ABSTRACT

The 52 mile Los Angeles River has six degraded and three lost beneficial uses due to its transformation into a flood control channel and deteriorated water quality. Currently, six uses occur in poor water quality, threatening the use and user. However, desire to restore beneficial uses, such as water supply, wildlife habitat, and recreation, is growing due to community awareness and availability of environmentally enhancing flood control technologies. Achievement of restoration requires improvement of specific water quality parameters. Monitoring results from 1988-1992 indicate: bacteriological >32,000 MPN/100ml, sporadically high biological oxygen demand, oil and gas 2.9 mg/l, nitrate as N, 10mg/l and phosphate as P, 2.8 mg/l. The wet regime, which averages 42 days per year, indicates detections of: Lindane, PCBs and twelve heavy metals River management requires knowledge of land use, water reclamation plant discharges, flow regimes, and channel surfaces. Land use analysis of thirteen sub-watersheds indicate that impacts are predictable and intensify downstream.

ACKNOWLEDGEMENTS

I wish to thank all of my committee members, who taught me throughout my college years, the skills necessary to complete this thesis. I wish to thank Dr. Prem Saint for his contributions as committee chair and for his enthusiasm for learning and teaching, to which I aspire. I value the contributions of each agency which supplied information and data for my research, and especially appreciate the efforts of those agencies whose staff were more than willing to provide water quality data. In addition, I wish to thank Friends of the Los Angeles River for providing me a means to learn and study the river. Also, I would like to acknowledge Lewis Mac Adams, whose vision and respect for the river essentially became my thesis.

CHAPTER I

INTRODUCTION

The Los Angeles River, The Transformations

The Los Angeles River drains the mountains surrounding the coastal valleys and plains in the greater Los Angeles Metropolitan Area. The river's length is 52 miles, flowing through the San Fernando Valley, past downtown Los Angeles, to San Pedro Bay in Long Beach (Figure 1). The river was once a natural free-flowing stream which provided many beneficial uses such as water supply, groundwater recharge, recreation, wildlife, and fisheries--the river was an asset to the city. The Los Angeles area population grew and flood plains were urbanized. When the river occasionally flooded these areas, the river was perceived as a liability and the river was soon channelized in concrete. This change from a natural river to a flood control channel was the first transformation, which caused the loss of several beneficial uses (Figures 2a and 2b).

Political pressure from environmental and community groups, recent droughts and growing urban pressures initiated a movement to investigate ways to transform the river back into a resource with restored beneficial uses. During the late 1980s through the early 1990s, several political offices and local agencies were considering options to increase beneficial uses of the river, although the uses have been limited to recreation and water conservation. This is the beginning of the second transformation of the river. A change in the perception of the Los Angeles River is underway: the river is again being perceived as an asset rather than a liability.

Beneficial Use and Water Quality Problems

Apart from political and social challenges in transforming the Los Angeles River into a river which can provide opportunities for expanded beneficial uses, the greatest challenge

VOL 12

1

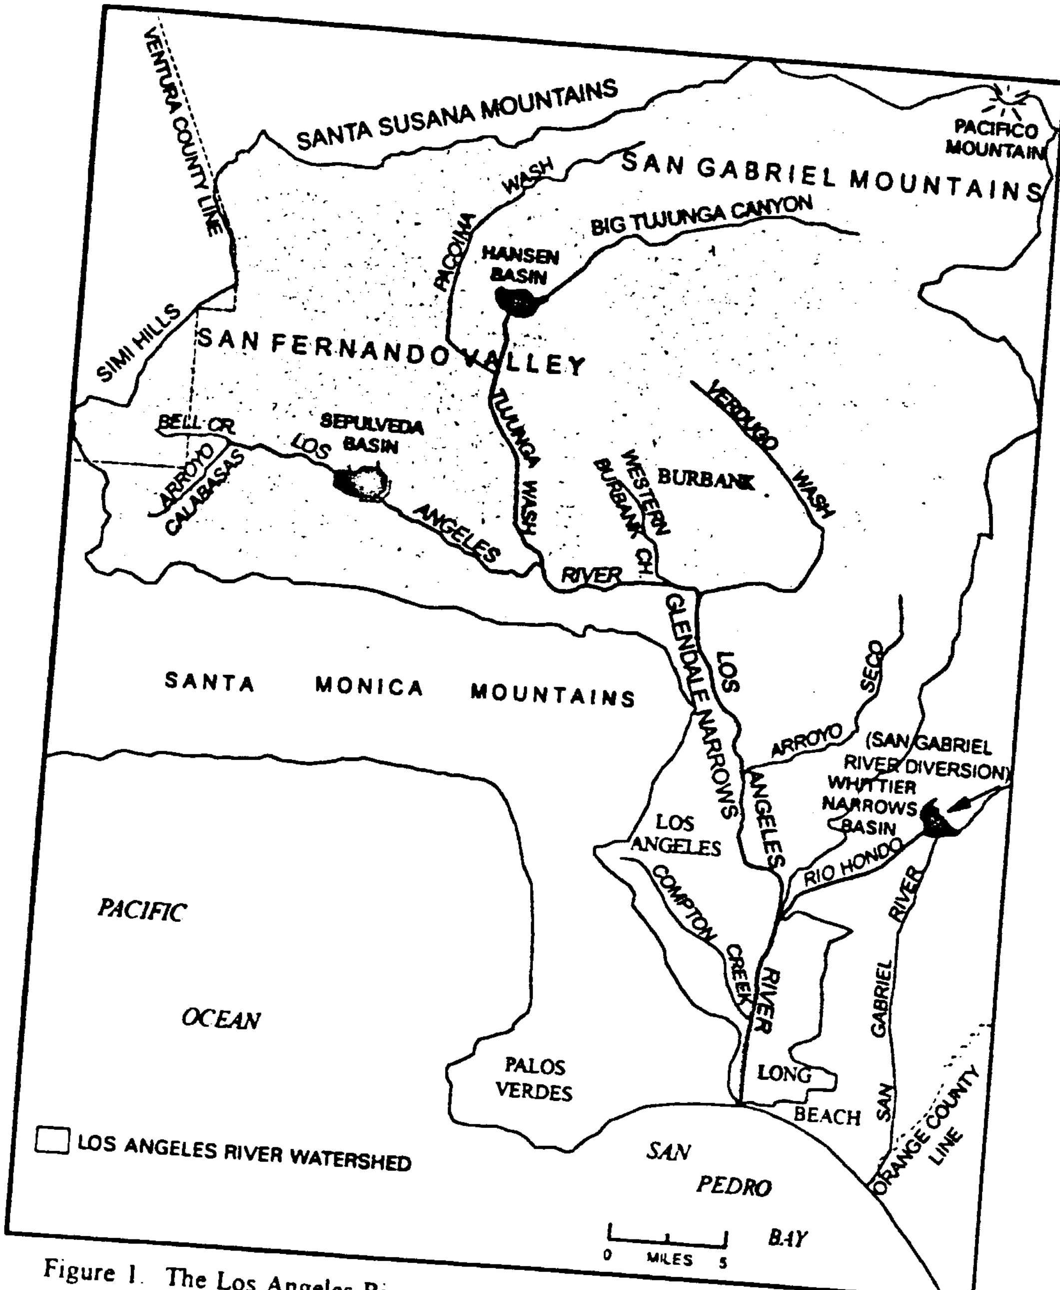

Figure 1. The Los Angeles River watershed. The river drains 832 square miles, making it the largest watershed in Los Angeles County.

Figure 2a. The Los Angeles River in Glendale Narrows at Los Feliz Bridge in 1932 (U.S. Army Corps of Engineers 1938). Before channelization with concrete, the river supported a rich diversity of plant life.

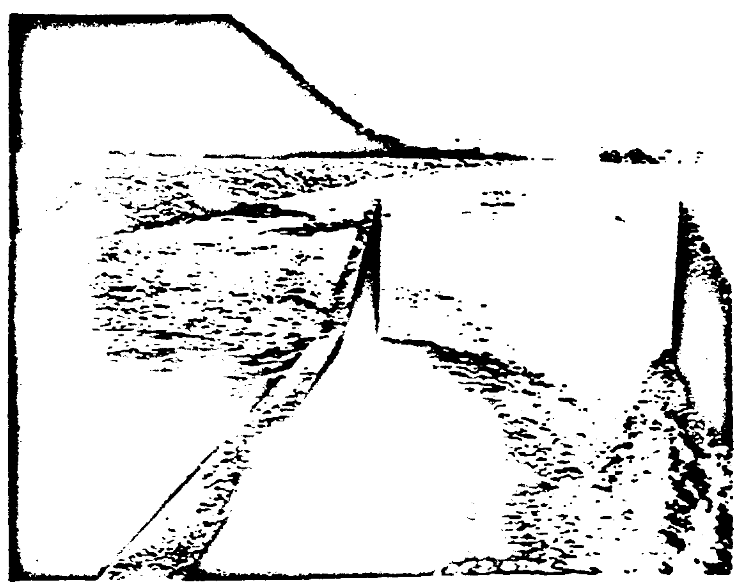

Figure 2b. The Los Angeles River at the same location as above after reinforcing banks with concrete and applying stone cobble bottom in 1938 (U.S. Army Corps of Engineers 1938). Channelization has significantly altered the river ecology.

is likely to be water quality management. Any resource development, such as water supply, recreation, habitat restoration, or aesthetic improvements, will require improvement of the river's water quality.

The U.S. Geological Survey (1965) defines water quality as "those traits that are distinctive to a body or supply of water in relation to some use — for example, drinking, irrigation of croplands, manufacturing, food processing, or recreation." The aspects of water quality which are important depend on the need or use for the water. However, regardless of need, quality of a water body can be rated as good or poor, using standards based on scientific data. On the Los Angeles River, water quality parameters which impact water usage include: dissolved minerals and organics, microorganisms, sediments, and urban trash. The water quality of the Los Angeles River has not been adequately studied in context of present or future uses.

Historical Perspectives on Beneficial Uses and Water Quality

The term "beneficial uses" is often used to describe waters being utilized by humans as well as by wildlife. The Federal Water Pollution Control Administration (FWPCA) (Interim Report, 1967) established criteria for major water uses: (1) aesthetics and recreation, (2) public water supplies, (3) fish, other aquatic life, and propagation of habitat, (4) agriculture, and (5) industrial water supplies. The California Regional Water Quality Control Board Los Angeles Region (IV) (RWQCB) recognizes 24 beneficial uses for water bodies in the region which includes Los Angeles and Ventura counties. These include: municipal and domestic water supply, agricultural supply, industrial service supply, industrial process supply, groundwater recharge, freshwater replenishment, navigation, hydropower generation, water contact recreation, non-contact water recreation, ocean commercial and sport fishing, warm freshwater habitat, cold freshwater habitat, preservation of areas of special biological significance, saline water habitat, wildlife habitat, preservation of rare and endangered species, marine habitat, fish migration, fish spawning, shellfish harvesting, estuarine, wetland, and aquaculture.

Beneficial uses are limited by and intrinsically tied to water quality. The study of water quality began with an emphasis on public health, but has shifted toward improving the quality of life for humans and wildlife. Hennigan et al (1969) described the historical development of water pollution control. In the past, the goals of most water pollution control programs were the prevention of communicable diseases through ingestion or body contact, prevention of fish kills, and elimination of nuisance conditions such as odors and trash. Post-World War II brought heavy industrialization and urbanization, and a greater concern about the quality of life. Both of these put more demands on water resources. With the growth of the environmental movement in the 1960s, the general public became aware of the sustained management of water resources. The result was the recognition of a limited water resource base and the ever-expanding need and demands, rising standards, and public insistence that effective action be taken to stop exploitation and degradation.

Emphasis in regulatory requirements has shifted over the years. Krenkel (1979) states that emphasis shifted from protection of public health to environmental protection. Regulatory requirements are based on water quality standards necessary to maintain and improve fisheries and aesthetic conditions in addition to consideration of the basic needs of the society. Hennigan et al (1969), called for more multi-disciplinary and interdisciplinary efforts in water resource research, including ecology, institutional reform, and public policy. They wrote "Water resource management and water quality management cannot be divorced and operated unilaterally very effectively. Stream flow regulation for water supply, recreation, power, flood control, and irrigation either is very dependent on quality control, or in the very operation itself, has a tremendous impact on water quality considerations." These ideas resulted in the designation of beneficial uses, whereby water use is inherently linked to water quality.

Pollutants limit the usability and safety of waters. Nemerow (1985) defines pollutants as too much of any given substance such that it renders the receiving water unusable in its existing state for its desired best usage. A study of water quality includes consideration of standards and tolerances that have been established (Hem 1989).

Water quality is considered in any discussion of beneficial uses. According to Krenkel and Novotny (1980), the intended use of water should its quality requirements and delineation of water allocated for specific uses is mandatory. Quality requirements can be defined as two respective terms; criteria or standards (U.S. EPA 1976). Criteria represent a constituent concentration or level associated with a degree of environmental effect upon which scientific judgment may be based. The term has come to mean a designated concentration of a constituent that, when not exceeded, will protect an organism, an organism community or a prescribed water use with an adequate degree of safety. Standards, on the other hand, use criteria as a basis for regulation or enforcement, but the standard may differ from criteria because of prevailing local natural conditions, economic considerations or desired safety. Establishing and meeting water quality criteria on the Los Angeles River allow the restoration of beneficial uses of the river. Thus, the achievement of safe water quality will allow attainable and sustainable beneficial uses to be established.

When water quality does not meet criteria for a beneficial use, the beneficial use is degraded. Other factors also can degrade beneficial uses, such as limited access to the river and poor resource management. The term "degraded beneficial use" is defined as an unused beneficial use or use occurring despite poor water quality. A potential beneficial use which does not occur because of some limiting factor is termed a "lost beneficial use."

Objectives and Methodology

This thesis examines beneficial uses of the Los Angeles River in the context of factors which influence the river environment and water quality. The objectives of this thesis are to:

1. Investigate the loss and degradation of beneficial uses of the Los Angeles River due to urbanization

2. Describe the present river environment and factors which affect the river environment

3. Analyze the river's water quality from 1988 to 1992, and determine existing and potential beneficial uses of the river in the context of water quality

A historical overview is presented to describe early beneficial uses of the river Historical information was obtained from historical accounts found in local history books and literature The historical perspective shows how the native Los Angeles River environment was transformed into its present environment

CHAPTER II

TRANSFORMATION OF THE RIVER

Ian McHarg (1969), in his book *Design with Nature*, stated: "Can you find the river that first made the city? Look behind the unkempt industry, cross the grassy railroad tracks and you will find...". This statement could not be truer than in the case of the Los Angeles and its river. Los Angeles was first settled along the river and later the river was surrounded by industrial and commercial developments. Now much of the area is in decline, holding true to McHarg's statement.

Rivers have always been the sites of human settlement. The Los Angeles River is no different. Early Indian and Spanish settlements were located along the river near present-day downtown Los Angeles. The Spanish settlement was located in the river flood plain, and as a result was flooded twice before it was moved to higher ground. Agriculture and industry grew around this settlement and along the river. The river was an intrinsic part of the city.

A few decades later, however, the perception of the river changed: the river was no longer perceived as an intrinsic part of the city. The river flooded, became polluted and drier, and water supply came from other sources; the river no longer had a value and was all but forgotten. This completed the river's first transformation.

A half-century later a movement began, and today is gaining momentum, to return the Los Angeles River to a more natural state so that it may provide opportunities for humans as well as wildlife. If successful, the river would become a valuable part of the city. This would be the river's second transformation. By returning value back to the river does not mean transforming the river to exactly what it once was. Needless to say, it would be impossible. However, modifications to its physical structure and management would allow the river to be an important part of life in the Los Angeles area--completing the second transformation.

Human and Natural History of the Los Angeles River

The native Los Angeles River (prior to channelization and urbanization) had an extensive system of brackish and freshwater wetland habitats, coastal dunes, and riparian woodlands (Garrett 1993). A vast forest of sycamores, alders, willows, wild grape vines and bramble bushes grew between the highlands to the north (near downtown Los Angeles) and the seaport of San Pedro to the south (Johnston 1962).

There is evidence of people living in the valleys of the Los Angeles River system 10,000 to possibly as much as 30,000 years ago (Jorgensen 1982). The Tongva, of the southern California Shoshone Indians and the Chumash of the Hokan group, shared the southern California coastline and spread into the inland valleys at least 1,000 years ago. The Indians sought a dependable water supply. They settled near springs and tule marshes such as in the area of Encino in the San Fernando Valley. Other villages were located along canyons and streams, especially ones which had year-round water. Rainfall and spring-flows varied, and streams changed their courses so the people of the time were capable of adjusting to those changes in their environment.

Later, the European explore came. Don Gaspar de Portola' camped at a site on the east bank of a river near present-day North Broadway Bridge in downtown Los Angeles (Mann 1976). He named the river *Rio de Porciúncula*, and recorded it as being very suitable for a mission and a large settlement because water flowed year-round. Twelve years later a settlement called *El Pueblo de Nuestra Señora la Reina de Los Angeles de Porciúncula* was founded in the same location. The name of the settlement and the river was shortened to Los Angeles.

Governor Felipe de Neve, receiving approval from King Carlos III of Spain, gave the pueblos of California the right to the water of the rivers on which they were located (Guinn 1901). Soon the founders of Los Angeles constructed a primitive water distribution system. The system made use of a dam made of brush and poles placed in the Los Angeles River with a ditch, or *zanja*, to convey the water from the river to the

VOL 12

1 4 7 8 3

fields and the plaza. Water for domestic use was taken from the *zanjas* in buckets and carried to the consumers by Indians.

In 1861, construction was completed of a new system of pipes, flumes, reservoir and dam. Water was diverted upstream for the settlement to use for domestic and irrigation needs (Figure 3). A large winter storm swept away the dam leaving the a water wheel and the flumes, and *zanjas* high and dry. A more elaborate system was built a year later, which consisted of a seven-foot-high dam on the river. The Los Angeles River supplied all of the water needs of the settlement. By 1888, the river was used to irrigate 10,987 acres (Hall 1888). Modifications and improvements to the system continued into the 20th century.

The source of the Los Angeles River was the mountains surrounding the San Fernando Valley. The agricultural water needs within the valley grew, which adversely affected downstream Los Angeles. The city defended its right to the river water through a State Supreme Court ruling in 1881 that allowed Los Angeles to succeed all rights of the former *pueblo* (Bowden, Edmunds, and Hundley 1982).

Los Angeles' water plant was situated at the point where all of the drainage from the San Fernando Valley would flow (Jorgensen 1982). The system used galleries and tunnels from which the city drew water. In a sense, water reclamation was occurring in the early 1900's as surface waters and groundwater. One out of every three gallons used for irrigation in the San Fernando Valley was reused, as it flowed through the Glendale Narrows.

The settlement soon grew. With the 1895-1904 drought in southern California, it became apparent that local water would not be sufficient to meet the needs of the growing city. As a result, in 1905, Los Angeles looked to the Owens Valley for more water. Until the water was delivered from the Owens Valley to Los Angeles in 1913,the Los Angeles River provided many beneficial uses, particularly the most sacred use, domestic water supply.

Although not a source of livelihood for Angelenos after 1913, the river still provided amenities for citizens. Susan Siegele (1982) quoted citizens who remember the river before the concrete:

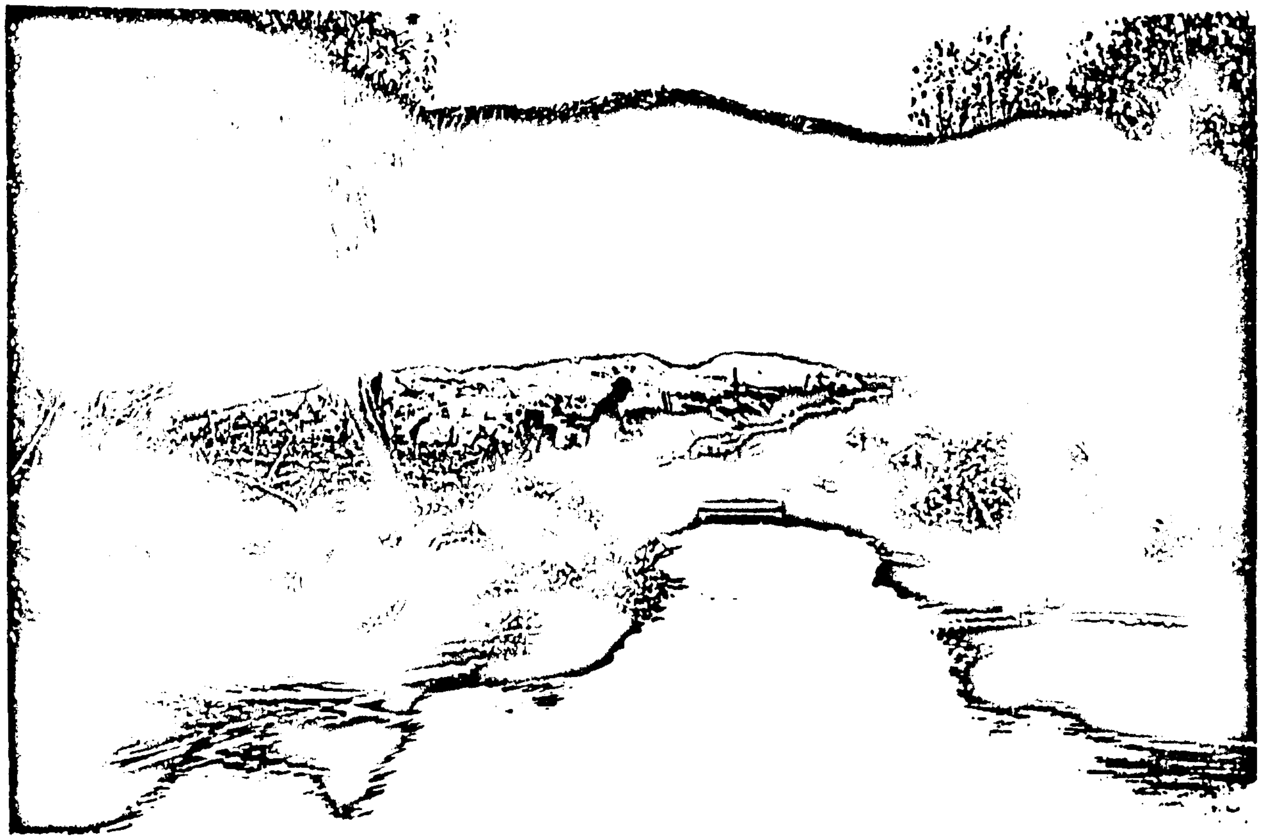

Figure 3. A *Zanjero* operates a gate on the Los Angeles River near Griffith Park, 1898 (Seaver Center, Los County Natural History Museum). The Zanja water supply system used ditches to deliver water for agricultural and municipal use.

Figure 4a. March 1938 flood near downtown Los Angeles. This flood was the most damaging flood to human settlement on the Los Angeles River.

Figure 4b March 1938, Tujunga Wash at Vineland Avenue, North Hollywood (U S Army Corps of Engineers).

provide for the control and conservation of flood, storm and other wastewaters of the district. Early bond issues financed the construction of dams. Debris dams were constructed and flood channel improvements were undertaken to confine the waters. Federal participation occurred through the U.S. Army Corp of Engineers (Corps), which became a leading force in the control of floods.

In the 1930s, the Comprehensive Plan was developed to control flooding and to conserve as much water as practicable, using debris basins, dams, and channelization. LACFCD submitted to the Los Angeles County Board of Supervisors in 1952 a report that investigated the best plan to control flood, storm and other wastewaters of the district and to conserve water for beneficial use (LACFCD 1952). The conclusion of the investigation found that the proper solution to these immediate problems will be realized upon completion of the Comprehensive Plan first developed in the 1930s. This continued the use of the Plan by the LACFCD, the Corps and the United States Department of Agriculture and the use of flood control dams, debris control basins, lined channels and bank protection, storm drains, and operation of spreading grounds. The Los Angeles County Department of Public Works (LACDPW) began administering LACFCD in 1985 LACDPW continued to pursue completion of the plan through the 1980s where it was 99 percent complete.

The Corps' role in flood control began in the late 1800s (Turhollow 1975). Demand for federal assistance increased in the Los Angeles basin with each flood. In 1936, the Corps' mission was modified to include the permanent supervision of future flood control projects. The 1938 flood resulted in federal legislation in 1938 and in 1941, which provided budgets for implementation of the Comprehensive Plan (Van Wormer 1991). The river was channelized and the majority of its length concrete-lined. Since then, the agencies implemented the Comprehensive Plan.

In 1938 the Corps prepared the report entitled, *Flood Control in the Los Angeles County Drainage Area*. The report cited that Los Angeles and its suburbs are "...under a more dangerous flood menace than any similar region in the United States."

Corps involvement in the Los Angeles River grew out of need for flood control as much as a need to put citizens to work during the post-Depression years. The Los Angeles District of the Corps employed 17,000 people, 90% of whom were obtained from relief rolls (Turhollow 1975). Paving of the river continued well into the 1960s.

In 1969 a U.S. Senate Resolution authorized the Los Angeles County Drainage Area Review studies (Corps 1992). A major finding of the study was the inadequacies of the Los Angeles River flood control system. The study also found that to improve flood protection, the river should be modified by raising the effective channel height by building parapet walls on 21 miles of existing levees of the Rio Hondo and lower Los Angeles River. In 1993 the project to build the parapet walls was in the design phase and the construction was expected to begin in 1995.

Beneficial Uses Lost

The beneficial uses of the river during the era of the Indians and Spanish were largely lost as flood control dykes were built and water was brought to the city from other watersheds. As the river was paved with concrete in the 1940s and 1950s, concern grew over the loss of the beneficial use of groundwater recharge. Regional water agencies in the coastal plain depended on rivers to recharge aquifers. According to the State Water Resources Board (1952), "As part of the channel improvement program, Los Angeles River has been lined to a point below its confluence with the Rio Hondo, with attendant reduction in percolation opportunity in the non-pressure area." In another report to the West Basin Water Association (1946), consulting engineer Harold Conkling stated that only an insignificant part of the stream discharge of the Los Angeles River now percolates the forebay. The groundwater levels dropped in the entire area since it was dependent on the Los Angeles River for years past.

Other portions of the flood control system have spreading grounds and reservoirs for water conservation. Only two water conservation structures are located on the Los Angeles River mainstem (Figure 5). The larger one, the Headworks spreading grounds, is operated by LADWP. Its operation is intermittent, depending on California Department of Health Services' regulatory activities and monitoring programs. A much smaller operation is the Dominguez Gap spreading grounds, which is operated by LACDPW. Water is diverted from the Los Angeles River to both of these facilities.

It is apparent that various other beneficial uses were lost or degraded. Table 1 is a compilation of beneficial uses before and after the river was concreted, using terminology adapted from RWQCB. RWQCB designations were used from the Los Angeles River

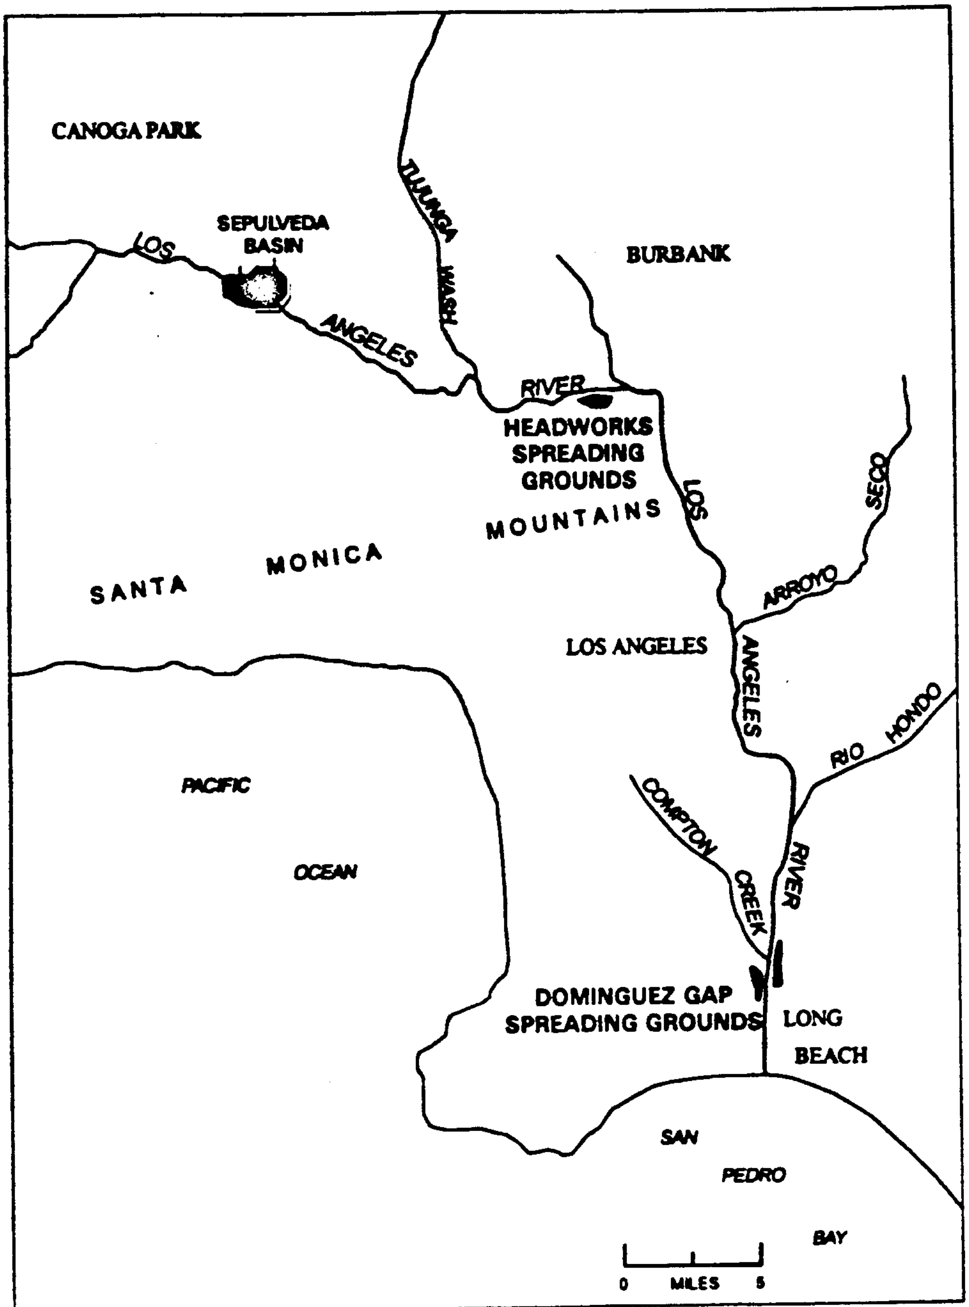

Figure 5. Location of Spreading Grounds on the Los Angeles River. These spreading grounds use water from the river.

The table shows how the present river environment has caused the loss or degradation of the beneficial uses of the Los Angeles River. Degraded beneficial uses can be grouped into two categories, sanctioned and unsanctioned. Sanctioned uses, such as groundwater recharge, are regulated and recognized by several controlling agencies. Unsanctioned uses, such as recreation and agriculture, are not allowed in the river bottom by agencies in designated areas, yet occur regularly.

Figure 6 is a graphic representation of the degradation of beneficial uses caused by the transformation of the river into a single-purpose flood control channel. Over time (the x-axis) the river was increasingly channelized and concreted, causing beneficial uses (the y-axis) to decrease. Note that beneficial uses are not eliminated, but are reduced in value (degraded) or in number (lost). Also note that channelization does not reach the maximum on the graph, taking into account the portions of the river that are not entirely concreted. Even if the entire river was concreted, some beneficial uses would still occur, albeit at a degraded level.

It may be useful to understand the processes which may have led to the first transformation, which caused the ensuing loss and degradation of the beneficial uses. The lining of the Los Angeles River seemed to take on facets other than flood control; the concrete proved to some that nature and her wild river could be tamed without regard to the river's natural endowment. This is exemplified in Turhollow (1975):

> "Thus, visitors to southern California should not be astonished at the sight of the immense, rock-lined or concrete "dry rivers" — but admire the perspicacity of their builders. The early Spanish settlers probably would not recognize these 'new' rivers, like the Los Angeles , but no doubt would appreciate the modifications"

While the Spanish might have appreciated the additional flood protection, they might have objected to the loss and degradation of beneficial uses which in their days included domestic water supply, agriculture, with high quality water.

Another element was the post-Depression economic need to provide jobs Over 17,000 people were employed by the Corps in the Los Angeles District alone Many public works projects were initiated in the post-Depression years This too may be a factor in the decision to taken on a Comprehensive Plan with zeal

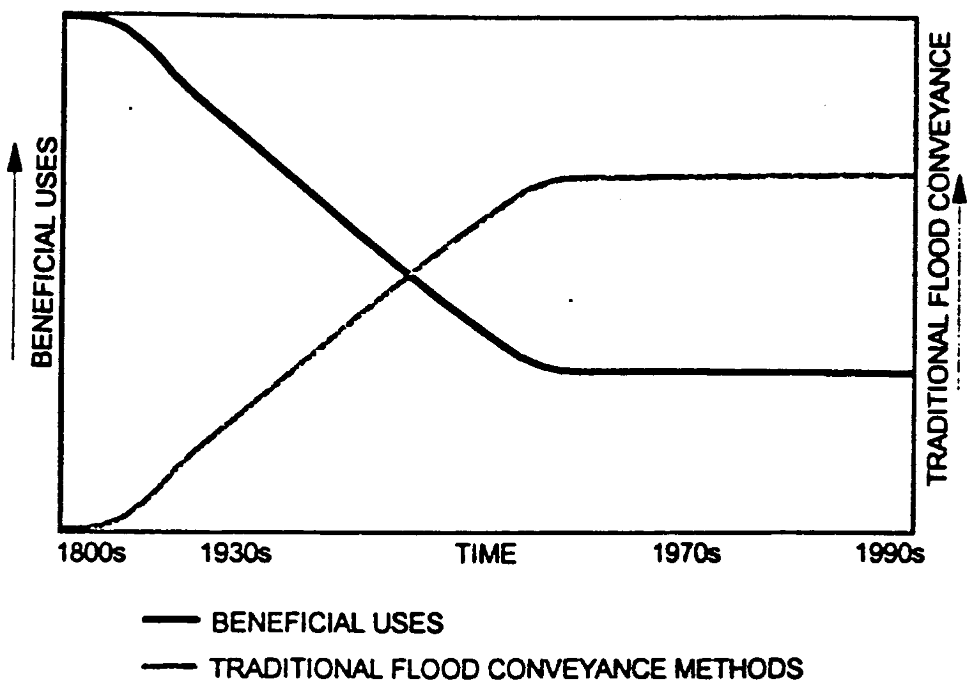

Figure 6. The Transformation Model. As flood conveyance projects are implemented, beneficial uses of rivers decrease.

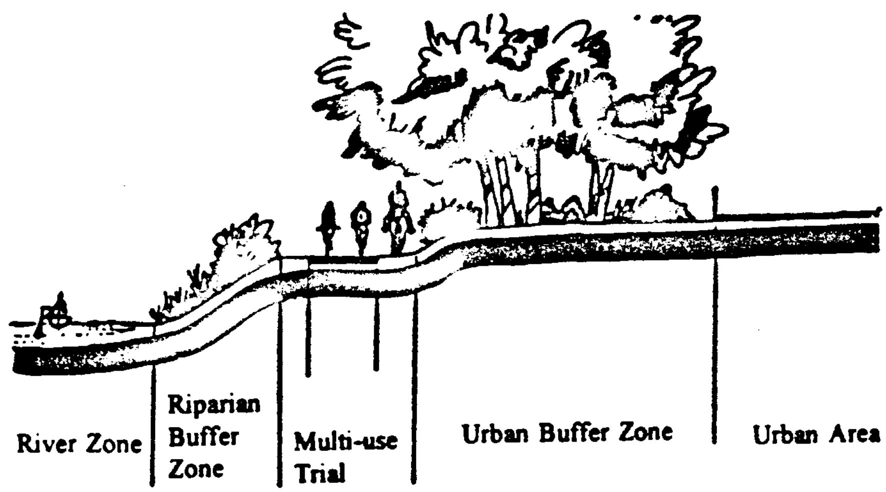

Figure 7. Common Design of Multi-use Channels. Designs such as this have been used in many places in the U.S. (National Park Service 1991).

Because of the efforts of the Friends of the Los Angeles River, a local community/ environmental organization, and growing wide-spread opposition to turning the river into another freeway, the plan slowly ran out of steam. Other similar ideas for transportation and other uses are routinely proposed.

Efforts to Restore Beneficial Uses on the Los Angeles River

Impetus to return the Los Angeles River to a more natural state began in the late 1980s with the formation of the Friends of the Los Angeles River. After years of media attention toward the "wild" concept, political support grew. As a result, several studies are completed or underway which, in some way, investigate the existing or potential resources of the river. They include:

- City of Los Angeles River Greenbelt Corridor Study
- Los Angeles County Natural History Museum Biological Inventory
- United State Army Corps of Engineers' Water Course Study (Recreational) on an 18-mile portion of the river
- United States Army Corps of Engineers' Water Supply and Conservation Study
- California Department of Water Resources, LACDPW, and Friends of the Los Angeles River Taylor Railroad Yard Multi-use study
- LACDPW Los Angeles River Master Plan
- Santa Monica Mountains Conservancy and Friends of the Los Angeles River Preliminary Integrated Upper Watershed Management Study
- Mountains Recreation and Conservation Authority Los Angeles River Parkway Project.

The Succession of River Transformations

River transformations can be considered a succession, where the river's importance to the city is lost and then returns. The importance of water quality is also a succession, varying directly with the transformation; being lessor important when the river has minimal beneficial use and more important when the river has maximized beneficial use. Figure 8 is a model which shows the urban river succession. The model begins with a river with many safe beneficial uses for humans, e.g. Indians and early Spanish settlements. Following down the model, the city is then founded on the river, but after several flood events, the river is viewed as a menace. Channelization caused the river to become a single-purpose feature, that is "a flood control channel." In addition, the river is no longer used as a primary water source, so water quality is less important. Urban development continues at a fast rate and water quality is further deteriorated. Later, lack of open space, urban stress, and droughts lead to a desire to restore beneficial uses of the river. Thus, water quality becomes very important. The last element of the succession is the restoration, which has not yet begun.

Controlling Water Quality

Urbanization is largely responsible for the flood problem and for water pollution. The imperviousness of urban areas increases runoff, thus even small rains may wash significant amounts of pollutants into surface waters (Krenkel and Novotny 1981). Thus, a logical solution to these problems lies in the urban areas themselves

Traditionally, flood control projects in southern California do not consider water quality, except for sediments, which have clogged channels and harbors. However, good resource management would consider water quality in flood control projects. The Federal Emergency Management Agency (FEMA) stated in a floodplain management report (FEMA 1991) that because the land and water resources of the floodplain and the flood-related problems and needs are highly varied, different strategies must be used to achieve desired objectives in different settings. Thus, if an objective is to improve the quality of the river, then flood control plans should be developed which consider this. The FEMA report lists several strategies to reduce flood damage. One strategy listed is land treatment measures whereby infiltration increases and runoff rate decreases (FEMA 1991). These methods, the report states, can be especially important in reducing erosion and the resulting amount of sediment and pollutants carried downstream.

Water Quality

Industrial businesses often settled near the channels for the purpose of discharging often

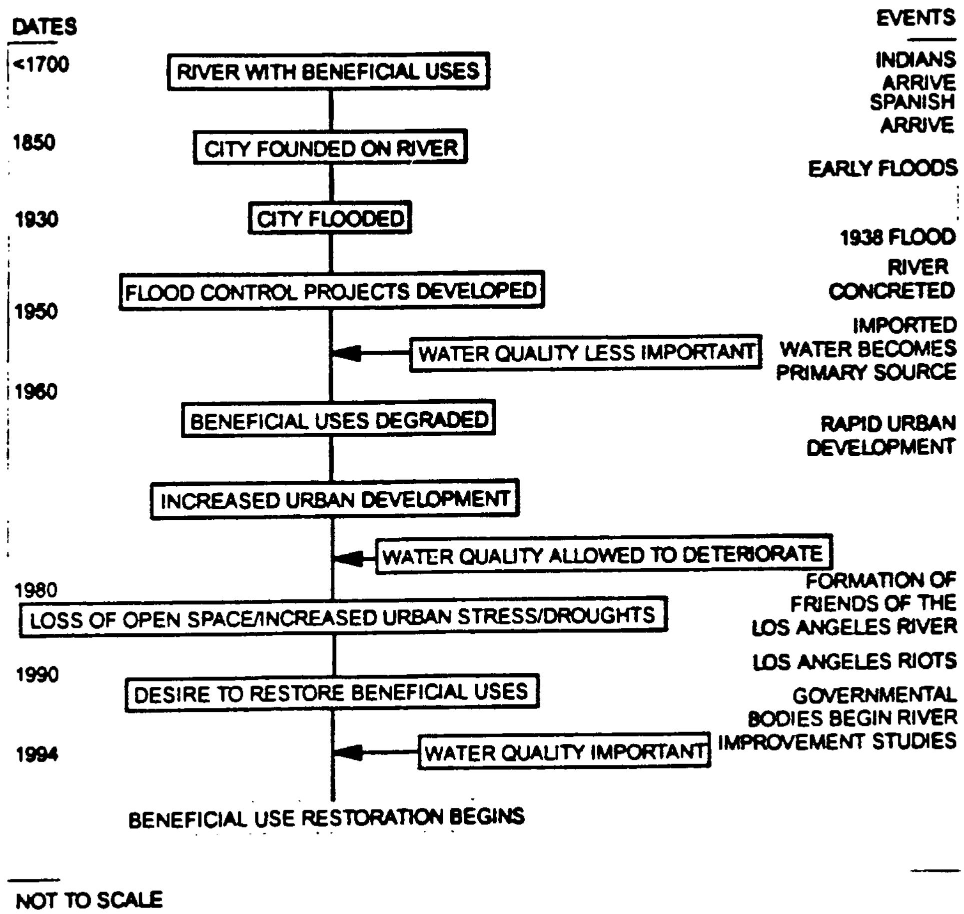

Figure 8. The Urban River Succession Model. Beneficial uses become degraded, and water quality deteriorates. Interest in restoring beneficial uses completes the succession.

polluted water. According to the California Regional Water Quality Control Board (RWQCB 1975), lower valley drainage courses have been the logical recipients of wastewaters from municipalities and industries to the detriment of sanitary conditions, aesthetics, and native flora and fauna. Public opposition to polluted waters has resulted in a correction of such overtly unsatisfactory conditions. In addition, public pressure for additional recreational use and aesthetic enjoyment of the waters increased, thereby expanding the recognized beneficial uses of many of these waters. The pattern, according to RWQCB, has been one of initial degradation, subsequent improvement of conditions, and eventual restoration, approaching complete recovery. This scheme is an example of the Urban River Succession Model presented in Figure 8.

Flood Control

Flood control is always the priority in river multi-objective planning because lives and property are at stake. However, flood control does not have to compromise beneficial uses. The paving of the Los Angeles River in the 1940s was largely responsible for the loss of beneficial uses. Today, many technologies provide an alternative to concrete (Table 2). Figure 9 is an application of the River Transformation model which shows the ideal situation, where flood control is maintained or improved, but is done by non-traditional means, using alternative flood control methods. In the model, as traditional flood conveyance methods are phased out, e.g., concrete channels, alternatives flood control methods are phased in. Meanwhile, beneficial uses increase on the river. The Transformation Models are a graphical representation of the Urban River Succession Model in Figure 8. These methods of flood control would enhance beneficial uses. If these methods are slowly implemented, then the need for traditional flood control conveyance would not be needed to the same extent and thereby can be phased out

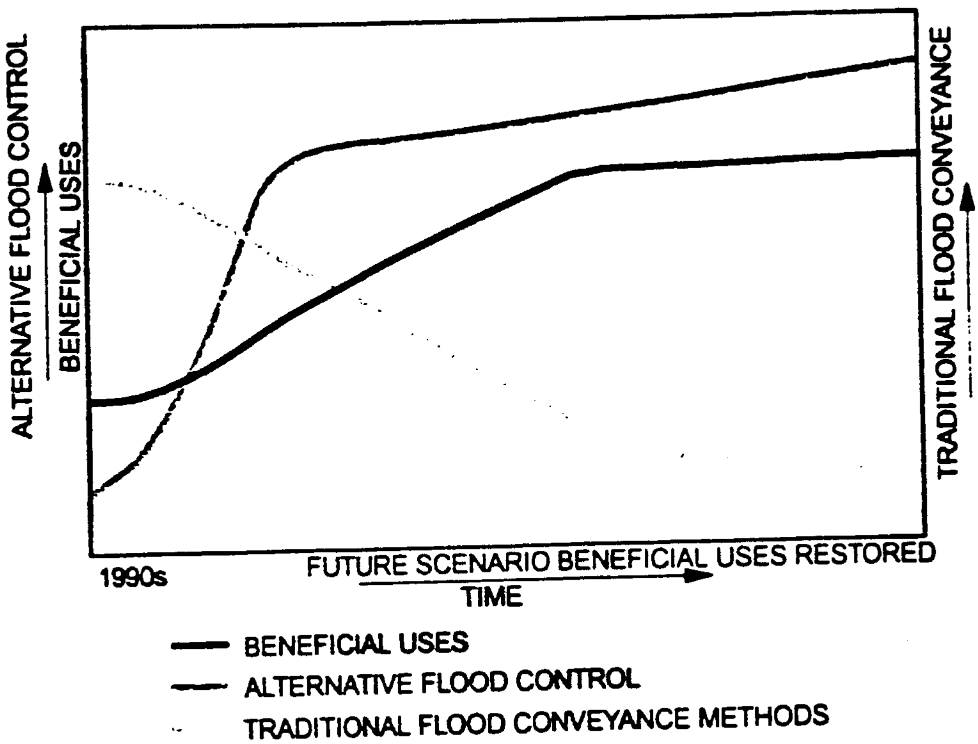

Figure 9. Ideal Transformation Model. As traditional flood conveyance methods are phased out and alternative methods are phased in, beneficial uses increase

Table 2. Flood control alternatives which would reduce need of concrete lining.

Use of permeable pavements in urban areas
On-site detention
Improved watershed management
Use of large storage areas such as gravel pits and parks
Wetland restoration
Storage in spreading grounds
Widening of the river

CHAPTER III

THE RIVER TODAY: WATERSHED AND RIVER CHARACTERISTICS

The Los Angeles River watershed is rimmed by the Transverse Ranges which include the San Gabriel Mountains, Santa Susana Mountains, Simi Hills, and Santa Monica Mountains (Figure 1, Chapter I). Tributaries emanating from these mountain ranges are the headwaters of the Los Angeles River. The river flows eastward through the San Fernando Valley, and then bends southward toward the ocean. The river crosses the coastal plain, passing over a gap in the Newport-Inglewood uplift, before reaching its final destination, the San Pedro Bay.

Physiography

The watershed drainage area, including the Rio Hondo drainage, is 832 sq miles.[1] The river begins at the confluence of Bell Creek and Arroyo Calabasas in the western San Fernando Valley (Figure 1). The Los Angeles River flows easterly from this point to the northeast end of the Santa Monica Mountains near Griffith Park. The river turns south as it enters Glendale Narrows, passes close to downtown Los Angeles, and flows across the coastal plain ending in San Pedro Bay. Calculated from U.S. Geological Survey maps, the river length is 52 miles with a designed capacity of 146,000 cubic feet per second (cfs) near its mouth (Corps 1992). Bridge crossings and confluences are commonly used to identify specific locations on the river, starting at the mouth of the river as mile zero (Figure 10).

The upper watershed is mountainous, containing steep-walled canyons with slopes greater

[1] Water can be diverted from the San Gabriel River watershed into the Los Angeles River via the Rio Hondo. The drainage area of the San Gabriel is 472 sq miles, giving a total of 1304 sq miles for the Los Angeles River system. The diversion to the Rio Hondo typically occurs during storm events.

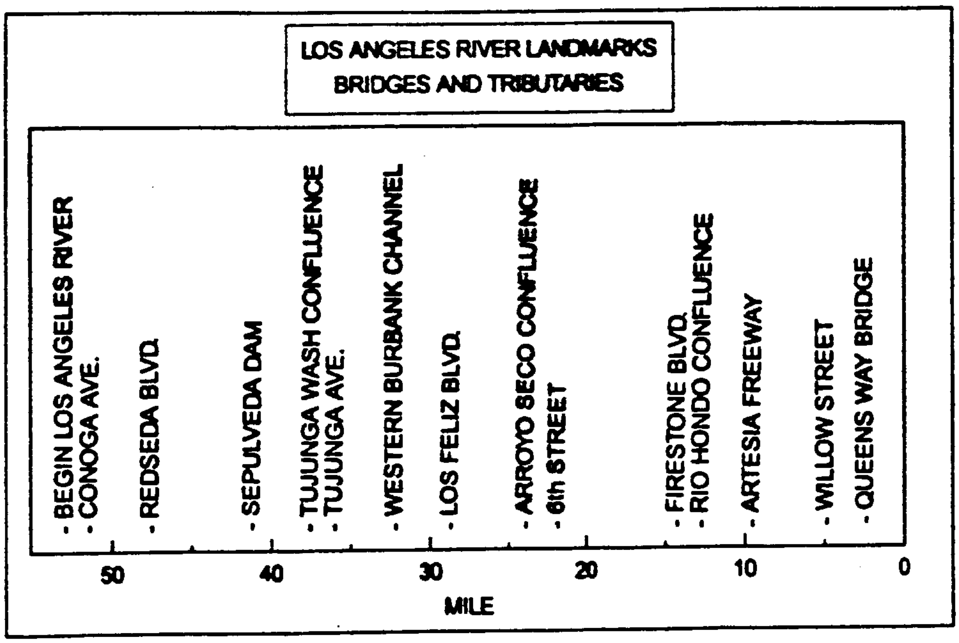

Figure 10. Bridges and Confluence Miles Upstream.

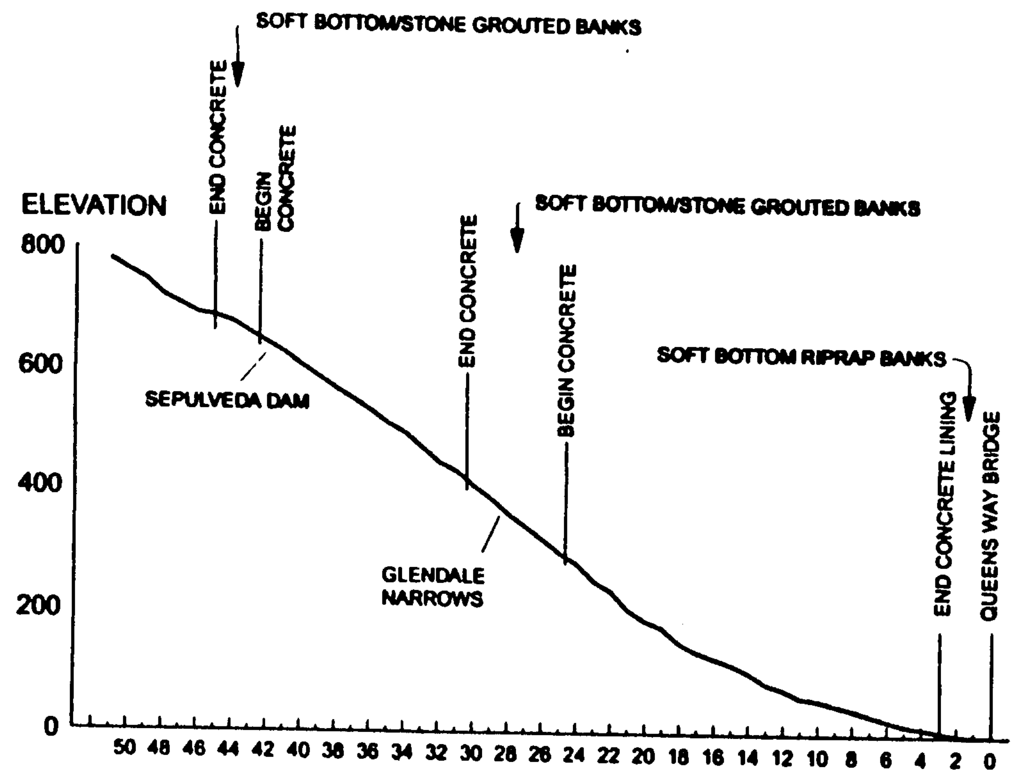

Figure 11. Profile of the gradient of the Los Angeles River. The river gradient is steepest in the San Fernando Valley and then levels out as it approaches the San Pedro Bay.

quality. The result is two distinct regimes, wet and dry. In general, inflows of the dry regime are consistent and inflows of the wet regime are variable (Figure 14).

Wet Regime. The wet regime is a result of precipitation during the winter months. The rainy season begins before mid-November and usually ends in March or early April (Bakker 1984). The river's hydrography tends to have a high peak during storms because of rapid runoff. This regime also includes periods of increased flows which can extend for months after an above-average rainy season.

Rapid runoff is a characteristic of the wet regime. Figure 15 shows hydrographs for the Los Angeles River above the Arroyo Seco confluence. Rapid runoff causes a very steep graph. Note that the peak flows occur over a three to ten hour period because of rapid runoff. Factors which contribute to rapid runoff are: 1) Steep gradients in the upper watershed, and 2) imperviousness and channelization of creeks in urban areas. Because rapid runoff in the wet regime is of short duration compared to the dry regime, the dry-regime is the dominant river condition.

Average days per year the river is in the wet regime can be calculated using average daily gaging station data. Typical precipitation events produce an average daily flow of at least 500 cfs. It is safe to assume that a flow of over 250 cfs is caused by a precipitation event because summer discharges have never exceeded 200 cfs. Thus, the wet regime is defined as when the river is above 250 cfs. Based on average daily gaging values from 1975 to 1992 at Wardlow Road from LACDPW, the river averages 42 days per year in the wet regime.

Dry Regime. The dry regime is characterized by a perennial flow, resulting from water reclamation plant (WRP) discharges, other permitted discharges (industrial), urban runoff, and rising groundwater. During the dry season, water from the local mountains does not typically flow into valley channels because the water infiltrates the alluvial sediments However, most urban areas have a minuscule, yet continuous flow of runoff into tributaries and the river.

The large volume of water flowing into the Los Angeles River is relatively recent A dependable flow of 100 cubic feet per second (cfs) developed in late 1986 For the past few years, the minimum flow of the river was 120 cfs (Figures 16a through 16g) Prior

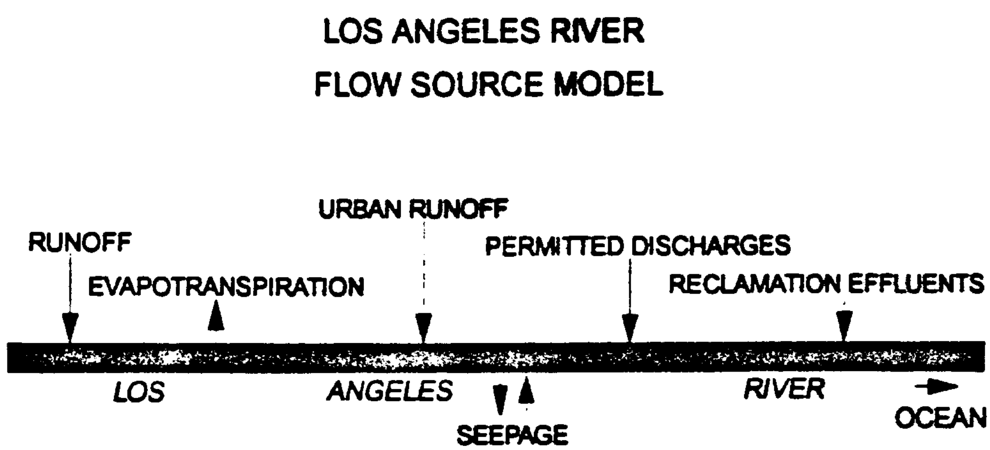

Figure 13. Flow Source Model for the Los Angeles River. The flow of the Los Angeles River is the result of various inflows.

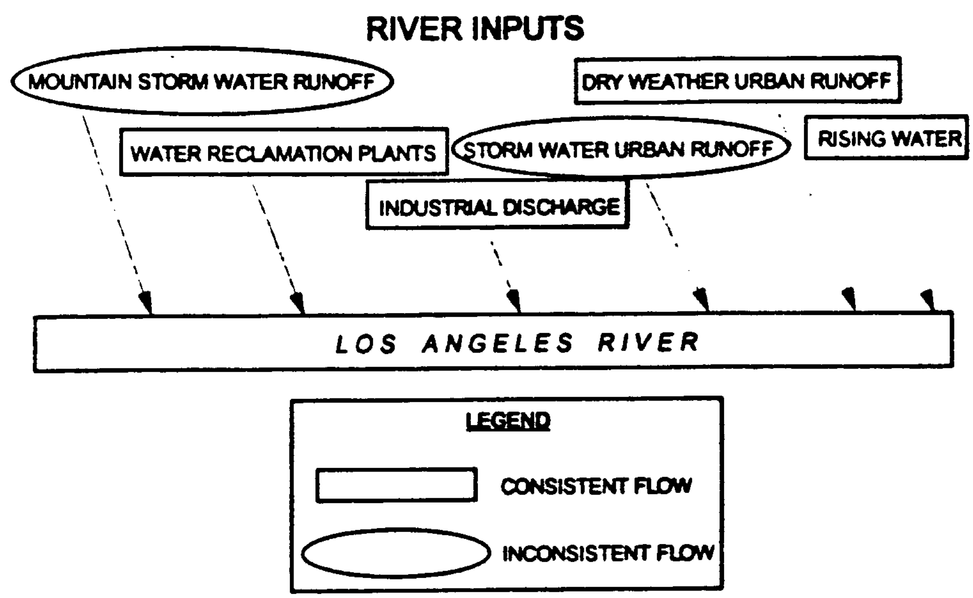

Figure 14. Inflows to the Los Angeles River consist of both consistent flow and inconsistent flow, both of which have various sources. To understand river dynamics, the inputs to the river must be recognized as the flow is the result of these impacts.

Figure 16 Continued

to 1986, the minimum flow was less than 50 cfs (Figure 17).

The largest contributor to flows in the dry regime is the water reclamation plants (WRPs) along the river and some of its tributaries. Plant locations are plotted on a map in Figure 18; Table 3 shows plant discharge amounts.

Direct use of reclaimed water is increasing, which has an impact on the water flow of the Los Angeles River. The largest planned project is the East Valley Water Reclamation Project (Figure 18). The Project would reduce the amount of water discharged from the Tillman WRP (LADWP 1991). However, the Environmental Impact Report (1991) states that a baseline flow would be maintained; the amount was unspecified. Overall, the dry regime is likely to decrease, especially in summer, when the demand for reclaimed water is the highest.

Urban runoff is the result of over watering of landscape, outdoor washing, and other residential, municipal, and commercial water discharges. The Los Angeles River receives urban runoff during wet and dry periods from storm drains. Storm drains are known to carry pollutants to streams and wetlands and are contributors to urban water quality problems (Davenport et al, 1990). Urban runoff has long-term and short-term effects, including: destruction of aquatic habitat through sedimentation and chemical buildup in aquatic organisms and sediments, and related toxicity (Davenport 1990)

Historically, portions of the Los Angeles River flowed year-round without industrial or municipal discharges. According to a report to the governor entitled, *Irrigation in Southern California* (Hall 1888), the river's flow was 65 to 80 cubic feet per second (cfs) downstream of the San Fernando Valley, resulting from rising groundwater. It is difficult to measure the native flow today. The Upper Los Angeles River Watermaster Report (1992) attempts to measure rising water through the Glendale Narrows. The calculation involves measuring the base flow (non-storm flow) and subtracting permitted discharges. However, the methodology does not take into consideration urban runoff during dry periods and other possible unaccounted discharges. Thus, the result of the calculation is the quantity of unaccounted-for water. The portion that is rising groundwater remains unknown. Because of groundwater pumping, the flow is less than it was in 1888. However, after six years of drought, springs were observed by the author flowing through the channel invert in Glendale Narrows area (Figure 19). As the river passes downtown

Los Angeles and enters the coastal plain, the river would become an influent stream in the forebay, but the concrete lining prevents infiltration. This causes a continuous flow to the ocean.

Changes in Stream Environment Along the River

Today, two major factors influence environmental changes along the river course. One change is the variation of the channel invert surfaces from concrete bottom to soft bottom and the other is the discharge of reclaimed water.

The river is channelized in all but three portions. These soft bottom sections are located in Sepulveda Basin, Glendale Narrows, and at the estuary in Long Beach Figure 20 summarizes these changes by reach. The soft bottom allows riparian vegetation growth and supports diverse wildlife. Occasionally, the concrete sections will have small sandbars or cracks where vegetation can take root. The contrasting concrete and soft bottom sections have a significant impact on the river environment.

The second factor which influences the river environment is the presence of reclaimed water. Portions of the river, especially in the coastal plain, would normally be nearly dry However, the ever-present reclaimed water has made the river a perennial stream Vegetation, especially emergent plants, have proliferated in the soft bottom sections largely because these flows contain plant nutrients Reclaimed water is a dominant influence on the quality of the river waters. The impact of the reclaimed water on the

Because of the springs in this area, the river bottom could not be sealed in concrete

concrete sections is also considerable. A few species of birds frequent a concrete section near Long Beach which is covered by a sheet layer of water outside of the low-flow channel. This water layer provides a micro-habitat of algae and invertebrates, from which some birds forage (Garrett 1993).

The reclaimed water provides a consistent flow of water and offers hydrological stability to the river environment. Figure 14 is a schematic of inputs, showing river stretches that have a consistent flow. Seasonal flow rates can vary significantly, daily to annually. WRP discharges vary diurnally, seasonally and annually, but on a much smaller scale. This dampening effect has led to highly diverse riparian communities on the river.

Watershed Characteristics and Water Quality

Streams are the sum of the conditions of the watershed. Physical, hydrological, and land use characteristics of a watershed have direct impact on streams, therefore, the stream's water quality is the sum of these conditions.

According to the U.S. Environmental Protection Agency (USEPA 1977), seven factors affect runoff characteristics. They are:

- Soil Porosity - Infiltration is affected by actions which change the imperviousness of the soil; such actions include soil composition and surface pavement, thereby reducing infiltration.

- Drainage - Infiltration is assisted by drainage which retains runoff, thereby providing additional time for the water to infiltrate. Bogs, swamps and other surface areas (wetlands) provide temporary retention areas, thereby providing increased infiltration times and a reduction in the peak flows of small runoffs.

- Infiltration - Both velocity and quantity of runoff determine amount of water which can be infiltrated; a reduction in either of these factors increases the potential amount of water which will infiltrate into the ground.

VOL 12 1483

- Channelization - The velocity of water being drained from the area is a function of the distance over which it has to travel, the surface bed, and the size of the channel: by creating a channel which shortens the distance and reduces the surface roughness, one facilitates an increased velocity. The quantity of runoff is increased by an increase in the effective cross-sectional-area of the channel.

- Slope - The velocity of the runoff is directly related to the slope of the watercourse, as demonstrated in the Manning equation (velocity is a function of the square root of the slope). Any increase in the slope will therefore increase the velocity of the runoff from the area.

- Surface Roughness - The velocity of water running off an area is inversely proportional to the coefficient of roughness associated with the surface.

- Velocity - The quantity of water which can runoff from an area is a function of the velocity of the runoff (and therefore all those factors which affect velocity) and the cross-sectional area through which the runoff can occur.

Urbanization often results in physical alteration of the environment which brings changes to the hydrologic cycle (USEPA 1977), such as:

- Decreased soil porosity through compaction
- Elimination of surface areas which retain precipitation
- Increase in impermeable surfaces
- Construction of channel and storm sewers to carry off the excess surface water
- Increase in site slope due to terracing
- Decrease in vegetation thereby deceasing transpiration and interception
- Increase in the smoothness of surfaces

According to USEPA, these changes in an area's natural hydrologic balance can lead to serious impacts on water quality.

The early data on the relationship of land use and water quality in the United States, particularly urban uses, came during the 1960s, when concern grew over pollutants identified in runoff. Many studies were commissioned by USEPA for urban and non-urban watersheds throughout the country in the mid-1970s. The results of these studies have provided useful data. However, remaining unknowns about the problem and high costs of runoff treatment prevented federal funding, so EPA began the Nationwide Urban Runoff Program (NURP) in 1978 and produced a final report (USEPA 1983). Results included in the report showed expected runoff quality for various land uses.

Impacts on the River

Watersheds affect the river in many ways, from physical character to spatial relationship to the river. Impacts can be put into three general categories: physical character of the watershed, hydrological, and land use.

Physical Character of Watershed Physical character of a stream refers to the topography and geological structure of the area. For example, steep slopes of granite will yield lower total dissolved solids quality water than would relatively flat marine deposits high in calcium carbonates.

Hydrological Characteristics. Hydrological characteristics include factors such as precipitation, local geology, and human-made channel designs.

Land Use. Land use has long been recognized as a controlling factor in the water quality of a stream. Urban and agricultural developments can affect surface water and groundwater quality (Krenkel and Novotny 1980). The Urban Land Institute (1981) states that major problems of water resources protection are a result of urbanization and land development. Water resources are adversely affected by runoff increases, decreases in infiltration, and greater degree of erosion and sedimentation, flooding, runoff pollution, and discharge of sewage effluent.

Points of Impact. Sub-watersheds impact the river on two spatial regimes One spatial regime is contiguous impacts, via numerous storm drains or small channels The smaller and more disperse the discharge points are on the river, the quicker the assimilation of the discharged waters The other spatial regime is point impacts such as at confluences or water reclamation discharge points, where the sum of the sub-watershed characteristics

VOL 12 1485

impact the river at one point on the river. At these points, assimilation is more dependent on distance and time downstream from the discharge point. Table 4 shows the spatial regimes for each sub-watershed.

Table 4. Contiguous and point impacts of each sub-watershed.

VII	X	
VIII	X	
IX		X
X	X	
XI	X	
XII	X	
XIII	X	

Critical Points. Sub-watersheds with intensive urban land uses potentially have a high impact on the river. As discussed above, the sub-watershed's impact can be contiguous or point, so high impact sub-watershed will result in critical portions or critical points on the river. Critical portions of the river are located at sections adjacent to intensive land uses, such as industrial and commercial. Critical points are located at confluences, where the overall character of the sub-watershed impacts the river.

Methodology for Investigation

A fundamental need of a water quality study of the Los Angeles River is to understand the impact the watershed has on the river. To accomplish this, a land use and water quality analysis was performed on the Los Angeles River and its drainage by.

1 Grouping drainages along the river into sub-watersheds, showing their respective impact points on the mainstem

2. Assessing the land use character of each sub-watershed and its impact point

3. Comparing runoff water quality to expected quality based on the land use in the sub-watershed

The results of the comparison are presented in Chapter IV.

Data Sources

Data on land use and watershed boundaries were obtained from local agencies. The Los Angeles River watershed boundary was traced from Los Angeles County Flood Control District maps onto a land use map obtained from Los Angeles County Department of Regional Planning. Thirteen sub-watersheds were drawn based on natural watershed boundaries. To limit the number of sub-watershed to a manageable number, smaller watersheds were grouped if they had similar character based on terrain, aspect, and predominant land use ratio. The County land use map provided 9 land uses categories, but for the purposes of the water quality analysis, like categories were condensed, resulting in five categories.

Data showing the relationship of land use and water quality were obtained from several reports by the United Stated Environmental Protection Agency (USEPA), which has conducted several studies of the pollutants for three land use types -- residential, commercial, non-urban and sometimes industrial. Monitoring by USEPA tends to focus on the primary pollutants of concern, so comparisons with other parameters is not possible, and likely not a concern.

Nationwide Urban Runoff Program (NURP). Data were needed to evaluate the runoff for the Los Angeles River watershed. A widely recognized program is NURP, which was designed to provide information and methodologies for water quality planning efforts. The objectives of the program were to provide credible information for decision makers and support the planning and implementation of the 28 separate planning projects throughout the United States. The results of the program were combined into the Final Report issued in 1983.

NURP identified priority pollutants for which data were gathered from field monitoring to characterize urban runoff flows and pollutant concentrations and mass loadings. The resultant data represented a cross-section of regional climatology, land use types, slopes, soil conditions.

NURP's Final Report provided a data table of the mean concentrations for all sites by land use category. Although caution is needed in applying these results to one geographic area, the report states that site variability was shown to be very well represented. Thus, the table indicates the effect of land use on urban storm runoff pollutant discharges. Because the table is the best source of data, it was used to identify drainages in the Los Angeles River watershed which may be negatively impacting the river. Pollutants studied in NURP, and in this thesis, consist of copper, zinc, biological oxygen demand, lead, nitrate, and phosphorus.

Characteristics of Los Angeles River Sub-watersheds

The geographical character of each portion of the watershed impacts the river. By analyzing regions which have similar character, water quality impacts of land use can be better understood. Based on the local geography, i.e. physical, hydrological and cultural, the Los Angeles River watershed was divided into 13 sub-watersheds (Figure 21). For example, the sub-watershed titled, Southwest Valley (XIII), has a land use character distinct from the North Valley (I) in that it has a larger rural area and little industry. Its impact is contiguous along the western part of the Los Angeles River via small channels and storm drains. This division from the North Valley is based on field observations and land use data.

The area of each land use category was added and the percent of each land use by sub-watershed was calculated (Table 5). Figure 22 shows pie charts of land use for each sub-watershed. Table 4 shows the spatial impact, i.e., contiguous or point, for each of the sub-watersheds.

Following are descriptions of each watershed based on geological data from California Division of Mines and Geology Los Angeles Sheet (1991), U.S. Geological Survey topographic maps, (various dates), Los Angeles County Department of Regional Planning map (1993), and author observations.

I. North Valley. Located on the west side of the San Fernando Valley, this sub-watershed is bounded by the Simi Hills on the west and the Santa Susana Mountains on the north (Figure 1, Chapter 1). The hills and mountains are under 3,000 feet in elevation and contain canyons and broad areas of alluvium mostly in the valley. The mountainous areas contain mostly marine deposits with several other sedimentary rocks.

Streams emanate from the foothills and then cross the valley to the Los Angeles River A common characteristic of watersheds in southern California is debris flows. Many of the streams have debris basins. Drainage through the urban environment is via various culverts and concrete channels. This sub-watershed has a contiguous impact (Table 4) Reclaimed water discharges are not part of the local hydrology.

The North Valley is largely residential, followed by open space.

II. Central Valley. Much the same as North Valley (I), this sub-watershed is bounded by the Santa Susana Mountains to the north and by Bull Creek on the west The hills contains marine and non-marine sedimentary rocks, with alluvium filled valley.

The main drainage channel is Bull Creek and a portion of Pacoima Wash, which is diverted into Tujunga Wash. The Tillman Water Reclamation Plant is located in this sub-watershed. The tributary area of Bull Creek and the Los Angeles River is impacted by the reclaimed water discharges.

The majority of the area is residential, followed by open space. The percentage that is commercial and industrial is higher than in North Valley (I).

III. Verdugo. Verdugo Mountains is the center of this sub-watershed bounded by Tujunga and Arroyo Seco watersheds and the Los Angeles River. The range is about eight miles long and three miles wide with its highest peaks over 2,500 feet in elevation, composed of granitics, metamorphics, and marine rocks.

The largest drainage channel is Verdugo Wash which drains the northeast slope and the south slope of the Verdugo Mountains. Several other mountain drainages flow southwest off the mountain through urbanized areas and then into the Los Angeles River.

Quite similar to the Central Valley (II), Verdugo is mostly residential, however, a much higher percentage is open space, largely in the Verdugo Mountains.

IV. Tujunga. Bounded within the Big Tujunga, Little Tujunga, and Pacoima watersheds, this area contains the highest point in the Los Angeles River watershed proper, Pacifico Mountain at 7,124 feet located in the heart of the San Gabriel Mountains. Both igneous and metamorphic rocks make up the majority of the upper watershed, with some sedimentary rocks located near the mouth of the canyon. Alluvium makes up the lower portion of the watershed.

Mountain elevations are high enough to allow the accumulation of snow during winter. Steep slopes quickly carry snow-melt and rainfall to the streams. Historically, the mouths of these canyons are the site of large debris flows and flash flood. A series of dams are located upstream and Hansen Dam is located downstream. Alluvial fans allow groundwater recharge from the canyons to the valley bottom. Several spreading grounds are located in the area for groundwater recharge. Lower Tujunga Wash is a concrete

VOL 12

1 4822

lined channel from the Hansen Dam to the Los Angeles River, where the sub-watershed has a point impact.

Much of the Tujunga (IV) sub-watershed is within the Angeles National Forest, thus the overwhelming majority of the land use is open space or significant ecological areas. The primary focus of management within the National Forest is watershed protection. The remainder of the area is rural and residential. The overwhelming majority of this watershed is open space.

V. Arroyo Seco. Bounded on the north by the ridges of the San Gabriel Mountains, this watershed contains peaks over 5,000 feet in elevation. The upper watershed has a similar rock make-up as Big Tujunga Canyon, but the lower watershed contains only a narrow band of alluvium between some granitic rocks and marine deposits.

The main drainage feature is the Arroyo Seco which flows from the San Gabriel Mountains south to the Los Angeles River. Lofty hills border the stream through most of its length. The channel is mostly concrete or stone grouted after it enters the lowlands

The upper portion of the watershed is also located in the Angeles National Forest, giving the watershed a high amount of open space. The second largest land use is residential

VI. San Gabriel. The San Gabriel watershed stands alone as a major watershed, but is considered a sub-watershed because it drains into the Los Angeles River and San Gabriel River. The highest peak is Mount San Antonio at 10,064 feet above sea-level. The upper watershed contains much of the same rock types as in Big Tujunga Canyon, which is dominated by granitic rocks. The lower watershed contains a broad plain of alluvium

Drainage of this watershed into the Los Angeles River is controlled by Whittier Narrows Dam. Mountain runoff from San Gabriel River and other various channels flow into Whittier Narrows Dam basin. The Rio Hondo and San Gabriel River both continue south from the Dam (Figure 1, Chapter I). The Rio Hondo flows into the Los Angeles River approximately twelve miles upstream from San Pedro Bay, and the San Gabriel flows south to the ocean. Water flow characteristics are similar to the Tujunga Wash - - derived largely from mountain snow melt and debris flows. A comprehensive system of dams are used for flood control and water conservation. Spreading grounds are located in the valley and coastal plain.

The majority of the land area is within Angeles National Forest. Because the watershed contains the San Gabriel Valley, the open space areas is not an overwhelming percentage as in Tujunga (IV).

VII. Southeast Coastal. This sub-watershed is bounded by a drainage network constructed for urban development. Thus, its geologic structure has little impact on water quality. The topography varies from very flat, to bluffs of 50 feet high, to Signal Hill with an elevation of approximately 350 feet.

The hydrological features of this sub-watershed is largely anthropogenic. A storm drain network flows directly to the Los Angeles River. Nearly all of the drainages are through culverts. Because of the high river levee, many of the drains flow to pump stations which pump the water into the Los Angeles River. The pump stations prevent large size debris from entering the river.

The Southeast Coastal area contains the second largest percentage of residential, followed by commercial and industrial. Little rural space is found in the sub-watershed.

VIII. Southwest Coastal. Bounded by Dominguez channel on the west, this small drainage is similar to Southeast Coastal in that it is heavily urbanized. Little topographical change is notable.

The hydrological features are similar to the Southeast Coastal, but are more heavily impacted by industrial land uses.

This area has the highest industrial land use compared to the other sub-watersheds

IX. Compton Creek. This watershed is bounded by the Compton Creek drainage area, which is an extensive storm drain network, but also contains Dominguez Hills to the southwest, also heavily urbanized.

The main drainage feature is Compton Creek which is a concrete channel, except for its last two miles, which is soft bottom with grouted rock banks. The creek has a low

Drainage of the mountain slopes is though various channels, many ending in culverts. Debris flows appear not to be a problem.

About half of the area is residential followed by open space because Griffith Park is included in the area. A small percentage is commercial.

XIII. Southwest Valley. Bounded to the south by the north-slope of the Santa Monica Mountains, this area contains largely marine deposits with a short alluvial slope before meeting the Los Angeles River.

The topography is similar to Southeast Valley (XII), but on a larger scale. Debris basins are located on some channels.

This area contains the largest rural land use of all sub-watersheds, although it too is dominated by residential. Open space is a significant part of the area, followed by commercial.

Overall Land Use Trends

The data show that the sub-watersheds range in open space from 92% in the Tujunga sub-watershed to 1% in two of the coastal sub-watersheds (Table 5). Open space decreases from upstream to downstream, while commercial and industrial uses increase, with the maximum of 38% industrial area in the Southwest Coastal sub-watershed. Table 6 ranks the sub-watersheds with land use categories that have the most intensive impact on water quality.

Table 6. Sub-watershed ranked by percent of intensive type land uses.

Rank	Commercial/ Public Facilities	%	Industrial	%	Residential	%

Watershed and Water Quality

Correlating water quality with upstream land use is not a new concept (Krenkel and Novotny 1980). Uncontrolled urban and watershore developments can easily result in a lowering of water quality (USEPA 1977). The source of this pollution can be traced to:

- Accumulation of dust and dirt trapped in the urban environment
- The residual product of automobiles, trucks and buses which are a source of suspended solids, chemical oxygen-demanding material, and heavy metals.
- Debris from litter in streets and other sources of organic material
- Runoff from construction sites
- Illegal discharges and dumping.

General Urban Runoff Characteristics. Since the discovery of the poor quality of urban runoff, several programs have been designed to quantify parameters (USEPA Executive Summary 1983). NURP concluded that :

- Heavy metals are by far the most prevalent priority pollutant constituents found in urban runoff
- Accumulation of dust and dirt trapped in the urban environment
- The residual product of automobiles, trucks and buses and as a source of suspended solids, chemical oxygen-demanding material, and heavy metals
- Debris from litter in streets and other sources of organic material
- Runoff from construction sites
- Illegal discharges and dumping

VOL 12

14826

highway rose and fell more rapidly than that in the undeveloped basins due to the impervious area of the highway. High metal concentrations were found in the soils within 100 feet of the highway and in the soil water infiltrating the soil zone. Chromium, copper, nickel and zinc concentration in the streams near the highway generally were above the maximum levels recommended by USEPA for the protection of aquatic life

Los Angeles River Runoff Characteristics Based on NURP. NURP data were chosen for comparing Los Angeles River runoff, because NURP results are commonly used by many other cities for planning purposes (this was the intent of the program). As part of NURP, Oltmann and Shulters (1989) studied runoff quality for four urban catchments in Fresno, California. This is of particular interest because this location is most similar in climate to Los Angeles as compared to the other cities in the study. Based on the USEPA, and Fresno results, the expected results for each parameter is listed in Table 7.

The land use character of the each sub-watershed dictates the vulnerability of the surface water. Table 8 is a listing of the sub-watersheds with land uses most vulnerable to the values in Table 7.

Table 7. Results of NURP for nationwide and Fresno, California average

Parameter	Residential NURP	Residential Fresno	Commercial NURP	Commercial Fresno	Industrial NURP	Industrial Fresno
Nitrate + nitrite (N) mg/l	0.7	0.4	0.6	0.4	N/M	0.6

VIII	XIII	VII

Areas with the highest intensity of land use will have the largest impact on the river Figures 23a through 23e show graphically each land use type and where it impacts the river. The graphs do not take into consideration area or runoff quantity, however, they help show how the river environment is impacted mile by mile, based on land use and its potential impact of water quality.

The first graph shows increasing contiguous impacts of residential land use, while point impacts tend to be lower land use. This is because the tributaries emanate from mountainous regions low in residential population. The effect of these point impacts are a buffer to the contiguous residential impacts and the water quality associated with residential land use.

Figure 23b indicates a slow but steady rise in commercial land use from upstream on the Los Angeles River downstream. In addition, Figure 23c indicates a marked increase of industrial land use.

Figure 23d indicates that rural development decreases significantly. The west end of the San Fernando Valley has the highest percentage, at 31 percent. The terminus of the river has less than 5 percent.

It is apparent from Figure 23e that the point source of the tributaries have a significant impact on the river. Most contiguous sub-watersheds have less than 50 percent open space, while all tributaries, except Compton Creek (IX), has greater than 50 percent open

Figure 23a-e. Percent land use for sub-watersheds draining into Los Angeles River by river mile. Contiguous impacts from sub-watersheds, denoted by line-bars and point impacts of tributaries denoted by squares.

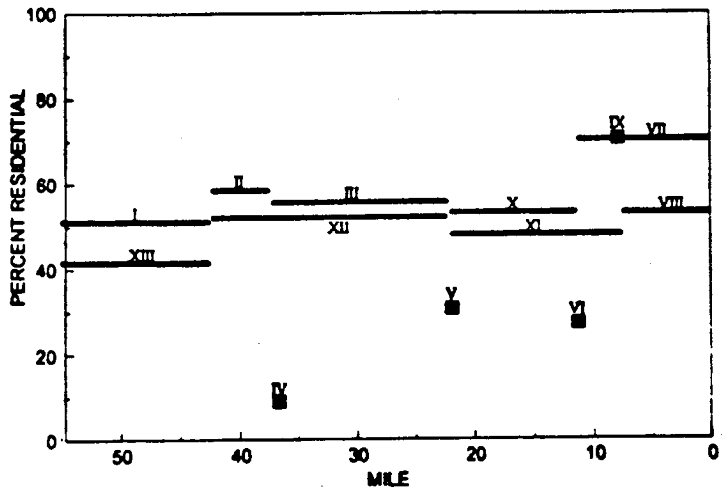

Figure 23a Residential land use increases downstream, however, all tributaries except for IX Compton Creek have smaller percentages.

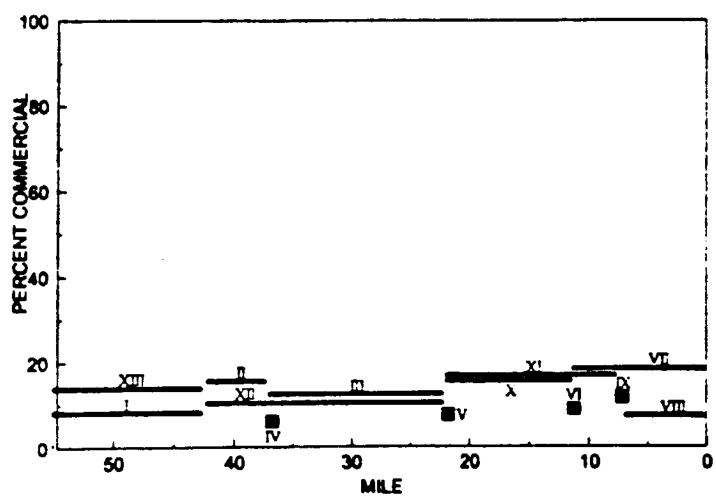

Figure 23b Commercial land use slowly increases downstream

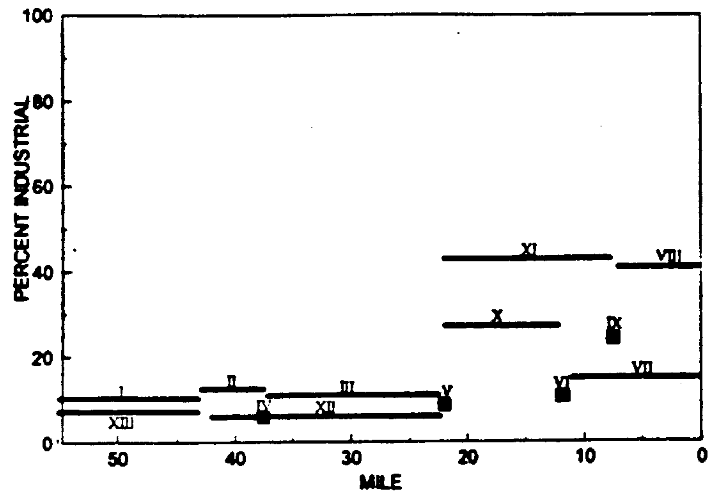

Figure 23c Industrial land use increases significantly near the end of the lower river

space. Also, the lower Los Angeles River has much less open space than the upper.

It has been demonstrated that the watershed is the key to understanding and controlling water quality in a stream. An understanding of the watershed, including physical, hydrological, and cultural impacts can be used to evaluate water quality impacts. Once the watershed impacts are understood and controlled, river quality will also be improved

VOL 12

CHAPTER IV

WATER QUALITY AND BENEFICIAL USE CRITERIA OF THE LOS ANGELES RIVER

Water quality plays an important role in human and environmental health. Periodic monitoring of a water body is common method to check the quality of water over time Water quality monitoring of the Los Angeles River is accomplished by several governmental agencies Overlapping jurisdictions, agency boundaries and mandates, make river monitoring and environmental protection complex To study the water quality of the entire river length, data from all possible agencies were gathered This chapter is a presentation and analysis of the data. Based on the results, two basic questions are addressed: What is the water quality of the Los Angeles River, and what beneficial uses are appropriate?

Water Quality and Beneficial Use Management

Two agencies perform the majority of the water quality monitoring and river system operation of the Los Angeles River. The California Regional Water Quality Control Board, Los Angeles Region IV (RWQCB) monitors the river and implements regulatory measures pursuant to the federal Clean Water Act and the California Porter-Cologne Water Quality Control Act (1969). The Los Angeles County Department of Pubic Works (LACDPW) also performs monitoring of surface waters, operates the flood control system, and maintains most of the flood control system including operations and pubic access to the Los Angeles River. The Corps does not monitor water quality, but operates portions of the river system.

California Regional Water Quality Control Boards are divided into nine regions throughout the state Los Angeles County and the Los Angeles River watershed is part of Region 4. RWQCB's primary duty is to protect the quality of the waters within the region for all designated beneficial uses. This is accomplished by formulating and adopting water quality control plans for specific ground or surface water basins and discharges (RWQCB 1993). RWQCB is responsible for regulating the activities and factors which affect or may affect the quality of the States waters (RWQCB 1975). The agency designates beneficial uses for the river, which can seldom be downgraded or removed from the list. Chapter V discusses the beneficial use designations by RWQCB

The agency designates beneficial uses of water bodies, sets water quality objectives, and adopts a water quality control plan to achieve objectives. The agency also performs annual water quality monitoring of nearly all the surface waters in the region.

Another facet of RWQCB's role in the water quality management of the Los Angeles River is its implementation of the National Pollutant Discharge Elimination System (NPDES) program and in particular the Stormwater NPDES program. The principal permittee for the Los Angeles County municipal stormwater NPDES permit is LACDPW and the local jurisdictions (cities) are the co-permittees (RWQCB letter to permittee June 17, 1993). RWQCB approved a program involving a stormwater monitoring program and Early Action Best Management Practice Plans in 1993. A successful program is expected to improve the water quality of the river.

LACDPW, incorporating the L.A. County Flood Control District, monitors the water quality of the river. Historically, this agency focused on waters used to recharge aquifers and for discharges to receiving waters (LACFCD 1981). With the NPDES program, LACDPW's role in water quality of the Los Angeles River has been expanded

Stormwater Quality Management

Research on methods to reduce pollution in runoff is growing. According to Urbonas and Stahre (1993), stormwater engineering and management has advanced more in the last 20 years than at any other time. Best Management Practices to enhance stormwater quality have proliferated and spread worldwide.

In 1987 the USEPA expanded the NPDES program to include municipal and industrial stormwater discharges as a result of the findings in a study titled the National Urban Runoff Program (Lee and Jones 1990). In California, the Stormwater NPDES program

VOL 12

1

4834

is implemented by the RWQCB which issues permits to stormwater dischargers. The Los Angeles River basin falls under the Los Angeles County municipal stormwater permit held by LACDPW. Various municipalities are the co-permitees under this permit. The NPDES Program requires monitoring and the implementation of best management practices in an effort to reduce pollution in runoff. Improved runoff quality is expected over the next few years as the efforts by municipalities are increased. The concepts presented in the land use section would be applicable to controlling pollution in runoff.

Data Collection

A significant amount of data is needed to make sound conclusions on the appropriate beneficial uses of a water body. Thus, all the data possible was gathered from eight local agencies. All parameters available from the 1988-92 study period were gathered.

Data Sources

Two key sources of data were the water reclamation plants (WRPs) and wastewater monitoring departments of various agencies. Agencies which conduct water quality monitoring of the river are listed in Table 9. Data results were from the laboratory analysis of field samples. Field sample locations varied with agency and depended largely on agency jurisdiction (Figures 24a and 24b). Water quality monitoring data were collected from the drought period 1988 through 1992. This allowed an investigation of the river when the watershed is dry, which is the prevailing condition. A total of over 50,000 data pieces were entered into a database for this study.

Data Analysis

Water quality data were categorized into the regime from which they were sampled Nearly all data was collected during the dry regime. Thus, this thesis focuses on the dry regime, which includes the four inflows as described in Figure 14: Reclaimed water discharges, industrial discharges, urban runoff, and rising groundwater. The dry regime is the most important regime to beneficial uses because it is present most often throughout the year. Wet regime results are discussed in the section following the dry regime analysis.

Data collected from agencies were entered into a database system designed for the specific purpose of analyzing the data. Most agencies had different sample points along the river, so sampling stations were assigned a letter code which indicated place-name, agency and river mile (River miles are designated from the mouth of the river upstream (Figure 25). The starting point (0 miles) is the Queensway Bridge in Long Beach.)

Inferential statistics was used to characterize the water quality of the Los Angeles River This is useful to draw conclusions about the characteristics of a large group from a small sample of that group (Gordon, Mc Mahon, and Finlayson 1992). This method is commonly used in environmental analysis where data are collected, described and related, and generalizations are made from the results This methodology provided a foundation for the discussion of potential beneficial uses of the river.

The sample station data were averaged for each agency and is presented in tables and graphics. The graphics are used to show temporal and spatial trends. The summarized data was compared to water quality criteria, which vary depending on the beneficial use For example, State of California drinking water standards were used for comparison purposes to assess quality of the water for municipal beneficial use Following the analysis of the data is a section which discusses beneficial uses which are acceptable based on the water quality data.

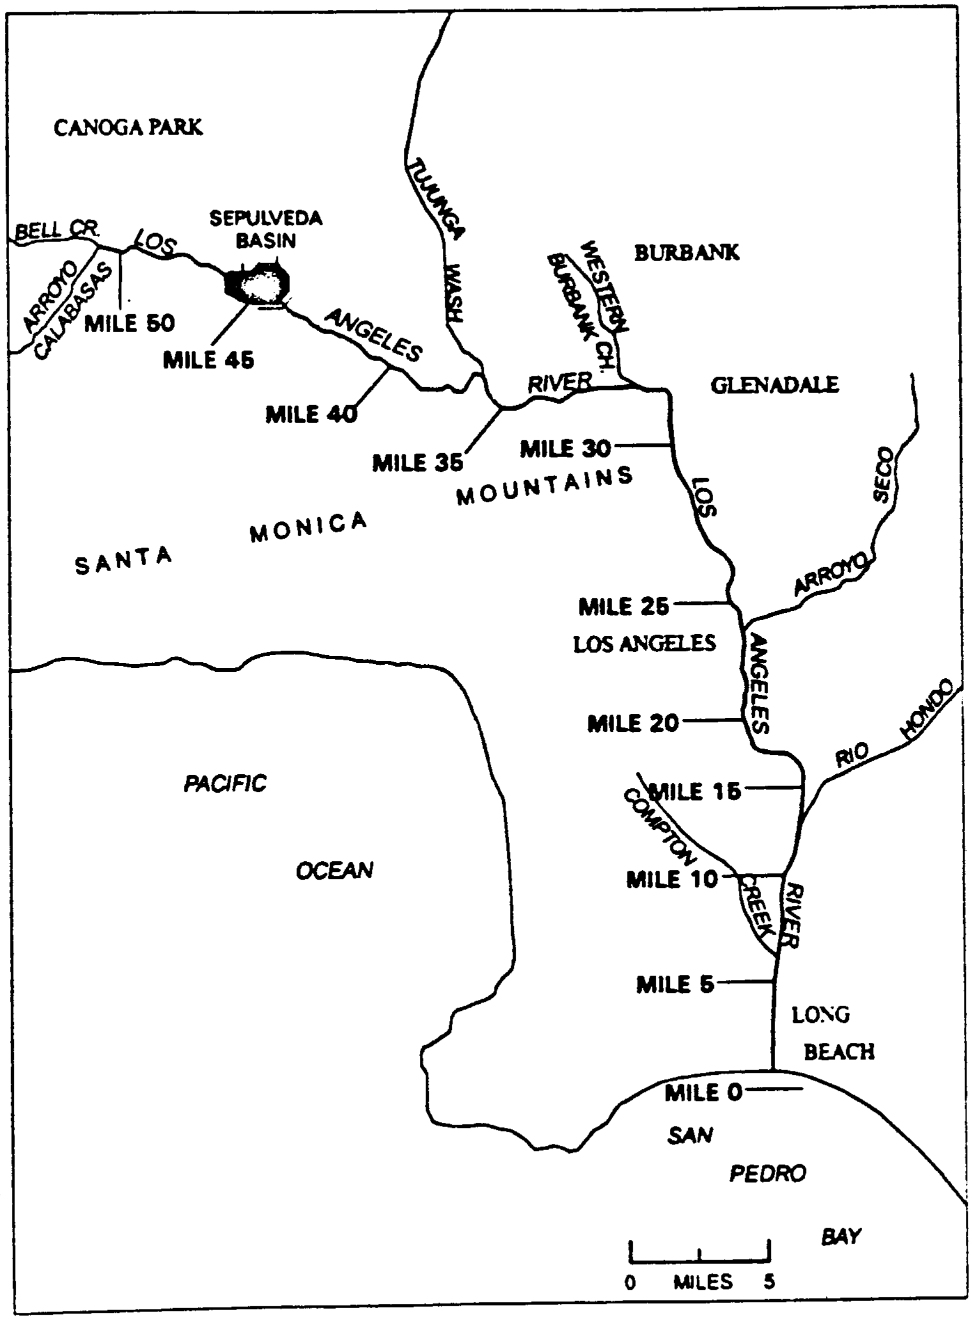

Figure 25 River Mile This figure is useful for comparing the water quality graph's river-mile to the location on the map

Dry Regime Water Quality Analysis Results

Water quality parameters that are below the accepted criteria have an impact ranging from health risk issues to the aesthetic issues. The analysis results of this section are useful to determine which parameters are at unacceptable levels. If these parameters are controlled in water quality control plans, then additional appropriate beneficial uses are attainable.

Dissolved Solids, pH, Oil and Gas

Treated municipal wastewater in southern California is often high in total dissolved solids (TDS). This condition has been exacerbated during the 1986-1992 drought. For instance, the city of Los Angeles increased its dependence on water from sources higher in TDS. Prior to the drought, Owens Valley and Mono Basin water with a TDS of 150 mg/l was used as a main source, but this source was cut in half during the late 1980's (MWD 1990). Make-up water was made available from the Colorado River Aqueduct with a TDS of 750 mg/l and the State Water Project with a TDS of 339 (Upper Los Angeles River Area Watermaster 1992). Drought conditions increased TDS levels in water supplies and as a result, discharges to the Los Angeles River through urban runoff and WRP discharges had elevated TDS concentrations.

Typical TDS values are shown in Table 10. However, TDS values can vary depending on local rainfall. Long periods of precipitation result in increased flow volume in the river which dilutes the dissolved solids. Although stormwater sampling results are scarce, TDS of under 500 mg/l is common during storm events.

Table 10. Electrical conductivity, TDS, pH, oil and gas values for the Los Angeles River.

