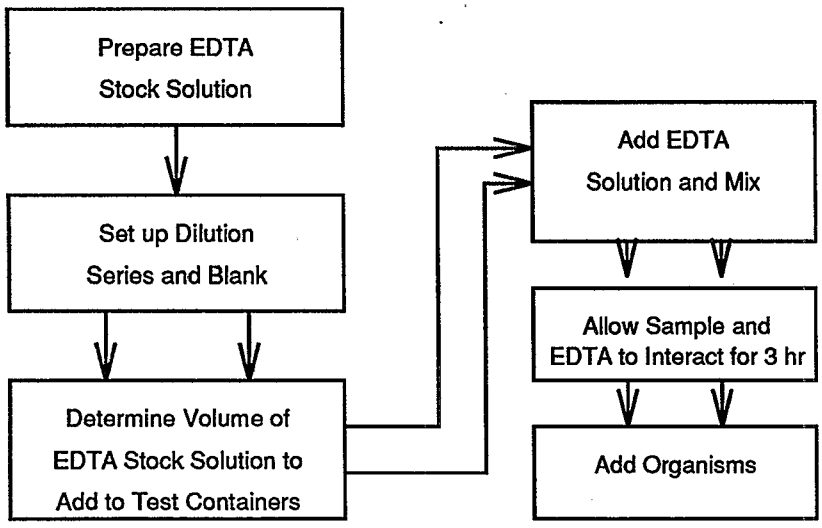

Figure 9-5. Overview Flowchart of EDTA Procedure.

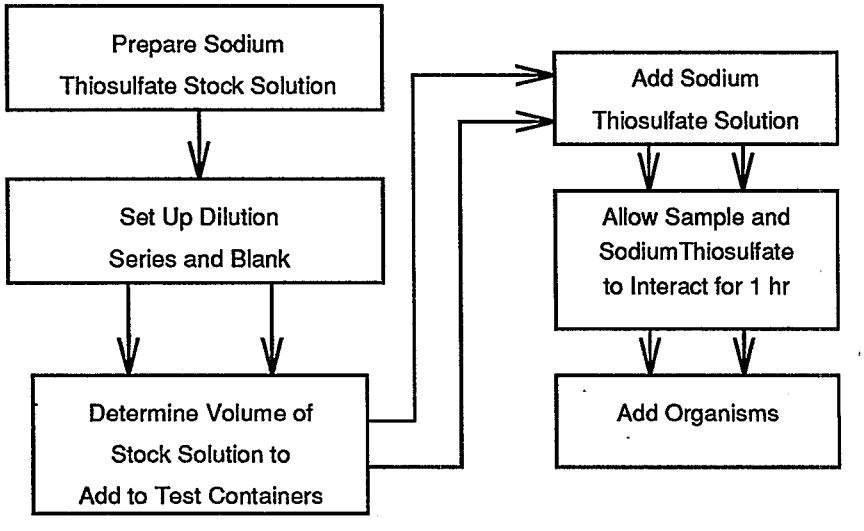

Figure 9-6. Overview Flowchart of Sodium Thiosulfate Procedure.

9.6 Sodium Thiosulfate Procedure

9.6.1 General Approach

Addition of sodium thiosulfate ($Na_2S_2O_3$), a reducing agent, to a sample containing oxidants (e.g., chlorine or bromine), results in a reduction reaction (White 1972) that may decrease sample toxicity. For example, chlorine (Cl_2) added to sewage effluent prior to release would undergo the following reaction:

$$Cl_2 + 2e^- \xrightarrow{2S_2O_3^{2-}} 2Cl^-$$

where the 2 electrons (e^-) provided by the thiosulfate (S_2O_3) reduce the toxic diatomic chlorine (Cl_2) to nontoxic chlorine ions (Cl^-). In this test, $Na_2S_2O_3$ is added to effluent samples to evaluate whether toxic oxidants are present. Table 9-5 provides recommended exposure concentrations and Tables 9-6 and 9-7 report the results of tolerance testing with Atlantic, Gulf, and Pacific coast species.

9.6.2 Materials

- $Na_2S_2O_3$ Stock Solution (15 g $Na_2S_2O_3$/L DI (94.9 mmols $Na_2S_2O_3$/L)). **This solution cannot be stored. Make up prior to use.**
- Glass Erlenmeyer flask (100-250 mL), microbalance, weighing pan, spatula and Teflon®-coated stirbar—for preparing $Na_2S_2O_3$ stock solution.
- Adjustable microvolume pipetter (10-1000 µL range) and tips—for dispensing $Na_2S_2O_3$ stock solution to exposure chambers.

9.6.3 Procedural Overview