Parameter	Tujunga Avenue	Arroyo Seco Confluence	Firestone Blvd.	Wardlow Street

Total Dissolved Solids (mg/l)	641	643	651	669
pH Units	7.5	7.7	8.3	8.5
Oil and Gas (mg/l)	3.1	2.5	2.4	3.7

Source: Los Angeles County Department of Public Works

VOL 12 1484

The Donald C. Tillman Water Reclamation Plant (Tillman WRP) significantly impacts TDS concentration of the river. During the dry regime, the Tillman WRP discharges are significantly higher in quantity and lower in TDS than the river flow. This reduces pollutant concentrations. For example: a review of semi-annual data for electrical conductivity, provided by the Tillman WRP, shows that TDS in the river is reduced at the discharge point. TDS values were estimated using the electrical conductivity data (EC x 0.6) from two sample stations; one located upstream from the discharge points and one located downstream from the discharge points: the estimated TDS values were 804 (mg/l) and 514 (mg/l) respectively.

In addition, three samples were taken by the RWQCB above the WRP discharge point at De Soto Ave. The dates and results were: March 1990 - 1168 mg/l, May 1991 - 1328 mg/l, and December 1991- 886 mg/l. The average TDS value for WRP discharges at the plant is 596 (mg/l). Mixed water (WRP discharge and urban runoff) value is 641 mg/l

Although upstream data is extremely limited, these data indicate that the WRP dilutes urban runoff, thereby improving water quality in regard to TDS. Thus, the WRP largely dictates the water quality of the river. Unfortunately, insufficient data are available upstream of the Tillman WRP to determine its impact on other parameters. Reclaimed water discharges control the water quality of the river. A comprehensive review of individual parameters values is provided in the summary section on the effects of reclaimed water discharges.

TDS steadily increases, however slightly, downstream. This is most likely because of inflows of urban runoff with high TDS and possibly because of evaporation (Figures 26a and 26b). Figure 27 is a comparison of TDS values of the different types of water. There are steady increases in pH downstream but values remain in the neutral range.

Most rivers in the Pacific Southwest have a high alkaline character, mostly due to high evaporation rates. Thus, surface water supplies in southern California and the Los Angeles River exhibit this characteristic.

According to LACDPW data, oil and gas are detected often in the river. Field observations by the author indicate that oil and gas originate from crank case oil dumping into the storm drain system and sheet-wash from road surfaces and parking lots

Beneficial Use Assessmet. The maximum allowable limit for TDS in drinking water is 1000 mg/l with a recommended level of 500 mg/l, according to Secondary Drinking Water Standards - State of California Title 22. However, for wildlife, a TDS less than 5,000 mg/l is desirable. Standards for industrial uses vary significantly depending on use, but for many uses less than 300 mg/l is desirable. The river averages about 650 mg/l at the four LACDPW sample stations (LACDPW station locations: Wardlow Bridge, mile 4.35; Firestone Blvd Bridge, mile 13.38; Arroyo Seco confluence, mile 23.8; and Tujunga Ave. mile 36.25.) This concentration meets drinking water standards, but is outside the desirable levels for some industrial uses without additional treatment to reduce TDS. The river water is well within criteria for the propagation of wildlife.

There is little variation in pH levels and they are acceptable for most beneficial uses. The minimum and maximum recorded levels were 6.7 and 10.2 respectively. Acceptable pH ranges for industrial uses vary with the type of industry use (Hem 1989). A pH between 9 and 10 is usually acceptable as a maximum and a pH minimum of 6 is usually acceptable as a minimum for industrial uses. However, industrial boiler feed water requires a minimum pH of 8. For fish, a range between 6.5 and 9.0 is considered safe (European Inland Fisheries Advisory Commission 1978).

Oil and gas detections are undesirable for all beneficial uses. The maximum concentrations for body contact and non-body contact recreation is 2 mg/l and for wildlife 5 mg/l. The river concentration ranges between 2 mg/l and 5 mg/l. Oil concentrations in the 1 mg/l range have been shown to be toxic to fish (Hann 1972).

Nitrogen and Phosphorus

When nitrogen and phosphorus are discharged to a stream, they promote biological responses which may interfere with some desired uses of the water (Allen and Mancy 1972). Excessive growths of attached algae, resulting in high BOD and undesirable aesthetics, often occurs. Other elements and compounds are limiting factors to algal growths, however, most attention has been focused on nitrogen and phosphorus.

Nitrogen appears in various forms in aquatic environments. The forms of nitrogen is reflective on the aquatic environment (Krenkel, Novotny 1980). During anaerobic conditions, nitrate may be reduced to nitrogen gas or ammonia. During aerobic conditions, ammonia can be oxidized to nitrite and nitrate (Figure 28). Nitrate, and to a

VOL 12 1 4845

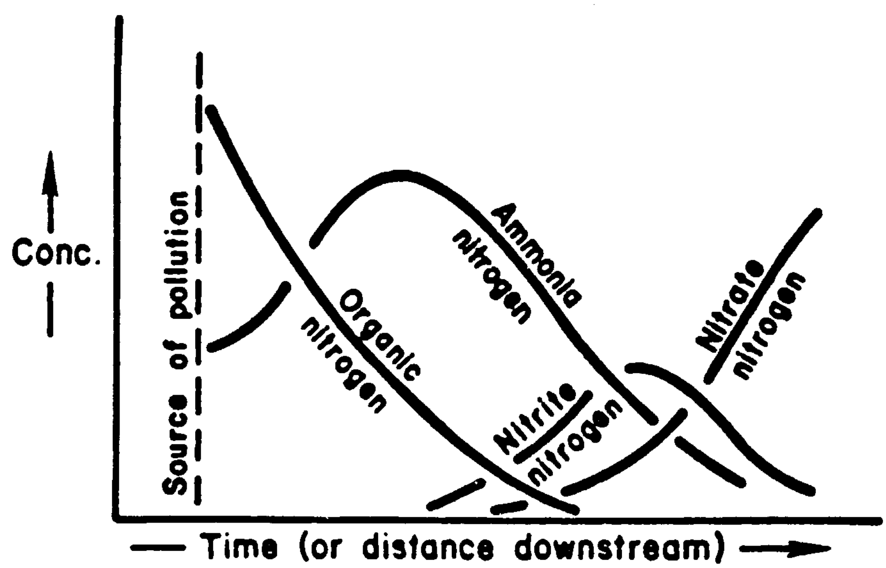

Figure 28. Nitrogen dynamics of streams. In typical streams, organic nitrogen and ammonia are transformed into nitrate. Source: Vesilind, Peirce and Weiner 1990

lesser extent ammonia, can be utilized by aquatic plants and algae.

Sources of nitrogen in surface waters include: municipal wastewater and fertilizers Nitrogen often occurs in polluted waters, but is seldom abundant in natural surface waters because of its value as a nutrient to plants (Hann 1972).

Ammonia is oxidized to nitrate in well aerated rivers. Aeration in the Los Angeles River occurs mostly in the soft bottom sections, while the concrete bottom sections have laminar flow. The two large reclaimed water discharge points from the Tillman and Los Angeles-Glendale WRPs are located at soft bottom sections of the river, thus allowing aeration. The Tillman WRP outfall has the shortest distance of soft bottom channel, which may inhibit oxidation of the ammonia.

The Tillman WRP main outfall is scheduled to be relocated in late 1994 The new discharge point will be just downstream of Sepulveda Dam and will discharge directly into the concrete channel This may alter the nitrogen dynamics, potentially delaying nitrification.

LACDPW has conducted monthly sampling for nitrate at four Los Angeles River locations and the City of Los Angeles Bureau of Sanitation (LABS) has conducted monthly sampling for nitrates at 18 sites. LACDPW had four Los Angeles River sites and LABS had 18. Figure 29a is a plot of nitrate values over distance. Each station is a composite of three years of monthly samples averaged for each agency. Average LACDPW value is 5.0 mg/l and LABS value is 10.5 mg/l, a steady state trend occurs in both data sets, however the averages vary significantly. Reasons for the variances between agency data may include: sample techniques, sample storage techniques and laboratory methodologies.

LACDPW data show a decrease in ammonia concentrations (Figure 29b) Insufficient number of data points fail to show nitrification dynamics, only general trends are shown LABS did not monitor for ammonia.

Phosphate occurs in increased amounts from fertilizer and detergent presence in waters A large proportion of the phosphorus in surface waters originates from municipal waste effluent Data from the three WRP along the Los Angeles River was

VOL 12 1 4847

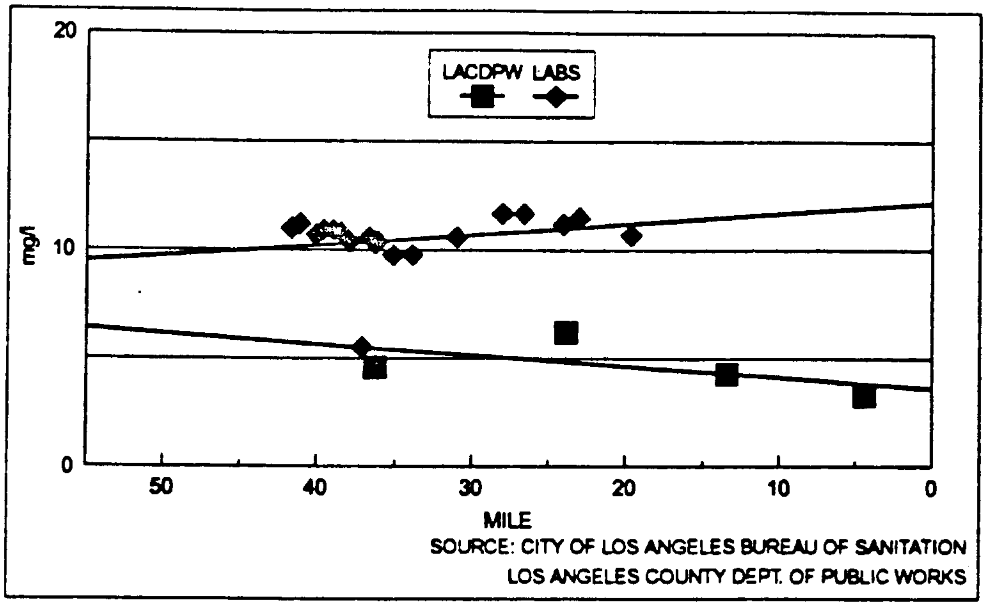

Figure 29a. Los Angeles River nitrate average, LACDPW May 1988-Jan 1992, LABS 1989-91.

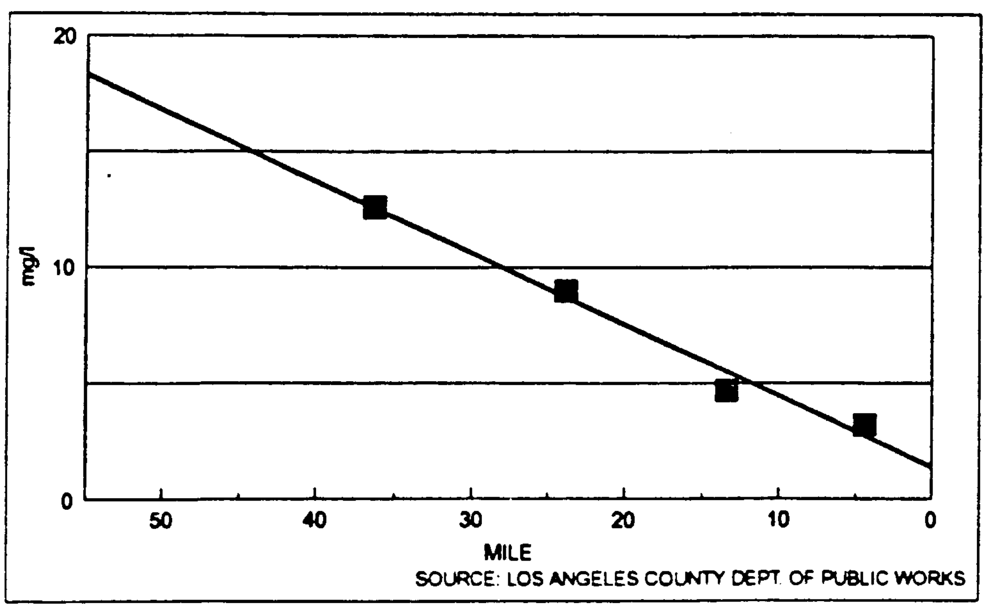

Figure 29b. Los Angeles River ammonia average, May 1988-Jan 1992

not available. Data from LACDPW showed phosphate levels averaging 2.8 mg/l. The average maximum of the four stations was 13.1 mg/l. Phosphate levels stay quite steady throughout the river length.

Beneficial Uses Assessment. High nitrate is tolerable for nearly all industrial processes except for food processing. However for drinking water supply, nitrate levels above 10 mg/l (as N) exceeds drinking water standards (USEPA, 1975). The river appears to approach this level, however inconsistent data and lack of adequate monitoring makes any conclusion unreliable.

Nitrogen is one of the two nutrients required for the growth of algae, the other is phosphorus (Allen and Mancy 1972). The quantity of phosphorus does not necessarily have a biological impact on surface waters since it must be in a biologically available form, such as orthophosphate (Krenkel and Novotmy 1980). Thus, river monitoring should include orthophosphate concentrations. The presence of nitrogen and phosphorus compounds create undesirable conditions by creating odors and rapid plankton growths. Beneficial uses, such as recreation, municipal and industrial water supply are hindered.

The Los Angeles River exhibits undesirable high nutrient loadings in most sections of the river. At times, the author has observed a continuous flow of algae globules from the concrete lined section to the estuary in Long Beach. The processes causing this phenomenon is not known, but is undoubtedly related to the nutrient levels discharged from the WRPs. Without further understanding of the nitrogen and phosphorus dynamics and its control, water quality control will not be attained and beneficial uses will be limited.

Eutrophication appears to be a problem on the river today. This has also been observed by the author at the estuary, especially in pools of water which become isolated from the main flow. These pools stagnate and produce strong odors, making the area undesirable for most uses. Reductions in nutrients may assist in improving the desirability of the estuary. Increasing the beneficial use of the river requires reduction of nutrients at the sources.

Biological Oxygen Demand

Biological oxygen demand (BOD) is used as a measure of the presence of organic materials which can support the growth of microorganisms (Stack 1972) BOD is a measure of oxygen required for biological and chemical oxidation.

Caution should be used when using BOD results for determining water characteristics. Stack (1972) states that BOD measurement is not a true quantitative entity in terms of water quality and translation of analytical information to the receiving waters is not a valid interpretation. In addition, Krenkel and Novotny (1980) state that the effects of many variables must be known before interpretation of the results can be made.

BOD levels in the river average about 5 mg/l. A high of 63.6 mg/l was detected in November 1991. The cause is not known. BOD discharge levels into the river were not available from all WRP. However, data from the Los Angeles-Glendale WRP showed that discharges are typically between <2.0 mg/l to 7.0 mg/l. Figure 30 shows the BOD levels along the river from LACDPW.

Beneficial Uses Assessment. The range of acceptable BOD for beneficial uses varies significantly. For example, BOD in drinking water is unacceptable, however, for wildlife propagation acceptable maximum concentrations are between 30 mg/l and 50 mg/l. Industrial uses usually require BOD values less than 10 mg/l. The river appears to have a typical BOD less than 10 mg/l. Closer monitoring and investigation of sources for the sporadic high BOD values should be performed. In addition, BOD and DO dynamics of the Los Angeles River are not well understood.

<u>Bacteriological Quality</u>

Several indicator organisms are used routinely to monitor the presence of possible parthenogenic organisms in water. Krenkel and Novotny (1978), provide an overview of the use of bacteriological indices of water quality. They explain that indicator organisms are used to identify waters which have potential pathogens because it is not practical to monitor for all pathogens. For example, total coliform has been the most important indicator of sanitary or pathogenic conditions in waters. This group of bacteria was monitored on the Los Angeles River by LACDPW.

Bacteriological quality is often measured by fermenting bacteria collected from a water sample and doing a plate count. Values are expressed are the number of bacterial colonies counted per unit volume. A statistical analysis is also used resulting in the most probable number per unit volume (MPN/100ml) (Krenkel and Novotny 1980)

As organic food concentration increases in a stream, bacterial numbers increase (Nemerow 1985). In the Los Angeles River, high counts are most likely related to waste loadings from urban runoff and nutrient levels from WRPs. Monthly total coliform values from LACDPW averaged 36,000 to 96,200 for the period May 1988 through January 1992 (Table 11). The highest value recorded was 800,000 in October 1990 and several low values under 500 occurred in the winter and spring of 1990.

Tillman WRP monitors receiving waters as required by a National Pollution Discharge Elimination System (NPDES) permit issued by the RWQCB. Tables 12a and 12b summarize monitoring results for total coliform counts from two sampling periods

The first time period included three sample stations during the period January 1988 through September 1991. The station locations were revised in the second time period. from October 1991 through February 1993 (sample locations are described in the tables)

Source: Tillman Water Reclamation Plant

During the first time period, the data table shows that R-1 has a slightly higher average than R-2, and R-3 is significantly higher. Again, it is likely that the WRP discharge is diluting urban runoff, which is high in total coliform. Downstream, at station R-3, a significant increase in total coliform is observed. This can be attributed to additional inflows from urban runoff into the river containing higher coliform levels and a time lag of bacterial growth downstream from the WRP. Thus, while the WRP is diluting urban runoff, it is providing additional nutrients for bacterial growth downstream.

Data from station R-1 may not be representative of the receiving-waters quality because of its proximity to the discharge point; a location where back-flow of reclaimed water could be occurring. Thus, the reduction of total coliform may be greater than available data suggests. Unfortunately, this reduction is apparently short lived, as R-3 shows significant increase in total coliform levels.

With the construction of Balboa Lake and the addition of discharge points along the river, a new sampling protocol began in October 1991. The lake, located in Sepulveda Basin, is a recreational lake which receives water from Tillman WRP. Excess water from the lake flows into the river. Under the revised sampling plan, R-1 was discontinued and two sample points were placed upstream of main discharge point, away from the back-flow problem zone and an additional sample station was placed 0.75 miles downstream from the main outfall. The second (revised plan) period shows very high total coliform at R-4, above both outfalls and a 75% reduction in total coliform downstream of the two discharges, (Table 12b).

Beneficial Use Assessment. Based on the above results, the river normally contains bacterial concentrations above all acceptable ranges for beneficial uses. The least stringent standard for bacterial quality is for wildlife propagation, which allows 1,000 bact/ml. Ninety-two percent of the 164 samples taken from May 1988 to January 1992 by LACDPW had results which were above the level acceptable for any other beneficial use.

WRP's along the Los Angeles River often use chlorine disinfection to control bacteria. Unfortunately, chlorination is complex and unpredictable in wastewater effluent (Chamber 1971). Levels of chlorination should extend to the desired level of coliform control. Research has shown that chlorine lowers BOD, however, the formation of chloramines can result in toxicity to fish (Zillich 1972). Chlorine residual is not allowed under the NPDES permit for WRP discharges.

Because nearly all samples are above acceptable levels, the river's water quality is unacceptable for all uses based on this parameter.

Dissolved Oxygen and Temperature

Dissolved oxygen (DO) in water is one of the most important measures of water quality (Stack 1972). The instantaneous concentration of DO is the result of many physical, chemical and biological factors. DO is a function of temperature, atmospheric pressure and the presence of other solutes (Allen and Mancy 1972). The solubility of oxygen in pure water at 25 degrees C is 8.4 mg/l. Uncontaminated surface waters are usually nearly saturated with oxygen. However, diurnal variations occur because of changes in photosynthetic activity.

Low DO may indicate excessive load of organic wastes which create a high BOD (Allen and Mancy 1972). Low dissolved oxygen has an adverse effect on aquatic life. DO averages range from 6.7 mg/l to 8.8 mg/l in the Los Angeles River. Variances in DO can be attributed to changes in the river sub-surface. The concrete sections exhibit laminar flow with less aeration, while the soft bottom sections have rapids that saturate the water with oxygen. In addition, algae and aquatic plants in the river add DO through photosynthesis.

Temperature is also an important factor, particularly for wildlife. Temperature affects the distribution of fishes (Moyle and Cech 1988). Warm water streams have temperatures that exceed 75 to 79 degrees F for extended periods of time. Common species in warm streams are smallmouth bass, green sunfish, catfish, and others small fishes. Cold water streams seldom exceed 75 to 79 degrees F. Trout is a common cold water stream species. Fish distribution is only partially dependent on temperature, however. Factors such as the presence of other species and stream gradient affect fish distribution.

Measurements of DO and temperature were made by the three WRPs on a regular basis. Data from the Tillman WRP is summarized because it is the farthest plant upstream to allow contrast of river with and without reclaimed water, (Tables 13a and 13b). Descriptions of the sample sites were described in the bacteriological quality section above.

Beneficial Use Assessment. The optimal DO concentration for nearly all beneficial uses including fisheries is 5 mg/l. Data collected from the Los Angeles River near the Sepulveda Basin averages above this amount. However, occasionally the concentrations fall below 5 mg/l with a low of 1.4 mg/l (It was noted that the sample time was 7:40 am when the photosynthesis rate is slow or non-existent. A sample taken at a later time of day may have provided a result with a high DO level). Of the 342 samples used in this report, (taken from January 1988 to February 1993) five percent had DO less than 5 mg/l. Thus overall, the portion of the river in Sepulveda Basin is close to being acceptable for most beneficial uses for this parameter. Because of lack of data, no other conclusions can be made about other portions of the river.

Anadromous fish, such as the endemic steelhead and Pacific lamprey, used to migrate from the ocean to the Los Angeles River and to Big Tujunga Wash. The migration took place after large storms while the water level remained high. The water temperature was between 32 and 55 degrees F (Swift 1993).

The WRPs provide a significantly warmer environment during the dry regime. However, these fish species would migrate after large winter storms, at a time when the volume of runoff is significantly higher than reclaimed water discharges. It is possible that water temperature is not a limiting factor of fish migrations. Loss of the supporting ecosystem, to the concrete channel and the invasion of non-native species probably play a more significant role in the loss of migratory fish.

<u>Minerals</u>

The majority of the mineral data available was from LACDPW. Table 14 contains averages of monthly data for four stations from May 1988 through January 1992. Note that all these sample locations are downstream of the Tillman WRP. Insufficient data was available upstream of the WRP discharge, making it difficult to assess the impact of the WRP on the river's mineral quantity. As discussed in the above section regarding TDS, the WRP does have a significant impact on mineral quality, apparently diluting urban runoff.

Table 14 Summary of minerals values for the Los Angeles River.

Parameter (mg/l)	Tujunga Avenue	Arroyo Seco Confluence	Firestone Blvd	Wardlow Street

Source: Los Angeles County Department of Public Works

The river's mineral content reflects the high TDS, discussed above. Mineral concentration increases downstream, attributed to additional inflows to the river from urban runoff.

A historical account of the river's mineral quality is provided in Table 15. Monthly and semi-monthly dry-season data from 1932 was averaged for a station in Van Nuys (California Division of Water Resources 1933). The average flow in the summer of 1932 was 0.40 cfs, attributed to rising groundwater. No industry or waste discharges upstream of the Van Nuys station were reported to have occurred. LACDPW's Tujunga Avenue-sample-station was selected to compare the 1932 results with recent sampling.

Beneficial Use Assessment. High mineralization of the river results from urban runoff, but is moderated by WRP discharges. It appears that mineral concentration in the river decreases as a result of the WRP plant discharges. This, in effect, improves the water quality of the river for these parameters.

Table 15. Historical and recent Los Angeles River data from Van Nuys area

Parameter (mg/l)	April-November 1932	May-October 1989
Calcium (mg/l)	160	48
Sodium (mg/l)	113	106
Magnesium (mg/l)	67	19
Chloride (mg/l)	48	122
Sulphate (mg/l)	504*only two samples	142
Nitrate (mg/l)	13* only two samples	7
EC (µmhos/cm)	159	986
Average discharge (cfs)	0.40	approx. 60

Heavy Metals

Some heavy metals commonly found in water, such as iron and manganese, pose no danger to aquatic life or humans below certain levels. They are usually associated with groundwater. In surface water, because of the presence of oxygen, they precipitate. When this occurs, it presents an aesthetic problem resulting from discoloration of the water.

Other metals can be toxic to humans, mammals, and aquatic life (Hann 1972). The concentration at which metals are toxic vary significantly. For example, arsenic ingestion in small quantities is dangerous because it can accumulate in animals. Arsenic can occur naturally in some waters, but normally enters streams from industrial wastes and agricultural runoff. The presence of a metal does not necessarily mean it is in a toxic form to cause biological damage. Many factors, such as pH and hardness, need to be considered before the toxicity of these metals is assessed.

Arsenic, barium, lead, nickel, and zinc are metals which are commonly detected in the Los Angeles River, (Table 16). Arsenic was detected at a maximum of 190 µg/l at the Firestone Blvd. sample station, but averaged between <10 to 10.7 µg/l. Barium consistently increases from upstream to downstream, with a maximum detected at 630 µg/l. Lead concentrations hovered near the detection limit of 10 µg/l, with several detections over 100 µg/l. Zinc detections were consistently high with all stations averaging over 100 µg/l.

Beneficial Use Assessment. The averages for the river meet the strictest water quality standards. The sporadic high concentrations of metals could impact beneficial uses. High

VOL 12

14859

levels may be detrimental to aquatic life and threatening to beneficial uses. More surveillance monitoring is needed to make conclusions on the effects of these sporadic high concentrations of metals. Comments on limiting values of metal concentrations are presented later.

Arsenic concentrations over 1000 µg/l is known to kill most fish species (Hann 1972) Because of the toxicity of arsenic, the drinking water standard in California is 50 µg/l (Title 22 Chap. 15). Based on LACDPW's data, the river is rarely above this level.

The drinking water standard for lead is 50 µg/l. A lead concentration over 100 µg/l would be lethal to fish (Krenkel and Novotny 1980). LACDPW monitoring results exceeded this level at three out of four stations.

Barium and nickel, and the other metals monitored had concentrations below the drinking water standards and the tolerances for most aquatic species. Iron and manganese seem to present no significant problems to water quality in the Los Angeles River.

<u>Volatile Organic Compounds</u>

Volatile organic compounds (VOCs) include such chemicals as solvents, fuels and byproducts of chlorination. The primary concern with respect to these compounds is in the area of groundwater resource management. However, surface waters are threatened by VOCs in the form of spills, dumping and runoff from contaminated surfaces. Many of these compounds at low concentrations volatilize quickly, especially in swift moving streams, so the threat of these compounds to rivers has not been as clearly defined as it has in groundwater. An exception to this is heavy amounts of oil and gas, which tend to float on the water often as a sheen. (See the section titled, Oil and Gas.)

VOCs are continually detected in the Los Angeles River at two locations (Figures 31a and 31b). The higher concentrations occurred in the Glendale Narrows area near Los Feliz Blvd., an area which is adjacent to groundwater contamination. Apparently, rising groundwater is a source of TCE and other VOCs. These compounds dissipate downstream fairly rapidly because large stones in the river aerate the water.

According to the Upper Los Angeles River Water Master Report (1992), the areas of groundwater contamination are within close proximity of the river (Figure 32).

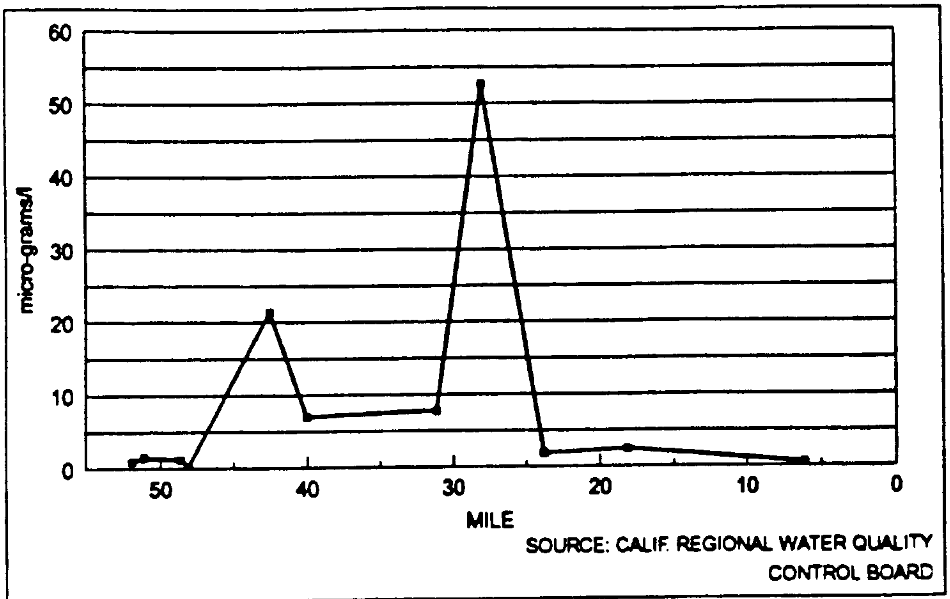

Figure 31a. Total volatile organic compounds in the Los Angeles River averaged from 1986-92. The highest peak occurs at the point where contaminated groundwater flows into the river. Most of these compounds volatize with aeration in the river bed.

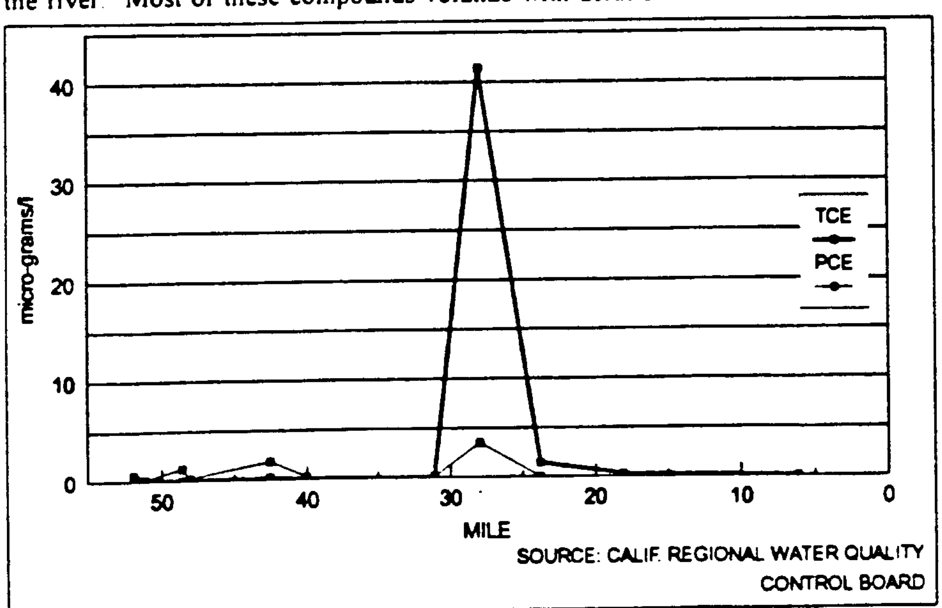

Figure 31b. Los Angeles River TCE and PCE averaged, 1986-92. These two compounds make up the majority of the contaminants from groundwater pollution at mile 28. They are seldom detected elsewhere in the river.

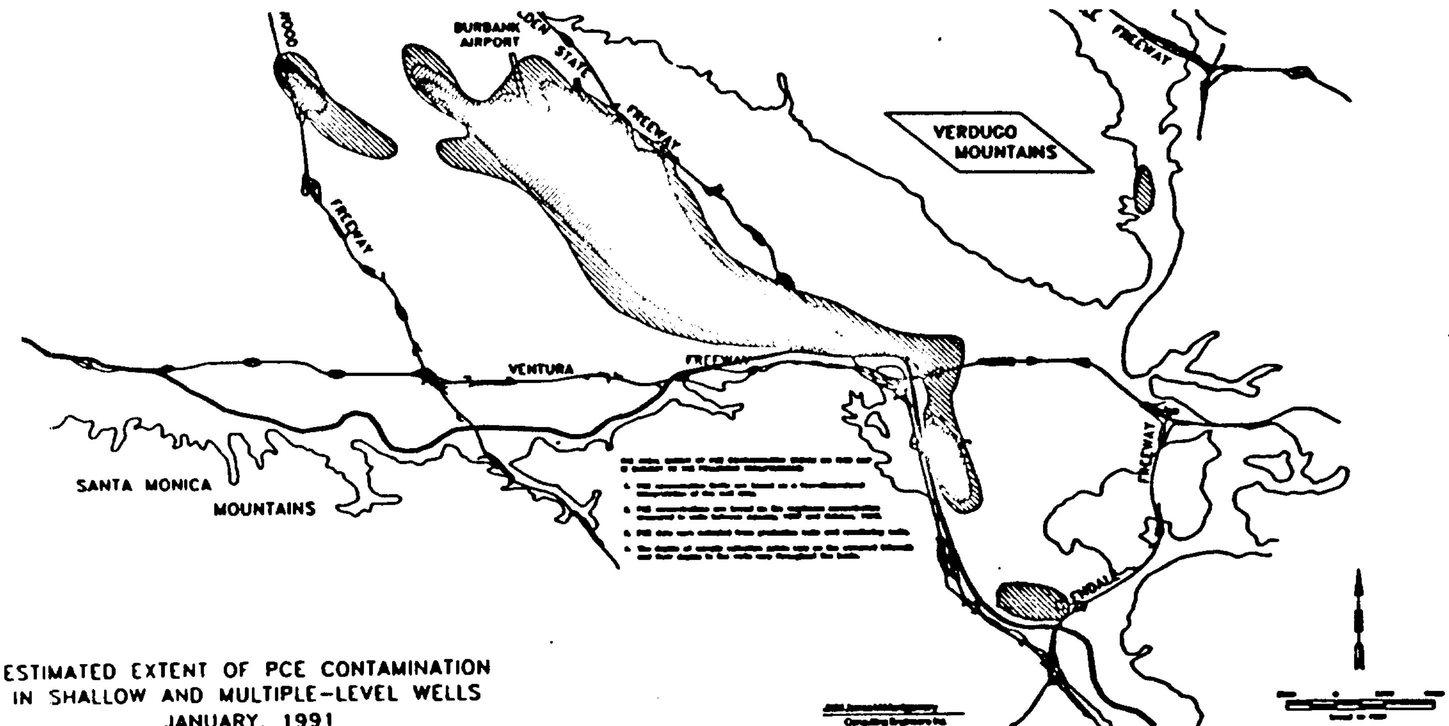
VOL 12

1

4861

Figure 32. Existing groundwater contamination plume, San Fernando Valley. The point of entry of many volatile organic compounds in the river is near the contaminated groundwater plumes. (Los Angeles River Watermaster 1992)



The second area of VOC detections is near the Sepulveda Dam Basin The source of the contamination is not clear. The VOCs do not dissipate as rapidly as in the prior case probably because there may be multiple sources along the stream length.

Trihalomethanes are a byproduct of chlorination and are commonly associated with reclaimed waste water. Trihalomethanes increase significantly at the Tillman WRP outfall, and then dissipate farther downstream (Figure 33). All results are well below the drinking water standard of 100 µg/l.

Beneficial Use Assessment. Standards for VOC are not established for beneficial uses, except for municipal water supply. The river is well aerated, so low amounts of some VOCs dissipate quickly. The impacts to wildlife are not known, but any impact would occur near the seeps and springs which contain the high values of the groundwater contaminants or near the WRP outfalls.

Pesticides and Herbicides

LACDPW performed monthly analysis of pesticides and herbicides from May 1988 through January 1992 Detection limits varied, but were mostly 1 µg/l to 0.05 µg/l, depending on the chemical analyzed Of the 24 chemicals monitored, none of the samples were within detection limits (Table 17) except three pesticides were detected one to three times each, Aldrin, Heptachlor, and O,P-DDD with concentrations less than 0.02 µg/l Based on this data, the river is free of pesticides and herbicides during the dry regime However, it is important to reemphasize that these samples do not include any wet regime results, samples taken during storm events would have significantly different results (See following section titled Wet Regime Analysis Results.)

Beneficial Use Assessment During the dry regime, pesticides and herbicides which were monitored appear to have no impact on the river. However, it is important to note that only one sample, about one liter of water taken once a month, is not indicative of pesticide free water Rather the data shows that these chemicals tend not to be in the water continuously, thus, pesticide contamination is sporadic This is not the case for the wet regime, when runoff during storm events carry higher levels of pesticides (see section on wet regime) An accurate assessment of pesticide and herbicide impacts on the river environment depends on better characterization of bioaccumulation and residuals present after storm events.

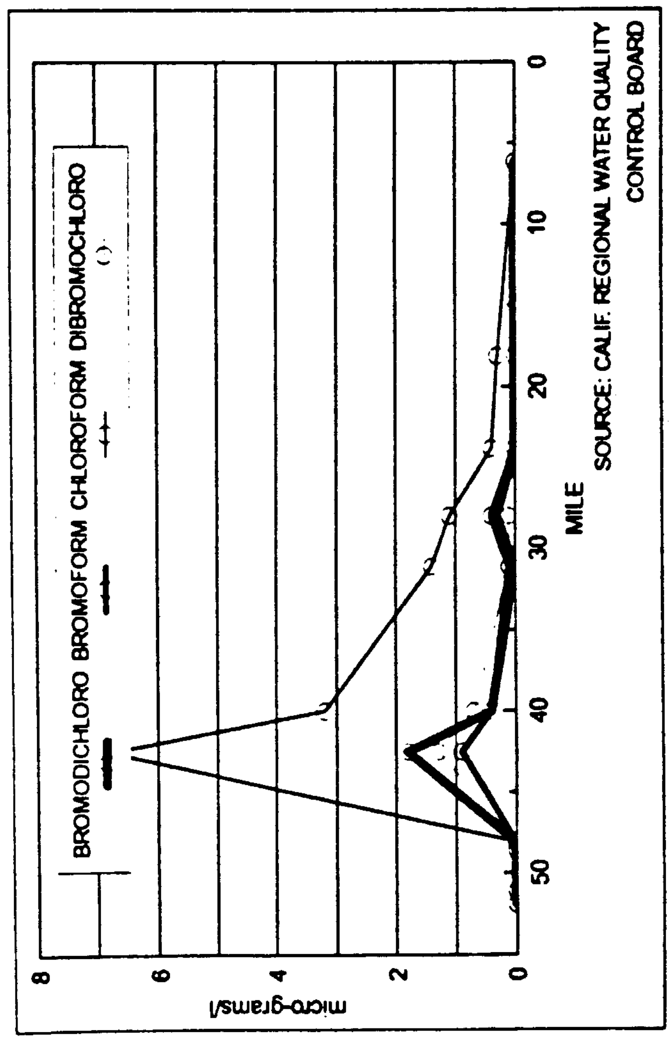


Figure 33 Los Angeles River averaged trihalomethanes values from 1986-92. The peak occurs at the water reclamation discharge point, the source, and then steadily decreases as they volatize.

<u>Phenols, Odors</u>

Phenols are common in industrial waste (Krenkel and Novotny 1980). They cause taste and odor problems in water and taste problems in fish. The USEPA recommends phenol concentrations less than 1µg/l for drinking water and aquatic life uses.

RWQCB performed annual sampling which included phenols, but none were detected. Results from LABS showed three detections in the two years of monthly monitoring of the river (detection limit of 100 µg/l). The WRP normally discharges phenols under 10 µg/l, except for one occurrence at 200 µg/l. The Los Angeles-Glendale WRP had a high detection of 35 µg/l. Phenol levels in the river appear to have no apparent adverse effect on any beneficial use.

Odors arise from organic and inorganic gases resulting from the decay of organic material, deoxygenation of rivers and lakes, and chlorination of water which may have been polluted by organic compounds (Stack 1972). Chemicals responsible for odors include halogens, sulfides, ammonia, phenols, various hydrogcarbons, organic compounds and pesticides. Odors can be controlled by preventing entry of these substances into receiving waters or by managing the water body using physical, chemical or biological techniques.

Although odors are not monitored, it is an important consideration if beneficial uses are

VOL 12

1 4865

to be expanded, especially if human contact and aesthetic beneficial uses are considered According to author observations, odors are often detected by people around the river.

Biotic Indicators

In early 1993, the Natural History Museum of Los Angeles released a biological inventory of the Los Angeles River. The report included a study on the diversity of species of algae. Algae can be used as an indicator of water quality. Anderson (1993) states in the report that algae associated with polluted water, *Scenedesmus* sp., *Euglena*, sp., *Oscillatoria* sp., and *Pediastrum* sp., were found at Willow Street. However, some clean-water algae, *Cladophora*, was also found at the site. It was recommended that future study should include regular chemical analysis of the water as well as algae identification by phycologists.

Mollusks are other indicators of water quality. Coney (1993) stated that the absence of an introduced bivalve pest, *Corbicula*, is indicative of serious water pollution problems One species, *Physa virgata*, flourish in the river because it can air breath and is able to withstand harsh conditions. In addition, it can restock the river from mountainous areas after a fish kill.

Swift and Seigel (1993) stated that extirpated native fish species, threespine stickleback (*Gasterostius aculeatus williamsoni*), Pacific lamprey (*Lampetra tridentata*, southern steelhead (*Oncorhynchus mykiss*), Pacific brook lamprey (*Lampetra pacificia*), speckled dace (*Rhinichthys osculus*) need strong improvement of water quality for them to exist in the river. They continue:

> "The problem could be as simple as excess nutrients (and concomitant increased algae biomass) using up too much oxygen, particularly at night, for fishes to thrive from dusk to dawn. The lack of aquatic insects and other organisms, except species like crayfish that can utilize air breathing, suggest this is one of the problems in the area."

They indicated that moderate improvements to water quality would allow the reestablishment of some native fish species.

Summary of Reclaimed Water Impacts

WRP discharges are the dominant factor influencing the water quality of the Los Angeles River today. Table 18 shows the trend of several parameters upstream and downstream of the Tillman WRP. The table is based on three to five samples from the Los Angeles River upstream and downstream of the Tillman WRP, and monthly samples from effluent The second column indicates changes in each parameter as the river flows past the discharge point. The third column indicates whether each parameter is detected in the plant effluent. Insufficient data, especially upstream of the WRP discharge point, makes it difficult to quantify the WRP discharge impact. In addition, detection levels may not be sensitive enough to detect changes.

Table 18 shows that some parameters increase in concentration because of the effluent, while other parameters decrease in concentration, possible due to dilution With additional data, it would be possible to verify which parameters detected in the river are in flux because of the effluent With this information, the impact of the effluent on the river would be better understood and the plant effluent could be chemically regulated to improve the quality of the river to meet the needs of beneficial uses.

Table 18. Effects of WRP discharge on the receiving waters near discharge point.

Parameter	Trend (3-samples)	Effluent detected	Parameter	Trend (5-samples)	Effluent detected

Wet Regime Analysis Results

Overview of Stormwater Sampling

Stormwater monitoring involves several challenges. Factors which cause very large fluctuations in sampling results are storm duration, portion of rainy season, rainfall intensity, and length of dry period prior to storm. Pollutant concentrations will peak at different times on the hydrograph curve (Tomo, Marsalek, and Desbordes 1986), thereby, making sample timing critical during the storm event. Conclusive results from a stormwater monitoring program requires a sample program extending over several years to compensate for climatic variation of any given year. However, the nature of southern California climate is highly variability in seasonal totals. Annual precipitation may range from less than a third of the normal value to nearly three times normal (Ruffner and Bair 1974). Because of the high variability of the precipitation, runoff water quality will consequentially be highly variable in any given year.

VOL 12

14868

Stormwater has been monitored by LACDPW and by the Southern California Coastal Water Research Project (SCCWRP). LACDPW collected one to three samples during storm events from 1987 to 1992. SCCWRP collected samples during several seasons and reported findings in annual reports, so the data was not re-analyzed here. Following is a review the findings of SCCWRP and a general analysis and review of LACDPW data

Stormwater Characteristics

The USEPA's National Urban Runoff Program cites that a variety of pollutants including heavy metals, pesticides and nutrients are present in elevated concentrations in urban stormwater runoff (Lee and Jones 1990). Pitt and Field (1990) support that contaminants in urban stormwater are causing significant adverse impacts on the quality of surface waters in the U.S. It has been shown that runoff contributes amounts of BOD, COD, suspended solids and heavy metals to receiving waters (Hunter et al 1979).

Torno, Marsalek and Desbordes (1986) summarize the characteristics of urban runoff Their description is paraphrased as follows:

...Urban runoff contains...

Solids: inorganic and organic solids in particulate or colloidal form Suspended solids fraction induces turbidity, pollutant adsorption, benthal accumulation.

Oxygen demand: Organic and other oxidized material exerts oxygen demands.

Toxicity: Highly charged with heavy metals, hydrocarbons, pesticides and PCB's However, toxicity is dependent on pH, ionic strength and organic content.

Bacterial: Large concentrations of bacteria, viruses and pathogens

Nutrients: Phosphorous and nitrogen loadings accelerate eutrophication problems in quiescent reaches exerting subtoxic effects on aquatic organisms

Krenkel and Novotny (1980) further state that metal in water is usually related to cultural activities including sources such as automobiles, industrial production, mining, vector control, macrophyte and microphyte control.

Los Angeles River Data. A significant amount of stormwater quality data was available from SCCWRP who measured contaminants in the Los Angeles River during three periods; 1971-1972, 1979-1980, and 1985-1989 (SCCWRP 1986,1990). Suspended solids, oil and grease, metals, and chlorinated hydrocarbons were analyzed. In 1986, SCCWRP also measured other streams in southern California, including: the Santa Clara River, Calleguas Creek, Ballona Creek, Dominguez Channel and the San Gabriel River. The monitoring results of these streams were compared to each other. However, because of limitations of comparing different streams, no conclusions are possible except that stormwater runoff is becoming a significant factor in coastal pollution especially because of improvements in sewerage plant outfalls.

In 1987, SCCWRP measured the toxicity of Los Angeles River stormwater using a system called the Microtox™ Toxicity Analyzer System (1988). The system uses bacteria added to water samples to indicate toxicity of the water. This information is inferred as to toxicity to other aquatic organisms. The results showed that stormwater was generally less toxic than effluent from sewage treatment plants. Again no conclusions are possible because of the lack of sufficient data (SCCWRP Raco, 1993 personal communication)

LACDPW also sampled a few storms from 1987 to 1992 on the Los Angeles River at two sample sites. Only one sample was taken from each station located at Firestone Blvd and Wardlow Rd. No composite samples at different times on the hydrograph were taken.

Variations in instream contaminant concentrations make accurate quantification difficult because of the limitations of stormwater research. However, SCCWRP and LACDPW data does prove to be useful on a qualitative basis, helping to identify pollutants associated with stormwater in the river. Presence of chemicals does not necessarily constitute toxicity. Table 19 lists chemicals detected in the Los Angeles River by LACDPW and SCCWRP (1987) during storm events.

Table 19. Stormwater detections.

Parameter	LACDPW 1987-92	SCCWRP 1986-87	Parameter	LACDPW 1987-92	SCCWRP 1986-87

Organic Nitrogen	Yes	N/M	Silica	Yes	N/M

Source: Los Angeles County Dept of Public Works and Southern California Water Research Project Yes = Detected, No = Not detected, N/M = Not monitored

LACDPW also performed bacteriological analysis using several genera Fecal bacteria in stormwater comes from sources such as cats, dogs and rodents in city areas and from farm animals and wildlife in rural drainage (Geldreich and Kenner 1969) The results of LACDPW's 24 samples over a six-year period are as follows Total coliform (average/maximum) 800,000/5,100,000 MPN/100ml; fecal coliform 81,500/790,000 MPN/100ml; KF Streptococcus 78,000/330,000 CFU/100ml.

Chapter III discussed the results of U.S. Environmental Protection Agency (USEPA) stormwater monitoring program, titled Nationwide Urban Runoff Program (NURP). Also discussed was the mean values from the Nationwide program and a program under NURP for the city of Fresno, California. Table 20 presents a comparison of the results of NURP to LACDPW data.

Data for individual sub-watershed was not available in sufficient quantity so the only

VOL 12

1 4871

classification considered is mixed. Table 20 shows that the Los Angeles River stormwater values are higher than NURP and Fresno values for Nitrogen compounds, phosphorus and BOD. Copper and Zinc are within range of the other two studies, but lead is far below the others.

Most winter storms wash debris into the local channels and carry it to the beach (Figures 34a and 34b). LACDPW and the city of Long Beach are responsible for the removal of debris on beaches resulting from debris washed down the Los Angeles River during and after winter storms. In the 1992/93 season, over 7,000 tons were removed. Floating solids are a pollutant which contributes to water toxicity and severe aesthetic problems (Krenkel and Novotny 1980).

Impact on Beneficial Uses

It is apparent, despite limitations in sampling stormwater, that quality of the Los Angeles River during the wet regime is poor. This can be concluded without the Los Angeles River data presented above because enough evidence from other watersheds have concluded that elevated levels contaminants are common in stormwater runoff. Therefore, the water quality during storm events is not appropriate for beneficial uses. Fortunately, beneficial uses, such as recreation, are unlikely to take place during or immediately after storms.

Table 20. Comparison of NURP, Fresno and Los Angeles River stormwater data

Parameter	Residential NURP	Residential Fresno	Commercial NURP	Commercial Fresno	Industrial NURP	Industrial Fresno	Mixed land use LACDPW
Nitrate+ Nitrite-N mg/l	0.7	0.4	0.6	0.4	N/M	0.6	1.3

Zinc µg/l	135	120	226	180	N/M	520	153

Figure 34a Compton Creek After Second Storm of Season. The channel is concrete lined upstream, debris is becomes caught in the foliage at the head of the soft-bottom

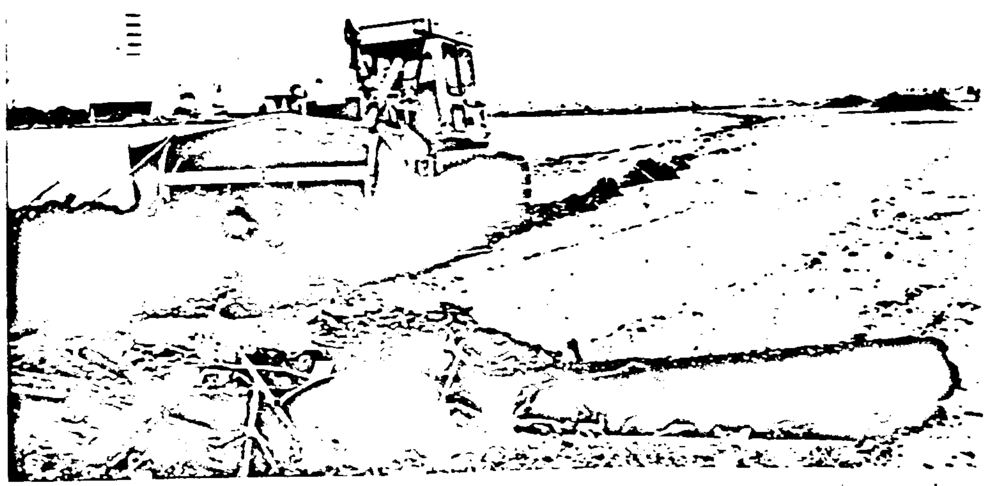

Figure 34b Long Beach After Winter Storms The Los Angeles River is a conduit for trash Better watershed management would help to alleviate this problem

VOL 12

1 4873

Improvement of stormwater quality is crucial in maintaining beneficial uses and increasing others. Successful implementation of the NPDES stormwater program along with implementation of structural (e.g. mechanical debris removal equipment) and non-structural (e.g. education programs) best management practices is needed to improve the overall quality of the river. Beneficial uses, such as fisheries and non-contact recreation, is contingent upon the success of improving urban runoff in both the wet and dry regimes

CHAPTER V

ASSESSMENT OF WATER QUALITY AND BENEFICIAL USES

The following section summarizes the current water quality of the Los Angeles River and its various beneficial uses. Three steps are used to assess water quality and beneficial uses. First, the beneficial uses are listed in a table, including sanctioned and unsanctioned uses. Second, appropriate beneficial uses based on the water quality data presented are listed in a table. Third, the two tables are compared to show which beneficial uses are occurring despite poor water quality. The last table presents the water quality needed to maximize beneficial uses on the river. This is followed by a discussion of how water quality objectives can be designed to increase beneficial uses.

Assessment of Water Quality and Beneficial Uses on the Los Angeles River

Many existing beneficial uses are unauthorized, yet occur regularly or are not recognized by some agencies as a use despite its occurrence. Table 21 is a summary of all beneficial uses either recognized or observed by the author. A variety of activities which take place on the river are shown on Figures 35a through 35d.

Unfortunately, most of the uses in Table 21 are not acceptable based on water quality criteria. Table 22 summarizes the acceptable beneficial uses of the water in the Los Angeles River as it exists based on the data summarized in this report. If an important parameter occurs over the acceptable limit with regularity, it was categorized as unacceptable. Less important parameters and infrequent high-pollution occurrences were categorized as moderately acceptable. Additional treatment would increase the usability of the water in all cases.

Because unsanctioned beneficial uses occur on the Los Angeles River, whether

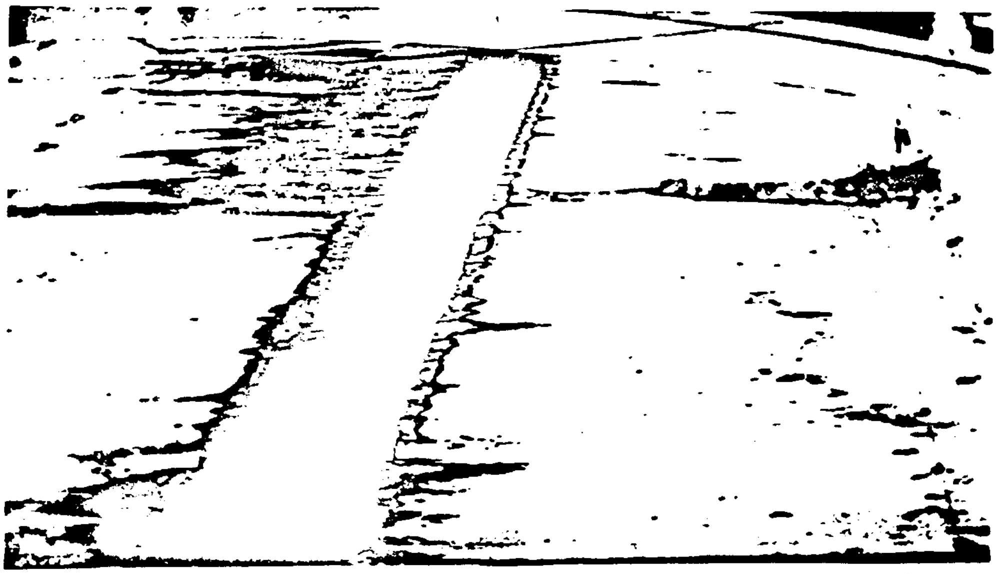

Figure 35a. An undressed man bathes and washes his clothes in the Los Angeles River near Downtown. The quality of the river is not appropriate for this use; however, uses such as this occur despite efforts to restrict it.

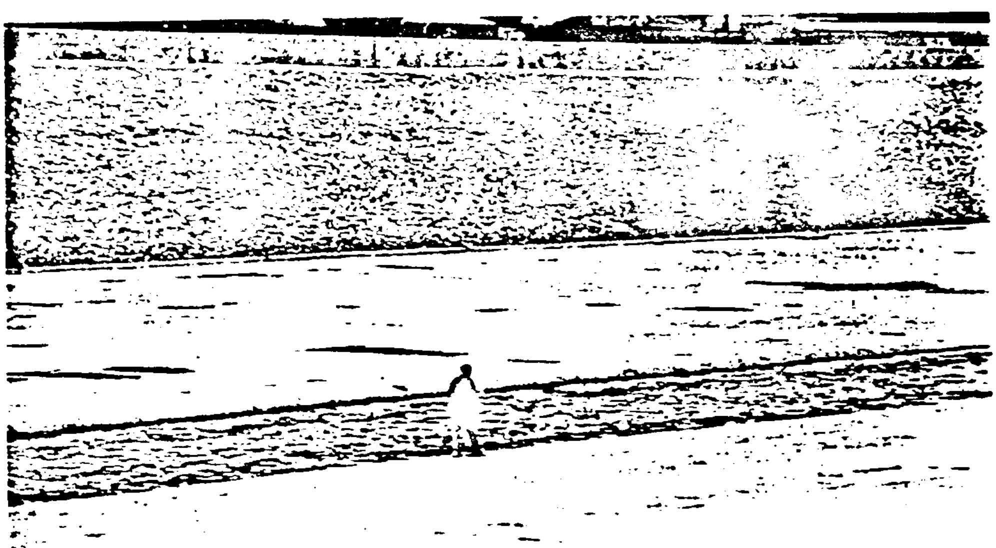

Figure 35b A man walks along the low-flow channel near South Gate Rivers have always attracted people.

Figure 35c. A man walks along the river bank in the southern San Fernando Valley in a restricted area.

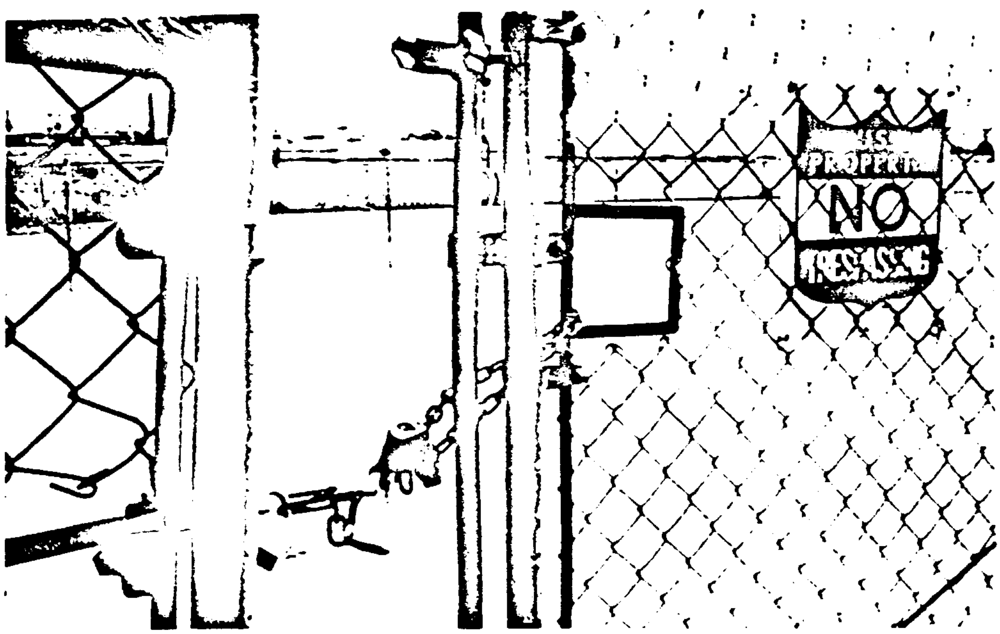

Figure 35d The man in 35c was walking behind this locked fence Despite warning signs of no trespassing, recreational activity occurs on the river regularly.

Agriculture (AGR)		X	
Groundwater Recharge (GWR)		X	

appropriate with the existing water quality or not, it should be recognized as such, and water quality criteria for those uses are to be met. It is impossible to fully regulate public access and uses on the river, but if a use occurs with regularity and by a number of people, every effort should be made to improve the quality of the river to an acceptable level to protect public health.

Some beneficial uses of the Los Angeles River are regulated by LACDPW. Safety, liability and vandalism has caused the County to limit access to most of the river and much to the flood control system. Portions of this system, however, have recreational and water conservation beneficial uses. At a minimum, the river should have water quality to allow safe use for the existing beneficial uses. With improved water quality, existing beneficial uses in Table 23 become appropriate.

<u>Stormwater Quality and Beneficial Uses</u>

Geldreich, Kenner, and Van Donsel (1968), and Evans et al (1968) performed some early work on the presence of bacteria in stormwater. They concluded that stormwater can be a major source of intermittent pollution at bathing beaches and to water supply reservoirs opened to limited public recreational uses. They recommended regulation of pets on public beach areas and adequate garbage control plans and that stormwater drains be diverted away from beaches and reservoirs or treatment methods should be developed.

- Require water treatment.

Recent work by Urbonas and Stahre (1993) outlined available technologies to reduce contaminants such as bacteria. Great strides have been made in the 1980's in these technologies; but they concluded that many current technologies are not well tested and more research is needed.

Design of Water Quality Criteria for Beneficial Uses

Water quality criteria are designed so that the water quality is safe for the beneficial use. In some cases, a beneficial use will occur whether or not the water quality is safe for that use. For example, migratory birds forage and breed on the river, thus a beneficial use is wildlife propagation, even though the water quality is not appropriate for this use. If the water quality is improved to make the use of wildlife propagation appropriate then an objective is met. Alternately, if the water quality does not meet certain standards, other beneficial uses will be restricted. For example, boating will not be allowed on the river unless the water is safe for non-contact recreation. As a priority, the river should be made safe for all existing uses first, and then for additional beneficial uses. Additional beneficial uses might be viewed as a luxury, so emphasis should be on improving existing beneficial uses.

Nemerow (1985) describes the goals of pollution abatement in water as not absolutely clear. He states that idealists and preservationists push for pristine purity of all receiving waters and conservationists want reasonable management of resources. In addition he asserts, some streams would best be used primarily for drinking water while others for fishing. He concludes that most persons are united in attempting to maintain water quality at the highest level possible consistent with technical and economic limits.

Nemerow's ideas may not be applicable to rivers such as the Los Angeles. Most rivers in the eastern United States, for example, have a multitude of beneficial uses maintained throughout historical times (e.g., water supply, fisheries, navigation). The Los Angeles River in the early days of the city, had many beneficial uses (e.g. water supply, fisheries, agriculture), but all uses are either degraded or lost with implementation of flood control projects. A superficial examination of the uses today would show that water of the river need not be clean because the primary use of the river is flood control and beneficial uses are virtually non-existent. Thus, Nemerow's economic limit is easily met (except for the issue of coastal pollution). However, with a more thorough examination of the uses of the river today, including the unsanctioned uses, plus the community desire to revitalize the river, it becomes apparent that the flood control channel indeed needs higher quality water and economic limits of water quality improvement need to be increased. Therefore, it can be concluded that the economic limits need not be set with current acceptable uses, but should be set for the sanctioned and unsanctioned uses, and the potential uses which would be derived from water quality improvements. For example, the cost of installing a trash removal rack on the Los Angeles River might be determined to be too costly. It can be argued that trash removal would only improve the river aesthetically and may help the river habitat. No direct economic gain is realized by the trash rack. If the trash rack were installed as part of a new water conservation system, then the investment might payoff. Consequently, communities along the river might find a sense of pride living next to the river and possibly lead to tourist dollars and investors as part of the communities redevelopment. Most importantly, the river would again be benefiting people and the environment as it once did.

Water Quality Criteria Formulation. In most watersheds, especially ones which provide municipal water supply, a combination of watershed management, reservoir management and water treatment is needed to achieve the desired level of water quality. According the American Water Works Association (1991), controlling contaminants at their source of origin is the most fundamental way to prevent degradation of water quality in water-supply reservoirs and finished water. Unfortunately, because the Los Angeles River has been viewed as a flood control channel for the past 4 decades and not as a water source,

VOL 12

1 4 8 8 1

the practice of managing land use to improve water quality has not been pursued. In other cities, where rivers are accessible and highly used for such uses as recreation and municipal water supply, the link between land use and water quality has been understood and good practices have occurred for many years. The American Water Works Association surveyed utilities which use surface waters and found the following percentage of water systems using the following watershed controls (Table 24). Water quality criteria can be designed for each specific beneficial use.

Table 24. Survey results of water systems which use surface waters.

Watershed Control	Percent
Watershed Entry Restrictions	38
Zoning Restrictions	29
Land Ownership Control	25
Prohibited Land uses	23
Informal Agreements with Land Owners	18
Formal Agreements with Land Owners	16

Source: American Water Works Association 1991

Case Example. The Anglian Water Authority (1980) has developed a basic approach to recognizing a wider range of river uses. The system included a list of all primary uses and criteria for specific use. Primary uses, in the first column of Table 25, are the general uses, which are then divided up into more specific uses or processes in the second column. Criteria for the items in the second column were prescribed. Criteria are specific levels of parameters acceptable for that use.

Table 25. The Anglian Water Authority's approach to recognizing a wider range of river uses.

Primary use	Uses for which criteria have been prescribed
Potable Water Supply	Direct to treatment Via impoundment
Fisheries	Anadromous Warm species Native Non-native
Industrial Supply	Cooling Process
Irrigation	Field crops Ornamentals/turf
Livestock watering	Livestock
Wildlife	Upstream mountainous Mid-stream Estuarine
Amenity/aesthetic appearance	High amenity Low amenity
Recreation	Contact Non-contact

Adopted from Anglian Water Authority (1980).

Instream Versus Offstream Beneficial Use

Long-range plans for expanded reclaimed water use will result in a reduction in the quantity of water discharged by the plants for use on other applications (Los Angeles Office of Water Reclamation 1990) Considerations which affect the river environment include both quantity and quantity of water discharged into the river, as these are directly related Water quality objectives need to be addressed to retain and enhance beneficial uses.

It can be argued that offstream reclaimed water uses, such as irrigation, may be a higher priority use because the water is used directly. However, this should not be done in a manner that jeopardizes the integrity of the river. By maintaining volume and quality in the river, beneficial uses would be derived instream and offstream, including instream uses such as recreation, wildlife, and economic developments. At the river terminus in Long Beach, offstream uses would be appropriate, uses such industrial and irrigation. Many heavy industries, including refineries are located in the area. With some treatment, some of this water could be used for industrial or processing water. Through watershed management to improve runoff quality, WRP discharges would become less important in guiding the quality of the river, so the quantity could be reduced.

<u>Water Quality Improvement Through Land Use Management</u>

Short-term and long-term management practices can be used to control pollution related to land use (Krenkel and Novotny 1980). Planning processes consider water resources in the area, determine the extent of pollution originating from non-point sources as compared to that from effluent outfalls, soil characterization, and the adequacy of existing and planned wastewater treatment facilities.

Several studies have shown that natural surfaces and vegetation may be effective at retaining pollutants as urban stormwater passes over them, thereby reducing impacts on receiving waters. Pratt, Mantle, and Schofield (1989) and many other researchers have found that permeable pavements effluent quality to be markedly better than in other urban areas with impermeable surfaces. In addition, flow reduction and peak discharge attenuation was achieved by using these techniques.

Beneficial uses are directly impacted by the waters of the river and the watershed from which the water originates. In a sense, the river is the sum of the watershed, therefore, the river is the telling feature of the landscapes environmental health.

VOL 12

CHAPTER VI

ACHIEVING RESTORATION OF BENEFICIAL USES

The 52 mile Los Angeles River is in a deteriorated state that adversely impacts beneficial uses which are either degraded, unsafe, or have been eliminated. Beneficial use restoration would benefit the communities in the area as well as the environment. Restoration is achievable with watershed management and alternative flood control strategies.

The river once supported a variety of beneficial uses for Indians and settlers, and played an important role in the history of Los Angeles by being its primary source of water Due to periodic flooding, the river was transformed into a flood control channel resulting in the 39 miles out of its 52 mile-length completely channelized in concrete Channelizing was the result of the Comprehensive Plan initiated in the early 1930's by Los Angeles County Flood Control District (now Los Angeles County Department of Public Works (LACDPW)) and the federal government's participation through the U.S. Army Corps of Engineers (Corps). The post-Depression public works project came at a time when controlling or degrading the environment was largely acceptable to meet immediate needs Five years after completion in 1964, the Corps was authorized to study water resources in the project area and found the flood control system to be inadequate The addition of flood walls on the river looms in the late 1990s to address this inadequacy

The Los Angeles River is Transformed

The Transformation Model shows that as traditional flood conveyance methods are increasingly implemented, beneficial uses decrease (Figure 6) This process, with additional impacts from urbanization throughout the watershed, caused the degradation or loss of beneficial uses Table 26 is a list of beneficial uses which historically occurred

14885

on the river, but are now impacted. This change from a river which provided all of these beneficial uses to one which does not provide any high quality uses marks the river's First Transformation.

Table 26. Beneficial uses degraded or lost on the Los Angeles River.

Beneficial uses	Degraded	Unsafe	Lost
Municipal Water Supply			X
Contact Recreation		X	
Non-contact Recreation	X		
Warm Freshwater Habitat		X	
Wildlife Habitat		X	
Fish Spawning/Migration			X
Industrial Service and Process			X
Agriculture	X		
Groundwater Recharge	X		

The environment of the Los Angeles River is influenced by variation of the channel invert surfaces from concrete bottom to soft bottom, and by water reclamation plant discharges The soft bottom sections support riparian vegetation and wildlife, while the concrete sections are normally devoid of vegetation. Reclaimed water discharges help to support vegetation and dilute pollutants found in urban runoff. Urban runoff and discharges combined produce a year-round flow of over 120 cfs. This improves the river environment during the dry regime.

Impacts on the River Today

The wet regime is the result of a higher water level in the river due to precipitation Land use is the strongest controlling factor of this regime because the river is the sum of the conditions of the watershed Therefore, control of quantity and quality of inflows improves the quality of the river Land use analysis can be used to assist in the development of plans to control urban runoff pollution from the watershed Permitted discharges have been regulated for many years Urban runoff, however, remains unregulated -- flowing directly into the river without any treatment

A method to study the impacts along the river is to divide the watershed into sub-watersheds. Each sub-watershed has a distinct land use pattern and spatial impact on the river. For example, Tujunga sub-watershed has 92% open space and impacts the river at one point -- the confluence; while the Southeast Coastal sub-watershed has seven percent open space and has a contiguous impact. Land use types which increase along the river are commercial and industrial, with the maximum of 38% industrial area in the Southwest Coastal sub-watershed. In general, sub-watersheds in the lower river tend to have higher percentages of intensive land use practices, with Southeast Coastal and North Coastal having the most intensive (Figure 22). Results from studies, such as National Urban Runoff Program, indicate that urban runoff from intensive urban-type land is typically of poor quality, containing high levels of heavy metals, bacteria, pesticides, and nitrates. Therefore, runoff from the highly urbanized Los Angeles area is adversely impacting the river.

Water Quality

Water quality data from various agencies show that the river in the dry regime is free of many toxic substances often found in the wet regime. However, close monitoring is needed to detect sporadic unsafe levels. The dry regime is dominated by effluent from WRPs. The following parameters and averages, all stations from 1988-1992, are acceptable for most beneficial uses: total dissolved solids, 651 mg/l; pH, 8.0, dissolved oxygen, 7.4 mg/l; biological oxygen demand, <5 mg/l (sporadically high results common). silver, <10 µg/l, and 26 commonly monitored pesticides and herbicides, none detected. Volatile organic compounds are detected sporadically, but tend to volatilize out of the water rather quickly.

The following parameters and averages are considered beyond acceptable levels to allow beneficial uses to occur safely: oil and gas, 2.9 mg/l, nitrate as N, near 10 mg/l (related to high bacteriological counts and excess algae growths); phosphate as P, 2.8 mg/l. and bacteriological, >32,000 MPN/100ml. Twelve heavy metals are detected at varying levels amounts (majority <100 µg/l). However, sporadic high detections are common and may be detrimental to beneficial uses.

The wet regime is dominated by runoff which tends to have more heavy metals, pesticides and herbicides, and higher bacteriological levels. Data for the wet regime is limited and it is difficult to capture accurate results, thus, average values could not be determined accurately for most parameters. Data from 1988-1992 indicate that all heavy metals monitored were

VOL 12

1487

detected except for silver. Other chemicals detected include: 111,-trichloroethane, trichloroethene, Lindane, PCBs, and phenol. Bacteriological averaged 800,000 MPN/100ml. These results show that the water quality is not safe for any beneficial uses during the wet regime.

Poor water quality in the Los Angeles River is the result of negligent watershed management practices and the degradation of natural systems. Channelization transformed the river into a flood control feature in which water quality is not normally considered important. This is compounded by the loss of beneficial uses, which, if remained, would have ensured water quality protection. Unfortunately, today the river's water is not safe for most beneficial uses. Agencies with jurisdictions over the river should recognize unsanctioned uses. For example: homeless persons are often observed bathing and washing clothes in the river near downtown Los Angeles; and persons are often walking, riding or playing in and around the channel. Although these activities are illegal in places, they continue to occur. Because people have desire for these uses, river water which runs through a metropolitan area should always be safe for body contact to protect public health and to meet community needs. The RWQCB is charged with listing beneficial uses of the Los Angeles River and in 1994 will expand the list and assign objectives for these uses. Once objectives are set, every effort should be made to achieve safe water quality to protect public health for these uses.

Achieving Restoration of Beneficial Uses

The Los Angeles River has long been managed as a flood control channel. By changing its management to that of a river, the means to restore beneficial uses will be in place. Two environmental conditions need to be addressed if restoration is to take place. One is the methodology used for flood control. Channelization with concrete limits beneficial uses, therefore alternatives which enhance beneficial uses should be used. The other environmental condition to be addressed is water quality. Existing and potential beneficial uses are degraded because of unsafe water quality.

Alternative Flood Control Strategies

Beneficial uses need not be sacrificed for flood control. This can be accomplished with the implementation of alternative flood control strategies, which are well tested throughout the United States. Alternatives recommended by Friends of the Los Angeles River (1993) include: on-site detention, permeable pavements, improved watershed management, use of large and small detention basins, wetland restoration, spreading grounds, and river widening. The Federal Emergency Management Agency (1991) states that land treatment measures where infiltration is increased and the amount and rate of runoff is decreased can be especially important in reducing erosion and the resultant amount of sediment and pollutants carried downstream. The California Legislature recognized the close relationship among flood management and wetlands, fish, wildlife, and recreation (California Department of Water Resources 1980). The California Department of Water Resources adopted this policy, adding groundwater recharge. Implementation of these alternatives and policies would allow the restoration of beneficial uses.

According to the Corps, additional flood protection is needed on the lower Los Angeles River. Current plans call for parapet walls up to eight feet high along the river on the existing levees. However, other cities are successfully reducing the flood threat by instituting many alternatives. For example in Bellevue, Washington, the surface water management agency's goal is to preserve and enhance water resources. A City of Bellevue resolution states, "Engineering designs should improve the effectiveness of natural systems rather than negate, or replace them. Technological solutions should emphasize the use of non-structural or 'natural' engineering approaches. These approaches should be consistent with the natural resources and process, and preserve and enhance the natural features of Bellevue."

In Los Angeles, a similar approach is possible. A single agency with authority and expertise over the river and its watershed begins to find feasible methods to restore beneficial uses to the river. Flood control, environmental protection and enhancement, public access and water quality management are four fundamental factors addressed by such an agency. It is important to gain public support for such efforts and provide the appropriate agency with the resources and trained staff to protect the communities from floods while improving the condition of the river. Based on author observations, the general public is unaware of local rivers and their potential to benefit them. This is due to a widely held incorrect-perception that the Los Angeles River is solely a flood control channel constructed for that purpose. Little is known about the river's history, the natural soft bottom sections, and existing and potential beneficial uses.

Improving Water Quality

Because water quality is intertwined with beneficial uses, restoration cannot occur without

VOL 12 14889

R0048194

a significant improvement. According to the AWWA (1991), nearly all variables should be targeted in watersheds to improve water quality. Listed are: turbidity and sediment, pH, nutrients, algae, bacteria, trihalomethane precursors, pesticides, other soluble and volatile organic compounds, heavy metals, and manganese.

Stream quality is the result of the inflows described in Figure 14. By studying this and the thirteen sub-watersheds of the river drainage area, water quality managers can predict impacts along sections of the river. This is a tool for accessing appropriate beneficial uses and for addressing water quality needs along the river. It is likely that if the most significant contributors of pollutants are controlled, beneficial uses limited by these will be restored. For example, only a few parameters in the dry regime are unacceptable: bacteriological, which is related to nitrates and phosphates; oil and gas; and occasionally high biological oxygen demand. The wet regime has additional pollution loads rendering beneficial uses unsafe, however this regime only occurs average 42 days per year. The priority for managing agencies is to firstly recognize the unsanctioned of uses of the river and make needed improvements and secondly be aware of the expansion of sanctioned uses in the future so that preparation can be made for additional water quality improvements.

Additional monitoring is not necessarily the answer, but better coordination of monitoring with specific goals is necessary. Agencies often do not share data. Better coordination of data-collection, storage and retrieval will increase the usefulness of the data. In addition, coordinating river monitoring is likely to be more cost effective.

Monitoring programs should have clear objectives. Key objectives of a monitoring program are to answer questions such as: implementation of beneficial uses, standards, sources of pollution, public perception of stormwater quality problems and effectiveness of stormwater management programs. Significant amounts of data are needed to make sound conclusions on the quality of the river and to understand the dynamics of water quality. With this understanding, sound decisions can be made regarding watershed and river management.

Eight governmental agencies perform regular river monitoring, each of which has distinct objectives. Yet, there is limited data to fully understand water quality dynamics. Coordination of monitoring plans would allow more efficient data collection and would allow the expansion of the monitoring program.

An encompassing study should be performed which includes data collection, analysis and conclusions, focusing on quality dynamics, pollution sources, and remedies to pollution. The most important element is action to improve the condition of the river.

Significantly more monitoring of stormwater is needed. Since SCCWRP no longer performs river monitoring, agencies and research groups should expand monitoring programs. Increased monitoring will result with the implementation of the NPDES program. In addition, a comprehensive study of stormwater effects on beneficial uses is recommended.

Benefits of Beneficial Uses Restoration

The loss of beneficial uses adversely affects general environmental quality, social well-being, and economic prosperity. A healthy river system in Los Angeles would provide additional clean water, provide riparian habitat with trees to improve air quality, would provide aesthetic improvement, and would allow restoration of wetlands.

Social well-being improves with restoration of beneficial uses. Appropriate unsanctioned beneficial uses would be allowed without restriction because the public health risks from poor water quality is eliminated. For example, non-contact recreation occurs without restriction, improving the quality of life for many communities. Community pride increases as the deteriorated water-front of the river is improved and revitalized. This is often the case with beach communities like Newport Beach's Balboa Peninsula or Long Beach's Shoreline Village.

Economic prosperity follows the restoration of beneficial uses. Dependable water supply increases, and business and work forces are attracted to the improved image of the area. The river becomes an attractive environment for tourism and money-generating recreation. Portions of the river can be used as boardwalks following the examples of San Antonio, Texas River Walk or Cleveland, Ohio renovated Cuyahoga River Flats Boardwalk.

Achieving the restoration of beneficial uses is the culmination of the Second Transformation of the Los Angeles River. The Los Angeles area is well on its way toward this goal. The city of Los Angeles, LACDPW, Corps, National Park Service,

VOL 12

14891

California Coastal Conservancy, Santa Monica Mountains Conservancy, have completed or are currently studying the Los Angeles River to find ways to improve the river, which result in enhanced beneficial uses.

The restoration of the Los Angeles River would mark the beginning of a new environmental ethic, where environmental tragedies of the early and mid-20th century are undone and urban culture recreates the city, only this time working with nature and becoming her champion.

Introduction

The primary objectives of the Southern California Coastal Water Research Project (SCCWRP) are to understand the sources, fates, and effects of contaminants entering the marine coastal environment. In order to emphasize each of these aspects, our report for this year is organized under four primary headings: Sources, Fates, Effects, and Communications.

As usual, the first article updates the contribution of contaminants to coastal waters by municipal wastewaters. A major event in late 1987 was the termination of the 7-mile sludge outfall in Santa Monica Bay, resulting in a 50% reduction of mass emissions during 1988. The inputs of contaminants from storm water in Los Angeles and Ventura Counties is described and compared with wastewater inputs. Aerial transport, storm water runoff, discharges of dredged material, industrial outfalls, and municipal wastewater effluents all represent significant sources of pollution. There is a tremendous amount of information on the mass emissions from municipal outfalls, but contributions from storm water, dredged material, or aerial sources are not understood well at this time. By sampling the sea-surface microlayer, SCCWRP investigators are finding the net result of contributions from aerial and floatable contaminants. Efforts to quantitate inputs from storm water will continue but will be restricted to the Los Angeles River, which contributes about 30% of the total volume to the Southern California Bight. Increased attention is required regarding the mass inputs and potential effects of aerial pollutants and contaminated dredged material.

Both oceanographic and geochemical studies will be covered under the heading of Fates, as physical and chemical factors control the distribution of contaminants in the coastal environment. The fate of discharged materials is obviously very important, but extremely difficult to assess. Environmental variability requires the collection of massive amounts of data to determine meaningful trends in the direction and magnitude of currents or the degree of sediment resuspension. Several reports were completed in the last year regarding actual and predicted distribution of discharged wastes. To aid in processing the numerous samples collected by SCCWRP scientists, the capabilities of the trace organics laboratory have been significantly expanded in the past year. The cornerstone of the laboratory is a Kratos Model MS25RFA gas chromatograph/mass spectrometer, which is capable of measuring picogram (10^{-12} gram) quantities of contaminants in samples. This piece of equipment was partially funded by a grant from the Los Angeles County Department of Harbors and Beaches.

Studies in the Effects section encompass a variety of projects including fish, invertebrates, and their larvae. Parameters measured include growth, reproduction, and survival. Research concerning the effects of contaminants on fish has been extended to different species in different locations. Results have confirmed SCCWRP's previous findings that increased contamination yields an increased frequency of micronuclei in the cells of affected fish. This past year SCCWRP scientists demonstrated that white croaker from contaminated areas of southern California exhibit impaired reproduction. We are taking advantage of a unique opportunity by measuring the rates of change in biota and chemistry around the terminated 7-mile sludge outfall. Also included in this section are studies about the effects of contaminated sediment on benthic species, an area that has been quite productive. These approaches will help us to understand the potential impacts of contaminated particles emanating from a range of coastal sources. The urchins and amphipods used in these studies are from southern California and they are appropriate for use in both acute and chronic effect studies. Better methods of measuring the toxicity of sediments and wastewater are being developed which will aid in interpreting and predicting impacts in the marine environment.

The communications we are attempting are of necessity quite diverse, ranging from presentations to interested groups to peer-reviewed publication in the scientific literature. Authors may need to view and prepare their data in three or more ways, but we feel this extra effort is required because dissemination of the knowledge obtained from the various projects to the public is an important function at SCCWRP. We plan to pursue all possible means of marine environmental education. SCCWRP has been involved with compiling information on regional monitoring for a case study on the Southern California Bight by the National Research Council (NRC). Recommendations from the NRC study suggest the design and implementation of a regional monitoring program. Quality assurance and comparability among laboratories in southern California has been handled in an excellent manner by two organizations called SCAMIT and SCECS, which you will learn more about in this report. We have also added some new and important projects during the last year that directly relate to our goals and will provide valuable information to the public of southern California and the scientific community.

Figure 1. Locations of the seven dischargers summarized in this report.

Characteristics of Municipal Wastewaters in 1986 and 1987

Since 1971, wastewater treatment plants that discharge in the coastal waters of southern California have monitored general constituents (e.g., suspended solids, oil and grease, biological oxygen demand, and nutrients), trace metals, and some chlorinated hydrocarbons (DDT [includes six isomers] and polychlorinated biphenyls [PCBs; includes Aroclors 1242 and 1254]). This report summarizes the results of the monitoring data from the seven SCCWRP sponsors (Figure 1) for 1986 and 1987 and compares the results with those of past discharges.

Flow from these seven plants (Table 1) constitutes over 90% of the municipal discharges to the Southern California Bight. For the past 17 years, the combined contaminant emissions from these treatment plants have largely decreased despite steady annual increases in total flow (Table 2). Since 1971 the flow has increased by 32% (Figure 2), while suspended solids and biological oxygen demand (BOD) have been reduced by 48% (Figure 3).

The concentrations of effluent constituents and mass emissions for each of the seven plants for 1986 and 1987 are listed in Tables 3 and 4. Changes in trace contaminant concentrations from 1985, when we last summarized data, have shown some of the greatest decreases since monitoring began (Table 2). The combined flow increased by 27 million gallons per day (MGD; 37 x 10^9 L/yr) while suspended solids, BOD, and oil and grease emissions were reduced by 25, 40, and 38%, respectively. During the same period the emissions of trace metals were reduced by 20 to 50% (Figures 4a and 4b). The output of DDT remained about the same at 50 kg/yr, while PCBs

were reduced by about 60% to 250 kg/yr (Figure 5).

Silver emissions in the last two years are similar to other metals' emission and show about a 50% reduction between 1985 and 1987. However, the long-term trend is unlike any other contaminant. Silver emission doubled between the early 1970s and 1979, whereas most metals exhibited decreases for that same period. Although the cause of this increase was never determined, increased photographic and other industrial processes have been suggested as likely causes. Silver discharges dropped 25% between 1979 and 1980 but decreased only about 10% over the next five years (1980-1985).

Although the recent reductions have been large, the present levels are about equal to the early 1970 values. Silver will

[a]SERRA and Encina data first included.
[b]Discharge from Hyperion 7-mile outfall was terminated in November 1987.
[c]Hyperion 7-mile outfall data excluded.
[d]Data include only JWPCP, Hyperion 5- and 7-mile outfalls, and Point Loma.
[e]Values for 1971-75 are from SCCWRP's final report to the U.S. Enivironmental Protection Agency for Grant Nos. 801153 and R803707.

remain an important contaminant for municipal wastewater monitoring because effluents are responsible for more than 90% of anthropogenic inputs, and elevated levels in transplanted and natural mussels have shown that it is one of the best indicators of the presence of municipal outfalls.

Whereas the combined discharge to the bight has generally shown a steady increase in flow and decreases in contaminant emissions, individual outfall emissions have exhibited much greater annual variations. Examples of local fluctuations in emissions are the Hyperion 5- and 7-mile discharges.

Discharges from the Hyperion Treatment Plant to Santa Monica Bay over the last six years have shown some of the greatest increases and decreases in emissions since monitoring has been conducted. Between 1981 and 1983, the 5-mile discharge volumes increased by over 40 MGD (55 x 10^9 L/yr) and suspended solids mass emissions more than doubled between 1982 and 1985 (39,000 to 87,000 metric tons/yr). Most of the trace contaminants showed little increase in concentrations or mass emissions during this time.

Expansion and rehabilitation of facilities upstream and at the Hyperion plant since 1985 have

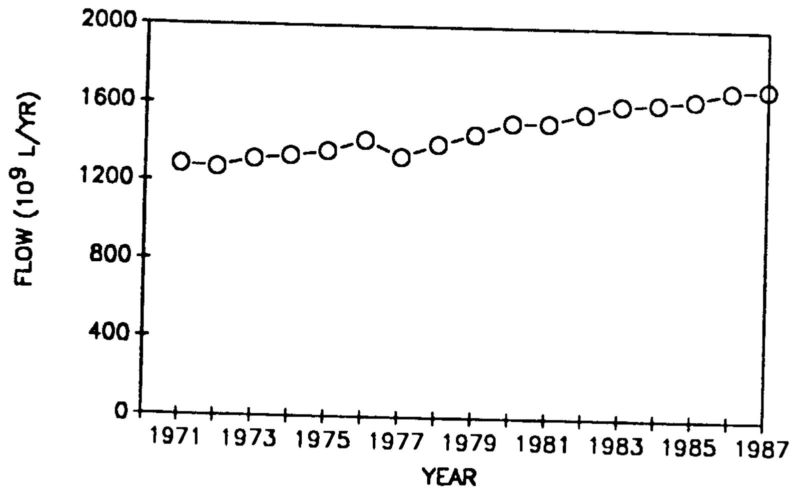

Figure 2. Combined annual flow from seven dischargers.

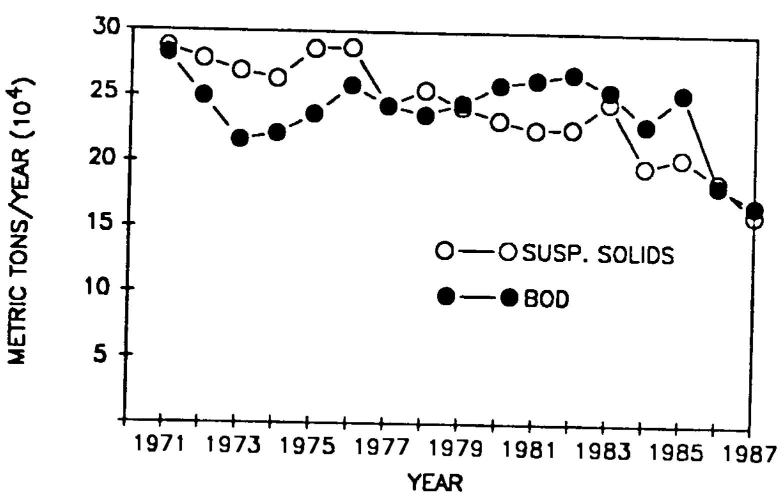

Figure 3. Combined BOD and suspended solids from seven dischargers.

reduced the 5-mile discharge by 30 MGD (48×10^9 L/yr) and the suspended solids by 57,000 metric tons/yr between 1985 and 1987. The latest data show that solids emissions are 15% lower than the 1971 emissions despite a 10% increase in flow.

The Hyperion 7-mile sludge outfall discharge has also undergone major changes in the past few years. Solids emissions increased 53% between 1985 and 1986 (44,000 to 70,000 metric tons/yr). Discharge was terminated in November 1987, and the solids are now transported to landfill. Although the outfall only operated for 10 months in 1987, it emitted 0.3% of the flow and 37% of the solids discharged by all municipal discharges to the bight. Its elimination will cause significant reductions in solids and trace metal annual inputs to the bight as of 1988.

The second largest discharge, the Joint Water Pollution Control Plant (JWPCP) outfalls at White Point, has continued to significantly reduce emissions. A steep decline in suspended solids occurred in 1984 after 200 MGD (276×10^9 L/yr) of secondary treatment was added in 1983. Between 1985 and 1987 suspended solids have been reduced an additional 15% and eight of the ten monitored metals have been reduced by 15 to 20%. Table 5 shows corrections for JWPCP 1985 data presented in SCCWRP's 1986 Annual Report.

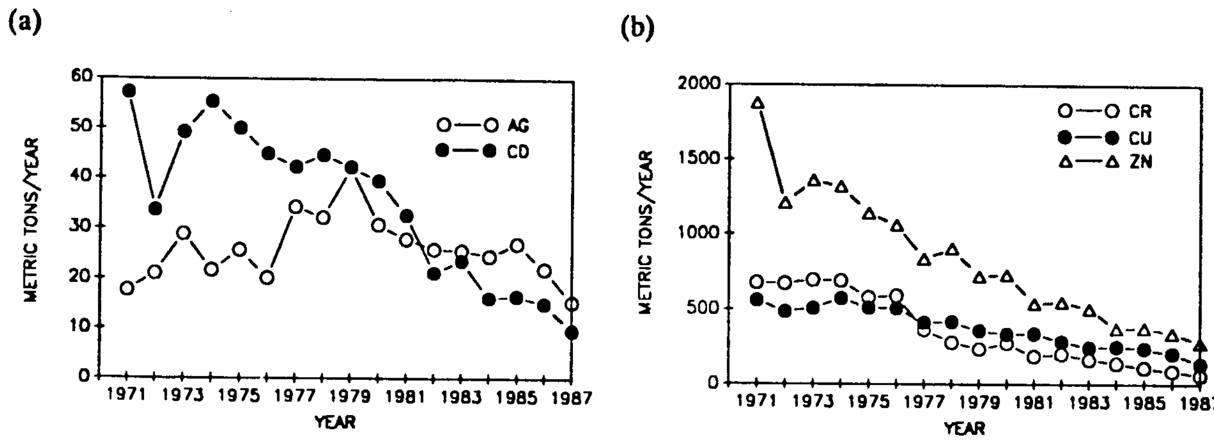

Figure 4. Emissions of (a) silver and cadmium, and (b) chromium, copper, and zinc to the Southern California Bight from seven dischargers from 1971 to 1987.

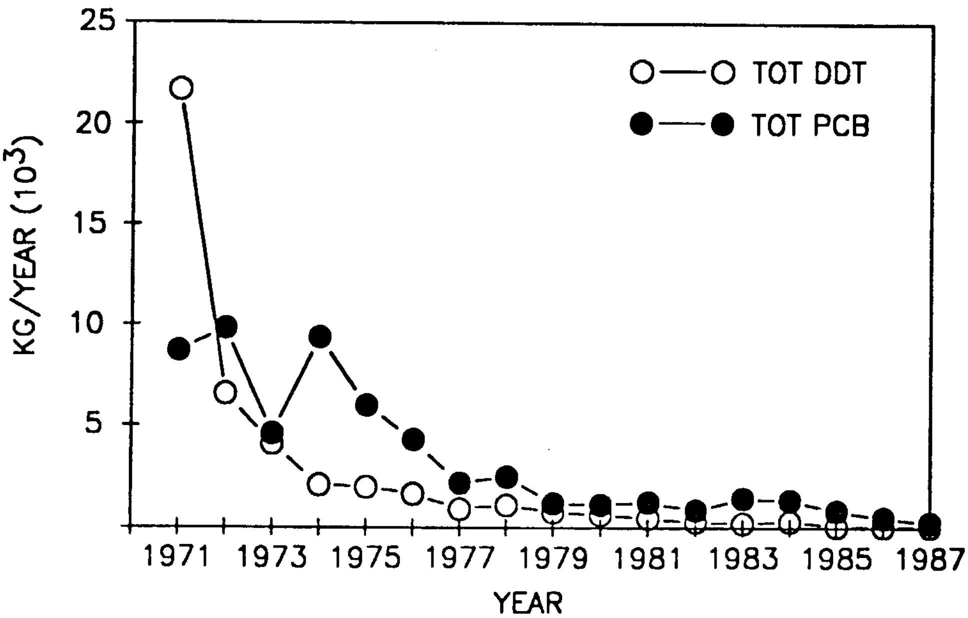

Figure 5. Output of DDT and PCBs to the Southern California Bight. Since 1985, the emission of DDT has remained about the same, but the output of PCBs has been reduced by about 60%.

The County Sanitation Districts of Orange County (CSDOC) operate the third largest treatment plant in Southern California and reported the largest discharge of PCBs to the bight for each of the last nine years. They report a 60% reduction (660 to 250 kg/yr) between 1985 and 1987. It is not clear how much of this reduction is due to actual reductions in concentrations and how much is due to a change to a more standard method of analysis. For years CSDOC used a unique method of sample preparation for PCB analysis that apparently caused the samples to be prone to laboratory contamination, thus producing much higher values than U.S. Environmental Protection Agency (EPA) methods produced or that other laboratories were able to detect in CSDOC effluent. Since 1986 the CSDOC laboratory has switched to EPA methods.

The reductions in municipal outfall emissions increase the importance of other sources of anthropogenic inputs. To assess these other sources, SCCWRP is investigating runoff and aerial inputs and will be reporting on this information in future publications.

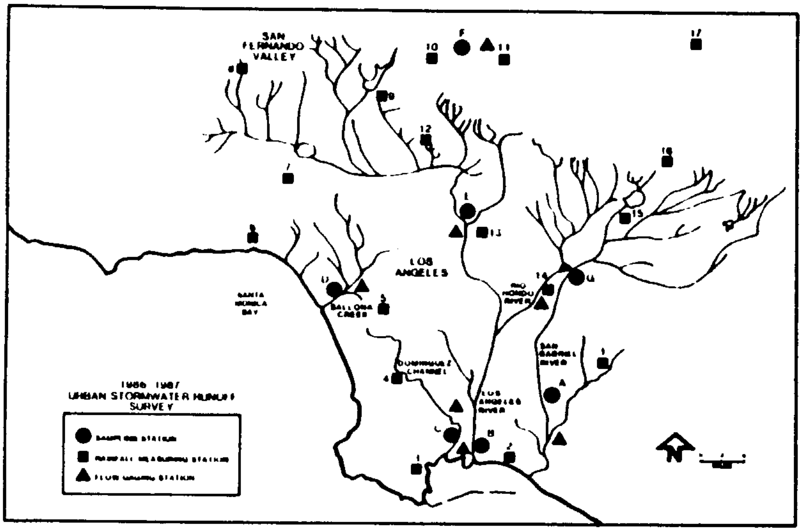

Figure 1. Los Angeles River Basin.

Storm Runoff in Los Angeles and Ventura Counties

One of SCCWRP's long-term projects is to update and improve past estimates of contaminant inputs to the Southern California Bight. By the summer of 1988, SCCWRP staff will have sampled storm runoff from the largest storm channels in four of the coastal counties of southern California.

On September 23-25, 1986, SCCWRP investigators collected 49 samples of storm runoff from eight sites in Los Angeles and Ventura Counties (Santa Clara River, Calleguas Creek, Ballona Creek, Dominguez Channel, Los Angeles River [Big Tujunga Wash, Fletcher Avenue Bridge, Willow Street Bridge], and San Gabriel River) (Figure 1). Each channel has a unique drainage basin, and most of the channels receive wastewater effluent from one or more municipal wastewater treatment plants, which contributes significantly to dry weather flows. Locations were chosen to provide safe sampling, to be used during adverse weather conditions, to provide access to the center channel of the flow, and to be downstream from the major sources of runoff contaminants.

The storm was very early in the rain season and was unpredicted. This made it difficult to take the samples as originally planned; however, low-flow, high-flow, and post-high-flow samples were obtained and concentrations of suspended solids, oil and grease, total extractable organics (TEO), trace metals, DDT, polychlorinated biphenyl compounds (PCBs), polynuclear aromatic hydrocarbons (PAHs), and *n*-alkanes were measured.

With these data, Henry A. Schafer and Richard W. Gossett were able to estimate mass emission of major runoff sources and compare the rates with previous runoff emission estimates and other sources of

contamination to the Southern California Bight. They also determined how the concentration and mass of contaminants varied throughout the storm to see if significant portions of the mass emissions were concentrated in a small part of the flow. Various sites were sampled to see how contaminant levels varied with land use. In addition, Schafer and Gossett measured concentrations of PAHs. For several channels, this was the first time that PAHs were measured; the molecular weight of the PAHs indicated that crankcase oil was present in the runoff.

Mass emissions and flow-proportioned mean concentrations were calculated for each sampling site. Mass emissions for each sampling period were first determined by multiplying the flow that occurred during the sampling period by the sample contaminant concentrations. Then the total storm emissions were computed by summing all of the interval mass emissions. The flow-proportioned mean concentrations were calculated by dividing the total mass emissions by the total flow.

Table 1 lists flow-proportioned mean contaminant concentrations and ranges for the sites sampled during this storm. The researchers found that the Santa Clara River and Calleguas Creek (both in Ventura County) had the highest and lowest concentrations of suspended solids, respectively. Generally, the Los Angeles River at Willow Street had the highest concentrations of hydrophobic (oil and grease, TEO, PAH, *n*-alkanes, PCBs, and DDT) contaminants. Exceptions occurred at Ballona Creek, which had 50% more oil and grease and a DDT concentration four times that of the Willow Street site, and at Santa Clara, which had a DDT concentration 11 times that of the Willow Street site. Trace metals concentrations were all highest at Ballona Creek followed by the Los Angeles River at Willow. Concentrations at Tujunga Wash were consistently below detection, while the other sites had roughly equal levels. Contami-

[b]These values are the average measurements of the two storms.

nant concentrations along the Los Angeles River increased significantly from the upper to lower stations.

Table 2 shows the calculated flow-proportioned mass emissions. The Los Angeles River is the largest source of runoff to the Southern California Bight. The flow rate at the Willow site is about 30% greater than that at Fletcher and contaminant emissions are 3 to 10 times greater, which indicates that for all constituents except DDT, there is a consistent pattern of greatest emissions coming from the Los Angeles River, then Ballona Creek followed by Fletcher and San Gabriel. The remaining sample stations had minimal inputs.

Emissions from the San Gabriel River were underestimated because the flow data were available only from the Coyote Creek branch of the San Gabriel River. Therefore, estimates for that station could be low by a factor of 2 or more.

Figure 2 shows the flow and concentrations of suspended solids, oil and grease, TEO, lead, total PAHs, total PCBs, and volatile solids for the Los Angeles River during the 48 h of sampling. There were two peaks in flow that occurred about 6 h apart. Peak contaminant concentrations (except percent volatile solids) occurred at either hour 22 or 24, which was before the first peak in flow. Although the

VOL 12

1497

sample taken at hour 30 was at the second peak flow, the concentrations of all contaminants dropped. This may be due to a washout of contaminants.

The cumulative percent flow and cumulative percent emissions of suspended solids, oil and grease, chlorinated hydrocarbons, and combined trace metals for the Willow station and Ballona Creek are compared in Figure 3. Approximately 80% of the flow and suspended solids was discharged within 10 h. In general, the first 25% of flow produced 50% of the contaminant emissions, and when 50% of the flow had occurred, 75% of the contaminant emissions had occurred. This pattern is representative of the other sites studied.

As contaminant emissions from outfalls continue to decrease, runoff emissions become a more important source of marine inputs. Variations in runoff concentrations were not significantly different in the Los Angeles River between 1971 and 1979 except for lead and PCBs, which were reduced by factors of 6 and 8, respectively (Young et al. 1981). Table 3 shows concentrations for the five storms measured in 1971 and 1979 and the present 1986 results. Between 1979 and 1986 copper and lead concentrations increased by about a factor of 2, while suspended solids and chromium were reduced by two-thirds and one-half, respectively. The rest

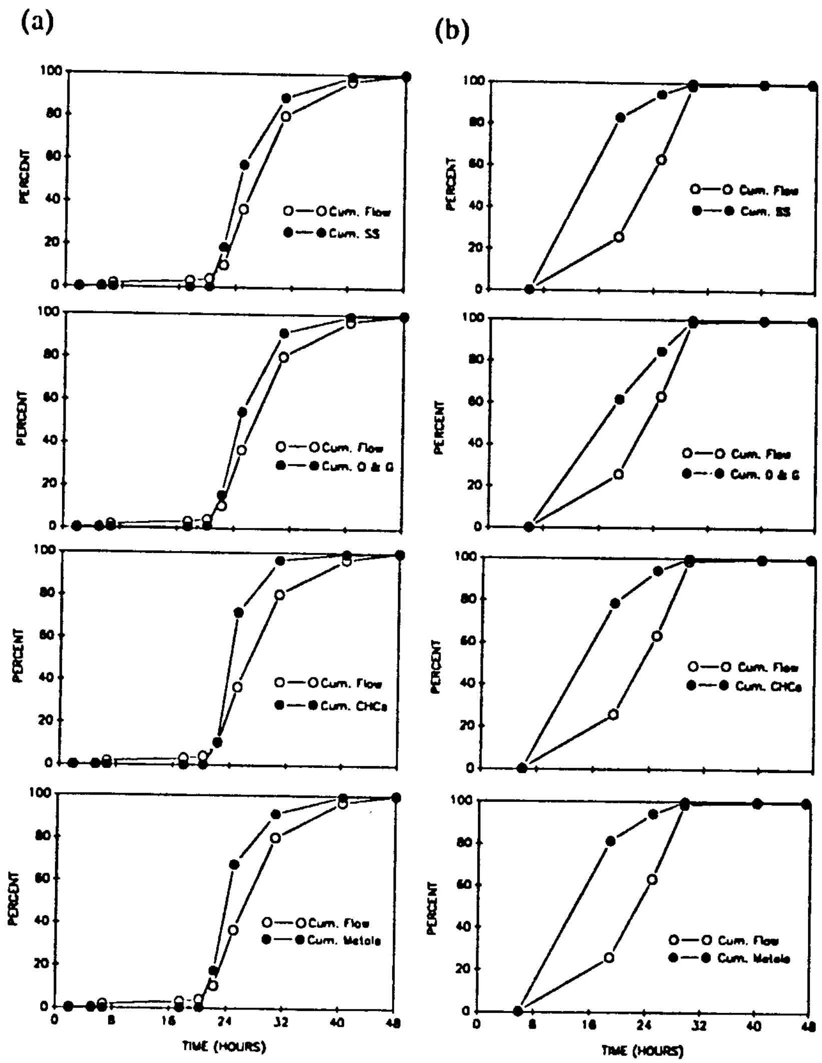

Figure 3. Cumulative percent flow and cumulative percent emissions of suspended solids (SS), oil and grease (O & G), chlorinated hydrocarbons (CHCs), and combined trace metals. (a) Los Angeles River at Willow Street. (b) Ballona Creek.

of the trace metals and PCBs varied by less than one-third. Levels of DDT changed the most; they were reduced by a factor of 4.

The highest concentrations of contaminants are associated with peak flows. Because the two Ventura sites were sampled while they had relatively low flow, these annual emission data may be less representative than those sites that were sampled during high flow. The two channels with the highest flows, Los Angeles River Willow and Ballona Creek, had the highest mean contaminant concentrations and consequently had the highest emissions of oil and grease, TEO, cadmium, chromium, copper, nickel, lead, zinc, PCBs, PAHs, resolved hydrocarbons, and *n*-alkanes.

Estimation of runoff should be viewed with the awareness of certain limitations. Factors that need further examination include annual variations in total rainfall within a drainage basin, the intentional retention of runoff for groundwater recharge, and diversions between drainage basin. These factors can combine to make each storm and year difficult to compare with other storms and years.

Acknowledgments

We appreciate the financial and field support that was provided by the Los Angeles Regional Water Quality Control board, especially A. Chartrand and M. Sowby. The Hyperion Laboratory kindly allowed us to use their facilities to measure oil and grease. We thank our fellow staff members who interrupted their work and sleep patterns to make this study possible.

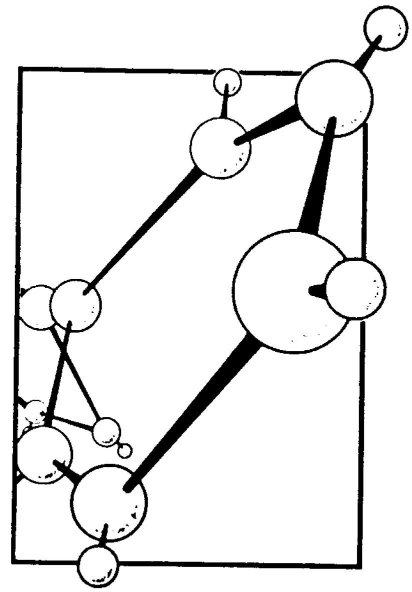
Polynuclear Aromatic Hydrocarbons in Waste Effluent and Sediments



In a previous annual report (SCCWRP 1987), SCCWRP scientists described early efforts to measure polynuclear aromatic hydrocarbon (PAH) concentrations in marine sediments from offshore southern California. The purpose of that survey was to determine the composition and concentration of PAHs in *surface* sediments at a variety of coastal sites presumed to be receiving hydrocarbon inputs. Here are results from a study by Robert P. Eganhouse and Richard W. Gossett of PAHs in final effluent from the Joint Water Pollution Control Plant (JWPCP; Los Angeles County) and sediments cored from the Palos Verdes Shelf.

PAHs are toxic substances that originate from a multitude of sources and exhibit a wide range of physico-chemical properties. Although globally distributed, they are typically found in greater abundance near urbanized coastal areas. The major sources of PAHs to coastal and estuarine environments are believed to be municipal waste discharges, urban runoff, and atmospheric particulates. Unfortunately, published information concerning the composition and concentrations of PAHs in municipal wastewaters, particularly in southern California, is extremely limited (Barrick 1982, Grzybowski et al. 1983). This makes it difficult to evaluate the importance of municipal waste discharges compared with other inputs of PAHs to the Southern California Bight. One of the objectives of the present study was to measure the concentrations of PAHs in the JWPCP's final effluent over the course of one year (1979). These data are used to estimate the mass emission rate of PAHs from this treatment plant as of 1979.

In addition to analyzing effluent samples, SCCWRP scientists examined sections of a sediment core collected from the Palos Verdes Shelf in connection with the County Sanitation District's coring program in 1981 (station 3C; 33°43.83 N, 118°24.01 W). Sediments from this core have been analyzed for elemental abundance, stable isotopic composition and molecular markers by Eganhouse and Kaplan (1988) and for a variety of inorganic and organic trace constituents by the County Sanitation District. Because the core is so well characterized, we felt it would provide an opportunity to estimate the accumulation rate of PAHs at station 3C.

Figure 1 illustrates the PAH composition of the JWPCP final effluent collected on October 15, 1979. This sample is generally representative of those taken in other months; however, some of the higher molecular weight PAHs found in low abundance in the October sample were not detected in effluent collected at other times during the year. The PAH distribution of the effluent is dominated by naphthalene, phenanthrene, and corresponding alkylated homologs. Higher molecular weight species (i.e., those having more than three fused rings) are in lower abundance. The alkyl homolog distributions (i.e., the relative abundances of parent and alkyl-substituted species) generally show a maximum for the C1- to

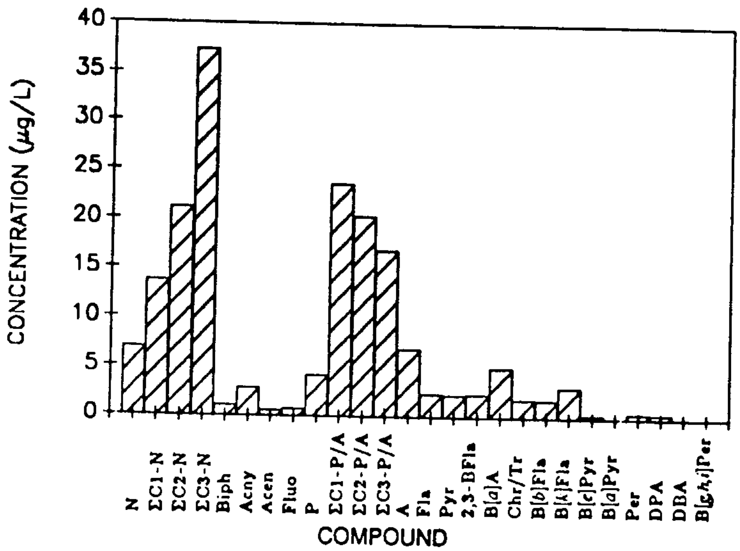


Figure 1. Distribution of PAHs in JWPCP final effluent, October 15, 1979. Figure 2. Alkyl homolog distribution of naphthalene series (C_nH_{2n-12}). N, Naphthalene.

C3-substituted naphthalenes and phenanthrene/anthracenes (Figure 2). In addition, the fluoranthene/pyrene series and other high molecular weight PAH groups exhibit dominance by the alkylated species. Together these results suggest that the PAHs found in the effluent samples are derived from fossil fuels, not combustion sources.

Table 1 provides a summary of the mean concentrations of PAHs in the effluents determined in this study along with data presented by Barrick (1982) for the Seattle METRO treatment plant (particulate concentrations) and Grzybowski et al. (1983) for waste effluent from Poland. Concentrations measured in the JWPCP effluent are approximately an order of magnitude greater than those determined for the METRO samples but generally fall within the range reported by Grzybowski et al. (1983). Some of this difference can be explained by the higher hydrocarbon concentrations of the California wastes. On average, the JWPCP hydrocarbon concentrations were five times greater than those reported for the Seattle METRO effluent. Despite the fact that the METRO plant receives inputs from storm water runoff, industrial contributions to the influent are relatively small. In contrast, the JWPCP receives substantial quantities of industrial wastes.

The JWPCP has monitored its effluent for the U.S. Environmental Protection Agency priority pollutants on an approximately quarterly basis since 1985. Non-detectable amounts have been reported for all PAHs except naphthalene and phenanthrene. In many cases, however, the reported detection limits are higher than the concentrations measured in this study.

There was an attempt by SCCWRP to measure priority pollutants in the JWPCP effluent in 1978. The only PAHs reported to be present at measurable concentrations were naphthalene (29 μg/L) and acenaphthene (7 μg/L). These concentrations are approximately 5 to 7 times higher than those observed for samples taken in 1979.

The variation in concentration of individual (or alkylated isomer groups of) PAHs found in all samples ranges from 46 to 74% (coefficient of variation), whereas the variation in total PAH concentrations (i.e., sum of 26 measured concentrations) is 53%. This is significantly greater than the variation in concentration of total hydrocarbons and extractable organics (Eganhouse and Kaplan 1982), possibly reflecting greater fluctuations of PAH inputs. Inspection of the data presented by Barrick (1982) indicates that similar levels of variation of individual PAH concentrations were observed in the Seattle effluent during 1978.

When the concentrations of total PAHs are applied to the mean monthly flows from the JWPCP, an annual mass emission rate of 110 metric tons is obtained. There are no known available data for other waste treatment plants or storm water drainage systems in southern California with which these figures can be compared for the year 1979. Recent studies at SCCWRP of a single storm in 1986 suggest that the total PAH emissions from the Los Angeles River during that event were 0.4 metric tons (see p. 13). More data are required to develop yearly estimates for this and other drainage systems in the southern California region.

Table 1. Concentrations of PAHs in municipal wastewater effluent.

[c]NR, Not reported.
[d]Total PAH is the sum of PAHs determined in this study.

Figure 3 depicts the distribution of PAHs found in sediments at a depth of 2 to 4 cm below the sediment-water interface at station 3C. The PAH composition is somewhat variable in different sections of the core, but the pattern shown here is fairly representative of those seen at other depths. In contrast to the effluent PAH composition (Figure 1), sedimentary PAH distributions are dominated by higher molecular weight species. Naphthalene, phenanthrene, and the corresponding alkylated homologs of these compounds were rarely seen and then only in low abundance. Because most of the hydrocarbons in this core down to depths of 24 cm are believed to be of sewage origin (Eganhouse and Kaplan 1988), it is likely that the lower molecular weight species so abundant in the effluent were lost via solubilization or biological degradation. The fact that the lower molecular weight species are not found in the uppermost section of the core indicates that alteration of the PAH assemblage occurs prior to

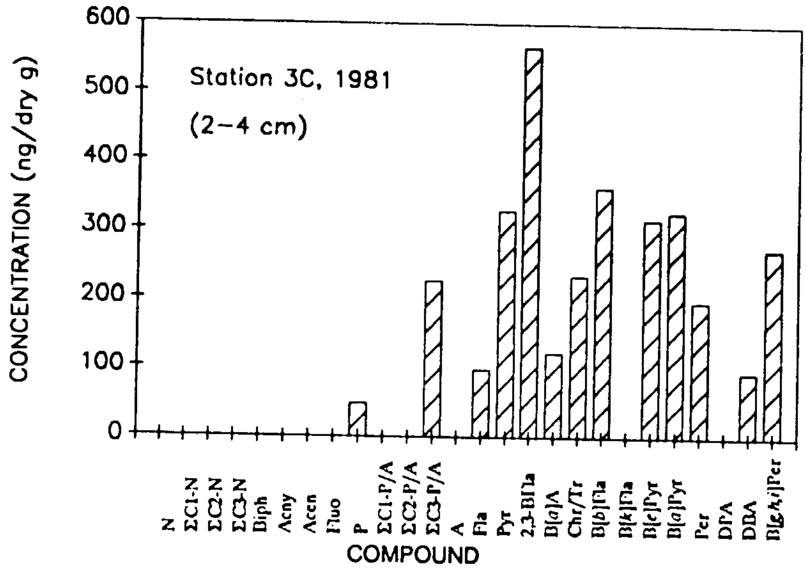

Figure 3. Distribution of PAHs in 2- to 4-cm section of sediment core at station 3C, 1981. Abbreviations are as in Figure 1.

sediment burial (i.e., in the water column and/or at the sediment-water interface).

Table 2 provides data for the sediment core along with results obtained from the literature. Although no measurements have yet been published for sediments from station 3C, Swartz et al. (1985) and Anderson and Gossett (1987) reported PAH data for whole grabs and surface sediments (0 to 2 cm), respectively, taken from the Palos Verdes Shelf in 1980 and 1986. Both surveys identified naphthalene and other lower molecular weight species at station 7C. The appearance of these relatively labile species at 7C and their absence at 3C may reflect differences in the sediment accumulation rates at these stations. Alkyl homolog distributions for the fluoranthene/pyrene series found in the highly contaminated sediment sections show maxima among the higher molecular weight alkylated species. This suggests that petroleum, not fossil fuel combustion products, is the dominant source of these PAHs.

A comparison of effluent particulate PAH/organic carbon ratios with those observed in the sediment sections suggests that even the higher molecular weight PAHs found in low abundance in the effluent may be subject to extensive removal during the sedimentation process. Whether this reflects desorption/dissolution, degradation, or some combination is unclear. The resistance of higher molecular weight PAHs to environmental alteration appears to depend, in part, on their physico-chemical speciation upon introduction to the environment (Readman et al. 1984, Gschwend and Hites 1981) with combustion-derived PAHs being more refractory than those occurring as petroleum residues. The present results are consistent with the hypothesis that the PAHs at station 3C are derived from petroleum.

Figure 4 illustrates the vertical concentration profile for total PAHs in the sediment core. Maximum concentrations are observed between depths (below the water-sediment interface) of 2 to 18 cm. With increasing depth below 18 cm, the PAH concentrations decline rapidly and appear to reach "background levels" at approximately 22 to 24 cm. At station 3C, the PAH distribution is similar to profiles observed for other waste-related contaminants, which typically exhibit a well-defined subsurface maximum at depths of 8 to 10 cm below the sediment-water interface (Eganhouse and Kaplan 1988, Stull et al. 1986). The appearance of high PAH concentrations over the same depth intervals as observed for other indicators of waste contamination (e.g., organic carbon and total hydrocarbons) strongly suggests that sewage is the dominant source of these compounds. The lack of a distinct subsurface maximum, however, indicates that changes in solids emissions alone (Eganhouse and Kaplan 1988) probably did not control accumulation rates of PAHs in these sediments.

Using tentative assignments for the ages of different depths of this core (Eganhouse and Kaplan 1988), one can calculate average accumulation rates of total and

individual PAHs in the sediments. Table 3 presents estimated average accumulation rates based on such calculations. It is clear that the average accumulation rates of total PAHs for sections occurring after about 1950 (i.e., <24 cm) are an order of magnitude greater than those for the pre-1950 period. Moreover, the average accumulation rates appear not to have changed significantly during the three decades since 1950. The estimated accumulation rates for deeper sections of the core (i.e., >24 cm) are similar to those made by Gschwend and Hites (1981) for sediments near urban centers such as Boston Harbor and Buzzards Bay, MA. These are, nevertheless, at least an order of magnitude higher than those found at remote locations where sedimentary fluxes are dominated by atmospheric deposition. This suggests that even the deeper sections of the 3C core may have been heavily influenced by local inputs (including natural oil seepage) with direct atmospheric deposition playing only a minor role. Such a hypothesis is consistent with stable isotopic and molecular evidence at this site and in San Pedro Basin.

The results discussed here demonstrate the need for further study of municipal wastewater inputs of PAHs to the coastal ecosystem. In recent years, there has been a marked reduction in the mass emission rates of suspended solids, oil and grease, and other trace constituents from the JWPCP (Stull and Haydock 1988). It is, therefore, important to determine if similar reductions have occurred for PAH inputs. Because these toxic compounds appear to be accumulating in nearshore sediments at rates far in excess of "natural" fluxes, information regarding the bio-

geochemical fate and chemical speciation of sewage-derived PAHs is also of interest. Current evidence clearly indicates that the dominant source of PAHs to the JWPCP effluent (as of 1979) is petroleum. A large, but unknown, fraction of these PAHs appears to have been lost during the early stages of diagenesis. Hence, only the more resistant, higher molecular weight PAH species tend to accumulate in waste-impacted sediments. Whether the presence of these carcinogenic substances represents a threat to the health of indigenous marine life remains to be investigated.

Current Flow Patterns in the San Diego Bight

During 1987, staff oceanographers Terry Hendricks and Niels Christensen developed methods to identify and quantify the flow patterns in the San Diego Bight. This information was required to ensure that the discharge from a proposed new ocean outfall would not contaminate the nearshore waters with bacteria.

A new ocean outfall may be constructed in the San Diego bight near the border with Mexico. Bathing water standards for total coliform bacteria must be met nearshore and in *Macrocystis pyrifera* kelp beds, so the treatment method, outfall design, and outfall location must be selected to meet these requirements. A variety of factors affects the presence of outfall-related bacteria in these protected waters. These include the concentration of bacteria in the effluent, the magnitude of the initial dilution, subsequent dilution by oceanic processes, die-off of the bacteria, and the rate and frequency of transport of wastewaters into the protected areas by ocean currents. The SCCWRP researchers were asked to quantify one element of this analysis: transport by ocean currents.

Figure 1 shows the study area. The indentation south of Point Loma and San Diego Bay forms the San Diego Bight. The dashed line extending offshore from the coast delineates the border with Mexico. The two solid lines near the border indicate possible alignments for the proposed outfall; the line extending offshore from Point Loma (terminating in a "vee") indicates the location of the existing outfall. The dashed line roughly paralleling the coast marks the offshore boundary of the area to be protected from bacterial contamination.

During 1986-87, Engineering Science obtained about one year of current meter data from the seven moorings indicated by the circles in Figure 1. Previous, but limited, measurements of currents in this area by SCCWRP (Hendricks 1981) have indicated that the presence of the bight introduces additional complexity into the coastal flow patterns. In view of this complexity, it would have been desirable to obtain information on the circulation in the middle and upper portion of the bight from additional current meter moorings. Unfortunately, this region lies within a U.S. Navy restricted area (indicated by the trapezoidal area in Figure 1).

The task faced by the SCCWRP researchers was to use this mass of current meter data to provide estimates of the frequency and rate of transport of wastewaters into the protected nearshore area for various possible termination locations of the proposed outfall. In order to do this, they developed the following five-step process.

(1) The currents were partitioned into two components--tidal (and shorter period fluctuations) and non-tidal flows. The latter dominate the transport between the proposed outfall terminus and the protected area; the former have the effect of additional dispersion superimposed on the flow.

(2) The non-tidal flows were examined for reoccurring patterns. Each observed flow pattern can be approximated as a combination of these elemental flow patterns.

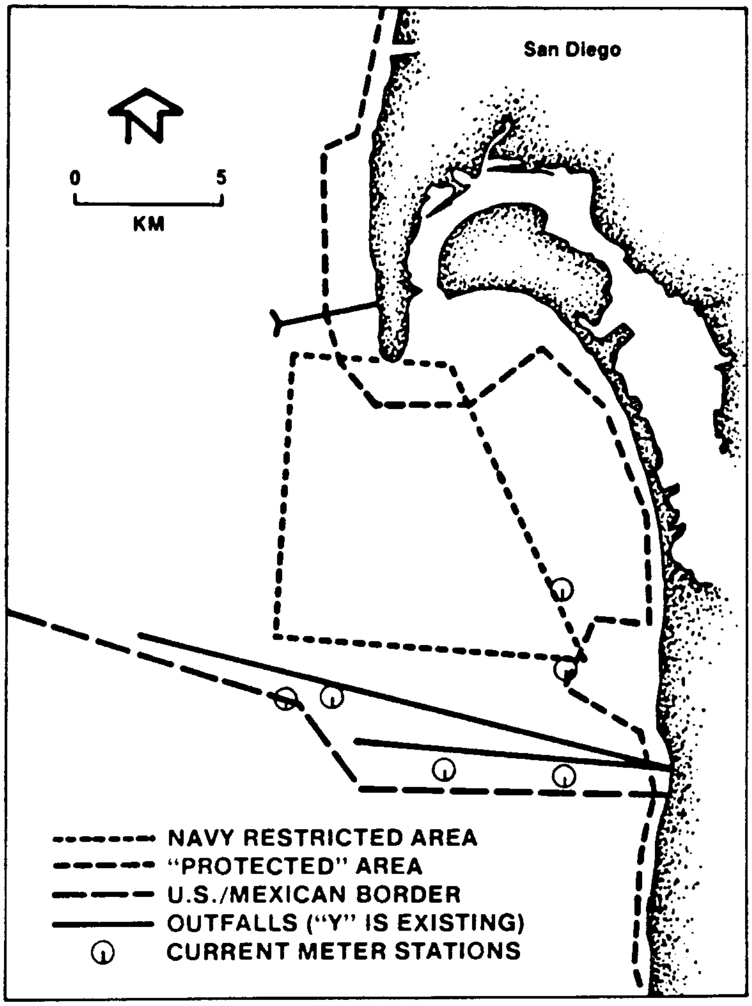

Figure 1. Study area.

(3) The variations in time for the strength of each elemental flow pattern were used to quantify the probability of occurrence for each composite flow pattern.

(4) The general characteristics of coastal flows were used in a numerical flow model to extend the composite flow patterns away from the current meter moorings and into other areas of the bight.

(5) The dispersion of wastewater associated with tidal (and shorter period) fluctuations was reintroduced to the transport estimates.

Through the use of this technique, it was possible to reduce the total of approximately 150,000 observations from the 10 meters used in the analysis to a few tens of circulation patterns, and to quantify the frequency of occurrence of each pattern.

A pair of velocity component (e.g., N-S and E-W) time-series was constructed from the speed-direction time-series for each current meter. A simple filter was applied to these series to remove fluctuations with tidal, or higher, frequency. Cross-correlation coefficients were then computed for each pair of the residual time-series. A mathematical technique, empirical orthogonal function (EOF) analysis, was used to identify statistically independent patterns in the correlations. For 10 current meters, and two components to the flow at each meter, 20 possible "elemental" flow patterns will be produced by this analysis. All the observed flows in the original time-series can be represented as a (time-varying) combination of these 20 elemental patterns. Up to this point, nothing has been gained by this analysis from the standpoint of reducing the number of observations required for the analysis.

It frequently happens, however, that most of the observed flows can be adequately represented as a combination of only a few of the elemental patterns. This turned out to be the case in the San Diego Bight. Two patterns, a more-or-less longshore flow and an eddy, were found to account for about 82% of the total observed variance (variability). Therefore, it was possible to approximate the observed flows as the combination of just two elemental flow patterns instead of the original 20.

So far, the flow patterns only describe the flows in the immediate vicinity of the current meter

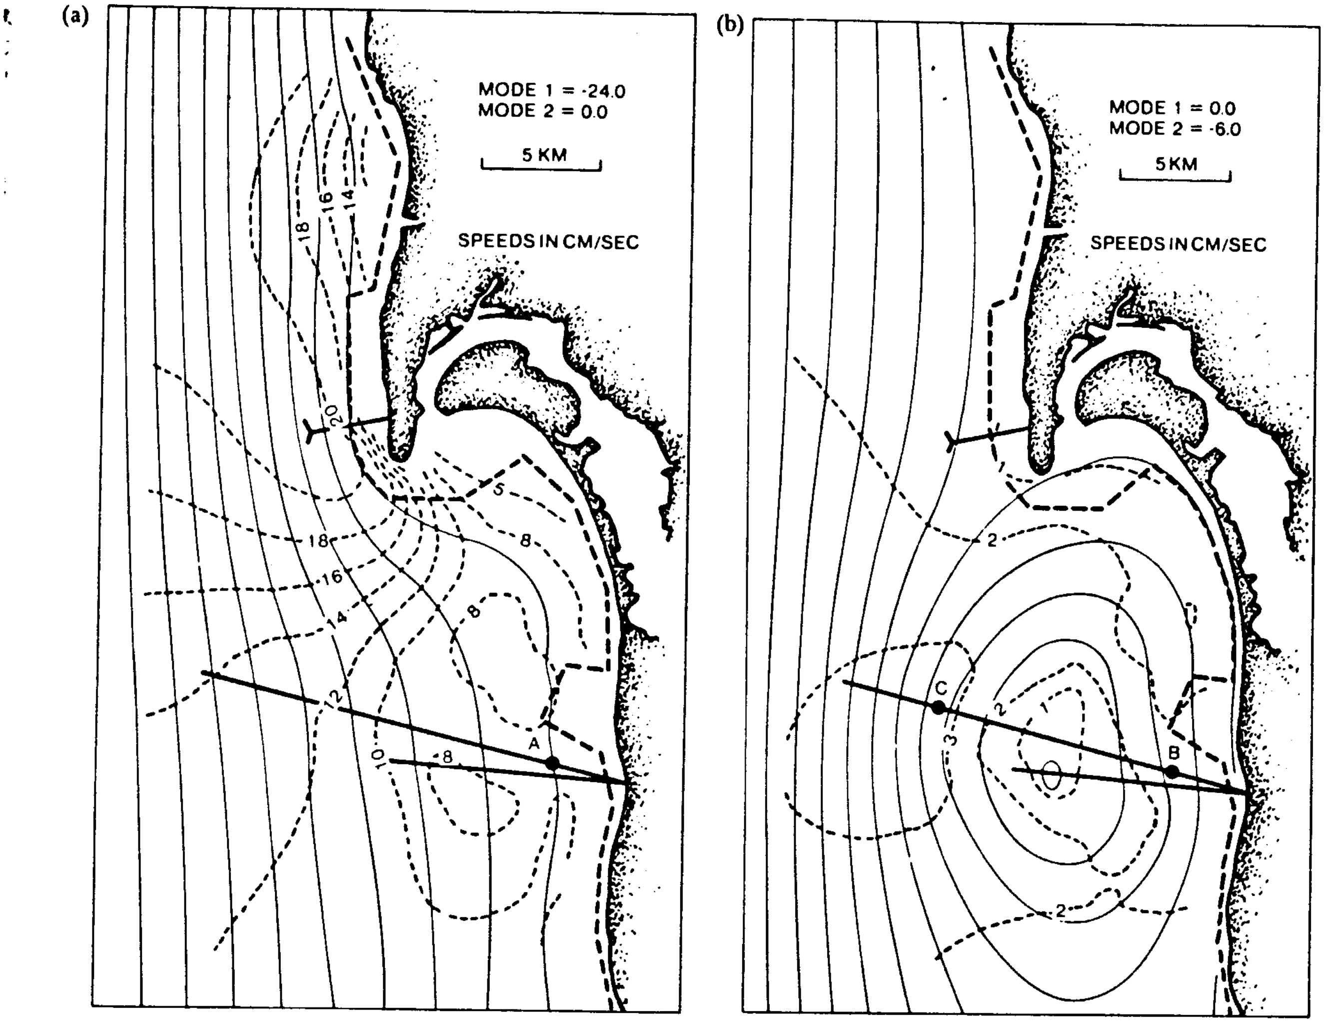

Figure 2. Two elemental flow patterns: (a) longshore flow and (b) eddy.

moorings. The presence of the coast can be expected to change the direction and strength of the currents from location to location, and it is necessary to estimate these variations to assess the frequency and rate of transport into the nearshore protected waters.

In order to do this, Hendricks and Christensen made a number of assumptions. First, they assumed that far offshore, the flow was essentially parallel to the general trend of the coastline. In addition, they noted that coastal flows frequently appear to be nearly in geostrophic balance--that is, the "force" associated with the earth's rotation is roughly balanced by the pressure gradients associated with the density stratification of the water column and the slope of the sea surface. They combined these assumptions with the requirement that the simulated flows reproduce the observed flows at each of the current meter moorings in a numerical model to simulate the circulation patterns over a larger area.

With these approximations, the circulations associated with the two elemental flow patterns identified from the EOF analysis are shown in Figures 2a (longshore flow) and 2b (eddy). In these figures, the light solid lines represent the trajectories of water as they move through the area. Where the lines are closer together, the currents move

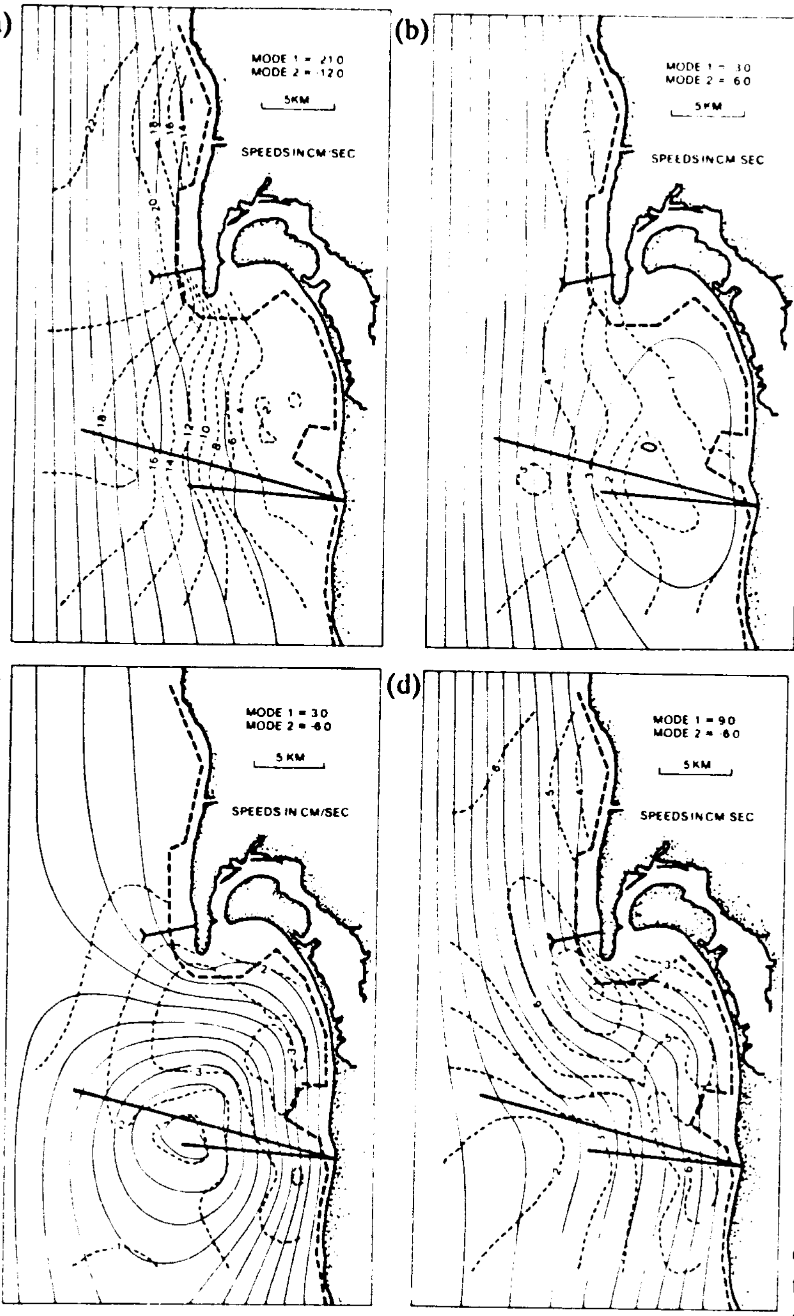

Figure 3. Four possible combinations of the two elemental flow patterns.

faster; where they are farther apart, the flows are weaker. From Figure 2a, it is immediately evident that if only the longshore flow pattern is present, wastewater discharged from the outfall offshore of point A will not come into contact with the protected area (actually, the dispersion associated with tidal motions still needs to be taken into account). On the other hand, only discharge from inshore of point B, or offshore of point C, in Figure 2b will impact the protected area. Thus these streamline diagrams provide a convenient method for analyzing the flow trajectories.

One should also note that these same trajectories exist whether the flow is strong or weak--only the rate and direction (e.g., upcoast/downcoast, clockwise/counterclockwise) of the flow depend on the magnitude and sign of the strength of the elemental flow.

As noted above, each of the observations during the course of the year-long study can be approximated as a simple combination of these two elemental patterns. Examples are shown in Figures 3a-3d for various strengths of the two elemental flow patterns. However, the strength of the contributions from each of two patterns will change during the passage of time and little would be gained by the previous analysis if a composite flow pattern must be generated for each observation time.

The time-series describing each of the elemental flow patterns can be generated from the original time-series for each current meter. It is convenient to describe the amplitude of each flow at each point in time in terms of the plot shown in Figure 4. In this plot, only a single point, corresponding to an amplitude of +10 and +5 for the two

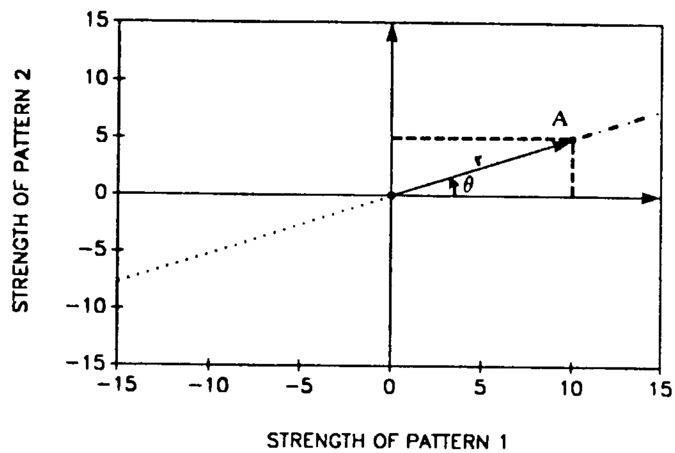

Figure 4. Representation of observations by the strength of the two patterns. Point A represents one observation in the time-series of observations.

components (respectively) is shown for clarity. However, the actual plot would contain as many points as there were observations in the original time-series used to compute the correlation coefficients.

The location of any point in this plot can be described in either rectangular coordinates (e.g., pattern 1, pattern 2), or by a radius and angle (as shown in Figure 4). The advantage of the latter approach is that all dots that lie along a line with the same angle have the same flow pattern and the same trajectory plot. The only difference between two flows lying at different distances from the origin along the line shown in Figure 4 is the strength (speed) of the flow. Moreover, dots lying along the same line extended through the origin also have the same trajectories--but with the flow in the opposite direction. Analysis also shows that dots lying close to this line have flow trajectories that are only slightly different from those lying on the line.

As a result, it is not only possible to substantially reduce the number of flow patterns that must be simulated, but to compute the probability of occurrence of each of the simulated flow patterns. Approximately 50 flow patterns were generated in the analysis (Figures 3a-3d represent 4 of the 50). This number was more than sufficient to describe the range of circulations contained in the original time series. Without this similarity analysis, it would have been necessary to generate more than 2600 flow patterns.

All the preceding analysis neglected the transport of wastewater by tidal currents. These motions were treated as a dispersion that is superimposed on the trajectories obtained from the previously described methods. The cross-shore component of the currents associated with tidal (and shorter period) motions (initially removed from the analysis) was used to compute this dispersion. It was found that the cross-shore distribution was essentially independent of time for elapsed times (i.e., the time since discharge from the outfall) of more than about 6 h. Approximately 50% of the time, the tidal motions would move the wastewater less than 0.5 km from the computed trajectory; about 90% of the time it would lie within 1 km of the trajectory; and virtually 100% of the time it would be within 2 km. These dispersion factors are easily applied to the trajectory diagrams to take into account the tidal motions.

The products of this study have been twofold. A new method has been developed to simplify the analysis of massive amounts of current meter data, and this method has been used to overcome the geographical constraints on the collection of oceanographic data required for siting the south San Diego outfall.

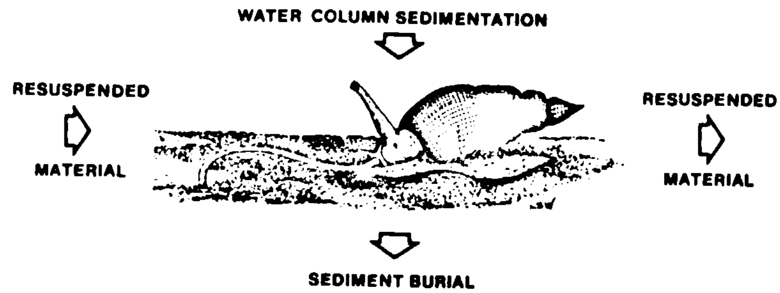

Figure 1. Possible sources of food to the benthic community.

Flux of Organic Material and Benthic Community Structure

Discharges from ocean outfalls are frequently accompanied by changes in the composition of the sediments and the abundance and structure of the animals living on and within the sediments. Staff oceanographer Terry Hendricks has been developing numerical simulation models to relate these changes to the characteristics of the effluent, the discharge system, and the receiving water environment (SCCWRP 1987).

These models attempt to predict the distribution, concentration, and accumulation of effluent and natural particles in the sediments around the outfall. Measurements of populations of benthic biota and organic content of the sediments showed an inverse relationship between these two variables (Hendricks 1985). In previous simulations, predictions of the distribution and concentration of organic material in the sediments were combined with this relationship in an attempt to provide estimates of the outfall-induced changes in the benthic community structure. The ability to predict community structure, as measured by the Infaunal Index, appeared to be better than the ability to predict concentrations of organic material in the sediments (Hendricks 1985). This was surprising because the biological predictions were based on the sediment organic content predictions.

Sediment trap studies conducted by Hendricks have provided a possible explanation for this paradox. It is assumed that the availability of food (e.g., organically enriched effluent particles) plays a role in regulating benthic community structure and abundance. This food may become available through sedimentation from the water column, accumulation in the sediments, or transport through the area by near-bottom currents (Figure 1).

The fluxes of resuspended material into sediment traps are generally one, or more, orders of magnitude greater than the rates of sedimentation from the water column or accumulation in the sediments. Thus the supply of organic matter to the benthic biota is likely to be dominated by the horizontal transport of organic matter by near-bottom currents. This flux of material, however, may have little relation to the concentration of organic material in the sediments.

In order to examine this hypothesis, Hendricks used the numerical simulation models SEDF2D and SEDR to simulate the deposition and the resuspension, transport, and accumulation of sediments, respectively. SEDR is an updated version of the model SEDP; SEDF2D and SEDP have been described previously (SCCWRP 1987). A by-product of the simulation process is an estimate of the transport fluxes of organically enriched outfall particles by the near-bottom currents.

Simulations were carried out for the Orange County (Newport Beach), City of San Diego (Point Loma), and Los Angeles County (White Point) outfall areas. Near-bottom transport fluxes were obtained for stations in each outfall area where Infaunal Index values were already available (Bascom 1979). Infaunal Index values for stations with comparable transport fluxes were combined into a composite value to reduce the natural variability.

The results for the Orange County and San Diego outfall areas are shown in Figure 2. At both sites, the Infaunal Index was inversely related to the flux of effluent material in the near-bottom waters. The Infaunal Index is observed to decrease by about 21 to 25 units for each 100 mg/cm² (bottom area) per year increase in near-bottom effluent particle transport flux. Although the two sites have approximately the same dependence on this flux, the natural (flux = 0) community structures are different. In the absence of any discharge, the expected Infaunal Index at the Orange County outfall is about 93; at the Point Loma site, it is about 77. The correlation coefficients for significant relationships at the Orange County and San Diego sites are -0.95 and -0.90, respectively, yielding 92 and 95% confidence levels.

Figure 3 shows the corresponding plot for the White Point area. Again a significant inverse correlation is observed ($r = -0.95$; $P < 0.02$). At this site, however, the reduction in Infaunal Index per unit near-bottom flux is only about one-quarter the rate at the other two sites. The reason for this difference is not known. Since the no-discharge Infaunal Index for the White Point area is estimated to be only about 57, it is possible that this substantially different assemblage of bottom dwellers responds differently than the communities at the other two areas. Alternatively, since the water column sedimentation and the accumulation fluxes are comparable in magnitude to the horizontal transport flux at this site (SCCWRP 1987), a more detailed estimate of the total flux of effluent material through the

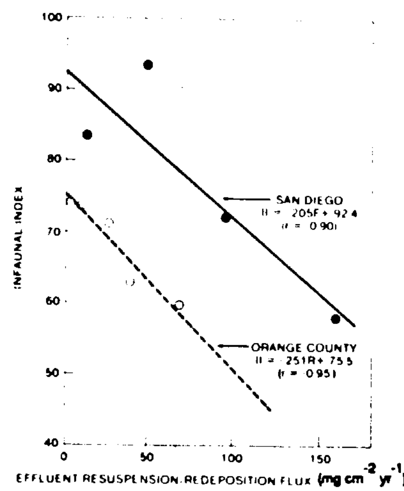

Figure 2. Infaunal Index values versus near-bottom flux for the City of San Diego and Orange County outfall areas.

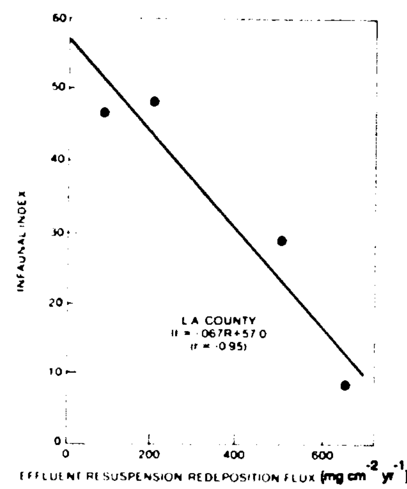

Figure 3. Infaunal Index values versus near-bottom flux for the Los Angeles County outfall area.

near-bottom environment may be required.

The correlation observed between Infaunal Index values and the (estimated) near-bottom transport of organically enriched particles is exciting because it offers the potential to estimate the effects on the benthic community structure associated with a discharge--and perhaps could assist in estimating the relative effects of toxicity and food supply on these assemblages. Additional work, including an explanation for the differences between White Point and the two other sites, will be required for this goal to be realized.

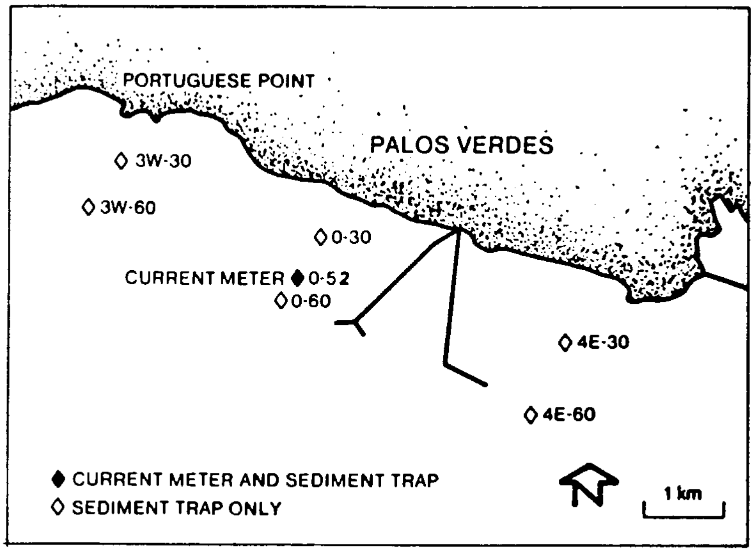

Figure 1. Current meter and sediment trap stations near the Los Angeles County outfall.

SCCWRP has been using sediment traps moored just above the sediment surface to obtain estimates of the rate of resuspension of sediment particles. Previous measurements in depths of water comparable with major outfalls (30 to 60 m) indicated resuspension flux rates that were one or more orders of magnitude greater than the accumulation rate of sediments (SCCWRP 1987). This difference in rates suggests that particles settling from the water column onto the sediments undergo a large number of resuspensions and redepositions before they become part of the "permanent" sediments. The dynamic nature of these surficial particles can substantially affect the distribution, concentration, and accumulation of effluent particles in the area around an ocean outfall.

Seasonal and Spatial Variations in Sediment Resuspension

In SCCWRP's 1986 Annual Report, Hendricks discussed some preliminary results from these sediment trap studies and the use of this data in a numerical simulation model (SEDP in SCCWRP 1987; the present, updated version is SEDR) of the resuspension, transport, and accumulation of effluent particles. That data represented a limited number of one-month observations from one or two locations in each of four outfall areas. Since that time, we have collected time-series of resuspension fluxes over a two-year period in the vicinity of the Orange County (Newport Beach) and Los Angeles County (White Point) outfalls. Measurements of the spatial variability in the resuspension rates and particle characteristics have also been made around the White Point outfalls during the summer of 1987. These measurements have provided new insight into sediment resuspension processes and have assisted in evaluating the validity of some of the assumptions contained in the simulation models.

Figure 1 shows the location of sediment trap moorings in the

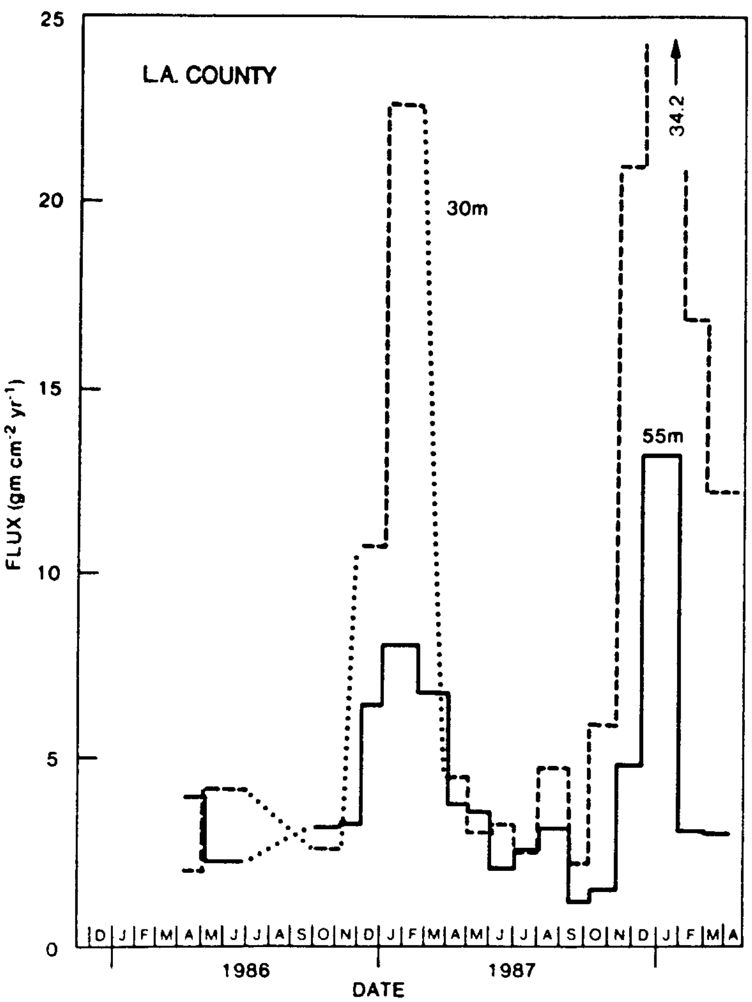

Figure 2. History of sediment trap fluxes near the Los Angeles County outfall at White Point. Dotted lines indicate no data.

White Point outfall area. Long-term time-series were collected at stations 0-30 and 0-52 (and/or 0-60); the remaining stations were only occupied during the summer and fall of 1987.

Figure 2 shows the fluxes of total particle mass collected during approximately one-month sampling periods beginning in April 1986 and extending to April 1988. The solid line represents the fluxes collected in 52 to 60 m of water; the dashed line represents the flux observed in 30 m.

The fluxes at both depths show a seasonal increase during the winter, with the greatest increase observed at the shallower depth. During both the 1986-87 and 1987-88 winters, the largest monthly flux was associated with the largest long-period swell during the winter. In summer, the fluxes collected at the 30- and 60-m depths are comparable. Wintertime fluxes vary from year to year. Maximum rates in the winter were about 23,000 and 34,000 mg cm^{-2} yr^{-1} during the two winters at a depth of 30 m, and about 8,000 to 12,000 mg cm^{-2} yr^{-1} at the 52- to 60-m depths. These rates are deceptive, however, since they are the average flux over the deployment period (typically 32 to 40 days), but most of the trapped particles were probably resuspended during the period of maximum swell (generally less than one day). Thus the "instantaneous" resuspension rates were probably at least an order of magnitude higher during the swell. The average fluxes over the two-year period were 10,600 and 4,400 mg $cm^{-2}\,yr^{-1}$.

The seasonal variations in the organic content of the material collected in the sediment traps are shown in Figure 3. Concentrations of organic material show an inverse relationship with the flux of total particle mass into the traps. The lowest concentrations occur in the winter; the highest in the spring-summer period. Since the net flow of near-bottom currents is upcoast and offshore flow, this change suggests that the inshore area may contribute a greater fraction of the material collected in the traps during the winter. Average total volatile solids (TVS) at both depths were about 10%.

Figure 4 shows the location of the two sediment trap moorings in the vicinity of the Orange County outfall. Figure 5 shows the seasonal variation in the flux of material into the traps at these stations from December 1985 until April 1988. In contrast to the observations in the White Point area, there is no clear seasonal signal. Average fluxes in 30 and 60 m of water are 2400 and 1100 mg $cm^{-2}\,yr^{-1}$, respectively. These fluxes are only about one-quarter the average fluxes in the White Point area.

The organic content of the material collected in the traps at the Orange County stations showed only a small seasonal effect. Again the highest concen-

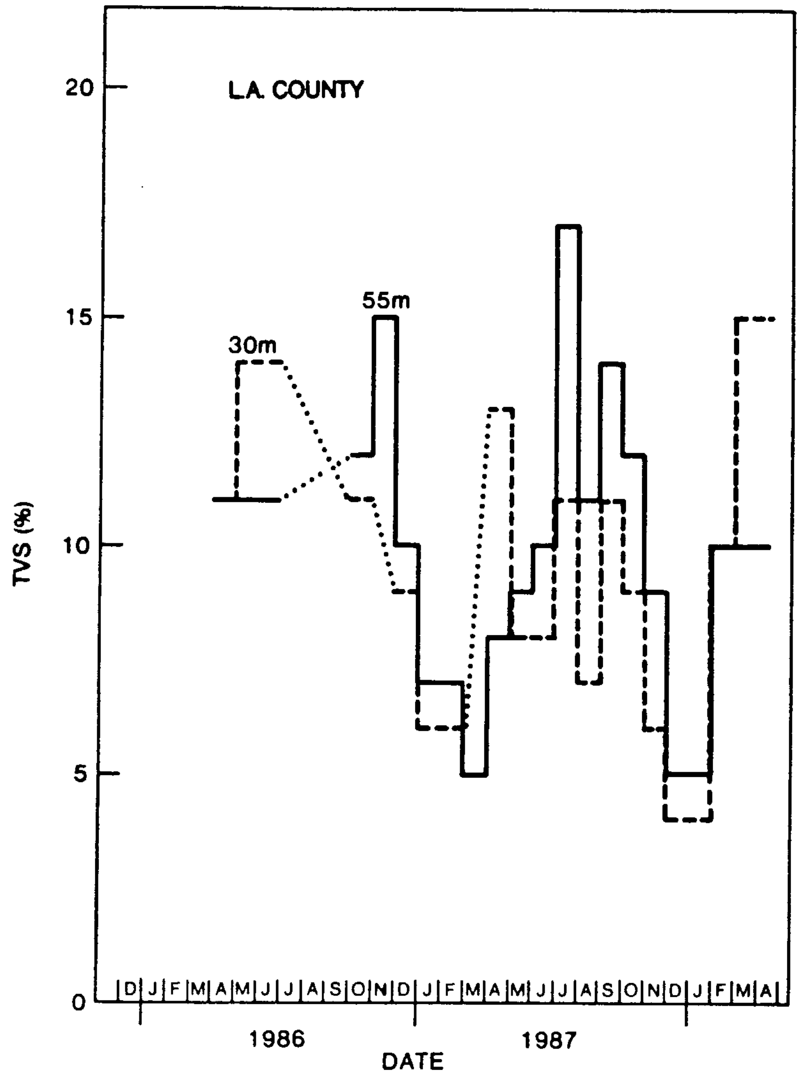

Figure 3. History of TVS collected in sediment traps near the Los Angeles County outfall. Dotted lines indicate no data.

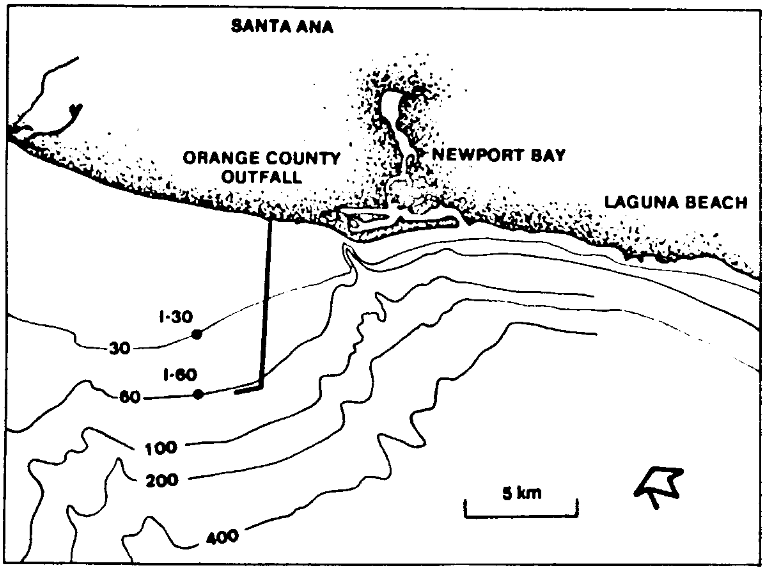

Figure 4. Locations of two sediment trap moorings near the Orange County outfall.

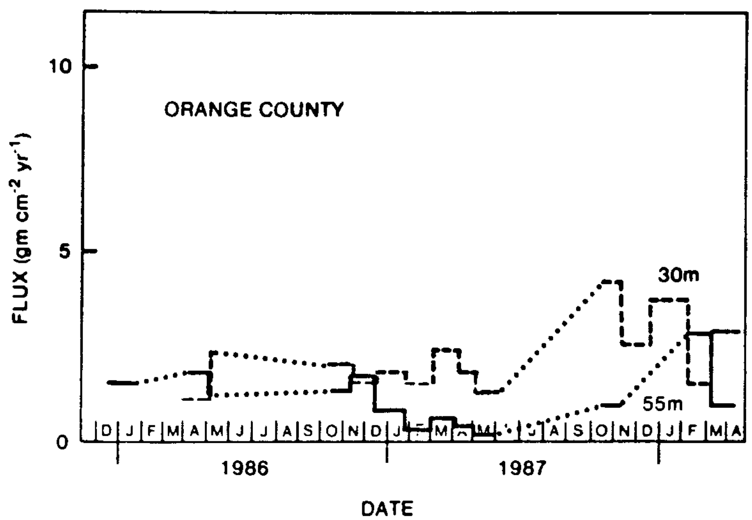

Figure 5. History of sediment trap fluxes near the Orange County outfall.

trations were observed in the summer. The average concentration of organic material in the traps (6%) was about 2 to 3 times that in the surface (0- to 2-cm depth) sediments (2 to 2.5%). This difference is consistent with differences observed in San Diego and Encina (Carlsbad) outfall areas.

Substantial differences in resuspension-redeposition fluxes have been observed between various outfall areas (e.g., White Point and Orange County, discussed above; and SCCWRP 1987). During the late spring to early fall of 1987, we deployed sediment traps at the 7 stations around the White Point outfalls shown in Figure 1 as part of a special study of sediment characteristics. One of the purposes of this deployment was to measure the spatial variability in sediment trap flux rates within a single outfall area.

Figure 6 shows the average resuspension-redeposition flux at each mooring for the period from May 1 until September 14. In 60 m of water, they ranged from about 2750 mg cm^{-2} yr^{-1} to about 3210 mg cm^{-2} yr^{-1}. This variation is within the normal range of variability between replicate traps ($\pm$ 30%). Along the "0" cross-shore transect, fluxes ranged from about 3060 mg cm^{-2} yr^{-1} in 30 m of water, to 4020 mg cm^{-2} yr^{-1} in 52 m, and about 2850 mg cm^{-2} yr^{-1} in 60 m of water-- again within normal variability.

There is, however, a significant, persistent, increase in flux at the station in 30 m of water just upcoast from Point Fermin. The source of this increased flux is unknown. A hint of increased flux rates is observed at the nearshore station near Portuguese Point. It was anticipated that increased fluxes might result from a local landslide in this area that terminates at the water's edge.

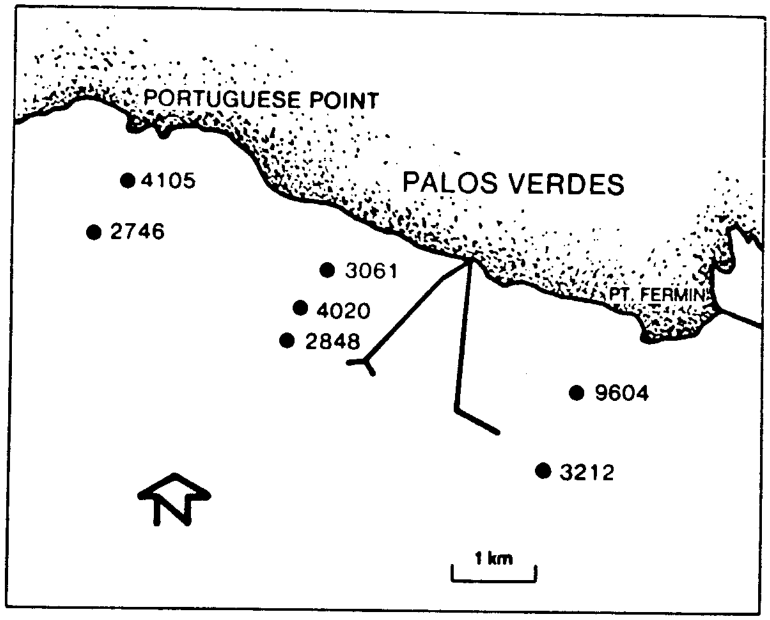

Figure 6. Apparent sedimentation flux (mg cm^{-2} yr^{-1}) for seven sediment traps near the Los Angeles County outfalls at White Point.

The fluxes into near-bottom sediment traps are substantially greater than net accumulation fluxes of material in the sediments. Significant variations in resuspension-redeposition fluxes occur between different regions of the coast, although they are relatively constant in 60 m of water over a 7- to 8-km section of the coast off White Point.

Large seasonal variations in the fluxes are observed in the White Point area in both 30 and 60 m of water. The increased fluxes are correlated with the presence of large-amplitude, long-period swells. In contrast, seasonal variations are negligible in both 30 and 60 m of water off Orange County.

The observed spatial and temporal variation in resuspension rates indicate that assumptions incorporated into the sedimentation/resuspension model set are only valid for selected areas and times (e.g., White Point in summer). Additional information on resuspension and redeposition mechanisms, the settling character of resuspension particles, and transport by near-bottom currents will be required to permit more universal simulations. Some of these questions will be addressed during the studies we have planned for the coming year.

Micronuclei in Starry Flounder from San Francisco Bay

In this study, Jeffrey N. Cross of SCCWRP and Jo Ellen Hose of Occidental College quantified micronuclei in peripheral circulating erythrocytes of starry flounder (*Platichthys stellatus*) and correlated micronucleus frequencies with body burdens of chlorinated organic contaminants. The flounder were collected by otter trawl from four sites in San Francisco Bay and two sites along the outer coast of central California (Figure 1) during two sampling periods in the winter of 1986-87.

Micronuclei are small, secondary nuclei formed after chromosome breaks (Schmid 1976). They may arise spontaneously, but the induction of micronuclei above background levels is a sensitive indicator of genotoxic damage resulting from exposure to mutagens (Heddle et al. 1983).

Blood was collected from each fish immediately after capture, and smears were prepared on the ship. The smears were then stained in the laboratory, and the number of micronucleated erythrocytes per 1000 erythrocytes was determined. The erythrocytes were studied for degree of pleomorphism (loss of the usual elliptical shape of the nucleus) (Table 1) and for the presence of detached and attached micronuclei (Figure 2). If a pleomorphic nucleus had a projection greater than about one-fourth the nuclear diameter and the projection terminated in a chromatin mass, it was considered an attached micronucleus.

Micronuclei (detached and attached) and nuclear pleomorphism are manifestations of cytotoxicity. Detached micronuclei are formed after chromosomal breakage or spindle damage. Attached micronuclei and severe nuclear pleomorphism may be

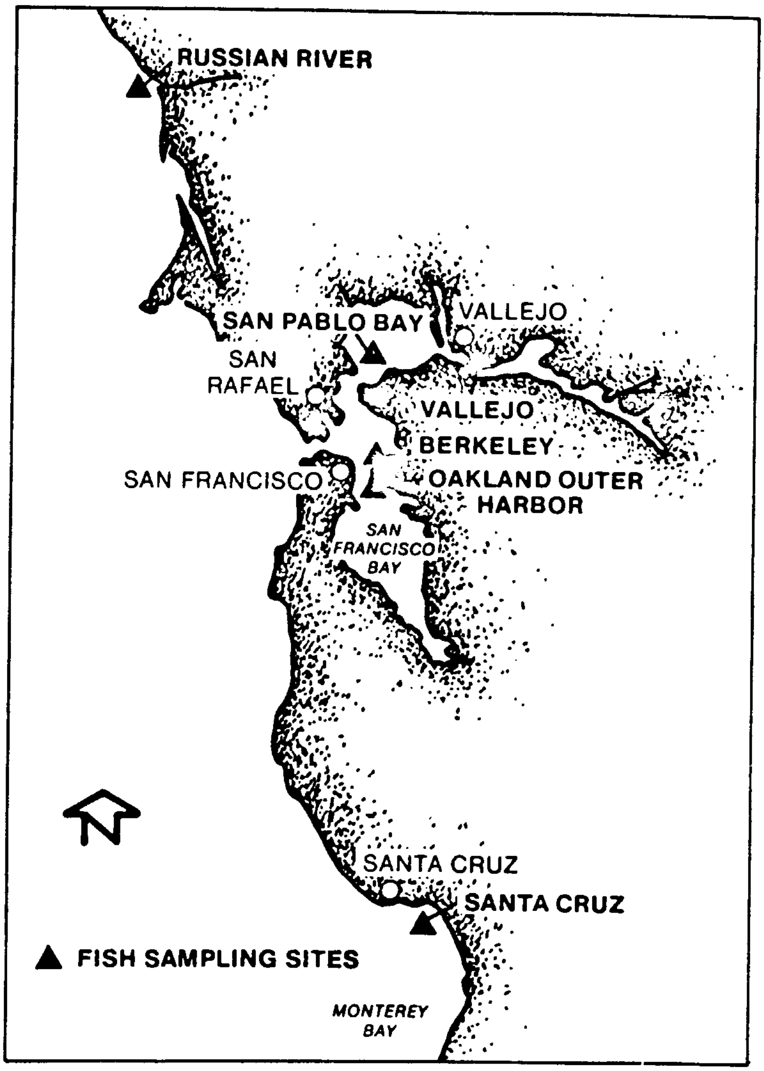

Figure 1. Map of the study sites.

the result of (1) chromosomal breakage or spindle damage, (2) destabilization of the nuclear membrane by certain chlorinated organics or intermediates of polynuclear aromatic hydrocarbon metabolism, or (3) agents that cause chromatin clumping (chromocenter formation) or margination (chromatin adhering to nuclear membrane).

Cross and Hose found that micronucleus frequencies were significantly higher among starry flounders collected within San Francisco Bay than among fish collected on the outer coast (Table 2). A significantly higher proportion of fish from the outer coast had no visible micronuclei. Within San Francisco Bay, there were no significant differences in micronucleus frequency. Fish with high micronucleus frequencies also had a high incidence of misshapen nuclei (nuclear pleomorphism).

In addition, micronucleus frequencies (1) were not significantly different among male starry flounders from the bay and the outer coast; (2) were significantly higher among females from the bay than among females from the outer coast; and (3) were positively correlated with fish size among females, but not among males, from San Francisco Bay stations.

The composition of organic contaminants in the livers of starry flounders was very similar among the four sites within San Francisco Bay and was slightly less similar between fish collected within the bay and on the outer coast (Figure 3). Fish from central San Francisco Bay had higher mean levels of contaminants than did fish from northern San Francisco Bay, and fish from the northern bay had higher mean levels than did fish from the outer coast (Table 3). Except for chlordane and lindane, contaminant concentrations were not correlated with fish size. Chlordane and lindane concentrations were higher in females collected in northern San Francisco Bay; these fish were generally smaller than females collected in the central bay.

The lack of compositional differences among fish from the different sites and the presence of fish with low organic contaminant concentrations at all of the sites suggest that (1) chlorinated hydrocarbons are present throughout the bay system and on the outer coast and (2) some starry flounders move throughout the bay and between the bay and the outer coast. In a review of data on chlorinated hydrocarbons in sediments and biota, Phillips and Spies (manuscript in review) concluded that some compounds, particularly polychlorinated biphenyls (PCBs), are widespread in the San Francisco estuarine system.

Micronucleus frequencies were not correlated with organic contaminant concentrations in this study. The results are consistent with the non-chromosome-breaking properties of DDTs and

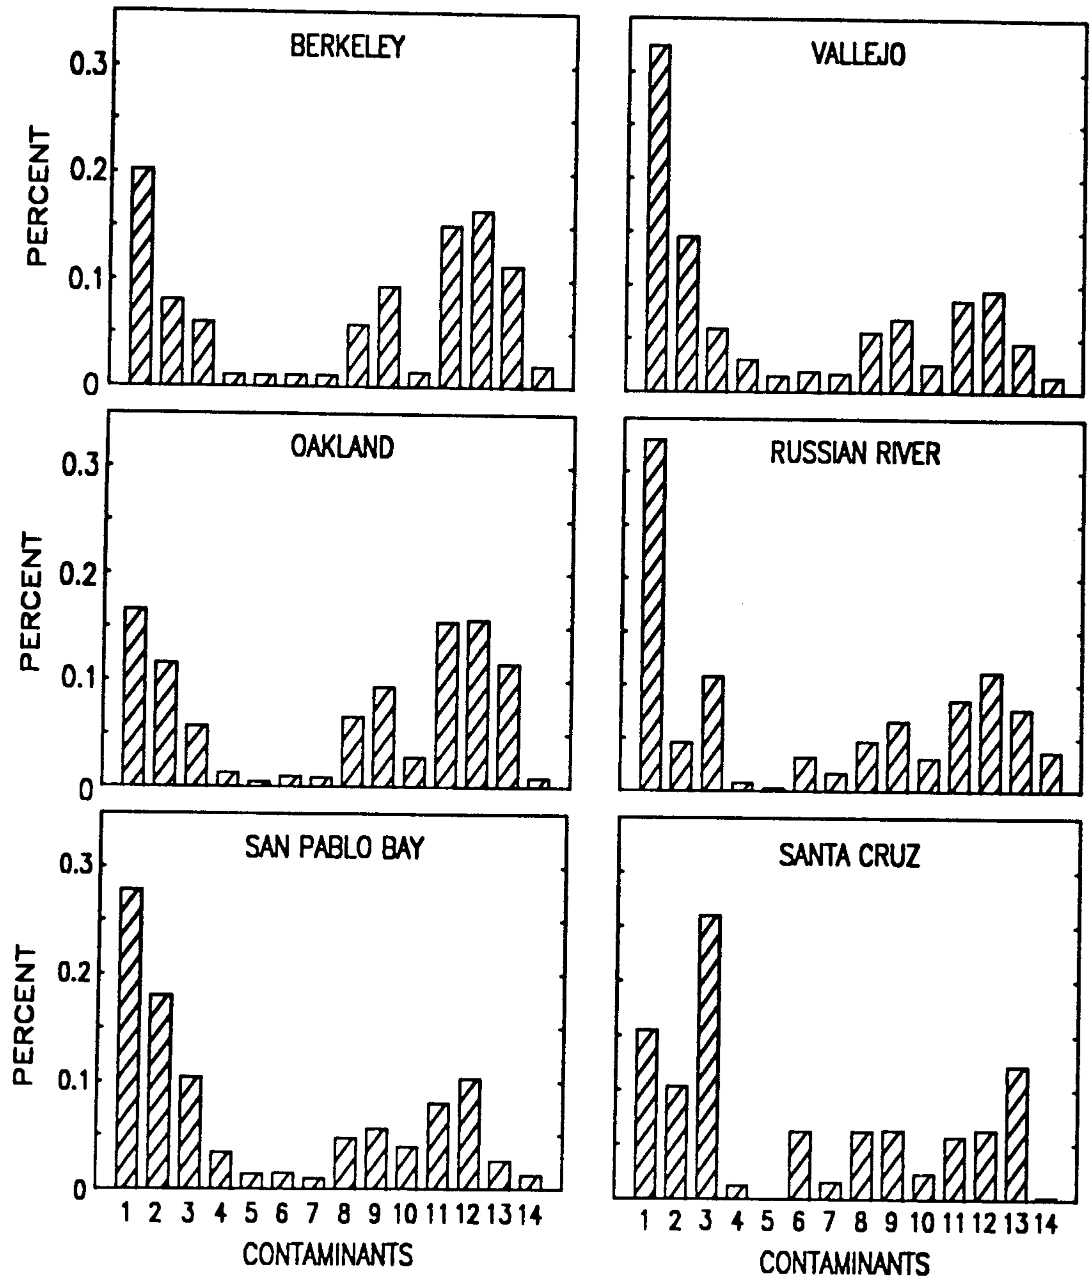

Figure 3. Normalized mean percentage of chlorinated hydrocarbons found in fish livers. Contaminant numbers on the abscissa are as follows: 1, *p,p'*-DDE; 2, *p,p'*-DDD; 3, dieldrin; 4, chlordane; 5, lindane; 6, heptachlorepoxide; 7, PCB44; 8, PCB101; 9, PCB118; 10, PCB128; 11, PCB138; 12, PCB153; 13, PCB180; 14, PCB206. PCB numbers indicate specific identities of the congeners (Ballschmiter and Zell 1980). Numbers increase with increasing molecular weight.

PCBs (Green et al. 1975, Heddle et al. 1983). It is well known from many mammalian and a few fish experiments that compounds such as metabolites of mutagenic polynuclear aromatic hydrocarbons (e.g., benzo[*a*]pyrene), mutagenic nitroaromatics and phenols, and carcinogenic volatile monoaromatics (benzene) enhance micronucleus formation (Schmid 1976, Hoofman and de Raat 1982, Heddle et al. 1983). These compounds were not measured in this study but are present in San Francisco Bay and may be responsible for the micronucleus frequencies observed.

Micronucleus frequencies of starry flounder from stations within San Francisco Bay (mean = 1.7‰, median = 0.5‰) were lower than micronucleus frequencies of white croaker (mean = 3.4‰, median = 2.5‰) and kelp bass (mean = 6.8‰, median = 4.3‰) from contaminated sites near Los Angeles (outer San Pedro Bay and eastern Palos Verdes Peninsula, respectively) (Hose et al. 1987).

Impaired Reproduction in White Croaker off Southern California

The coastal waters off Los Angeles have received thousands of tons of domestic and industrial contaminants during the past 40 years. Exposure to these contaminants has been implicated in a decrease in catches of several species of sport and commercial fish. In this study, Jeffrey N. Cross of SCCWRP and Jo Ellen Hose of Occidental College examined white croaker (*Genyonemus lineatus*), an important sport and commercial fish inhabiting the coastal waters off Los Angeles, to determine if reproduction was impaired in fish from this contaminated region.

White croaker were collected from outer Los Angeles Harbor, a contaminated area in San Pedro Bay, and from Dana Point, a reference site 80 km southeast of San Pedro Bay. After the fish were collected, they were taken to the laboratory, where the females were induced to spawn with the hormone human chorionic gonadotropin. The resulting eggs were fertilized with sperm that was pooled from at least three males from the same locations as the females.

Statistical analysis showed that there was not a significant difference in the proportion of spawning females between the two locations. The ovaries from non-spawning fish were examined under a microscope, and the scientists found that non-spawning fish from Dana Point had hydrated oocytes, which indicates that they were maturing and spawning would occur soon. However, the non-spawning fish from San Pedro Bay had only yolky oocytes and remained unresponsive to the hormone injections.

Table 1 shows that white croaker from San Pedro Bay had higher concentrations of chlorinated hydrocarbons in their livers and gonads than the fish from Dana Point did. The San Pedro fish also produced fewer eggs and had lower fertilization rates.

At the beginning of the reproductive season, numbers of early oocytes were compared among females to account for potential differences in the timing of oocyte maturation at the two locations. Fish from San Pedro Bay produced fewer oocytes and had a greater number of these cells degenerating than the fish from Dana Point did (Table 1).

Concentrations of polychlorinated biphenyls (PCBs) were not significantly different between spawning fish from San Pedro Bay and the general population in that area. DDT concentrations in the ovaries of spawning fish from San Pedro Bay averaged 2.1 ppm (mg/kg wet weight), which was significantly less than the ovarian DDT concentrations (4.2 ppm) of fish from the general population in that area. None of the spawning fish from San Pedro Bay had ovarian DDT levels greater than 3.8 ppm, but in the general

Table 1. Contaminant body burdens and reproductive success of female white croakers collected during December and January (1985-86) and spawned between January and March (1986). Data are mean ± standard deviation (sample size).

population 38% of the fish had DDT levels greater than 3.8 ppm. Apparently, white croaker with ovarian DDT levels greater than 4 ppm do not spawn. In salmonid hatchery studies, Burdick and co-workers (1964, 1972) found there was a 3-ppm threshold for spawning. Although DDT concentrations are correlated with reproductive impairment, they are probably not the only cause of the effects found in this study. It has previously been found (Malins et al. 1986) that other contaminants (polynuclear aromatic hydrocarbons and trace metals) occur at high concentrations in sediments and fish from San Pedro Bay.

This study by Cross and Hose shows that white croaker inhabiting contaminated areas near Los Angeles have higher chlorinated hydrocarbon body burdens, greater early oocyte destruction and preovulatory degeneration, lower fertilization rates, and decreased egg production than do fish from the reference location. The mechanisms for reproductive impairment similar to that found in this study are not completely understood but may include a change in essential hormone levels, toxicity to developing gametes or nutritive cells, and generalized stress responses.

Sediment Toxicity to Kelp Bass Larvae

This sediment toxicity experiment by Dario W. Diehl (SCCWRP) and Jo Ellen Hose (Occidental College) focused on larval kelp bass (*Paralabrax clathratus*). Adults and juveniles are found in kelp beds and rocky reefs along the coast. They are a primary sport fish available throughout the year in the southern California region and become reproductively active in early summer. Kelp bass are very hardy fish, which makes them excellent laboratory animals. Some of these fish were spawning naturally after one year of captivity at Southern California Edison's research and development laboratory in Redondo Beach.

Kelp bass, like many other fish species, have larvae that develop in the water column during the spring and early summer. A previous study found that different species of fish larvae have different survival rates when exposed to seawater extracts of sediment from Charleston Harbor, SC (Hoss et al. 1974). Another study suggested that polychlorinated biphenyl (PCB) concentrations in anchovy larvae, *Engraulis mordax*, were dependent on the PCB concentrations in seawater and not on the PCB concentration in the food the larvae ingested (Scura and Theilacker 1977). For the present experiment the researchers tested the response of kelp bass larvae to sediments from four southern California coastal areas instead of seawater extracts.

Fish were captured from Catalina Island during the summer of 1986. Sediment was collected just prior to the experiment in the summer of 1987 from a relatively uncontaminated reference area (San Mateo Point), an industrialized harbor (Los Angeles), and two areas adjacent to large municipal wastewater outfalls (Orange County and Los Angeles County).

The static bioassay consisted of 5-gallon aquaria containing 2 cm of sediment and 15 L of filtered seawater. Control tanks contained only seawater. Five replicates of each sediment and seawater control were prepared. Water was changed carefully every 2 to 3 days, so little sediment resuspension occurred. One hundred and fifty 10-day-old yolk sac larvae were added to each aquarium. After 13 days, the surviving larvae were counted, weighed, microscopically measured, and examined for malformations. Larvae were fed daily with rotifers and brine shrimp nauplii during the experiment.

Chemical analysis showed that San Mateo Point is relatively clean, Orange County outfall is moderately contaminated, and Los Angeles Harbor and Los Angeles County outfall are fairly contaminated (Figure 1). Mean polynuclear aromatic hydrocarbon (PAH) concentrations were lowest at San Mateo Point (2 ng/g [ppb] wet weight) and highest in Los Angeles Harbor (2872 ppb). Mean PCB concentrations were lowest at San Mateo Point (2 ppb wet weight) and highest at Los Angeles

County outfall (345 ppb). Low levels of PAHs (47 ppb) and PCBs (18 ppb) were detected at Orange County outfall. Mean total DDT concentrations were lowest off Orange County and San Mateo Point (4 and 8 ppb wet weight, respectively). The highest level of DDT was found at Los Angeles County (2097 ppb) and Los Angeles Harbor had a moderate level (109 ppb) of DDT contamination.

Larval survival ranged from 11% in the control to 1.9% in Los Angeles Harbor sediment (Figure 2a). Larvae in Orange County, Los Angeles County, and Los Angeles Harbor sediment had statistically significant lower survival than those in San Mateo Point sediment. Survival of larvae in seawater control and reference area sediment were not statistically different and survival rates are typical of species with floating larvae. No statistical differences were found among the three contaminated areas.

Larval weight ranged from 0.93 mg in Orange County sediment to 0.57 mg in Los Angeles County sediment (Figure 2b). No statistical difference could be found among larvae from San Mateo Point, seawater, Orange County, Los Angeles County, and Los Angeles Harbor.

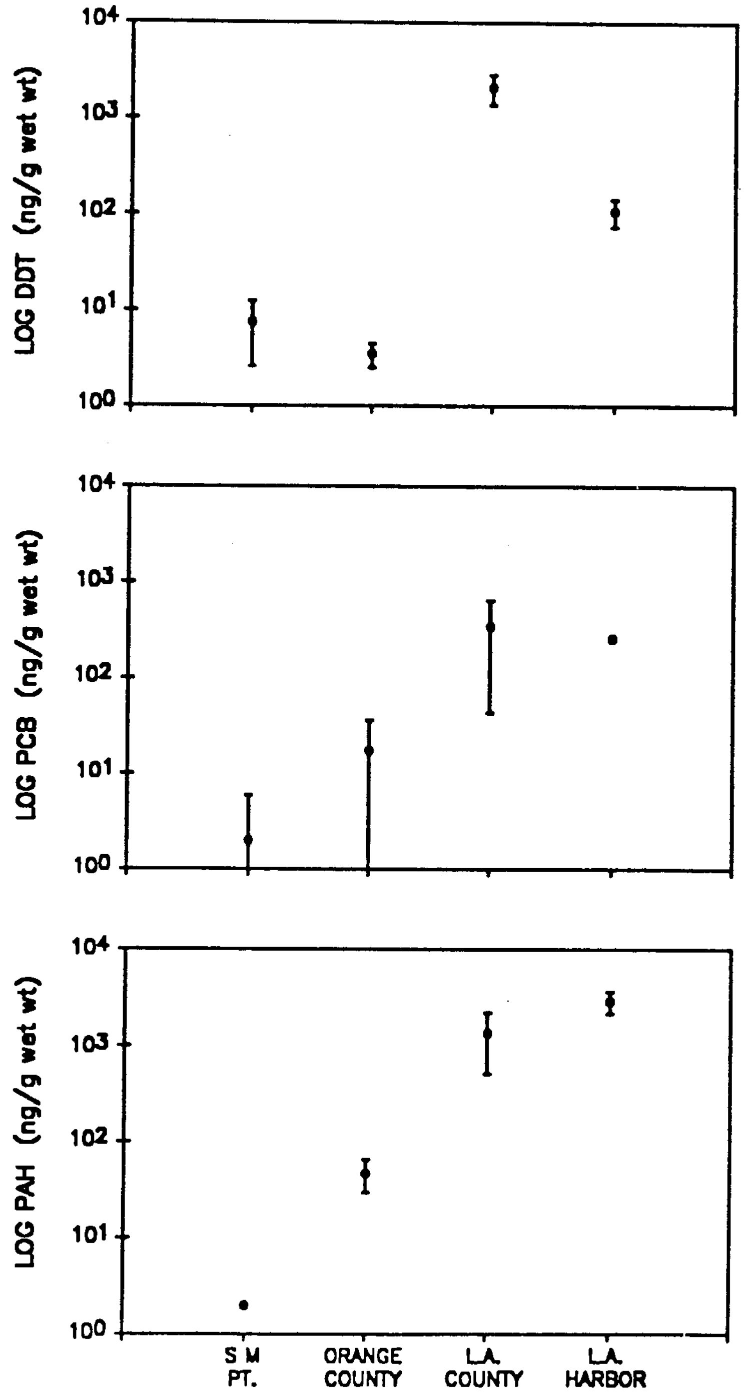

Figure 1. Organic contaminant concentrations in sediments from four southern California sites. Data shown are means; vertical lines indicate 95% confidence intervals. Note that data are plotted on a logarithmic scale.

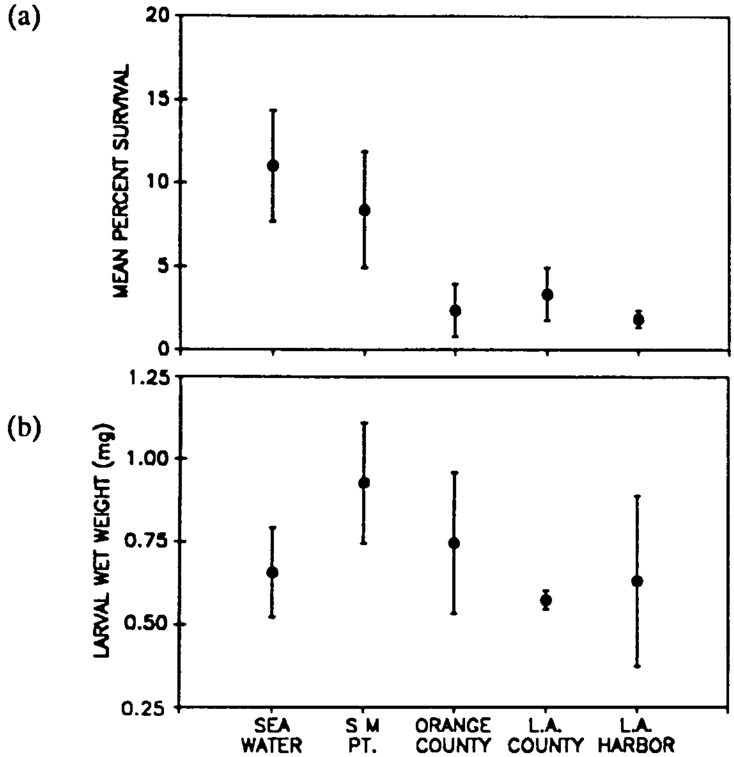

Figure 2. (a) Percentage of larval survival after 13-day exposure to seawater or sediment. Data shown are the means; vertical lines indicate 95% confidence intervals. (b) Weight of larvae after 13-day exposure to seawater or sediment. Data shown are the means; vertical lines indicate 95% confidence intervals.

Malformations were rarely observed. Only one malformed larva was observed during the experiment; it was exposed to sediment from Los Angeles Harbor (7.1% malformation rate). Larval mortality was so high in the contaminated sediments that the likelihood of deformed larvae surviving was slight.

These results suggest that even moderate levels of sediment contamination cause mortality among floating fish larvae. The moderate and higher levels were equally lethal to the larvae. Chronic toxicity (growth), however, was roughly proportional to sediment contamination. Further experiments need to be done to determine which contaminant caused mortality.

Kelp bass larvae have been successfully used in sea-surface microlayer bioassays (Cross et al. 1988) and appear to be promising candidates for sediment toxicity tests. Larval growth and survival endpoints are also used by the U.S. Environmental Protection Agency in their inland silverside (*Menidia beryllina*) bioassay for whole effluents (Heber et al. 1988). An advantage to the use of kelp bass over other indigenous species is that they have been induced to spawn outside of their natural reproductive period.

Acknowledgments

Responses of Biota and Sediment to the 7-Mile Outfall Termination

In the SCCWRP 1986 Annual Report, the Hyperion Recovery Study was described briefly. At that time the researchers, Bruce E. Thompson of SCCWRP and John Dorsey of the Hyperion Treatment Facility, had started pre-termination sampling but did not report any data. Technical delays pushed back the projected date of shutoff, so the researchers postponed the sampling times accordingly. A revised sampling schedule is shown in Table 1. A third set of pre-termination samples was collected in the summer of 1987. Discharge from the Hyperion 7-mile sludge outfall was discontinued in November 1987, and quarterly post-termination sampling began in January 1988.

This report summarizes some of the data from the first set of pre-termination samples (February 1986), which show conditions in the bay under full sludge discharge.

Using dissolved sulfides in sediment interstitial (pore) water as an indicator of the sludge field, the scientists estimated that it exists mainly along the axis of the upper part of Santa Monica Submarine Canyon. Concentrations up to 284 mg/L of pore water were measured at the outfall terminus (Figure 1). Deep sediment cores, collected in October 1986, showed that the sludge field was about 50 cm deep, but cores collected in April 1988 showed that it was more than 140 cm deep.

Patterns similar to those in Figure 1 can be seen for such outfall-associated contaminants as polychlorinated biphenyl compounds (PCBs), polynuclear aromatic hydrocarbons (PAHs), and zinc (Figures 2a-2c), but peak concentrations were measured at sites deeper in the canyon, not at the outfall terminus. Additionally, elevated contaminant concentrations were measured farther from the outfall than sulfides were.

Infaunal indicator taxa such as the polychaete *Capitella capitata* were collected in highest abundances on the periphery of the sludge field; apparently, they are affected by high sulfide concentrations (Figure 1). Only about 10 species were collected from the sites near the outfall terminus. Most of these (mean, 655 organisms per square meter) were unusual polychaete taxa, such as *Ophryotrocha* spp. (three undescribed species), that are found only in highly contaminated areas. How they can exist in such areas is not understood. Exposures of most species to this sediment (see pp. 50, 58, and 65) caused death; however, another species found there, the gutless clam *Solemya reidi*, has biochemical mechanisms that can detoxify sulfide (Powell and Somero 1985).

Sites at intermediate distances from the outfall are dominated (abundance and biomass) by the clam *Parvilucina tenuisculpta* (560 organisms per square meter), and the reference sites are dominated by the ophiuroid *Amphiodia urtica* (760 organisms per square meter). *A. urtica* is the most abundant macrofaunal species at reference sites all along the southern California

mainland shelf (Thompson et al. 1987). Similar patterns of species composition and abundance in Santa Monica Bay were shown by Bascom (1979) and Dorsey (in press).

Otter trawl catches contained similar species and abundances at sites near the outfall and at the reference sites. The prawn *Sicyonia ingentis* and the urchin *Lytechinus pictus* were the most abundant megabenthic invertebrates collected. These species were also reported to be the most abundant species all along the mainland shelf. The plainfin midshipman and stripetail rockfish were the most abundant fish collected in the trawls.

Contaminant concentrations in tissues of two species were measured. Table 2 shows that the highest PCB concentrations were in *S. ingentis* hepatopancreas and Dover sole livers collected near the outfall. Concentrations of DDT and other contaminants in muscle tissue were all low and showed no obvious outfall-related trends. These results show that only a small area (about 3 to 4 km²) was observably affected by sludge discharge.

During the April 1988 cruise, the scientists noticed that some of the canyon sites on the periphery of the sludge field had changed. At station 52 (Figure 1), pre-termination samples had the highest contaminant concentrations and the most *C. capitata*. In April, that station contained mostly *P. tenuisculpta* and *Pectinaria californiensis*, organisms more common in the

(a) (b) (c)

transition sites. Thus, it appears that recovery has begun at some sites on the periphery of the sludge field. Sites at the outfall terminus, however, were still as described above during February 1986.

Quarterly sampling will continue through next January (1989). Depending on the progress of recovery, sampling will probably continue semi-annually for another year. We expect that the transition sites and sites on the periphery of the sludge field will recover the fastest. As sediment conditions improve, more infaunal species normally found in reference areas will move into those areas. Recovery at the outfall terminus will probably take longer. Recovery at any site will be defined as occurring when parameters measured are not statistically different from those at the reference site.

Upon completion of analyses of all pre-termination samples, a summary of that information will be prepared. Researchers anticipate that will occur in the fall of 1988.

Effects of Contaminated Sediments on Three Benthic Invertebrates

This paper summarizes three separate sediment exposure experiments conducted by Bruce E. Thompson, Steven M. Bay, and co-workers in laboratories at SCCWRP and California State University, Long Beach. Three different species of animals were used to test the same four sediment types: (1) SMB 50, sedimented sludge from near the Hyperion 7-mile outfall in Santa Monica Bay; (2) PV7.3, collected near the Palos Verdes outfall; (3) Los Angeles Harbor sediment taken from the East Basin; and (4) sediment collected near Dana Point, used as a control (Figure 1).

The sediment samples were collected with a Van Veen grab from which the top 5 cm was used. In the laboratory, they were homogenized by stirring, then sampled for analysis of sediment composition. Components analyzed were percent sand, percent total organic carbon (TOC), concentration of dissolved sulfides, chlorinated hydrocarbons (DDTs and polychlorinated biphenyls [PCBs]), polynuclear aromatic hydrocarbons (PAHs), and trace metals (Cd, Cr, Cu, Pb, and Zn) (Table 1). Sediment from SMB 50 had the highest levels of total organic carbon, sulfides, Cd, and Cu; PV7.3 had the highest concentrations of DDTs, PCBs, Cr, and Zn; and the harbor sediment contained the most PAHs and Pb. Although the reference sediment contained measurable quantities of most of these contaminants, they were an order of magnitude lower than the contaminants at the other sites and were within the range of reference values for this region (Thompson et al. 1987). The control sample also contained considerably less sand than the other samples.

Amphiodia urtica (brittlestar) is the most abundant infaunal organism in reference areas of the southern California mainland shelf, but it does not inhabit contaminated areas. This exposure was done to evaluate the sensitivity of *A. urtica* to contaminated sediments, to determine its usefulness as a test organism, and to determine an appropriate exposure system and endpoints for *A. urtica* in sediment toxicity testing. For this experiment, 10 individual ophiuroids were placed in each of three replicate aquaria containing each sediment type for 10 days in a static renewal exposure; the temperature was maintained at 15°C.

The mortality of *A. urtica* on each sediment type is shown in Figure 2. The control and harbor sediments had no mortalities. On PV7.3 sediment, only one organism in one tank died. All ophiuroids on the sludge sediment died. Thus, SMB 50 sediment (sludge) is acutely toxic to *A. urtica.*

Sicyonia ingentis (ridge-backed prawn) is one of the most abundant megafaunal species on the outer mainland shelf of southern California. It has been commercially harvested in a small fishery at Santa Barbara. This species was exposed to the four sediment types for 30 days at 12-15°C in a flow-through system in Dr. Donald J. Reish's laboratory at California State University, Long Beach. Ten adult prawns were used in each of three replicates of each sediment type. The parameters measured were mortality, growth rates (final-initial carapace lengths),

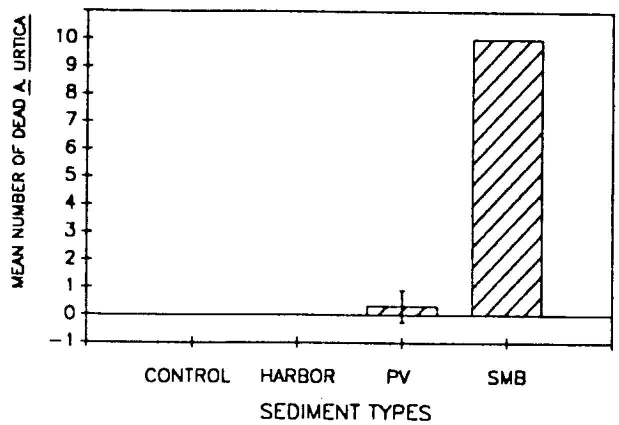

Figure 2. Mean (± standard deviation) mortality of *A. urtica* in each sediment after 10-day exposure. All brittlestars in SMB 50 died in all three replicates.

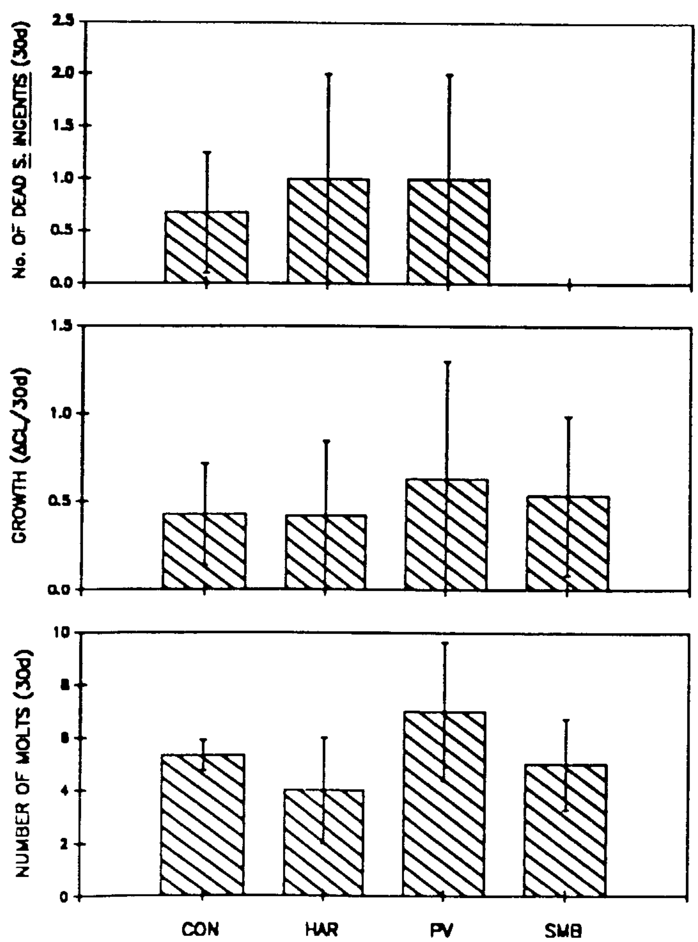

Figure 3. Mean (± standard deviation) mortality, growth, and number of molts for *S. ingentis* (n = three replicates; 10 prawns per replicate).

number of molts (counts of exoskeletons that were shed), and accumulation of contaminants in their hepatopancreas (Figures 3 and 4).

Prawns from PV7.3 sediment accumulated significant quantities of DDTs and PCBs; yet, no significant growth, mortality, or molt differences were found among prawns from any sediment type. The final trace metals concentrations in the hepatopancreas of prawns decreased from the initial concentrations and were similar among prawns from all four sediment types.

Lytechinus pictus (white sea urchin) is also one of the most abundant species on the mainland shelf off southern California. For this experiment, 15 urchins (diameter, 8 to 22 mm) were placed in each of three replicates of the four sediment types. They were exposed for 60 days in a flow-through system. The temperature was maintained at approximately 12°C throughout the exposure period. The parameters measured were mortality, growth rates (final-initial test diameter), gonad production (change in wet weight), and contaminant accumulation in urchin gonads (Figures 5 and 6).

No urchins on the control sediments died. On the harbor and PV7.3 sediments, only 1 and 3 urchins died, respectively, which was not significantly different from the controls. However,

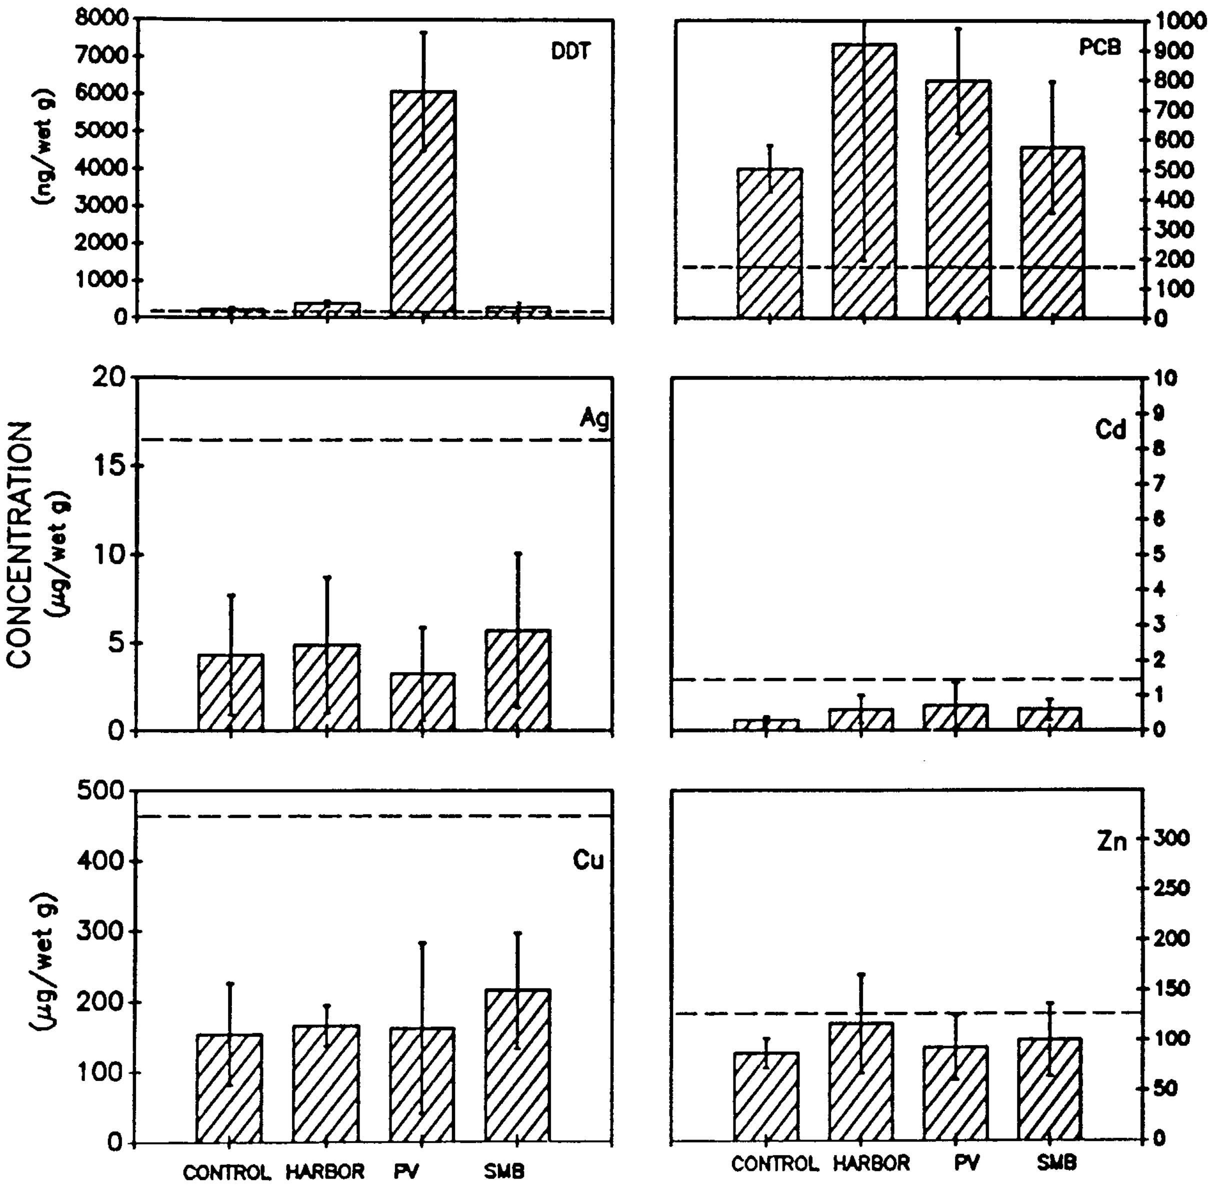

Figure 4. Mean (± standard deviation) contaminant concentrations in *S. ingentis* hepatopancreas after 30-day exposure in each sediment type. Dashed lines indicate initial concentrations.

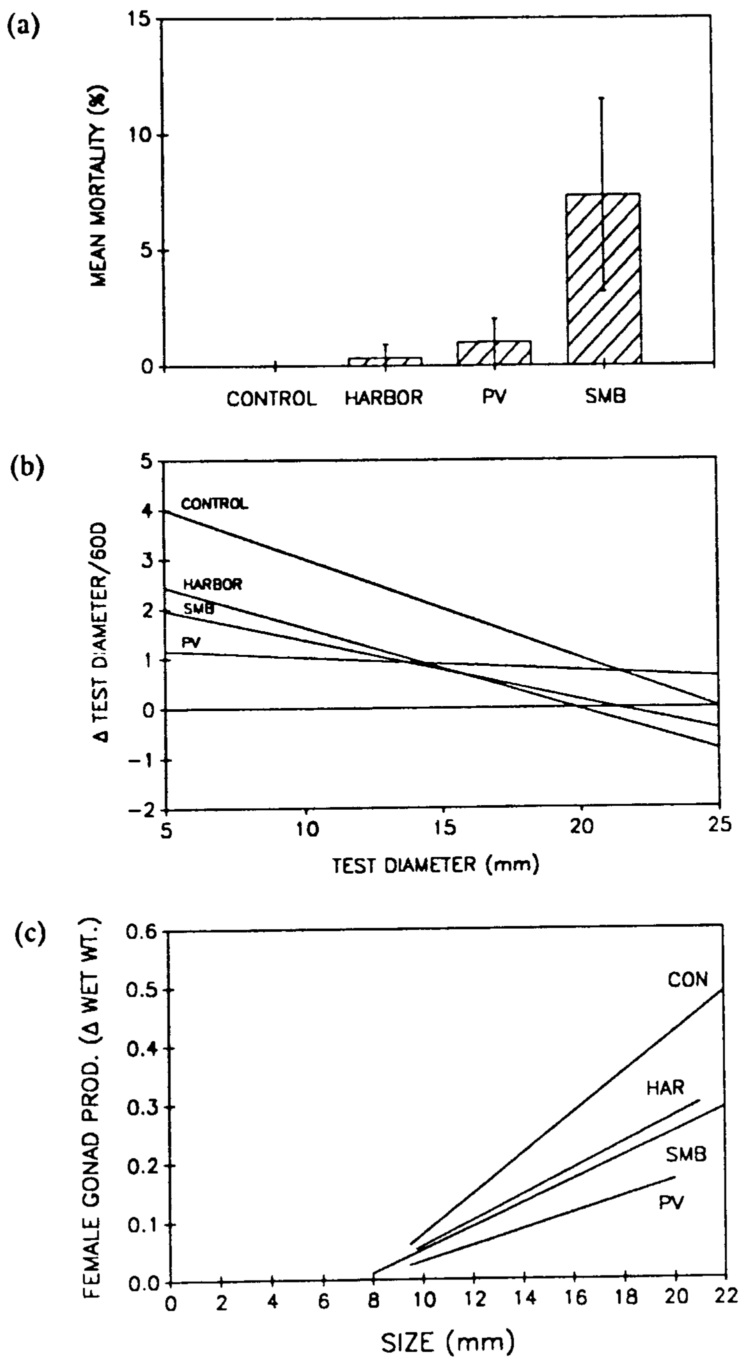

Figure 5. (a) Mean (± standard deviation) of *L. pictus* on each sediment type. (b) Size-growth regressions for *L. pictus* on each sediment type. (c) Size-gonad production regressions for *L. pictus* on each sediment type (n = three replicates; 15 urchins per replicate).

the urchins on the sludge sediment had significantly higher mortality than the control; about 49% of the SMB 50 urchins died. There were white bacterial mats on the surface of the sediment and a strong odor of sulfide.

For *L. pictus*, mortality rates in contaminated sediments were positively correlated with levels of dissolved sulfide, Cd, and Cu in the sediment and with Zn concentrations in the gonads. Hydrogen sulfide is suspected as the cause of the mortalities in the urchins.

Growth occurred in urchins from all sediment types, but the rate was significantly lower in urchins from contaminated sediments (Figure 5). In harbor and SMB 50 sediments, some urchins exhibited negative growth. Growth was inversely correlated with concentrations of PCBs, Cd, and Cr in sediments and DDTs in gonads.

Before exposure to contaminated sediments, urchin gonads accounted for approximately 2.3% of the wet body weight. There was a significant increase in gonad mass for urchins on all sediment types during the exposure because gametogenesis was apparently induced. After the 60-day exposure, gonad weight had increased to 11.3% wet body weight for the controls and 7% (the smallest increase) for the PV7.3 urchins. Female gonad production was significantly lower in SMB 50 and PV7.3 urchins than in the controls and

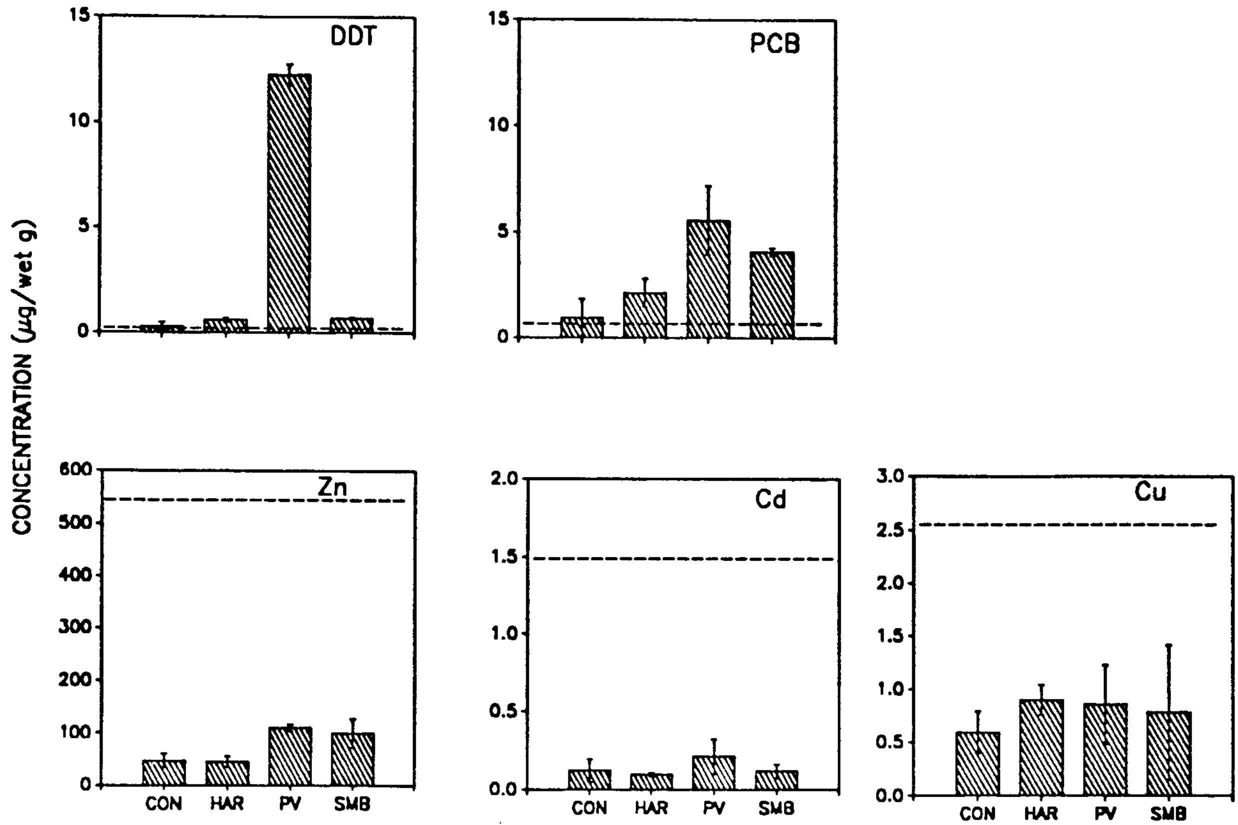

Figure 6. Mean (± standard deviation) contaminant concentration in *L. pictus* on each sediment type (n = three replicates; 15 urchins per composite sample). Dashed lines indicate initial concentrations.

was inversely correlated with sediment content of chlorinated hydrocarbons and trace metals.

The gonads of PV7.3 and SMB 50 urchins accumulated significant quantities of DDTs and PCBs; harbor urchins had a large increase in PCBs, but it was not significantly different from the control levels. As with *S. ingentis*, urchins from all four sediment types had a large decrease in Cd, Cu, and Zn concentrations.

Each of the three species exposed to contaminated sediments gave slightly different

Table 2. Summary of responses to contaminated sediments. A + indicates that a significant response was measured, - indicates that no significant response was measured, and NM indicates that the response was not measured.

Organism	Mortality	Growth	Gonad Production	Bioaccumulation
A. urtica	+	NM	NM	NM
S. ingentis	-	-	NM	+
L. pictus	+	+	+	+

responses (Table 2). Acute mortality occurred on SMB 50 sludge in *A. urtica* and *L. pictus*, but not *S. ingentis*. No significant chronic effects (growth or molt interruption) were observed in *S. ingentis*, but growth and gonad production were affected in *L. pictus*. Interestingly, accumulation of chlorinated hydrocarbons was observed in both *S. ingentis* and *L. pictus*, but in *S. ingentis* there were no measured effects. This demonstrates that measurement of bioaccumulation does not necessarily imply adverse effects. These results also show that both acute and chronic endpoints should be considered in evaluation of sediment toxicity.

The decrease in trace metals concentrations in both urchin gonads and prawn hepatopancreas is hard to explain. Since the decrease occurred in organisms from all four sediment types, including the control, it may simply reflect the dilution of trace metals in a growing tissue mass. It could indicate that the form of metals (in solution or on very fine particles) producing uptake in the field was not present in the exposure system.

In these exposures, it was not possible to ascribe causes of mortality, or impaired growth and gonad production to any one component in sediment. Effects may be due to any of the contaminants present, some unmeasured contaminant, or the additive nature of many contaminants. In addition, different contaminants may have different mechanisms of toxicity.

Exposures to separate contamination treatments (i.e., hydrogen sulfide only) are planned for this year. Size-specific mortality, growth, and reproduction rates are important terms in most population growth equations. Changes in any of these components probably translate into effects on populations. These exposure experiments are important to help achieve the goal of relating laboratory results to effects on populations in discharge-receiving areas.

Toxicity of Contaminated Sediments to the Amphipod Grandidierella japonica

During the past several years, SCCWRP has been developing and evaluating methods useful for studying the toxicity of sediments in southern California. Reports elsewhere in this volume describe results obtained by using sea urchins (embryos and adults), shrimp, and fish larvae (see pp. 50, 58, and 70). In addition to these test systems, SCCWRP scientists Steven M. Bay and Darrin J. Greenstein have also been developing test methods with a local species of amphipod.

Short-term tests with marine amphipods have been widely used to assess sediment toxicity. This group of crustaceans contains species that burrow or build tubes in the sediment. Previous studies have demonstrated the sensitivity of amphipods to environmentally realistic levels of pollutants (Swartz et al. 1982). The most commonly used species, *Rhepoxynius abronius*, does not occur in high enough densities in southern California to be used in tests. This species is also stressed by the silty sediments characteristic of sewage outfall sites and other contaminated areas.

Initial toxicity studies with amphipods at SCCWRP have focused upon the species *Grandidierella japonica*. This is a tube-dwelling species common in intertidal and shallow estuarine areas of central and southern California. *G. japonica* has several characteristics that indicate its potential value in sediment toxicity studies. This species has a short generation time in laboratory culture (30 days at 19°C) and is tolerant of wide fluctuations in temperature, salinity, and sediment grain size.

Preliminary studies by Dr. Donald J. Reish of California State University, Long Beach (CSULB), demonstrated the utility of this species for sediment toxicity testing. With the assistance of Dr. Marion Nipper, a visiting environmental scientist from Brazil, Bay and Greenstein refined the acute test methods developed at CSULB and also developed a chronic test.

G. japonica was one of three test species used in a survey of sediment toxicity, contamination, and infauna funded by the California State Water Resources Control Board. All of the results from this project will be reported later, when the chemical and statistical analyses are complete. The effects of sediment from several highly contaminated sites in southern California on amphipod survival, reburial, and growth are reported here. To discriminate between pollutant effects and other environmental factors, the sediments were also analyzed for chemical composition, grain size, and organic carbon content.

Sediments were collected from a total of 11 southern California coastal areas (Figure 1). These sites included a relatively uncontaminated reference area, industrialized harbors, and areas adjacent to three large municipal wastewater outfalls. Sediment from the amphipod collection site in Newport Bay was collected for use as a control. A wide range of sediment texture and contamination levels was represented by these locations (Table 1).

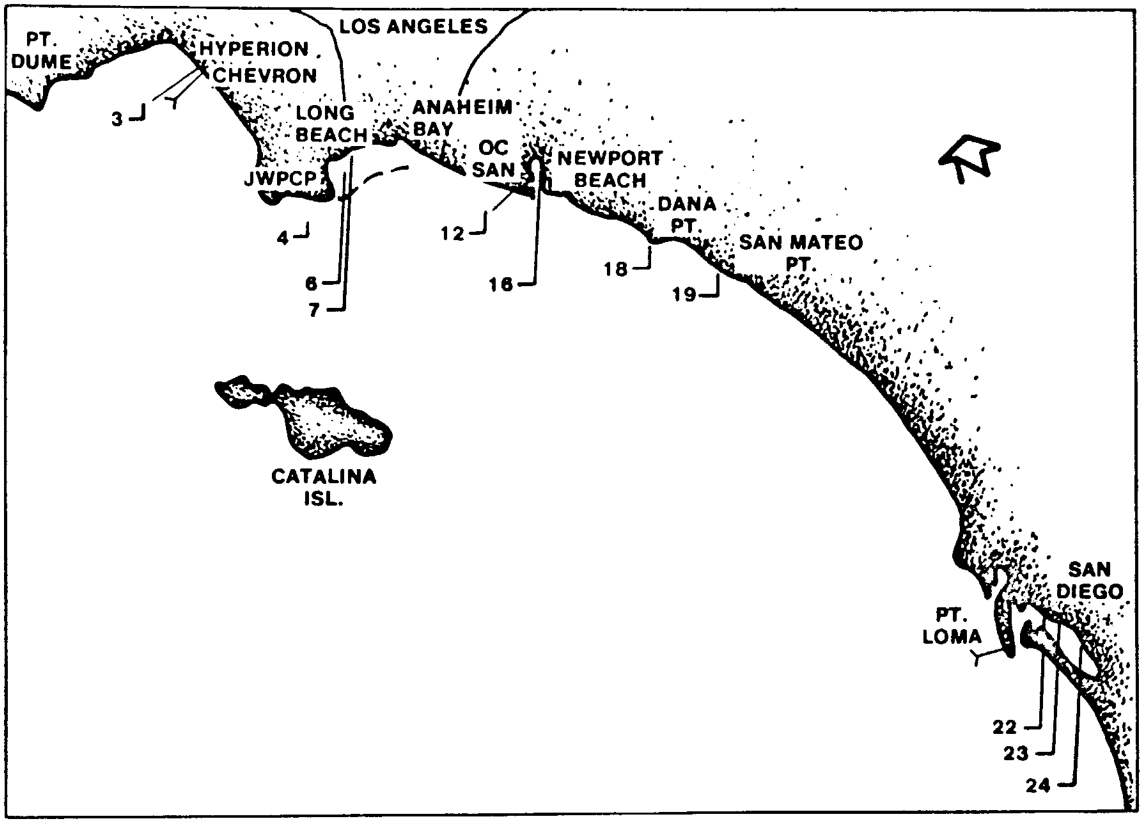

Figure 1. Location of sites examined in this study.

All bioassays were conducted by using flow-through conditions to minimize the effects of contaminants leaching into the water column. The exposure system consisted of 1-L polypropylene beakers containing a 2-cm layer of the test sediment.

G. japonica specimens were collected from Newport Bay. Acute (10-day exposure) bioassays were conducted with young amphipods which had not yet reached sexual maturity. This test was conducted at 15°C according to the procedure described by Swartz et al. (1985) for *R. abronius* and modified for a flow- through system. Animals were not fed during the test.

Bioassays were terminated after 10 days by passing the test sediments through a screen and counting the surviving amphipods. The number of surviving amphipods able to rebury within a 1-h period was also determined. The reburial test was intended to evaluate the organisms' condition, by observing if they responded normally to a favorable environment.

Chronic (28-day) toxicity tests with recently hatched amphipods were also conducted during this study. These tests were conducted on selected sediment types representing contamination from both sewage disposal and harbor activities.

Chronic tests were conducted at 19°C in a manner similar to the acute tests, except that newly released juveniles were used and food was given to the animals throughout the 28-day exposure period. Juvenile amphipods were obtained by

placing egg-laden females in petri dishes containing only seawater. Offspring released from the females 1 to 2 days before the test were used in the bioassays.

Amphipods were retrieved at the end of each experiment by passing the test sediment through a screen. The number and total body length of surviving animals were determined. Growth during the experiment was calculated by subtracting the animals' initial size (determined on a subset of the test population) from their final size.

The 10-day acute exposure produced reduced amphipod survival at most of the highly contaminated stations (Table 2). The lowest survival values were for animals exposed to sediment from the San Diego Bay and sludge outfall stations. The data from the sludge outfall site were highly variable, with survival ranging from 0 to 70% within the three replicates.

A statistically significant decline in acute survival was not found in sediment from Palos Verdes, even though high levels

of chlorinated hydrocarbons were present. Reduced survival was found at stations having total polynuclear aromatic hydrocarbon (PAH) levels above 4,000 ng/g (ppb, dry weight), except for the Los Angeles River mouth and Dana Point Marina stations. Although the Los Angeles River site had substantial levels of hydrocarbon and metal contaminants, amphipod survival was unaffected. An unexpected result was the observation of moderate toxicity at the Dana Point Marina site. Sediment from this location had contamination levels similar to that from San Mateo Point and the Orange County outfall, where survival was greater.

No significant differences were found in the reburial activity of amphipods from the acute test. The lowest reburial percentage (88%) was at the Los Angeles Harbor site. These data indicate that the surviving *G. japonica* did not have reduced activity as the result of exposure to contaminated sediment.

Results from the chronic test of sediment from six locations are shown in Table 2. A different pattern of amphipod survival was observed compared with the acute test results. Survival at the Palos Verdes site was the only value significantly lower than the Newport Bay control value. Significant differences in amphipod growth were found for all of the sites tested, however. The greatest inhibition of growth was found at Palos Verdes, where the change in length during the test was only 16% that of the controls. These chronic test results contrast with the relatively small, acute effects seen for the Palos Verdes site. These data suggest that the high concentrations of chlorinated hydrocarbons or metals at this site may require chronic exposure before toxic effects are expressed or that the process of growth by molting in these crustaceans is very sensitive to the contaminants present at this site.

Significant differences in growth were found for amphipods in the remaining test sediments; these values were 46 to 69% of the control growth. An unexpected result that we found was the reduced growth of amphipods in the San Mateo Point sediment. Amphipod growth in the Orange County outfall sediment was greater than that at San Mateo Point, suggesting that the finer grain size or higher organic carbon content of the sediment may have had an important effect on the chronic test results.

This study has proven the usefulness of *G. japonica* as a sediment toxicity test organism. Both the acute and chronic test results have demonstrated the sensitivity of this species to environmentally realistic levels of sediment contamination. Results from these tests have also corresponded well to results obtained with chronic exposure of the white urchin, *Lytechinus pictus*, to the same sediments.

G. japonica is a suitable alternative to *R. abronius* for use in amphipod tests in southern California. The short life history of *G. japonica* also permits chronic tests with the measurement of sublethal responses such as growth and reproductive success, information necessary for determining the effects of contaminants on population size.

SCCWRP researchers are presently using chronic tests with this species in laboratory studies of the toxicity of individual PAH compounds. This work, also funded by the California State Water Resources Control Board, will further refine these amphipod test methods and produce a greater understanding of how factors such as PAH structure and sediment organic carbon content affect the toxicity of marine sediments.

Sea Urchin Embryo Bioassay Methods For Use with Sediment Elutriates

The suitability of using sea urchin embryo and gamete test methods to assess the toxicity of sediment was evaluated during January-May of 1987. This project was funded by the National Oceanic and Atmospheric Administration (NOAA) as part of a nationwide comparison of several promising sediment bioassays. All participants in the project tested the same sediments, which were collected from sites in and around San Francisco Bay (Figure 1). The sites were selected based on previous studies to form a gradient of contamination, ranging from the control site at Tomales Bay to the most contaminated site at Oakland Inner Harbor. The general order of contamination was Oakland > Vallejo > Yerba Buena > San Pablo > Tomales Bay. The sites had various types of contamination, but high molecular weight polynuclear aromatic hydrocarbons (PAHs) were the dominant chemical group at the most contaminated sites (Table 1).

Steven M. Bay, Darrin J. Greenstein, Karen D. Englehart, and Valerie E. Raco performed SCCWRP's part of the project. Their goals were threefold: (1) to compare the biological responses between the stations, (2) to compare the results of several endpoints of the urchin bioassay, and (3) to compare the responses of three different species of urchins for one of the endpoints. Each of these goals was met with varying degrees of success.

Sea urchin embryo and gamete tests have been used at SCCWRP for many years for the testing of aqueous solutions, such as wastewater effluent and dissolved metal and organic contaminant solutions (Oshida et al. 1981). To provide an aqueous solution from the sediments, the scientists added clean laboratory seawater to the sediments and then allowed this to be stirred overnight. The sediment slurry was then centrifuged, and the overlying water (sediment elutriate) was removed for the assays.

Bay et al. used three species of urchins in this test: the purple urchin (*Strongylocentrotus purpuratus*), the white urchin (*Lytechinus pictus*), and the green urchin (*Strongylocentrotus drobachiensis*). These species were chosen to represent differences in geographic distribution and spawning season.

Four possible endpoints to the urchin assay were investigated. The first endpoint was fertilization success of sperm exposed to the elutriates. For this test, Bay and co-workers employed the methods of Dinnel et al. (1987). The second endpoint was normal embryo development after 48 h of exposure. This involved examining the embryos microscopically and rating their development. Subsamples of these embryos were also used for the third and fourth endpoints, the third being the production of the pigment echinochrome by the embryos. This test used the methods of Bay et al. (1983). The fourth endpoint was a microscopic examination of the embryos for cytologic/cytogenetic abnormalities. This part of the project was completed by Dr. Jo Ellen Hose of Occidental College using methods which she developed (Hose 1985). Only the 48-h development test was performed on the white and green urchins.

The sperm test showed results different from what was expected based on the relative degree of contamination at each station (Table 2). The elutriate samples from the Vallejo and Yerba Buena sites had significantly greater fertilization percentages than the other stations and the laboratory seawater control samples. The 48-h urchin development test showed few differences between stations; however, embryos from the Tomales Bay station had a significantly greater number of abnormalities than the other sites. The echinochrome pigment assay showed that exposure to elutriates from the Oakland, Vallejo, and San Pablo Bay sites resulted in significantly lower pigment production than that for Tomales Bay (Table 2).

The cytogenetic analysis produced the most responsive results and also had patterns which closely followed the contamination gradient. For most of the parameters examined, embryos exposed to Tomales Bay and San Pablo Bay elutriates usually were significantly less affected than those at the other sites (Table 3). The toxicity at Tomales Bay for the 48-h development test was not encountered in cytogenetic analysis, which suggests that the mechanism for the abnormal development was due to something other than genetic damage. The results of the white urchin test were similar to those for the purple urchins, with the Tomales Bay station having the greatest percentage of abnormally developed embryos. The green urchin test was completely unsuccessful as none of the fertilized eggs developed beyond the early cleavage stage. This was probably caused by stress resulting from their shipment from the East Coast.

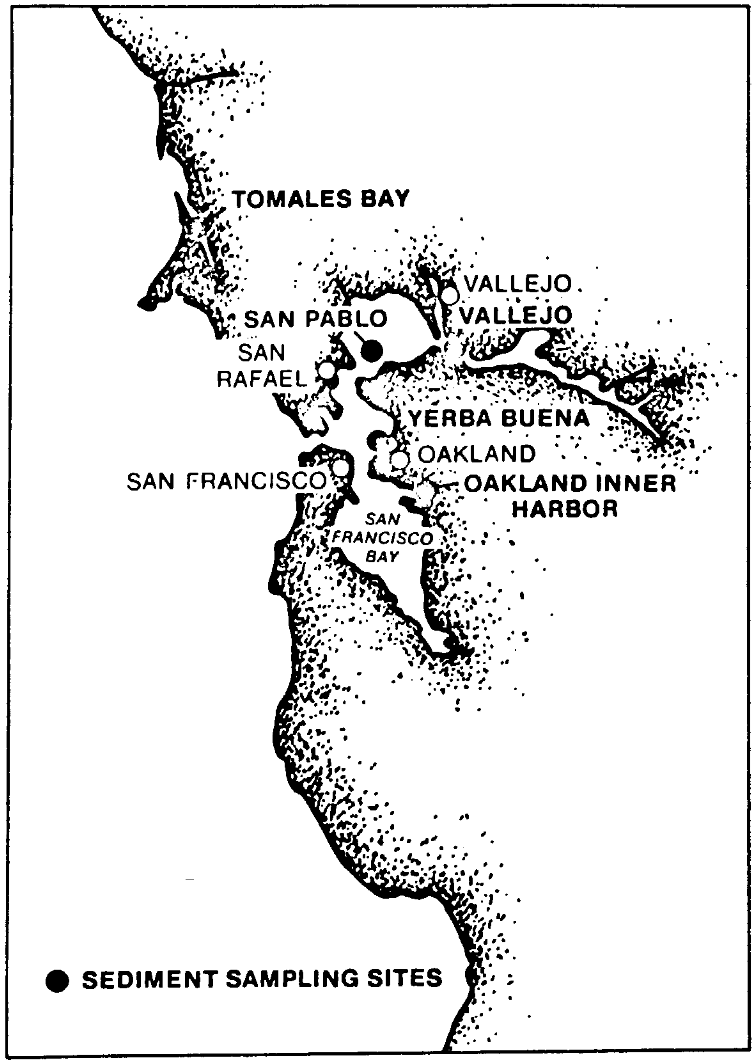

Figure 1. Locations of sediment sampling sites for this study.

One factor affecting the usefulness of an endpoint is the variability of the data between replicates. This variability was expressed as the coefficient of variation (CV, which is the standard deviation divided by the mean). For this project, the

fertilization, percent abnormal development, and echinochrome production endpoints all had low CVs of less than 10%. The cytogenetic endpoints all had moderate to high CVs, ranging from 10 to 118%.

The identification of the specific contaminants responsible for the observed biological effects was not possible in this project because changes in individual contaminant concentrations were highly correlated with each other. However, PAHs seemed to be a likely cause of toxicity because of their high concentrations at the most contaminated sites and previous documentation of their genotoxicity to urchin embryos (Hose 1985).

In conclusion, while all of the endpoints were technically feasible and sensitive, examination of the embryos for mitotic aberrations and cytologic abnormalities was the most useful technique. The variability that was encountered with these endpoints may be reduced by examining more embryos per replicate.

The other bioassay tests of these sediment samples conducted under NOAA sponsorship included a mussel larvae test, amphipod tests with two species, and a polychaete test. Although a great diversity of responses was obtained from all of these tests, many of the responses seen with the sea urchin embryo test methods were also found by the other scientists. A technical report summarizing and evaluating all of the test results from this program is scheduled for production in 1988 by NOAA.

Acknowledgment

This project was funded by NOAA Contract No. 50-ABNC700092.

Wastewater Toxicity Tests

Toxicity tests with sea urchin gametes and embryos have been used at SCCWRP since the late 1970s. This test system has been used effectively for measuring the toxicity of seawater, sewage effluent, and sediment extracts (this report). Several different responses can be measured with this test system including fertilization success of sperm, occurrence of abnormal embryonic development, and production of echinochrome pigment by developing embryos. Sea urchin bioassays were first used at SCCWRP to test the toxicity of sewage effluents in 1978 (Oshida et al. 1981). Effluent toxicity was measured again in 1982 and included samples from southern California's five largest ocean dischargers: Hyperion (City of Los Angeles), Joint Water Pollution Control Plant (JWPCP; Los Angeles County), Orange County, Point Loma (City of San Diego), and Oxnard (Oshida et al. 1983).

SCCWRP scientists Steven M. Bay, Darrin J. Greenstein, Valerie E. Raco, and Karen D. Englehart repeated these effluent tests in April and May of 1987, with the addition of test samples from two smaller treatment plants, Encina and South East Regional Reclamation Authority (SERRA) (located in San Diego and Orange Counties, respectively). In addition to the urchin bioassay, Bay and coworkers also performed the Microtox (Microbics Corp., Carlsbad, CA) bacterial luminescence test (Bulich 1982) on all of the effluents. The objective of this project was to see if a decrease in toxicity that would be expected after improvements in sewage treatment over the past few years could be detected. In addition, the researchers wanted to compare the relative sensitivities of the sea urchin and Microtox test endpoints to aid in their evaluation for routine use in effluent monitoring.

The samples used in this project were 24-h composites of final effluent collected by the dischargers as part of their routine chemical and biological monitoring. This allowed the SCCWRP scientists to compare their results with the measurements of effluent composition and fish toxicity gathered by the dischargers.

The sea urchin bioassay consisted of two parts with three separate endpoints, all performed by using gametes from the purple sea urchin, *Strongylocentrotus purpuratus*. The first part was the exposure of sperm to seawater dilutions of the effluent by using the methods of Dinnel et al. (1987). This was a 60-min test, with the endpoint being fertilization success of eggs added to the solution.

The other two endpoints were measured after a 48-h exposure of fertilized eggs to dilutions of effluent. After 48 h, purple sea urchin embryos normally attain the prism stage of development (Figure 1). Toxic effects were determined by measuring the percentage of normally developed 48-h embryos. The last endpoint evaluated was the amount of pigment echinochrome produced by the embryos. Toxic effects are expressed by a reduction in the amount of pigment present in an extract of an embryo subsample (Bay et al. 1983). The level of pigment in a sample was measured as light absorbance with a spectrophotometer.

The Microtox bioassay involved the exposure of luminescent marine bacteria to dilutions of the effluents. A sodium chloride solution was used as the

Figure 1. Normally developed sea urchin embryo at the 48-h prism stage.

diluent in this test. Toxicity was indicated by the loss of light output after 30 min of exposure.

The results from this study have been expressed as the percentage of change relative to the dilution water control, facilitating the comparison of results from different experiments and test methods. The effluent concentrations chosen for these tests were selected to include the no observable effect concentration (NOEC). This value is defined as the highest effluent concentration tested not resulting in a statistically significant toxic response. The NOEC value has been suggested to be the most appropriate way to describe bioassay results for monitoring purposes.

The results for each of the bioassay endpoints are shown in Table 1. Large differences in effluent sensitivity were found between the different test methods. A similar pattern of relative toxicity between effluent samples was indicated by each method, however. Toxicity was strongly related to differences in effluent

flow at each treatment plant (Table 2). Effluent samples from plants having flows greater than 138 x 10^9 L/yr (100 million gallons per day) usually had much greater toxicity than did effluent from facilities with lower flows. This pattern is illustrated most clearly by the sperm test data (percent fertilized eggs).

The suspended solids content of the effluent samples also appeared to have an influence on the degree of toxicity. Among the larger treatment plants, effluent samples with the lowest suspended solids content (Hyperion and Orange County) generally elicited the least toxic response. Similar results were found for the smaller treatment plants. The Encina effluent sample had the highest suspended solids concentration and greatest toxicity of similar sized treatment plants.

The relationships between toxicity and flow or suspended solids illustrated by these results are to be expected because these parameters serve as general descriptors of the quantity of toxic chemicals likely to be present in the effluent. Large treatment plants (high flow) are often located near areas of increased industrial activity and the suspended solids in the effluent generally contain the highest concentrations of most contaminants. The concentrations of many toxic constituents were measured in these effluent

samples (Table 2). Multivariate statistical analyses are planned to help interpret these data, with the intent of determining which constituents are most closely associated with the toxicity observed.

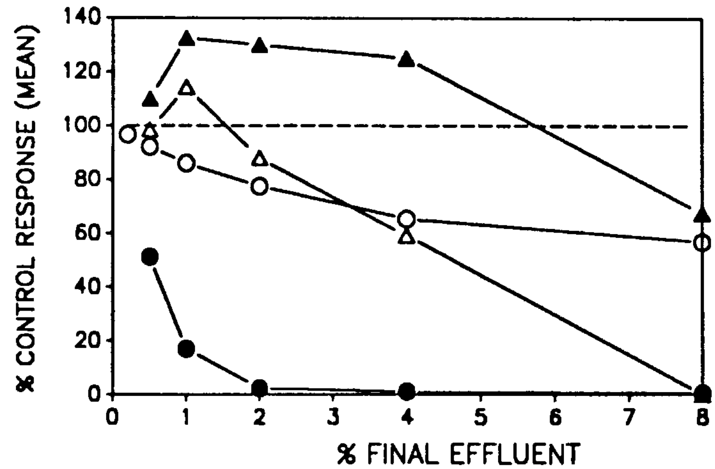

Figure 2. Results of Microtox and sea urchin sperm and embryo tests of Pt. Loma sewage effluent toxicity. The dashed line indicates the control response of 100%. Symbols: O, microtox; ●, sperm; △, % normal after 48 h; ▲, echinochrome.

Temporal changes in effluent toxicity can be identified by comparing these current test results to those from these researchers' 1982 survey, in which only echinochrome was measured (Table 3). The echinochrome data show that a decrease in toxicity has occurred for the effluent from the five treatment plants studied in 1982. Improvements in sewage treatment and source control practices appear to be responsible for these toxicity changes. Comparison of the current chemistry values with the annual averages for 1982 shows decreases in suspended solids, biological oxygen demand (BOD), and many chemical constituents (Table 2).

An important result of this study is the illustration of the diversity of effluent toxicity estimates that can be obtained through the use of different test methods. The variations in test sensitivity to effluent are demonstrated by a comparison of the various test results for the Point Loma effluent sample (Figure 2). For all of the effluents, the sperm test showed by far the greatest sensitivity to effluent; statistically significant reductions in fertilization at effluent concentrations below 1% were found for samples from the largest treatment plants.

The sperm test data cannot be used to determine the NOEC for many of the effluent samples because toxic effects were seen at every dilution tested. The inability to identify a NOEC for a given effluent in this study does not necessarily mean that that sample was the most toxic, since different dilutions were tested in many cases. The fertilization percentages show that the Oxnard and Encina effluents were among the least toxic, even though the NOEC was not bracketed by the concentrations chosen for the test.

The Microtox test also demonstrated toxic effects at low effluent concentrations. Although statistically significant effects were detected at very low concentrations, bacterial luminescence did not change as rapidly with increasing effluent concentration as did the sea urchin test endpoints (Figure 2). As a result, the relative sensitivity of effluent toxicity estimations from Microtox results is dependent upon the data analysis method. If relative toxicity is expressed in terms of the NOEC, the Microtox test is much more sensitive than the 48-h embryo test. If concentrations producing a 50% change (EC_{50}) are used to describe toxicity, the Microtox test is often less sensitive than the sea urchin sperm or embryo test.

The high sensitivity of the sperm and Microtox test methods is probably due to the rapidity of these methods, rather than to biological differences in contaminant susceptibility. Laboratory tests with individual contaminants usually show that the sperm and Microtox tests have similar or lower sensitivities compared with sea urchin embryo tests. The apparent reduced sensitivity of the sea urchin embryo test observed in this study was probably due to reductions in effluent contaminant levels during the exposure from volatilization and adsorption processes.

The State of California will require the use of sensitive marine bioassay tests for effluent monitoring by 1991. The State Water Resources Control Board is considering regulatory policy that would require effluents not to produce toxic effects in these tests at concentrations lower than the one resulting from initial dilution in the ocean. This effluent toxicity study provides an indication of the type of results which can be expected for future monitoring programs. The sperm test is one of the methods recommended by the U.S. Environmental Protection Agency for effluent testing and will probably be used in some monitoring programs in southern California. Results from the sperm tests by Bay et al. indicate that the proposed regulations would be exceeded by most of the effluents tested because toxicity was often found at levels below those produced by the treatment plants' assigned initial dilutions, which range from 0.6 to 1.2%.

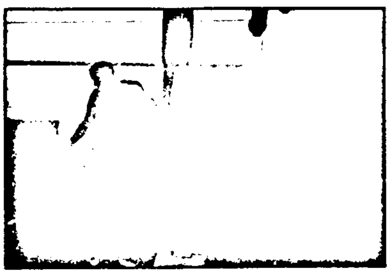
Communications



Sampling at Sea

Scientific research requires collecting various types of information to thoroughly understand oceanographic processes.

SCCWRP uses a variety of small ships and boats which are either made available by our sponsors contributing in cooperative projects or chartered from independent operators.

During the period ending December 31, 1987, our scientific staff conducted or participated in 133 cruises involving 402 man-days at sea. Usually this involved two or more persons (averaging three persons) at sea every working day.

Table 1 shows the distribution of effort by ship, date, and project. The dedication of Harold Stubbs and Dario Diehl, who start early and work long hours in sometimes rough seas, is much appreciated by all who have worked with them.

Historical Review of Monitoring in Southern California for the NRC

The National Research Council (NRC) determined that there was a national need for a comprehensive study of marine monitoring programs. Their study design included at least two case studies of specific regions of the United States where there were public concern and strong historical data bases on marine environmental monitoring. The Southern California Bight was selected as one such region, and SCCWRP scientists compiled a review of monitoring in the region.

Only those programs for which samples were taken at the same locations for at least three years were included in the study. Parameters that were used in the compilation were bacteriological contamination, water column quality, sediment contaminants and infauna, and epifauna including fish. Three primary categories of monitoring programs were noted during this study: (1) municipalities that discharge to the ocean, (2) power plants that are cooled with seawater, and (3) state and federal agencies that collect marine life to determine the dynamics of marine resources.

Historically, monitoring in California began in 1914 with the organization of the Department of Commercial Fisheries, whose responsibilities were to collect statistics; study fishing methods and processing; and learn about fishes, their habits, migrations, and spawning (Clark 1982). Many species were overfished during World War II to try to meet the increased demand for food. After the war, California's tremendous population growth increased water pollution and destruction of the aquatic habitat, and generally put a strain on all marine resources (Croker 1982).

The collapse of the sardine fishery in 1947 prompted the industry to propose and fund the Marine Research Committee (MRC). Revenue that was collected from taxes levied on the purchase or capture of certain species of fish went into the Fish and Game Preservation Fund. This money was dispensed by the MRC to finance research in developing the commercial fisheries of the Pacific Ocean and in developing marine products to be made available to Californians.

In 1948 the MRC established the California Cooperative Sardine Research Program to pursue research on physical and chemical oceanography, productivity, spawning and recruitment of sardines, availability of sardines to the fishery, fishing methods, and dynamics of the sardine population and fishery. In 1953, the program was renamed the California Cooperative Oceanic Fisheries Investigation (CalCOFI) to recognize the expansion of the sardine program to other species (Talbot 1973, Baxter 1982).

By 1960 the objectives of CalCOFI had been reformulated from understanding the sardine's behavior, availability, and abundance to understanding the factors that govern the abundance, distribution, and variations of pelagic marine fishes, emphasizing the oceanographic and biological factors affecting

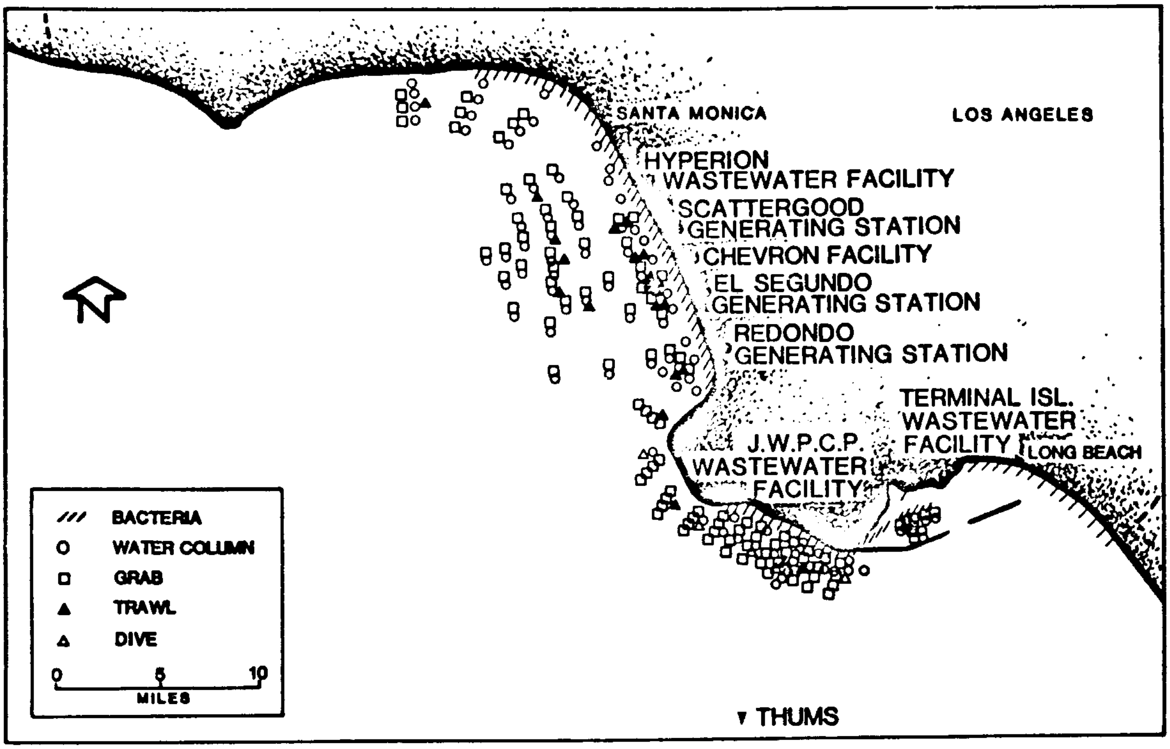

Figure 1. Monitoring efforts in Los Angeles County. Thums, Dump site for Texaco, Humble, Union, Mobil, and Shell Oil Companies.

sardines and their associates in the California Current system (Baxter 1982).

During this study for the NRC, SCCWRP scientists compiled short historical summaries of the activities related to marine monitoring conducted by the State of California and large municipal dischargers, including the Hyperion Wastewater Treatment Plant (City of Los Angeles), the Joint Water Pollution Control Plant outfall at Palos Verdes (County Sanitation Districts of Los Angeles County), CSDOC Treatment Plant No. 2 (County Sanitation Districts of Orange County), and the Point Loma Treatment Plant (City of San Diego). Also included were seven non-nuclear generating stations operated by San Diego Gas & Electric, Southern California Edison, and the Los Angeles Department of Water & Power. A list of monitoring activities and studies was compiled for the Southern California Edison San Onofre Nuclear Generating Station.

Marine monitoring objectives are to document short- and long-term effects of the discharge on receiving waters, sediment, biota, and beneficial uses of the receiving water; to determine compliance with National Pollution Discharge Elimination System (NPDES) permit terms and conditions; and to assess the effectiveness of toxic control programs.

To determine compliance with water quality standards, the receiving-water quality monitoring program must document water quality in the vicinity of the zone of initial dilution (ZID) boundary, at reference stations, and at areas beyond the ZID where discharge impacts might reasonably be expected. Monitoring must reflect conditions during all critical environmental periods.

Receiving-water monitoring comprises the following:

(1) *surf zone monitoring* to assess bacteriological conditions in

areas used for body-contact activities (such as swimming) and to assess aesthetic conditions for general recreational uses (such as picnicking),

(2) *nearshore monitoring* to assess bacteriological conditions in areas used for body-contact sports (such as scuba diving) and where shellfish or kelp may be harvested and also to assess aesthetic conditions for general boating and recreational uses,

(3) *water column monitoring* to determine if the applicant's discharge causes significant impacts on the water quality within the ZID and beyond the ZID as compared with reference stations, and

(4) *ocean current studies* to determine the potential for onshore transport of effluent and to aid in the predictions of effluent dilution and sediment accumulation.

Samples of bottom sediment are analyzed to assess the presence of pollutants and to evaluate the physical and chemical quality of the sediments.

Biological monitoring includes benthic biota monitoring to assess the presence of pollutants in organisms and to monitor the status of the benthic community; trawl sampling to assess the populations of demersal fish, to assess the bioaccumulation of toxic pollutants, and to determine whether a significant difference exists between those populations near the outfall diffuser and those in reference areas; rig fishing to monitor pollutant body burdens in fish consumed by man in order to determine whether the effects of the waste discharge may constitute a threat to public health; and kelp bed monitoring to assess the extent to which the discharge of wastes may affect the aerial extent and health of coastal kelp beds.

Municipal dischargers provide the greatest amount of monitoring data for the greatest cost. The four largest dischargers spend between $1 and 2 million per year on marine monitoring activities. Power plants spend an average of $105,000 per year, but the nuclear generating station at San Onofre requires an expenditure of $1.1 million per year, and an additional $6 million per year was given to the MRC for 10 years for a program designed to measure potential impacts of the station's discharge.

There are numerous specific monitoring programs, ranging from Santa Barbara to San Diego, compiled in this study. Copies of NPDES permits were obtained from the dischargers or the Regional Water Quality Control Boards. These permits provide much useful information including the name of the program, the reasons and objectives for monitoring, and a contact for the program. In addition to the specific monitoring programs, this compilation contains an extensive list of programs funded by dischargers and state and federal agencies that do not qualify as monitoring programs by the standards of this study because although many were conducted for several years, the same measurements at the same stations were not made. However, these programs still provide valuable reports on the physical, chemical, or biological characteristics of locations within the Southern California Bight.

Within the next year the final Southern California Bight case study and the NRC marine monitoring assessment should be available from their office in Washington, D.C. This will be a valuable analysis of the usefulness of monitoring measurements, and we look forward to their recommendations.

Evaluation of Monitoring Methods

Monitoring of the marine environment to determine the effects of wastewater discharge has been conducted since the late 1950s in southern California. Currently, the four largest wastewater dischargers in the region spend over $4 million per year on mandated monitoring programs. These activities have produced an enormous amount of data that have seldom been evaluated. Regional analyses of all monitoring data have not been made.

Beginning about 1978, regulatory agencies, dischargers, and SCCWRP staff began discussing the possibility of a regional monitoring program. These discussions blossomed into a concept called ROMP--Regional Ocean Monitoring Program. Committees to determine sampling design and data management were established and made recommendations on how to set up such a program. Everyone agreed that regional monitoring should be established, but disagreement among regional, state, and federal regulators concerning who should administer the program essentially brought the discussions to a halt.

SCCWRP's role in the regional monitoring discussions was to coordinate the program and provide information necessary for making decisions about monitoring practices in the region. One of the main issues in regional monitoring is the selection of reference sites. SCCWRP felt that under current monitoring programs, the reference sites being sampled were not providing an adequate view of reference areas along the coast. To provide information about reference areas in the region, the 1985 Reference Site Survey was conducted (Thompson et al. 1987). Another issue was that of replication. SCCWRP and EcoAnalysis, Inc. (Ojai, CA) conducted analyses of power and precision of infaunal sampling and trawling (Bernstein et al. 1985, Cross 1983).

The subject of regional monitoring began to surface again in 1987 when the National Research Council (NRC) decided to investigate monitoring practices in the United States with the Southern California Bight as a case study (see p. 85; SCCWRP 1988, NRC [in press]).

The staff of SCCWRP fully agrees with the NRC's findings that regional monitoring is sorely needed in southern California. Setting up such a program will be very difficult. It is essential that all discharge agencies, regional and state boards, and the U.S. Environmental Protection Agency (EPA) agree to participate and to determine program structure and administration. It is also important that representatives of environmental organizations have opportunities for input in the development of the plan and review of progress.

In reviewing the National Pollution Discharge Elimination System (NPDES) monitoring programs of the major sewage dischargers for the NRC, we found that it is not possible to put together a comprehensive regional data base with that data.

By using offshore benthic monitoring programs as an example, different times, depths, numbers of replicates or composite samples, and different suites

Table 1. Partial listing of benthic parameters measured in 1987 southern California monitoring programs.[a]

Parameter		Oxnard	L.A. City Hyperion	L.A. County[b]	Orange County	San Diego Pt. Loma
	No. of sites:	7	39	18 (44)[c]	13 (40)[d]	18

BOD		S	-	-	-	Q
Metals		S	A[e]	5 yr	Q[e] (A)	S[e]
DDTs		S	A	5 yr	Q (A)	S
PCBs		S	A	5 yr	Q (A)	S
PAHs		A	A	5 yr	Q (A)	S
Biology						
Infauna		S	S	S	Q (A)	Q
Trawls		S (3 sta.)	Q (6 sta.)	Q (12 sta.)	S (8 sta.)	S (6 sta.)
Tissue chemistry		A	A	-	S	-

[a]Abbreviations: A, annual; S, semiannual; Q, quarterly; -, not measured.
[b]The NPDES monitoring program was modified in 1988 to include more frequent sediment chemistry monitoring than these data indicate.
[c]An extended 44-station survey is to be conducted every 5 yr or after any major event. Trace chemistry is conducted at these times.
[d]Monitoring is done quarterly at 13 sites and annually at 40 sites.
[e]Metals, DDTs, PCBs, and PAHs are measured as priority pollutants.

of sediment contaminants are sampled in each monitoring program (Table 1).

Infaunal data are collected by all agencies, and all agencies participate in the Southern California Association of Marine Invertebrate Taxonomists (SCAMIT), whose goal is taxonomic standardization. Species names submitted to the Ocean Discharge Evaluation System (ODES) may be consistent within a discharge agency, but there is no provision to merge species lists from two or more agencies and check for standardized species names so that a regional analysis of the data may be accomplished.

Similar problems exist for sediment data. For example, Hyperion, Orange County, and Point Loma are required to measure priority pollutants in sediments, but Los Angeles County is required to measure selected contaminants every five years. Point Loma does not measure total volatile solids (TVS) or total organic carbon (TOC). Although not shown in Table 1, some agencies measure two Aroclor mixtures (polychlorinated biphenyls [PCBs]) while others measure seven. The Southern California Environmental Chemists Society (see p. 91) was organized to standardize analytical chemistry methods which must also be addressed in a regional monitoring program. Not all dischargers use ODES. Therefore, data would have to be requested and verified manually. Most multivariate analyses cannot be performed with data sets that contain such gaps. Standardized regional monitoring could resolve these problems.

Many other technical issues must be resolved before regional monitoring can be established. A few of the important questions are the following:

(1) Which parameters are useful?

(2) How could compliance be determined for each parameter measured?

For example, for sediment contaminants, should the 95% confidence intervals of reference values, or toxicity limits be used as compliance criteria.

(3) How should reference sites be used in monitoring programs?

(4) How can we reconcile statistical significance with environmental significance?

(5) What additional information do we need to facilitate better monitoring decisions?

For example, analyses of power and precision for sediment and tissue contamination parameters have not been made for our region and would help guide decisions on replication, etc.

(6) Is it possible to define a balanced indigenous population?

(7) What if biological parameters are within compliance limits, but sediment parameters are not?

Some portion of the regional plan should be special studies to develop better approaches for determining which organism responses are best for use as early warning signals. Studies on sediment contaminants would be designed to develop better criteria for sediment impacts on biota.

SCCWRP hopes to assist in establishing a regional monitoring program by co-sponsoring a workshop to produce a consensus on the strategy for implementing such a program. Additional technical workshops will need to be held to work out details.

In anticipation of regional monitoring we have compiled a regional demonstration data base that includes permit monitoring data from the Hyperion Treatment Plant, Los Angeles County, Orange County, and Point Loma, as well as the 1985 Reference Site Survey data. It contains data from 93 sites at 30, 60, and 150 m sampled in the summer of 1985. This data base is available for use in addressing the numerous technical questions about regional monitoring, some of which are those listed above.

Most importantly, working together on the NRC case study produced a new spirit of cooperation and interest by southern California discharge agencies and regulatory agencies. That momentum should be carried forward towards a viable regional monitoring program.

SCAMIT and SCECS: An Overview

The Southern California Association of Marine Invertebrate Taxonomists (SCAMIT) was founded as a result of SCCWRP's original Taxonomy Standardization group, which was beginning to suffer from a lack of interest. SCAMIT was instituted in 1982 through a cooperative effort and renewed interest of taxonomists from SCCWRP, sanitation districts from Oxnard to San Diego, and local consulting agencies. Its primary functions are to develop a regionally standardized taxonomy and to disseminate taxonomic information.

Currently, SCAMIT has over 100 members throughout the world, including Mexico, Canada, Belgium, Great Britain, the West Indies, and the USSR. Many members are taxonomists by trade and study the local fauna for laboratories (such as SCCWRP) and consulting agencies, while others teach at universities or work in museums.

Each month, members meet at the Cabrillo Marine Museum in San Pedro, where the SCAMIT library of taxonomic literature and comprehensive listing of local marine invertebrates are stored for the members' use. Different taxonomic groups are chosen for study at each meeting, and representative species from that group are described on a voucher sheet and preserved in a reference collection. The monthly meetings give the members an opportunity to discuss and resolve problems in systematics, which ensures a standardized taxonomy. Members also receive a monthly newsletter that not only provides information concerning the meetings but also contains taxonomic descriptions, keys, and bibliographies.

In addition, SCAMIT hosts special workshops and lectures that are pertinent to taxonomic and ecological issues. Dr. J. L. Barnard is a world authority on gammaridian amphipods and has shared his expertise with SCAMIT at three workshops to date. SCAMIT members bring in specimens they are having problems assigning to a specific taxon and with the help of Dr. Barnard one of three things may be concluded.

(1) The specimen is a new undescribed species which needs to be described in the literature.
(2) The specimen is a currently described valid species.
(3) The systematics of that particular group is confused and needs more work.

At the workshops, SCAMIT members are able to work out taxonomic problems at a much accelerated pace than at their regular meetings.

Southern California Environmental Chemists Society

The Southern California Environmental Chemists Society (SCECS) was founded in 1985 by a group of chemists from municipal wastewater monitoring laboratories and SCCWRP. The purpose in forming SCECS was to promote communication among chemists who analyze environmental samples and to move toward standardizing analytical procedures. Up to this point, the diverse analytical methods and strategies used in monitoring and research programs were not always comparable. Also, it was apparent that the California State Water Resources Control Board and the Environmental Protection Agency would soon be requiring these laboratories to develop analytical capabilities for new classes of compounds (e.g., priority pollutants). Since most members had little experience doing this, it was felt that SCECS would help tremendously to provide an opportunity to interact with chemists who were developing similar methods. Thus the objectives of SCECS are to exchange scientific information on advances in analytical methodology, applications, and findings, and in general, to act as a medium for the improvement of chemical procedures and laboratory efficiency.

An important part of any chemistry program is quality assurance/quality control (QA/QC) and indeed a considerable amount of time and money is spent on QA/QC by analytical laboratories. SCECS also recognized this as an area in which its members needed to have a means of exchanging ideas and improving their understanding of how to manage a high-caliber QA/QC program. Laboratory managers have supported this need and consider time spent at SCECS meetings as an integral part of their QA/QC program; thus SCECS devotes much effort to this subject.

As of May 1988, SCECS had approximately 130 members including chemists from ocean monitoring laboratories and SCCWRP, as well as chemists and biologists from several private laboratories and other government agencies such as the National Oceanic and Atmospheric Administration, the Environmental Protection Agency, the South Coast Air Quality Management District, the California Department of Fish and Game, and the California Department of Agriculture.

Meetings are held every two months and the location rotates to different host laboratories so that members get a chance to experience laboratories other than their own. At each of these meetings specific subjects related to analytical techniques are discussed so that problems can be solved and helpful hints may be shared. Some of SCECS' goals include developing an ongoing intercalibration program, a standard reference material program, and a handbook of systematic analytical methods. SCECS members are currently compiling a manual for sample collection techniques which will aid those who often are not chemists themselves, but who are collecting environmental samples for chemical analysis.

SCAMIT and SCECS assure QA/QC for SCCWRP by integrating the thoughts of many scientists with common goals: standardization of their specialized fields, refinement or introduction of methods, and solutions to problems. Involvement with these organizations leads to improvement of SCCWRP methods by assuring constant refinement of procedures and review of methods used by other organizations. These two vital groups promote standardization of procedures among agencies conducting monitoring and research in their respective fields.

Readers interested in knowing more about SCECS or in joining the Society may contact the SCECS President, Richard Gossett, at (213) 435-7071. For information about SCAMIT membership, please contact Ann Martin at (213) 322-3131 (ext. 317).

New Projects

In addition to conducting studies that are funded by the SCCWRP sponsors, the SCCWRP staff also receives grants and contracts from other government agencies and private organizations. The information gathered through these projects helps in understanding the Southern California Bight, which is a benefit to all concerned. Recently, SCCWRP became involved with two new contracts, one from the U.S. Department of the Interior's Minerals Management service (MMS) and one from the American Petroleum Institute (API).

The Ocean Studies Institute (OSI; a consortium of the California State University campuses at Dominguez Hills, Fullerton, Long Beach, Los Angeles, Northridge, and Pomona) received a 30-month $333,000 contract from MMS to produce a graduate level textbook, which is tentatively titled *Ecology of the Southern California Bight: A Synthesis and Interpretation*. SCCWRP became part of the proposal to provide its expertise regarding the Southern California Bight.

Twenty-four scientists from the Pacific Northwest to Southern California will be contributing to the text which will contain chapters on various aspects of the Southern California Bight including physical oceanography, geochemistry and chemical oceanography, microbiology, phytoplankton, zooplankton, algae and marine spermatophytes, benthic invertebrates, fish, birds, marine mammals, major natural events, anthropogenic inputs and effects, complexity of governance, and ecosystem interrelationships. The project will also provide a current bibliography on the Southern California Bight to MMS, the result of a thorough literature search, which will list research done in the bight.

In addition to writing portions of the text, Murray Dailey (Director of OSI) will oversee the project as Program Manager, Jack W. Anderson (Director of SCCWRP) will aid the project as Publications Editor, and Donald J. Reish (Professor of Biology at California State University, Long Beach) will serve as Science Editor. A review board consisting of several scientists, all with well-known expertise in their respective fields, has been put together by the management team to ensure a high-quality text.

Jack W. Anderson of SCCWRP and Donald J. Reish of California State University, Long Beach, received a $100,000 contract for the first year of research from API to study the effects of produced waters on selected marine species through bioassays. In order to attain these goals, the principal investigators will develop methods for the collection, transport, and dilution of produced water samples; determine the chemical composition of produced water samples during specific time periods; compare mysids with five other organisms to evaluate test procedures and comparative sensitivities; and measure the toxicity of reference compounds and produced water samples with various salinities on five organisms. A second year of funding at approximately the same level is anticipated to complete the project.

MONITORING SOUTHERN CALIFORNIA'S COASTAL WATERS

Panel on the Southern California Bight of the
Committee on a Systems Assessment
of Marine Environmental Monitoring

Marine Board
Commission on Engineering and Technical Systems
National Research Council

NATIONAL ACADEMY PRESS
Washington, D.C. 1990

NOTICE: The project that is the subject of this report was approved by the Governing Board of the National Research Council, whose members are drawn from the councils of the National Academy of Sciences, the National Academy of Engineering, and the Institute of Medicine. The members of the panel responsible for the report were chosen for their special competence and with regard for appropriate balance.

This report has been reviewed by a group other than the authors according to procedures approved by a Report Review Committee consisting of members of the National Academy of Sciences, the National Academy of Engineering, and the Institute of Medicine.

The National Academy of Sciences is a private, nonprofit, self-perpetuating society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare. Upon the authority of the charter granted to it by the Congress in 1863, the Academy has a mandate that requires it to advise the federal government on scientific and technical matters. Dr. Frank Press is president of the National Academy of Sciences.

The National Academy of Engineering was established in 1964, under the charter of the National Academy of Sciences, as a parallel organization of outstanding engineers. It is autonomous in its administration and in the selection of its members, sharing with the National Academy of Sciences the responsibility for advising the federal government. The National Academy of Engineering also sponsors engineering programs aimed at meeting national needs, encourages education and research, and recognizes the superior achievements of engineers. Dr. Robert M. White is president of the National Academy of Engineering.

The Institute of Medicine was established in 1970 by the National Academy of Sciences to secure the services of eminent members of appropriate professions in the examination of policy matters pertaining to the health of the public. The Institute acts under the responsibility given to the National Academy of Sciences by its congressional charter to be an adviser to the federal government and, upon its own initiative, to identify issues of medical care, research, and education. Dr. Samuel O. Thier is president of the Institute of Medicine.

The National Research Council was organized by the National Academy of Sciences in 1916 to associate the broad community of science and technology with the Academy's purposes of furthering knowledge and advising the federal government. Functioning in accordance with general policies determined by the Academy, the Council has become the principal operating agency of both the National Academy of Sciences and the National Academy of Engineering in providing services to the government, the public, and the scientific and engineering communities. The Council is administered jointly by both Academies and the Institute of Medicine. Dr. Frank Press and Dr. Robert M. White are chairman and vice-chairman, respectively, of the National Research Council.

The program described in this report is supported by Cooperative Agreement No. 14-12-0001-30416 between the Minerals Management Service of the U.S. Department of the Interior and the National Academy of Sciences, Contract No. P-32690 with six California municipalities, and State of California Contract No. 6-213-250-0 with the California State Water Resources Control Board. Federal agencies that actively worked with the authoring committee include the Environmental Protection Agency, Minerals Management Service, National Oceanic and Atmospheric Administration, and U. S. Army Corps of Engineers.

Preface

PURPOSE

In 1987, the Marine Board of the National Research Council established the Committee on a Systems Assessment of Marine Environmental Monitoring. The committee's goal was to identify how monitoring contributes to environmental management, to determine why monitoring does not always produce useful information, and to recommend how more effective monitoring programs could be designed. The committee decided to carry out three case studies: the Chesapeake Bay, the Southern California Bight,[1] and particulate dispersion.

The following goals were established for this case study:

- to assess the design of monitoring programs in Southern California in terms of their technical components and linkages to relevant policy issues;

[1] The purpose of this case study was to conduct an overall review and assessment of marine monitoring in the Southern California Bight. Although there is a long tradition of monitoring in the bight, there is widespread concern that intensive monitoring activities are not efficient and that the information that results is not sufficiently used for decision making by governmental agencies. There is also concern that monitoring does not produce a readily accessible, coherent picture of conditions in the bight's marine environment. Accordingly, this study examines monitoring as a system that includes both institutional and technical aspects, then recommends possible improvements to this system. This study thus concentrates on the interface between technical or scientific issues and institutional and policy issues. It does not, other than for illustrative purposes, attempt to describe environmental impacts or actual conditions of marine waters and living resources in the bight.

• to use the assessment to develop guidance for future monitoring practice and institutional frameworks in the region; and

• to assess whether monitoring meets society's needs as manifested in regulations, public opinion, and scientific research.

In pursuit of these goals, this study accomplishes four main objectives:

1. it describes the natural environmental setting, including the physical setting and sources of environmental pollutants and habitat change;
2. it reviews the regulatory and institutional framework, including monitoring responsibilities in the government, academic, and public sectors;
3. it discusses the evolution of monitoring and current monitoring activities in the bight; and
4. it analyzes current monitoring practice in the context of the first three objectives and describes a conceptual framework for improved monitoring.

In combination, these objectives define the overall environmental, regulatory, historical, and institutional framework within which this study assesses monitoring in the bight. The emphasis is on systematic use by regulatory and management agencies of the data collected and not on the technical adequacy of individual collection activities.

METHODS

The Committee on a Systems Assessment of Marine Environmental Monitoring established a case study panel to pursue the goals and objectives described above. The case study panel performed much of its work through a series of fact-finding meetings held throughout Southern California to seek viewpoints from the monitoring community. A planning meeting was attended by panel members, representatives of the California state and regional water quality boards, the U.S. Environmental Protection Agency, the National Oceanic and Atmospheric Administration, municipal dischargers, and various research groups. This initial meeting achieved three results:

1. members identified important issues for the panel to investigate,
2. prepared a list of knowledgeable experts who would be invited to make presentations to the panel about these issues, and
3. specified background information needed for the panel's deliberations.

The Southern California Coastal Water Research Project prepared a report for the panel providing background information for each monitoring program in the bight, including detailed maps and data on sampling design, parameters sampled, sponsoring agency, relevant permits, and cost.

Experts invited to address the panel at subsequent fact-finding meetings were asked to make written and oral presentations. They were asked to consider specific questions about monitoring effectiveness and about their personal experiences with monitoring programs. As a result, the panel received information from experts knowledgeable about and experienced with a variety of issues, including fisheries management, the relationship of large-scale ecological processes to monitoring objectives, institutional relationships, public health, nonpoint sources of pollution, legal and regulatory requirements, wastewater treatment, thermal discharges from coastal power plants, public perceptions and interests, marine science, and monitoring design and implementation. In addition, some panel members made field visits in the region. At the conclusion of these fact-finding sessions, the panel held further meetings to discuss the structure and content of the case study report and to review and discuss draft material.

ORGANIZATION

This case study is organized into seven chapters:

Chapter 1 — The Southern California Bight provides a basic description of the geography, hydrology, water quality, climate, habitats, and natural resources of the area. It also describes land use patterns and economic activities.

Chapter 2 — Sources of Pollution and Habitat Change discusses major activities that result in pollution and habitat change, such as oil exploration and production, municipal and industrial wastewater discharges, power plant thermal discharges, stormwater and surface runoff, aerial fallout, and ocean dumping. It also contains a discussion of the characteristics of the resultant pollutants and their concentrations in the environment.

Chapter 3 — Regulatory Framework and Public Concerns sets forth the basic state and federal regulatory framework (water quality control, public health and safety, and natural resources protection) and the concerns and perceptions of the public about certain policy objectives for the bight.

Chapter 4 — Monitoring and Research Programs in the Southern California Bight discusses the relationship between research and monitoring and the general types of monitoring applied in studies of the bight. It characterizes the roles of government and of the private sector in these activities.

Chapter 5 — A Framework for the Analysis of Monitoring sets forth in general terms the theoretical objectives for a monitoring program and discusses in detail a conceptual framework that will ensure that the objectives are achieved.

Chapter 6 — Analysis of Monitoring Efforts examines specific aspects of certain monitoring efforts in the bight and evaluates the results in light of the conceptual framework and the societal expectations in Southern California. Recommendations for change are set forth in this chapter.

Chapter 7 — Conclusions and Recommendations sets forth the committee's conclusions and recommendations.

THE STUDY'S AUDIENCE

This study was requested by the parent Committee on a Systems Assessment of Marine Environmental Monitoring. Its findings and conclusions and the underlying discussion are an important source of information for the work of that committee. However, because of high interest in the condition of the environment and marine monitoring in Southern California this report will be of substantial interest to parties in that region.

Although environmental monitoring is most often considered to be within the exclusive domain of the scientific community, successful design and use of environmental monitoring depends on a system that reaches beyond scientists. The general public and interest groups have substantive questions about the condition of the marine environment that monitoring must address. Political leaders and policy makers need to make tough decisions about the allocation of monetary resources to particular control strategies, and monitoring results provide information upon which their success may be documented. Public and private managers must implement control programs and be able to predict as well as determine their success or failure on the basis of monitoring information. Finally, the scientific community is vital to the appropriate design and implementation of monitoring programs.[2]

This study, based on an examination of the monitoring system as a whole, makes recommendations about marine monitoring that respond to the needs and responsibilities of all these interests. Thoughtful consideration, debate, and (undoubtedly) modification can contribute to the evolution of marine monitoring in Southern California to make it a strong component of the overall program of environmental protection and restoration.

[2] The incorporation of relevant scientific knowledge in monitoring programs helps ensure that important questions will be properly addressed. Appropriate scientific analysis of monitoring results will also increase understanding of how the marine environment functions and responds to human impacts.

Acknowledgments

The Panel on the Southern California Bight would like to express its gratitude to a number of individuals whose assistance has been invaluable in the development of this report. The committee thanks Dr. Jerry M. Neff for his efforts as rapporteur. Appreciation is also conveyed to Jack Anderson and staff scientists at the Southern California Coastal Water Resources Project for providing the committee with the background document *A Historical Review of Monitoring in the Southern California Bight*, as well as a wealth of additional assistance. Brock Bernstein worked long and hard to shape the final report.

Many thanks also to the following individuals for their valuable input to the report: Blake Anderson of the Orange County Sanitation District, Gary Davis of the National Park Service, Dorothy Green of Heal the Bay, Robert Grove of Southern California Edison Company, Janet Hashimoto of the Region IX office of the Environmental Protection Agency, George Jackson of Scripps Institution of Oceanography, Burton Jones of the University of Southern California, Edward Liu of the Santa Ana Regional Water Quality Control Board, John McGowan of Scripps Institution of Oceanography, John Melbourn of the San Diego Department of Health Services, Richard Methot of the National Marine Fisheries Service, Robert Miele of the County Sanitation District of Los Angeles, John Mitchell of the Los Angeles Department of Public Works, Paul Papanek of the Los Angeles County Department of Health Services, John Stephens of Occidental College, and Ken Wilson of the California Department of Fish and Game.

The committee also expresses its special appreciation to the federal government liaisons who played an integral part in helping to make this a relevant and useful document: Alan Mearns of the National Oceanic and Atmospheric Administration, Brian Melzian of the Region IX office of the Environmental Protection Agency, Fred Piltz of the Minerals Management Service, and Douglas Pirie of the U.S. Army Corps of Engineers.

Finally, a special thanks to the state and local representatives of California whose concern for the region's coastal ocean environment and support for this project allowed this endeavor to transpire: Susan Hamilton of the city of San Diego, Irwin Haydock of the Los Angeles County Sanitation District, Robert Montgomery of the city of Oxnard, Michael Moore of the Orange County Sanitation District, John Norton of the California State Water Resources Control Board, Jan Stull of the Los Angeles County Sanitation District, Frank Wada of the Hyperion Treatment Facility, and Craig Wilson of the California State Water Resources Control Board.

Executive Summary

With nearly 15 million people in the region, Southern California's coastal ocean[1] is coming under increasing environmental stress. There is little coastal space that is not subject to some form of development or resource utilization—including oil extraction, commercial and recreational fisheries, municipal and industrial wastewater discharge, ship traffic, and recreation.

There is in the region a broad public perception of environmental degradation. This is set against a backdrop of extraordinarily complex natural ecosystem processes that are not fully understood, extensive public and private efforts to protect and restore environmental systems, and great public concern for the environment.

Environmental management efforts have included numerous marine environmental monitoring programs. These efforts have been both extensive (for example, the long-term time-series resource assessments of the California Cooperative Oceanic Fisheries Investigation [CalCOFI]) and elaborately detailed, such as the monitoring programs for municipal waste water and electric power plants. The total amount of money and effort expended by public utilities, private industry, and government agencies in marine monitoring efforts in Southern California is conservatively estimated at well over $17 million annually.

[1] This report addresses the region known as the Southern California Bight, the oceanic region from Point Conception, California to Mexico and seaward from the coast to the California Current.

VOL 12

As part of a larger assessment of marine environmental monitoring, the National Research Council analyzed the effectiveness of marine environmental monitoring in the Southern California Bight. The study committee found an extensive system of monitoring of environmental conditions in the bight, but also widespread concern that the system is not efficient and that its products are not sufficiently used for decision making.

The committee found that because monitoring in the bight is predominantly organized around discharge permits responding to water quality regulations, there is a fragmented approach to assessing environmental quality. There are deficiencies in monitoring for public health concerns and nonpoint discharges. Also, there are no existing formal mechanisms for integrating the wide array of monitoring activities and their findings; as a result, it is difficult—if not impossible—to present a coherent picture of the state of the bight as a whole. There is a glaring need for a regionwide monitoring system and for effectively reporting findings to the public, the scientific community, and policy makers.

In response to these findings, the committee recommends that a regional monitoring program be established that would address public health impacts, natural resources and nearshore habitat trends, nonpoint source and riverine contamination, and cumulative or areawide impacts from all contaminant sources.

A regional program should involve participation by the public and scientific communities at local, state, and federal levels and should include built-in mechanisms to communicate its conclusions to regulatory agencies and the public, the committee noted. It should also include review mechanisms and allow easy alteration or redirection of monitoring efforts, whenever justified by monitoring results or other information. Anticipated benefits from a regional program would include:

- *greater cost efficiency* through use of standardized sampling, analysis, data management, and coordination of effort;
- *ability to address specific questions* about environmental conditions and resources and to alter or redirect monitoring efforts as needed; and
- *more effective use of monitoring information* in decision making by ensuring better communication with and involvement by the public and scientific community.

Implementing a regional program will require coordination among local, state, and federal agencies and the integration of their regulatory, data, and management needs. Only through an integrated systemwide approach can important environmental and human health objectives identified by society be successfully attained: ensuring that it is safe to swim in the ocean and eat local seafood, providing adequate protection for fisheries and other living resources, and safeguarding the health of the ecosystem.

1 5014

1
The Southern California Bight

No system of marine monitoring exists in the abstract. Monitoring occurs in specific geographic regions that have particular qualities derived from their natural characteristics and processes. The marine environment in turn is affected by the human activities that take place in and adjacent to it. Understanding the strengths and weaknesses of monitoring in the Southern California Bight therefore requires a basic knowledge of the physical setting and human activity within it.

This chapter describes the physical setting of the Southern California Bight: its bathymetry, drainage basin, circulation and ocean-ography, climate, and hydrology. It also describes the natural habitats and resources of the region and the land use and economic activities of the adjacent coastal areas. Chapter 2 will describe in greater detail the sources and types of habitat change and pollutant loadings to the marine environment that stem from human activities in the bight.

PHYSICAL SETTING

The Southern California Bight is bounded on the north, east, and southeast by a long curve of the North American coastline extending from Point Conception in Santa Barbara County, southeast 357 mi to Cabo Colnett, Baja California in Mexico (Figure 1-1). It is bounded to the west by the California Current, which flows southeasterly approximately parallel to the coast and the edge of the continental shelf. The bight system includes more than 37,000 mi^2 of ocean and approximately 8,700 mi^2 of adjacent coastal areas draining into it.

Bathymetry

The bathymetry underlying the Southern California Bight has many features unique to the continental shelf surrounding the United States. For this reason the area was named "continental borderland" by Shepard and Emery (1941). Topographic features in the continental borderland and adjacent mainland drainage basin are summarized in Table 1-1.

The waters of the bight overlay an alternating series of 2,000- to 8,000-ft-deep basins and surfacing mountains that form 9 offshore islands or island groups and several large submerged banks and seamounts. Nearshore, 12 large submarine canyons influence movement of sediments and other materials deposited on the bottom. There are also 32 submarine canyons on the continental slope bordering the U.S. portion of the bight, including 20 canyons that cut into the mainland shelf (Emery, 1960). Offshore, there are 18 marine basins, 3 of which are essentially anoxic.

These submarine canyons and deep basins are important sites of accumulation of fine-grained sediments and particulate materials from land runoff, ocean discharges, and ocean dumping. An important feature throughout the bight is that deep water is close to shore. All slopes are steep, ranging from 5 to 15 percent. Island and mainland shelves are narrow, from less than 0.6-mi wide to a maximum of 12.5-mi wide. The mainland and island shelves constitute only about 11 percent of continental borderland area; marine basins cover about 80 percent of the borderland area.

The most important embayments of the mainland shelf are Santa Monica Bay and San Pedro Bay (separated from each other by the prominent and steeply sloping Palos Verdes Peninsula and shelf), San Diego Bay, and Todos Santos Bay in Baja California. Although no true estuaries penetrate the mainland coast, there are at least 26 wetland systems in coastal lagoons and at the mouths of transient streams and rivers in the U.S. portion of the bight (Figure 1-2)(Zedler, 1984). The total area of these coastal wetlands is only about 129 mi^2, an estimated 25 percent of the area they encompassed when the first Europeans arrived in Southern California in the late 1500s.

Drainage Basin

The onshore mainland drainage basin of the Southern California Bight, occupied by an ever-increasing human population of nearly 15 million, is a triangle-shaped, higher elevation extension of the offshore bathymetry. It consists of nearly equal areas of mountains and basins or plains (Table

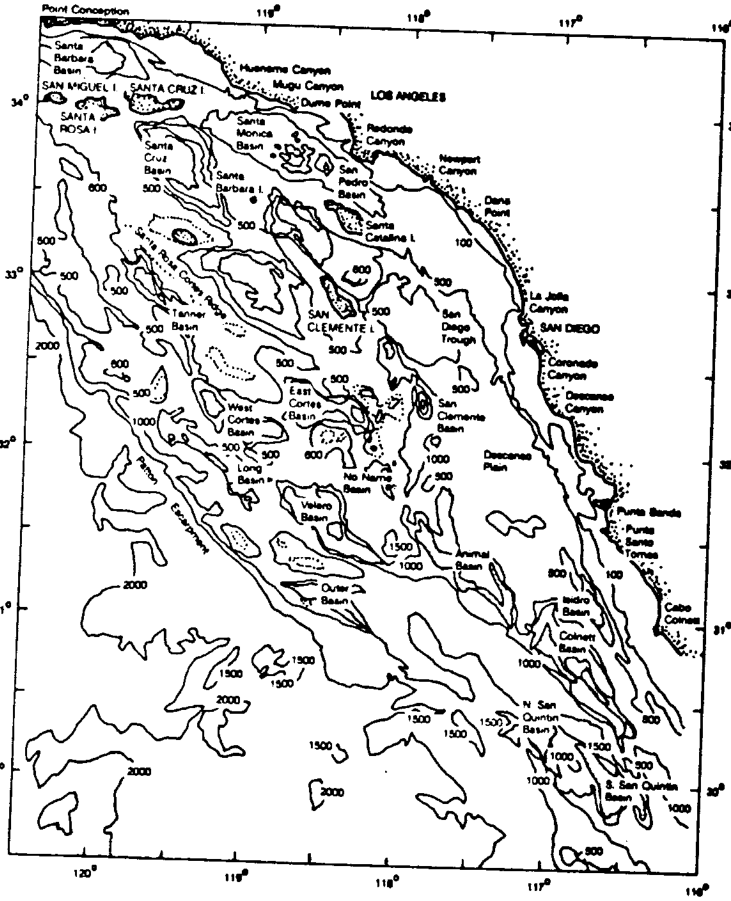

FIGURE 1-1 Bathymetry of the Southern California Bight, emphasizing its deep basins (shaded). Depth contours are shown in fathoms (1 fathom = 6 ft). SOURCE: Moore, 1969.

1-1). The rising shoreline is characterized by vertical scarps and wave-cut cliffs. There are as many as 20 raised marine terraces on land that are an extension of the 5 submerged terraces that lie at depths to 289 ft along the mainland shelf (Emery, 1960).

The drainage basin is bordered on the north by transverse (east-west ranges extending from Point Conception eastward along the Santa Monica,

San Gabriel, and San Bernardino mountains; and on the east by coastal ranges that continue southward down the length of the Baja Peninsula (SCCWRP, 1973). These mountain ranges separate the semiarid coastal plain from the very arid desert basins.

Because of the semiarid nature of the drainage basin and the highly seasonal pattern of annual precipitation, most of the rivers draining into the bight are small and are dry for much of the year. From north to south, the major rivers in the drainage basin are the Santa Clara, Los Angeles, San Gabriel, Santa Ana, San Luis Rey, San Diego, and Tijuana rivers (Figure 1-2). Much of the length of the Los Angeles and San Gabriel river beds and other major drainages are now lined with concrete. Most rivers have dams and debris basins constructed upstream to aid in flood control. In Southern California, there are separate systems to handle stormwater runoff and municipal wastewater flows.

Circulation and Oceanography

The western border of the Southern California Bight is marked by the California Current, which flows southeastward along the coast, continuing the clockwise geostrophic transport of water in the North Pacific Ocean (Figure 1-3). Water current regimes in the Southern California Bight are

FIGURE 1-2 Location of Southern California coastal wetlands and major rivers. SOURCE: Zedler, 1984.

complex and variable on seasonal and longer time scales. Only the general patterns will be described here. Because of the eastward indentation of the coast in the Southern California Bight, a surface counterclockwise gyre, the Southern California Eddy, breaks off the California Current and carries water northward through the central bight (Jones, 1971; Hickey, 1979). The eddy is usually well developed in summer and autumn and weak in winter and spring.

Closer to the shore along the mainland shelf, prevailing onshore (northwesterly) winds reverse this flow, resulting in a net alongshore surface flow toward the southeast at speeds of 1 to 3.3 cm/s (Lentz and Winant, 1979). Hendricks (1977) reported that the mean direction and velocity of water currents just below the thermocline are upcoast at 3 cm/s, and that this near-bottom current has a significant offshore component. Coastal currents reach maximum velocity in water depths of about 197 ft (Jackson, 1986). These complex nearshore currents are interrupted by coastal headlands and upwelling epicenters and respond to both regional and local land-sea breezes. During the afternoon, sea breezes are responsible for both cooling on land and shoreward movement of natural and man-made floating materials.

There is also a very nearshore circulation pattern caused by surf along

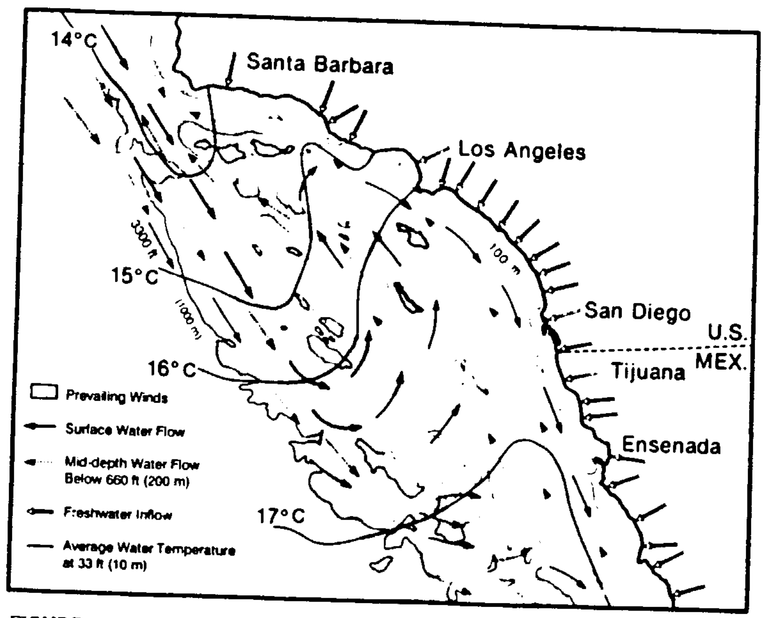

FIGURE 1-3 Patterns of nearshore bathymetry, wind, and ocean circulation in the Southern California Bight. SOURCE: Zedler and Nordby, 1986.

the beaches (Jones, 1971). The surf-driven current consists of transport alongshore inside the breaker zone to zones of outward-flowing water called "rip currents." The rip currents carry water transported inshore by the surf back offshore. This local circulation is important in beach erosion and nourishment and in transport of wastes from offshore discharges and stormwater runoff into and through recreational areas.

Below about 500 ft, there is a northwestward current flow of 25 cm/s or less inshore of the California Current (Figure 1-3). This water is of equatorial Pacific origin and has a higher temperature, salinity, and phosphate concentration and a lower oxygen concentration than the deep water in the California Current located at the same depth but farther offshore (Jones, 1971). This northward flow is weak but progressive through the deep basins and more vigorous along the mainland shelf and slope. Ordinarily, the northward countercurrent does not surface within the bight, except occasionally during the winter. This flow may surface nearshore off Los Angeles in late fall and winter and move northward as the Davidson Current, possibly as far as Vancouver Island, Canada, particularly during the periodic climatic anomalies known as "El Niño" events (described in detail later in this chapter). There is still some uncertainty about the continuity between the Davidson Current and the deep countercurrent in the bight (Hickey, 1979).

Because surface waters in the bight originate primarily from the south-flowing California Current, they are more nutrient-rich, less saline, and cooler (annual range 13° to 20°C) and undergo less seasonal temperature variation than nearshore surface waters at similar latitudes along the east coast (e.g., South Carolina and Georgia). Temperature drops with increasing water depth to about 4°C in the basins. Dissolved oxygen concentration also tends to decrease with depth, such that waters below the sill depths of the Santa Barbara, Santa Monica, and San Pedro basins are periodically or permanently anoxic (Emery, 1960). Due to anoxic conditions, bottom water and sediments in these basins are virtually devoid of higher life forms. The basins are major repositories for sediments and other particulate materials (including sludge) transported onto the shelf from the land and coastal waters.

Climate and Hydrology

The climate of Southern California is like that of the Mediterranean, with most of the precipitation occurring during winter months. Monthly mean temperature and precipitation for Los Angeles and San Diego are summarized in Table 1-2. Monthly mean temperatures in both cities vary by only about 10°C, though periodic extreme temperatures may range over about 35°C. Mean monthly precipitation ranges from near zero in June, July, and August to 2.0-3.3 in. (50 to 85 mm) in December, January, and February.

It is now clear that many environmental changes in the bight are connected more with long-term, low-frequency, interannual patterns than with seasonal cycles. Displacement of cool surface waters—including their inhabitants—in the bight by clear, nutrient-poor warm water is correlated with periodic warm-water events off the coast of Peru and in the tropical Pacific. These are the El Niño events, which occur several times per decade (e.g., 1976, 1979, 1982-1984, 1986-1987) and are characterized by warm water, a deeper surface-mixed layer, elevated sea levels, increased abundance of southern planktonic and pelagic organisms, alterations of benthic community structure, and degeneration of coastal kelp beds (Jackson, 1986). El Niño events and other long-term oceanographic changes also affect the weather in the bight. In some years (e.g., 1969 and 1982-1983) floods rule the coastal plain; in other years drought occurs (e.g., 1976-1977). In some years, there is a deep-penetrating, southerly ocean swell that mixes and resuspends mainland shelf sediments.

SOURCE: Rudloff, 1981.

Crustal blocks between numerous faults move with alarming frequency, causing earthquakes. Oil and tar continuously ooze from shelf and island seeps, periodically creating large marine oil slicks. During some droughts, brush fires, fed by northeasterly Santa Ana winds, spew plumes of ash and soot onto the adjacent sea and coastal plain. Landslides and subsidence are common and predictable in certain hill and bluff areas. In short, the predominantly mild sunny climate of the Southern California Bight area does not reflect the major impacts of occasional meteorological and geological events.

Fresh water enters the bight from a variety of sources. Riverine runoff from rain and melting snow is very seasonal. Much of the water imported from Northern California through the California Aqueduct, from the high Sierra Mountains through the Owens Valley Aqueduct, and from the Colorado River through the Metropolitan Aqueduct (Table 1-3) eventually finds its way to the bight through land and subterranean runoff and discharges of waste water. The cost of wastewater disposal from municipal and industrial activities is 5 to 10 times the cost of supplying the water (World Bank, 1980). Disposal costs for agricultural drainage are about half those of water supply, unless treatment is required.

Because of the semiarid climate of the bight drainage basin, the volumes of water entering the bight from wastewater discharges are comparable to those from riverine and storm drain inputs. Because stormwater flow is more variable than wastewater flow, in dry seasons and years wastewater flow far exceeds that of storm water. For example, the mean treated wastewater flow to Santa Monica Bay between 1967 and 1982 was 346 million gal/day, with the annual mean increasing from 320 million in 1967 to 379 million gal/day in 1982 (Garber, 1987). Stormwater flow to Santa Monica Bay over the same period averaged 143 million gal/day and ranged from 51 million gal/day in 1972 to 400 million gal/day in 1969. However, nearly all of this stormwater flow occurred during and shortly after a few winter storms each year. Thus, the only continuous freshwater flow to the bight is treated municipal waste water. This includes primary, secondary, and tertiary treated sewage discharged directly to the ocean from coastal treatment plants and tertiary treated sewage discharged from inland treatment plants to Southern California rivers and streams. This pattern of freshwater input to coastal waters is quite different from that in much of the rest of the coastal United States, where riverine and stormwater flow far exceeds wastewater flow.

HABITATS AND NATURAL RESOURCES

Natural habitats and resources characteristic of the Southern California Bight include abundant deep water close to shore, extensive coastal

and offshore oil reserves, commercially or recreationally valuable fish and shellfish stocks, wildlife breeding and overwintering areas, kelp beds, beach and water recreation areas, and a climate tempered by the special oceanographic processes reviewed above.

As a result of the local oceanographic regime, particularly the Southern California Eddy, the bight is an enclave of communities of marine life specific to the area, except during El Niño years. It is also a trap for warm water and natural and anthropogenic materials entering the area from land, sea, and air.

Six species of seals and sea lions and the northernmost Pacific population of pelicans breed on several islands. Regional populations of porpoises occur in the bight, and the entire population of gray whales spends a portion of fall and winter there during its annual migration between the Bering Sea and Baja California.

Commercially exploitable stocks of anchovies, sardines, and mackerel spawn and grow primarily in the bight, as do bass, croakers, flatfishes, and rockfishes. Mariculture operations have been established in Agua Hedionda Lagoon in San Diego County (mussels and oysters) and in the Santa Barbara Channel (oysters, mussels, and scallops) (California Department of Health Services, 1988b). Deeper waters of the bight host a diversity of mesopelagic fishes that spend part of their life cycle in surface waters. The benthic fauna of the continental shelf, especially polychaetes and crustaceans, are very diverse and constitute an important food source for many fish species.

Rocky intertidal and subtidal areas, which cover large areas of the shoreline of the bight, host a rich diversity of epifauna (snails, mussels, crabs, etc.) and attached seaweeds. Beds of the giant kelp Macrocystis pyrifera, which attach to the bottom and can grow to over 164 ft in length, extend along the coast of the bight. There are 33 locations in the bight between Point Conception and San Diego where kelp beds are found at least periodically at water depths ranging from 20 to 65 ft. From the 1930s to 1979, individual kelp beds occupied up to 2,720 acres, with the total area occupied by kelp beds in the range of 12,000 to 15,000 acres (Foster and Schiel, 1985). The size and distribution of kelp beds varies spatially and temporally in response to changes in natural and anthropogenic conditions. Natural changes in surface water temperature and nutrient concentrations associated with El Niño events, and possibly with longer-term ocean warming trends, have resulted in declining kelp beds in some areas, and winter storms like those of 1983 and 1987 can devastate large kelp beds. These storms probably are the most important factor influencing the condition and areal extent of kelp beds, but human activities—such as kelp harvests, boat traffic, and possibly wastewater discharges at Palos Verdes and Point Loma—have also affected local giant kelp beds.

LAND USE AND ECONOMIC ACTIVITY

A combined U.S.-Mexico population of about 15 million people lives in, works in, and enjoys the coastal climate and resources in the drainage basin of the Southern California Bight. The population in this area has increased steadily since the 1890s.

Although once primarily an agricultural region, Los Angeles and adjoining counties now comprise the manufacturing, petrochemical, commercial, and aerospace center of western North America. There also are large military bases throughout the area. Accessible land space is now largely occupied by several hundred cities, hundreds of square miles of residential areas, highways, airports, and citrus groves.

Because of current land and water use practices, the entire region is heavily dependent on water diverted from northern and eastern California and the Colorado River system (Table 1-3) that would otherwise flow into the San Francisco Bay and delta area, Mono Lake, the Owens Valley east of the Sierra Mountains, and the Gulf of California. Water utilization in Southern California is projected to increase in the next 22 years due to an expected 16 percent increase in population, and despite a projected slight decrease in per capita consumption of water (Table 1-3). However, at the same time, total freshwater supply will decrease due to partial loss of water rights to the Colorado River. Disputes over other water sources continue, and these supplies are by no means assured for future use by Southern California. As a result, demand will be greater than supply by the year 2010, requiring increased conservation and on-site reclamation.

As described in "Climate and Hydrology," the base flow for most of the Southern California drainage system is now derived from treated waste water (see Chapter 2, Figure 2-2 for further detail). Secondary or tertiary treated sewage from inland treatment plants makes up much of the permanent flow of the Los Angeles, San Gabriel, Rio Hondo, and Santa Clara rivers in Los Angeles and Ventura counties. These discharges, as well as other NPDES-permitted (National Pollutant Discharge Elimination System) flows to the rivers are strictly regulated to protect water-contact recreational areas. However, storm drains and nonpoint source runoff to rivers are not regulated. Such flows may contain elevated concentrations of chemical contaminants and pathogens.

Highways are the principal basis of transportation in Southern California. Heavy manufacturing (metals, chemicals) is located near the coast and within convenient access to well-developed port facilities in Los Angeles, Long Beach, and San Diego harbors. The most active shipping, shipbuilding, and maintenance in western North America occurs in the combined complex of Los Angeles-Long Beach harbors; and military activities occur around Mugu Lagoon and Anaheim Bay (munitions), along the north San Diego County coastline (Camp Pendleton Marine Base), and at San Clemente Island (target practice). The harbors of Long Beach and San Diego were principal Pacific staging areas during World War II (1941-1945) and continue today as active naval and ship building bases.

Oil extraction has occurred for eight decades within and offshore of coastal city limits of Goleta, Carpinteria, Ventura, Oxnard, Santa Monica, Redondo Beach, Wilmington, San Pedro, Long Beach, Seal Beach, and Huntington Beach. Terminal Island and adjoining areas sank up to 30 ft (Allen, 1973) when oil was pumped out in the 1930s and 1940s. Offshore oil extraction from shore-based facilities began near the turn of the century along the Santa Barbara Channel and slightly later in southern Los Angeles and Orange counties. Oil production from offshore platforms began 35 years ago on nearby shelves (1 to 3 mi from shore) and now extends nearly to the shelf break. Proposals for more extensive offshore oil exploration and development in the bight are being hotly debated because many Southern Californians consider them a great potential pollution hazard to the marine environment. An extensive shore-based infrastructure has sprung up to support offshore oil production activities—including pipelines, refineries, produced water treatment facilities, and oil terminals.

Year-round commerce, fisheries, and marine recreation, combined with steady population growth, have resulted in constant development of harbors, marinas, and coastal home sites in Southern and Baja California. The region's 30,000 to 40,000 pleasure boats are concentrated primarily in Marina del Rey on Santa Monica Bay, in the new Los Angeles City Cabrillo Marina, in Alamitos Bay, Long Beach Marina, Huntington Harbor, Balboa-Newport harbors, northern San Diego Bay, and Mission Bay; and secondarily in marinas at Oceanside and Dana Point, and in Oxnard, Ventura, and Santa Barbara. Because pleasure boats are sources of fuel leaks and toxins from antifouling paints, they constitute a potential environmental problem that has not yet been quantified.

Fourteen coastal electric power plants in Southern and Baja California supply much of the region's power and recirculate nearly 11 billion gal/day of nearshore seawater, some of which controls circulation in harbors and marinas. Most generating plants operate on oil delivered by offshore tankers, and oil spills occasionally result from accidents involving tankers supplying fuel to plants in Southern and Baja California (e.g., Nishikawa-Kinomura et al., 1988). For example, in Los Angeles/Long Beach harbors where most of the tanker terminals are concentrated, an estimated 1.3 million gal of oil and fuels have been spilled since 1976; in the Santa Barbara Channel, since 1969 over 3.5 million gal of oil have been spilled from two oil platforms and a tanker collision. The San Onofre Nuclear Generating Station (SONGS) is the only nuclear plant on the coast of the bight.

Much of the region's 1.5 billion gal/day of raw sewage is collected via large-scale intercity networks of trunklines and transferred to 13 coastal Publicly Owned Treatment Works (POTWs) where effluent is subjected to primary, advanced primary, and in some cases secondary treatment and discharged to the ocean via submarine outfall diffusers at depths from 65 to 328 ft. Tertiary treatment currently reclaims almost 150 million gal/day of water, and there is a future potential to reclaim 0.5 billion gal/day. The reclaimed water is used for landscape irrigation, groundwater recharge, industrial processing, and control of saltwater intrusion into coastal aquifers. Storm water is completely separated from sewage in all major systems, but overflows occasionally occur. However, as discussed above, several POTWs discharge secondary or tertiary effluent to Southern California rivers for transport to the ocean. For example, the Los Angeles and San Gabriel rivers each receive about 100 million gal/day of treated waste water. Percolation of storm water into aging sewer lines during storms occasionally overwhelms the system, resulting in release of raw sewage to the bight.

The least developed areas of the bight include the northwesternmost 37-mi stretch of coast between Point Conception and Santa Barbara, the 12-mi coastline of Camp Pendleton in northern San Diego County, the central San Diego County coastline, the Cnannel Islands, and the Baja California coast south of Todos Santos Bay, near Ensenada.

In summary, there is little coastal space that has not been subject to construction, mineral extraction, or other forms of resource utilization. There is keen competition for coastal space, access, and resource utilization and, as a consequence, conflict among the many potential users. The California Coastal Commission, formed as a result of a 1969 ballot initiative, resolves conflicts related to multiple uses of the coastal zone.

SUMMARY

There are several natural and anthropogenic features of the Southern California Bight that are important for the consideration of environmental impacts and marine monitoring in the bight. The continental shelf throughout the bight is very narrow, and deep water exists near shore as a result of the bight's many submarine canyons and basins. The bight's western border is defined by the California Current, and the complex pattern of currents, eddies, and counter currents creates enclaves of indigenous biological communities. Many important environmental processes and changes are related more to long-term, low-frequency, interannual patterns than to yearly or seasonal cycles. The semiarid drainage basin of the bight receives sparse rainfall and much of the human activity in the area depends on imported water. As a consequence, many area rivers are dry much of the year, and wastewater flows constitute the only continuous freshwater input to the bight. Wastewater flows from treatment plants exceed natural flows from runoff and storms. Because waste water and storm water are managed by separate systems, however, the bight does not have the combined sewer overflow problems that characterize other coastal areas in the United States.

The Southern California Bight contains rich biological resources that support diverse commercial and recreational activities. In addition, many marine mammal species, including the entire gray whale population, spend part or all of each year in the bight.

Finally, as a result of Southern California's large population and attendant intense economic and recreational activity, there is little coastal space that has not been subject to construction, mineral extraction, or other forms of resource utilization. This activity has resulted in extensive habitat change and large and varied inputs of contaminants to the bight. These are reviewed in the next chapter.

2
Sources of Pollution and Habitat Change

Southern Californians have lived with contaminants and habitat change since before 1572, when Juan Cabrillo's ship entered the Bahia de Los Fuomos (Bay of Smokes, now Santa Monica Bay) and witnessed coastal Indians sealing their boats with tar from local oil seeps. Today, the ever-growing population of about 15 million has dramatically increased its utilization of marine resources and the types and amounts of contaminants produced and released to the Southern California Bight. These contaminants stem from sewage discharges, aerial fallout, land runoff, industrial and munitions disposal, dredged material disposal, and thermal enrichment. As a result, some of the bight's coastal waters and underlying sediments have become polluted and marine resources have been degraded.

This chapter describes the major human activities that have impacted the bight's marine environment and discusses in detail the various contaminants that may derive from these activities. They include wastes from petroleum exploration and production, radionuclides, pathogenic organisms, waste heat, organic matter, nutrients, trace metals, and synthetic organic chemicals. Since this chapter is intended to provide an overview of contamination, sources and amounts of contaminants—rather than their environmental impacts—are emphasized, followed by a brief overview of the regional and local environmental problems that have attracted public, regulatory, and scientific attention.

MAJOR SOURCES OF CONTAMINANTS

Sixteen municipal sewage treatment plants discharge partially treated sewage directly into the U.S. waters of the Southern California Bight. In addition, more than 230 million gal/day of treated sewage is carried by coastal rivers and storm drains from inland Publicly Owned Treatment Works (POTWs). In 1985, over 1.2 billion gallons of effluent were discharged daily into the bight's coastal waters by seven major municipal wastewater dischargers (Table 2-1 and Figure 2-1).

Over the years, major strides have been made to decrease the amounts of total solids and contaminants in the discharges, even as the total volume of sewage discharges has increased (Figure 2-2) (Southern California Coastal Water Research Project [SCCWRP], 1986a; Summers et al., 1987).

This has been accomplished primarily by a gradual but progressive shift over the last 100 years from discharge of raw sewage, to discharge of primary treated sewage, to discharge of advanced primary and secondary treated sewage (Figure 2-3); by a gradual phaseout of pipeline discharge of sludge; and, most important, by source control. In 1985, 62.4 percent of the total sewage from the seven major dischargers received primary treatment, 37.2

percent received secondary treatment, and 0.4 percent was anaerobically digested sewage sludge, discharged from the Hyperion Treatment Plant.

The Hyperion Treatment Plant operated by the city of Los Angeles discharged sludge from 1957 through 1987 via an ocean outfall in 318 ft of water at the head of the Santa Monica submarine canyon in Santa Monica Bay. The County Sanitation Districts of Los Angeles discharges the liquid phase produced by dewatering sludge by centrifugation. Prior to 1983, this waste water contained high concentrations of solids (sludge). In 1983, new centrifuges with improved solids recovery (90 to 95 percent) came on line, resulting in a significant reduction in solids emissions. The Sanitation Districts of Orange County ceased discharging sludge to the ocean in 1984. The city of San Diego's Point Loma Treatment Plant discharged sludge to the ocean only during emergencies, when a pipeline to the Mission Bay drying beds was inoperative.

Most sewage sludge is now disposed of onshore. However, the shift from primary to secondary treatment results in a substantial increase (approximately double) in the volume of sludge generated. Although it has been suggested that various ocean disposal options may be reconsidered for handling increasing volumes of sludge (Conrad, 1985), ocean dumping is no longer an option. Other possible uses of sludge are composting, use in industrial processes, and landfill cover.

Because the Southern California Bight region is semiarid, design requirements for storm water and sanitary sewer-handling systems are quite different. As a consequence, storm drainage and sanitary sewer systems have been separate throughout the history of the region, unlike nearly all other major U.S. coastal urban areas. Surface runoff from land enters the bight through 150 natural streams (Figure 1-2) and 18 hydrologic units. In addition, there are several major channels in Los Angeles, Orange, and San Diego counties for stormwater runoff. In the Los Angeles County Flood Control District alone, there are 2,000 mi of underground drains, 500 mi of open channels, and 50,000 catch basins. Most of the surface water flow of 405 million gal/day (peak value) enters the bight from 20 major streams and channels, mostly in pulse inputs during winter storms. There are, in addition, hundreds of individual storm drains that discharge directly to the ocean.

Harbors and marinas are sources of local and, in some cases, regional contaminant inputs to the bight. For instance, a 1973 study (SCCWRP, 1973) indicated that 80,000 gal of antifouling paints containing 180 tons of copper were applied annually to many of the 35,000 recreational boats and numerous commercial and naval vessels that use these facilities. Most of this copper eventually dissolved into the water. In recent years, organotin compounds have largely replaced copper in antifouling paints, creating an even greater problem because of their high toxicity to marine animals. San Diego Bay and Los Angeles and Long Beach harbors are contaminated with organotins, with measured concentrations in the water column in the range of 0.02 to 0.93 mg/liter, and concentrations in sediments at least a hundredfold higher (Grovhoug et al., 1986). Many power boats and

submerged metal structures are equipped with sacrificial anodes designed to help prevent corrosion of submerged metal structures. These anodes leach aluminum, copper, and zinc.

Along the coast of the bight, there are 14 steam electricity generating stations that use sea water for once-through cooling. Total cooling-water flow from the plants is about 10.7 billion gal/day. The San Onofre Nuclear Generating Station (SONGS) alone has a base flow of about 2.4 billion gal/day. These flows introduce heat and small amounts of biocides (chlorine), radionuclides, and metals (Table 2-2) into the bight ecosystem. In addition, cooling-water intakes entrain large numbers of fish larvae and plankton and impinge adult fish and other marine organisms. During the special 316b study period from October 1978 through September 1980, Southern California Edison Company's eight coastal power plants impinged an average of 2.2 million fish per year, at an average total weight of 215,000 lbs (Herbinson, 1981). Fish impingement since this study period has averaged approximately half this amount. This is because surf perches, which made up a large percentage of fish impinged during the study period, decreased drastically in abundance during the El Niño periods of the 1980s and have only recently begun to reappear (K. P. Herbinson, Southern California Edison, Co., personal communication).

Other sources of contaminant inputs to the bight include more than 60 discharges permitted under the National Pollutant Discharge Elimination System (NPDES), from coastal industrial operations, more than 25 permitted discharges of produced water from offshore oil and gas platforms, spills, atmospheric fallout, and permitted ocean dumping of dredged material and drilling muds. The volumes of permitted discharges from coastal industries and offshore oil production platforms are small compared to wastewater discharges from municipal treatment plants. The Chevron refinery at El Segundo discharges about 6.5 million gal/day of treated brine and process water to Santa Monica Bay. Offshore oil or gas production platforms may (if permitted by NPDES) discharge up to about 0.25 million gal/day of produced water.

Inputs of various waste waters are not evenly distributed along the coast. Most of the inputs are located between Point Dume and San Mateo Point. They include approximately 82 percent of municipal wastewater effluents, 95 percent of discrete industrial wastewater discharges, 70 percent of power plant cooling water returns, and 71 percent of surface-water runoff. Oil and gas production and associated discharges occur in state and federal waters between Point Conception and Huntington Beach. Thus, there are large areas of the bight north and south of Los Angeles where discharges of waste waters to the bight are minimal.

CLASSES OF CONTAMINANTS

Oil Exploration and Production Wastes and Petroleum

Natural seeps along the coasts of Santa Barbara, Ventura, Los Angeles, and Orange counties intermittently or continuously discharge large quantities of oil and tar to nearshore waters of the bight. Fischer (1978) estimated that as few as 2,000 and as many as 30,000 metric tons (10 million gal) of oil enter the Santa Barbara Channel each year from natural seeps, the best known at Coal Oil Point. (By comparison, the 1989 *Exxon Valdez* oil spill in Prince William Sound, Alaska, leaked 11 million gal of oil into marine waters.) The intertidal zone at Goleta is chronically contaminated with oil and tar from this seep. One hundred years ago, the U.S. Fish Commission steamer *Albatross* dispatched an observer to report on a huge fish kill extending from Santa Barbara to San Diego. He counted thousands of pelagic and demersal fish on the Santa Monica Bay beach at Redondo, many of them smelling of petroleum, and suggested that the event was caused by seepage from offshore "oil springs."

The first offshore oil well in the world was drilled in 1898 from a wooden pier extending into the surf zone near Summerland, California. By the mid-1980s, more than 25,000 oil and gas wells had been drilled in U.S. coastal and outer continental shelf waters. In Southern California, a large number of oil and gas fields has been discovered along the coast, both in state waters and in federal lease tracts between Point Conception and Huntington Beach (Figure 2-4). Additional fields are now being developed in federal waters north of the bight between Point Conception and San Luis Obispo. As of July 31, 1987, a total of 318 exploratory and 633 development

wells had been drilled in federal lease tracts off Southern California, most of them in the bight (Minerals Management Service [MMS], 1987).

As early as the 1920s, state fish and game wardens were frequently citing oil operations for beach spills and fish and shellfish kills. By the 1930s, these officers began reporting cooperation, cleanup, and adoption of preventive measures by the offshore oil industry to avoid oil spills. However, in large part because of the highly visible Santa Barbara Channel oil blowout of 1969, many people in Southern California consider offshore oil exploration and production to be a highly hazardous and polluting activity. In U.S. waters, spill records from offshore platforms show that of 5 billion barrels of oil produced on 41 million acres of offshore tracts leased in federal waters since 1954, 61,000 barrels were spilled (MMS, 1987), less than 0.001 percent of production.

During the 1950s and 1960s, marine life barely existed in the inner

Long Beach and Los Angeles harbors, due mainly to oxygen depletion resulting from the discharge of refinery waste waters directly into the inner harbors (Soule and Oguri, 1979; Reish et al., 1980). By the late 1960s, these inputs were reduced and partly diverted to the Los Angeles County sewage treatment plant at Carson, from which they were discharged with treated sewage off Palos Verdes. The harbors recovered, but their sediments remain heavily contaminated with petroleum hydrocarbons, metals, and other contaminants.

Today, many sources of petroleum hydrocarbon inputs to the ocean are recognized (National Research Council [NRC], 1985), and discharge of treated sewage may be a major source of aromatic and aliphatic hydrocarbons in coastal waters. Eganhouse and Kaplan (1982) estimated that the five largest municipal wastewater treatment plants in Southern California discharge a combined total of 17,400 metric tons per year of petroleum hydrocarbons to the Southern California Bight.

Dunn and Young (1976) measured elevated concentrations of the carcinogenic aromatic hydrocarbon, benzo(a)pyrene, in the mussel *Mytilus edulis* in Southern California. The highest concentrations occurred in mussels collected at harbor entrances. More recently, Anderson and Gossett (1986) confirmed that some Southern California harbor sediments and biota contain elevated concentrations of polycyclic aromatic hydrocarbons. Results of the National Oceanic and Atmospheric Administration's (NOAA) Mussel Watch Program reveal three locations in the bight where mussels contain elevated concentrations of total polycyclic aromatic hydrocarbons: San Diego Bay, Los Angeles Harbor, and Marina del Rey (Boehm et al., 1988). These high-molecular-weight aromatic hydrocarbons are derived from creosoted pilings, industrial (especially refinery) effluents, domestic sewage, oil spills, aerial fallout, and bilge water from ships, particularly crude oil tankers.

It is difficult, if not impossible, to construct a complete mass balance and describe long-term trends for all sources of inputs of petroleum hydrocarbons to the bight. However, inputs of petroleum hydrocarbons in treated sewage are known to have declined as the "oil and grease" fraction of the sewage declined during the last 15 years due to improved removal methods and implementation of source control and pretreatment programs. For the major treatment plants monitored by SCCWRP (1986a), oil and grease discharges decreased by approximately one-half, from 63,000 metric tons per year in 1971 to 34,300 metric tons per year in 1985.

Concentrations of total oil and grease in runoff from land and stormwater flows can be quite high. Gossett et al. (1985) estimated that the mass emission of oil and grease from the Los Angeles River was 28,600 metric tons in 1985. Some of this undoubtedly is derived from treated waste water discharged to the river by sewage treatment plants upstream.

Produced water containing up to 59 mg/liter total oil may be discharged to the ocean. If there were 25 platforms in the Southern California Bight, each discharging 0.25 million gal/day of produced water containing 50 mg/liter total oil, the amount of petroleum discharged each year from this source would amount to 450 metric tons, which is significantly less than the amount discharged from municipal wastewater outfalls in the bight. Refinery discharges have not been quantified but probably contribute a similar amount.

Radionuclides

During the 1940s, 1950s, and early 1960s, atmospheric testing of nuclear weapons by the United States, France, and the Soviet Union in the tropical Pacific, the southwest United States, and elsewhere led to the release of large amounts of radioisotopes into the atmosphere and to significant fallout of radionuclides throughout the Northern Hemisphere. There was considerable concern in California about contamination of leafy vegetable crops. Young and Folsom (1973) reported that in 1967 mussels and barnacles were contaminated with radio-manganese, cobalt, and zinc in a gradient extending from shore to far out to sea. By 1971, these radionuclides were no longer detectable in mussel tissues. Concentrations of plutonium and americium in mussels from the bight are not elevated above normal background values (Goldberg et al., 1978b). Two ocean dump sites designated in the bight for the disposal of radioactive wastes were used between 1947 and 1968. There is continued public concern about possible emissions of radionuclides to the bight from SONGS at San Clemente, and in treated sewage effluents. All discharges to the air and water from SONGS are monitored for radioactivity (Southern California Edison Company, 1987; see also Chapter 4). Sea water from the cooling-water outfall region contained natural background levels of potassium-40, but no radionuclides derived from the station. Ultratrace concentrations of cobalt-58, cobalt-60, silver-110, and cesium-137 derived from the station were detected in fish and invertebrates around the outfalls. Monitoring data from 1979 to 1985 revealed that concentrations of these radionuclides were not increasing over time in the animal tissues. The highest concentrations observed were only 1.8 percent of the levels that must be reported to the Nuclear Regulatory Commission.

Bacteria and Pathogens

Raw sewage was discharged directly into the Southern California Bight beginning before the turn of the century. However, it was not until the 1940s that public concern about the human health risks from pathogens associated with this discharge led to closure of beaches along Santa Monica Bay and in Orange County. During the late 1950s, these beaches were reopened to swimming as treatment practices improved and wastewater outfalls were diverted to deeper locations. Daily monitoring of bacteria has revealed that coliform counts at beach stations in Santa Monica Bay declined by several orders of magnitude between 1945 and 1964, and have since fluctuated around this lower level (Figure 2-5).

In spite of improvements elsewhere in the bight, significant bacterial contamination of swimming beaches persists south of San Diego. This is due to the discharge of raw sewage from Tijuana, Mexico, directly into the surf zone just south of the U.S.-Mexican border or into the Tijuana River, which empties into the bight just north of the border (Hickey, 1986). As a result, Border Field State Park and beaches as far north as Imperial Beach remain under quarantine. This problem persists despite the diversion of up to 13 million gal/day of sewage from Tijuana to the San Diego metropolitan sewer system, which occurred until 1986, when the Tijuana treatment facility came on line. San Diego now only treats emergencies (averaging less than 1 million gal/day). The total sewage flow for Tijuana has been estimated by the U.S. EPA and the International Boundary and Water Commission at between 32 and 38 million gal/day.Today, regulatory limits for coliforms in recreational waters are occasionally exceeded at some beaches following pump failures or overflows at treatment plants or flows into the stormwater drainage system due to infrequent heavy precipitation. Discharge of toilet wastes from recrea-tional vessels can be a major source of bacterial contamination in Newport Harbor and other marinas (Santa Ana Regional Water Quality Control Board, 1985). While regulatory limits have not been established for enteroviruses and other viral pathogens, the presence of such viruses in wastewater effluent and in sea water has been established (Morris et al., 1976).

Concern about pathogens in coastal waters of the bight has historically focused on beaches and the adjacent surf zone. However, increased use of offshore kelp beds by recreational and commercial divers prompted the State Water Resources Control Board to amend the California Ocean Plan to extend monitoring of surface waters for bacterial contamination to offshore kelp beds.

Thermal Discharges

The 14 coastal power plants along the U.S. and Mexican shore of the Southern California Bight generate a tremendous amount of excess heat annually. In 1972 coastal power plants generated an estimated 2 x 107 kw of excess heat (SCCWRP, 1973), and that amount is substantially higher at present. Much of this heat is discharged to the coastal zone

VOL 12

1504 0

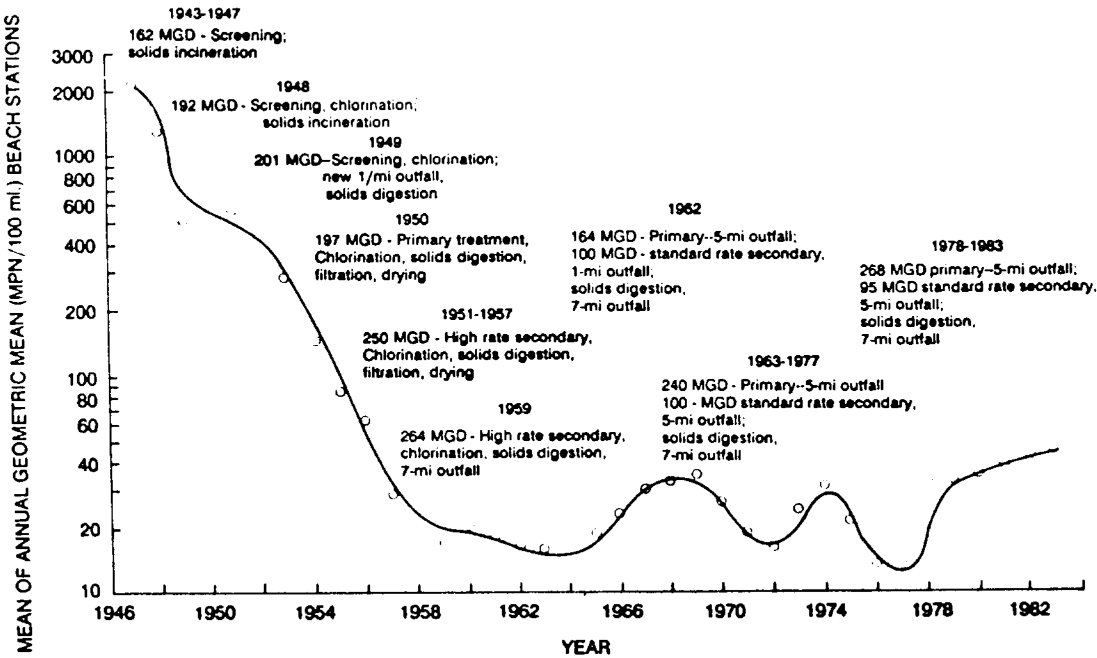

FIGURE 2-5 Counts of coliform bacteria at beach stations adjacent to the Hyperion sewage treatment plant between 1946 and 1983. SOURCE: Garber, 1987.

of the bight as waste heat in once-through cooling water. Approximately 10.7 billion gal/day of sea water is used by coastal power plants in the bight for once-through cooling water (personal communications, Southern California Edison Co., Los Angeles Department of Water and Power, San Diego Gas and Electric Company). This water may be discharged to the ocean at elevated temperatures, provided the temperature of the receiving water does not exceed 4C above ambient at 1,000 ft from the cooling-water discharge (California thermal plan [State Water Resources Control Board, 1975]). The potential effects of thermal discharge have been studied extensively and found to be either minimal or not extending beyond the immediate vicinity of the pipe (Southern California Edison Co., 1973). Traces of biocides and metals dissolved from the cooling coils are discharged (regulated by NPDES permits) with the cooling water.

Particulate Organic Matter and Solids

In lakes, estuaries, and poorly mixed marine basins, high concentrations of organic matter and inorganic nutrients from human and industrial wastes can stimulate bacterial and phytoplankton growth, leading to eutrophication and oxygen depletion. Oxygen depletion of the water can lead to severe damage to benthic and pelagic biotic communities (Rabalais et al., 1985).

The index most frequently used to indicate the tendency of a waste to cause oxygen depletion in the receiving water is the biological oxygen demand (BOD). BOD emissions to the bight have been estimated synoptically only once for all major sources—sewage, runoff, and industrial effluents (SCCWRP, 1973). However, new studies are under way. In 1971 and 1972, about 95 percent of the 297,000 metric tons of BOD discharged to the bight each year was from sewage. By 1985, BOD emissions from the seven major treatment plants had dropped to about 255,000 metric tons per year, and showed a substantial further decrease when ocean discharge of sewage sludge ceased.

It should be noted that since the early 1960s, sewage-derived BOD has been discharged directly to the ocean, not to bays, harbors, or estuaries (discharge of cannery wastes at Terminal Island ceased in 1978). Before that time, serious hypoxia in the bottom waters of Los Angeles and Long Beach harbors and San Diego Bay was nearly chronic. Since the 1960s, depressions in the concentration of dissolved oxygen in the sediments have always been minor in the open bight, even within offshore sewage discharge zones. Depressions of dissolved oxygen in the water column due to wastewater discharge have not been detected. Thus, little benefit to the dissolved oxygen resource is apparent from the substantial efforts to reduce BOD in sewage effluents. This issue merits further investigation.

The total suspended solids emissions in sewage from the seven major treatment plants have declined from 288,000 metric tons per year in 1971 to 205,000 metric tons per year in 1986, due in large part to the use of advanced primary treatment and the progressive shift to secondary treatment (SCCWRP, 1986a). These changes, along with source control, decreased chemical contaminants discharged to the bight (Figure 2-6). These improvements have not been without costs. They have resulted in increased loadings of sludge to landfills and could add to air pollution from sludge incineration in the future. Thus any regional approach to waste disposal options must ultimately consider the tradeoffs among air and water quality and land use.

A budget for suspended solids mass emissions to the bight from all sources has not been completed. Total suspended solids concentrations in stormwater flows have been monitored routinely for many years, but this information has not been synthesized and analyzed for long-term trends. In 1971 and 1972, the amount of suspended solids introduced in stormwater runoff was nearly equal to that introduced in municipal wastewater discharges (SCCWRP, 1973). The amount of suspended solids introduced in nonsewage industrial waste waters is much less than that introduced in sewage and stormwater. In the early 1980s, suspended solids discharged in waste water from five coastal refineries amounted to about 10,000 metric tons per year. By comparison, natural fluxes of suspended solids in the bight, mainly from erosion, are many-fold greater than those due directly to man's activities (Emery, 1960; Kolpack, 1987).

Dissolved Nutrients and Eutrophication

Various forms of nitrogen and total phosphorus are monitored routinely in municipal waste waters, but are rarely monitored in other effluents to the bight. The amount of ammonia nitrogen (the most useful form to phytoplankton) discharged in municipal waste water from the seven largest treatment plants, has not varied much over the years. Between 1971 and 1985, mass emission of ammonia ranged from 36,200 to 56,600 metric tons per year (SCCWRP, 1986a). Discharges of nitrate, nitrite, and organic nitrogen were much smaller and more variable. By comparison, discharges of ammonia in industrial waste water and runoff from land in 1971–1972 was estimated to be 9,500 and 440 metric tons, respectively (SCCWRP, 1973a).

Eppley (1986) compared the rate of input of ammonia and particulate organic nitrogen to the Southern California Bight in waste water to the rate at which these materials are generated by natural biological processes. The flux of ammonia and particulate organic nitrogen in municipal waste water is equivalent to the natural fluxes of these forms of nitrogen taking place under 772 mi^2 and 127 mi^2 of sea surface, respectively. Thus, it is likely

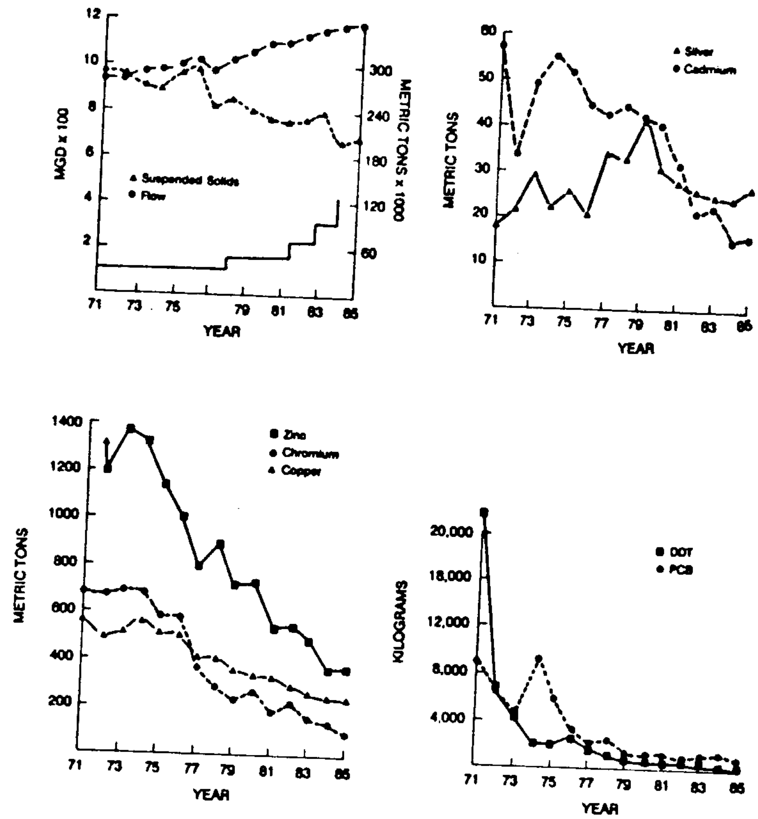

FIGURE 2-6 Mass emissions from seven large municipal sewage treatment plants discharging to the Southern California Bight, 1971 through 1985. SOURCE: SCCWRP, 1986a.

that growth of phytoplankton communities will be stimulated in the immediate vicinity of sewage and refinery outfalls if the waste water is allowed to mix into the near-surface euphotic zone. However, the likelihood of this occurring depends on the location of the outfall. For example, municipal wastewater outfalls discharge at approximately 197-ft depth, well below the thermocline. Refinery outfalls, in contrast, discharge into surface waters. Santa Monica Bay and other coastal waters of the bight have experienced several episodes of elevated ammonia concentrations and blooms of phytoplankton, possibly enhanced by wastewater discharges. Because the blooms

VOL 12

1 5044

are quite rare and wastewater discharges are continuous, it appears that factors other than these discharges play a more important role in causing blooms.

Dairy wastes, irrigation tailwaters, and urban lawn fertilizers in runoff can contribute to eutrophication in coastal estuaries and lagoons. High concentrations of nitrate in runoff water have been implicated in blooms of nuisance algae in Newport Bay (Santa Ana Regional Water Quality Control Board, 1987).

Trace Metals

There have been several attempts to estimate the fluxes of metals to the Southern California Bight from different sources. In studies performed in the 1970s, municipal waste water was found to be the major source of several metals (Table 2-2). In contrast, most of the lead entering the bight came from dry fallout from the atmosphere and stormwater runoff from land, derived primarily from combustion of leaded gasoline in automobiles. Garber (1987) found that from 1967 through 1982 the amounts of lead and mercury entering Santa Monica Bay in stormwater runoff were 40 and 52 percent, respectively, of the amounts entering the bay in municipal wastewater discharges. Garber also confirmed earlier conclusions that wastewater discharges were the major source of all other metals entering the bay. Dry or wet deposition of metal from brushfire smoke may be an additional source of metals in coastal waters (Young and Jan, 1977).

In the past 15 years, municipal sewage treatment plants have undertaken source control programs, enforced stringent pretreatment programs, and adopted procedures (including secondary treatment) that reduce the particulate emissions with which most metals are associated. As a result, the concentrations and mass emission rates of most metals have decreased dramatically in recent years (Figure 2-6). Mass emissions of several metals in sewage have decreased five- to sixfold between 1971 and 1985 (SCCWRP, 1986a). One exception is silver, for which the mass emission rate has increased from 17.7 metric tons in 1971 to 27 metric tons in 1985 (SCCWRP, 1986a).

The history of metal inputs to the bight from all sources is neatly recorded in layered sediments in its basins. They reveal that inputs increased annually through the late 1960s, then began decreasing, probably due to decreases in mass emissions of metals in sewage (Bruland et al., 1974).

Synthetic Organic Chemicals

Polychlorinated biphenyls (PCBs) and the pesticide DDT have been

VOL 12

15045

TABLE 2-3 Estimated Annual Emissions (Kilograms/Year) of Selected Chlorinated Hydrocarbons to the Southern California Bight from Different Sources

Source	Year	Total DDT	Dieldrin	Total PCBs
Municipal waste water[a]	1972	6,490	100	≈ 19,460
	1973	3,920	≤ 280	3,410
	1974	1,580	95	5,290
	1975	1,270	—	3,080
	1976	940	—	2,810
	1977	770	—	1,560
Harbor/industrial	1973-74	40	10	≤ 100
Antifouling paint	1973	< 1	—	< 1
Surface runoff	1971-72	100	20	190-280
	1972-73	320	65	250-830
Aerial fallout[b]	1973-74	1,400	—	1,100
Ocean currents	1973	≤ 7,000	—	≤ 4,000

[a]Values are lower than those in SCCWRP (1986) because fewer treatment plants were considered.
[b]Includes only the inner, nearshore zone of the bight (400 x 50 km).

SOURCE: Young and Heesen, 1978; Young et al., 1981.

monitored extensively in the bight ecosystem since the early 1970s. At that time, municipal waste water was the principal source of these contaminants (Table 2-3), with additional inputs from aerial fallout and surface runoff from land (Young et al., 1976). Garber (1987) reported that between 1967 and 1982, stormwater runoff contributed 7 percent of the total identifiable chlorinated hydrocarbons contributed by municipal waste water to Santa Monica Bay. The DDT came from a local manufacturer, which discharged its wastes into the Los Angeles County sewer system from 1947 to 1971 (Chartrand et al., 1985), and other pesticides and PCBs came from a variety of sources. Analysis of dated sediment cores from the Santa Barbara Basin revealed that deposition (and therefore discharge) of PCBs to the bight began about 1945 and deposition of DDT began about 1952 (Hom et al., 1974).

Gradients of DDT and its breakdown products in coastal mussels and sediments clearly point to the Los Angeles County outfalls as the major source of DDT (Figure 2-7). Body burdens of DDT in commercial fish also are highest off the Los Angeles metropolitan area and decline steadily from Southern California to Alaska, with slight elevations in fish from San Francisco Bay and Puget Sound (Malins et al., 1987; McCain et al., 1988). Among west coast mussels sampled in the NOAA National Status and Trends Program, those from the Los Angeles area had the highest body burdens of DDT (Matta et al., 1985; Boehm et al., 1988). In 1987, mussels from San Diego Bay contained the highest mean concentrations of PCBs along the west coast (2.1 ppm). Mussels from the Los Angeles

VOL 12

15046

area contained a mean of 0.72 ppm PCBs (Boehm et al., 1988). Mussels in the San Diego area have contained elevated concentrations of PCBs since at least 1976 (Farrington, 1983). The source of this contamination is uncertain.

In the 1970s, manufacture and use of DDT and PCBs in the United States were banned by the Environmental Protection Agency (EPA), and since that time emissions of these highly toxic contaminants to the U.S. environment have declined dramatically. With cessation of discharges of DDT to the Los Angeles County sewage treatment plant in 1971, emissions of DDT from the seven largest municipal wastewater plants dropped dramatically, from 21.7 metric tons in 1971 to 6.6 metric tons in 1972 (SCCWRP, 1986a). Emissions of DDT continued to drop each year and were about 58 kg in 1985. Discharges of PCBs reached a peak of 9.8 metric tons in 1972 and have declined gradually to 0.82 metric tons in 1985. This decline is reflected in the sediments of the anoxic Santa Barbara Basin (Hom et al., 1974).

By 1970, the California brown pelican had been driven almost to extinction in U.S. waters from eating DDT- and PCB-contaminated anchovies (Chartrand et al., 1985). Although still on the endangered species list, the bird has made a significant comeback in the 16 years since DDT was banned (Schreiber, 1980).

Much less attention has been paid to fluxes of other synthetic organic chemicals. There is evidence that several other pesticides are important contaminants in municipal waste and storm waters. The state mussel watch program has identified several hot spots of dieldrin, chlordane, and toxaphene in shallow coastal waters and bays. The pesticides aldrin, heptachlor, and heptachlor epoxide were found in tissues of mussels from coastal regions of northern Baja California (Gutierrez-Galindo et al., 1983), but not in mussels collected by the California Mussel Watch Program along the U.S. coast of the bight (Ladd et al., 1984). A possible source of these pesticides is the Tijuana raw sewage discharge at San Antonio de Los Buenos Creek.

Priority pollutant scans of sewage of the effluent in the monitoring programs of the major municipal dischargers have revealed a wide variety of chlorinated solvents and other synthetic organic chemicals. No attempts have been made to date to estimate the fluxes of these chemicals to the bight from different sources.

Ocean Dumping

Fourteen ocean dump sites designated for disposal of a wide variety of waste materials operated for various lengths of time between 1931 and 1973 in the Southern California Bight (Figure 2-8; Chartrand et al., 1985).

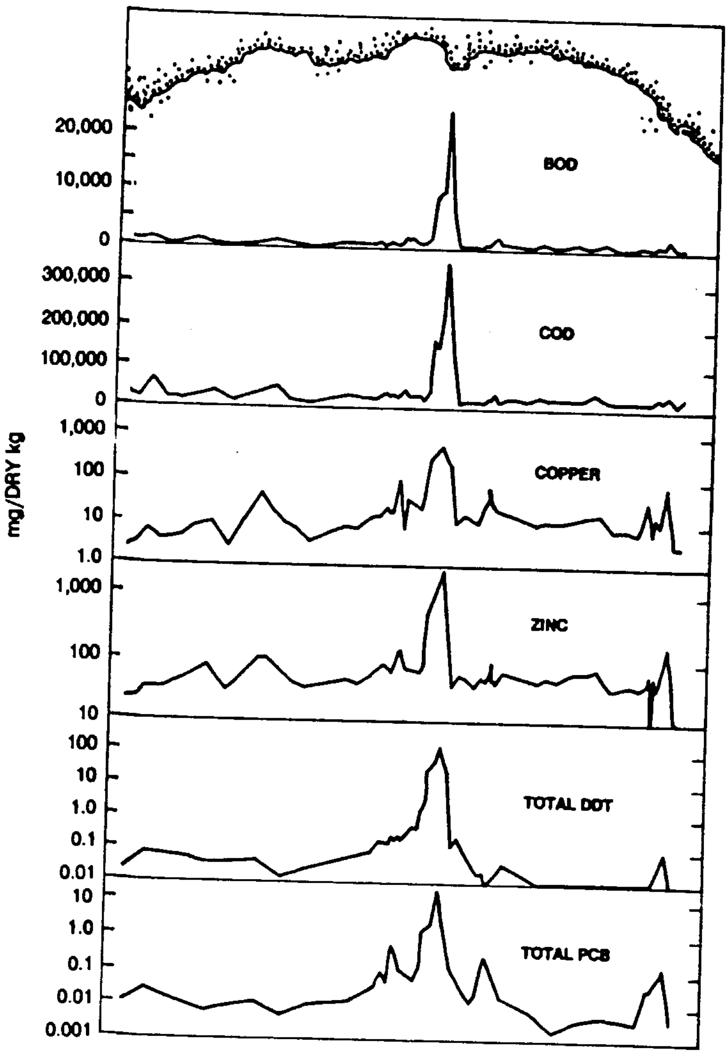

FIGURE 2-7 Variations in concentrations of six materials in surficial sediments from 77 stations along the 60-m isobath during spring and summer, 1978. The large peak is centered around the Palos Verdes discharge. Secondary peaks for some parameters are centered around the other major discharges. The major source of DDT is the Palos Verdes outfalls. SOURCE: Word and Mearns, 1979.

VOL 12

1

5048

Between 1947 and 1961, the California Salvage Company dumped a variety of liquid industrial wastes, including approximately 2,000 to 3,000 gal/day of an acid sludge containing DDT from Montrose Chemical Company, at Dump Site No. 1 located about 10 nautical miles north of Santa Catalina Island. In 1961, the Los Angeles Regional Water Quality Control Board began regulating ocean dumping off Los Angeles County and legal ocean dumping of DDT ceased. All legal ocean dumping at this site ceased in 1973. Chartrand et al. (1985) cite instances of illegal dumping of DDT-contaminated wastes off Palos Verdes in the 1970s.

Since 1977, four open-ocean locations have been designated by the EPA for use by the U.S. Army Corps of Engineers (COE) as interim disposal sites for dredged materials (P. Cotton, U.S. EPA Region IX, personal communication; 40 CFR 228 12A). Dump site LA-1 is off Port Hueneme, LA-2 is off Los Angeles and Long Beach harbors, LA-3 is off Newport Beach, and LA-5 is off Point Loma. Approximately 2 and 3 million yd^3 of dredged material from Los Angeles and Long Beach harbors and San Diego Harbor have been dumped at the LA-2 and LA-5 dump sites, respectively. This dredged material probably was contaminated with a wide variety of chemicals, but no monitoring is being performed to determine if chemicals are being leached from it.

EPA recently designated an ocean disposal site for oil well drilling muds and drill cuttings. The site is about 16 nautical miles from Long Beach Harbor and is near the center of the San Pedro Basin. It has been used by the THUMS Long Beach Company for disposal of drilling muds and cuttings generated during drilling from four islands in Long Beach Harbor.

OVERVIEW OF ENVIRONMENTAL PROBLEMS

Contaminant input, resource exploitation, and habitat modifications due to construction and other economic activity have led to a suite of environmental problems in the Southern California Bight. Some of them are regionwide, while others are relatively localized. It is beyond the scope of this case study to present a detailed review of all environmental problems, however, awareness of their diversity is important to understanding the monitoring programs described and analyzed in Chapters 4 through 6. The following sections therefore present a brief listing of major environmental problems in the bight, and describe two of them in more detail: DDT contamination and the transport of sewage contamination from Mexico into U.S. waters.

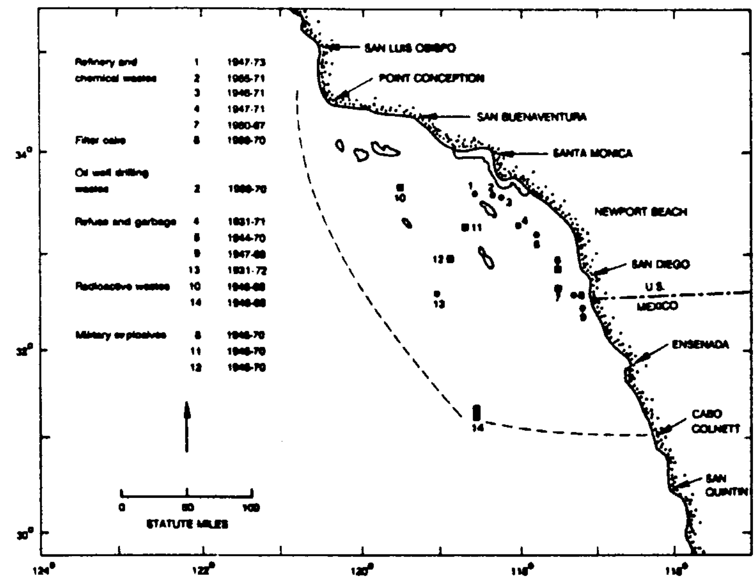

FIGURE 2-8 Ocean dump sites designated and used between 1947 and 1973. The THUMS dump site is near position 2. SOURCE: Chartrand et al., 1985.

Bightwide Environmental Issues

Many environmental problems from both human activity and natural processes in the bight extend throughout the entire bight or are extensive enough that they cross regulatory and legal boundaries. They include:

- impacts on fish and shellfish populations from commercial and sport fishing;
- impacts on fish populations from entrainment of larvae and impingement of adults by coastal power plants;
- large changes in fish populations (e.g., sardines) resulting from incompletely understood interactions between natural environmental changes and fishing activity;
- impacts on individual fish species from loss of nursery habitat due to construction and dredging;
- large changes in the areal extent of kelp beds resulting from natural environmental changes and contamination;

- regional changes in plankton populations due to nutrient enrichment by waste water;
- regional contamination of sediments and biota resulting from toxics in waste water, storm drain, and nonpoint source inflows;
- regional contamination of water resulting from pathogens in waste water, storm drain, and nonpoint source inflows; and
- cumulative effects that derive from the combination of regional and local impacts on specific resources.

DDT Contamination

One regional problem has attracted international attention. In 1967, high concentrations of DDT were reported in fish from California coastal waters (Risebrough et al., 1967). By 1970, it was known that the Montrose Chemical Company was disposing of large amounts of DDT via the Los Angeles County ocean sewage outfalls off Palos Verdes and by ocean dumping. During the next decade, numerous surveys documented the occurrence of the pesticide throughout the bight, south to Baja California, and far up coast to the north in many species of marine animals, including sea birds, seals, sea lions, and porpoises. Retrospective analyses of museum fish and dated sediment samples revealed that regionwide contamination began as early as 1950 (Chartrand et al., 1985). Until it was banned in the United States in the early 1970s, large amounts of DDT were used for agricultural and insect control. Some of the DDT reached the bight in aerial fallout, runoff from land, and municipal sewage (Young et al., 1976).

DDT continues to be used in Baja California and some of it continues to reach the bight in stormwater runoff. In recent years, large concentrations of DDT in mussels from Newport Bay have been reported (Santa Ana Regional Water Quality Control Board, 1985). These increased concentrations may be derived from agricultural soils being plowed or cleared for subdivision development and contaminating stormwater runoff. During the last decade, DDT emissions have been reduced a thousandfold (Figure 2-9) and contamination of intertidal organisms and fishes has declined (Matta et al., 1986). The widespread contamination that resulted from the combination of a large point source and many nonpoint source inputs dramatically illustrates the potential for localized problems to become regional problems over time.

U.S.-Mexico Sewage Contamination

The headwaters and mouth of the Tijuana River are in the United States, although 70 percent of its stream bed and drainage basin lie in

VOL 12

1505 1

the Mexican state of Baja California (Figure 2-10). The river has been used for disposal of raw sewage since the 1920s, and rapid population growth in the Tijuana area after World War II led to the quarantine of Imperial Beach (San Diego County) in 1959. The quarantine was lifted in 1962 after Tijuana completed its sewage system, but was reimposed in 1965 as the system failed repeatedly. As a stop-gap, an emergency pipeline was constructed to carry up to 13 million gal/day of sewage to the San Diego metropolitan system. By 1980, this pipeline was continuously at full capacity. Because of population pressures on both sides of the border, the pipeline agreement is currently being renewed on a year-to-year basis.

By the early 1980s, overflows, leakage, and failures at the Playas de Tijuana Treatment Plant and at other points in the sewer system led to multiple discharges of raw sewage (Figure 2-10)(Hickey, 1986), including the discharge of 1 million gal/day of raw sewage directly to the ocean less than 1 mile south of the Mexican border. In addition, raw sewage from some of the approximately 50 percent of Tijuana's population that is not sewered flows down open channels into the Tijuana River drainage. As a result, Border Field State Park and beaches as far north as Imperial Beach have remained under quarantine.

The regional contamination resulting from uncontrolled sewage flows from Tijuana provides a clear example of how environmental problems can cross regulatory and legal boundaries. As a result, in 1980 the San Diego County Department of Health Services, in cooperation with the San Diego Regional Water Quality Control Board and the U.S. State Department's International Boundary Commission, an agency formed by the U.S. and Mexican governments to deal with trans-border issues, implemented a monitoring program to determine the influence of Mexican sewage discharge on beaches in the border zone.

Local Environmental Problems

Many environmental problems in the bight are local; they are restricted to an area or time surrounding a specific identifiable disturbance or contamination source. Because they are easier to identify and monitor, these localized impacts are more completely understood than bightwide impacts. Localized impacts include:

- changes in benthic infauna around wastewater outfalls;
- changes in the makeup of fish communities around wastewater outfalls resulting from alterations in their food supply;
- contamination of sediments and biota in the immediate vicinity of wastewater outfalls;

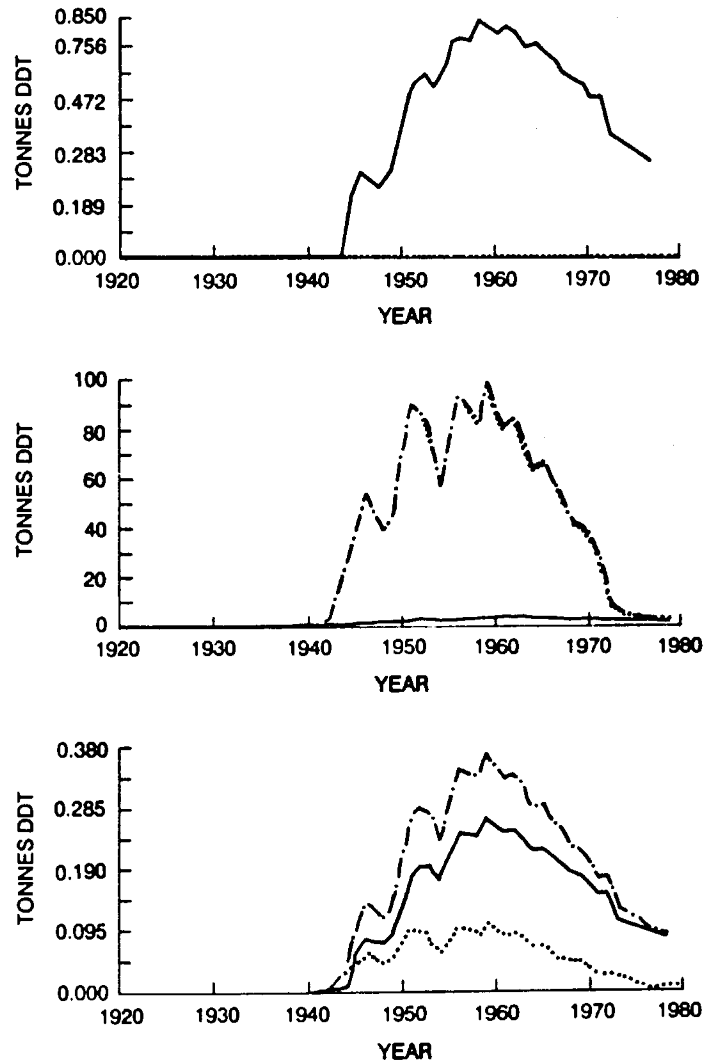

FIGURE 2-9 Total (—), nonpoint (-.-), and point source (...) estimated yearly input of DDT to the Southern California Bight from (a) Santa Barbara and Ventura counties, (b) Los Angeles, Orange, Riverside, and San Bernardino counties, and (c) San Diego County. SOURCE: Summers et al., 1987.

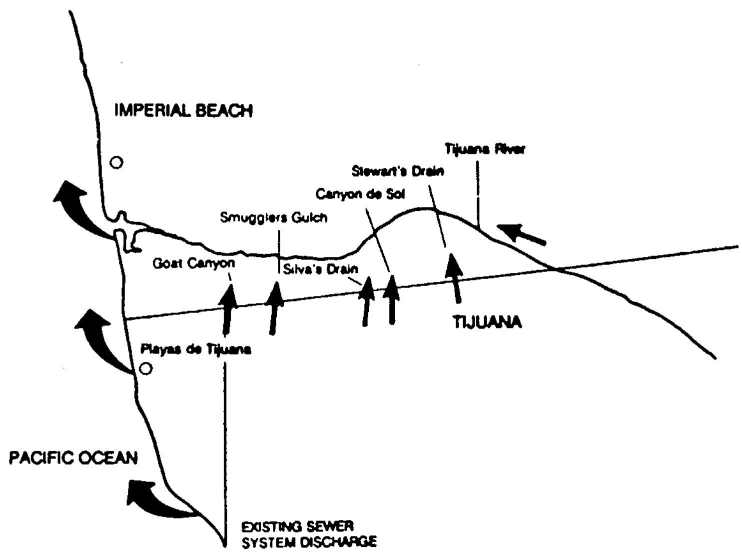

FIGURE 2-10 Locations where raw or partially treated sewage enters U.S. territory from Baja California, Mexico. SOURCE: Hickey, 1986.

- potential effects on kelp beds from the White Point and Point Loma wastewater outfalls and SONGS;
- effects on fish communities from heated power plant effluent;
- contamination of nearshore water in the immediate vicinity of storm drains;
- impacts on benthic communities from disposal of dredged material; and
- impacts on plankton populations resulting from SONGS' effects on nearshore circulation patterns.

SUMMARY

The sources of pollution in the Southern California Bight are quite varied and typical of those found in any highly urbanized coastal area of the United States, except that there are no major riverine inputs. Some of these sources are among the largest (sewage treatment plants) or most extensive (oil production) of their type found anywhere. The range of contaminants discharged is broad, and in some cases the volumes have been among the largest found in the country (for example, the historic DDT discharges through the Los Angeles County sewage treatment plant). In recent years, as a result of control strategies or changed production practices, the amounts of many contaminants discharged have declined dramatically. These reductions have resulted in decreased concentrations in the marine environment.

This great variety in sources and types of pollutants poses a formidable challenge for society as it seeks to impose appropriate controls on discharges to the marine environment. The statutory and regulatory system responsible for achieving these reductions is discussed in Chapter 3. In addition, the complexity of sources and pollutants has resulted in a set of intensive monitoring programs in the Southern California Bight, which are discussed in detail in Chapter 4.

Regulatory Framework and Public Concerns

As public concerns over the condition of the nation's environment grew during the 1970s and 1980s, statutes were enacted to address them. This chapter discusses the major federal, California state, and international laws that address water quality and related issues, and the agencies responsible for implementing them. Many of the decisions made by these agencies in the context of the statutory requirements are based, in part, on information derived from the monitoring system in the Southern California Bight.

Public concern over water quality has not abated, and in many ways has grown sharper in recent years. Hearings held in 1988 on the California ocean plan provided a forum for restating these concerns as they relate to monitoring and are therefore summarized in this chapter.

REGULATORY SECTOR

State and federal agencies have regulatory authority over three types of environmental issues in the Southern California Bight:

1. water quality control,
2. public health and safety, and
3. natural resources protection and management.

Marine Water Quality

The two major federal laws that regulate marine water quality are the Federal Water Pollution Control Act Amendments of 1972 and 1987 (the Clean Water Act, as amended, or CWA), and the Marine Protection, Research and Sanctuaries Act (MPRSA) of 1972. The CWA regulates all discharges into navigable waters of the United States, from fresh waters through the estuaries, the territorial sea (0 to 3 nautical miles—hereafter called the 3-mi limit), the contiguous zone (3 to 12 nautical miles), and beyond (Figure 3-1). It covers pipeline discharges to estuaries, the territorial sea, and federal waters beyond the 3-mi limit. It also covers runoff from land and dumping of wastes (primarily dredged material) from vessels into estuaries. The MPRSA regulates the transportation and dumping of wastes in marine waters from the mean low-water line of the open coast to the outer limit of federal jurisdiction. Thus, the CWA covers pipeline discharges from coastal sewage treatment plants, electric power plants, and commercial and industrial operations to fresh and marine waters, as well as discharges from oil platforms in state and federal waters. The MPRSA covers any dumping of materials from barges or ships into the ocean, including incineration of hazardous wastes at sea.

An important difference between the two laws is that the CWA is a water pollution abatement law and as such is not required to consider effects on the air and land of abatement actions for water. MPRSA on the other hand requires evaluation and assessment of all potential water, air, and land impacts before an action (e.g., dump site designation) can be taken. Thus, pipeline discharge of sewage sludge is illegal under CWA.

The primary purpose of the CWA is to restore and maintain the chemical, physical, and biological integrity of U.S. water resources (Office of Technology Assessment [OTA], 1987). This was to be accomplished by a federal grant and loan program to help municipalities to build or upgrade sewage treatment plants and by pollution control programs with regulatory requirements for industrial and municipal discharges.

The Environmental Protection Agency (EPA) is the federal agency that administers the CWA. In the state of California, the pollution control provisions of the CWA are administered by the California State Water Resources Control Board and the regional water quality control boards under authority of the Porter Cologne Act (Water Code Sections 13000 et seq.).

Section 402 of the CWA authorizes the EPA to establish and administer the National Pollutant Discharge Elimination System (NPDES) permit program. All municipal and industrial facilities discharging directly into navigable waters are required to obtain a NPDES permit. Pollution control is implemented primarily by "end of the pipe" (effluent) limitations on specific conventional chemicals that may be present in the discharge. These limitations are based primarily on considerations of current available technology (technology-based limits). Recently, there has been a growing emphasis on basing permit limitations on consideration of the quality and

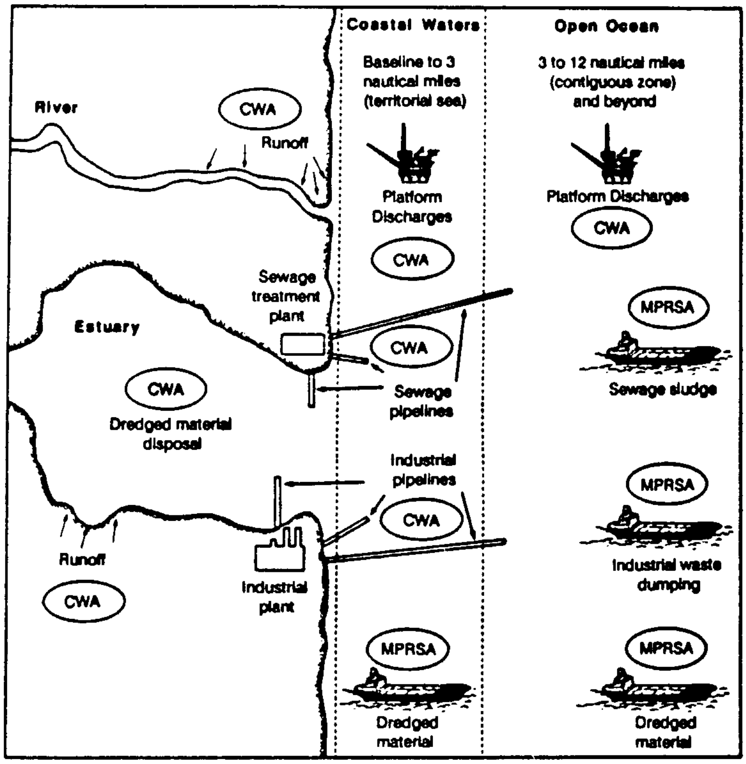

FIGURE 3.1 Jurisdictional boundaries of environmental laws affecting marine disposal.
SOURCE: Office of Technology Assessment, 1987.

uses of the receiving waters (water quality-based limits). Dischargers are required to report periodically on compliance with technology-based limits. In addition, if water quality-based limits are included in the permit and the discharge is to state waters, a monitoring program is required to ensure that water quality standards and requirements are met.

EPA issues permits for discharges outside state waters (beyond the 3-mi limit) and reviews NPDES permits issued by the regional water quality control boards. EPA is also the primary permitting authority for special permits identified by the CWA, such as section 301(h), which authorizes waivers from secondary treatment of effluent discharged into marine waters if water quality objectives to protect the marine environment can be met.

In the bight, the CWA is administered through the State Water Resources Control Board by four regional boards: Central Coast (Region 3), Los Angeles (Region 4), Santa Ana (Region 8), and San Diego (Region 9). The regional boards have primary responsibility for:

- developing and adopting waste discharge requirements (limits on the discharge of wastes to state waters),
- administering monitoring programs (used to determine compliance with permit requirements), and
- developing and adopting water quality control plans (basin plans) within their respective regions.

The state board determines state policy for water quality control and reviews the basin plans developed by the regional boards to ensure that they are consistent with state policy. The state board may also adopt statewide water quality control plans or policies, which supersede the regional basin plans if there is a conflict. Statewide plans and policies dealing with estuarine, coastal, and marine waters of California are:

- the California ocean plan (Water Quality Control Plan for Ocean Waters of California [State Water Resources Control Board, 1983]),
- the California thermal plan (Water Quality Control Plan for Control of Temperature in the Coastal and Interstate Waters and Enclosed Bays and Estuaries of California [State Water Resources Control Board, 1975]), and
- the enclosed bays and estuaries policy (Water Quality Control Policy for the Enclosed Bays and Estuaries of California [State Water Resources Control Board, 1974]).

Statewide and regional water quality control plans designate:

- beneficial uses to be protected,
- water quality objectives (limits or levels of water quality constituents for beneficial use protection), and
- implementation of a program for achieving water quality objectives (waste discharge requirements).

The designation of beneficial uses and water quality objectives constitute water quality standards for California. Waste discharge requirements are derived from the relevant basin or statewide plan.

The California ocean plan sets the scope for most of the discharge-related marine monitoring programs in the bight. The plan has been reviewed three times (1978, 1983, and 1987) and amended twice (1978 and 1983). Additional amendments were proposed in 1988 (State Water Resources Control Board, 1988). These amendments, as well as those to the CWA in 1977, 1981, and 1987 resulted in increased monitoring requirements for dischargers.

The regulatory process and the public are linked by the regional boards, which deal with regional and local regulatory issues. Board members are local residents and the staff deals directly with local governments, agencies, and dischargers. The boards hold hearings for discharge permits, and the staff (and, when appropriate, EPA—e.g., NPDES permits for discharges into federal waters) develop ocean monitoring programs, interpret monitoring results with respect to permit compliance, and inform the public.

The MPRSA, which regulates transportation of materials to be dumped in the ocean or incinerated at sea, authorizes EPA to designate and manage ocean dumping and incineration sites. EPA also evaluates ocean dumping criteria for all permits and issues permits for ocean disposal of materials other than dredged material. The U.S. Army Corps of Engineers (COE), under Title I, Section 103, administers the permit program for disposal of dredged material at ocean sites designated by EPA. However, EPA does have the authority to review applications for dredged material disposal permits. Both agencies must determine that the proposed dumping will not unreasonably endanger human health or the marine environment according to the ocean dumping criteria, and that ocean disposal is the best environmental option.

Section 404 of the CWA regulates discharge of dredged or fill material within the 3-mi limit and in estuaries and wetlands (Figure 3-1). The COE regulates such discharges, using guidelines they developed jointly with EPA (Office of Technology Assessment, 1987). Under Section 401 of the CWA, such discharges must be certified by the affected state as complying with applicable water quality criteria. In the event of a conflict between the state and COE, or outside of COE jurisdiction, the regional boards have independent authority under the California Water Code to regulate such discharges.

Under Title I, Section 107, of the MPRSA, the U.S. Coast Guard is responsible for surveillance and enforcement to prevent unlawful dumping of prohibited material, dumping outside designated ocean dump sites, and illegal transportation of material for dumping. Title I expressly prohibits the disposal of high-level radioactive wastes and chemical and biological warfare agents. Certain other materials are allowed only under certain circumstances.

Title II requires EPA and the National Oceanic and Atmospheric Administration (NOAA) to conduct research and monitoring to assess the environmental impacts of waste disposal.

Title III of MPRSA gives NOAA the authority to establish marine sanctuaries. Inland waters and marine areas as far offshore as the edge of the continental shelf can be designated as marine sanctuaries if such designation is determined necessary to preserve or restore the area for conservation, recreational, ecological, or aesthetic purposes. The Channel

Islands National Marine Sanctuary, located in the bight, is an example. Two international conventions address ocean dumping. The first is the London Dumping Convention (LDC), which was negotiated in 1972 and became effective in 1975. It requires that all signatory nations adopt marine disposal criteria that, at a minimum, are equivalent to and contain the basic constraints of those in the LDC. The United States, Mexico, and 59 other countries have ratified the LDC. In 1974, the MPRSA was amended so that all U.S. marine disposal criteria would be consistent with and contain all the basic constraints set forth in the LDC.

The second agreement, the International Convention for the Prevention of Pollution from Ships (1973 and protocols of 1978, known as MARPOL 73/78) regulates discharges from ships. Annex 1 (covering discharges of oil) and Annex 2 (covering discharges of bulk chemicals) have been ratified by the required number of nations and are in effect. Annex 3 (covering sewage discharges), Annex 4 (covering hazardous substances in packaged form), and Annex 5 (covering garbage) await approval. The U.S. Senate recently enacted the Marine Plastic Pollution Research and Control Act of 1987 (P.L. 100-200, Title II, Sections 2001 to 2305), which includes provisions of Annex 5 of MARPOL 73/78 and prohibits ships from dumping plastics anywhere in the ocean and from discharging garbage to the ocean within 12 mi of shore, including the bight. Ports will be required to provide garbage disposal facilities for ships, and ship captains will be required to keep a waste management log, which must be available to port officials.

Public Health and Safety

State and federal agencies with primary responsibility for public health and safety within the bight's waters and along its shores are the California State Department of Health Services (DHS), the county and municipal public health agencies, and the federal Food and Drug Administration (FDA). The California Health and Safety Code and the California Administrative Code authorize the DHS to supervise sanitation, healthfulness, and safety of public beaches and public water-contact sports areas. The main focus of DHS monitoring activities is marine recreational areas from the beach out to a depth of 30 ft or 1,000 ft from shore, whichever is farther (the surf zone), and coastal kelp beds. DHS has been relying on bacteriological standards developed in 1942 (total and fecal coliforms) to judge the safety of water bodies (California Department of Public Health, 1943). When standards are exceeded, DHS or local health officials may post warning signs or declare beach closures. Permanent warning signs have been posted in the vicinity of major storm drain outlets into Santa Monica Bay and near the U.S-Mexican border. Upper Newport Bay has been closed to water-contact sports since 1974 (Santa Ana Regional Water Quality Control Board, 1985).

Under present laws and regulations, DHS can close fishing and shellfishing areas because of bacterial contamination and the presence of paralytic shellfish poisoning (PSP) organisms in marine animals. Since 1978, upper Newport Bay has been closed to shellfish gathering for human consumption because of bacterial contamination from the bay drainage area (Santa Ana Regional Water Quality Control Board, 1985). A commercial shellfish growing operation in Agua Hedionda Lagoon in San Diego County is required by its state permit to cease harvesting for seven days after rain in excess of 0.25 inches due to bacterial contamination from the lagoon watershed (California Department of Health Services, April 7, 1988). The DHS has maintained that elevated fecal coliform levels in coastal waters and in shellfish meats at a mariculture operation in the Santa Barbara Channel have resulted from the intermittent impact of undisinfected sewage effluent from both the Goleta and Santa Barbara wastewater treatment plants. In 1987, the Goleta plant initiated disinfection of its effluent prior to discharge (California Department of Health Services, 1988b, letter to Pacific Seafood Industries).

There is no specific authorization under current law to close fishing and shellfishing areas due to chemical contamination. Until recently, there was no systematic sampling of edible tissues of fisheries products from the bight to evaluate potential effects on human health from chemical contamination. However, the DHS recently issued a health advisory warning against consumption of white croaker from the Santa Monica Bay, Palos Verdes Peninsula, and Los Angeles Harbor areas because of heavy DDT and PCB contamination.

The DHS is also overseeing a year-long assessment of chemical contamination of recreational and commercial fish sampled from 25 areas in the bight. More recently, experimental quantitative risk assessment methods have been used to evaluate suspected or potential human carcinogens in fishery products. Such methods may lead to estimates of health risks from levels of contamination well below current FDA action limits.

Monitoring for coliform or other enteric bacteria is also a part of all monitoring programs administered by the regional water quality control boards and EPA around municipal wastewater outfalls. This bacterial monitoring is intended to track the wastewater plume and evaluate possible hazards to the water contact recreation shorelines.

Natural Resource Protection and Management

Several state and federal resource agencies are involved in protecting and managing the natural resources of the Southern California Bight. The

California Department of Fish and Game, the National Marine Fisheries Service (NMFS) of NOAA, and the Fish and Wildlife Service (FWS) of the U.S. Department of the Interior (DOI) are all involved in protecting and managing living marine resources. Their activities include fish stock assessments and habitat protection. The State Lands Commission is responsible for leasing tidal and submerged lands out to the 3-mi limit for energy and mineral development, subject to the Public Trust Doctrine. The California Department of Fish and Game and the Department of Health Services issue permits for commercial shellfish growing, subject to review by the State Lands Commission. The DOI's Minerals Management Service (MMS) is responsible under the Outer Continental Shelf Lands Act of 1953 (OCSLA) for leasing energy and mineral rights in federal waters extending from the 3-mi limit to the outer limit (200 mi) of the Exclusive Economic Zone (EEZ).

Resource exploitation, management, and protection activities must comply with several federal regulations in addition to those dealing with water quality. The National Environmental Policy Act of 1970 (NEPA) requires that an environmental impact statement (EIS) be prepared for all proposed legislation and all major federal actions that could significantly affect the quality of the environment. Thus, the MMS prepares an EIS before leasing offshore tracts for oil and gas exploration. Although EPA is not required to prepare an EIS for ocean disposal site designations, its policy is to do so voluntarily for dump site and incineration site designations. EPA also prepared an EIS in 1977 when it proposed revisions to the ocean dumping regulations and criteria.

The Endangered Species Act of 1973 requires all federal and state agencies to ensure that any action they authorize, fund, or carry out will not jeopardize the existence of an endangered or threatened species or result in damage or destruction of critical habitat for such species. The act authorizes the NMFS and FWS to render a biological opinion about the potential effect of a proposed activity on endangered species. As part of the EIS process, one of these agencies, usually upon consultation with the California Department of Fish and Game, must attest that the proposed action is compatible with the Endangered Species Act.

The NMFS and FWS are empowered by the Marine Mammal Protection Act of 1972 to enforce a moratorium on the taking or importation of marine mammals and marine mammal products except by special permit from the Secretary of Commerce. The National Historic Preservation Act protects historic and prehistoric archaeological resources.

The Coastal Zone Management Act of 1972 (CZMA) administered by NOAA provides grants to coastal states to develop coastal management plans. It also provides for state review of federal actions, including leasing of tracts for oil development and designation of ocean dump sites in federal waters that might directly affect the coastal zone. Although the State Water Resources Control Board has primary authority to regulate water quality, the California Coastal Commission is responsible for reviewing federal actions for consistency with the state's coastal management plan. In this role, the commission has had a major influence on proposed oil and gas development activities on California's outer continental shelf.

Under the CZMA National Estuarine Reserve Research Program, the Secretary of Commerce may designate a state or estuary as a national reserve upon nomination for such designation by the state's governor. The Tijuana Estuary is the first estuary in the Southern California Bight to receive such status.

The California Coastal Commission controls development within the coastal zone by issuing permits and approving local development plans in accordance with the California Coastal Act of 1976. The California Coastal Conservancy is authorized to make grants to local governments to acquire and restore critical habitats, including coastal wetlands.

INTERAGENCY COOPERATION

Complex environmental problems may not fall neatly within the areas of responsibility of individual agencies. They may involve the responsibilities of several agencies, or none, and may cross jurisdictional boundaries. In delegating responsibility for regulatory activities in the bight to different state and federal agencies, the U.S. Congress and the state legislature have not always been able to anticipate such problems. As a result, agencies must deal with policy conflicts, gaps, and overlaps. In addition, monitoring and research results generated by one agency can relate to the statutory responsibility of another. There are several examples in the bight of interagency cooperation that has successfully resolved such conflicts, and a few are mentioned below.

The previous chapter described how the San Diego County Department of Public Health, the San Diego Regional Water Quality Control Board, and the U.S. State Department's International Boundary Commission cooperated on the design of a monitoring program to assess sewage contamination from Tijuana. In addition, the EPA's Region IX office cooperates with the U.S. Army COE and with the Regional Water Quality Control Boards in establishing discharge and disposal limitations and monitoring programs.

The California Cooperative Oceanic Fisheries Investigation (CalCOFI) program is a long-standing example of a joint monitoring and research program involving federal and state resource agencies and an academic institution. The State Water Resources Control Board and the California Department of Fish and Game have combined resources to establish a statewide Mussel Watch Program to monitor toxic contamination. This program complements NOAA's National Status and Trends Program. The NOAA Sea Grant programs (which receive matching funds from the state of California), the U.S. FWS, the Coastal Conservancy, and the California Department of Fish and Game have cooperated in coastal wetland restoration projects.

Responding to mounting public concern over the condition of Santa Monica Bay, the Southern California Association of Governments (SCAG), funded the Santa Monica Bay Study. The study's goal was to compile all data relevant to the bay, perform an overall assessment of the state of its marine environment, and develop an implementation plan for specific actions to improve it. The study's steering committee is a consortium of representatives from local and state governments, environmental and academic groups, federal agencies, and local dischargers. Ten local entities and the SWRCB (using Clean Water Act monies) are funding the study. The San Diego Regional Water Quality Control Board has initiated a similar program to address environmental problems in San Diego Bay.

PUBLIC CONCERNS FOR THE BIGHT

There is intense public interest and awareness about environmental quality in Southern California. As a result, the public has been very vocal in advocating strong and effective environmental protection policies for the Southern California Bight. A sampling of public concerns and perceived policy needs for the bight ecosystem can be gained from the October 1986 triennnial review of the California ocean plan (State Water Resources Control Board, 1987) and from the presentations of interested parties to the case study panel. The following points were made by representatives of citizen organizations:

- The California ocean plan (State Water Resources Control Board, 1987) needs clearer definitions of narrative terms such as "degrade." It is difficult to assess the information provided by monitoring in the context of such vague objectives.
- Not enough attention is being paid to nonpoint sources of contaminants entering the bight, such as stormwater drains and aerial fallout. The plan should consider placing monitoring requirements on these sources.
- There should be a shift from discharge standards and effluent limitations based on allowable concentrations of contaminants in receiving waters to standards and limitations based on mass emissions of contaminants. This would better reflect the loading of the marine environment.
- A more complete assessment of the cumulative effects of marine contamination is necessary.

- The plan should require monitoring of sediments and biota to better assess cumulative levels of contaminants and their associated effects.
- There should be more independent review and oversight of the monitoring programs performed by dischargers.
- Self monitoring should be eliminated and monitoring put in the hands of state agencies.
- There should be better analysis of monitoring data submitted to public agencies and better communication of that information to the public.
- An oceanic institute associated with local universities should be established to conduct regular monitoring currently performed by dischargers, to coordinate monitoring by other agencies, and to perform related research.
- Standardized bioassay protocols and bioaccumulation tests should be required to better assess the toxicity of effluents to marine life and the hazards of eating fishery products from coastal areas.

The public appears to expect monitoring activities to provide information that answers four basic questions:

1. Is it safe to swim in the ocean?
2. Is it safe to eat the local seafood?
3. Are fisheries and other living resources being adequately protected?
4. Is the health of the ecosystem being safeguarded?

These are the public expectations that the panel perceives drive the actual monitoring programs. However, monitoring is carried out within a broader societal context, which includes such issues as cost, the effects of competing uses on land, water, and air quality, and tradeoffs between short and long-term costs and benefits. The challenge is valid and useful to management decision making in that it provides information addressing public concerns.

SUMMARY

The regulatory framework in the Southern California Bight is indeed complex and far reaching. Successful implementation of monitoring programs often requires a high degree of cooperation among state and federal officials. The efficient design of a monitoring system that can meet the various objectives of regulatory interests and not impose unreasonable burdens on the regulated community is a formidable task. In succeeding chapters, the details of this system are discussed and its success at meeting these criteria assessed.

In part, the success of the regulatory program and the role that monitoring plays depend on public confidence. The public continues to question the efficacy of monitoring and the status of the marine environment. Subsequent chapters will offer suggestions about the technical design of monitoring programs that may address those questions.

Monitoring and Research in The Southern California Bight

The relationship between research and monitoring activities in the Southern California Bight is complex, making it difficult to arbitrarily and consistently distinguish between the two. In this report, monitoring generally refers to repeated measurements taken to comply with specific regulations: research refers to measurement and experimental programs undertaken to answer more open ended questions. In the panel's view, monitoring and research are complementary activities that support each other and that both provide important information needed for resource management. Often the same agency will fund and/or direct both monitoring and research. Monitoring results have stimulated research programs, and research results have provided information that has been helpful in reducing impacts and refining monitoring requirements. In addition, research activities are often an integral part of monitoring programs in the bight.

Although this chapter reviews research and monitoring programs separately, it is important to remember the significant links and interactions between the two activities. These links exist because both monitoring and research are concerned with measuring and understanding processes of marine environmental change.

In general, monitoring in the bight is focused on four broad areas of concern:

1. the effects of effluent from municipal sewage treatment plants;
2. the effects of effluent from other sources, such as power plants, refineries, and nonpoint sources;

3. the status of resources such as fisheries and kelp beds; and
4. effects on public health from water contact sports.

Although these are useful organizing principles, in reality specific programs overlap the boundaries between them. Monitoring related to each of these four concerns is complemented by active research programs.

The main characteristic of research and monitoring activities in the bight is their broad diversity. Federal, state, and local agencies, along with universities and private industry, are active members of the research and monitoring community. This diversity stimulates innovation and careful evaluation of research and monitoring results, but it also makes coordination and integration of monitoring more difficult.

THE MONITORING SECTOR

The four monitoring areas described above reflect the existing regulatory environment (Chapter 3), with each kind of monitoring responding to a different set of laws, regulations, permits, and limitations. (A comprehensive review of past and present monitoring programs can be found in SCCWRP, 1988.) Effluent discharge and monitoring are controlled by National Pollutant Discharge Elimination System (NPDES) permits, which can contain effluent limitations (pertaining to the effluent) and water quality objectives (pertaining to the receiving waters). In California, these are determined by EPA, based on provisions of the Clean Water Act, as amended (CWA), and by the regional water quality control board issuing the permit, based on the California ocean and thermal plans (State Water Resources Control Board, 1975, 1987). Effluent limitations are specific numerical standards; water quality objectives include both numerical (Table B of the California ocean plan) and narrative standards (such as degradation of the environment).

The numerical effluent limitations are a combination of federal and California ocean plan (State Water Resources Control Board, 1987) regulatory requirements and are based primarily on consideration of current available technology (the technically or financially most feasible level of contaminant removal attainable). Effluent limitations may be stated as maximum acceptable concentrations of a constituent in the effluent or as the maximum allowable mass emission per day. For thermal effluents, for example, the maximum allowable difference in temperature between the effluent plume and the receiving waters at 1,000 ft from the outfall or diffuser is 4°C (California thermal plan [State Water Resources Control Board, 1975]). Compliance with such effluent limitations is determined directly by analysis of effluent at specified intervals.

The water quality objectives are also determined according to federal laws and regulations and California ocean plan requirements (State Water

Resources Control Board, 1987). They are numeric or narrative expressions of the maximum allowable changes in various environmental parameters that will not result in serious or long-term damage to the affected marine ecosystem. Numeric objectives define allowable concentrations of waste constituents after allowing for mixing within the zone of initial dilution (ZID), the region within a specified horizontal distance from the end of an outfall or any point along a discharge diffuser. The horizontal distance is usually equal to the water depth at the discharge. In contrast to establishing numeric objectives, demonstrating compliance with the narrative water quality objectives can be difficult. It is based on periodic monitoring of environmental conditions in the vicinity of the effluent discharge, and criteria used to measure compliance with these narrative objectives are often subjective and inferential.

In contrast to this system of effluent monitoring, resource monitoring is structured around compilation of commercial and sport catch statistics and studies of the status of particular stocks.

Routine health effects monitoring measures concentrations of bacterial indicators (e.g., coliforms) along beaches to determine whether to close sections of the coast to body contact sports.

The following sections describe monitoring activities related to the major sources of effluent and habitat change in the bight.

Municipal Discharges

There are 16 municipal wastewater dischargers operating under NPDES permits in the bight (Table 4-1). Of these, only the discharges in Goleta, Orange County, and Encina have received waivers under Section 301(h) of the Clean Water Act, as amended. Encina voluntarily relinquished its waiver in 1988. The largest of the 16 discharges are operated by the city of Los Angeles (Hyperion), the County Sanitation Districts of Los Angeles County (White Point), the County Sanitation Districts of Orange County, and the city of San Diego (Point Loma) (Southern California Coastal Water Research Project [SCCWRP], 1987). (Detailed histories of the regulatory actions and monitoring programs at each of these four large discharges can be found in SCCWRP, 1988.) In general, monitoring evolved from measurements of fecal contamination in the nearshore zone to more comprehensive assessments of environmental conditions over a broader area.

Table 4-1 summarizes the required monitoring programs at each municipal discharge in the bight. The wide variety in monitoring requirements among these discharges reflects differences in the size of each discharge, the levels of contaminants present, and the nature of the nearby marine environment (e.g., presence of kelp beds or other valued resources). In addition, permits were granted at different times, and their requirements reflect improvements in knowledge about the environment and changes in regulatory emphasis. Differences among monitoring programs also stem from the diverse orientations of the four regional water quality control boards that administer NPDES permits in the bight. These are the Central Coast, Los Angeles, Santa Ana, and San Diego regional boards. Boards differ in their staffing, level of experience, and responsiveness to local issues. As described in Chapter 3, the regional boards are relatively autonomous.

The current monitoring programs at two large municipal discharges, along with their historical contexts and existing permit conditions, are described in detail below. This will illustrate how monitoring has developed, as well as the relationship among regulatory requirements, public concerns, monitoring programs, and management decisions based on monitoring data.

County Sanitation Districts of Orange County

The County Sanitation Districts of Orange County (CSDOC) currently provide service to more than 2 million people in 23 of the county's 26 cities (CSDOC, 1987; SCCWRP, 1988). Two treatment plants, one at Fountain Valley and the other at Huntington Beach, process about 255 million gal/day of waste water. About 80 percent of the flow is from residential and commercial users, and 20 percent from industry. The effluent, consisting of about 40 percent primary treated and 60 percent secondary treated waste water, is discharged through an outfall 5 mi from shore in 200 ft of water off Huntington Beach.

The discharge at Orange County was initiated in the 1920s with screened effluent disposed of a short distance into the surf near the mouth of the Santa Ana River. In 1949, bacterial monitoring along the beach within 5 mi of the discharge was instituted at the request of the state health department. In the mid 1950s, expanded treatment facilities and a new outfall that discharged approximately 1 mi offshore were constructed. As a consequence, the monitoring program was expanded in 1960 to include offshore sampling of both the water column and sediments. In the late 1960s, sampling at additional nearshore stations was begun, and bacterial monitoring at shoreline stations was increased to 5 days per week.

In 1971, effluent was diverted from the old outfall 1 mi from shore to a new outfall 5 mi from shore. At this time, the Santa Ana Regional Water Quality Control Board designed a monitoring program to study the effects of the change. Additional parameters and stations were added to the existing monitoring program. The following year, monitoring of fish populations began with the addition of trawl sampling to the program.

The 1974 NPDES permit for the discharge increased the nearshore bacterial monitoring effort and required additional stations and parameters

TABLE 4-1 Monitoring programs of the 16 Municipal Wastewater Dischargers in the Southern California Bight

	Flow MGD	Bacteria	Water Column	Sediments/ Infauna	Epifauna/ Fish	Tissue Analysis	Histopathology	Mussel Cages	Kelp

in the offshore monitoring program. In particular, metals, phenols, biological oxygen demand (BOD), pesticides, and PCBs were to be measured in offshore sediments. In the late 1970s, this program was amended to reduce sampling for benthic biota to twice yearly instead of quarterly.

In 1978, the districts began operating an activated sludge facility at the first of their two treatment plants, and in 1983 at the second. These facilities improved the quality of the wastewater discharge.

In 1985, the Environmental Protection Agency (EPA) granted the CSDOC a 301(h) variance for a five-year waiver from the complete secondary treatment requirements of the CWA. An expanded monitoring program was required as a condition of the NPDES permit issued jointly by the Santa Ana Regional Water Quality Control Board and EPA Region IX (Table 4-2). EPA will use the monitoring data to assess whether the 301(h) permit should be renewed upon expiration, while the regional board will use them to determine compliance with the 1983 California ocean plan (State Water Resources Control Board, 1983). EPA must conduct a public hearing to consider any major changes to the permit conditions. If there is major opposition to such changes, they may not be allowed. Regional board action is also required for any substantive modification of the permit conditions.

As described above, the NPDES permit contains effluent limitations and water quality objectives. It also contains specific provisions and time tables for meeting the limitations of the permit and submitting various reports. The overall objectives of this 301(h) monitoring program, as specified by EPA (1987) and 40 CFR 125.62, are to:

- determine compliance with NPDES permit terms and conditions;
- document short- and long-term effects of the discharge on receiving waters, sediment, biota, and on beneficial uses of the receiving water; and
- assess the effectiveness of toxics control programs that limit discharge of toxic chemicals to the receiving waters.

To accomplish these objectives, the permit (No. CA0110604) specifies several kinds of monitoring (Table 4-2) and their objectives (Table 4-3).

City of Los Angeles

The city of Los Angeles' Hyperion treatment plant in Playa del Rey, with a design capacity of 420 million gal/day, is the largest sewage treatment plant discharging treated waste water to the bight (SCCWRP, 1988; John Dorsey, Hyperion Treatment Plant, personal communication). Planning is currently under way to double its capacity. The flow averages approximately 75 percent primary treated and 25 percent secondary treated waste water.

Treated wastes are discharged to Santa Monica Bay through an outfall

TABLE 4-2 Summary of the 301(h) Water Quality Monitoring Program Performed by the County Sanitation Districts of Orange County

Program element	Number of stations and frequency	Replicates/ station	Parameters measured
Beach coliforms	17 daily	1	Total coliforms (MPN/100 ml)
Water quality	9 monthly; 17 quarterly	1 each every 3 (or 6) m to bottom	Temperature, salinity, light transmission, total suspended solids, ammonia, coliforms, water color, dissolved oxygen, pH
Trawls (demersal communities)	8 semiannually	2	Fish/epifauna taxonomy, health, length/weight of 30 species
Benthic grabs	13 quarterly; 40 annually	Quarterly—infauna, 3 chemistry; annually—1 infauna, 1 chemistry	Infauna retained on 1 mm screen, grain size, oil, cyanide, sulfide, volatile solids, metals, extractable organics, pesticides, PCBs, volatile organics, total organic carbon
Bioaccumulation			
infauna	6 annually	5 g tissue total	Metals, synthetic organics, pesticides
fish	5 annually	20–60 specimens	Metals, synthetic organics, pesticides
epifauna	5 annually	5–58 specimens	Metals, synthetic organics, pesticides
Fish histopathology	8 semiannually	60 specimens	Liver histopathology, visual for tumors and lesions
Sport fishing survey	4 semiannually	As many as possible	Metals, synthetic organics, pesticides; liver histopathology, visual for tumors and lesions

terminating about 5 mi from shore in about 187 ft of water. Until November 1987, digested sludge and secondary effluent in a ratio of 1 to 3 were discharged through an outfall terminating nearly 7 mi offshore at the head of Santa Monica submarine canyon in about 300 ft of water. Periodically, during unusually high flows or in emergencies, chlorinated secondary effluent may be discharged through an outfall that terminates 1 mi from shore in 50 ft of water.

The city of Los Angeles began discharging raw sewage into Santa Monica Bay at Hyperion in 1894, and constructed a central outfall sewer in 1908. At the time, the area was relatively remote and there was minimal awareness about potential health hazards associated with the discharge of raw sewage. The State Department of Health began receiving complaints about fouled beaches in the vicinity of the discharge by 1912. As a result, an outfall was constructed in 1924 to carry screened effluent 1 mi offshore. However, a break in the outfall pipe 500 ft from shore, a growing urban population, and the need to bypass the screen during storm flows led to

TABLE 4-3 Objectives Specified in the NPDES Permit for the 301(h) Monitoring Program Performed by the County Sanitation Districts of Orange County.

Program element	Objectives
Beach and surf zone	Assess bacteriological conditions in areas used for water contact sports and shellfish harvest. Determine effectiveness of treatment to remove floatables that affect health and aesthetics.
Water column	Determine compliance with water quality objectives. Provide data to support interpretation of biology data.
Trawls (demersal communities)	Assess presence of balanced indigenous populations of demersal fish and benthic invertebrates.
Benthic grabs	Assess presence of balanced indigenous population of benthic invertebrates. Evaluate physical and chemical quality of the sediments.
Bioaccumulation (mussels, infauna, fish, epifauna)	Determine accumulation of toxic pollutants.
Fish histopathology	Assess prevalence of lesions, tumors, and liver abnormalities in local fish.
Sport fishing survey	Monitor uptake of pollutants in fish consumed by humans in order to determine impact on public health. Assess impacts on local fish populations.

repeated recontamination of Santa Monica Bay beaches. This caused the Department of Public Health to close beaches near Hyperion in Santa Monica Bay from 1946 to 1951 due to bacterial and grease contamination.

These continued problems with bacterial and aesthetic contamination led to legal action that resulted in construction of a larger outfall and a secondary treatment system in 1950 (Garber and Wada, 1988). Treated effluent and about 50 percent of the sludge were discharged to the bay, and reduced levels of contamination allowed the beaches to be reopened in 1951.

By 1952, growing public concern about contamination of Santa Monica Bay prompted comprehensive investigations by the Scripps Institution of Oceanography and the University of Southern California's (USC) Allan Hancock Foundation. The studies' objectives were to determine the bay's physical and biological conditions, sources and magnitude of pollution, and optimal design and location for deep-water outfalls. Based on data showing that bacterial contamination never traveled more than 5 mi along the beach in either direction from the outfall, a 5 mi-long effluent outfall was built in 1959. Prior to that, a 7 mi-long outfall had been built in 1957 to carry sludge to the head of Santa Monica Canyon.

Monitoring began coincident with the closure of public beaches in 1946, when routine daily surf and water column monitoring for coliforms was initiated by the Department of Public Health. This program was later incorporated into the monitoring mandated by the Regional Water Quality Control Board, and in 1956 was expanded to include additional water column and shoreline stations throughout the bay. This was the first such marine monitoring program in Southern California.

Hyperion's monitoring program was significantly enlarged in 1974, with the issuance of the plant's NPDES permit by the EPA and the state and regional water quality control boards. This permit required monitoring of infauna, some sediment chemistry, and water column bacteria. In 1980, the city signed a consent decree to cease sludge discharge to the ocean by February 15, 1986 (later extended to December 31, 1987). In 1982, the city of Los Angeles applied for a 301(h) waiver from the requirements to convert to secondary treatment, which EPA initially approved. The Los Angeles Regional Water Quality Control Board did not concur, and a waiver was not issued. However, in 1984 monitoring requirements under the existing NPDES permit were increased with the addition of trawling and replication at several benthic stations both within and outside the ZID of the 5-mi outfall. Hyperion received a new NPDES permit in 1987 that included a greatly expanded and modified monitoring program (Table 4-4).

The overall objectives of the Hyperion monitoring program differ somewhat from those of the Orange County program, partly because Hyperion is not operating under a 301(h) waiver. The overall objectives of this NPDES monitoring program are to:

- determine compliance with NPDES permit terms and conditions; and
- determine that state water quality standards are met (40 CFR 122.41[j] and 12.48[b].

As in Orange County's permit, subsidiary objectives are specified that generally parallel those described in Table 4-3. However, Hyperion's NPDES permit (No. CA0109991) contains one important difference. It incorporates language stating that the monitoring program may be modified based on information generated by the program. This is an important source of flexibility that is discussed in greater depth in Chapter 6. Specifically, the permit states:

> Once an adequate background database is established and predictable relationships among the biological, water quality, and effluent monitoring variables are demonstrated, it may be appropriate to revise the monitoring program. Revisions may be made under the direction of the EPA and the Regional Board at any time during the permit term, and may include a reduction or increase in the

VOL 12

TABLE 4-4 Monitoring Program for Hyperion (1987)

Monitoring program	Parameters	Frequency
Shoreline water quality (17 stations)	Total and fecal coliforms, enterococcus, temperature, visual observations	Daily
Nearshore water quality (11 stations)	Total and fecal coliforms, enterococcus, temperature, DO, transmissivity profiles, visual observations	Weekly
	Above parameters plus suspended solids, oil and grease	Monthly
Offshore water quality (25 stations)	Profiles for DO, temperature, salinity, pH, visual observations	Weekly
Microlayer (12 stations)	Profiles for transmissivity and transparency; discrete samples for ammonia-nitrogen, suspended solids, TOC, oil and grease	Monthly
Sediment chemistry (39 stations)	Three replicate samples for oil and grease and TOC	3 times per year
(subset of 7 stations)	TOC, H_2S, oil and grease, grain size, 122 priority pollutants (one sample)	Annually
Sediment biology (39 stations)	Three replicate samples for above sediment parameters	Quarterly
(subset of 7 stations)	Macrofaunal community analysis (one sample)	Semiannually
		Quarterly
Demersal fish and macroinvertebrates (trawling) (6 stations)	Five replicates for macrofaunal community analysis	Quarterly
	Duplicate trawls for community analysis	Semiannually
Contaminants in sport fish (rig-fishing) (2 sites)	Three replicates for priority pollutants in tissues of hornyhead turbot and ridgebacked prawn	Semiannually
	Three replicate samples for priority pollutants in muscle of selected sport fish	

DO = dissolved oxygen; TOC = total organic carbon

(Table 4-4)

number of parameters to be monitored, the frequency of monitoring, or the number and size of the samples collected.

In addition to this permit language related to flexibility, the Hyperion program also includes a chemical sampling plan that allows monitoring resources to be used more efficiently. In the first year of the program, the entire list of priority pollutants is sampled in the effluent, the sediments, and selected organisms. In the second and third years, only those pollutants found during the first year are sampled for. Then in the fourth year, the entire list of pollutants is sampled for again. The rationale for this approach was to focus monitoring effort on those pollutants that occur in the effluent and the environment.

Coastal Power Plants

The history of monitoring of heated cooling water discharges from coastal electric power plants is much less involved than that for sewage discharges. Conventional generating stations on the shore of the bight were all completed before 1971. Between 1971 and 1973, thermal effects monitoring programs were required by the regional boards. Temperature profiles were measured in the water column; sediment grain size distribution was measured; and infauna, epifauna, plankton, and nekton communities in the vicinity of the outfalls were investigated. Some power plants continued these studies on their own through 1978, but others monitored only entrainment of fish in the water intakes. At the Encina generating station, a study of effects of thermal discharges on the giant kelp community was initiated in 1975 and continued through 1986.

In 1978, new NPDES permits were issued and annual monitoring programs were begun at most power plants (Table 4-5). As described below (see "The Research Sector"), the Southern California Edison Company (SCE) maintains an extensive program of special studies to develop information to supplement that gained through the monitoring programs.

San Onofre Nuclear Generating Station

The San Onofre Nuclear Generating Station (SONGS), located on the coast south of San Clemente, includes three units: Unit 1 was put in operation in 1968, and Units 2 and 3 came on line in 1985. The three reactors have enormous cooling-water requirements. The once-through seawater cooling system takes in approximately 6,300 m^3/s from nearshore intakes. The diffusers for Units 2 and 3 are unique to the bight. Each is approximately 0.6-mi long. In order to meet California thermal plan (State Water Resources Control Board, 1975) requirements, they were designed to entrain a volume of water 10 times the original discharge flow.

TABLE 4-5 NPDES Monitoring Programs at 10 Coastal Power Plants in the Southern California Bight[a]

Generating station	Max flow (MGD)[b]	Water column	Sediments	Infauna	Epifauna and fish	Kelp
Alamitos	1,270	12 stations	grain size; 5 stations	4 stations; 4 repetitions	7 stations; 2 repetitions	No
Ormond Beach	688	8 stations	7 stations	6 stations; 4 repetitions	6 stations; 2 repetitions	No
Long Beach	772	8 stations	grain size; 6 stations	6 stations; 4 repetitions	3 stations; 2 repetitions	No
Mandalay	255	15 stations	5 stations	5 stations; 4 repetitions	3 stations	No
Scattergood	495	12 stations	grain size; 4 stations	4 stations; 4 repetitions	2 stations; 2 repetitions	No
El Segundo	606	12 stations	No	4 stations	12 stations	No
Redondo Beach	1,140	16 stations	grain size; 7 stations	7 stations	6 stations; 2 repetitions	No

Huntington Beach	519	3 stations	Metals, organics and grain size; 6 stations	3 stations	3 stations; 2 repetitions	No
SONGS	3,268	Temp and transmissivity at 22 stations; DO[c] & pH at 4 stations quarterly. Metals 5 stations and chlorine 8 stations triannually	No	No	Fish, 9 stations bimonthly	Acoustic at 3 stations semi-annually
Encina	860	10 stations	No	No	No	Aerial photo

[a] Water column monitoring focuses primarily on temperature, dissolved oxygen, pH, and transmissivity, and does not include sampling for contaminants. Sampling at all plants except Huntington Beach and San Onofre is done semiannually, that is, once every two years. Huntington Beach is sampled every year during the summer, and San Onofre is sampled as indicated in the table. Also note that Huntington Beach and San Onofre, unlike the other plants, sample different numbers of stations for epifauna and fish.
[b] MGD = millions of gallons per day
[c] DO = dissolved oxygen

SOURCE: From SCCWRP, 1988.

The resultant plume is directed offshore and has been shown to severely influence nearshore circulation patterns in the vicinity of the plant.

Marine monitoring at SONGS has been more intensive than that at other coastal power plants. The programs carried out at SONGS have been unique in the bight in terms of the intensity of monitoring devoted to a single discharge.

Monitoring and special studies have been performed continuously at the site since 1963. In 1964, baseline environmental monitoring was performed prior to operation of Unit 1. These included profiles of temperature and water clarity in the water column; measurements of local ocean currents; and characterization of intertidal, subtidal hard bottom, and kelp communities.

In 1974 and 1976, monitoring determined the environmental effects of sand disposal and dredging for emplacement of the Units 2 and 3 outfalls. In 1976, the San Diego RWQCB issued NPDES permits, including receiving-water monitoring requirements, for all three units. Current NPDES monitoring requirements are summarized in Table 4-5.

Along with these NPDES monitoring requirements, SCE is obligated to carry out further monitoring by other agencies. Impingement of fish in the intakes is monitored for the California Department of Fish and Game. Periodic monitoring of radionuclides is required by the Nuclear Regulatory Commission. Most monitoring occurs within 6 mi of the plant, with reference stations at 30 or 37 mi. Direct radiation is monitored continuously; airborne radiation is monitored weekly; ocean water is monitored monthly; beach sand and bottom sediments are monitored twice a year; and tissues of nonmigratory marine animals are monitored quarterly.

In addition, the California Coastal Commission required Southern California Edison to form the Marine Review Committee. This independent committee was established in 1974 by the California Coastal Zone Conservation Commission (now called the California Coastal Commission) in response to controversy about, and as a condition of, the permit for discharge of cooling water from SONGS Units 2 and 3. The specific responsibility of the committee was to protect marine life and resources from potential or actual damage directly related to the design and operation of the cooling water system of Units 2 and 3. Its studies focused on four areas:

1. determining the effects of SONGS Unit 1 on the marine environment,
2. predicting the effects of Units 2 and 3 on the marine environment and recommending needed design changes in the cooling water system to the California Coastal Commission,

VOL 12

15082

3. determining the effects of SONGS Units 2 and 3 by performing both pre- and post-operational monitoring programs, and

4. investigating possible mitigation and enhancement measures for any damage encountered.

An important feature of the committee was its authority to make recommendations about operational and design changes to the cooling system, up to and including the construction of cooling towers.

The Marine Review Committee's program was noted for intense and comprehensive investigations, length of time committed to the study, and magnitude of total expenditures. Virtually all aspects of the marine environment near SONGS were investigated, including soft- and hard-substrate benthos, ichthyoplankton and adult fish, kelp beds, phytoplankton, zooplankton, epibenthic plankton, and the physical and chemical oceanography of the coastal zone. Investigations began in 1974, and study designs were, in most cases, firmly established by 1979. The resulting data sets cover eight years, and total expenditures for the program through production of the final report are estimated to be $47 million.

The committee's studies are unique among large monitoring programs in the bight in several important ways. First, the program was several times larger than any other monitoring program in the bight. Second, because the MRC was an independent entity, program designs could be adapted as needed. Third, monitoring plans were deliberately devised to detect predetermined amounts of change. Finally, repetitive, time series monitoring was integrated with modeling and research to constantly improve the ability of the monitoring programs to detect change.

Field work on nearly all projects was completed in December 1986, and final contractor reports were due in December 1987. The final report of the committee was scheduled for submission to the California Coastal Commission in 1989. Coincident with the end of the committee's studies, Southern California Edison began implementing procedures to make the committee's data available to investigators.

Oil Exploration and Production

There are few ongoing monitoring programs in the bight associated with oil exploration and production. This is partly because, except for platforms in the Santa Barbara Channel, the nearshore THUMS project in Long Beach, and the Aminoil project in Huntington Beach, there is no oil production in the nearshore regions of the bight. In addition, there are relatively few refineries along the coast discharging directly into the ocean. Finally, further exploration in the offshore regions of the bight has been delayed pending resolution of conflicts between the state and the federal government over oil and gas development policy for California's outer continental shelf.

EPA Region IX is considering the establishment of a monitoring program in the Santa Barbara Channel where extensive oil production occurs. The program's objectives will be to document production impacts from existing platforms and follow recovery after drilling ends. The THUMS project in Long Beach monitors a range of water column and sediment parameters at six stations. Sampling began before disposal. In the water column, salinity, temperature, pH, and dissolved oxygen are measured continuously, while heavy metals, oil and grease, suspended solids, cyanides, and organohalogens will be monitored quarterly during the first two years of the program. In the sediments, a range of parameters—including barium, EPA priority pollutants, grain size, petroleum hydrocarbons, and BOD—will be monitored semiannually. The Aminoil project in Huntington Beach measures grain size, barium, and heavy metals, and collects five replicate cores for infauna analysis at six sediment sites annually.

In Carpinteria, in the northern region of the bight, Chevron monitors water column, sediment, infauna, and epifauna parameters annually at four stations in the vicinity of the discharge from its wastewater treatment plant. The plant discharges 0.6 million gal/day of treated oil process waste. Water column variables measured include temperature, transmissivity, dissolved oxygen, pH, and ammonia. Sediment variables measured include sulfides, grain size, heavy metals, BOD, total organic carbon, total nitrogen, nitrate, oil and grease, and aromatic hydrocarbons. Infauna samples are identified to species, biomass is measured, and large epifaunal algae are identified.

Chevron also operates a refinery at El Segundo, in Santa Monica Bay. Organic matter is measured annually at two offshore sediment stations. In the water column, temperature, oil and grease, dissolved oxygen, and pH are measured monthly at four shore stations and two offshore stations.

Ocean Dumping and Dredge Disposal

There are no long-term ocean dumping monitoring programs for offshore sites in Southern California. Ocean dumping in the bight is currently limited to dredge material disposal. Two of the three active dredge dumpsites (LA2 and LA5) have only been sampled as part of the EIS/EIR process to designate them as permanent disposal sites. The first environmental survey of the third site (LA3) is currently in progress. The designation of LA2 and LA5 dump sites expired at the end of 1988, leaving only LA3 available to receive material from new projects. Routine ocean monitoring at the dump sites is under consideration by both EPA and the U.S. Army Corps of Engineers.

Dredge permit applications do not require monitoring at the dumpsite.

They do require chemical, bioaccumulation, and bioassay testing at the dredging site, in order to determine the suitability of the material for ocean disposal.

Nonpoint Sources

Nonpoint sources of contaminants are those that are diffuse or poorly defined. They include rainout or fallout from the air, surface runoff from land, and multiple small inputs, such as those from individual houses, businesses, and farms. Monitoring nonpoint source contamination is difficult precisely because it is so diffuse. It is technically challenging both to monitor such contaminant input and to clearly identify sources of elevated levels found in the environment.

Nonpoint sources are attracting greater attention from both regulatory agencies and the public, with most of this attention devoted to storm drains and riverine input. As a result of a steady decrease in the mass emissions from coastal wastewater treatment plants, mass emissions of some chemicals from stormwater runoff now approach those in effluents from coastal wastewater treatment plants (Table 4-6). As described in Chapter 1, precipitation in Southern California is highly seasonal. As a result, during dry periods a significant percentage of riverine flow can be composed of secondary and tertiary treated municipal wastewater from inland sewage treatment plants. Such inland treatment plants discharging to the Los Angeles or San Gabriel rivers may have flows in the range of 20 to 100 million gal/day.

As Garber (1987) points out, stormwater and riverine drainage enters the nearshore zone directly, while treated municipal wastewater is discharged 2 to 7 miles offshore, usually in deep water (about 100 ft). Potential impacts on recreational beaches may therefore be greater from land runoff than from offshore discharge of treated waste water.

In spite of these potential impacts, there is presently no mandated responsibility for monitoring land runoff. Individual county agencies responsible for stormwater systems may voluntarily perform such monitoring. For example, in Los Angeles County the County Department of Public Works monitors drainage facilities, and in Orange County such monitoring is performed by the County Environmental Management Agency. The only existing statutory basis for managing storm drainage systems is the NPDES permit program. However, agencies with overall management responsibility for stormwater drainage systems (e.g., Department of Public Works) are not now required to administer NPDES permits granted by other agencies for the multitude of individual discharges to the drainage system. There is thus no clear responsibility to monitor the drainage system itself or its discharges to the ocean.

TABLE 4-6 Estimated Average Emissions in Metric Tons Per Year of Several Constituents from the Los Angeles River and from the Two Largest Municipal Sewage Treatment Plants Discharging to the Southern California Bight

Constituent	Los Angeles River			JWPCP[a]	Hyperion[b]

SOURCE: SCCWRP, 1986c.

Currently, nearly all NPDES-permitted discharges to drainage systems in the bight have strict effluent limitations and dischargers are required to do effluent monitoring. For example, all municipal wastewater treatment plants discharging to the river/stormwater system in Southern California measure priority pollutants in effluent semiannually and volatile organics quarterly. The 1987 amendments to the Clean Water Act require more monitoring of stormwater discharges.

The Los Angeles County monitoring program provides an example of the type of voluntary monitoring performed by agencies managing stormwater drainage systems in Southern California. Los Angeles County encompasses a drainage area of 4,100 mi^2 with a population in excess of eight million. Drainage of the area, primarily into the Southern California Bight, is provided by several rivers (such as the Los Angeles and San Gabriel rivers) and an extensive system of underground drains and open channels. The main flows to this system are from:

- precipitation;
- NPDES-permitted discharges of treated industrial and municipal wastewater;
- fire-fighting waste water (often containing high concentrations of contaminants);
- nuisance water (e.g., wash-down, excess lawn watering, etc.);
- accidental sewer overflows; and
- daily, weekly, and other periodic plant and site cleanup and wash down from business, commercial, and residential sources.

The Los Angeles County Flood Control District (since renamed the Los Angeles County Department of Public Works) began monitoring the drainage system in the 1930s because some of the runoff was used for groundwater recharge. In the mid 1960s, the water quality program was expanded to consider ocean disposal of stormwater runoff. The monitoring program was greatly reduced between 1984 and 1987, but much of it was reinstituted in 1988.

Water samples are collected during two to four storms per year from 20 stations along rivers, creeks, and drains. They are analyzed for inorganic minerals and pH, bacteria (total and fecal coliforms and enterococcus), total petroleum hydrocarbons, 12 heavy metals, total organic carbon, BOD, 8 volatile organic compounds, 15 pesticides, total suspended solids, and volatile suspended solids. Samples from the Rio Hondo Channel and San Gabriel River are also analyzed for priority pollutants.

Samples of dry weather (non-storm) flows are collected from 27 stations every month. These samples are analyzed for minerals, bacteria, total petroleum hydrocarbons, heavy metals, and oil and grease. Total organic carbon, BOD, and volatile organic compounds are analyzed quarterly or semiannually.

Shoreline Erosion and Beach Replenishment

The U.S. Army Corps of Engineers (COE) and the California Department of Boats and Waterways carry out the Coast of California Storm and Tidal Wave Program. This is intended to be a long-term program to develop baseline information on changes in beach profiles and ocean conditions along the California coast. The data will be used to monitor beach erosion and to assist in planning beach replenishment activities.

Approximately 60 sites between Oceanside and the U.S.-Mexican border were monitored semiannually between 1983 and 1988. Profiling efforts are expected to move to Orange and Los Angeles counties for the next five years. Semiannual monitoring of beach profiles in association with a sand bypass project at Oceanside Harbor has occurred since 1985 and may continue in the future.

A related program is carried out by the Ocean Engineering Research Group at the Scripps Institution of Oceanography, which monitors wave climatology at ten nearshore and offshore sites in Southern California. This project has collected over 10 years' worth of data for use by mariners and in coastal physical and oceanographic studies. The project is funded by the U.S. Army COE and the state of California.

Resource Monitoring

Resource monitoring is the responsibility of the California Department of Fish and Game, which collects information on sport and commercial fish catches and on exploitation of kelp beds in the bight. The present system of collecting catch information is straightforward and is described below, however the history of fisheries monitoring in California is long and complex. It is intimately associated with the California Cooperative Oceanic Fisheries Investigation (CalCOFI) program, which is unique for the spatial extent and consistency through time of its investigations into oceanography and fisheries biology. This history is summarized below and recounted in more detail in SCCWRP (1988).

Current Resource Monitoring

Commercial fishermen are required to report catch statistics to the Department of Fish and Game. Both fin and shellfish (e.g., abalone, sea urchins, lobsters) are included in these reporting requirements. Finfish catches have been monitored since 1918, and statistics currently include species caught and the location and weight of the catch. Daily logs of sea urchin and lobster catch numbers and locations have been reported for at least the last 10 years.

Commercial party-boat operators in the sport fishery are required to keep a log of the number and species of fish caught, number of anglers fishing, hours fished, and area fished. These records have been kept continuously by the Department of Fish and Game since 1935, with the exception of the five years during World War II (Young, 1969; Clark, 1982).

In 1975, the department initiated the Southern California Independent Sport Fishing Survey to monitor catches by recreational anglers. In 1979, the department, in collaboration with the National Marine Fisheries Service (NMFS), began a statewide program to monitor recreational catches. The objectives of these programs were to determine the magnitude and composition of the catch, to estimate effort expended by anglers and divers from private boats, and to assess the degree of compliance with state fishing laws (Wine, 1979).

Monitoring of artificial reefs began off Southern California in the late

1950s, in order to test the effectiveness of artificial reefs in increasing the availability of marine organisms and improving fishing. This program ended in 1964 and no formal studies were undertaken for 15 years, although reef building continued. In 1979, the Department of Fish and Game, in conjunction with Southern California Edison, began a six-year monitoring study of the development of marine life on the Pendelton Artificial Reef near the San Onofre Nuclear Generating Station. The objective was to develop a method of mitigating potential losses of kelp beds due to power plant operations. The success of this study resulted in an expanded program by the department to build and monitor artificial reefs throughout the Southern California Bight (Grant, 1987). This monitoring program is designed to identify the effects of important variables such as depth and reef topography on the biological communities that colonize reefs.

Historical Monitoring and the CalCOFI Program

Monitoring of marine fish and shellfish resources in the Southern California Bight has continued for more than 70 years. This monitoring has almost from the beginning been closely associated with research programs on fisheries. For this reason, the CalCOFI program is described here rather than in the research section below. In 1914, the California Department of Commercial Fisheries was established to collect fisheries statistics, develop improved methods for catching and processing fish, and study the life histories of commercially important fish and shellfish (Hewitt, 1988). Beginning in 1918, the Department of Commercial Fisheries collected catch data from commercial fishermen and fish dealers on species composition, weight, gear type, location, and intended commercial use. Much research was also performed during the 1920s and 1930s on fishery stock size, year class abundance, and fish distribution along the Pacific coast.

After World War II, state fishery agencies in California, Oregon, and Washington formed the Pacific Marine Fisheries Commission, and were later joined by fishery agencies in British Columbia. The commission's original focus was to study the Pacific sardine fishery, but when the fishery collapsed in 1947, it turned its attention to salmon, albacore, bottomfish, Dungeness crab, and shrimp (Croker, 1982).

After the sardine fishery collapsed, the California State legislature established the Marine Research Committee, composed of members from the commercial fishing industry and the California Department of Fish and Game. The committee set up a Fish and Game Preservation Fund to support research to improve the commercial marine fisheries of California and develop new commercial marine products.

In 1948, the committee established the California Cooperative Sardine Research Program. Its purpose was to study the distribution and natural history of sardines, their availability to the commercial fishery, fishing methods, and the physical, chemical, and biological oceanographic processes influencing sardine populations off California. The program included members from the California Department of Fish and Game, the Federal Bureau of Commercial Fisheries, Hopkins Marine Station, the California Academy of Sciences, and Scripps Institution of Oceanography. In 1953, the program was renamed the California Cooperative Oceanic Fisheries Investigation (CalCOFI) and was expanded to include consideration of species other than sardines. By 1960, CalCOFI's objectives had evolved to understanding factors governing abundance, distribution, and variations of pelagic marine fishes, emphasizing the oceanographic and biological factors affecting sardines and other marine life in the California Current system (Baxter, 1982).

The Fisheries Conservation and Management Act of 1976 (FCMA) gave the federal government management authority over commercial fisheries in the exclusive economic zone (the EEZ, 3 to 200 mi from shore), superseding the management role of the Marine Research Committee. The FCMA established regional fisheries management councils to develop plans for regulating harvesting of commercially valuable fish stocks and for controlling access of foreign fishing or processing vessels to U.S. territorial waters.

However, the NMFS, the California Department of Fish and Game, and Scripps decided in 1979 to continue CalCOFI as a long-term marine resources monitoring and research program (Radovich, 1982). The scope of and funding for the program have been greatly reduced in recent years (Figure 4-1). Fisheries and oceanographic data continue to be entered into the CalCOFI online data system at the Southwest Fisheries Center in La Jolla. This system contains a large-scale, multivariate time series of physical, chemical, biological, and meteorological data from approximately 40,000 stations and 300 cruises in the eastern North Pacific Ocean, collected since 1949.

Cooperation with scientists from Mexican institutions remains an important part of the CalCOFI program. This includes joint scientific symposia and cooperative studies of anchovy abundance and sardine spawning stocks. In addition, Mexico's fishery agency, the Secretatiat de Pesca, has expressed interest in funding a reestablishment of the CalCOFI time series transects in Mexican waters that were discontinued several years ago.

Kelp Bed Monitoring

Kelp beds along the California coast represent both a recreational and a commercial resource. Because of kelp's unique characteristics, separate programs have been instituted to monitor this resource. The California

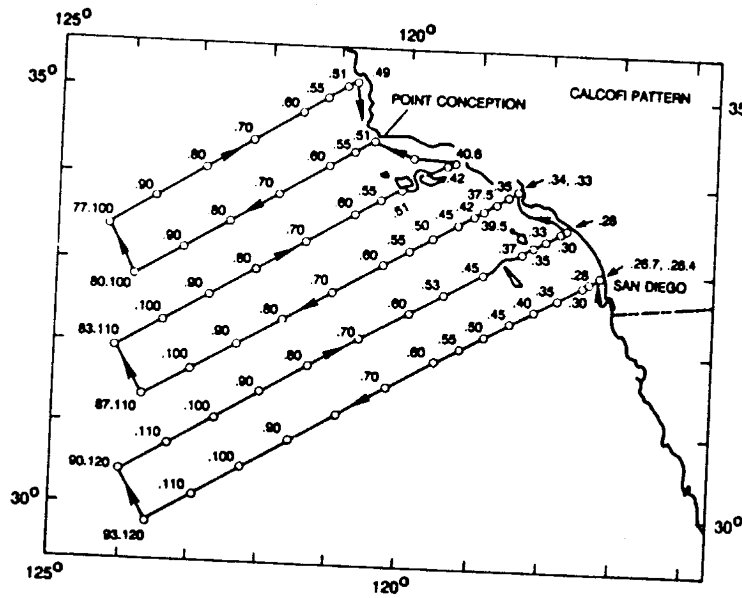

FIGURE 4-1 Location of the 1987 field survey stations sampled by CalCOFI during quarterly cruises. Station numbers and a typical cruise track are also shown.

Department of Fish and Game has conducted quarterly aerial surveys of kelp beds in Los Angeles County since 1974. Since 1987, these overflights have been extended south to San Onofre, near San Clemente. The goal of this program is to document fluctuations in bed size, and short-term studies have been conducted at the offshore islands and north of Los Angeles on special occasions.

In addition to these aerial surveys, diving surveys have been carried out since 1977 at five sites around the Palos Verdes Peninsula as part of the Nearshore Sportfish Habitat Evaluation Program. The goal is to increase understanding of kelp bed ecology.

In San Diego County aerial surveys have been carried out quarterly since 1967 by Dr. Wheeler North of the California Institute of Technology in Pasadena. These data are used by the six municipal dischargers in the county to fulfill NPDES monitoring requirements.

The Kelco Co. of San Diego compiles kelp harvest data by month and by kelp bed. However, only total annual values are available to the public due to lease agreements between Kelco and the state.

Noncommercial Resources

Another type of resource monitoring is mandated by Title III of the Marine Protection, Research and Sanctuaries Act (MPRSA) in the Channel Islands National Park. At the national park, long-term, time series monitoring is used to assess and maintain the ecological conditions (National Park Service, 1984). The main focus of the monitoring, much of it done with volunteers, is to determine the population dynamics and long-term environmental trends for key species of marine plants and animals in the park.

The National Estuarine Reserve Research Program of the Coastal Zone Management Act (CZMA) mandates research and monitoring programs in designated estuaries. In fiscal year 1988, the National Oceanic and Atmospheric Administration (NOAA) initiated a competitive grants program for studies in the 17 designated national estuarine reserves. The Tijuana River estuary is the only national estuarine reserve in the Southern California Bight area. Research and monitoring will be focused in five areas:

1. water management—the relationship between freshwater inflow and estuarine productivity;
2. sediment management—the effects of different types of sediments and sedimentation processes on estuaries;
3. nutrients and other chemical inputs—effects of anthropogenic inputs on estuaries;
4. coupling of primary and secondary productivity—nature of estuarine food webs and energy flows; and
5. estuarine fishery habitat requirements—values of estuaries as nursery areas for commercial and recreational species.

In the case of the Tijuana River estuary, these data will be extremely useful in influencing the design of sewage management strategies for Tijuana, Mexico (see "The U.S.-Mexican Sewage Contamination Problem," Chapter 2).

Water Quality Monitoring for Public Health

The California Health and Safety Code specifies that the State Department of Health Services is responsible for supervising sanitation, healthfulness, and safety of public beaches and public water contact areas of the state's bays and ocean waters. The State Department of Health Services may delegate some monitoring and enforcement activities to the county health services departments. When a public beach or water contact sports area fails to meet standards, the local health officer or the State Department of Health Services, after considering the causes of the failure, may post the area with warning signs or otherwise restrict use of the area until corrective action has been taken and the two following standards are met:

1. physical–no sewage sludge, grease, or other physical evidence of sewage discharge shall be visible at any time on any public beaches or contact sports areas; and
2. bacteriological–samples of water at a public beach or water contact sports area shall have a most probable number (MPN) of coliform bacteria less than 1,000 per 10 ml, provided that no more than 20 percent of the samples at any station in a 30-day period exceed 1,000 per 10 ml, and provided further that no single sample, when verified by a repeated sample taken within 48 hours, shall exceed 10,000 per 10 ml.

The monitoring programs performed by county health agencies in support of these management activities are of two types: (1) routine bacteriological sampling, and (2) bacteriological sampling following a waste discharge into recreational waters. Special studies are also carried out by county health agencies. However, there are no health monitoring programs targeted specifically at human health effects (e.g., gastroenteritis) related directly to water-contact sports.

Orange County has performed a monitoring program in recreational waters for several years. Los Angeles County is now monitoring routinely. In San Diego County, monitoring is performed along the shore at four sewage treatment plant ocean outfall sites: city of Oceanside, Encina Water Pollution Control Facility, San Elijo Water Pollution Control Facility, and city of San Diego. The outfall from the Point Loma Plant was constructed before kelp beds were included as water contact sports areas and the treatment plant is experiencing difficulty meeting bacterial standards at the outer perimeter of the kelp beds.

For over 30 years, the San Diego County Department of Health Services has performed beach and bay surveys annually. About 60 stations are usually sampled on these surveys. From three to five samples are collected at each station in April and May of each year. In addition, surveys of 40 stations, with a single sample from each station, are performed in early July and September. Many of these stations are interspersed with the shoreline stations sampled by the dischargers.

A routine weekly survey of water quality in Mission Bay was started in 1977 and continued through January 1987. The city of San Diego has replaced it with a more intensive monitoring program with more stations sampled more frequently. This monitoring program was initiated voluntarily by the city because of strong public concern about poor water quality. The data collected in all these monitoring activities is shared with the State Department of Health Services, regional water quality control boards, and other state and federal agencies concerned about recreational water quality.

National and Statewide Monitoring Programs

NOAA's National Mussel Watch Program and National Status and Trends Program represent national monitoring programs that have included sampling and measurement stations within the Southern California Bight. While the numbers of stations are too few to present a comprehensive picture of contaminant levels in the bight, they do provide a basis for making comparisons with contaminant levels in other parts of the country.

The original National Mussel Watch Program, developed by Dr. Edward Goldberg of Scripps and 10 other principal investigators, was first funded by EPA in 1976. Mussels and oysters were sampled at approximately 78 coastal and estuarine stations along the Atlantic, Gulf, and Pacific coasts of the United States in 1976, and again in 1977/1978. There were eight stations in the Southern California Bight. Mussel tissues were analyzed for six metals, three radionuclides, DDT (and its breakdown products), PCBs, and petroleum hydrocarbons (Goldberg et al., 1978a). Total funding for the program was about $400,000 per year. The national program was not continued past 1978, but several local programs were continued.

In 1984, NOAA's Ocean Assessments Division initiated the National Status and Trends Program that includes a National Benthic Surveillance Project and a Mussel Watch Project (NOAA, 1987). In the Benthic Surveillance Project, sediments and demersal fish have been collected annually since 1984 from 50 sites along the U.S. coast, including Alaska. In the Mussel Watch Project, mussel and oyster samples have been collected once each year since 1986 from 150 sites along the U.S. coast, including Alaska and Hawaii. Sediments are also collected at many of the Mussel Watch stations. There are 6 Benthic Surveillance stations and 16 Mussel Watch stations in the Southern California Bight (Figure 4-2). An extensive suite of metals (17), polynuclear aromatic hydrocarbons (18), pesticides (15), and PCBs is analyzed in the animal tissues and sediment samples. In addition, the fish are examined for diseases and histopathological lesions.

The overall objective of the National Status and Trends Program is to assess and document the status of coastal and estuarine environments. Specifically, the program is intended to define the geographic distribution of contaminant concentrations in biological tissues and in sediments from U.S. coastal and estuarine waters, determine temporal changes in those concentrations, and document biological responses to contamination (e.g., Malins et al., 1986). This information will be used to make decisions about the use and allocation of resources in the nation's coastal and estuarine regions.

Since 1976, the California Department of Fish and Game, under an interagency agreement with the California State Water Resources Control Board, has performed a Mussel Watch Program for monitoring marine and

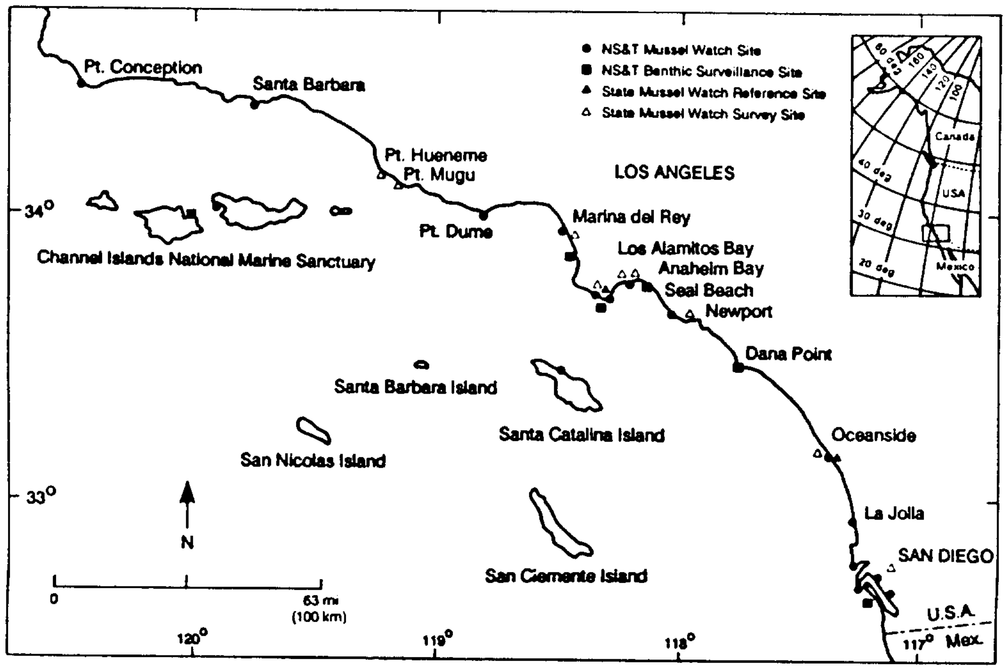

FIGURE 4-2 Locations of the NOAA National Status and Trends' Mussel Watch, and benthic surveillance sampling stations and the California Mussel Watch reference and survey sampling sites in the Southern California Bight. All California Mussel Watch Survey sites include several mussel sampling or transplant stations.

estuarine waters (Stephenson et al., 1987). Its purpose is to provide the state board and six coastal regional boards with an ongoing assessment of the geographic and temporal trends in levels of chemical contamination in coastal waters. The state's Mussel Watch Program is somewhat different than the national program in that it includes only five reference stations and several site-specific "hot spot" survey sites.

The latter may change from year to year. Resident mussels are used at the reference sites, but transplanted mussels or the Asiatic clam, *Corbicula fluminea*, are used at most site-specific stations. The two reference stations in the Southern California Bight are at Palos Verdes (Royal Palms State Park) and Oceanside. They are also National Mussel Watch sampling sites, providing an opportunity for intercalibration of results from the two programs. In 1986-1987, 11 site-specific surveys were performed in the Southern California Bight (Figure 4-2). These studies were performed at one or more locations inside harbors, marinas, or enclosed bays. All but two of the site-specific surveys were designed to collect baseline estuarine data. The survey in Los Angeles/Long Beach harbors was to document the levels of DDT, PCBs, and metals; the survey in San Diego Bay was intended to assess the level of contamination of PCBs, silver, copper, and zinc.

Citizen and Community Monitoring

Interest in the bight and its resources by community and environmental groups has extended to voluntary participation in monitoring and research programs. Three examples of these efforts have provided useful information.

Over 200 organizations and their personnel, mostly volunteers, monitor marine mammal strandings along the California coast as part of the Marine Mammal Stranding Network. The data generated by the Network are collected and managed by NOAA's Southwest Fisheries Center in La Jolla. Notification of strandings has been useful to scientists studying chemical contamination, diseases, and population trends of marine mammals (Seagars et al., 1986).

Volunteer reporting of physical evidence of sewage entering recreational waters has provided local health departments with timely information needed to determine whether to close recreational beaches and swimming areas.

Finally, annual volunteer beach cleanups coordinated by the California Coastal Commission have resulted in estimates of the type and quantity of plastic debris littering beaches. Such information has proven useful enough that the Center for Marine Education in Washington, D. C. plans to develop a uniform data reporting system for beach cleanups nationwide. These data will help in monitoring the magnitude of the plastic debris problem, as well as the effectiveness of source control and recycling programs. These efforts are supported officially, since Section 2204 of the 1987 Marine Plastic Pollution Research and Control Act directs the Secretary of Commerce, in cooperation with EPA, to encourage the formation of volunteer groups, to be designated as "Citizen Pollution Patrols," to assist in monitoring, reporting, cleanup, and prevention of ocean and shoreline pollution (1987 Marine Plastic Pollution Research and Control Act included as Title II in the U.S. Japan Fishery Agreement Approval Act of 1987).

Monitoring Expenditures

Marine monitoring programs are expensive, primarily due to staffing needs. Trained scientists and technicians are required to conduct field sampling, perform laboratory analyses, interpret resulting data, and write reports. Many activities involved in monitoring, such as benthic infaunal analysis and analytical chemistry, are labor-intensive. Tetra Tech (1984) estimated the costs to perform representative monitoring activities to be:

- $200 to $1,200 for a single benthic infaunal analysis, and
- $920 to $2,300 for a single priority pollutant scan of sediments.

These estimates are low compared to current rates, but they do show that monitoring is not cheap. In the Orange County 301(h) monitoring program, 300 benthic infaunal samples and 196 sediment chemistry samples are analyzed each year. Assuming that each benthic sample costs $600 and each chemistry sample costs $1,500 to analyze, the total cost per year to analyze these samples alone is $474,000.

Equipment and facilities that must be purchased are also costly. A good gas chromatograph, needed to measure PCBs, DDT, and other organic contaminants, may cost $10,000 to $50,000. An atomic absorption spectrophotometer, used to analyze metals, will have a similar cost. Research vessels equipped for accurate navigation and for collecting diverse sample types may cost $2,000 to $5,000 per day for an offshore vessel and $500 to $1,000 per day for a smaller vessel suitable for sampling close to shore.

Table 4-7 summarizes estimated costs incurred during the last five years in different types of monitoring in the Southern California Bight. This summary is incomplete, since it does not include several voluntary (nonmandated) monitoring programs and research efforts performed by different dischargers, environmental agencies, or universities. In addition, the costs of effluent monitoring activities are probably under-recorded, since they often are not consolidated with receiving water monitoring budgets.

Facilities and overhead costs for those aspects of monitoring performed

in-house by municipal wastewater treatment plants and industrial dischargers usually are not reported. While an accurate accounting of overhead costs is not available, these have been estimated to be equivalent to the direct costs, effectively doubling the total. Expenses incurred by county public works departments in monitoring chemicals in stormwater runoff are also not included in Table 4-7. Costs for the NOAA Status and Trends (Mussel Watch) monitoring of mussels, sediments, and fish in the bight are not included. (The estimated cost for sampling all stations in the bight and analyzing the samples is $175,000 per year.) Despite these omissions, the costs summarized in Table 4-7 do give a rough impression of the minimum level of expenses incurred in monitoring water quality, natural resources, and public health.

Table 4-7 reveals some important facts. Total estimated costs in 1987 for all monitoring in the bight are over $17 million. Because of the large budget of the Marine Review Committee's study of SONGS (ending in 1989), monitoring costs for the electric utilities are higher in this year than for the municipal wastewater treatment plants. Among the treatment plants, the most expensive monitoring program, at nearly $2 million per year, is the 301(h) monitoring program being performed by the County Sanitation Districts of Orange County. Total natural resource assessments cost about $3.3 million per year, while public health monitoring by the separate counties costs about $310,000 per year.

Of the total annual monitoring expenses of over $17 million in the Southern California Bight, nearly 80 percent are borne by the public sector. Much of the remainder is spent by the California Department of Fish and Game for marine resource monitoring.

Summary of Monitoring Activities

The review of monitoring activities in the Southern California Bight highlighted several important features that will be treated in more detail in the analysis of monitoring (Chapter 6). For the most part, monitoring is performed in response to permit requirements that regulate discharge activities. There are many agencies, federal, state, and local, involved in establishing standards and regulations under which these permits are administered. Despite the many agencies and programs, there is no overall coordination of monitoring in the bight. There is, however, cooperation among agencies that jointly regulate specific discharges such as the Hyperion outfall.

Individual monitoring programs are carefully carried out using state-of-the-art methods, and the quality of the resulting data is typically very high. Finally, Table 4-7 reveals that, with the exception of the recently ended Marine Review Committee program at San Onofre, the bulk of monitoring funds are devoted to measuring the effects of municipal wastewater discharge.

THE RESEARCH SECTOR

A great deal of research is performed in the bight by federal, state, and local agencies, and by universities and private industry. Some of this research is oriented specifically toward environmental problems (such as the effects of municipal wastewater outfalls) that are also addressed by monitoring programs. Other research is oriented toward more general issues in oceanography and marine ecology.

Research results can benefit monitoring programs by:

- increasing understanding of the marine environment and thereby enhancing the ability to predict, measure, and assess human impacts;
- identifying physical, chemical, or biological changes that are better indicators of pollution impacts than the parameters currently used in monitoring programs;
- providing information on the character and variability of natural processes in the marine environment that can be used as references against which to compare changes due to human activity;

• establishing a link or correlation between a parameter measured in a monitoring program and an adverse outcome of concern to society (e.g., link between fecal coliforms and disease);

• determining whether measurements made in monitoring programs provide meaningful assessments of the health of the marine environment and the nature of human impacts on it; and

• developing new techniques and instrumentation for use in monitoring programs.

The research sector is even more diverse than the monitoring sector, with a wide variety of programs that span the range from large-scale studies carried out by multidisciplinary research groups to narrowly focused studies performed by individual scientists. The following sections describe representative research activities sponsored by federal, state, and local agencies, universities, and private industry. This is not meant to be an exhaustive listing of programs and certainly does not come close to describing all the research carried out in the bight.

Federal Agencies

Marine research in the bight is sponsored by the National Science Foundation (NSF), the National Oceanic and Atmospheric Administration (NOAA), the Environmental Protection Agency (EPA), the Minerals Management Service (MMS), the Department of Energy (DOE), and the Fish and Wildlife Service (FWS).

The NSF funds individual investigators as well as research programs and institutes at universities throughout the bight. This research is described more completely in the section below on university research.

NOAA funds several important programs in the bight. The National Status and Trends Program was described above as part of the monitoring sector. In addition, NOAA funds the National Marine Fisheries Service (NMFS) and the Sea Grant College Program.

NMFS performs studies of the biology of commercially important fish species and of the relationships between stocks of these species and the physical and chemical oceanography of the bight. Such studies include investigations of habitat requirements, reproduction, feeding biology, population dynamics, geographic distribution, and response to contaminants. NMFS is also an active participant in the CalCOFI program, which combines monitoring and research focused on commercial fisheries (see Historical Monitoring and the CalCOFI Program above). Because of its long history, archived samples from the CalCOFI program have proven valuable in studies of trends of contaminants such as DDT.

NOAA also funds the Sea Grant College Program, which is administered through the University of California. The federal Sea Grant legislation requires that at least one-third of the total federal funds received by each program be matched with local (nonfederal) funds. Since 1973, the state of California has made successive five-year commitments to provide up to two-thirds of the required matching funds (University of California, 1989). Sea Grant studies have addressed a wide variety of coastal problems, including, at present, the functioning of wetlands, physical processes in the coastal zone, aquaculture, marine products chemistry, and ocean engineering.

The U.S. EPA funds research targeted at specific environmental problems. This research is not extensive compared to that carried out by other agencies, since EPA's regional activities are predominantly enforcement related. As an example of such targeted research, EPA supported a study in 1980 to investigate fish catch and consumption among population subgroups in the Los Angeles area. The study was designed to furnish information useful in formulating local regulatory approaches, and was motivated by awareness that certain parts of the local population consume larger than average amounts of locally caught seafood containing elevated concentrations of DDT and PCBs (Puffer et al., 1982, 1983; Puffer and Gossett, 1983; Gossett et al., 1983). In addition, research carried out at the various EPA research laboratories is often relevant to environmental issues in the Southern California Bight.

The Pacific Outer Continental Shelf Region of the MMS funds an Environmental Studies Program (established in 1973) designed to provide basic information needed to make management decisions about the outer continental shelf (F. Piltz, personal communication; Piltz, 1990; MMS, 1990). Although most of this region lies outside the boundary of the bight, some portions of these studies are carried out inside it. Southern California region studies have investigated air quality, potential toxicity of oil to seabirds and marine mammals, adaptation of marine organisms to chronic exposure to petroleum hydrocarbons, and the effects of geophysical acoustic survey operations on important commercial fisheries. In addition, MMS has carried out large-scale reconnaissance of benthic hard- and soft-bottom communities and assessments of long-term changes in benthic communities in oil and gas development areas. Some MMS studies (e.g., Fauchald and Jones, 1978) are notable for their wide geographic coverage and commitment to long-term data collection.

The Ecological Research Division of DOE is sponsoring three regional studies in the bight. One of these, the California Basin Study (CaBS), begun in 1985, is a multidisciplinary effort to examine and understand the production, transport, and ultimate fate of biogenic particulates and the energy-related products (e.g., radionuclides) associated with them. One of the major goals of CaBS is to develop a carbon budget for the Southern California Bight that incorporates the contributions of bacteria, phytoplankton, and zooplankton.

The U.S. FWS Biological Services Program has performed an ecological inventory of the entire Pacific coast, including the bight. The FWS has published several reports on critical habitats within the bight, including kelp forests and coastal marshes, and has developed a series of profiles of environmental requirements for coastal fishes and invertebrates.

State Agencies

Marine research in the bight is sponsored by the California Department of Fish and Game, the Water Resources Control Board, and the Department of Health Services. In addition, state funds contribute to the support of the Sea Grant College Program.

The Marine Resources Branch of the Department of Fish and Game conducts research designed to protect and enhance specific fishery resources. The department has studied the effectiveness of artificial reefs in enhancing fish stocks and evaluated various methods for rehabilitating kelp beds. In addition, the department participates in funding the CalCOFI program, which investigates the biology of commercial fisheries.

The State Water Resources Control Board funds research specifically related to identifying environmental problems and developing water and sediment quality criteria and regulatory standards. For example, the board has supported a survey of PAH levels throughout the bight, followed by laboratory studies of PAH uptake and toxicity. The board has also requested studies of sediment transport and alternative methods of establishing sediment quality criteria.

The California Department of Health Services has examined levels of chemical contamination in fish caught in Santa Monica Bay and Los Angeles and Long Beach harbors. The results of this investigation will be useful to EPA and the Food and Drug Administration (FDA) in revising action limits for some highly nonpolar organic contaminants, such as DDT and PCBs. These are of special concern because of their high potential for bioaccumulation and toxicity.

Local Agencies

The single largest and most focused body of research on pollution problems in the bight is that performed by the municipal and regional sanitation agencies and the research organization they jointly fund, the Southern California Coastal Water Research Project (SCCWRP). In addition, local public health departments conduct research into the health effects of marine contamination and the regional water quality control boards carry out occasional studies targeted at the development of regulatory criteria.

The four major sanitation agencies in the bight all maintain active marine research programs that are beyond the activities mandated by their discharge permits. These four agencies are Los Angeles City, the County Sanitation Districts of Los Angeles County, the County Sanitation Districts of Orange County, and San Diego City. These agencies typically fund research on questions that are relevant to the management of their discharges and the understanding or mitigation of environmental impacts. They consider this research necessary to answer questions that are not addressed by mandated monitoring programs. Research has included both field and modeling studies of sediment transport and plume behavior, as well as investigations of nutrient dynamics in the water column, sediment toxicity, benthic community structure, and kelp bed ecology. In conjunction with SCCWRP, Los Angeles City is currently conducting an experimental study of the rate and character of ecological recovery around the city's sludge outfall, which suspended discharge operations in November 1987. In addition to these active research programs, all discharge agencies in the Southern California Bight belong to the Southern California Association of Marine Invertebrate Taxonomists (SCAMIT). This organization works to ensure that all studies use a consistent, standardized, and up-to-date species list of marine invertebrates. This list has proved invaluable in regional analyses, which otherwise would have been impossible to perform. Discharge agencies also are active members of the Southern California Environmental Chemists Society (SCECS), which performs an analogous function for environmental chemistry.

SCCWRP was founded in 1969 with the aim of conducting both basic and applied marine research relevant to the discharge of municipal wastewater to the bight. At present, SCCWRP is supported by a yearly allocation from the seven major municipal dischargers in the bight, and to a lesser extent by contract funds from state and federal agencies. SCCWRP investigates generic problems of interest to all the dischargers, develops and refines new methods, and performs regional analyses that are beyond the scope of individual dischargers. SCCWRP's work has resulted in important additions to knowledge about the marine environment and improvements to monitoring practice. For instance, SCCWRP researchers have evaluated alternative methods for sampling benthic communities and developed the Infaunal Trophic Index for characterizing the degree of change in benthic communities. They have also investigated histopathological and biochemical indicators of pollutant stress in marine species, documented pollution induced changes in reproduction of key fish species, and monitored regional trends in the incidence of effects such as fin rot and tumors on fish. SCCWRP has performed a vital function because of its ability to collect and integrate data from all the municipal dischargers in the bight. As a result, SCCWRP has been able to complete significant analyses of bightwide patterns and trends in contamination and environmental change. The periodic SCCWRP Report series is available to the public on request.

County health departments and municipal governments in the bight have carried out periodic research studies to assess the likelihood of specific health effects from environmental contamination. For example, the Los Angeles County Department of Health Services has carried out lifeguard surveys in response to inquiries about the health of lifeguards.[1] These studies were stimulated in part by the finding that seven lifeguards in the Los Angeles area had developed cancer. The department is currently planning an additional epidemiological study of lifeguards that will focus on short-term health outcomes. Lifeguards were chosen as a sentinel group for monitoring possible adverse health outcomes due to marine pollution because they are more heavily and consistently exposed than the general public to contaminants in the ocean. The department is also investigating the relationship between consumption of ocean fish and concentrations of DDT, DDE, and PCBs in the milk of lactating mothers.[2] Another example of research performed by local agencies is the city of San Diego's study to assess health risks from the municipal wastewater discharge at Point

[1] In 1982, following notification that seven lifeguards in the Los Angeles area had developed cancer, Dr. Thomas Mack of the University of Southern California Cancer Surveillance Program undertook a study of cancer prevalence in Los Angeles County. He concluded that, although the number of cancer cases was higher than predicted, the elevation was not statistically significant. Neither was there evidence of a causal link between work as a lifeguard near Santa Monica beach and the subsequent appearance of cancer. In addition to these studies, investigations by the Department of Health Services have shown that industrial health claims demonstrate no clear pattern of illness in relation to where the lifeguards work. Prevalence of hepatitis A serology among lifeguards does not differ from control populations.

[2] Previous mammal studies showed that PCBs and DDT adversely affect neonatal development at doses that might be encountered by a small percentage of people eating contaminated fish from the bight (Allen and Barsotti, 1976). To address this concern, the Department of Health Services has selected approximately 50 post-partum breast-feeding women, predominantly from lower socioeconomic groups, as subjects in a study of the relationship between consumption of ocean fish and concentrations of DDT, DDE, and PCBs in breast milk. Preliminary results indicate that PCB concentrations (measured on a fat basis) are typically between 0.1 and 0.3 ppm. There are no values over 0.9 ppm. DDT is present in breast milk at concentrations from 1 to 5 ppm, with a few values over 10 ppm as measured on a lipid basis. It appears that the major source of PCBs in these women is the consumption of fishery products from the bight. However, there is an association between prior residence in Mexico or Central America and elevated (5 ppm or higher) concentrations of DDE in breast milk. All concentrations measured to date are well below the FDA action limits for whole milk (on a whole milk basis).

VOL 12 1 5/05

Loma to recreational divers who use the Point Loma kelp bed or consume seafood caught there.[3]

The regional water quality control boards, which act independently of the state board, occasionally support research targeted at specific local problems. As one example, the Los Angeles board recently funded a study of contaminants in river runoff in the Los Angeles basin.

Universities

The are more than 200 academic institutions in the region of the Southern California Bight. Some of these have extensive and diverse marine research programs, while others may have only one or a few marine scientists active in particular specialties. The great number and wide variety of the academic marine research programs carried out in the bight make it impossible to review this work in detail. The following paragraphs therefore summarize only those programs that are large, well known, or have contributed significantly to knowledge about the marine environment and environmental effects.

The Scripps Institution of Oceanography of the University of California (UC) system carries out the largest and most varied set of marine research programs in the bight. Scripps is one of the largest oceanographic institutions in the country. It coordinates Sea Grant projects carried out by schools in the UC system and is a member of the University National Oceanographic Laboratory System (UNOLS), partially funded by the National Science Foundation. The research performed at Scripps is worldwide in scope and the institution maintains a fleet of oceangoing research vessels. However, a significant proportion of this work is focused on the California Current system and the Southern California Bight.

Scripps has several large research groups that focus on particular aspects of marine studies. The Food Chain Research Group's focus is the food web dynamics and biogeochemical cycles of plankton, and the nature of environmental effects on these. The Marine Life Research Group focuses on understanding the distribution and variability of the living resources of the California Current system. This research is carried out primarily

[3] Between June and September 1986, 346 recruited divers made 1,371 dives in the Pt. Loma kelp bed. Over 90 percent of the divers took seafood from the kelp bed and 25 percent of those who ate the seafood ate it raw. Raw seafood was consumed underwater by 18 percent of the divers. Twelve illnesses that fit the highly credible gastrointestinal symptoms (HCGI) as defined by EPA were reported. If all reported HCGI illnesses were genuine, then there were eight HCGI cases per 1,000 divers. The new EPA Water Contact Criteria that use enterococcus as the indicator organism for marine waters set a maximum allowable geometric mean enterococcus concentration that would permit an estimated 19 illnesses per 1,000 swimmers. The apparent health risk to divers in the Pt. Loma kelp bed is thus relatively low.

in conjunction with the CalCOFI Program. The Center for Coastal Studies emphasizes investigations of sedimentology and physical and chemical oceanography in the coastal zone. The goal of these studies is to increase the ability to assess and predict the effects of human activity in the coastal environment. In addition to these large groups, individual investigators at Scripps carry out research on the physical and chemical oceanography of the bight, as well as on the biology of kelp bed communities, fish populations, and other resources.

The University of California at Santa Barbara (UCSB) supports the Marine Science Institute and the Coastal Research Center. These research groups carry out basic and applied studies on specific marine resources such as kelp beds and fish stocks, as well as on more general problems such as the toxicity of pollutants. The Center for Remote Sensing and Environmental Optics is developing methods for applying remote sensing (i.e., satellite imagery) technology to the assessment of patterns and processes in the marine environment.

The University of Southern California (USC), a private institution in Los Angeles that is designated as a Sea Grant Institutional Program and is part of UNOLS, operates the Santa Catalina Island Marine Science Center. Historically, the USC Allan Hancock Foundation conducted pioneering programs emphasizing the coastal sedimentology and benthic ecology of the bight. USC has also conducted diverse applied studies, such as baseline inventories in marinas, harbors, and nearshore and continental shelf waters, and environmental assessments in support of the siting of the Hyperion Treatment Plant deepwater outfall and the Terminal Island Treatment Plant outfall. USC has also cooperated with the County Sanitation Districts of Los Angeles County in studies of the plume from the districts' White Point outfall. Other studies performed by USC researchers have examined the effects of oil seeps, the Santa Barbara oil spill, harbor dredging, and disposal of fish processing wastes.

The California State University (CSU) system, originally termed the State College system, is distinct from the University of California system. In the Los Angeles area, the State University system operates the Southern California Ocean Studies Consortium (SCOSC), which coordinates marine research, education, and community service programs at several state university campuses. The consortium recently completed a baseline biological survey for the Terminal Island dry bulk handling terminal in Los Angeles Harbor. Prior to and since the formation of SCOSC, faculty at CSU Long Beach have studied the effects of pollution on nearshore benthos and on reproduction of benthic invertebrates and have developed alternative bioassay/toxicity testing techniques. Faculty at CSU Fullerton and CSU Northridge have focused on the ichthyology of wetlands and embayments. Researchers at San Diego State University have performed studies of wetlands degradation and restoration and of the impacts of sewage from Mexico on the Tijuana estuary.

The California Institute of Technology (Cal Tech) supports the Environmental Engineering Program and the Environmental Quality Laboratory. Scientists in these two groups have been involved in the design of major wastewater outfalls in the bight and in developing design modifications for power plant cooling-water intakes that drastically reduced the numbers of fish taken in with the cooling water. In addition, Cal Tech scientists have studied the chemical and physical processes related to the movement and ultimate fates of discharged materials in the bight, have examined the chemistry of wastewater effluent, and investigated the fractionation of sewage sludge discharged to the ocean. For many years, Cal Tech also housed the Kelp Habitat Improvement Project, a long-term effort to understand the biology of kelp beds and enhance their survival and growth.

Notable among the research programs at small colleges in the bight is that at Occidental College, which has operated the R.V. *Vantuna* program for more than a decade. This ship-based program focuses on extensive otter trawling and diver ichthyological surveys, and on research on the effects of heated wastewater plumes from coastal power plants.

Private Industry

Private industries in the bight maintain research programs that are targeted at understanding the effects of specific discharges or other activities. With the exception of Southern California Edison's program, however, most of these are small and narrowly focused. Since 1972, the company has operated a research and development laboratory in Redondo Beach, and for many years supported a program of voluntary research termed the "Special Studies Program." These studies were carried out at SCE's initiative in order to:

- more clearly describe the effects of the company's permitted intake and discharge of power plant cooling water, and
- develop a greater understanding of the mechanisms underlying these effects.

Southern California Edison's research has included investigations of the effect of chlorinated discharges and thermal stress on various life stages of coastal fishes, fish behavior around cooling water intakes, the bightwide distribution patterns of ichthyoplankton and adult fishes, the biology of kelp beds, and remote sensing studies of surface-water temperature patterns throughout the bight. An unusual aspect of much of Edison's research is its emphasis on bightwide patterns and processes. For example, the company has attempted to determine whether its numerous coastal power plants, in the aggregate, have had any effect on larval and adult fish abundance and distribution in the bight. This orientation reflects the fact that Southern California Edison, unlike other dischargers, operates throughout the entire bight.

Research Successes

Research programs have contributed greatly to both the evolution of monitoring technology and to the mitigation of the impacts of human activity in the bight. These contributions are too numerous to list completely, but a few historical examples will indicate the breadth and importance of the relationship between research and monitoring programs in the bight.

For many years, scientists at USC's Allan Hancock Foundation carried out research on the biogeography of the bight. These studies described the fauna of the continental shelf and slope and the offshore basins. The resulting comprehension of zonation patterns was important in understanding the impacts of wastewater discharge. This information was also instrumental in determining the placement of outfalls and designing monitoring programs.

When Southern California Edison was first constructing coastal power plants in the bight, it worked closely with scientists and engineers at Cal Tech to redesign cooling water intakes to reduce the numbers of fish taken in with the cooling water (or impinged). Modeling and experimental studies showed that fish were disoriented by the vertical flow fields around intakes. As a result of this understanding, Southern California Edison fitted velocity caps to all intake structures. These velocity caps create a horizontal flow field around intakes, thus reducing the numbers of fish impinged by over 90 percent. Both the severity of the original problem and the efficacy of the velocity caps were documented by monitoring.

The diversion in 1971 of the County Sanitation Districts of Orange County's wastewater discharge from a shallow inshore outfall to a deeper outfall offshore provided a unique opportunity for research on both the recovery and disturbance of benthic communities. Gary Smith, of Scripps, studied the dynamics of community recovery at the old discharge site and the progress of disturbance effects at the new outfall site (Smith, 1974). The increased understanding of impact mechanisms that resulted from this study was extremely valuable in the continued improvement of monitoring around outfalls in the bight.

SUMMARY

Monitoring and research programs in the Southern California Bight are both diverse and intensive. They are carried out by a wide variety of federal, state, and local agencies, as well as by universities and private industry. Virtually every aspect of the marine environment is currently being monitored or otherwise investigated.

In many instances, research and monitoring activities have been closely coordinated, with research results being used effectively to improve and refine monitoring efforts. The active marine research community in Southern California has produced many innovations that have advanced the state of the art in marine monitoring. In addition, the large monitoring programs represent a valuable source of time-series data on the marine environment in the bight.

One of the most striking features of the monitoring and research system in the bight is the great number of programs carried out by an almost equally great number of agencies, universities, and industries. This has led to examples of interagency cooperation that could serve as a model for other regions facing similar problems. However, it has also led to fragmentation and a lack of integration, which has hampered monitoring efforts. These issues and others related to the technical design of monitoring programs will be dealt with in Chapters 5 and 6.

5
A Framework for the Analysis of Monitoring

The previous chapter documented the wide range of monitoring programs being carried out in the Southern California Bight. Because these programs can be evaluated from many different perspectives, it is important to clarify the criteria the panel used in its analysis of monitoring efforts. These criteria summarize the conceptual framework developed by the parent committee. They provide the basis for determining whether individual programs, as well as the monitoring system as a whole, are effective or not, and can be expressed as six questions:

1. Does monitoring address clearly stated management and societal objectives?
2. Does monitoring address the major environmental problems facing the bight?
3. Do the spatial and temporal scales of monitoring reflect those of the major environmental problems?
4. Are the technical design and implementation of monitoring of high quality? This includes proper statistical design of sampling and analysis, use of state-of-the art field and laboratory techniques, and adequate links to relevant research programs.
5. Do monitoring programs respond in a timely way to changing conditions and needs?
6. Are monitoring resources allocated effectively both within and among monitoring programs?

These criteria reflect the literature on monitoring (e.g., Holling, 1978;

VOL 12 1 5/1/1

Green, 1979; Beanlands and Duinker, 1983; Fritz et al., 1980, National Research Council, 1986; Isom, 1986; Rosenberg et al., 1981; and Bernstein and Zalinski, 1983, 1986) and the experience of the panel members.

It is important to recognize that issues addressed by the evaluation criteria are not strictly technical. This is because monitoring is defined by and carried out within a complex context that includes the interests and information needs of the public and the regulatory agencies and the requirements (procedural and otherwise) of relevant laws and permits, as well as strictly scientific and technical concerns. The analysis of monitoring must therefore look as much at the interface between policy and technical issues as at the technical issues themselves.

The following sections address three areas that are especially relevant to the analysis of monitoring and that underlie the evaluation criteria:

- the importance of clear objectives,
- the role of technical design and its statistical component, and
- the necessity for identifying, evaluating, and prioritizing environmental problems.

THE IMPORTANCE OF OBJECTIVES

Monitoring programs are intended to produce information for quantifying and evaluating the effects of human activity on the marine environment. Monitoring is intended to provide decision makers with the information they need to make appropriate management decisions about how to protect the marine environment and its resources. Ideally, these information needs should be expressed as objectives that guide the design and implementation of monitoring programs.

The objectives that currently motivate monitoring programs in the bight can be loosely structured as a hierarchy. At the highest level are broad concerns about human health and the status of the ecosystem. Beanlands and Duinker (1983) make the point that objectives at this level often reflect sociopolitical values that cannot always be quantified or supported scientifically. This, however, does not necessarily lessen their importance or relevance as the basis of management and monitoring efforts. At the next level are the laws and regulations that embody these concerns as more specific objectives or requirements. At the next level are permits for individual discharges or other activities, which in some cases contain numerical monitoring criteria. Finally, the monitoring design itself is based on decisions about what, specifically, to measure, when, where, and how often to measure it, and about what degree of uncertainty in the final answer is acceptable. Ideally, each level should incorporate the content and intent of the preceding level. Westman (1985) has described an analogous hierarchy in terms of successively more specific and detailed goals, policies, strategies, and tactics.

As the foregoing discussion implies, clear objectives are crucial for both the monitoring and decision-making aspects of environmental management. For monitoring practitioners, they direct monitoring efforts toward the measurement of specific parameters and of specific amounts and rates of change. Without such clear objectives, it is impossible to effectively use such technical design tools as conceptual, numerical, and statistical models, and power and optimization analyses. For managers and regulators, they provide a standard against which environmental change can be measured in order to determine if corrective action is required. It is therefore necessary to completely specify objectives at each level of the hierarchy, from broad public concerns to specific, numerical criteria.

THE ROLE OF TECHNICAL DESIGN

Technical design involves making decisions about what to monitor; how, when, and where to take measurements; and how to analyze and interpret the resulting data. The parent Committee on a Systems Assessment of Marine Environmental Monitoring developed a design methodology that the panel used to structure its evaluation of this aspect of monitoring in the Southern California Bight (Figures 5-1 to 5-4) (National Research Council, 1990). Figure 5-1 shows that technical design must be considered in relation to the initial definition of goals and objectives and the ultimate effective dissemination of monitoring information. Figures 5-2 to 5-4 provide additional detail about the relationships among specific elements of the methodology.

The methodology summarized in Figures 5-1 to 5-4 reflects definite concepts about effective monitoring design and its benefits. These concepts are not the only ones that could have been used to structure an evaluation of the technical design of monitoring programs. They do, however, reflect many of the important themes that recur in the literature on monitoring design. The following is a summary of these concepts:

- Appropriate technical design ensures that data collection, analysis, and interpretation will address management needs and objectives. oTechnical design can be performed adequately only when objectives, problems, questions, or hypotheses are stated explicitly.
- Sampling, measurement, and analysis designs should be developed with the goal of detecting specific kinds and amounts of change.
- Predictions about the kinds and amounts of change expected should be derived from conceptual models that specify how particular human activities (causes) will lead to environmental impacts (effects).

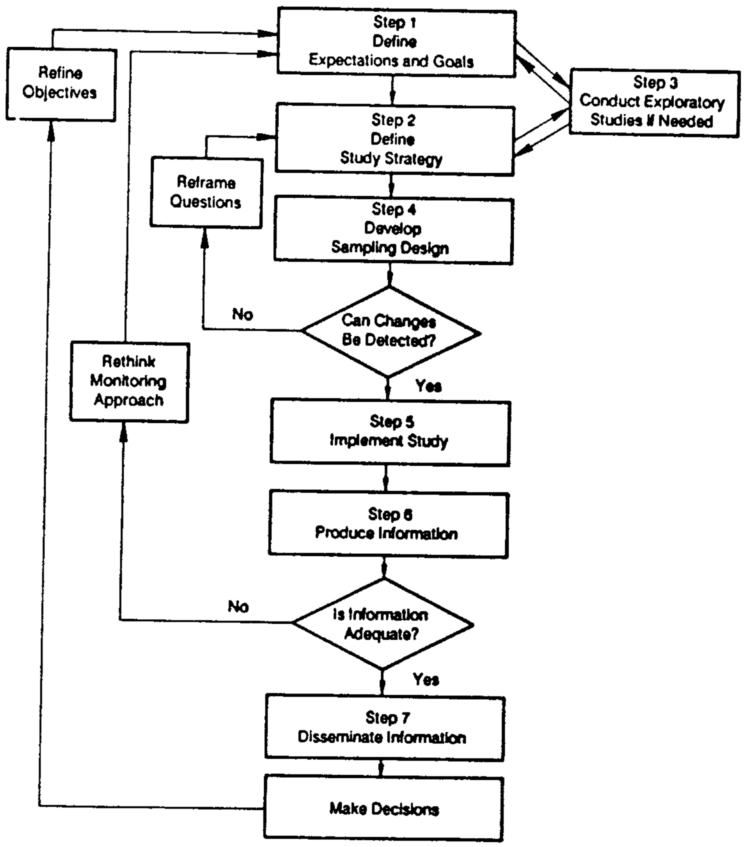

FIGURE 5-1 The elements of designing and implementing a monitoring program.

- Sampling and measurement designs should account for important sources of natural variability.
- Sampling and measurement designs should be evaluated beforehand to determine their ability to detect predicted changes.
- Analysis approaches should be selected before data collection to correspond to the statistical assumptions of the sampling design.
- Data base systems should make authorized versions of the data readily available to analysts and managers, and should provide easy access to a wide range of analysis, graphics, and reporting tools.

VOL 12

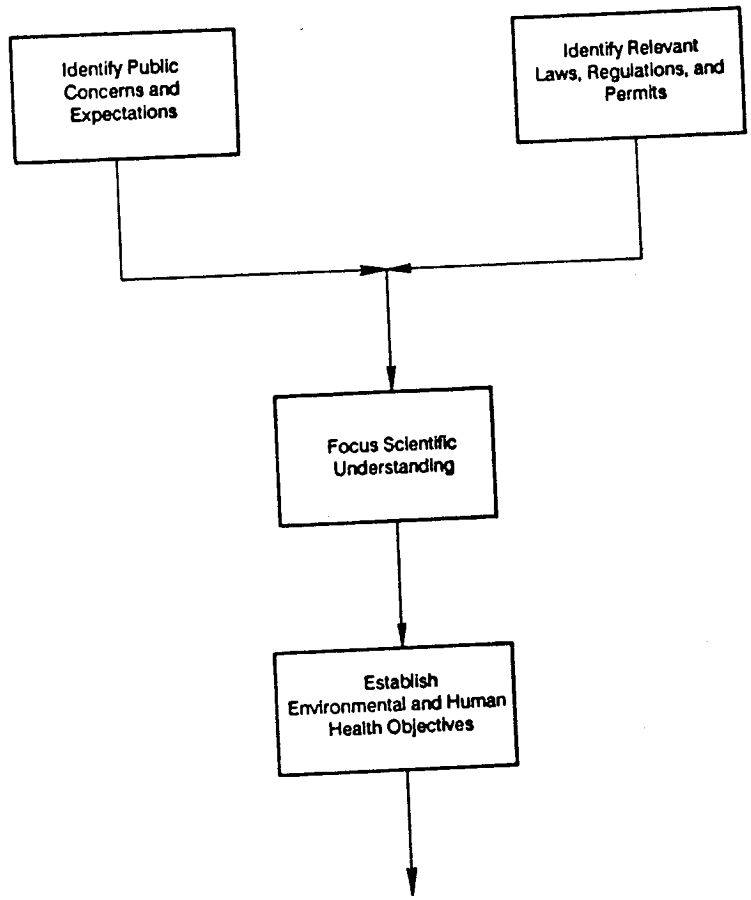

FIGURE 5-2 Step 1: Defining expectations and goals of monitoring.

The technical design process illustrated in Figures 5-1 to 5-4 furnishes a framework for translating broad questions and objectives into specific decisions about what to measure, where to measure it, and how many measurements to take. Using this framework as an evaluation tool enabled the panel to use a common set of standards in considering the technical design of monitoring programs in the bight.

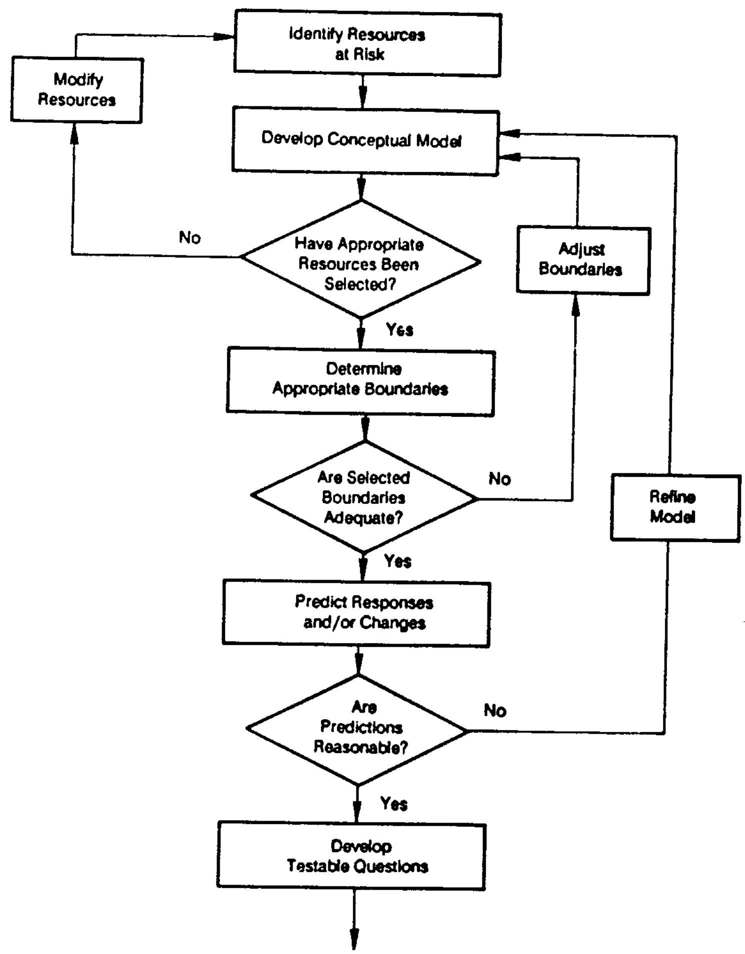

FIGURE 5-3 Step 2: Defining study strategy.

A FRAMEWORK FOR PRIORITIZING PROBLEMS

As stated previously, this case study is oriented toward examining the monitoring system in the bight as a whole. In addition to evaluating whether individual programs meet their objectives, this necessitates determining whether the entire collection of monitoring programs produces

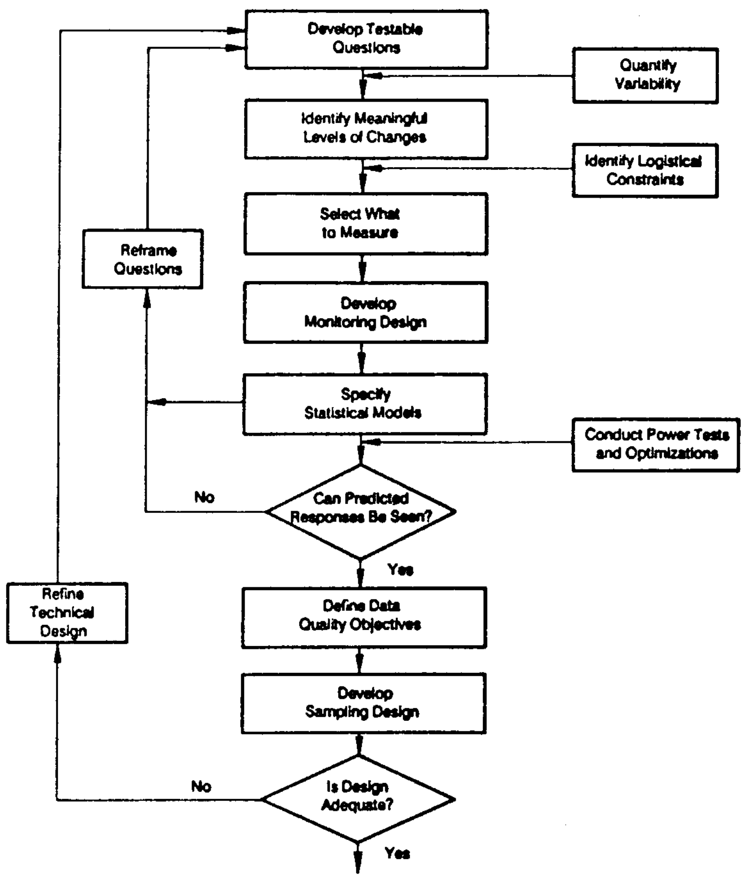

FIGURE 5-4 Step 3: Developing sampling and measurement design.

the information needed to satisfy both management and the public. The technical design methodology described above provided a means of structuring the analysis of individual programs. However, there was no similar framework available for the overall analysis of the monitoring system. The panel therefore adapted existing methods in order to perform a summary assessment of environmental impacts on resources in the bight. This assessment was intended to summarize the nature and severity of impacts on a range of important resources in the bight and was designed to help the panel address specific questions.

- Does monitoring address clearly stated management and societal objectives?
- Does monitoring address the major environmental problems facing the bight?
- Do the spatial and temporal scales of monitoring reflect those of the major environmental problems?
- Are monitoring resources allocated effectively both within and among monitoring programs?

The Assessment Framework

While many useful frameworks have been proposed for environmental assessments (see examples in Beanlands and Duinker, 1983; Westman, 1985; NRC, 1986), constructing one for monitoring in the bight in the context of the case study presented special difficulties. First, the goal of the assessment was to produce a synthetic overview that would aid in drawing conclusions about the entire monitoring system in the bight, both technical and institutional. This is in contrast to more typical assessments that focus only on identifying and quantifying the environmental impacts of individual projects. Second, the time available for developing this overview was necessarily short and the technical and financial resources available were limited. Third, there are extensive and diverse human and natural sources of perturbation in the bight and methods for characterizing multiple and cumulative impacts are not well developed. For example, effects on fish populations may derive from:

- coastal power plants–entrainment of larvae, impingement of adults;
- municipal wastewater outfalls–habitat alteration, changes in food supply, contamination;
- dredged material disposal–habitat alteration, contamination;
- storm runoff—contamination; and
- sport and commercial fishing–increased mortality.
- El Niños–changes in distribution and community structure, habitat alterations; and
- major storms–habitat alteration.

Such effects act on different spatial and temporal scales, and this adds to the challenge of understanding and portraying impacts.

To accommodate these constraints and difficulties, the panel used a combination of matrix and ad hoc assessment methods (Westman, 1985).[1]

[1] The matrix approach was adapted from a framework developed by Clark (1986) for identifying

VOL 12 1 5/1/8

The assessment produced synoptic overviews that were useful in evaluating the overall pattern of monitoring in the bight. However, before reviewing the assessment products and explaining the supporting detail, it is important to understand the limitations of the matrix and ad hoc methods used. In most cases, the limitations of each method were somewhat balanced by the strengths of the other. The procedure described by Clark (1986) proceeds through a series of steps that specify:

- valued ecosystem components (VECs),
- marine constituents (both natural ecosystem parameters and anthropogenic contaminants) that cause changes in the VECs, and
- sources of natural and human-induced perturbation that create or cause changes in these constituents, which are linked in a matrix with specific VECs to show how they—along with contamination in the bight—affect marine resources (Figure 5-5).

The selection of perturbations, constituents, and VECs is necessarily somewhat arbitrary. Given the size of the bight and the multiplicity of resources and sources of impact, some selection among these was unavoidable. This selection reflects the values and biases of the panel, but the critical reviews by experts and scientists outside the panel were designed to balance competing points of view. However, there is no denying that other reviewers might have generated parameters that would have led to a different assessment.

The matrices do not specifically identify primary, secondary, and higher order interactions among perturbations, constituents, and VECs. This would be a severe shortcoming if the matrices were used as a stand-alone assessment method. In this case, however, the matrices were used as a cross check for the conclusions derived from the ad hoc approach and to enforce a degree of systematic thinking. While the matrices themselves do not specify interactions, they were discussed at length during preparation of the matrices and as part of the ad hoc approach.

The matrix products do not quantify effects and impacts. Rather Figure 5-5 scales two impact attributes, the potential influence of each source of perturbation and the degree of scientific certainty associated with this conclusion. This is similar to the scaling of impact magnitude and importance proposed by Leopold et al. (1971) in a similar matrix. This subjective scaling would be a major shortcoming if the panel's intent was to perform a damage assessment, a detailed project assessment, or a comparison of two or more alternative development scenarios. However, in

cumulative impacts. The ad hoc portion of the assessment (Rau and Wooten, 1980) consisted of brainstorming sessions with experts and critical review of the matrix products by individual scientists. The matrix products were modified a number of times to incorporate feedback from brainstorming sessions and individuals' reviews.

VOL 12

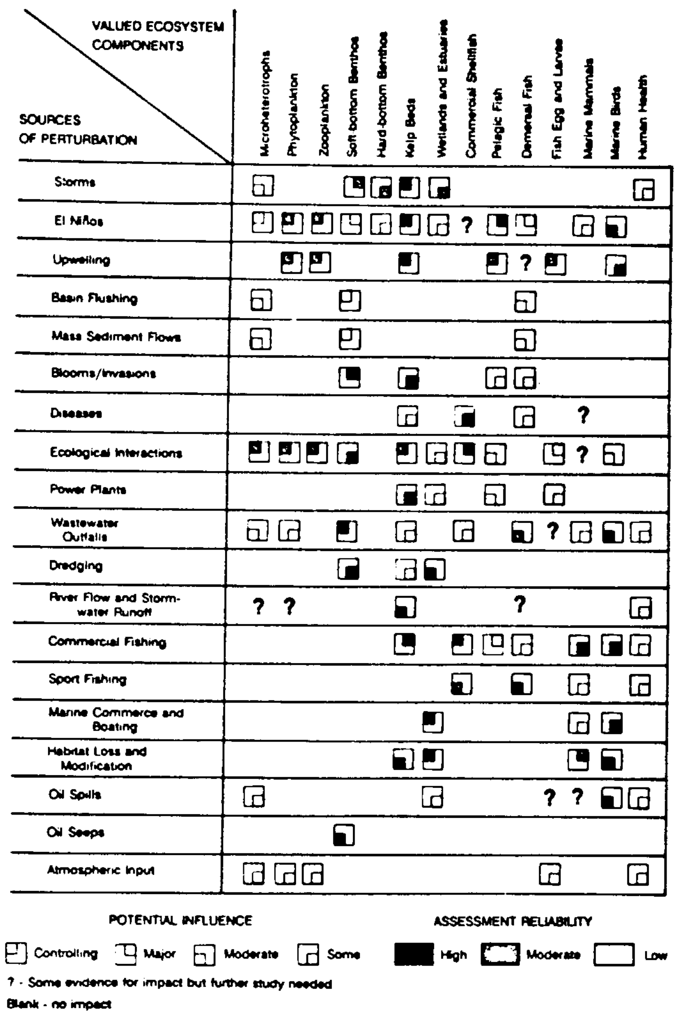

FIGURE 5-5 Impacts on the marine environment of the Southern California Bight. Individual cells of the matrix illustrate the presumed relative impact of each source on each component, along with the associated scientific certainty. Each column represents cumulative impacts on individual components; each row shows the effects of individual perturbations on all components. This figure was used to summarize and investigate ways of identifying and ranking impacts in the bight. SOURCE: After Clark, 1986.

1 5/20

this case the panel's goal was to produce a high-level overview that would assist in comparing the overall pattern of impacts with the overall pattern and structure of monitoring programs. In addition, much of the background information used in both the matrix and ad hoc efforts was derived from extensive and quantitative research, monitoring, and modeling programs.

The overviews that resulted from the assessment lack detail about the nature of the effects they represent. Again, this is less of a problem given the panel's task. In fact, the high-level, summary character of the overviews was actually helpful in elucidating the weaknesses of the existing monitoring structure.

The ad hoc method depends on the collected experience and insights of the participants. As a result, conclusions are dependent not only on the selection of participants but also on their values and biases. Under the circumstances, the panel believed that enlisting the participation of a cross section of scientists from the bight region was the most efficient means of integrating the wealth of scientific and technical information available. Involving scientists of differing affiliations helped to balance individual values and biases. In addition, the matrix method helped to focus, systematize, and cross check each person's opinions and judgments.

No assessment method is perfectly objective. While quantitative models are increasingly valuable, even they depend on certain simplifying assumptions and often are challenged. Similarly, even a moderately sized monitoring program must make judgments about which aspects of the environment to measure or ignore, since it is impossible to measure everything. The panel used the assessment products to derive conclusions about the structure and focus of the monitoring system in the bight. The conclusions were judged to be robust enough to form the basis for conclusions and recommendations, even in light of the acknowledged limitations of the assessment methods used.

A Synoptic Overview

The matrix in Figure 5-5 is a useful heuristic tool. It shows that all ecosystem components are impacted by more than one kind of perturbation. It also shows that perturbations typically affect more than one ecosystem component. For example, storms affect soft benthos, kelp beds, and human health; wastewater outfalls affect soft benthos, microheterotrophs, and demersal fish populations.

Figure 5-5 helps categorize the types of monitoring programs in the bight. Some programs examine the effects of one perturbation on a single resource. These programs focus on one cell of Figure 5-5 and are called single-cell assessments. For example, the impingement sampling program carried out by the Southern California Edison Company is intended to assess the potential impacts of coastal power plants on pelagic fish populations. Other monitoring programs examine the effects of one perturbation on a range of resources. These programs focus on an entire row of Figure 5-5 and are called row assessments. For example, the 301(h) monitoring program around the Orange County wastewater outfall is designed to document the effects of the outfall on a range of resources, including soft benthos, water quality, and demersal fish populations. Monitoring programs that consider how several perturbations, acting together, affect a single resource would focus on an entire column of Figure 5-5 and are called column assessments. There are no examples of such programs in the bight, a fact which will be addressed in more detail in Chapter 6. Further, there are no coordinated monitoring programs in the bight that focus on the effects of two or more sources of perturbation on a range of related resources. Such a program, for example, might document the combined effects of fishing, power plants, and wastewater outfalls on demersal and pelagic fish populations.

Figure 5-5 also presents subjective judgments about the relative importance and degree of scientific certainty associated with each impact. For example, wastewater outfall impacts on soft benthos are more severe and extensive than those from dredging. As another example, it also shows that conclusions about kelp bed impacts are probably more reliable than those about effects on fish eggs and larvae. Such comparisons aid in analyzing existing monitoring programs by suggesting where further research would be more appropriate and useful than routine monitoring. As Chapter 6 makes clear, available financial and technical resources in the bight are not systematically allocated to research and monitoring on the basis of a comprehensive overview like the one in Figure 5-5.

As with Figure 5-5, Figure 5-6 is a useful heuristic tool that supplies insights about the structure of existing monitoring programs in the bight. It shows quite clearly that the impacts that are relatively well understood (e.g., coastal power plant plumes, disposal of coarse dredged material, nutrients, fine particles) are those whose scales are either less than or of the same order of magnitude as those of monitoring programs. It also demonstrates that, with the exception of the CalCOFI program, the temporal and spatial scales of individual monitoring programs are insufficient to resolve patterns of effects on larger scales. While the effects of scale are becoming a matter of concern to ecologists (Wiens, 1989), Figure 5-6 demonstrates that monitoring programs in the bight are not consistently designed with such scale effects in mind. As Wiens (1989) points out, these effects can be complex, and—if not considered carefully—". . . we may think we understand the system when we have not even observed it correctly."

Supporting Detail

As the first step in the matrix assessment procedure, the effects of the constituents on the VECs are identified (Figure 5-7), and the ways in which sources of perturbation cause changes in these constituents are then specified (Figure 5-8). This permits sources of perturbation to be linked (through changes in the constituents) directly to effects on VECs in a matrix (Figure 5-5). This in turn allowed the panel to summarize the effects of various human and natural processes on the VECs. Finally, the temporal and spatial scales of constituents and perturbations (Figure 5-6) are compared to the spatial and temporal scales of relevant monitoring programs.

Figure 5-7 qualitatively shows the effects of changes in marine constituents on valued marine ecosystem components. VECs include important ecosystem components and major fisheries, as well as demersal and pelagic fish life stages that occupy distinct habitats and might be affected differentially. Constituents are divided into physical oceanographic parameters (e.g., waves or temperature), and into floating, dissolved, suspended, and settleable categories. Figure 5-7 shows that specific constituents impact more than one VEC and that some VECs are affected by more than one constituent.

The constituents shown in Figure 5-7 were selected because they are typically measured in monitoring programs. Their division into floating, dissolved, suspended, and settleable categories reflects the fact that their association with particles of different sizes significantly influences the fates and effects of most contaminants. However, the selection and arrangement of these constituents is certainly not the only one possible. For example, rather than focusing on physical and chemical parameters, the constituents could include important dynamic processes, such as production, nutrient regeneration, the flux of organic matter, and recruitment and mortality.

Figure 5-8 furnishes the next link in the matrix-based assessment by showing which sources of perturbation affect which constituents. This then permits connecting sources of perturbation to effects on VECs. For example, the amount and distribution of fine particles and nutrients are affected by wastewater outfalls (Figure 5-8), and such changes can potentially affect the soft benthos (Figure 5-7). This suggests a potential mechanistic link between wastewater outfalls and effects on the soft benthos. Similarly, marine commerce and boating create floating debris (Figure 5-8), which affects marine birds (Figure 5-7). (These admittedly simplistic examples were chosen for illustrative purposes; the reader is encouraged to investigate other links suggested by Figures 5-7 and 5-8).

These two figures can be integrated to furnish a synoptic view of the impacts of both natural and human perturbations on the VECs. Thus, one

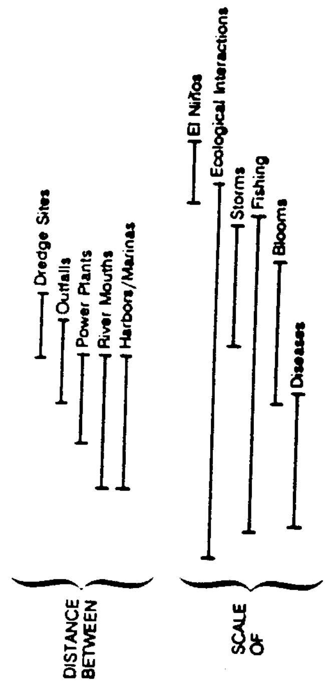

FIGURE 5-6 Characteristic temporal and spatial scales of important constituents and sources of perturbation. Constituents are the same as those in Figure 5-6, but have been abbreviated. "Temp *" refers to temperature changes from coastal power plants, and "Temp" to natural temperature changes (i.e., El Niño events). "Path *" refers to bacterial contamination from wastewater outfalls and storm runoff, and "Path" to pathogens from natural sources that cause diseases in urchins, fish, and other organisms. The abscissa represents a crude estimate of the half life or recurrence time of each constituent. The ordinate represents the spatial displacement likely to occur over that time, or the scale of activity. For example, nonmobile metals and hydrophobic organics are presumed to persist in the environment and spread much more widely than nutrients. The temporal and spatial boundaries of existing monitoring programs are outlined by a solid line, with the exception of the CalCOFI Program, whose parameters are indicated by an "X" in the upper right of the figure. Constituents with similar temporal and spatial scales are outlined with dotted lines. SOURCE: After Clark, 1986.

FIGURE 5-7 Major impacts of natural features of the ecosystem and anthropogenic contaminants on valued ecosystem components. The dots indicate that the listed constituent (left) is presumed to have a significant impact on that ecosystem component (top). Both direct and indirect impacts are included. Volatile organics include phenols and halomethanes; polar organics, PAH, DDT, and PCB. Nonmobile metals include lead and cadmium; complex metals—nickel and copper; organometallics—mercury, tin, selenium, and arsenic. Nutrients include both dissolved nutrients and nutrients associated with particles. Pathogens include those from both anthropogenic (e.g., coliforms) and natural (e.g., urchin disease) sources. Dissolved constituents are those less than .04 μm in size. Settleable constituents are defined operationally as those that settle to the bottom as a function of size and specific gravity. Valued ecosystem components include various parts of the food chain, communities associated with specific habitats (e.g., kelp beds), and important fisheries. Commercial shellfish include abalones, lobsters, and urchins. SOURCE: After Clark, 1986.

can start with VECs such as soft benthos or demersal fish populations, identify the constituents that affect them, and then trace these constituents back through their relationships with sources of perturbation to finally determine all the kinds of perturbations that affect these ecosystem components. The result of this process can be displayed as a matrix (Figure 5-5) that summarizes the impact of each kind of perturbation on each ecosystem component.

Figure 5-5 was constructed using other knowledge from the ad hoc method in addition to the mechanistic linkages shown in Figures 5-7 and 5-8. This points up shortcomings in the selection and organization of the constituents shown in Figure 5-7. For example, Figure 5-5 shows that sport and commercial fishing impact pelagic and demersal fish by directly removing individuals from the population. However, since Figure 5-8 does not include mortality as one of the marine constituents, Figures 5-7 and 5-8 do not combine to predict impacts on fish from fishing, an obvious failing. In addition, Figure 5-5 indicates that blooms, natural diseases, and especially ecological interactions have significant effects on the VECs. However, Figure 5-7 shows that none of these important sources of perturbation interact strongly with any of the constituents other than temperature and dissolved oxygen. The panel thus combined insights from both the matrix and ad hoc methods without rigidly adhering to the limitations of either.

Figure 5-5 is an informative way to organize existing knowledge about impacts on marine resources. However, the spatial and temporal scales of both perturbations and ecosystem processes vary widely and this information is necessary to evaluate the effectiveness of monitoring. The overall assessment framework therefore includes a means of organizing and comparing the temporal and spatial scales of constituents and perturbations. A preliminary approach is presented in Figure 5-6. The constituents are placed in a logarithmic time-space coordinate system based on crude estimates of their half-lives in the marine environment (for contaminants) or their typical scale of activity (for ecosystem features). The temporal and spatial range of existing monitoring programs is indicated, and the temporal and spatial scales of important perturbations shown along the x and y axes, respectively.

SUMMARY

This chapter presents the criteria and concepts used to organize the analysis of monitoring efforts reviewed in the next chapter. Six key questions made up the evaluation criteria used to assess both individual monitoring programs and the collection of monitoring programs in the bight. These questions addressed both the policy and technical aspects of monitoring,

FIGURE 5-8 Sources of major perturbations to the bight's marine ecosystem and their major impacts on marine constituents. The dots indicate that the listed perturbation (top) is presumed tc have a significant effect on the listed constituent (left). Both direct and indirect impacts are included. Perturbations include both human and natural sources of change. Basin flushing refers to the turnover of near-bottom water in offshore basins; mass sediment flows to sudden, large movements of sediment on the shelf; blooms or invasions to rapid increases in population levels of otherwise rare species (e.g., the echiuran *Listriolobus* or the kelp isopod *Pentidothea resecta*). Multiple sources of impacts of one kind (e.g., power plants, dredging) have been lumped to provide a consistent level of generality among perturbations. SOURCE: After Clark, 1986.

emphasizing the panel's focus on the functioning of the monitoring system as a whole.

Three areas that are especially relevant to the evaluation criteria were also discussed. Clear objectives are crucial in providing direction for monitoring design and implementation. An effective technical design then translates these objectives into decisions about what to monitor; how, when, and where to take measurements; and how to analyze and interpret the data. Finally, an overall assessment of environmental problems in the bight provides a framework for determining if all important questions are being addressed and whether monitoring resources are being allocated effectively.

6
Analysis of Monitoring Efforts

As described in Chapter 4, there exists a wide range of current and historical monitoring efforts in the Southern California Bight. Analyzing each of these in turn would be an unrealistic task, but examining only a few in detail might cause us to neglect important insights and patterns that could be derived from a broad survey. This review therefore identifies important conceptual issues, and illustrates them using examples from existing monitoring programs.

Many of these issues and examples identify shortcomings of the monitoring system and existing programs, and others stress positive developments. The analysis that follows emphasizes that monitoring efforts in Southern California are characterized by a commitment to technical excellence and continued evolution toward more sophisticated and effective planning and implementation. There is a broad consensus in the monitoring community that programs today are, in general, vastly improved over those in effect 10 or more years ago. This progress has highlighted remaining problems and has allowed attention to shift to broader concerns. The willing participation in this case study by all parts of the monitoring community is clear evidence of their interest in continuing to improve monitoring efforts.

This chapter focuses on four main topics:

1. institutional objectives and their limitations,
2. technical design and implementation,
3. technical interpretation and decision making, and

4. the overall allocation and organization of monitoring.

Judgments about monitoring's effectiveness in each of these areas are based on the criteria and concepts outlined in Chapter 5. This chapter discusses these concepts more extensively, in light of evidence from specific programs.

The panel's analysis of monitoring was based in large part on the written and verbal comments of invited speakers at the fact-finding sessions and further in-depth interviews with members of the monitoring community. The specific comments of these participants in the case study contributed to a consensus about the overall strengths and weaknesses of monitoring in the bight. This consensus is presented here as a series of statements and is amplified in the following sections.

The strengths of the monitoring system include:

- an established legal requirement for addressing environmental issues and problems;
- important contributions to environmental decision making;
- active links to ongoing research programs;
- innovative monitoring program designs and techniques;
- high-quality methods for collecting, analyzing, and interpreting data;
- raw monitoring data of high quality and integrity;
- large data sets that have greatly increased understanding of localized impacts, particularly of municipal wastewater discharges; and
- a few long-term data sets that are valuable for examining large-scale and long-term effects of human activities on the bight.

The weaknesses of the monitoring system include:

- poorly defined management objectives;
- poorly defined monitoring endpoints or decision criteria, especially for narrative water quality objectives;
- lack of explicit conceptual designs that link monitoring to specific hypotheses or paradigms about the ocean environment;
- inability to address regional or cumulative effects in the bight as a whole;
- sampling designs that do not take into account spatial and temporal scales of natural variability;
- reliance on a shotgun approach that measures many parameters, regardless of their relevance to operational, environmental, or public health decisions;
- rigidity that does not permit dropping redundant or outdated parameters, incorporating research with defined endpoints, or making adjustments in the light of new information;

- over-commitment of resources to well-understood problems;
- lack of a data management system containing a wide range of data types from all major monitoring programs;
- absence of synthesis that provides usable information to managers and other decision makers; and
- inability to effectively report the overall status of the resources and water quality in the bight to the public, the scientific community, and policy makers.

It should be emphasized that this consensus reflects the judgment of many people actively involved in designing, carrying out, and using the data from monitoring programs. Thus, in spite of the strengths mentioned above, and the fact that monitoring data have been used in decision making, there is evidence that the monitoring system could be more efficient, focused, and comprehensive.

INSTITUTIONAL OBJECTIVES AND THEIR LIMITATIONS

As described in Chapter 5, the objectives that motivate marine monitoring can be considered as a hierarchy or continuum. This begins with broad public concerns about public health and the status of marine resources; extends through laws, regulations, and permits; and ends with the specifications of individual monitoring programs. In Chapter 3 the public's concerns were reviewed in the section "Public Concerns for the Bight," while the laws that furnish the regulatory context for monitoring were reviewed in "The Regulatory Sector." Finally, the structure of effluent limitations and water quality criteria was described in Chapter 4 in "The Monitoring Sector."

These objectives influence the design of monitoring programs. They also influence the institutions that oversee the monitoring system. As a result, objectives are expressed explicitly in permits and other documents and implicitly in the behavior of the institutions that regulate monitoring. The following two sections address each of these aspects in turn.

Objectives

Because of the vast number of parameters that could be measured in the marine environment, monitoring programs require clear and precise objectives. The numeric effluent limitations and water quality criteria in discharge and other permits provide such precision. However, the narrative water quality criteria relating to unacceptable degradation or change do not furnish this level of precision. For example, the NPDES permit for the County Sanitation Districts of Orange County states that marine communities shall not be degraded. To monitor degradation in fish communities, a program could legitimately focus on any of the following parameters:

- diversity,
- species richness,
- community trophic structure,
- relative abundance of numerically dominant species,
- population sizes of numerically dominant species,
- population sizes of trophically important species,
- size-age relationships,
- reproductive potential as measured by gonad weight,
- mortality of one or more species,
- incidence of fin rot, tumors, and other abnormalities, or
- body burdens of specific contaminants.

Although these are all measurable parameters that may be indicators of degradation, they do not define it. To design a monitoring program with the objective of ascertaining "degradation," the term must be defined in a meaningful way. Thus, monitoring program objectives should be stated as clear, preferably quantitative, questions or null hypotheses: for example, a program could be designed to determine if the three most abundant fish species within 3 mi of the Orange County outfall had decreased in abundance by more than 50 percent from one year to the next. Such a decrease might be defined as a degradation of these fish populations.

One of the most comprehensive efforts to state monitoring objectives in Southern California is an Environmental Protection Agency (EPA) document titled *Objectives and Rationale for the County Sanitation Districts of Orange County 301(h) Monitoring Program*. For each program element, objectives of the relevant laws and regulations are stated, and sampling and analysis plans are specified. Objectives are precisely stated for influent, source control, effluent, and solids-handling monitoring. Although objectives for receiving-water monitoring are stated more clearly than ever before, they still contain no quantitative criteria for the kinds or amounts of change that should be monitored for. This is an important shortcoming because receiving-water monitoring focuses directly on determining whether human and ecosystem health objectives are being met.

This demonstrates that another level of detail is needed if monitoring in the bight is to consistently provide useful information. It should consist of specific descriptions of the kinds of changes, along with quantitative criteria about the amount of change, that should be monitored for. Hypothetical examples of such objectives, framed as null hypotheses, might be as follows:

- The operation of diffusers for the discharge of cooling water will not decrease the monthly average light transmission in the upcoast quarter of the adjacent kelp bed more than X percent below light transmission in the downcoast quarter of the kelp bed.

- The area around the sewage outfall outside the zone of initial dilution (ZID) exhibiting a change in benthic diversity of X percent or more shall not increase from year to year. Background diversity shall be defined as that found at reference stations A, B, and C.
- The long-term trend of DDT in the muscle tissue of adult Dover sole from the Palos Verdes Shelf shall not increase. Long-term shall mean a period of five years or more, and sampling shall be designed to detect a change in the long-term average of at least 5 percent.

These null hypotheses define a specific parameter and the amount of change to be measured. Before actual sampling begins, additional detail relating to confidence limits, background levels, and other factors must be decided. In the first hypothesis above, locations (surface, bottom, midwater, water column average), time scales (daily, weekly, monthly averages), and distribution of sampling stations must all be established. These decisions can be made with the support of the technical design tools outlined in Figures 5-1 to 5-4. In contrast to most objectives used as the basis of receiving-water monitoring, the three examples above provide the foundation for focused, efficient monitoring programs.

In contrast to other major monitoring programs in the bight, the Marine Review Committee (MRC) programs around the San Onofre Nuclear Generating Station (SONGS) were all designed with a specified probability of detecting definite amounts of change (Chapter 5). This policy was based on predictions of impacts and on a management decision that these amounts of change would be accepted as evidence of power plant impact.

There are two impediments to establishing this detailed level of objectives: (1) incomplete scientific knowledge (for example, an inability to establish source/receptor relationships), and (2) the institutional environment of monitoring. The environmental effects of all human activities cannot be predicted accurately. Where they cannot, objectives must necessarily remain more subjective, or research should be performed. In other cases, however, environmental effects are well enough understood that reasonably accurate predictions could be used to design more efficient monitoring programs. The changes that occur in the benthos around municipal waste discharges are a case in point. Changes in community composition, abundance, diversity, etc., have been well documented and could be used to develop more ecologically relevant and precise receiving-water objectives. Even where clearer and more quantitative objectives could be developed, however, there may be institutional constraints against implementing them.

For example, quantitative receiving water objectives could decrease regulatory flexibility if they were rigidly interpreted as a measure of compliance and automatically triggered management actions or litigation.

Despite these impediments, clearer monitoring objectives would result in beneficial gains in clarity, efficiency, and useful information. These gains would make the effort involved in developing them and integrating them into the regulatory framework worthwhile. In spite of these benefits, a danger of quantitative monitoring objectives is that they may be applied blindly, with little regard for naturally occurring effects. For example, between 1973 and 1977, there was a massive influx of the echiuran worm *Listriolobus* into benthic communities in the bight (Stull et aL, 1986). This organism's burrowing, respiratory, and feeding activities aerated and reworked sediments throughout the bight. In areas of wastewater impacts (particularly White Point on the Palos Verdes Shelf) these activities reduced apparent impacts from the Los Angeles County outfalL When the worm disappeared, impacts reappeared. Without awareness of this naturally occurring but anomalous and confounding event, the strict application of quantitative criteria would have led to the erroneous conclusion that impacts of wastewater outfalls had decreased and then increased.

Institutional Limitations

The statutory and regulatory framework within which monitoring is conducted in Southern California has evolved piecemeal over time, and as a result, deficiencies and inconsistencies exist within the institutional structure. These affect not only the way monitoring is carried out but also the quality of the information monitoring can produce. The most important of these limitations are:

- lack of attention to nonpermit activities that may have large environmental impacts;
- rigidity and lack of flexibility; and
- a piecemeal, permit-by-permit approach to problems that may actually be larger in scope.

These limitations will be discussed in turn and illustrated with specific examples.

Nonpermit Activities

The vast majority of monitoring in the bight is compliance monitoring; that is, it is required as a condition of obtaining a permit. The unstated assumption underlying this policy is that the permitting process addresses all aspects of discharges and other activities that potentially affect the environment. This is not always the case, however, since some large inputs of contaminants are not covered by permits. These include rivers, which contain runoff, treated municipal waste water, and upstream discharges; storm drains; fallout of airborne pollutants; and diffuse inputs of hydrocarbons and other contaminants from marinas and harbors.

Although rainfall is sporadic in Southern California, winter storms can dump 1 to 3 or more inches of rainfall within 24 hours, washing accumulated contaminants from streets, sidewalks, and other surfaces into rivers and storm drains, where they are carried out to the ocean. The river system in the Los Angeles basin (Figure 1-2) drains a watershed of over 4,100 mi^2. During a major storm, the Los Angeles River alone can discharge 65 billion gal of water during a 24-hour period. Additional runoff enters the ocean directly from storm drains. For example, 75 separate storm drains discharge into Mission Bay in San Diego. Many of the industries that discharge into rivers and storm drains operate under National Pollutant Discharge System (NPDES) permits, and there is some monitoring in the Los Angeles basin rivers. However, many river and storm drain inputs are not monitored, and the system as a whole is not managed as a source of contamination.

The bight is adjacent to urban areas that are major sources of air pollutants. Aerial fallout to the ocean surface constitutes a significant source of contaminants (e.g., Table 2-2). The many marinas and harbors are sources of hydrocarbons and other contaminants derived from bilge pumping, sewage discharge, fuel loading and transfer, marine construction and maintenance activities, and ship traffic. Therefore, it is clear that monitoring to satisfy permit requirements does not address all of the large inputs of pollutants to the bight.

Inflexibility

Because monitoring programs are typically defined in regulatory permits, it is difficult to alter them as knowledge accumulates. The lengthy public hearing process required for updating permits has occasionally deterred permittees from attempting to modify their monitoring programs. In addition, there is a natural reluctance to discard or modify parameters that have traditionally been measured, but which may now be outmoded. As a result, monitoring programs often include outdated or inappropriate measurements. Further, procedures that are experimental or in development have been incorporated as routine elements of monitoring, even though the data they produce are not adequate for decision making.

Oil and grease (a generic contaminant category including petroleum, synthetic, and biological "oily" materials) are measured throughout the water column as a part of several wastewater outfall monitoring programs. However, because most oil and grease float, and therefore are rarely found above detection limits in the water column, it is not cost effective to sample there. In addition, dissolved and dispersed oil and grease derive from many other sources, such as oil seeps, bilge pumping, aerial fallout, refinery effluents, stormwater runoff, and even from natural biological sources. Therefore, they are equivocal indicators, at best, of outfall impacts. It was suggested that floating grease balls, which can more directly be related to wastewater outfalls, would be a better indicator.

Biological and chemical oxygen demand (BOD and COD, respectively) have traditionally been measured as part of benthic monitoring programs around wastewater outfalls. These parameters were originally included in receiving-water monitoring programs because they were used by sanitary engineers to monitor in-plant sewage treatment processes. There was a consensus among practitioners in the bight that these parameters are less biologically relevant in an open ocean environment and therefore cannot be meaningfully interpreted. It was suggested that measuring organic carbon and carbon flux, ammonia-nitrogen, and total nitrogen would be more ecologically meaningful (see pages 28–29).

As a condition of their 301(h) permit, the County Sanitation Districts of Orange County are required to routinely measure a wide range of chemical contaminants, even though many of them are never found in effluent or sediments. This represents a large expenditure of resources where past experience has shown there is likely to be little contamination. In contrast, in Los Angeles City's Hyperion monitoring program, the search for chemical contamination is more focused. Priority pollutants in the effluent are measured monthly (quarterly for volatile organics), thus providing regular information about what is entering the environment. During the first monitoring year, all priority pollutants are measured in sediments, trawl-caught fish and invertebrates, and sport fish. Contaminants that were not found in the first year are not monitored during the second and third years. In the fourth year, the entire range of priority pollutants is measured again.

The city of San Diego is required to monitor suspended solids in the water column around the Point Loma wastewater outfall. However, because sampling stations are near the Point Loma kelp bed, the suspended solids samples sometimes contain larval crustaceans or pieces of kelp, seriously compromising the utility of this outfall plume indicator. More useful approaches here might be to measure light transmission or use sediment traps to determine fluxes of suspended particles in the water column.

The location of sampling stations can also be inappropriate. The sampling grid around the Point Loma outfall contains a southern control station that is of little or no use as a control because it is close to a dredged material disposal site and the sediments are predominantly extremely coarse sand. Even assuming that movement of material from the disposal site has not compromised the control station, the unusual sediments will necessarily be associated with a different benthic community, making meaningful comparisons with the outfall stations difficult if not impossible. At the northern end of the sampling grid, the city's permit required sampling a control station called B-2, located in 50 ft of water. This station was sampled for years, but was never used in analyses because there were no other stations at this depth. A transect had originally been planned at 50 ft, but all the stations, with the exception of B-2, were located in areas of rocky bottom, where benthic grab sampling was impossible. The city requested that it be allowed to stop sampling B-2 and instead add a control station at 150 ft. This would have been a more efficient use of resources because the sampling grid already included a transect at the 150-ft outfall depth, but lacked a control. Implementing this change in the sampling design required several years and a public hearing, at a cost of wasted sampling effort at B-2 and reduced ability to monitor impacts at 150 ft.

As part of its NPDES permit to discharge cooling water from coastal power plants, the Southern California Edison Company is required to monitor for thermal effects on marine resources despite the fact that nearly 20 years of studies have documented the limited nature of these effects. This example is indicative of the lack of clearly defined endpoints in monitoring studies, which hinder reallocation of monitoring resources to unresolved or more pressing issues.

Histopathology, tissue analysis for contaminants, and enterococcus measurements have been included as routine parts of monitoring programs, even though many participants in the case study believe they require more research and development before they can provide useful information. The panel stresses that these comments derived from a sincere desire to produce useful information and a frustration with requirements to perform studies whose results are ambiguous or uninterpretable.

Several unresolved issues apply to tissue chemistry studies. The basis of presentation of data has not been standardized, making it difficult to interpret and compare results. For example, data may be presented on a dry weight or lipid weight basis, with each method presenting a different picture of contaminant levels. The problem of confounding due to seasonal and reproductive cycles also has not been resolved. In the spring and summer, fishes' reproductive season, fats are mobilized and transferred from the liver to the gonads. This may affect contaminant levels not only in these tissues but in others as well (Cross et al., 1986). There may be differences in both the timing of reproductive cycles and in tissue chemistry between different species. However, because it is not possible to predict which species will be abundant enough for tissue chemistry studies at any one time, dischargers are allowed to sample species of opportunity. This means that no two dischargers consistently sample the same suite of species at the same time. It also means that the same discharger will sample different species in successive surveys. Given the unresolved issues related to seasonal cycles and interspecies differences, the lack of consistent target populations makes it extremely difficult to interpret tissue chemistry data and relate them to discharges.

The issues of standardization of measurement techniques, seasonal physiological changes, and inconsistent target species also plague histopathology studies. In addition, the interpretation of histological changes in marine organisms can be demanding and ambiguous, and it was suggested by several participants that this technique is not yet suitable for routine monitoring.

In contrast to these two examples of incompletely developed techniques being used as routine monitoring tools, the city of Los Angeles' Hyperion monitoring program includes a microlayer study that is explicitly experimental in design. The permit states that the first-year sampling results will be used to determine the scope and direction of future monitoring. It also defines first-year requirements of an otter trawl sampling program and stipulates that first-year data be used to refine the sampling design for subsequent years. In addition, Hyperion's permit includes specific language that allows for further flexibility as needed (see pages 63 and 65). These examples suggest that permits can be structured to be flexible and adaptable. This produces two important benefits. First, it allows for improving and refining monitoring programs as data become available. Second, it allows resources to be used more effectively by recognizing that some questions are more appropriately dealt with in a research context than in routine monitoring. Repeatedly collecting the same data over and over again is not always the best way to address unresolved questions about the utility of new technical methods.

The Southern California Edison Co. recognized this when it began its program of special studies in the marine environment (see Chapter 4). The special studies were explicitly experimental in nature because it was understood that it is often difficult to define research programs succinctly enough to make them part of routine monitoring. They produced information that was important in understanding and reducing impacts without becoming a part of routine monitoring activities. On the other hand, Edison personnel pointed out to the case study panel that they found the data from mandated monitoring programs based on conventional measurements to be of relatively little value in managing marine resources.

Permit-by-Permit Approach

The existing regulatory framework necessarily forces monitoring into a permit-by-permit approach to environmental problems in the bight. This results in monitoring programs that look at each activity in isolation from all others. Taking monitoring results at face value requires making two related and scientifically dangerous assumptions. The first is that there are no cumulative, overlapping, or interactive effects. The second is that the measurements taken to document the effects of a particular activity reflect that activity and no others. Neither of these assumptions is especially robust, as several examples will make clear.

The County Sanitation Districts of Orange County carry out a monitoring program around their wastewater outfall. Within or very near the sampling grid are other biological and physical/chemical patterns that interact with the effects of the outfall. On the eastern edge of the sampling grid is an active EPA interim-designated, dredged material disposal site for dredged material from upper Newport Bay. This dumpsite is in temporary use, and many of the contaminants found in the outfall effluent are also found in the dredged material. Just inshore of the outfall is the mouth of the Santa Ana River, which seems to be associated with a plume of modified sediments that affect benthic community patterns in the sampling grid. On the western edge of the sampling grid is a region of elevated contaminant levels of unknown origin. The permit-by-permit approach makes it more likely that these potentially confounding influences will be disregarded when designing a monitoring program for the Orange County outfall.

The city of Los Angeles and the County Sanitation Districts of Los Angeles and Orange counties all carry out fish trawling programs around the Hyperion, White Point, and Orange County wastewater outfalls, respectively. These sampling programs are used to independently assess the effects of each outfall on fish populations in the region of the outfall. However, it is likely that at least some portion of the studied fish populations moves throughout the entire area. This means that, for example, the monitoring program at White Point may actually also be measuring some effects of Hyperion and Orange County.

The city of Los Angeles' trawl sampling program in Santa Monica Bay is designed to document effects of the Hyperion outfall on fish populations. However, the Southern California Edison Company and Los Angeles Department of Water and Power also operate coastal power plants in Santa Monica Bay. Entrainment of large numbers of fish larvae by cooling water intakes and impingement of adults may affect fish population sizes and community structure in the bay. In addition, some of the species monitored in the trawling program may spend part or all of the juvenile phase of their life cycle in harbors and marinas in and around the bay. This example illustrates that patterns in fish populations (particularly population size and community structure) measured by the Hyperion monitoring program may actually reflect the effects of a suite of impacts, some of them occurring on other life stages than those targeted by the monitoring program. Other sources of effects were not incorporated into the design of the Hyperion trawling program despite the outfall's close proximity to coastal power plants; permitted and accidental discharges from oil refineries, stormwater drains, and nonpoint sources of pollution; marinas; and contaminated juvenile habitats.

The permit-by-permit approach to establishing monitoring programs also leads to important inconsistencies among monitoring programs. Some of these reflect the fact that permits were written at different times, with more recent permits incorporating more up-to-date knowledge. However, other inconsistencies reflect differences in approach or expertise among the regional water quality control boards and EPA Region IX personnel. As discussed more completely below, such inconsistencies make it difficult to develop an integrated view of impacts and trends in the bight as a whole.

Specific examples of inconsistencies among monitoring programs include the following:

- The city of Los Angeles has a flexible approach to measuring priority pollutants in sediments and organisms, whereas the County Sanitation Districts of Orange County measure priority pollutants regularly.
- Trawl sampling around wastewater outfalls is usually conducted quarterly or semiannually, but trawl sampling around coastal power plants is conducted every two months.
- The city of Los Angeles conducts offshore water quality sampling weekly because its discharge is near areas of intense water-contact recreational areas, whereas the County Sanitation Districts of Orange County conduct offshore water sampling monthly for some parameters and quarterly for others.
- No two dischargers consistently use the same organisms for tissue chemistry measurements.
- The city of San Diego is not required to conduct trawl, rig fishing, or tissue chemistry studies, although other dischargers are required to do so. However, trawls are performed on a voluntary basis to contribute to a regionwide assessment of fisheries resources.

TECHNICAL DESIGN AND IMPLEMENTATION

This section summarizes the extent to which monitoring programs in the Southern California Bight meet the criteria for technical design presented in Figures 5-1 to 5-4. The discussion is organized around

- the issues of statistical design of monitoring plans,
- the establishment of field and laboratory procedures that ensure valid, high quality measurements, and
- data management strategies.

Statistical Design

There is still room for improvement in how statistical tools—quantitative null hypotheses, statistical models, quantification and partitioning of variability, optimization analyses, and power tests, for example—are applied to program design. These tools are beginning to be applied to monitoring programs in the bight, and the EPA has produced 301(h) guidance documents that provide instructions for their use; however, lack of clear quantitative objectives prevents effective application. New monitoring tools can be properly applied only in the context of clear statements of management needs and the questions and/or hypotheses that reflect them. The following examples illustrate this point:

- Power tests can estimate the likelihood that a sampling plan will detect a change, such as an increase in the diversity of the benthic infaunal community of 0.1, 0.2, 0.3, 0.4, etc. Without guidance from regulations or ecological theory about what specific amount of change is important, it is still possible to perform power tests for a wide range of possible changes, then choose the sampling plan that is most likely to detect change (any change). However, a more useful approach would be to decide that a specific increase of 0.3, for example, is a strong indicator of outfall enrichment effects, then use power tests to design a sampling plan with a high probability of detecting that precise amount of change.
- Measurements of background variability can be extremely useful in designing efficient sampling plans. In spite of this, great time and expense could be wasted attempting to measure variability on all scales (e.g., feet to hundreds of miles and days to decades). However, if managers determine that only present effects within 6 mi of an outfall are of interest, other variability scales can be deemphasized. If managers are also interested in change from year to year, annual background variability would become relevant. If managers are interested in longer-term trends—more than 10 years, for example—then interannual variability on that time scale would become relevant.
- There has been discussion in the development of 301(h) monitoring plans about the proper number of "replicate" benthic grabs to take at each station. This discussion has used the results of technical design tools such as power analysis. Even these tools cannot resolve the issue because there is no one right number of replicates to collect. The proper number depends on the question(s) being asked, the amount of predicted change sampling

should detect, and the sources of variability that could obscure monitoring results.

This last point deserves further discussion because of the mistaken assumption that the same number of replicates is appropriate for all situations. As one example, if concern is focused on the difference in diversity inside and outside the ZID boundary at one point in time, then a different number of grabs at each station may be required than if the concern is about how the relationship between diversity inside and outside the boundary changes over five years. Further, if concern is focused on how diversity inside the ZID changes over five years in response to changes in the output of suspended solids, then another number of grabs might be appropriate.

Some of the deficiency in the consistent and proper use of technical design tools in monitoring programs in the Southern California Bight stems from the incorrect use of statistical concepts. Two such important concepts are "significance" and "replication."

Portions of permits and regulations state that a particular activity shall not cause a "significant" alteration, change, decrease, or degradation in some physical, chemical, or biological parameter. The California ocean plan (State Water Resources Control Board, 1987) defines a "significant" difference as "a statistically significant difference in the means of two distributions of sampling results at the 95 percent confidence level." The problem with this definition is that it provides no guidance in determining how large a change is of importance and should therefore be detected by a monitoring program. This is because virtually any change can be a statistically significant difference, depending on the intensity of sampling. Thus, a monitoring program with a low intensity of sampling will find only large changes to be statistically significant, while one with a high intensity of sampling could find even minuscule changes to be statistically significant. Permits and regulations should replace the word "significant" with another such as "meaningful" or "important" and then define the terms clearly.

There is an emphasis on replication in Southern California Bight monitoring programs but no equivalent awareness that replication has at least two different meanings, and that many aspects of a sampling plan can conceivably be replicated. Replication is loosely used to refer to the process of collecting repeated measurements, samples, or comparisons. However, in a stricter sense, it refers to the process of repeating entire experimental treatments. In addition, a sampling plan may have many levels of sampling, any and all of which may be repeated. For example, a monitoring program set up to determine whether benthic infaunal diversity inside the ZID is decreasing over time with respect to diversity outside the ZID might include:

- several stations inside the ZID,

- several stations outside the ZID,
- one or more "replicate" grabs at each station, and
- several sampling periods over time.

This sampling plan thus includes replicate grabs at each station, replicate stations within each area, and replicate times or surveys during which all stations are sampled. Depending on the resolution desired, technical design tools such as power and optimization analysis might indicate different numbers of "replicates" at each level of sampling (e.g., two grabs per station, five stations per area, and nine surveys over time). When different kinds of "replication" are not clearly distinguished, monitoring programs tend to emphasize repeated samples at a single place and time. A balance has to be struck between extensive replication of all samples and spreading limited sampling resources over other levels of a sampling plan.

Field and Laboratory Procedures

Many field and laboratory procedures are of commendable quality in Southern California monitoring, where an attempt is made to use state-of-the-art methods, particularly in the larger programs. In addition, an emphasis on improving monitoring methods has resulted in standardization of invertebrate taxonomy, benthic grab sampling techniques, and chemical analysis procedures. Monitoring programs at the municipal wastewater discharges benefit directly from research carried out at SCCWRP. New questions and new methods of sampling and analysis have been incorporated quickly into ongoing monitoring programs.

Although monitoring methods are state of the art, they may not always be adequate to address monitoring objectives. Such an example was described above with reference to tissue chemistry and histopathology studies. As another example, public health surveillance methods are not precise enough to detect brief episodes of mild illness among swimmers due to bacterial or viral agents in marine waters. In addition to the epidemiological problems, studies of putative viral agents are hampered by lack of culture techniques. There is growing recognition that there may well be a better indicator of fecal contamination than the coliforms (i.e., the enterococcus group), and health agencies are actively acquiring information to assess these new indicators. Because epidemiological studies are expensive to perform and marine epidemiological studies often yield equivocal results, especially when performed on a small-scale local basis, state and federal public health and water quality agencies have been reluctant to fund such studies.

Data Management

Data management is vitally important to monitoring efforts because it determines the final accessibility and utility of the data. Data management should include quality control procedures that ensure data accuracy at every step from initial collection to final analysis and reporting. It should also include methods for making the data readily available in usable formats to those responsible for analyzing and examining them. Another important but little-recognized aspect of data management is the importance of specifying data tabulation methods, structures, and handling procedures before a sampling program starts. This allows data to be collected and processed in ways that are appropriate to their final use, dissemination, and storage. This specification of data management procedures at the beginning of a program can save significant effort and money that would otherwise be spent correcting errors in raw data, analyses, and reports.

At present, there is a wide variety of approaches to marine monitoring data management in the bight. In spite of this variety, the panel found that the major monitoring programs all have well-developed and active systems for ensuring the accuracy and quality of their raw data. These data are continually reviewed and updated when necessary. The following examples are representative of data management approaches in the bight.

The 301(h) programs configure their data in the National Oceanographic Data Center (NODC) format and are now required to submit monitoring data to the EPA Ocean Data Evaluation System (ODES). ODES, designed to provide ready access to 301(h) data, has recently become fully operational and includes formal quality control procedures. However, not all historical outfall monitoring data are in digital format. For example, the Los Angeles County sanitation districts have computerized past monitoring data from the White Point outfall, whereas such data from the County Sanitation Districts of Orange County are available only in written reports.

Data from the California Cooperative Oceanic Fisheries Investigation (CalCOFI) program are in NODC format and are available in published data reports. The Southern California Edison Company maintains its own data base for a wide range of monitoring data. The National Marine Fisheries Service and the California Department of Fish and Game have fisheries monitoring data available on magnetic tape; however, these agencies do not maintain user-oriented data bases to provide access to these data. Scientists at the Scripps Institution of Oceanography monitor temperature and wave energy and provide these data on magnetic tape on request. Data from smaller studies (e.g., Los Angeles Harbor, Marina del Rey) are typically stored on floppy disks or on consultants' computer systems.

The city of San Diego and the County Sanitation Districts of Orange

County have initiated analogous programs to centralize and automate their in-house data management procedures. These systems provide computerized data entry functions that automatically perform quality control checks on a range of raw data. Validated data are stored in a centralized data base and a set of menu-driven options allow users to update and extract data. Additional menu options permit users to automatically produce standardized regulatory reports and automatically format data for submission to ODES. Finally, the systems incorporate links to a variety of analytical tools, such as spreadsheets and analysis and graphics software.

The taxonomic efforts of the Southern California Association of Marine Invertebrate Taxonomists (SCAMIT) and the ODES data base represent important steps in setting consistent standards for standardization, quality control procedures, error checking, and digital formats for monitoring data. However, there is currently no easily accessible, user-oriented data base system to provide access to analysts interested in integrating data from several different kinds of studies. Such a system would greatly facilitate attempts to study regional and longer-term questions related to environmental effects in the bight.

There are two prototypes for such a system, each with its own strengths. These are the operational environmental data base developed by the Environmental Research Group of Southern California Edison and ODES. Both systems are unusual in that they include extensive quality control procedures and on-line documentation and are designed to permit data analysts to use menu-driven routines to readily extract data needed for analyses. Southern California Edison's system was designed to perform the following functions:

- store corrected and updated archival versions of important data sets so that all analysts access the same version of the data;
- store important data sets in a data base management system that provides the ability for easy extraction, updating, and manipulation of data;
- provide comprehensive on-line documentation of methods, error corrections, data characteristics and peculiarities, and publications for each data set;
- provide automated browse, search, retrieval, and reporting facilities;
- provide flexible links to the Statistical Analysis System (SAS) and other data analysis systems; and
- allow easy addition of novel data types to the system.

This system is fully operational and contains a wide variety of monitoring studies in standardized formats, thus facilitating comprehensive analyses. These studies currently include:

- benthic infauna and sediment data from monitoring programs at San Diego, Los Angeles city and county municipal wastewater outfalls;
- Southern California Coastal Water Research Project's (SCCWRP's) 198-ft (60-m) survey;
- Scripps' shoreline temperature data for the west coast of the United States, and wave energy and wave direction database;
- California Department of Fish and Game sportfish catch;
- National Marine Fisheries Service commercial fish catch data;
- benthic infaunal and sediment data from the Bureau of Land Management (BLM) study of the bight;
- complete impingement data for all Southern California Edison coastal power plants;
- data from bightwide ichthyoplankton studies and fish trawl studies performed for Southern California Edison; and
- selected Marine Review Committee studies.

This system is proprietary and is not accessible to scientists outside of Southern California Edison. It does, however, illustrate that such comprehensive databases can be constructed. The main strength of Southern California Edison's system is that it contains a wide range of data from biological and physical oceanographic studies that are bightwide in scope. The experience of constructing this database substantiated the fact that locating, acquiring, correcting, and standardizing disparate data sets is a significant effort.

The other system that points the way toward bightwide data management is ODES. ODES is intended as a national database to contain 301(h) monitoring data, which includes (among others) benthic infauna and sediment chemistry, otter trawl, water quality, and other data types. It includes a wide range of menus that assist users in extracting and combining data from different studies, in performing common types of analyses, and in creating maps and graphics. In addition, ODES provides for extracting raw data for analysis with other software packages.

Despite its strengths, ODES has shortcomings that restrict its utility and that must be corrected in any future system that successfully provides access to a range of monitoring studies. There is widespread dissatisfaction with ODES within the Southern California monitoring community. This dissatisfaction results from the difficult and labor intensive procedures required to format data for submission to ODES. It also stems from the lengthy wait required for feedback to requests for new species codes and answers to technical questions. There is therefore a long delay between the initiation of the submission process and the final availability of the data. Users of ODES have access only to the analysis and reporting routines that have been programmed into the system. While many of these are very useful, they do not cover the full variety of approaches required for a comprehensive analysis of monitoring data. Requests for additional analytical tools must wait until they can be programmed into the system, since ODES does not allow users to directly access other analysis systems. Users can, however, extract data from ODES and download them to their own computer systems. Another shortcoming is that when new data types are encountered, ODES must be reprogrammed to accept them, a process that can take several months. In contrast, data base systems that are designed for adaptability use table-driven data definition approaches to allow for rapid modification of data base structures.

ODES provides the ability to combine data from more than one study in order to perform regional or national analyses. However, in practice this capability is severely limited because ODES lacks an aggressive program to update data sets in the system and to standardize taxonomy among data sets. Experience in the bight has shown that such taxonomic updating and standardization is crucial if data sets are to retain their utility and if different studies are to be combined. Species names, particularly of benthic invertebrates, change continually over time as scientists adjust taxonomic affinities. Thus, for data sets to remain current, even historical data must be updated regularly. Taxonomic standards invariably differ among different studies. This is true even when efforts are made to use common standards. Thus, in order for data from two or more studies to be combined, careful attention must be paid to reconciling these superficial dissimilarities. As a result of the lack of such updating and standardization procedures, only analyses that do not depend on merging or matching species data can be performed with ODES. Such analyses include those using derived variables such as diversity indices, total abundance, numbers of species, or summaries of higher taxonomic groups.

TECHNICAL INTERPRETATION AND DECISION MAKING

The ultimate goal of monitoring is to provide data and information to support informed decision making. In this section, the technical interpretation of data obtained in monitoring programs and its use in decision making are addressed. Some examples show that monitoring data have been adequately interpreted and used in decision making. Overall, however, considering the effort that has been put into data collection, no comparable effort and expense has been devoted to translating that data into useful information and using it in decision making.

In spite of the shortcomings in the interpretation and decision-making process (reviewed below), it is important to recognize that monitoring information has played a significant role in many far-reaching management decisions in the Southern California Bight. Water quality and bacteriological monitoring data from Santa Monica Bay documented the severity and extent of nearshore contamination from sewage discharges in the 1940s and 1950s. These data helped make the case for construction of offshore outfalls in 1957 and 1959 that dramatically reduced nearshore sewage contamination.

In 1977, the California Department of Fish and Game closed the abalone fishery from Palos Verdes Point to Dana Point. This decision was based on monitoring surveys and catch data. As another example, scientists of NOAA's Ocean Assessments Division have used data from SCCWRP and the municipalities to evaluate environmental conditions relating to the body burdens of chlorinated hydrocarbons in coastal marine organisms (Mearns and O'Connor, 1984; Matta et al., 1986; and Mearns and Van Ness, 1987).

The inability of the city of San Diego's Point Loma wastewater treatment plant to consistently meet bacterial standards contained in the 1983 California ocean plan (State Water Resources Control Board, 1983) for offshore kelp beds contributed to a decision by the city to extend its outfall farther offshore. Earlier monitoring data generated by Southern California Edison Company showed that unacceptably large numbers of fish were being taken into cooling-water intakes of power plants. As a result, intakes were redesigned with velocity caps and other changes to reduce entrainment and impingement. Monitoring data were then used to confirm that the design changes were effective.

Data generated over the last eight years by the Marine Review Committee on the environmental impacts of SONGS will be used to make decisions about changes in the design or operation of the cooling-water system. These data will also be used to support the development of mitigation measures to offset impacts documented through monitoring. The recently released first-year report for the 301(h) monitoring program performed by the County Sanitation Districts of Orange County resulted in adjustments to the districts' permit. In addition, the data in the report suggested that no changes were needed in the waste discharge or treatment processes.

By far the greatest effort in data interpretation between the 1950s and the present has been the work of SCCWRP scientists. Starting with the 1973 report on conditions in the bight and implications for management (SCCWRP, 1973), their periodic reports and scientific journal publications have become internationally recognized. Although their work has included much more than evaluation of routine monitoring data, it has resulted in improved monitoring methods and in quality control activities that increase the reliability of the data. In fact, the scientific publications of the majority of SCCWRP scientists are cautious, if not silent, on interpretation of monitoring data with respect to regulatory actions. Instead, their interpretations generally focus on environmental conditions and, to a somewhat lesser extent, on possible impacts of pollutants.

On a smaller scale, the Channel Islands National Park monitoring program has generated data since 1981 from diving surveys at 14 stations, conducted primarily by volunteers. These data are used to make decisions about visitor access, harvesting of resources, and development of the park resource. As another example, the program conducted by Occidental College for Southern California Edison was originally related to monitoring the effects of waste heat discharge from coastal power plants. It has also yielded useful resource information on a sedentary reef fish community. This latter example demonstrates that if data were made available scientists would find monitoring programs useful for filling in information gaps about marine resources.

In many instances, the use of monitoring data is not as clearcut as in the examples just cited. In some cases, it is difficult to document whether decisions were based on monitoring results, particularly when decisions were made not to change existing procedures.

In some instances, disagreements about the interpretation of data can hamper the ability to make resource management decisions. For example, during the 1940s and 1950s, major differences of opinion among scientists working on sardines hindered implementation of the management measures needed to protect this fishery resource (Baxter, 1982). Scientists from the U.S. Bureau of Commercial Fisheries contended that year-class size was independent of the size of the spawning stock and that catch size therefore had no effect on stock size in subsequent years. California Department of Fish and Game scientists believed that there was a strong link between year-class size and spawning stock size. By the time the disagreement was resolved in 1966 in favor of the Department of Fish and Game, the fishery had collapsed.

Complicating such scientific uncertainty is the fact that the societal implications of resource decisions can be quite extensive. Thus, decisions based on limited data impose risks that managers have to weigh against expected benefits and the time constraints of required actions. For example, decisions involving the economic livelihood of fishermen who harvest pelagic fish stocks may require a decade to correct if the result of the decision is not as expected. In fact, a decade or more may sometimes be required to produce a signal sufficient to determine if the decision was correct.

In addition to scientific uncertainty, institutional limitations can limit the effective use of monitoring information in decision making. All too frequently, data reports sent to regulatory agencies are not subjected to thorough scrutiny and summarized for policy makers and the public. This is because the human resources and budgets of the regulatory agencies are inadequate to interpret the growing masses of data generated each year and translate them into information useful to environmental managers and policy makers.

Dischargers and other permittees often perform extensive analysis and interpretation of monitoring data. However, their reports are usually too lengthy and detailed to be readily accessible to policy makers and the public. In most cases, budgets earmarked for data analysis and interpretation by both the regulatory agencies and the permittees are judged inadequate. It was the consensus of the case study participants that monitoring data were incompletely synthesized and inadequately used in decision making. This is unfortunate because many monitoring reports contain extensive data sets that are not available in scientific journals even though they are peer reviewed to rigorous standards. In spite of this, some are suspect because the quality and quantity of the reviews are not documented. A statement at the beginning of such reports documenting the review process would have a favorable payoff in building confidence among the aware lay public who are trying to sort out technical issues. There are some exceptions to this generalization (for example, Matta et al., 1986) that provide both data, frequently from monitoring programs, and analysis of data. These are widely distributed and are cited in many regulatory documents such as the 301(h) decision documents.

Another institutional limitation derives from the differing responsibilities of the various regulatory agencies involved in managing monitoring activities. The EPA acts primarily as an enforcement and compliance agency. The state of California, through the State Water Resources Control Board has primary responsibility for the development of ocean policy in general, represented by the California ocean plan (State Water Resources Control Board, 1987). Evaluation of monitoring data is one part of the process of developing this policy and the specific regulatory actions intended to implement it. The state board establishes overall policy and the regional water quality control boards determine individual permit requirements.

Both the EPA and the regional boards believe that most monitoring programs are well planned, well executed, and yield data that are useful in demonstrating compliance and in documenting regulatory changes. The state board, however, has the additional responsibility of identifying beneficial uses of marine resources and establishing water quality objectives to protect those uses. The state board staff believe that the question, "Are beneficial uses being protected?" is of more fundamental importance than mere compliance, but that monitoring data are not presently adequate to answer this question. As explained in the next section, this may be because the available monitoring data are not sufficient to fully address this broader question and because the specific questions are not asked precisely enough to guide monitoring efforts.

OVERALL ORGANIZATION OF MONITORING

The preceding description and analysis of monitoring efforts in the Southern California Bight show that monitoring has achieved important successes. It has documented the extent of impacts from point sources such as power plants and wastewater outfalls. It has tracked the improvement of gross contamination in areas such as Los Angeles Harbor and the beaches of Santa Monica Bay. Longer-term studies, such as those carried out at the White Point outfall by the County Sanitation Districts of Los Angeles, have provided valuable insights into how human impacts interact with natural disturbances.

However, the same analysis shows that the existing monitoring system does not address all important sources of impacts (e.g., storm drains). In addition, Figure 5-5 shows that many important resources are affected by more than one kind of human or natural perturbation. In spite of this, there are no monitoring programs that focus on resources by integrating data about the cumulative effects of more than one kind of perturbation. This is because the monitoring system derives predominantly from a focus on regulating specific human activities, rather than managing natural resources. Finally, Figure 5-6 shows that many contaminants and other sources of change act on time and space scales much larger than those of the typical monitoring program. As a result, the existing monitoring system has difficulty resolving bightwide patterns of change that may be just as important as the localized impacts that are the current focus of monitoring.

In Chapter 5, four questions were identified as being especially pertinent to evaluating the overall success of monitoring in the bight. These were as follows:

- Does monitoring address clearly stated management and societal objectives?
- Does monitoring address the major environmental problems facing the bight?
- Do the spatial and temporal scales of monitoring reflect those of the major environmental problems?
- Are monitoring resources allocated effectively both within and among monitoring programs?

The foregoing analysis provides the basis for answering these questions. In each case, the summary answers below are focused on assessing the performance of the monitoring system as a whole, rather than on individual monitoring programs.

Objectives

As described previously, there are different kinds of objectives that motivate monitoring, from the broad concerns of the public to the detailed specifications of individual monitoring programs. These objectives can be classified as those pertaining to the effects of specific activities (e.g., dredging), to the overall status of important resources (e.g., kelp beds), and of the bight as a whole. Because of the institutional structure of the regulatory and permitting system, only the first of these is addressed in any detail by the existing monitoring system. In Figure 5-5, this can be represented as looking only at each row in isolation, ignoring both columns and the matrix as a whole.

While objectives relating to measuring and managing the impacts of individual activities may not always be clearly stated, they nevertheless are the unmistakable focus of permits and monitoring programs. In contrast, important concerns about the status of resources and the bight as a whole are not manifested in the more detailed objectives that structure monitoring programs.

Major Environmental Problems

There can be no arguing with the fact that monitoring addresses many of the major environmental problems facing the bight. However, it is also clear that the existing monitoring system cannot address other problems that are just as pressing. These include nonpermitted sources, such as storm drains and atmospheric input of contaminants. They also include cumulative impacts stemming from the action of more than one kind of human or natural perturbation on a single resource. Finally, the existing monitoring system cannot adequately assess the existence and importance of large-scale and long-term environmental trends in the bight.

The importance of these other environmental problems is a result of two major trends in the bight. First, increasing population and attendant utilization of marine resources have magnified the potential for cumulative and large-scale impacts. Sources of contamination and perturbation are more numerous and more closely spaced than in the past. Second, the existing monitoring and management system has been remarkably successful in removing gross pollution from the bight. As a result, concerns about cumulative impacts and subtle changes over time have become relatively more important.

Spatial and Temporal Scales

As a general rule of thumb, the spatial and temporal boundaries of a monitoring program should match those of the phenomena it is attempting to monitor. As Figure 5-6 shows, the spatial and temporal boundaries of existing monitoring programs match those of some but by no means all of the relevant processes in the bight. As a result, the existing monitoring system has only a limited ability to resolve trends and changes occurring on larger time and space scales. Such trends and changes can be natural, in which case they represent a moving background against which human impacts must be compared. Large-scale changes can also result from human impacts that by their nature cannot be restricted to one location (e.g., DDT contamination).

The CalCOFI program (e.g., Chelton et al., 1982) and the Bureau of Land Management study of benthic communities in the bight (e.g., Thompson and Jones, 1987) provide examples of the ability of larger-scale sampling programs to describe important patterns that cannot be detected by point-source monitoring programs. Because monitoring occurs throughout the bight, the existing monitoring system has the potential for measuring events on larger time and space scales. However, this potential cannot at present be fully realized because separate monitoring programs are not sufficiently coordinated and integrated.

Allocation of Monitoring Resources

Despite the large amount of time and money (at least $17 million per year) spent on monitoring in the bight, it is not possible to perform all the monitoring that would be desirable given unlimited resources. The available resources should therefore be allocated based on criteria that prioritize environmental problems and impacts. Such a process should be based in part on an overall assessment like that summarized in Figure 5-5. At present, this is not possible. Each monitoring program is developed independently, and its scope and cost are established in negotiations between the permittee and the regulatory agencies. As a result, some problems receive a disproportionate share of monitoring resources while others receive little or none.

SUMMARY

The analysis of monitoring in the Southern California Bight led to conclusions and insights about individual programs and about the monitoring system as a whole. In general, monitoring programs in the bight use state-of-the-art methods and produce accurate and reliable data. In addition, monitoring data have contributed to many important decisions related to pollution abatement and the management of natural resources. In general, monitoring has been successful in identifying and quantifying the impacts of such point-source activities as wastewater outfalls and coastal power plants.

In spite of these successes, the panel found several shortcomings, some related to the execution of individual programs and some to the institutional structure of the monitoring system as a whole. The most important of these were:

- poorly stated objectives that provided insufficient guidance for monitoring efforts;
- inability to monitor the effects of activities falling outside the existing permit structure;
- inflexibility that inhibits needed adaptability;
- overemphasis on a permit-by-permit approach to monitoring and environmental decision making, thus limiting the ability to monitor cumulative and large-scale impacts;
- insufficient use of statistical design tools in the development of sampling and measurement plans; and
- lack of a bightwide data management system to support integration and synthesis of data from different studies.

The panel performed a preliminary synoptic assessment of environmental problems in the bight. This assessment, combined with the analysis of individual programs, led to important conclusions about the structure of the overall monitoring system. Because the existing system focuses on individual permitted activities, it is unable to foster the higher level planning and coordination needed to assess cumulative and larger scale environmental problems. In addition, the focus on individual human activities makes it difficult to focus on important resources that are affected by more than one type of impact. As a result, it is difficult tc draw conclusions about the status of the bight as a whole and about whether beneficial uses of the marine environment are being protected.

7
Conclusions and Recommendations

CONCLUSIONS

Current Monitoring Effort

1. The total amount of money and effort expended by public utilities, private industry, and government agencies in monitoring of water quality, natural resources, and public health in the Southern California Bight is extraordinarily large. A conservative estimate is that current annual expenses for monitoring far exceed $17 million (see Chapter 4).

2. Most water quality monitoring programs are organized around the outfalls of several large coastal municipal wastewater treatment plants and electric power generating stations and are elaborately detailed in their requirements.

3. The California Cooperative Oceanic Fisheries Investigation (CalCOFI) for natural marine resources in the California Current system and Southern California Bight has been unparalleled among marine resource monitoring programs in terms of its commitment to a long-term time-series assessment. However, station coverage has been reduced by budget cuts.

4. Significant sources of chemical and microbial contaminants contained in riverine and stormwater discharges to the bight have not been adequately monitored as part of the marine monitoring system in the bight.

Lack of Program Integration

5. There are no formal institutional mechanisms for integrating the findings from the different ongoing monitoring programs. This means that there is no mechanism for integrating the results from monitoring of various point sources with each other or with the findings of the resource or public health monitoring programs.

6. There is no system for interrelating the findings of various monitoring programs to present a coherent picture of the whole. This precludes evaluating the human impacts of bightwide human inputs in the context of natural variability, and thus it is difficult to evaluate whether corrective actions are effective.

7. There currently is no effective system for reporting findings of monitoring programs to the public, the scientific community, or policy makers.

8. The monitoring programs in specific permits have been designed to address small-scale discrete questions with little attention paid to the overall question of the status of natural resources and water quality of the Southern California Bight as a whole.

9. In the past, there have been recommendations for bightwide water quality, public health, and natural resource monitoring programs. These recommendations have not been implemented.

RECOMMENDATIONS

A Regional Approach

10. The questions of bightwide inputs and their impacts are growing in importance. Many of them could be addressed in a regional monitoring program. A regional program should be established that:

- addresses specific questions about the current environmental condition of the bight and the resources therein, including those associated with public health impacts, spatial and temporal trends in natural resources, nonpoint source and riverine contributions, nearshore habitat changes, and cumulative or areawide impacts of large and small point and nonpoint source inputs;
- incorporates standardized sampling, analysis, and data management methods;
- establishes a comprehensive data base management system for all monitoring and resource data in the bight, which could provide access to the historic and current data needed to perform comprehensive and bightwide analyses;

- can be facilitated through the coordination of local, state, and federal entities, which integrate their regulatory, data, and management needs and responsibilities to optimize the utilization of available resources;
- can be achieved largely through coordination, integration, and modification of existing efforts, rather than through the addition of another layer of monitoring in the bight;
- can be developed to involve the public and the scientific community as participants in the program;
- includes built-in mechanisms to ensure that its conclusions are effectively communicated to the public, the scientific community, and regulatory agencies; and
- includes mechanisms to require periodic review and to allow easy alteration or redirection of monitoring efforts when they are justified, based on the results of the monitoring or new information from other sources.

The effort to develop a regional program will need to address the needs of the agencies and parties involved in monitoring; synthesis of existing data and information in order to construct meaningful questions and null hypotheses; drafting of an organizational framework; drafting of a monitoring program; and allocating the financial resources required to carry out the program. If properly implemented, the benefits and the costs of a regional monitoring program can be shared by all sectors of society. However, it should also be noted that a regional approach ultimately has to consider the effects of competing uses on land, water, and air quality, and tradeoffs between short- and long-term costs and benefits.

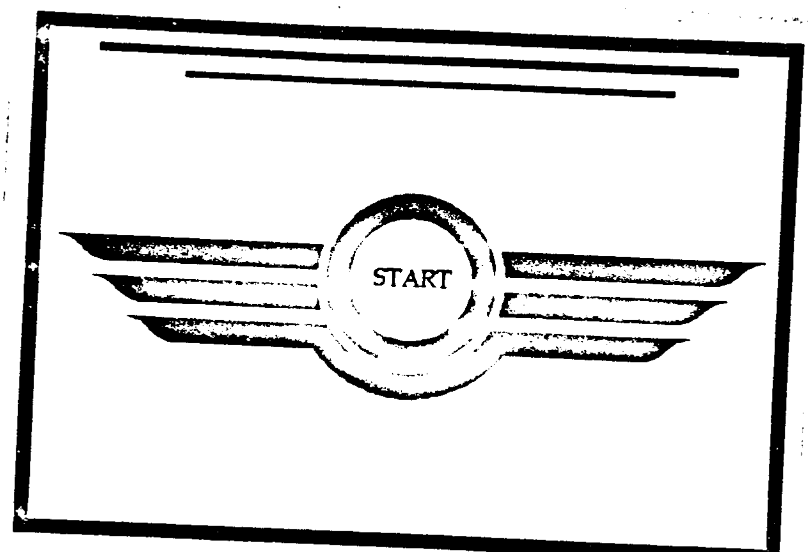
Item 66



Toxicity of Stormwater Runoff in Los Angeles County

Previous studies of stormwater runoff by the Southern California Coastal Water Research Project produced estimated mass emission rates of solids and contaminants into the Southern California Bight (SCCWRP 1973, Young et al. 1980, SCCWRP 1988), but toxicity levels were never tested. Valerie Raco conducted this study to obtain estimates of stormwater runoff toxicity on marine life, to compare the water toxicity of different rivers (storm channels) during a single rainstorm, and to monitor a single river during a series of rainstorms during a one-year period.

The Microtox Toxicity Analyzer System was used to measure the toxicity of stormwater runoff samples by exposing luminescent marine bacteria to each aqueous sample and measuring changes in light output. The amount of light produced by the luminescent bacteria is an indicator of the general health of the bacteria, therefore the light is reduced when the bacteria are exposed to toxic solutions.

Samples of runoff water were collected from three storm channels in Los Angeles County: the Los Angeles River, San Gabriel River, and Ballona Creek (Figure 1), during four rainstorms in 1987 and analyzed for contaminant and toxicity levels. The Los Angeles River, which accounts for the largest flow in southern California (mean annual flow volume for 1983-1987 was 1.8 x 10^8 m^3 [1 m^3 = 35.31 ft^3]), drains west Los Angeles County from the San Fernando Valley, through downtown Los Angeles, to Long Beach. The San Gabriel River, which has the third largest flow in southern California (1.3 x $10^8 m^3$), drains southeastern Los Angeles County from the San Gabriel Mountains through the San Gabriel Valley to Long Beach. Ballona Creek, with the fourth largest flow (0.36 x 10^8 m^3), drains the western part of the City of Los Angeles. The drainage basins of the Los Angeles River, the San Gabriel River, and Ballona Creek encompass 2,110 km^2, 598 km^2, and 229 km^2 respectively. Both the Los Angeles and San Gabriel Rivers receive secon-

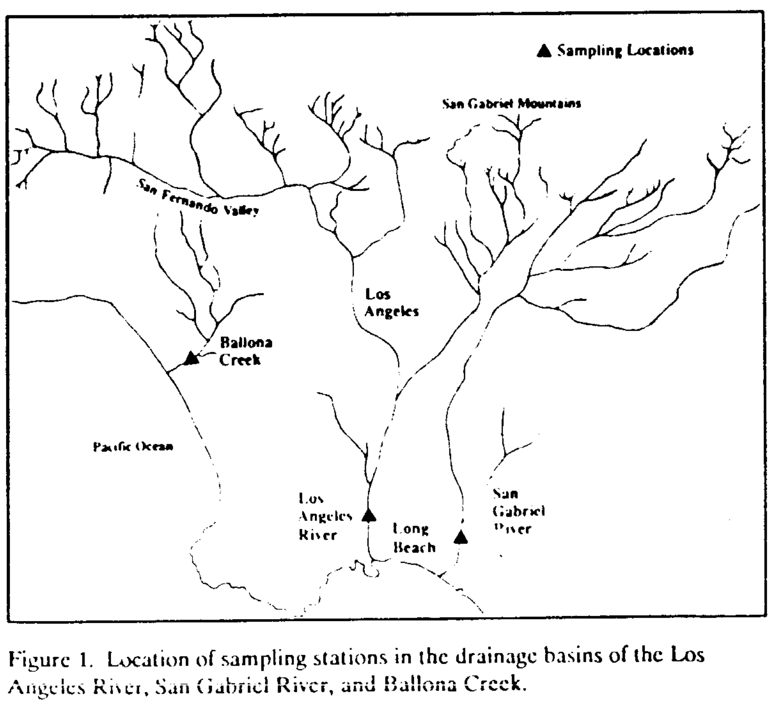


Figure 1. Location of sampling stations in the drainage basins of the Los Angeles River, San Gabriel River, and Ballona Creek.

dary and tertiary effluent from upstream municipal wastewater treatment plants throughout the year, but these discharges represent a minor flow component during storm runoff events.

Methods

Runoff samples were collected from the Los Angeles River, San Gabriel River, and Ballona Creek during rainstorms on January 4-5, March 21, October 22-23, and December 4-5, 1987. In this paper, the January runoff data is presented for all three storm channels, but only the Los Angeles River data are presented for the March, October, and December storms. Low-flow (non-storm) samples were also collected on October 31, 1986 from the Los Angeles River and Ballona Creek. The Los Angeles River collecting station was located at Willow Street in Long Beach, the San Gabriel River station was located at College Park Drive in Long Beach, and the Ballona Creek station was at Inglewood Boulevard in Los Angeles. Collecting stations were located as close to the mouth of each river as possible without encountering the tidal prism.

Runoff samples were collected during and sometimes immediately after each rainstorm. Toxicity testing was conducted within 2 days of sampling; samples were stored at 4°C until tested. Suspended solids in each sample were allowed to settle before a portion was removed for testing; if the sample remained turbid, it was centrifuged.

The Microtox Toxicity Analyzer System was used to

dary and tertiary effluent from upstream municipal wastewater treatment plants throughout the year, but these discharges represent a minor flow component during storm runoff events.

Methods

Runoff samples were collected from the Los Angeles River, San Gabriel River, and Ballona Creek during rainstorms on January 4-5, March 21, October 22-23, and December 4-5, 1987. In this paper, the January runoff data is presented for all three storm channels, but only the Los Angeles River data are presented for the March, October, and December storms. Low-flow (non-storm) samples were also collected on October 31, 1986 from the Los Angeles River and Ballona Creek. The Los Angeles River collecting station was located at Willow Street in Long Beach, the San Gabriel River station was located at College Park Drive in Long Beach, and the Ballona Creek station was at Inglewood Boulevard in Los Angeles. Collecting stations were located as close to the mouth of each river as possible without encountering the tidal prism.

Runoff samples were collected during and sometimes immediately after each rainstorm. Toxicity testing was conducted within 2 days of sampling; samples were stored at 4°C until tested. Suspended solids in each sample were allowed to settle before a portion was removed for testing; if the sample remained turbid, it was centrifuged.

The Microtox Toxicity Analyzer System was used to

test runoff water toxicity as described by Bulich (1982). The Microtox procedure utilized freeze-dried marine bacteria *(Photobacterium phosphoreum)* which were reconstituted, diluted, and allowed to stabilize. All analyses were conducted at a salinity level of 20 ppt; all samples were adjusted to a salinity of 20 ppt by adding a concentrated sodium chloride solution to promote osmotic protection of the bacteria. Initial light produced by the bacteria was measured with the system's photometer and recorded. The samples and a control consisting of 20 ppt sodium chloride solution were then introduced to the Microtox bacteria, which diluted the samples to 45% of the original concentrations. After 30 min of exposure, light output was measured and recorded again. Toxicity levels were calculated by measuring the decrease in light output and normalized to the control.

Results

Toxicity results for the individual samples from each storm were plotted on graphs in relation to river flow rates in Figures 2 and 3; toxicity expressed as percent light loss (relative to the control) is graphed for the Microtox values. The toxicity of runoff collected during the January 4 rainstorm ranged from 13% to 36% light loss for Los Angeles River samples, 15% to 22% light loss for San Gabriel River samples, and 29% to 40% for Ballona Creek samples (Figure 2). Los Angeles River toxicity levels for all four storms ranged from 6% to 67% (Figure 3). It appeared that there was an elevated

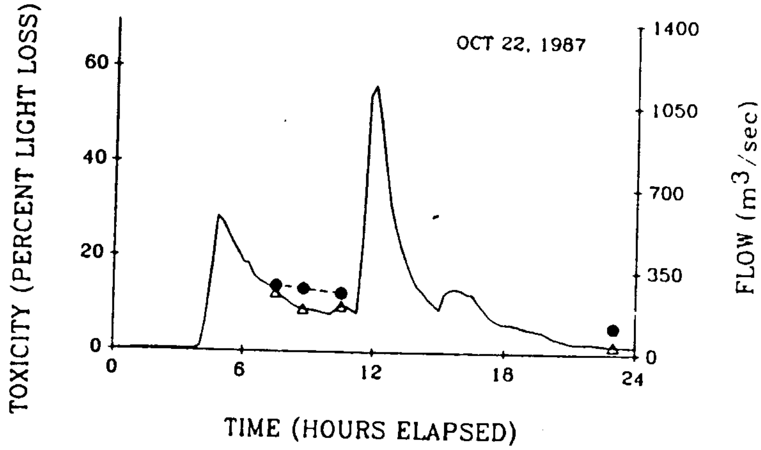
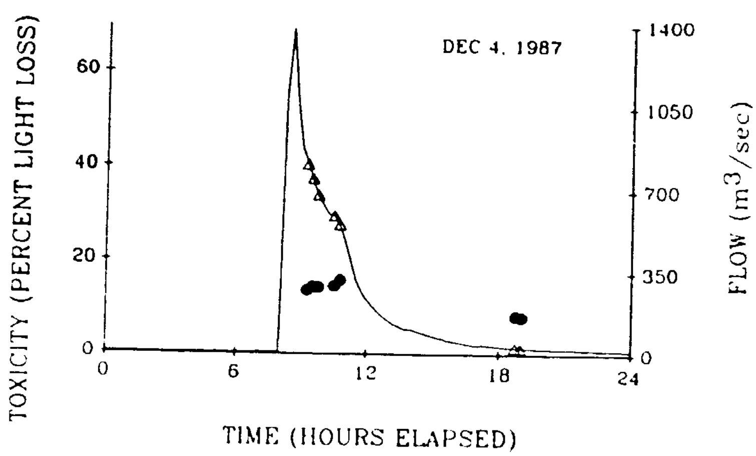
R0048479





storms in 1987. The time axis represents the number of hours that elapsed after

level of toxicity in runoff waters at the beginning of the storms that roughly corresponded to the first peak of the flow rate; runoff toxicity generally decreased as the storms continued.

Because real-time measurements of flow rate were not available at the time of sampling, the important first peak in flow was missed at Ballona Creek during the January rainstorm and at the Los Angeles River during the March and October 1987 storms. However, March storm samples collected before the initial flow peak indicated that the toxicity changed rapidly and reached relatively high levels, which illustrates the importance of sampling during the initial phase of a rainstorm.

The Los Angeles River data presented in Figure 3 suggests that the maximum flow rate for the four storms had an inverse relationship with the maximum toxicity present; runoff from storms with larger flow rates generally had less toxicity than storms with lower flow rates. However, storm runoff sampled January 17, 1988 (data not presented in this paper) had a relatively low flow rate and low toxicity values.

The wide range of toxicity present at different sampling stations and during different storms is evident when comparing the toxicity data for each storm summarized in Figure 4. Mean toxicity levels for the storms was 18% for the San Gabriel River, 31% for Ballona Creek, and 13% to 45% for the Los Angeles River. The toxicity levels of the Los Angeles River and Ballona Creek for

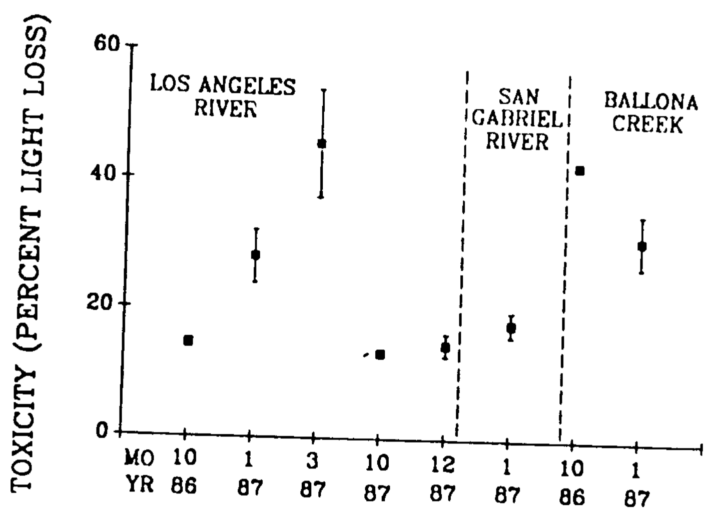


Figure 4. Stormwater toxicity levels (mean percent of light loss ±95% confidence intervals) for each storm sampled in 1987. Two low flow samples are included (October 31, 1986). Data collected after 90% of the total storm flow volume passed were not included in calculating the means.

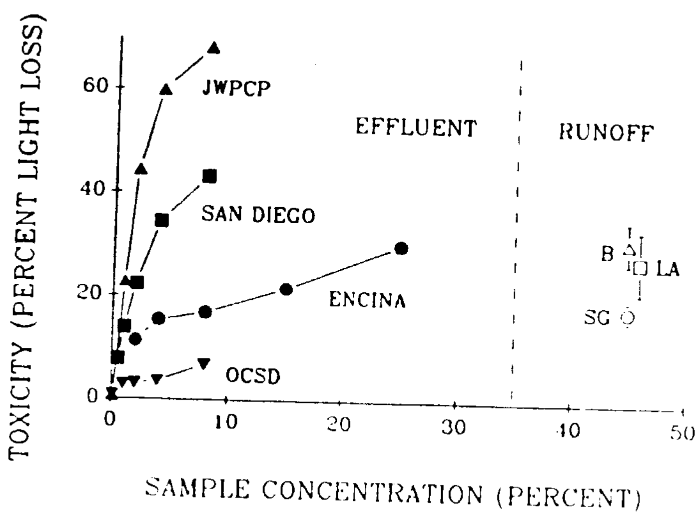

Figure 5. Comparison of wastewater effluent and runoff toxicity. Runoff data are means ±95% confidence intervals of all storms combined for each sampling station. Runoff data does not include low-flow sampling or samples taken after 90% of the total storm flow passed. Wastewater effluent toxicity was measured on 24 hr composite samples collected in 1987 or 1988.

January runoff samples were similar, while the San Gabriel River toxicity was much lower. This is probably a result of more commercial and industrial activity in the drainage basins of the Los Angeles River and Ballona Creek. However, the toxicity of the Los Angeles River low-flow sample (October 1986) was three times less than the Ballona Creek low-flow sample, possibly owing to the dilution of the Los Angeles River from the relatively clean tertiary effluent it receives. Due to insufficient sampling of the Los Angeles River during the March and October storms, trends that appear with respect to time (i.e. toxicity increases from October 1986 to March 1987, then decreases for October 1987) may be spurious.

Most southern California wastewater effluents seem to be more toxic than river runoff (Figure 5). When runoff and sewage effluent toxicities were compared, most effluent samples tested at much lower concentrations (≤25%) produced similar or greater Microtox effects than storm runoff samples tested at 45% concentrations.

Multivariate statistics were used to determine if runoff toxicity was related to the concentration of specific contaminants in the samples. A principal components analysis statistical procedure was used to reduce the number of variables by grouping those contaminants with highly correlated abundance patterns. Concentrations of suspended solids (SS), suspended volatile solids (SVS), trace metals, chlorinated hydrocarbons (CHCs), and chloroform extractables were included in this analysis. Polynuclear aromatic hydrocarbons (PAHs) were not included because they have not yet been measured.

Principal component analysis grouped the data into three factors: factor 1 was most highly correlated with concentrations of SS, SVS, Cr, Ni, and Cu; factor 2 had high correlations with the CHCs (total DDT, PCBs [Aroclors 1254 and 1242], and lindane), chloroform extractables, Pb, Zn, and Cu (almost equal to the correlation of Cu in factor 1); factor 3 was only highly correlated with Cd.

A multiple regression was performed on the principal component analysis scores versus the Microtox analysis results, which indicated that 59% of the runoff toxicity could be accounted for by changes in measured runoff characteristics. Factor 1 was the only contaminant group that had a significant correlation with toxicity (a subsequent principal component analysis on PAHs may yield different results). Within factor 1, toxicity increased with increases in SVS and decreases in SS, Cr, Cu, and Ni. Because the regression results indicated that toxicity decreased when Cr, Cu, and Ni concentrations increased, it is unlikely that the total concentrations of these trace metals were responsible for the observed toxicity. The results of principal component analysis indicate the SS or SVS content of storm runoff may substantially affect its toxicity, or that the runoff toxicity is strongly influenced by a type (e.g. PAH) of contaminant not yet measured.

Valerie Raco conducting Microtox analyses.

Discussion

This study provides information to help us understand the contribution of toxicity from stormwater into southern California marine waters. The data presented herein indicates that stormwater was generally less toxic than sewage effluent, and that runoff toxicity can vary substantially during a storm period, among a series of storms, and among runoff sampling stations.

Poor correlation between toxicity and conventional contaminant measurements calculated by principal components analysis indicate that toxicity should be measured directly by Microtox analysis or other bioassays to assess the biological impacts of stormwater runoff, instead of inferring toxicity from chemical measurements.

Continued research may provide information about which contaminants control the toxicity of stormwater and how these inputs affect nearshore organisms.

Mr. Stan Sysak
Wastewater Program Management Division
City of Los Angeles
200 N. Main Street, Room 600
Los Angeles, CA 90012

Dear Stan:

Enclosed please find three copies of the revised Project Work Plan for the Santa Monica Bay Stormwater Pollutant Reduction Study. This version reflects and incorporates comments made by your staff, the Hyperion staff, and Dr. Rainer Hoenike of the Regional Board. It incorporates all requests made by you for materials to be included for submission of the document to EPA for their review.

Upon approval of the Work Plan by EPA, Engineering-Science, Inc. (E-S) will provide a sufficient number of copies of the document to meet your internal and distribution needs.

The Project Work Plan document completes the first five tasks of the overall project work plan, as outlined in the revised document submitted to you by Mr. Phil Storrs on 12 August 1987, and reflected in the "Project Schedule and Management" section of the Work Plan. Upon contract approval, E-S will initiate plans for deploying equipment to collect rainwater runoff samples for analysis of target pollutant constituents. Other work tasks will follow in the progression described in the Project Work Plan.

E-S looks forward to working with you and your staff toward the successful completion of this project.

BACKGROUND

On 19 February 1986 the City of Los Angeles (City) entered into an agreement with the Environmental Protection Agency (EPA) and the State of California in settlement of a lawsuit regarding violations by the City of its NPDES permit for wastewater discharges from the Hyperion Treatment Plant.

This agreement, as amended, termed the Consent Decree, placed several obligations on the City regarding waste treatment and cleanup. One of the terms of the consent decree was Item XIV, Stormwater Control Project, which required that funds be obligated for a stormwater discharge control project. Specifications and schedules were set forth in Appendix C of the Consent Decree. The City was directed to perform the study to "assess the nature and extent of discharges of pollutants from stormwater runoff from the Hyperion service area into Santa Monica Bay." The result of the study would be to recommend projects "to reduce effectively the discharge of such pollutants" into the Bay. The Consent Decree mandated that the City spend $3 million to implement control measures based on contractor recommendations and EPA approval.

The schedule for completion of the study was to be as follows:

Choose Project Manager	15 August 1987
EPA Approval	15 November 1987
Submit Work Plan and Budget	15 May 1988
EPA Review	15 August 1988
Submit Results and Alternatives	per study schedule
EPA Approval	90 days
Schedule to Implement Projects	90 days
Implement Projects	per schedule

1518 6

Engineering-Science, Inc. (ES) was chosen as the prime consultant to the City to perform the study. ES officially began work on the project on 7 September 1986. A work plan outline and budget were submitted to the City on 3 November 1987 for submission to EPA. The schedule associated with the ES proposal included:

Complete Data Review	March 1988
Complete Water Quality Sampling	September 1988
Land Use/Loading Summarization	September 1988
Project Identification	November 1988
Draft Report	December 1988
Final Report	February 1989

The schedule for the data review and water quality sampling components of the study have been accelerated slightly to take advantage of the 1987-88 Winter season. ES and its subcontractors have agreed to operate under a Letter of Agreement with the City, during negotiation of a final contract, in order to facilitate study initiation.

VOL 12

INTRODUCTION

This Work Plan draws from information previously presented in ES's proposal and in a revised proposed work plan developed by ES to better define the tasks to be completed within the scope of work. The outline of this document corresponds closely with that revision. Major divisions include:

- o Summary of Available Data
- o Selection of Key Pollutants
- o Preliminary Pollutant Load Assessments
- o Selection of Detailed Study Areas
- o Proposed Monitoring Program
- o Use of Collected Data to Estimate Pollutant Loading
- o Identification of Pollutant Reduction Projects
- o Project Schedule and Management
- o Public Involvement

Input from several citizens groups and regulatory agencies suggested the need for more extensive collection and evaluation of offshore water quality data than is detailed in the work plan. Other comments were directed toward comparisons of pollutant loading by sewage discharges, other permitted discharges, and stormwater runoff. A suggestion to quantify the loading and relative impacts from stormwater and other inputs was also advanced. The approach and proposed sampling program developed for the work plan was deliberately restricted to collection of historical information and sampling of stormwater runoff that would provide information to give engineers and planners data needed to recommend the most effective control measures. A more extensive program to evaluate the toxicological effects and exposure pathways of the target pollutant materials once they entered the marine environment of Santa Monica Bay, or to comparatively quantify the effects of stormwater runoff, was deemed outside the scope of this study as mandated by the Consent Decree.

Discharge data for Hyperion Treatment Plant has been included in this report as a basis from which to quantitatively compare the relative importance of stormwater runoff constituents. Data from discharge

1 5188

monitoring at Hyperion exists for a number of years and is well-documented as a known level of input. Pollutant loading in stormwater runoff is a relative unknown in Santa Monica Bay. This study does not attempt to compare the relative impacts of stormwater runoff and sewage discharges, nor is it an indictment of Hyperion, which is a permitted discharge. A study currently in progress (MBC 1988) will attempt to quantify the impacts of sewage discharges and stormwater runoff in Santa Monica Bay.

SUMMARY OF AVAILABLE DATA

INTRODUCTION

Potential marine pollutants enter Santa Monica Bay via several pathways. These include advection of marine waters to the Bay from other areas (e.g. California Current, southern tropical waters during El Nino events), upwelling of deeper waters (especially near submarine canyon heads and southwest-aligned coastlines), aerial fallout, sewage discharges, surface runoff (from storm drains and natural streams and rivers), human marine activities (commercial and recreational boating, fishing, etc.), and the movement of contaminated marine life into the Bay from other areas.

The relative importance of these pathways varies with the pollutant of concern. During 1971-1972, surface stormwater runoff into Santa Monica Bay was estimated to contribute smaller amounts of most constituents examined than did municipal wastewater. Only iron emissions were greater in surface runoff. Nevertheless, except for large contributions of chemical oxygen demand (COD) and oil and grease by industrial discharges, surface runoff was considered to be the second most important source of most contaminants into the Bay (SCCWRP, 1973).

For the Southern California Bight in general, surface runoff emissions amounted to less than 10 percent of these contributed by municipal wastewater except for suspended solids, nitrates, iron, manganese, lead, and cobalt. These constituents are thought to have higher mass emission rates (kilograms or tonnes per year) in surface runoff than in municipal wastewaters (SCCWRP 1973). Lead in surface runoff in the Los Angeles River in 1979 had decreased by a factor of six relative to that found in 1971-1972 (presumably due to a decrease in the use of lead in gasoline). Total polychlorinated biphenyls (PCBs) had decreased by a factor of eight (presumably due to a ban on their use in open systems). In general, the mass emissions from surface runoff were an order of magnitude less than those found in municipal waste water, except for lead and zinc (Young et al. 1980). In 1985-1986, surface runoff from the Los Angeles River contributed greater mass emissions of suspended solids, lead, and zinc than did the Orange County Sanitation

Districts wastewater effluent (SCCWRP 1986). A continuing program of plant upgrading and secondary effluent treatment at Hyperion Treatment Plant (HTP) has reduced the loading of many of the pollutants of concern into Santa Monica Bay. In addition, the City of Los Angeles ceased discharges of treated sewage sludge into the Bay in late 1987, further decreasing the loading of potentially toxic constituents. As a result of these reductions, stormwater runoff loading is currently contributing a larger share of total pollutant loading to the Bay than it has in the past.

About 70 percent of the surface runoff in the Southern California Bight is the result of stormwater flows. The average annual flow from the storm drainage system into Santa Monica Bay is estimated to be 213 x 10^9 L/y, based on measured flows from Ballona Creek and extrapolated to include all storm channels draining into Santa Monica Bay (COWT, NRC 1984). During 1971-1972, the estimated storm flow of Ballona Creek was 26 x 10^9 L/y and the estimated dry flow was 15.7 x 10^9 L/y. The estimated storm flow of the Pico-Kenter drain was 1.2 x 10^9 L/y and the dry flow was estimated at 3.6 x 10^9 L/y. The storm flow of Malibu Creek was estimated at 3.4 x 10^9 L/y (SCCWRP 1973). Because stormwater runoff includes both street and land wash, it may include more trace contaminants than are found in municipal wastewater. Based on estimated mass emissions of constituents, the contribution of stormwater to the pollutant loading of Santa Monica Bay is thought to be substantial (COWT, NRC 1984).

Interest in the importance of stormwater runoff as a pollutant pathway to Santa Monica Bay has increased in recent years as environmental groups have pressed for removal of storm drain runoff from the beaches and surf and for better treatment of low flows and stormwater before it enters the ocean. These groups assert that stormwater runoff into Santa Monica Bay may represent a significant health hazard to that portion of the public which uses or resides near the Bay and to the marine life of the bay (Crow 1987).

A total of 24 storm drains discharge into Santa Monica Bay from the drainage area served by HTP (Hyperion Treatment Plant data, unpubl.). Although a considerable effort has been made to describe the nature of the wastewater that is discharged into the Bay by HTP and the effects of this wastewater on marine life, few studies have examined the nature of stormwater runoff. Those studies that have been conducted generally either have been conducted upstream in the storm drains or have monitored coliform along the beach. Little information exists on the constituents of stormwater for most storm drains or in the ocean.

SURFACE RUNOFF CONSTITUENTS

The importance of stormwater runoff as a pollution source to freshwater and marine receiving waters has long been recognized. Stormwater runoff typically consists of several major fractions: water, suspended solids, oil and grease, drifting macrodebris (human trash, plant debris), stream bed particulates (gravel and some human and organismal debris), and living organisms (including bacteria and small plants and animals). Most runoff studies have dealt with those components found in small parcels of water and these consist primarily of water, suspended solids, oil and grease, and bacteria. Most pollutants in stormwater runoff are associated with either the suspended solid fraction or the oil and grease fraction. The bacterial fraction is generally used as an indicator of the potential for human disease, as stormwaters may include septic tank overflows or sewerage system bypasses.

The relative abundance of the major constituents varies from region to region and is determined largely by the nature of the drainage basin and the intensity of the storm. Thus, concentrations of suspended solids are generally greater in runoff from natural or agricultural areas, whereas oil and grease are found in higher concentrations in areas draining transportation corridors and industrial areas. With the exception of silt and silt-associated constituents, stormwater in the Southern California Bight does not carry significantly higher or lower concentrations of constituents than does dry weather flow. Surface runoff is the primary source of beach sand supply (SCCWRP 1973).

Stormwater studies conducted in other regions have identified a number of basic constituents to stormwater runoff. These include sediment, heavy metals (lead, cadmium, copper, zinc, manganese, iron), and polynuclear aromatic hydrocarbons (PAHs; Hoffman et al. 1984, Ellis et al. 1986). In stormwater entering Narragansett Bay, Rhode Island, urban runoff accounted for 71 percent of the total inputs of higher molecular weight PAHs and 36 percent of the total PAHs (Hoffman et al. 1984). In the Los Angeles River, chlorinated hydrocarbon concentrations (i.e. DDT, PCB, and dieldrin) increased in a similar pattern with silt concentrations during storms, and decreased when storm flows subsided. Surface runoff throughout southern California during 1971-1972 accounted for about 1 percent of the amount of chlorinated hydrocarbons contributed to the coastal waters of southern California by municipal discharges (SCCWRP 1973).

Iron, manganese, and cobalt are natural constituents of surface runoff that are found in virgin soils (SCCWRP 1973). Other heavy metals accumulate near highways in proportion with the increasing traffic densities. Aerial deposition is the major source of metals entering the road drainage system. Urban deposition rates of zinc are greater than for lead. Zinc is primarily deposited as aerial fallout during storms whereas much lead is deposited directly from vehicular activities (Ellis et al. 1986). The oil and grease fraction is primarily composed of auto exhaust and derivatives, but petroleum hydrocarbons may have a variety of sources, including crude oil seepage (CRWQCB 1986). Although some kinds of PAHs occur naturally, most environmental PAHs result from combustion (e.g. forest fires and fossil fuels -- especially coal) and are deposited on land and water as aerial fallout. PAH concentrations are higher near highway and industrial land use areas than near commercial and residential areas. Some, however, are deposited directly from petroleum products, such as motor oil leakages. The kinds of PAHs occurring in urban runoff are similar to those found in aerial fallout but are dissimilar to those found in municipal effluents (Hoffman et al. 1984). Aerial fallout, surface runoff, and municipal wastewater are all sources of these pollutants entering the marine environment.

DYNAMICS OF STORMWATER RUNOFF EPISODES

Rainfall does not occur uniformly in space or time during a storm. For instance, rainfall does not occur equally over the drainage basin and several peaks in rainfall intensity may occur during a storm. Although stormwater runoff appears to follow a similar cycle to runoff intensity in the upstream drainage, the greatest runoff intensities occur after a time lag following the period of greatest storm intensity (Hoffman et al. 1984). This length of this lag will vary with the nature of the drainage and the intensity and quantity of rainfall occurring during the storm. If the drainage includes a significant quantity of nonabsorbent surfaces (i.e. streets, storm drains, parking lots), the lag time should be short, whereas if a significant amount of absorbent surface (i.e. porous soils) exists upstream, the lag time should be longer. Surface runoff volumes may represent 30 to 85 percent of the total incoming rainfall volume for the catchment basin, with losses resulting from surface characteristics, seasonal variation, and instrument limitations (Ellis et al. 1986).

There is some uncertainity concerning the importance of the length of the dry period preceding a storm in determining the amount of a given constituent that has built up prior to a storm. Higher levels of some runoff contaminants are often found in the first storms of a season, with lower levels in later storms ("first flush"; SCCWRP 1986). For instance, some constituents such as suspended solids are likely to occur in greater quantities after a long dry period. However, amounts of others, such as heavy metals and PAHs, appear to be unaffected by the antecedent dry period (Hoffman et al. 1984, Ellis et al. 1986). In addition, other factors associated with the dry period (i.e. chemical responses to temperature and light which may cause the loss of volatile materials to the atmosphere, or greater binding to other materials) or pre-storm conditions (i.e. winds which may carry airborne dust outside of the drainage basin) may influence this buildup (Hoffman et al. 1984).

Estimates of the relative importance of rainfall, runoff volume, and intensity in increasing metal loadings in runoff vary between studies (Hoffman et al. 1984, Ellis et al. 1986). Pollutant loadings (sediment and lead, cadmium, and manganese) in storm runoff from roadsides in England were most closely associated with total runoff volume and storm duration. The antecedent dry period and rainfall intensity were not important in controlling the removal of pollutants associated with particulates (Ellis et al. 1986). Concentrations of PAHs in storm drains in the Narragansett Bay, Rhode Island, watershed were most concentrated during the first or second flushes of the storm. Rainfall volumes and the length of the antecedent dry period were not correlated with the amount of PAHs in the runoff (Hoffman et al. 1984). In general, however, it appears that runoff volume is the most important factor controlling the loading of pollutants, with the preceding dry period and peak rainfall intensity controlling concentrations of pollutants (Athayde et al. 1982).

The constituents in stormwater runoff are not mobilized (i.e., released) equally during a storm. Some constituents are mobilized quickly and others are not mobilized until later (Hoffman et al. 1984, Ellis et al. 1986). The characteristic solubility and volatility of a compound contribute to the facility with which it is incorporated into the surface runoff of any particular storm. For instance, oil and grease are highly water-insoluble, and not likely to be flushed into the runoff unless the flow is sufficient to pick up particles with which they are associated (CRWQCB 1986). Suspended solids show a similar runoff pattern, as does both volume of runoff flow and high molecular weight PAHs which are associated with suspended solids. Some of these are enriched on small particles and some on large particles; these particles are differentially removed during a storm (Hoffman et al. 1984). Thus it is important to measure the quantity of each constituent mobilized at various parts of the storm cycle.

STORMWATER RUNOFF STUDIES IN THE SANTA MONICA BAY DRAINAGE BASIN

Several agencies and organizations have conducted or are conducting stormwater pollution or marine sampling programs that may measure stormwater pollution in Santa Monica Bay as a side benefit. These include the Los Angeles County Department of Public Works (Water Quality Division -- formerly Flood Control), Los Angeles County Health Department, Los Angeles City Department of Public Works (Hyperion Treatment Plant), Southern California Coastal Water Research Project (SCCWRP), the University of Southern California (Institute for Marine and Coastal Studies) and the Office of the Chief Administrative Officer of the County of Los Angeles (OCAOCLA). The Los Angeles County Department of Public Works and SCCWRP have collected samples in upstream portions of storm drains as well as at outlets. Both, as well as OCAOCLA, have measured a variety of constituents found in stormwater, with OCAOCLA conducting the most complete analysis of constituents. The Los Angeles County Health Department and the Hyperion Treatment Plant have monitored the inshore areas of the ocean in Santa Monica Bay for coliform bacteria. The University of Southern California (Soule and Oguri 1977) has sampled runoff at the mouth of Marina del Rey and SCCWRP has sampled runoff upstream in Ballona Creek; both sampled specifically during storms.

A report on investigations concerning reported cases of cancer in lifeguards and of the Pico-Kenter storm drain conducted by the Office of the Chief Administrative Officer of the County of Los Angeles (OCAOCLA 1981) described the characteristics of storm channel runoff of the Santa Monica Bay drainage. A wide variety of heavy metals and other toxic materials were measured in storm channels in this drainage. The storm channel water was dominated in yearly emission rate by total dissolved solids, chloride, sodium, sulphate, and chemical oxygen demand (COD). More than 250 components of each sample were assigned to polar and nonpolar groupings; the Ames test (Ames et al. 1987) showed the nonpolar grouping to be mutagenic, but no specific mutagen was found. Petroleum products, phthalate esters (in thinners, lacquers, and varnishes), and automobile coolant constituents (e.g. ethylene glycol esters and propylene glycol) were measured, and these are potentially mutagenic (COWT, NRC 1984).

The Waste Management Section, Water Quality Division of the Los Angeles County Department of Public Works (LACDPW) has examined the constituents of stormwater at the outlets of four storm drains since 1971 and upstream in Ballona Creek (Cheung 1987; Waste Management Section, LACDPW, unpubl. data). At present, storm drain outlets are sampled at Short Street (Santa Monica Canyon) and Pico (Kenter storm drain), and upstream on Ballona Creek at Sawtelle Avenue. The storm drains at Malibu Creek (sampled at Cross Creek Road) and Topanga Canyon (at Pacific Coast Highway) were also sampled before 1984. These stations are sampled quarterly for certain constituents and annually for a wide range of constituents (Cheung 1987). From 1974 to 1984 the full complement of constituents was sampled monthly. Recent surveys have not purposely sampled during storms. In general, flow data were not measured, but these data are kept by the Hydrology Department. After 1 January 1988 the Pico and Short Street outlets will be sampled more frequently and during storms (Cheung 1987).

The Recreational Health Program, Bureau of Environmental Protection, Los Angeles County Public Health Department, has sampled 13 stations along the beach in Santa Monica Bay during 1986 and 1987. These station extend from Pulga Canyon, Pacific Palisades, to Avenue I, Redondo Beach, and include the following storm drains: Pulga, Chautauqua, Santa Monica Pier, Pico-Kenter, Ashland, Windward, Marina del Rey swim area, Ballona Creek, Imperial Highway, Grand Avenue, 34th Place, Redondo Pier, and Avenue I. Each station was sampled about 50 m upcoast and 50 m downcoast from the outlet on a weekly schedule (Recreational Health Program, Bureau of Environmental Protection, Los Angeles County Public Health Department, unpubl. data). Samples were collected at the edge of the ocean and analyzed for total coliform, fecal coliform, and enterococcus. Samples were not collected at the storm drains for three to four days after a storm because of high coliform counts. These high coliform counts are often associated with nonhuman sources (i.e. horse corrals, soil bacteria, bird droppings) and the high counts rapidly decline to normal within a few days after a storm. Enterococcus is likely to be used more frequently in future studies because it is a better indicator of potential human contamination (Kebabjian 1987, pers. comm.).

Hyperion Treatment Plant has also conducted a similar monitoring program of the beach and storm drain outlets of Santa Monica Bay. Hyperion has collected water samples for 30 years from 17 beach stations and 8 offshore stations (along the 9 m isobath); storm drain outlets and areas of temporary special concern have also been sampled (Bartlett 1987, pers. comm.). Three additional stations were added in August 1987. Beach stations were located from Piedra Gorda Canyon to Malaga Cove and offshore stations from off Las Tunas Beach to off Hermosa Beach

(Hyperion Treatment Plant data, unpubl.). Beach stations have been sampled once daily and offshore stations once weekly. The Pico and Ballona Creek storm drains are monitored daily and several other storm drains (Entradero, Pulga Canyon, Sunset, Brook, Ashland, Market Street, Imperial Highway, Grand Avenue, and Avenue I) have been sampled Mondays, Wednesdays, and Fridays except when high dry weather flows occur, at which time they are sampled during high flows. Water quality is sampled at the surface and 2 m above the bottom (the latter since August 1987) at the nearshore stations; beach samples are taken by wading into the surf (Bartlett 1987, pers. comm.). In general, total coliform and enterococcus are the primary constituents measured, although fecal coliform is also measured at weekly intervals.

Bay mussels (Mytilus edulis) and California mussels (M. californianus) growing in Marina del Rey and Ballona Creek were examined for enteroviruses in 1975. The Ballona Creek mussels were also examined for total coliform and enterococci. Enteroviruses were found in both areas and coliform and enterococci counts were high at Ballona Creek. The source of this contamination was not discovered (Morris and Kim 1975).

POTENTIALLY IMPORTANT CONSTITUENTS FOR ANALYSIS

Stormwater samples have been analyzed for many conventional water quality parameters as well as those known to be important in municipal wastewater. In addition, other constituents have been suggested as being important, and ultimately a complete list of EPA priority pollutants could be examined. At present 126 pollutants are on this list. These include the following major classes: metals and inorganics; pesticides; PCBs and related compounds; halogenated aliphatics; ethers; monocyclic aromatics; phenols and cresols; phthalate esters; polycyclic aromatics; and nitrosamines and miscellaneous compounds. These pollutants are variously compartmentalized between the water (suspended solids or dissolved), sediments (organic or inorganic fractions), and biota (phytoplankton, zooplankton, macrophytes, benthos, fish, birds, and mammals) (Chapman et al. 1982). Some heavy metals and PAHs accumulate in the sea surface microlayer (i.e. upper 0.05 to 0.10 mm)

(CRWQCB and EPA 1987). Hence different fractions of the stormwater runoff should be examined to obtain the greatest concentrations of these constituents. In addition, the priority pollutants vary in their volatility, ability to accumulate in the environment, and their persistence (Chapman et al. 1982).

Because of the high cost of a complete analysis of EPA priority pollutants, the pollutants chosen for analysis should be ranked according to their persistence and potential harmful effects. Based on chemical properties and behavior, the most persistent, nonvolatile constituents that accumulate in the environment would be of most concern and hence should be targeted in monitoring studies. These include many of the metals and inorganics (arsenic, beryllium, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, thallium, and zinc). Among the pesticides these include DDD, DDE, DDT, dieldrin, endrin, endrin, aldehyde, heptachlor, heptachlor epoxide, TCDD, and toxaphene. Six PCB arochlors and 2-chloronaphthalene also fall into this category. Only 2 of 22 halogenated aliphatics fall into this category; these are hexachlorobutadiene and hexachlorocyclopentadiene. Of the ethers, 4-chlorophenyl phenyl ether and 4-bromophenyl phenyl ether are potential target compounds by these criteria. Only one of 12 monocyclic aromatics (hexachlorobenzene) is a potential target. Pentachlorophenol and 2,4 -dimethylphenol are the most important of the phenol/cresol category. All phthalate esters and polycyclic aromatic hydrocarbons on the EPA list are persistent, nonvolatile, and accumulative as well as diphenyl nitrosamine, di-n-propyl nitrosamine, 3,3'-dichlorobenzidine, and 1,2-diphenylhydrazine (Chapman et al. 1982).

From the human health standpoint, human disease and disease indicators are important, along with potential carcinogens. Human disease indicators, such as total coliform, fecal coliform, and enterococcus, are frequently examined in water quality samples (Kebabjian 1987, pers. comm.). Coliform and fecal streptococcus (i.e. enterococcus) are common in fecal material and sewage and are generally not pathogenic. Fecal streptococci may survive better in coastal waters than coliform bacteria. Salmonella bacteria were the only pathogenic bacteria that were detectable in seawater near the Hyperion outfalls during 1974 and 1975 and these occurred in low abundance. Most bacteria causing infectious and enteric human diseases would be expected to enter the sea in municipal wastewater. Antibiotics produced by marine algae, diatoms, and fungi as well as competition from marine bacteria and selective predation by microorganisms contribute to the poor survival of enteric bacteria in the ocean (Kim 1975). Enteric viruses (e.g. poliovirus, coxsackie virus, echovirus, and the virus that causes infectious hepatitis) have been found in sewage effluent and these have been found in mussels in Marina del Rey and Ballona Creek. The virus that causes infectious hepatitis is the most dangerous and the most difficult to detect (Morris and Kim 1975).

Although many potential substances are carcinogenic to rats and mice, the normal exposure of humans to these carcinogens may be less than would be expected to cause cancers. In addition, the risk of acquiring cancer from the concentrations of many popularly-targeted carcinogens (at concentrations normally experienced by humans during their normal activities) may be much less than the risk associated with other substances that are normally encountered in daily activities (but which are less frequently recognized as carcinogens). A recent study (Ames et al. 1987) suggests that the conventional manner of ranking potential human carcinogens may be in error and hence may require re-evaluation. Based on their analyses, current levels of pesticide residues and water pollution may be of minimal concern relative to the background levels of natural substances. Nevertheless, until their method has gained wide acceptance, rankings of carcinogenicity of contaminants given by regulatory agencies should continue to be used, particularly since the health of the marine life is also at risk.

From the marine life standpoint those constituents that occur at acutely toxic concentrations would be of greater concern than those that cause sublethal effects, although these could also effect future generations of a species.

Additional compounds to be considered are dioxins, furans, and chlorophenols (Dahlgren 1987, pers. comm.). Dioxins are produced as a byproduct of defoliants, by incineration of PCB, and may occur in some waste oil (Dahlgren 1987, pers. comm.; Sims 1987, pers. comm.). Dioxins occur at parts per trillion levels in human adipose tissue. In addition, organic compounds of mercury and other metals are important contaminants as well as organophosphate, pyrethrate, and carbamate pesticides, phthalate esters (associated with plastics), and tetrachlorethane (a dry cleaning solvent).

MEASUREMENT OF PRECIPITATION AND SURFACE RUNOFF

The Los Angeles County Department of Public Works collects precipitation records at 300 stations in the County; three of these stations lie within the areas chosen for detailed study (See "Selection of Detailed Study Areas"). However, only the Civic Center gage includes 15-minute values and can therefore be used directly in modeling runoff events. Runoff gages with 15-minute sampling frequency are also maintained by the County. While historical records are available at eighteen sites within the study area, only six of these are currently maintained. Runoff is tabulated for daily mean values; 15-minute values must be computed by hand from punched gage records using rating tables.

The location and length of record for currently maintained stations are shown in Table 1.

In the early 1970s the then Los Angeles County Flood Control District estimated 100-year runoff values based on land use, impervious cover, slope, and area using the Modified Rational Method. While the results from this study would not be directly applicable to estimating runoff volumes from smaller storms, these raw data would provide useful input to a more storm-specific model.

STORMWATER POLLUTANT REDUCTION TECHNIQUES

Both structural and non-structural techniques will be considered in evaluating proposed projects to control pollutant runoff associated with stormwater transport. Traditionally, structural techniques (physically intercepting the runoff waters and treating them in some manner) have been favored by engineers and planners due, in part, to the ability to

TABLE 1

PRECIPITATION AND STREAMFLOW GAGES IN STUDY AREA

* = 15-minute records available

better quantify the results of such actions. Some of the more prominent techniques used in past stormwater control efforts have included:

- o skimming of runoff surface to remove floating objects and oil and grease fractions
- o swirl or loop sections of conduit to promote settling of particulates in the flow
- o screens and filters to remove larger particulates
- o settling basins to remove particulates
- o detention basins to reduce overall runoff and promote groundwater recharge
- o wetland areas to filter stormwater flows in passage

Problems associated with these techniques have included low rates of successful removal of target fractions, restricted land availability for implementation, inability to handle water volumes associated with larger storms, contamination of groundwater resulting from recharge efforts, increasing urbanization in the target area, and technical difficulties with the control equipment.

Non-structural control techniques rely on urban planning, management practices, and increased regulatory measures to reduce the amounts of pollutant material available to be removed by stormwater runoff flows. These techniques include:

- o initiation or increase in frequency of vacuum street sweeping
- o restrictions on certain land uses
- o improved construction practices and requirements
- o increased enforcement practices by regulatory agencies
- o increased initiation and public awareness of monitoring programs for toxics and other illegally-discharged materials to deter violations

Problems associated with these techniques have included lack of operational effectiveness data, low or uncertain rates of pollutant reduction, public disinterest or refusal to comply with regulations, lack of committment to enforcement by regulatory bodies, and budget limitations.

Based on a review of the historical effectiveness of both structural and non-structural control technologies, the wide diversity of land uses in the study area, and the lack of any large concentration of a single land use, the solutions to the control of stormwater runoff into Santa Monica Bay will probably be a combination of structural controls intercepting stormwaters from large areas and areawide non-structual techniques. During the course of the project, these perceptions will be re-evaluated in light of more extensive land use mapping, data acquired during the monitoring phase, and evaluations of cost-effectiveness.

NATIONAL URBAN RUNOFF STUDIES

The National Urban Runoff Program was conducted by the EPA and local authorities between 1977 and 1982 to clarify the role of stormwater runoff as a pollution source. Twenty-eight locations across the national were selected to participate. Common data management procedures were established which permitted comparing the data at the end of the study. Some of the main conclusions were:

- It is possible to characterize stormwater quality by a quantity called the Event Mean Concentration (EMC). Using this parameter, storm events at a given site, as well as at different sites, can be compared. With relatively simple statistics it is possible to characterize both the storms and the resulting pollution.

- Log-normal statistical distributions adequately represent both the storm-to storm variations in pollutant EMCs at an urban site and site-to-site variations in the median EMCs which characterize individual sites.

- Heavy metals, especially copper, lead, and zinc are by far the most prevalent priority pollutant.

- The organic priority pollutants were detected less frequently and at lower concentrations than the heavy metals.

- Coliform bacteria are generally present at high levels.

- Total suspended solids (TSS) concentrations are fairly high compared to wastewater treatment plant discharges. In general, TSS contains more man-made products such as particles from tires and street surfaces and less biogenic particulates than does municipal sewage effluent.

- Nutrients are generally present in runoff but concentrations are not high compared to other sources.

- Although runoff volume and total pollutant load are generally highly correlated, little correlation was found between event mean concentrations and runoff volumes. At only thirty percent of the sites was a correlation found to be significant at the ninety percent level. Some sites showed positive correlations, indicating scouring, while others showed negative correlations. All in all, the variability among sites overwhelmed differences in EMC among different land uses or geographic regions.

The standard pollutants measured in the NURP study were total suspended solids, biochemical oxygen demand (BOD), COD, fecal coliform, total and soluble phosphorus, total Kjeldahl nitrogen, nitrite and nitrate nitrogen, total copper, total lead, and total zinc. In addition, the priority pollutants were examined at many of the sites. Event mean concentrations and coefficients of variation were given for the standard pollutants. In general, only ranges for the priority pollutants were given.

The main value of the NURP study is the developed methodology for sampling and analysis. Also, significant advances are being made in designing remedies to stormwater pollution such as detention basins which take advantage of statistical approaches.

An ongoing national program on urban runoff is being conducted by the U.S. Geological Survey. Results from this and other studies will be included as acquired.

STUDY WORK PLAN

This section details the work to be completed during the monitoring and evaluation phases of this study.

SELECTION OF KEY POLLUTANTS

Criteria for Selected Pollutants

Criteria include identification with adverse effects on human health or with adverse biological and aesthetic effects in Santa Monica Bay and on beaches, public concern, contribution of stormwater runoff loading versus total loading, implementability of controls, and cost of analysis (not a criterion for elimination). Recommendations were taken from evaluation of the historical literature, meetings with the City and other interested groups, and discussions with the project's toxicologist, Dr. James Dahlgren.

Target Pollutant List

	Analysis	
	Method	Cost
-Enterococcus	SM 910[a]	$ 25
(Particulate-associated)		
-suspended solids	SM 209C[a]	$ 10
-arsenic	206.3[b]	22
-mercury	245.5[b]	22
-silver	272.1[b]	40
-copper	220.1[b]	40
-cadmium	213.1[b]	40
-nickel	249.1[b]	40
-chromium	218.1[b]	10
-lead	239.1[b]	40
-zinc	289.1[b]	40
-dioxins	613[c]	400
-PAHs	610[c]	150
(Lipid soluble-associated)		
-oil and grease	413.2[b]	$ 60
-pesticides and PCBs	608[c]	80
-chlorophenoxy herbicides	8150[c]	125
	Total	$ 1,144

b EPA (1979)
c EPA (1982)

Pollutants Receiving Consideration

Laboratory analyses of the following pollutants were not performed for the listed reasons:

-Biochemical oxygen demand	-not a health hazard in open Bay waters
-Chemical oxygen demand	-not a health hazard in open Bay waters
-Total petroleum hydrocarbons	-picked up in oil and grease analysis
-Phthlate esters	-exposure path not through marine contact
-Chlorinated hydrocarbons	-soot; prevalent over wide areas
-Purgable organics	-exposure path not through marine contact
-Total coliforms	-Common in runoff from variety of sources
-Fecal coliforms	-Common in runoff from variety of sources

Recommendations of the Final Report may contain reduction measures for the pollutants not analyzed for, as listed above. Additionally, control measures recommended for those constituents on the analysis list will also be effective against the substances not tested for, as many of the latter are contained in the same water column fractions (particulate, lipid soluble).

PRELIMINARY POLLUTANT LOAD ASSESSMENT

Preliminary estimates of pollutant loads have been calculated using loading factors obtained from several sources. The results are presented in Table 2. In certain cases, the data were extrapolated from results of other studies. In particular, the following sources were used:

- The Final Report (Volume 1) of the Nationwide Urban Runoff Program (NURP) conducted by the EPA between 1977 and 1982. The loadings were calculated by multiplying the Event Mean

Concentrations (EMC) by the estimated runoff volume for the whole study area.

- Water quality data from the Sawtelle Blvd. sampling station on Ballona Creek provide concentrations of pollutants taken during both dry and storm conditions. These data are from analyses of grab samples taken approximately monthly by the Los Angeles County Department of Public Works. Ballona Creek drains about 46 percent of the study area and is therefore quite representative of the whole study area, assuming no sanitary sewage overflows. (In many cases the concentrations of target pollutants were at or below the lower level of detectability and were reported only as less than a given amount.) The calculations of loadings were made as follows:

  Loading = Concentration x Rainfall x Runoff Coeff. x Area

  where,
  Loading = metric tons per year
  Rainfall = 375 mm per year
  Runoff coeff. = 0.32 (based on percent impervious surface)
  Area = 50,302 ha

A forthcoming statistical analysis of the concentration data from the County will help to update this information.

- The Southern California Coastal Water Research Project data (1973 and later) was used for some of the estimates such as oil and grease.

The preliminary pollutant data presented in Table 2 will be updated as additional information is obtained.

In order to make a preliminary pollutant load assessment, the pollutant loads from the surface runoff were compared to the annual loads from the Hyperion Treatment Plant effluent stream. This comparison is useful in judging the approximate relative impact of the surface runoff on an annual basis. Only the 1985 values for the effluent from the combined secondary and primary processes are shown, since the sludge stream will be directed elsewhere in the near future. If the sludge stream had been included, the relative impact of the runoff pollution would be even smaller.

The evaluation of overall importance of each pollutant was based partly on the following criteria:

Load in runoff more than 10 percent of amount discharged by Hyperion Treatment Plant for:

- o Oil and Grease
- o Total Suspended Solids

Load between 5 and 10 percent for:

- o Arsenic
- o Chromium
- o Lead

Load less than 5 percent for:

- o Cadmium
- o Copper
- o Mercury
- o Nickel
- o Silver

In the 1973 Southern California Coastal Water Research Project (SCCWRP) report, a comparison of pollutant sources for the entire Southern California Bight was presented. Also included were contributions from industrial wastes, vessels, ocean dumping, and aerial fallout. In many cases, the estimates were very rough and may no longer apply because of changes in regulations concerning PCBs, pesticides, and lead in gasoline. To the extent possible, these data will be updated to reflect current pollution sources in the Santa Monica Bay.

SELECTION OF DETAILED STUDY AREAS

Selection of areas for detailed study was based upon the need to characterize stormwater runoff characteristics and identify candidate areas for pollutant control of key pollutants. The methodology developed anticipates the need to identify pollutant loads by land use types occurring within the study region and to prescribe pollutant reduction techniques that are specific to varying land use types. Land use criteria for the City of Los Angeles were used in site selection. These criteria are included in Appendix A.

The methodology for selection of areas for detailed study included development of information on land use, drainage patterns, and availability of access to drains to collect stormwater data.

Candidate areas for detailed study were selected based upon the need to collect information on relatively homogeneous land use types that could be isolated for purposes of monitoring without a high degree of interference from other land use activities. These desirable characteristics included the need to identify a single location to monitor runoff volumes and stormwater pollutant values draining an area representative of the land use type. Land use and drainage maps and aerial photographs for areas within the study region were analyzed for candidate sites for detailed study by identification of areas satisfying the above criteria.

A series of candidate areas was identified for each of the five land use types to be evaluated (i.e. heavy industrial, light industrial, commercial, residential, and transportation). In addition, a monitoring location that would provide integrated information on the above land use types was sought. Preliminary monitoring locations were located based on drainage maps. All of the candidate areas for evaluation were located within the Ballona Creek watershed area, which constitutes approximately 46 percent of the drainage area and is the single largest stormwater input to Santa Monica Bay.

Each of the candidate areas was inspected to verify the land use types within the area drained, to identify monitoring locations, and to isolate any potential problems in data collection that may not have been apparent based upon the evaluation of land use and drainage maps and aerial photographs. The location of the monitoring station was identified in the field for each candidate area.

The candidate areas were screened against the selection criteria. Several of the candidate sites were deleted because of land use types that were not representative of the mapped classification, drainage

VOL 12

1

5212

VOL 12

patterns that did not correspond with mapped information, and problems in gaining access for field monitoring. The field inspection also identified potential problems in collecting representative samples of areas upstream due to incomplete mixing or in monitoring flow volumes at the confluence of several flow streams where backwater conditions may interfere with the accuracy of flow readings.

To increase the effectiveness of any proposed pollutant reduction measures or projects, the monitoring program will focus on data collection, analysis and control strategies that correlate these factors to specific land use types that produce the highest loadings, and concentrations of key pollutants. For instance, national studies have demonstrated that transportation facilities (e.g., highways) contribute high concentrations and a significant percentage of the loading of PAHs. By evaluating areas used for transportation for both the percent contribution to this loading and for potential control strategies, the most effective control projects for this pollutant are likely to be identified.

1523

Criteria used in choosing specific areas for study included:

1. Land uses specified in the request for proposal
2. Land uses deemed to contribute significant pollutant loading based on historical information
3. Location of an area of sufficient size to extrapolate to the overall study area
4. Area "representative" of citywide land use
5. Ability to sample a single land use from a single drain
6. Location within the Santa Monica Bay drainage area
7. Location within the City of Los Angeles, if possible.

The different land use types selected included residential, commercial, light industrial, and transportation. Criteria applicable to each site as listed above included the following:

- Residential — #s 1, 3, 4, 5, 6, 7
- Commercial — #s 1, 3, 4, 5, 6, 7
- Light Industrial — #s 1, 3, 4, 5, 6, 7
- Transportation — #s 2, 3, 4, 5, 6, 7

No Heavy Industrial land use sites that corresponded to the listed criteria were available in the City of Los Angeles. Alternate sites in other cities were investigated for conformance to the remaining criteria. These areas encompassed a number of small metal fabricating, metal plating, and similar industries that are potential sources for many of the target pollutants. None of the sites examined were suitable for monitoring due to:

- o inaccessibility of storm drainage in the candidate areas
- o non-availability of sampling locations collecting runoff from the industrial area only
- o lack of sufficient area at the candidate locations to make extrapolation to the study area realistic

Engineering-Science recommends that the Heavy Industrial land use be dropped from the study due to:

- o very low percent occurrence in the study area as compared to other land uses
- o lack of a suitable sampling area in the drainage basin
- o low probability of cost-effective treatment of stormwater runoff due to low level of accessibility to the runoff stream; most locations accessible by storm drains represent parcels of only 15 to 20 acres
- o City land use requirements mandate that Heavy Industrial areas must capture and treat storm runoff prior to releasing it to the storm drain system

The Transportation land use was added to those originally required in the Request for Proposal due to the importance of automobile transportation in the City region, the extensive area of the study basin covered by road and highway networks, and the importance of runoff pollutants from transportation land uses evident in the literature.

The locations of proposed study sampling locations are listed in Table 3.

The recommended Residential land use site is an area of mixed single-family and multi-family housing, and was deemed to be representative of overall study area residential land uses. Within the

selected area is a oil/gas production site, a potential source of contaminant runoff into the sample collection area. Communication with the operator of the site (UNOCAL) indicated that, for the past year, all surface runoff from the site has been retained on-site and reinjected into existing older wells on the property. Visual examination of the culvert below the production site showed no evidence of oil or grease discharges (dead vegetation, staining of the street pavement, etc.). The area was deemed suitable for use as the Residential land use study site. Other potentially suitable sites are available in Rancho Park and Culver City. The Rancho Park site is a primarily upper-class neighborhood of single-family homes that may not be representative of the study area. The Culver City site is more of an older middle-class area with all single-family dwellings.

The Combined Use area indicated in the table was chosen to provide a site to examine the physical mode of transport for the target pollutants. This concept will be more fully detailed in the section titled "Proposed Monitoring Program."

Locations of candidate and other sites examined are shown in Figure 1. Detailed maps of the proposed sites listed in the table above are included in Figures 2 through 5.

PROPOSED MONITORING PROGRAM

The proposed monitoring program encompasses both onshore and offshore sampling. The onshore program at the storm drain locations described above will be used to determine pollutant loading associated with the different land use types.

The offshore collection program will be used primarily to ascertain the presence of the target pollutants in offshore waters. No attempt will be made in this study to relate pollutant presence offshore with studies of the fates of these compounds in the marine environment.

Conceptual Sampling Plan

The sampling plan was designed to provide the information needed to characterize runoff and provide necessary input to engineers and planners for development of pollutant runoff reduction projects. This information included:

- o Spatial - where pollutants are coming from
- o Temporal - when pollutants are transported
  - -event (rainfall)
  - -season
  - -year
- o Physical - how pollutants are transported

Proposed Sampling Plan

Approach

Based on the design outlined above, the following sampling plan is proposed to gather the necessary planning and decision-making information:

PROPOSED TRANSPORTATION CORRIDOR
LAND USE STUDY AREA

FIGURE 5

222251 VOL 12

- Spatial - comparison of runoff characteristics from different land use types

Land use types to be sampled during the study include:

- residential
- commercial
- light industrial
- transportation

- Temporal - hydrograph and "pollutograph" comparison to determine the time response of pollutant washoff to duration and intensity of rainfall:

    - Three storm events
        - first seasonal storm (see text below)
        - heavy midseason storm
        - late seasonal storm
    - dry season low flow - composite over 24 hours

- Physical - mode and location of transport as indicated in the table of sampling sites:

    - One station sampling from three discrete water column fractions
        - hydrophobic "floating" fraction (oil and grease, etc.)
        - midcolumn
        - particulate "bedload"

- Offshore - confirmation of pollutant presence

    - Seven stations, two water column levels (upper 1/4 meter, midwater)

Location of Offshore Sampling Stations

The location of monitoring stations for the offshore sampling program are as follows:

TABLE 4

OFFSHORE SAMPLING STATIONS

Station	Latitude	Longitude	Bottom Depth (m)	Sample Depth (m)
A	33°58'20"	118°28'25"	9	S,4
B	33°58' 0"	118°28' 3"	9	S,4
C	33°57'33"	118°27'30"	5	S,2
D	33°57'11"	118°27'22"	9	S,4
E	33°56'44"	118°27' 7"	9	S,4
F	33°57'27"	118°28' 2"	14	S,7
G	33°57'14"	118°28'29"	18	S,9

S - upper 1/4 meter

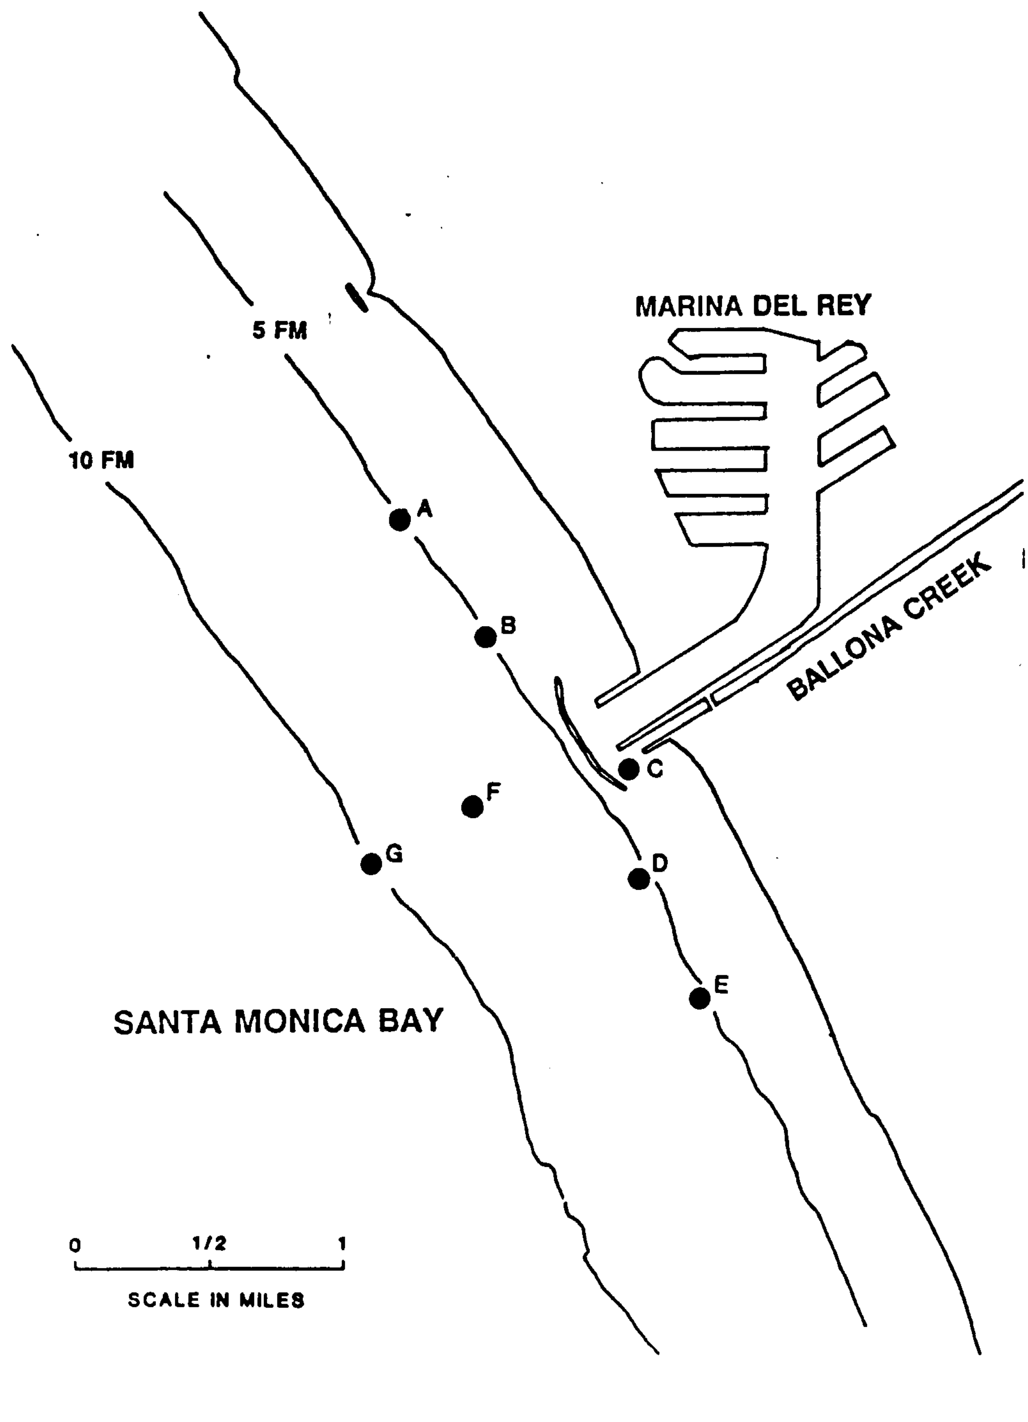
Station locations are presented in Figure 6.

Onshore station samples will be collected using automatic water collection pump samplers (ISCO or equivalent) to collect discrete samples at specified intervals. The samplers will be coupled with a flow-monitoring device programmed to activate the samplers based on a preprogrammed increase in flow rate within the storm drain resulting from rainfall runoff. The samplers themselves are time-programmable, allowing a fixed or variable time interval between sample collection. The sampling interval will be determined by examining historical duration/intensity data for rainfall events in the study area. A 15-30 minute interval is currently planned. Sufficient sample volume will be collected to provide water for all chemical analyses.

Offshore collections will use a manually-activated closing bottle device (Van Dorn or equivalent) to collect both near-surface (upper 1/4 meter) and midcolumn discrete samples. Only one sample at each depth from the seven proposed stations is planned. Collections will be made within two to three hours of the beginning of a storm to catch the expected maxima in pollutant concentrations, minimize influence of other runoff sources near the mouth of Ballona Creek, and complete sampling before the buildup of infiltration waters into the sewerage system that may result in sewage spills into Ballona Creek. The timing of offshore collections will necessarily be influenced by weather and safety considerations.

FIGURE 6

PROPOSED WATER QUALITY SAMPLING STATION IN STORMWATER POLLUTION REDUCTION STUDY



ENGINEERING-SCIENCE

Methodology

Offshore collections will be made within two to three hours of the beginning of the storm event, during the same period that runoff samples are being collected. As indicated by Table 4 and Figure 6, the offshore stations are concentrated off the mouth of Ballona Creek.

A conceptual example of sample collection strategy is depicted in Figure 7. The two curves represent volume of runoff flow and concentration of some pollutant in the flow. While runoff flow volume is expected to build over the initial period of the storm, some pollutant constituents are mobilized very quickly, and reach peak concentrations prior to the peak of runoff flow volume.

Collection of water samples from storm sewers will be initiated soon after the beginning of the rainfall event, as the flow meters monitoring runoff levels are triggered by the increase in flow and activate the samplers. Sample collection will continue until runoff flows drop to their pre-event levels. Bottles will be replaced as necessary to collect samples over the duration of elevated flows.

Volume of samples collected will be sufficient to satisfy requirements of the analyzing laboratory to complete testing using EPA or SM methodology (see "Selection of Key Pollutants"). The bottles contained in the ISCO samplers hold between 350 and 1,000 ml; more than one bottle may have to be filled for each sample to satisfy analysis requirements. Sampler servicing will be scheduled based on types of samples being collected, volume requirements, etc. Strict adherance to preservation techniques, handling, holding times, and other analysis protocols will be observed.

The figure also indicates a potential time sequence of samples chosen for analysis of target constituents. As suggested by the literature and indicated by the curve of runoff pollutant concentration versus time in Figure 7, many of the major pollutants are mobilized early in the storm event. It may be necessary to analyze a greater number of samples collected near the beginning of the rainfall event in order to best characterize the presence of such pollutants in the runoff stream. Analysis of fewer samples at longer intervals near the end of

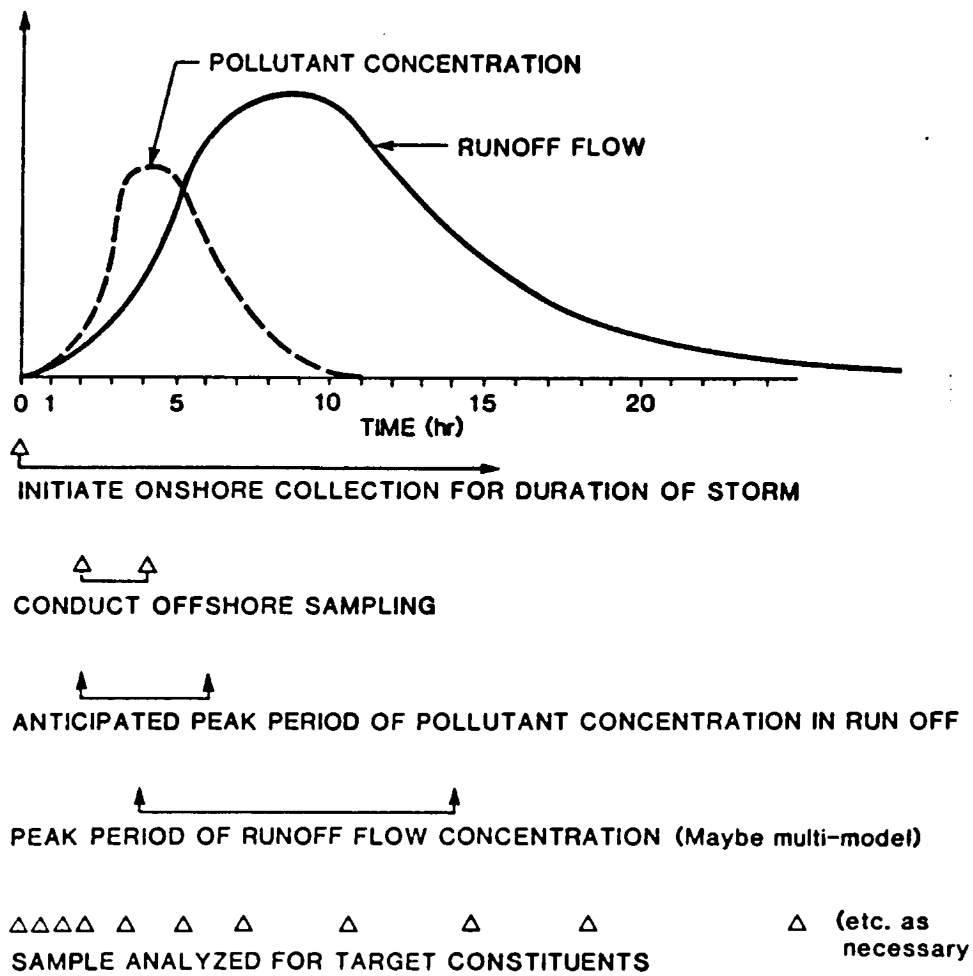


FIGURE 7. CONCEPTUAL RUNOFF AND POLLUTANT CONCENTRATION REPONSE FOR WINTER STORM SHOWING INITIATION OF SAMPLING MODES AND POTENTIAL SPACING OF SAMPLES ANALYZED FOR TARGET CONSTITUENTS

the event will assure that significant concentrations of such pollutants are not missed in assessing loading to the Bay during the storm.

Collection and analysis of runoff samples during three winter storms is currently planned. The absence of certain pollutant constituents during the first storm will be cause to eliminate their analysis in subsequent storms. Analysis for these constituents will again be conducted during summer low flow collections. Using this procedure, the limited laboratory budget can be directed toward constituents found frequently in runoff samples and requiring more extensive analyses.

Analysis of Samples

Analytical techniques for listed pollutants were detailed in the table of target constituents. Detection limits will be different for runoff samples and samples collected offshore because of the higher salinities associated with the latter.

During the first part of the sampling program, determination of pollutant constituents will be identical for all onshore and offshore monitoring locations. Results of the first sample collection may indicate that some constituents can be eliminated from further analysis on an individual land use or onshore/offshore basis.

Collection and analysis of water samples for Enterococcus group is complicated by the need for sterile equipment and methods during sampling. It is therefore impractical to collect Enterococcus samples via the automatic samplers deployed in the study area. Bacterial samples will be collected by hand, using appropraite sterile techniques, by technicians while servicing the samplers during the rainfall/runoff event. This will restrict the number of samples at each location, and will not allow for time-synchronous collections; however, the bacterial samples are deemed less important than other constituents due to their frequent occurrence in stormwater runoff and their low potential for effective control. Bacterial samples collected offshore will be handled in a similar manner, but will be collected only once at each sampling depth at each station.

First Seasonal Storm

The contract between Engineering-Science and the City of Los Angeles was not signed in sufficient time for sample collections during the first storm of the 1987-88 water season. Plans are being made to deploy samplers and collect runoff from the first storm during the fall of 1988, to determine the extent of pollutant concentrations in the "first flush" following the summer dry season.

POLLUTANT LOADING ESTIMATES

Characterization of Stormwater Hydrology

The study area has a rainfall pattern typical of the western coast, with dry summers and moderately wet winters. Rainfall from May through September is insignificant and the first major storms generally arrive in November.

Variations in rainfall due to topographic (land elevation) differences are minor in the immediate study area, but average annual precipitation is significantly greater in the Santa Monica Mountains than in the urbanized areas. Because the character of storms and annual variation are quite constant across the area of interest, point precipitation values for measured storms could be adjusted by the ratios of monthly or annual average precipitation for areas in which hourly precipitation values are unavailable.

Precipitation characteristics of several storms as measured at the Los Angeles Civic Center are illustrated in Figures 8 through 10. The first figure shows hourly precipitation for the first significant rains of the 1984-85 water year, in November and December 1984. A two day December storm is illustrated in the second figure. Finally, the first three days of the significant storms in February 1986 are depicted in Figure 9.

Physical Parameters

The existing telemetered precipitation gage at Los Angeles Civic Center and the flow gage on Ballona Creek near Culver City provide almost 60 years of historical data in the detailed study area. Data

ENGINEERING-SCIENCE

from these gages will be supplemented by runoff flow information from the sampling stations established for this project. Specifically, during storm events precipitation may be measured at other locations within the detailed study area to establish the areal as well as temporal extent of the storm. Maximum storm intensity and duration is available directly from historical precipitation data, which are tabulated in 15-minute intervals.

Runoff rates at the five proposed monitoring stations will be estimated from theoretical stage-discharge relationships for open-channel flow. Exact runoff volumes at these sites will be computed from the resulting flow hydrographs, extended forward or backward in time as necessary to incorporate unmonitored flows. Runoff at sites outside the detailed study area will be estimated using the Modified Rational Method and by the Los Angeles County Department of Public Works. This method computes peak discharge as

$$Q = C \times I \times A$$

where Q is the peak discharge, C is the runoff coefficient, and I is the rainfall intensity over the time of concentration of the catchment area, and A is the drainage area. The runoff coefficient is a function of soil and land use type and of rainfall intensity. Flow hydrographs can then be estimated by transposing the measured hydrographs from locations with similar times of concentration, and checked against total flow computed from the total amount of precipitation received during the storm multiplied by the average runoff coefficient.

Characterization of Stormwater Quality

In accordance with the results from NURP, the best parameters for characterizing the stormwater quality are the event mean concentration and the coefficient of variation. The event mean concentration is calculated by dividing the total mass of pollutant in the runoff by the total volume of runoff. Event mean concentrations can be obtained in several ways:

(1) A flow-weighted composite can be analyzed directly for concentration.

(2) Discrete samples during the course of a storm event can be analyzed. From the concentrations and flows, a graph of mass flow vs. time is obtained which is then integrated for the total mass. This value is then divided by the total runoff volume.

For a given site, the EMCs for various storms are averaged assuming a log-normal distribution. The coefficient of variation is calculated by dividing the standard deviation by the mean. Collected data will be analyzed to determine if the assumption of log normality is valid. If it is not, non-parametric statistical methods will be used.

For some pollutants, the second method will be used to demonstrate how the pollution load varies over time for a given storm. This information may be useful in selecting a remedial strategy. Additional comparisons will also be made with various water quality standards.

Land Use and Water Quality Relationships

An analysis will be performed to determine whether parameters such as land use, impervious cover, or population can be correlated with the values for pollutant loadings. Statistical techniques similar to those presented in the NURP report will be used. One method involves normalizing the sites by dividing the site median concentration and its upper and lower 90-percent confidence limits by the average median value for the constituent in question. The sites can then be compared using a simple graphical procedure.

A comparison will be made between an estimate of total loadings for the entire study area extrapolating from both the Ballona Creek and from the single land use areas.

Modeling Methodology

The method of modeling pollutant loadings is derived from the stochastic screening model used in the National Urban Runoff Program report. The method relies on the fact that event mean concentrations (EMC), runoff volumes, and flows in receiving waters tend to be log-normally distributed; that, is the logarithms of the appropriate variables fit the normal distribution. The four variables normally considered in the model are:

1. Urban runoff flow
2. Urban runoff concentration
3. Streamflow in receiving waters
4. Stream concentration

The stochastic NURP model can be modified if event mean concentrations and/or runoff volumes fail to fit the log-normal distribution. Certain distributions other than log-normal can be modeled analytically, in that properties of the distribution of pollutant loadings can be found from the properties of the distributions of EMC and runoff volume. In the more general case, the distribution of loadings can be developed empirically using a simple Monte Carlo simulation of the EMC and runoff distributions, including appropriate correlations if these are found to be significantly different from zero. Goodness of fit could be ascertained using the Filliben correlation test (for normal or log-normal distributions) or the Kolmogorov-Smirnov test (for general distribution); normally at least fifteen to twenty observations are required to determine distribution parameters and goodness of fit.

The distributions of event mean concentrations will be developed from the results of the monitoring program, with the EMC for each storm event computed as the flow-weighted concentration observed in the tests. The distribution of runoff volumes for the detailed study area will be derived directly from measurements made during the study and from historical flow records of Ballona Creek. Elsewhere, flow distributions will be derived from runoff volumes computed using the modified rational approach described earlier. Event mean concentrations at other sites will be derived from the results of the land use and water quality study of the previous section.

VOL 12

15236

IDENTIFICATION OF POLLUTANT REDUCTION PROJECTS

Data collected during the monitoring phase will be combined with historical stormwater control information to identify appropriate pollutant reduction projects. Engineering-Science planners and engineers will work with the City of Los Angeles to reach a consensus on criteria for evaluation of alternatives. The procedure for identifying these projects will include:

- assess existing, operating structural stormwater control technologies for feasibility in the study area (area requirements, structural acceptibility, availability of land, etc.)
- eliminate technically non-feasible structural alternatives
- quantify effectiveness of pollutant reduction potential of remaining alternatives on several sizes of project application (volume handled, etc.)
- determine suitability of selected projects to control pollutant runoff from selected areas and land use types
- develop cost estimates for alternatives (document estimating techniques)
- categorize projects as to fundability within the $3 million mandated for control projects
- assess non-structural control options for feasibility
- eliminate technically non-feasible non-structural alternatives
- quantify pollutant reduction potential of remaining non-structural alternatives on a range of areal or statutory applications
- determine suitability of selected applications to control pollutant runoff from selected areas and land use types (effectiveness)
- develop cost estimates for implementation/enforcement of recommended alternatives (document estimating techniques)

- o examine pollutant reduction potential and costs for combined structural and non-structural projects, either by land use or for a specific area
- o rank recommended projects by:
  - effectiveness in reducing pollutant runoff
  - cost of implementation
  - combined effectiveness and cost
- o recommend projects on a specific land use or specific area basis

Recommendations for projects will also discuss the implications of costs related to maintenance requirements of selected techniques, proposed management/regulatory practices, and evaluation of the extent of reduction of pollutant loading into Santa Monica Bay.

PROJECT SCHEDULE AND MANAGEMENT

The study has been organized into a Work Plan and a Study Phase with a number of general tasks. These work plan phase tasks are:

Task 1 - Review and Evaluate Existing Data

The data that have been developed in the past on the quality and characteristics of Santa Monica Bay and storm runoff in the watershed are available from diverse sources. These include published reports, professional papers, and agency files. These data will be collated and evaluated for use in the subsequent tasks and to help determine what additional data will have to be collected in the monitoring program. A source list, annotated as necessary, will be compiled and incorporated as an appendix in the final project report.

Land use data and drainage system maps will be obtained from the City of Los Angeles and other agencies in the study area.

Task 2 - Identification of Key Pollutants

The objective of this task is to develop a list of pollutants that will be monitored during the project and that are likely candidates for control. The criteria for selection of these key pollutants will include:

- o Identification with adverse biological and aesthetic effects in the bay and on the beaches.
- o Identification with adverse effects on human health
- o Public concern
- o Ability to implement controls

Task 3 - Preliminary Pollutant Load Estimates

Land use in each drainage basin will be reviewed in relation to the available runoff and bay water quality data to provide a basis for preliminary estimates of pollutant generation rates in each land use category. These will be used to make preliminary estimates of mass pollutant loads (metric tons per year) for each of the key pollutants.

Task 4 - Selection of Areas for Detailed Study

One or more drainage areas will be selected for detailed study and for monitoring. The selection of the areas will be based on the preliminary land use analysis and pollutant load estimates. Other considerations will include the likelihood developing effective mitigation measures and the probable applicability of these measures to the entire study area.

Task 5 - Development of Project Work Plan

The work plan for the study phase of the project will define three main areas of work:

- o Monitoring of drainage system runoff and bay waters.
- o Problem analysis
- o Alternative project development

For the monitoring program, the work plan will delineate the locations of sampling points, sampling plans and schedules, parameters to be measured, methods of analysis of samples, sampling equipment, etc. The work plan has been prepared as a result of Task 5 above and is based on information developed by the first five tasks.

The remaining tasks of the Study Phase are:

Task 6 - Runoff and Receiving Water Monitoring

Monitoring of runoff from the drainage system will be done on a regular basis for dry weather flow and during rainfall events. To the extent possible sampling during rain events will be designed to catch the early part of the runoff on the leading slope of the storm hydrograph.

Sampling of water quality parameters in Santa Monica Bay will be done on a regular schedule and, consistent with safety, during or after storm to detect immediate effects of runoff from the watershed.

Task 7 - Land Use Analysis

Land use, topography, and street patterns in the study area will be digitized for entry into a computer data base. This will permit rapid analysis of areas, slopes, land use characteristics, runoff quality data, summary tabulations, etc., which will be needed for subsequent tasks.

Task 8 - Problem Identification and Analysis

The pollutant load estimates will be extended refined using the information gained from the monitoring and from the land use and drainage pattern analysis. These estimates coupled with information from limited field observation will be used to identify areas that contribute significant pollutant loads and in which there is a good probability of developing measures to reduce pollutant loads significantly.

Task 9 - Development of Projects

Projects and measures to reduce the pollutant loads identified in Task 8 will be formulated and evaluated. Criteria to be used in the evaluation will include:

- o Capital and operations costs in both the public and private sectors
- o Effectiveness in pollutant reduction

- o Environmental impact including the effects of alternative disposal of pollutants excluded front the drainage system
- o Relation of alternative controls or measures to other pollution control programs
- o Feasibility (legal, regulatory, technical, reliability etc.)
- o Public acceptance

The results of this task will be a prioritized list and discussions of possible structural and nonstructural controls with cost estimates.

Task 10 - Public Involvement and Meetings Support

This project and the recommended controls that will result from it are of high concern and interest to the public and to a number of government agencies. This task covers the efforts that will be made to obtain input from and to inform these groups.

Task 11 - Preparation of the Final Report

Task 12 - Project Management

The detailed schedule must take the following factors into consideration:

- o The storm season
- o Concurrent execution of the Study Phase Tasking
- o The organization of the project team

PUBLIC INVOLVEMENT

The public involvement program for this study has not yet been finalized. The subcontractor for this portion of the project (Renette Anderson and Associates) is currently providing support to the City in transferring information to the Pico-Kenter Task Force. The latter is acting in an advisory role for the conduct of this study. It is anticipated that public contacts and meetings may be required to disseminate the information and recommendations resulting from the monitoring and evaluation phases of the study. A more extensive public involvement program is envisioned at that time.

APPENDIX A

GENERALIZED SUMMARY OF CITY OF LOS ANGELES
ZONING REGULATIONS

Land use designations used to select study sites for this project were taken as broad indicators of classes of zoning as expressed in the City of Los Angeles Planning and Zoning Code (Chapter 1 of the Los Angeles Municipal Code). A generalized summary of that code is included for reference in this Appendix.

The study sites chosen conformed to the zoning designations described below:

Land Use	Comparable City Designation	Brief Description
Residential	R4	Mixed single-family and ulti-unit homes (near 50% each), good condition; exteriors, lawns well-maintained, neighborhood age 20-40 yr
Commercial	C2	Retail and office, with associated parking
Light Industrial	MR1	Light manufacturing of various types of products (sewing machines, etc.), storage and repair of automobiles, manufacture and cleaning of clothing, small warehousing
Transportation	*	Freeway corridors, major highways, Los Angeles and other smaller airports

* No comparable City zoning designation; some overlap with City designation for parking buildings ("PB")

A more complete description of the individual study areas, including a breakdown by type and square footage of industry, percent of single and multi-family housing, etc. will be included in the Final Report.

RESIDENTIAL FOOTNOTES

1. "H" Hillside or Mountainous Area designation may alter these requirements in the RA-H or RE-H Zones, subdivisions may be approved with smaller lots, providing larger lots are also included. Each lot may be used for only one single-family dwelling. See minimum width and area requirements below.

ZONE COMBINATION	MINIMUM TO WHICH NET AREA MAY BE REDUCED	MINIMUM TO WHICH LOT WIDTH MAY BE REDUCED
RA-H	14,000 Sq. Ft.	63 Ft.
RE9-H	7,200 Sq. Ft.	60 Ft.
RE11-H	8,800 Sq. Ft.	63 Ft.
RE15-H	12,000 Sq. Ft.	72 Ft.
RE20-H	16,000 Sq. Ft.	72 Ft.
RE40-H	32,000 Sq. Ft.	No Reduction

2. See Section 12.08 B1 of the Zone Code.
3. See Section 12.08 C4 of the Zone Code.
4. For two or more lots the interior side yards may be eliminated, but 4 Ft. is required on each side of the grouped lots. See Section 12.09.5C of Zone Code.

CHAPTER 1
INTRODUCTION

Santa Monica Bay is an open embayment on the central part of the southern California coast which lies seaward of Los Angeles County (Figure 1-1). The Bay is bordered offshore by Santa Monica Basin, on each end by rocky headlands (Point Dume and the Palos Verdes Peninsula), and onshore by the Los Angeles Coastal Plain and Santa Monica Mountains.

Five hundred years ago the shores of Santa Monica Bay and the Palos Verdes Peninsula were probably inhabited by less than 10,000 native American Indians. These natives used the natural resources of the Bay for a variety of purposes, but there were so few of them that any impacts on the environment were probably not perceptible. From the time of European contact to the twentieth century human impacts on the environment remained relatively minor: much of the area remained undeveloped or was used for ranching. However, during the twentieth century the area became a major population and industrial center which increasingly imposed itself on the natural environment of the area.

Today Santa Monica Bay is a valuable natural resource that contributes to the local economy and enhances the quality of life for those who work or live in the area or visit it. The Bay supports a commercial party boat fishing industry and offers recreational fishing from piers, beaches and private boats. Approximately 500,000 tourists and local residents visit the beaches annually to surf, swim, and pursue the many recreational activities. This influx of visitors bolsters the local economy and constitutes an important source of revenue. Greater Los Angeles is the second largest metropolitan area in the United States, and is home to about 15 million people, nearly 6% the population of the United States (Hoffman 1992). This population uses the Bay not only for recreation, but also for domestic and industrial waste disposal. Multiple uses of a single resource inevitably lead to conflicts of interest and opinion.

PUBLIC CONCERN FOR THE BAY AND WATERSHED

Although concern for the condition of Santa Monica Bay and its watershed has increased dramatically during the last 25 years, solutions to some multiple-use conflicts were enacted long ago. For example, prior to 1884 raw sewage was discharged across the beach near the present Hyperion Treatment Plant and in the following decades nearshore discharges also contaminated the beaches with oil, grease, other floatables, and enteric bacteria. However, as the population and volume of discharge grew, sewage treatment was improved and discharge outfalls were moved further offshore into deeper water, so recreational use of the shore would not be affected. In 1935 the California Department of Fish and Game recognized the value of Santa Monica Bay for sport fishing and prohibited commercial fishing (by most methods) throughout the Bay. Public concern for the condition of Santa Monica Bay grew gradually after World War II and received a major impetus when the Federal Clean Water Act was established in 1972. The heightened awareness of the impacts of pollution which accompanied this legislation has resulted in public pressure to restore the natural state of the Bay.

In 1987 the Southern California Association of Governments (SCAG -Appendix A lists all acronyms used in this report) established the Santa Monica Bay Steering Committee and Santa Monica Bay Scientific Review Committee, and conducted public workshops at which issues and concerns about the Bay were aired. SCAG initiated one study to evaluate the state of Santa Monica Bay and another to guide the management of resources and problems in the Bay and its watershed. The studies were followed by the preparation of two State-of-the-Bay reports: Assessment of Conditions and Pollution Impacts (MBC 1988) and Management Framework (SCAG 1988). The information, findings, and recommendations of the two reports were publicized at a "State-of-the-Bay" conference in November 1988.

THE NATIONAL ESTUARY PROGRAM

The National Estuary Program (NEP) was established by U.S. Congress in the Water Quality Act of 1987 and is administered by the United States Environmental Protection Agency (EPA). The purpose of the NEP is to create a conservation and management plan which will protect and enhance water quality in specific bodies of water (USEPA,OMEP 1987). In 1988 California Governor Deukmejian nominated Santa Monica Bay to be included in the NEP and in July 1988 the Bay became one of 21 bodies of water nationwide to be granted this status (Table 1-1).

Santa Monica Bay Restoration Project

Under sponsorship by EPA, State Water Resources Control Board (SWRCB), and State Environmental Affairs Agency (SEAA), the Santa Monica Bay Restoration Project (SMBRP) was established and mandated to meet the goals outlined by the NEP. A Management Conference was established to overview the activities of the Project and is being conducted by a Management Committee composed of representatives of 54 organizations, including Santa Monica Bay area Congressional and State legislative representatives, cities bordering Santa Monica Bay, Los Angeles County, regulatory and resource agencies, major dischargers, environmental and industry groups, and public interest groups. A Technical Advisory Committee (TAC) provides scientific and technical expertise to the Management Committee while a Public Advisory Committee (PAC) advises those affected by the Management Committee's recommendations and actions.

Comprehensive Conservation and Management Plan

The goal of the SMBRP is to develop a Comprehensive Conservation and Management Plan (CCMP) for the Bay which includes the following goals:

- To restore the beneficial uses of Santa Monica Bay and to protect present and future beneficial uses of the Bay. Beneficial uses include active and passive recreation, sport fishing, shellfish harvesting, and protection of marine habitat, including habitats for rare and endangered species and for fish spawning.

- To improve or eliminate discharges to the Bay that may adversely affect biologically sensitive sites, including wetlands, or important swimming and fishing areas.

- To improve water quality to a point where local marine species are not degraded and human health is not threatened.

To accomplish these goals, the SMBRP concentrates is in the process of building a consensus among all user groups; identifying the major environmental problems in Santa Monica Bay; and preparing a plan that can be implemented to protect the Bay and its resources.

PURPOSE AND OBJECTIVES OF THE STUDY

In 1990, the SMBRP adopted the "State of the Bay: Assessment of Conditions and Pollution Impacts" report (MBC 1988) as its preliminary characterization report. Since then the SMBRP has developed an outline of the CCMP, drafted Action Plan Elements to be addressed in detail in the Plan (Table 1-2), and has commissioned several studies to fill data gaps identified in the State of the Bay report. Meanwhile, the need to document present conditions in the Bay was recognized. In April 1992 MBC Applied Environmental Sciences was contracted to update the State of the Bay report.

The objectives of the present study are to update the State of the Bay Report and to provide a final characterization report for the Santa Monica Bay Restoration Project, emphasizing the tentative Action Plan Elements identified. The general aims of the update, like those of the original study, are to assess historic and present levels of pollution and to evaluate the impacts of that pollution in the study area. Specific goals include the following:

- to document what is and is not known about the condition of the Bay and its watershed, with an emphasis on the effects of pollution on human health and the marine environment;

- to determine inconsistencies in the literature regarding the condition and effects of pollution in the Bay and its watershed;

- to summarize the reviewed literature and evaluate conclusions from major documents and reports;

- to identify areas where additional research is needed to resolve inconsistent findings or to clarify appropriate clean-up measures; and,

- to prepare recommendations based upon this information.

STUDY APPROACH

The basic study approach was to collect, compile, review, summarize, and evaluate new information (collected between 1988 and 1992) relevant to the issues of concern. No field collections or measurements were made and few original analyses were performed. The original working bibliography of more than 1,000 citations was reviewed, leading to the identification of additional pertinent studies. Some of the information in this report was derived from published studies, but most of the recent data were collected from unpublished reports and personal communications from knowledgeable persons. Unpublished data from local agencies were integrated into existing figures and tables. However, the large number of studies and the quantity of data which have been generated precluded the inclusion of all information; only the more important references are actually cited.

HUMAN USES OF THE BAY

The developed area adjacent to Santa Monica Bay is important to southern California for its social, economic, and environmental resources. The Bay forms the western-most edge of much of the Los Angeles metropolitan area and is simultaneously a marine environment and a densely populated urban area. The kinds of human uses that occur at the interface between the Pacific Ocean and Los Angeles have varied over time, including:

- Recreation, Tourism, and Aesthetic Enjoyment
- Sport and Commercial Fishing
- Coastal Development
- Industrial Uses

C. Beaches and Intertidal Zones	3,8
D. Watersheds	3,6

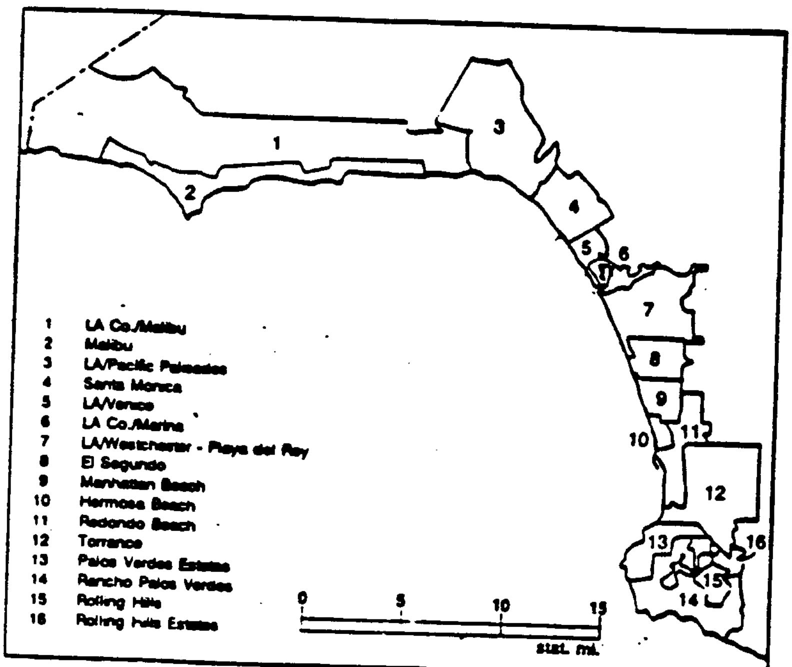

Figure 1-2. Local coastal jurisdictions in the Santa Monica Bay study area, 1992 (modified from MBC 1988).

These uses constantly compete with each other for the limited amount of land and water, resulting in the current patchwork of open space as well as commercial, residential, and industrial development. Some uses are mutually exclusive, others can coexist. Recreation, tourist facilities, and aesthetic features (views and mild climate) have a symbiotic relationship in which the elements reinforce one another; in contrast, some shipping and industrial uses are incompatible with fishing and recreational uses.

The following inventory of human uses in and adjacent to Santa Monica Bay emphasizes the social, environmental, and economic significance of these activities. When possible, the economic value is described. Coastal Santa Monica Bay includes the eleven incorporated cities adjacent to the Bay plus the communities of Playa del Rey, Westchester, Venice, Pacific Palisades (City of Los Angeles), and Marina del Rey (County of Los Angeles) (Figure 1-2). The eleven incorporated cities are El Segundo, Hermosa Beach, Manhattan Beach, Malibu, Palos Verdes Estates, Rancho Palos Verdes, Redondo Beach, Rolling Hills, Rolling Hills Estates, Santa Monica, and Torrance. Malibu was incorporated in April 1991 and has a population of about 15,000. Major factors behind incorporation were the local residents' desire for low-growth policies and to block construction of a new county sewer system.

Recreational, Tourist, and Aesthetic Uses

Recreation features and activities can be natural or developed, commercially or non-commercially operated. Examples of the four possible combinations abound throughout the Bay area.

Natural Open Space

Undeveloped natural recreation areas are scarce along the predominantly urban coastline; pristine wildlife conditions no longer exist in the study area. Yet significant natural resources remain. The Ballona wetlands (between Marina del Rey and Playa del Rey at the mouth of Ballona Creek) is a surviving wetlands that contributes to recreation, tourism, and aesthetic enjoyment. Urban development has impacted the marsh in recent decades, but efforts to reestablish and enhance 151 acres of degraded wetlands habitat are being advanced (MBC 1988). Some relatively undisturbed marsh and riparian habitat is also found in the Malibu Creek drainage and the Santa Monica mountains offer a wide range of natural habitats, especially inland of the Malibu and Carillo coasts.

Developed Beach Facilities

The many miles of bathing beaches between Torrance and Point Dume almost define Santa Monica Bay for many persons. The 22 public beaches along the shore provided more than 46 million person-days of recreation in 1991. Activities include sunbathing, swimming, boating, and surfing as well as access to the nearshore waters for skin- and SCUBA-diving. Most of these beaches are at least partially developed, offering parking, restrooms, concessions, and rental equipment. The natural state of most of them is supplemented with imported sand and/or landscaping. The busiest beach in the County is the three-mile long Santa Monica Beach. Other developed natural recreation facilities include the beach bike path, which extends from Santa Monica to Redondo Beach, and several bluff-top parks overlooking the Bay.

Recreational use of Los Angeles County beaches increased sharply until the early 1980s, attendance peaking in 1983 at 79 million visitors. While the region's population and visitors to the area have increased steadily since then, beach attendance has decreased 56% since 1983

VOL 12

1 5393

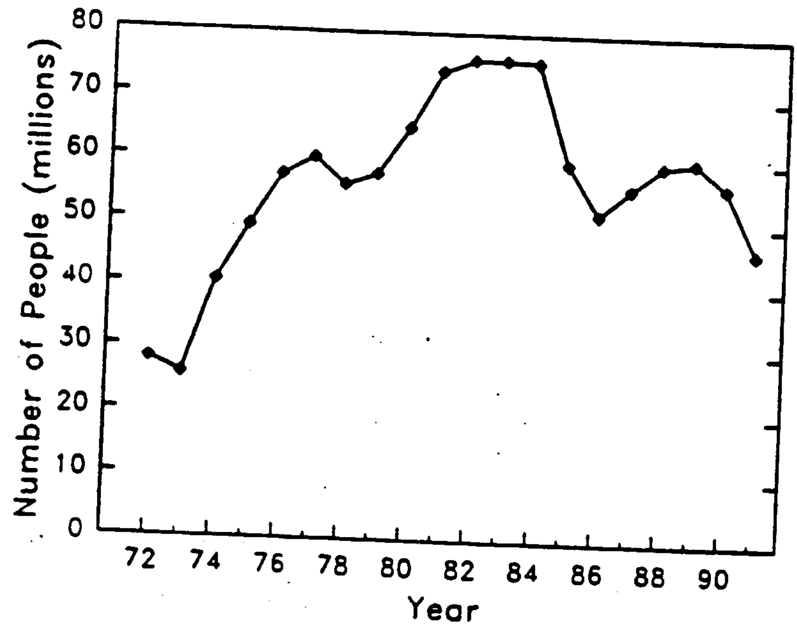

Figure 1-3. Beach attendance along Santa Monica Bay, 1972-1991 (LAC,DBH unpubl. data).

(Figure 1-3) (LAC,DBH 1987, 1992). Although changes in the weather account for annual fluctuations, the dramatic decline may indicate basic changes in recreational conditions at the beaches. In particular is public fear of water pollution, congestion, and lack of parking. For example, despite warm temperatures, beach attendance declined in late October and November 1987 following two sewage spills into the Bay from the Hyperion Treatment Plant (HTP) when some beaches were closed for up to seven days (LAC,DBH 1987). In 1991, beaches were closed on five occasions due to spills or overflows, and in 1992 beaches were closed at least eight times, including several days following contamination flowing from the storm drains created from the civil unrest in the spring of 1992.

Commercial

Commercial recreation opportunities range from bicycle and roller skate rentals, and "fun zone" arcades, to restaurants, bars, and art galleries. Most of these establishments capitalize on the pedestrian traffic attracted to the beach and some areas have evolved into recreation attractions of their own: Main Street and Santa Monica Pier in Santa Monica; Fisherman's Village in Marina del Rey; and King Harbor in Redondo Beach.

Tourist facilities and activities are abundant around Santa Monica Bay. Hotels, motels, apartments by the week, restaurants, shops, and conference facilities all cater to day visitors and out-of-town visitors. While neither the local economy nor the beach environment alone would attract tourism, in combination they create a powerful magnet for visitors. In addition, Los Angeles International Airport (LAX) is situated directly on Santa Monica Bay and it funnels a large percentage of its 48 million annual passengers into the Santa Monica Bay area for at least a portion of their stay.

Tourist services and attractions are not distributed evenly in the Bay area. Hotel development is centered around LAX, although small numbers of guest rooms and conference facilities are available in Santa Monica, Marina del Rey, El Segundo, Manhattan Beach, and Redondo Beach. An average of 9,372 guest rooms are available daily in the Santa Monica-LAX area, 10.4% of Los Angeles County's total (Pannell Kerr Forster 1992). The Santa Monica market has performed well despite the recession and is expected to remain strong even after the addition of two high-end hotel properties that are being added and will diversify the supply.

Demand in the LAX market has declined in recent years due to reductions in domestic and international tourism and in corporate travel. In addition, 700 new rooms were added to the market in 1991. Hotel supply in Los Angeles County outpaced demand by moderate levels: between 1986 and 1990 the daily average number of rooms available increased by 5%. Growth in new hotel rooms during the 1990s is expected to be at a slower rate than in the late 1980s due to the slow economy, cutbacks in corporate and leisure travel, escalating land prices and a more difficult development climate (Pannell Kerr Forster, 1992). There are few parcels of land left in the coastal area which are large enough to accommodate hotel-conference complexes (LAVCB 1988, pers. comm.).

Tourism is a powerful economic factor in the Bay area. Complete visitor data are not available for most jurisdictions, but a profile of Santa Monica's experience indicates the magnitude of visitor contributions to the local and regional economy. Santa Monica reports 2.5 million visitors annually, 64% of them day visitors. On average, day visitors spend $25 per day; overnight visitors staying in hotels spend $81 per day and constitute 15% of the city's visitor volume. Visitors who lodge with friends and relatives spend approximately $30 per day and make up about 20% of the total. In 1986 these visitors added $232 million and more than 3,000 jobs to Santa Monica's

VOL 12

15284

The sport fishery catch has some economic value as food, but fees paid to charter operators and other onshore expenditures have a much greater impact on the local economy. Expenditures on saltwater fishing in southern California totalled $536.3 million in 1989, 16% of which was on licenses and gear, 23% on boat related expenses, and 61% on trip-related expenses. Los Angeles County residents accounted for 37% of that total. About 465,000 of the 6.1 million households in Southern California coastal counties included at least one member who went sportfishing in 1989.

Los Angeles residents spend an average of $27.13 per fishing trip on tackle, food, lodging, boat fuel, boat fees, and gasoline. Shore anglers spend an average of $27.44 per fishing trip and party boat anglers spend an average of $72.76 per fishing trip. The average expenditures noted above, if applied to the totals counted by CDFG, would account for a total contribution to the local economy by sport anglers in Santa Monica Bay in excess of $3.6 million.

Recreational fishing facilities in the Bay area include piers at Malibu, Santa Monica, Venice, Manhattan Beach, Hermosa Beach, and Redondo Beach and a fishing barge off Redondo Beach. There are small craft harbors at Marina del Rey and at King Harbor in Redondo Beach. Fourteen artificial reefs designed to enhance marine life and improve sport fishing opportunities have been installed offshore at Malibu, Paradise Cove, Santa Monica, Marina del Rey, Manhattan Beach, Hermosa Beach, and Redondo Beach since 1958 and nine of these remain (Lewis and McKee 1989). Commercial passenger fishing vessels (party boats) can be taken at Marina del Rey, Malibu, and Redondo Beach. Party boats from Los Angeles, Long Beach Harbor also fish in the area.

Coastal Development in the Santa Monica Bay Area

Development of the Santa Monica Bay area is extensive: of the 67.6 mi^2 of land adjacent to the Bay (for which data exist) about 55% are devoted to residential uses; 14% commercial uses; 11% industrial uses; and 3% to transportation corridors (Table 1-3)(SCAG 1992a). Although 17% of the area are vacant, few sizable vacant parcels remain, the Hughes Playa Vista property is the largest.

Like the rest of the region, the Santa Monica Bay area is under pressure for living and working space; several regional employers in the area have fueled competition for the limited supply of coastal land. Density in areas adjacent to the Bay has increased in response to the demand for housing and business locations with coastal amenities.

For the most part land-use is regulated by the individual jurisdictions bordering the Bay and are specified in each cities' General Plan. The California Coastal Commission also regulates development in the Coastal Zone through Local Coastal Plans which are formulated by the jurisdictions in accordance with Commission policies and planning principles.

Coastal development itself is a major economic activity. The assessed valuation of property in jurisdictions around Santa Monica Bay ranged from $296 to $7,618 million in 1987 (Table 1-4) (LAC,AC 1988) and the full-market value of residential, commercial, and industrial properties in the area exceeded $30 billion. This figure does not include the value of publicly-held or otherwise tax exempt property such as libraries, schools and colleges, and parks and recreation facilities, nor does it include City and County of Los Angeles Plan areas, for which statistics were unavailable. Nevertheless, this indicator of private investment accounts for 9.7% of the Los Angeles County total.

economy and the city received $4.2 million in tax revenues generated by tourist expenditures. In total, Santa Monica garnered approximately 6.8% of the state's $3.4 billion tourist income (MBC 1987).

Noncommercial

The aesthetic features (especially marine) and favorable climate of Santa Monica Bay enjoy a worldwide reputation. These resources are an amalgam of natural and man-made features which have been achieved through merging of coastal themes with urban development.

The Santa Monica Bay shore offers numerous opportunities to appreciate physical beauty: broad beaches, boardwalks, and piers; vistas of Palos Verdes Peninsula, Malibu, and Santa Catalina Island; and a variety of public and private facilities and spaces. Local jurisdictions review proposed development plans in order to preserve and enhance existing aesthetic resources and scenic areas.

Aesthetic resources make an intangible but important contribution to the local economy. They tend to boost tourism and recreation and are closely tied to specific businesses such as television and motion picture filming, two staples of the regional economy.

Sport and Commercial Fishing

Fishing is one of the most fundamental human uses of the Bay and includes commercial passenger boat fishing (party boats), pier fishing, private boat fishing, scientific collecting, and limited commercial fishing. While sport fishing is allowed throughout the Bay, commercial fishing has been prohibited in about 62% of Santa Monica Bay proper to protect local fish populations, which could be depleted by a combination of both commercial and sport fishing. Commercial fishing for white croaker off Palos Verdes has been banned since 1989 due to white croaker contamination problems (Velez 1993, pers. comm.). Purse seining, gillnetting, and traps are prohibited in parts of the Bay east of a line between Malibu Point and Palos Verdes Point; thus commercial fishing activities there is restricted to hook-and-line fishing.

Commercial fishing activity in the rest of the Bay centers around gillnetting for California halibut west of Malibu and south of Palos Verdes Point, and purse seining for northern anchovy in the outer portions of the Bay (MBC 1985). Under Assembly Bill 2315, experimental gear permits are issued for round haul net fishing for live bait (Velez 1993, pers. comm.). Commercial catches from Santa Monica Bay are negligible. Limited commercial marine life collections are made for scientific and educational specimens and unauthorized commercial fishing and poaching may occur to some extent, although its magnitude is not known.

Although statistics are not available for Santa Monica Bay alone, 5.5 million sport fishing trips were made in southern California in 1989. It is estimated that 11% of those trips involved beach fishing, 22% involved pier fishing, 30% involved commercial passenger fishing vessels (CPFVs), and 37% involved private fishing boats (NMFS 1991). The sport fishery catch from Santa Monica Bay is monitored by the California Department of Fish and Game (CDFG). In 1987 the sport fishery catch (79,197 anglers) was dominated by Pacific bonito, chub (Pacific) mackerel, and barred sand bass (CDFG,MRD, unpub. data). In 1991-1992 the sport fishery of the Bay was dominated by chub mackerel, barred sand bass, and kelp bass (MBC, in prep.).

R0048594

In addition to its ultimate assessed value, development contributes to local and regional economics during construction. Construction jobs and expenditures are a major segment of the southern California economy. Coastal development also supports the local economy through property taxes and development fees, which are used in part to fund recreation and open-space amenities that encourage still other economic benefits, primarily tourism.

The predominant human use in the Santa Monica Bay area is residential (Table 1-3). The Bay's recreation and air quality resources make it one of the most desirable sectors of the region in which to live: housing unit vacancies fall well below the County's 4% average in all but a few of the Bay jurisdictions. Except for the Palos Verdes Peninsula, the average household size is also below the Los Angeles County average, indicating a trend toward smaller, denser housing units (LAC,DRP 1987). The Bay area's housing stock is 7% of the Los Angeles County total (Table 1-5) (SCAG 1992b) and it houses 7% of the County's population, underlining the small household size along the coastal area. Torrance, Santa Monica, and Redondo Beach have the greatest number of housing units (Table 1-5) (SCAG 1992b). Between 1987 and 1992, the number of housing units increased 450% in Playa del Rey; the next highest rates of increase were Marina del Rey with 16% and Rancho Palos Verdes with 7% (Table 1-5). Pacific Palisades, Westchester, and Venice had fewer housing units in 1992 than in 1987, with decreases of 66, 58, and 20%, respectively.

Commercial and industrial land uses in the Santa Monica area contribute to the regional economy in terms of employment. In 1980 commercial and industrial land users in the Bay area provided 18% of the five-county region's jobs on only 4% of its land. These figures include inland portions of West Los Angeles, but exclude major job centers such as UCLA, Westwood, and Century City. Jobs within the Bay area are diffused throughout the 16 jurisdictions, although there are major concentrations in Santa Monica, South Bay, and at LAX. While the absolute numbers of jobs have changed since 1980, the general patterns have been reinforced through additional land development and employment growth.

Commercial and industrial land uses in the area support 17% of the region's retail jobs, 16% of financial jobs, 22% of business sector employment, 23% of service and entertainment jobs, 16% of professional workers, and 15% of public administration positions. The area also accommodates 20% of the region's manufacturing workers, 23% of transportation employment, and 18% of wholesale employment. This impact is augmented by the goods and services produced by the workers, which have regional, national, and international significance (Gordon 1988, pers. comm.).

Marine development in the Bay area includes piers, artificial reefs, and breakwaters. Commercial and industrial activities which depend on a coastal location are clustered in and around the small craft harbors and piers. Boat building and maintenance, fishing, and tourist facilities are coastal dependent commercial and industrial activities. However, electric power generating stations and an oil refinery must also be included as coastal-dependent, the former for cooling water and the latter for tanker access.

Secondary economic impacts from the Bay area's commercial and industrial activities emanate to the rest of the Los Angeles region. Employees from outside areas spend most of their income elsewhere, thus boosting sales and tax revenues there. Goods and services produced in the Bay area are often sold or consumed in other sectors of the region.

With the exception of the Playa Vista land holding, which is being planned for mixed-use development, the study area is at or near build-out. Future coastal development is limited by the

The Los Angeles County Sanitation Districts' Joint Water Pollution Control Plant (JWPCP) discharges approximately 325 mgd of treated municipal wastewater onto the Palos Verdes Shelf. The JWPCP disposes of a mixture of 60% secondary- and 40% advanced primary-treated wastewater through two outfalls, 90- and 120-in. diameter, with a 72-in. diameter outfall for emergency backup. JWPCP is the processing facility for 5 upstream water reclamation plants located in Los Angeles County; these plants provide primary, secondary, and tertiary treatment for 150 mgd wastewater (Stull 1993, pers. comm.).

Each of these industrial/municipal uses impacts the economy in two ways. Each generates employment and goods for the local economy and each also provides a regional service with a high replacement value. Replacement costs for SCE's electrical generating stations at Redondo and El Segundo illustrate the magnitude of the economic value that major industrial uses for the study area and the region. Based on 1987 totals for capital investment, operations and maintenance expenses (including payroll and repairs), fuel expenditures, property taxes, and electricity sales, SCE estimates the power replacement value of its El Segundo station at $918,000,000, and for its Redondo station at $1,442,000,000 (SCE,SGD 1988).

HTP also represents a substantial replacement value, although no estimates are available. Some facilities might not be able to replace the loss of a Bay location or resource, at any cost. For example, loss of its marine terminal pipelines across the Bay could force Chevron to relocate to an area without transportation constraints.

Future impacts of industrial facilities on regional economics will depend on the amount of expansion and updating that occurs. LAX is the hub of a regional airport system, which is expected to grow to 65 million passengers annually by the year 2000 (CLA,DA 1992). HTP is being expanded and upgraded at present and is expected to remain the linchpin of Los Angeles' wastewater treatment system, whether or not additional capacity is added elsewhere. However, as additional land is unavailable, any expansions can only occur with more intensive use of existing land holdings and water resources, or through eminent domain.

Plans for further oil and gas development in and around Santa Monica Bay have changed in recent years. The Department of the Interior Lease Sale No. 95 Offshore Drilling Proposal for southern California, which would have made areas immediately west of Santa Monica Bay available for oil and gas exploration and development, has been dropped. Lease Sale No. 95 was originally slated for January 1990 but in June of that year President Bush deferred the sale until 1996 and in 1992, a moratorium was placed on offshore drilling and Lease Sale No. 95 was canceled. In addition, Occidental Petroleum's 22 year effort to drill for oil on the company's two acres of coastal property along Pacific Coast Highway ended in 1992. Occidental decided not to pursue the drilling plan any further and transferred ownership of the property to the City of Los Angeles (LA Times 1992).

VOL 12

1 5291

lack of available vacant land. Future growth, along with its primary and secondary economic benefits, will be restricted to scattered infill development, recycling, and redevelopment activities. Thus, significant expansion of the Bay area's economic position in the region is likely to result in a denser pattern of human activities and development.

Infrastructure constraints - the willingness of local jurisdictions to work together to fund and construct new streets, parking, and sewage treatment capacities - will also limit future growth,. Downzoning and other growth-curtailing planning and policy actions are now being considered in several local jurisdictions. Some of these proposals affect residential growth only, others address commercial growth, and some would impact all development. The outcome of these deliberations may freeze the present land use pattern and thus limit the area's current contribution to the regional economy.

Industrial Uses of the Bay Area

Industrial land use is found in all but two Bay area jurisdictions. El Segundo, Torrance, and Westchester-LAX-Playa del Rey contain industrial centers of 1,500 acres or more, while Santa Monica, Redondo Beach, and Manhattan Beach contain industrial centers of 250 to 500 acres (LAC 1987). Industrial uses also affect the marine environment directly through wastewater discharges and use of the ocean for transport.

The industrial/municipal activities that most impact the Bay are power generation, oil refining, and waste disposal. Most of the industrial facilities of concern are located nearshore, between Marina del Rey and Redondo Beach: the Los Angeles Department of Water and Power's Scattergood Generating Station; Southern California Edison's (SCE) El Segundo and Redondo Generating Stations; the Chevron USA's El Segundo Refinery; and the City of Los Angeles Hyperion Treatment Plant (HTP).

Los Angeles International Airport (LAX) is an industrial facility and aerospace-related manufacturing center which is located on the Bay but provide essential regional services; the airport relies upon its proximity to the Bay for safe flight paths exiting the airport.

The three power generation facilities use Bay water for condenser cooling and disposal of a small amount of treated effluent. Together, these plants circulate up to 238 billion gallons of seawater per day. Southern California Edison's plants generated $625.5 million worth of electrical energy sales to the region in 1987 (SCE,SGD 1988).

Chevron USA uses Santa Monica Bay to transport crude oil and refined petroleum products to and from its El Segundo Refinery. Small coastal lightening tankers load and off-load at the refinery using a three-berth offshore facility which connect the marine terminal to the refinery with subsea pipelines (Chevron USA 1988, pers. comm.). Small amounts of treated effluent are also discharged.

HTP discharges treated municipal wastewater at a distance of 5 miles from shore, relying on ocean water to dilute the effluent to safe levels. HTP disposes of a mixture of secondary- and primary-treated wastewater via a 5-mi long outfall pipe into the Bay. The 5-mi outfall discharges 60% secondary and 40% primary treated effluent. A 1-mi outfall is used for emergency purposes, to discharge chlorinated secondary treated effluent. A 7-mi outfall was used for sludge disposal until November 1987.

CHAPTER 2
THE PHYSICAL SETTING

Santa Monica Bay is an open embayment on the southern California coast just west of Los Angeles, with natural boundaries which extend from Point Dume to Palos Verdes Point. For the purposes of this study, the Bay has been defined as extending from the Ventura-Los Angeles County Line (west of Point Dume) to Point Fermin (south of Palos Verdes Point) and offshore to water depths of about 1,650 ft (Figure 2-1).

Santa Monica Bay is a relatively small feature in a larger geographic region [the Southern California Continental Borderland (Emery 1960, SCCWRP 1973)] – the offshore, submerged lands from Point Conception, California to Cape Colnett, Baja California and seaward to the Patton Escarpment. Without the geological connotation, this region is known more commonly as the Southern California Bight, the seaward boundary of which is the California Current.

The study area consists of three regions: Santa Monica Bay itself; its natural watershed; and the wasteshed which drains to it (Figure 2-1). Santa Monica Bay includes the marine waters and seafloor of the area already defined. The watershed is that region of coastal land from which surface waters drain naturally to the Bay. The wasteshed is that area from which municipal wastes are collected before being treated and discharged to the Bay. The surface area of Santa Monica Bay is approximately 266 mi^2 and that of the combined watershed and wasteshed is approximately 1,380 mi^2. Most surface runoff from the wasteshed is carried to Los Angeles' Long Beach Harbor (east of the Palos Verdes Peninsula) but some is carried to the Bay.

The physical characteristics of the Santa Monica Bay ecosystem are determined primarily by the geology, climate, and oceanography of the region. Geological features provide the framework for the system within which climate and oceanography determine many natural environmental cycles.

GEOLOGY

The present configuration of the Southern California Continental Borderland is largely the result of the movement of the Pacific tectonic plate against the North American tectonic plate, the San Andreas fault marking the line of contact between the two. Many local features in the area result from block-faulting, a geological process in which large blocks of the earth's crust are thrown upwards or downwards. Offshore islands and banks represent upthrown blocks whereas basins represent downthrown blocks (Emery 1960). The Santa Monica Mountains were uplifted, then shifted to the West.

Santa Monica Bay is the submerged portion of the Los Angeles Coastal Plain, which extends southeast of the Santa Monica and San Gabriel Mountains, southwest of the San Bernardino Mountains, and north of the Santa Ana Mountains. The Los Angeles Basin lies beneath the Coastal Plain and the Bay and was formed as a downthrown block. Sediments eroded from the surrounding mountains have subsequently filled the basin to its present surface, near sea level (Terry *et al.* 1956, Emery 1960, Miller and Hyslop 1983). Sediments near the surface of the Basin have been deposited during the last 2 million years (BLM 1981).

Offshore of the Los Angeles Basin is the Santa Monica Basin, which is a downthrown block that has only been partially filled with eroded sediments; hence it is still a fairly deep marine basin. The shelf in Santa Monica Bay is partly the sediment-filled Los Angeles Basin and partly the sill that separates the Los Angeles and Santa Monica Basins. Bedrock lies much nearer the sediment surface beneath the sill than beneath the two basins (Emery 1960).

VOL 12

15294

The Palos Verdes Peninsula is an uplifted block that appeared as an island about 3 million years ago; it was later connected to the mainland as a result of sedimentation on the Coastal Plain (Reiter 1984). During ice ages, which occur about every 100,000 years, sea level drops as much as 425 ft because water is retained in polar glaciers (Covey 1984); during interglacial periods sea level rises, to present levels or higher. Most of the terraces which are obvious on the Palos Verdes Peninsula (and can be detected on the adjacent seafloor to water depths of 500 ft) were formed by wave erosion of the shore when sea level was at a different height for a considerable period of time. Terraces far above the shoreline on Palos Verdes Peninsula were probably exposed as a result of uplifting of the peninsula in recent geologic time.

The present continental shelf has only been submerged for the last 10,000 years and to the present depth for the last 3,000 years. During the peak of the last ice age (18,000 years ago), sea level was 384 ft lower than now (Nardin *et al.* 1981); this would have exposed the entire shelf and dry land would have extended as much as 12 mi offshore of the present shoreline.

Topography of Santa Monica Bay

Santa Monica Bay is characterized by a gently sloping (about 0.5°) continental shelf which extends seaward to the shelf break at a water depth of about 265 ft (Terry *et al.* 1956). At the break, the seafloor steepens along the continental slope but decreases again as the floor of the Santa Monica Basin is approached at a water depth of about 2,630 ft.

The shelf in the Bay ranges in width from a few hundred yards to about 12 mi (Figure 2-2). It is broadest off El Segundo, narrowest off Redondo Beach, and is transected by three submarine canyons: Dume Submarine Canyon across the northwestern shelf off Point Dume; Santa Monica Submarine Canyon 7 mi offshore of Ballona Creek; and Redondo Submarine Canyon, a few hundred yards off King Harbor. In this report the region between Santa Monica and Point Dume is called the Malibu Shelf and the region between the Ventura-Los Angeles County Line and Point Dume is called the Carillo Shelf.

The Palos Verdes Shelf extends from the southern edge of Redondo Canyon around the Palos Verdes Peninsula to Point Fermin and offshore to water depths of about 245 ft (SDWG 1988). The Palos Verdes Shelf ranges in width from about 1.2 to 4.6 mi, and is steeper than in the Bay proper. The shelf break is shallower but less pronounced; below the break the seafloor is relatively steep to the boundary of the study area at depths of 1,640 ft.

Shores

The shore of the study area is generally mountainous, with coastal cliffs between the Ventura County and Santa Monica and along the Palos Verdes Peninsula. Prior to development, the coast between the palisades at Santa Monica and Malaga Cove consisted of sand dunes; wetlands were abundant in the vicinity of Ballona Creek. At present approximately 50% of the shore of Santa Monica Bay is sandy, constituting the popular recreational beaches from Torrance Beach to Santa Monica and intermittently from there to Ventura County. The coast from Point Dume to Pulga Canyon consists of narrow, sandy beaches interrupted by rocky outcrops or short stretches of rocky shore. Along the Palos Verdes Peninsula the shore is largely cobble with some small sandy pocket beaches (Terry *et al.* 1956); these beaches comprise coarser sand than those along the rest of Santa Monica Bay and contain some cobble.

VOL 12

15295

VOL 12

1 5296

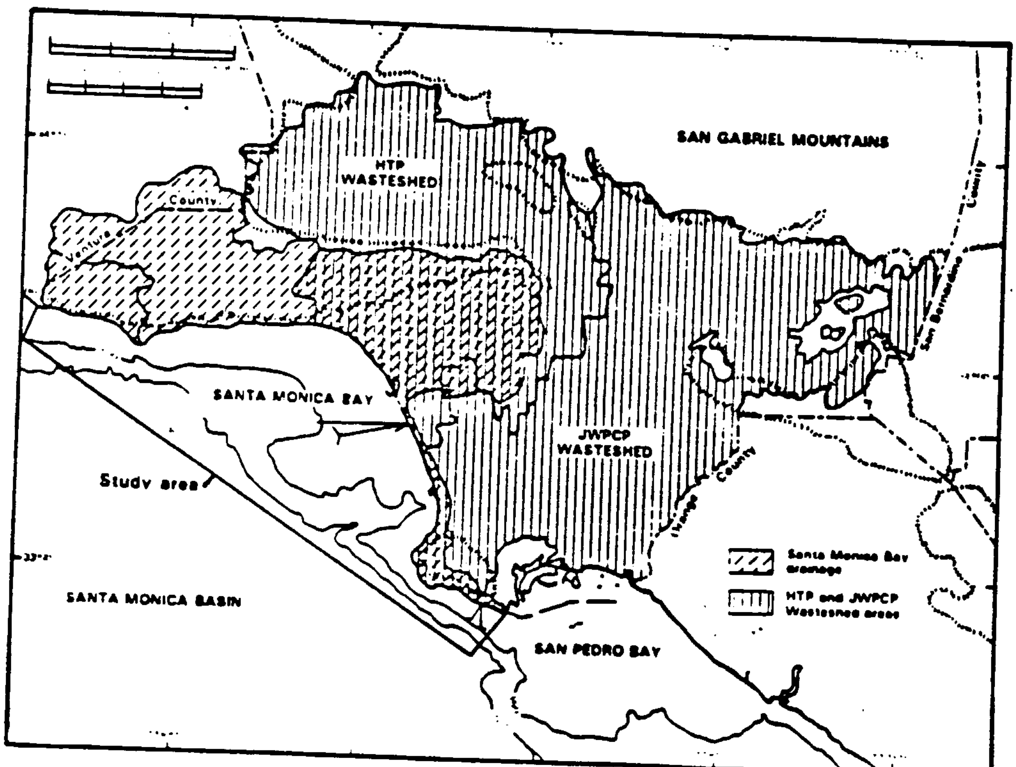

Figure 2-1. Santa Monica Bay study area, watershed, and wasteshed (modified from MBC 1988).

Since creeks in the Ballona Creek drainage were channelized in the 1930s, little sand is transported to the Bay from the coastal plain. In the past, occasional shifts in the course of the Los Angeles River to Santa Monica Bay probably replenished beach sand. Now the primary source of beach sand is cliff erosion (Woodell and Hollar 1991) with some inputs from runoff from the Santa Monica Mountains (Mitchell 1987, pers. comm.) and the Santa Clara River (Kolpack 1988, pers. comm.). A landslide at Portuguese Bend has been an important source of sediment to the Palos Verdes Shelf since 1956, contributing about 9 million MT of sediment (Stull 1988, pers. comm.); it has been particularly important since 1980 (SDWG 1988).

Sandy beaches are an extension of the intertidal zone, as they are formed by the combined action of wind and waves. The source of the sand on Santa Monica Bay beaches is bluff erosion and sediment carried from the watershed by coastal streams and rivers. Sand is transported longshore and is eventually lost into Redondo Canyon. In some locations, beaches have been augmented by nourishment projects which have added more than 24 million cubic meters of sand to the shoreline (Woodell and Hollar 1991).

Dunes depend on a supply of sand which is moved onshore by waves, then further inland across low-lying areas by frequent strong winds. Coastal dunes protect low-lying inland areas from ocean storms, but they may be completely eroded during a single winter storm and reformed during calmer periods. The El Segundo Dunes are the only significant dunes remaining in the Santa Monica Bay area.

Historical. Prior to development, the coast between the palisades at Santa Monica and Malaga Cove consisted mostly of sand dunes. Adjacent to Ballona Creek were wetlands with fine sediments. Occasional shifts in the course of the Los Angeles River to Santa Monica Bay through Ballona Creek probably replenished beach sand. Since the channelization of creeks in the Ballona Creek drainage in the 1930s, little sand has been transported to the Bay from the coastal plain. Now the only natural source of sand besides bluff erosion is in runoff from the Santa Monica Mountains (Mitchell 1987, pers. comm.) or from the Santa Clara River in Ventura County via longshore transport (Kolpack 1988, pers. comm.). The few remaining natural dunes are just west of Los Angeles International Airport (Sharp 1978).

The shoreline of Santa Monica Bay is gradually eroding because sea level is slowly rising. Early developments in the Santa Monica Bay coastal zone included the construction of commercial structures on beaches and in the littoral zone and, later, other projects to protect these investments from the impacts of natural events. The first efforts to rebuild eroding beaches began in 1930 with the establishment of the Los Angeles County Coastal Studies Division. Periodic surveys of the beaches began in 1933; there have been 36 surveys to date. As a result of many efforts to counteract the erosion process (construction of groins and beach replenishment), beaches along much of Santa Monica Bay are wider than in the past (Woodell and Hollar 1991).

Location and Jurisdiction. The beaches of the Santa Monica Bay study area are variously under the jurisdiction of the state, county, city, and private groups. State beaches are run by the California Department of Parks and Recreation and include Leo Carrillo, Westward, Point Dume, Corral, Malibu Lagoon (Surfrider Beach), Las Tunas, Topanga, and Will Rogers to the west of Santa Monica and Dockweiler, Manhattan, Redondo and Royal Palms south of there. Beaches, parks, and reserves falling under the jurisdiction of Los Angeles County include Nicholas Canyon Beach, Zuma Beach Park, Torrance Beach, Abalone Cove Beach, and Abalone Cove Ecological Reserve.

52998

R0048603

Soft-Bottom Sea Floor

The bottom type of the seafloor is largely a function of the water movement in the overlying water mass, although the proximity of the sediment source can be important. Coarse sand and gravel are found under swiftly moving water whereas fine silt and clay settle to the bottom in quiet water. In most parts of Santa Monica Bay the seafloor consists primarily of fine to moderately coarse, unconsolidated sediments. However, hard bottoms of bedrock, gravel, and phosphorite are found in some areas (Figure 2-3).

Unconsolidated (soft) sediments are classified on the basis of grain size into sand, silt, and clay fractions. In general, sediments grade from coarse nearshore to fine offshore; thus sediments on the shelf are sand whereas those on the slope are silt. Most nearshore sediments of Santa Monica Bay are olive green sands, which form an elongate bed which is broadest off Manhattan Beach and extending from Venice Beach to the central shelf (Terry *et al.* 1956). Sediments on the northwestern part of the Palos Verdas Shelf are generally coarser than those on the Santa Monica Shelf whereas those on the southern part of the shelf are finer (SDWG 1988).

Silty sand is found over much of the central plateau and on the Palos Verdes Shelf, but only in a narrow, nearshore band along Malibu and on the southern portion of the central shelf. Sandy silt is characteristic of the upper portion of the basin slope, much of the middle and deep depths off Malibu, and the outer portion of the central plateau. Deeper portions of the basin slope have silty sediments (Terry *et al.* 1956). Clay was a minor fraction of Santa Monica Bay sediments in the 1950s (Terry *et al.* 1956), but was more common in the 1970s (Bascom 1978).

Most sand on the shelf is fine quartz-feldspar that is being eroded from land, although small patches of relict red sand are found on the central plateau and south of Redondo Canyon (Terry *et al.* 1956). Relict red sands were deposited when the sea level was lower; they represent ancient beaches or sand dunes that have been reexposed. Much of the sand on the basin slope and the outer portions of the shelf are glauconite; shell sand occurs on some of the basin slopes.

Sediment composition and distribution change in time and place due to prevailing currents and storms. Winter storms move beach sand offshore to deeper (10 to 20 ft) water; in summer reduced wave intensity allows the sand to reaccumulate onshore (Grant and Shepard 1939). Currents generally move sand east along the Carillo Shelf toward Dume Canyon (Kolpack, 1988, pers. comm.), east along the Malibu Shelf, south along the central shelf toward Redondo Canyon, and north from Malaga Cove to Redondo Canyon (Grant and Shepard 1939). From time to time sand flows down Redondo Canyon and is lost to the nearshore system (Drake and Gorsline 1973). Numerous dikes, groins, and jetties have been constructed to help sand accumulate (Woodell and Hollar 1991). Sediments along the upper slopes of Santa Monica Canyon and the Palos Verdes Shelf occasionally slump into basins as a result of earthquakes and turbidity currents (Haner and Gorsline 1978, Gorsline *et al.* 1984, SDWG 1988).

Sediments are typically exposed to oxygen and any organic material is processed by aerobic infauna and bacteria which live in the sediments. However, if there is insufficient oxygen in the sediments for aerobic decomposers, anaerobic sulfur bacteria may dominate. These produce hydrogen sulfide which gives the sediments the odor typical of rotten eggs.

VOL 12

1

5299

City jurisdictions include beaches (Santa Monica, Venice, and Hermosa Beaches) and piers (Santa Monica Municipal, Venice Fishing, Manhattan Beach Municipal, Hermosa Beach Municipal, and Redondo Beach Municipal Piers). Seaside Lagoon at, and the Palos Verdes Estates Shoreline Preserve. Private beaches include Paradise Cove and Marina del Rey Public Beach. Private piers include Paradise Cove Pier, Redondo Sportfishing Pier, and Monstad Pier.

Rocky Intertidal. On coasts exposed to the full force of incoming waves, loose sediments have been stripped away leaving underlying bedrock exposed as rocky intertidal habitat. In the study area, natural rocky intertidal habitat is found along the Carrillo coast, on the Malibu coast from Point Dume to Paradise Cove, along occasional rocky patches from there to Big Rock Beach, and along the coast of Palos Verdes Peninsula. Reefs around Point Dume are primarily bedrock, but those on the Palos Verdes Shelf include cobble, which is less stable than bedrock. Jetties, groins and piers provide artificial intertidal hard-bottom habitat along the central Bay.

The rocky intertidal can be divided into four discrete zones (Hedgpeth and Hinton 1961, Carefoot 1977). The splash zone is above the high tide mark and is essentially terrestrial, although it is splashed by waves. The upper intertidal zone extends from the bottom of the splash zone to about mean high tide, and it is exposed to the air longer than it is under water. The middle intertidal zone extends from about mean high water to mean low tide mark; it is exposed and submerged for about equal periods of time. The lower intertidal extends from mean low tide to the subtidal and is submerged longer than it is exposed.

The demarcation of zones is also affected by the prevailing wave heights. In an area which is exposed to frequent and high waves, the upper zones are displaced upward and the boundaries between adjacent zones are blurred. In protected areas where the average wave height area is low, there is no splash zone and the other zones are marked distinctly.

Sandy Intertidal. Where the coast is not directly exposed to strong waves, sand accumulates to form beaches. The sandy intertidal is exposed to extremes in temperature, hydration, salinity, and movement. During high tides it is covered with cool salt water; on hot days during low tides it dries out and heats up rapidly. On rainy days when the tide is out it may be exposed to freshwater. Organisms in the sandy intertidal are also subjected to forceful wave shock and shifting sand with each high tide. Sandy beaches are less productive of plant and animal life than most other marine habitats and zonation is less apparent than on rocky shores.

Sandy beaches have relatively large spaces between sand grains which permits the ready flow of water and oxygen well below the sediment surface. Where the sand is coarse and wave action is great, fixed burrows are impossible to maintain and most inhabitants are small enough to live between the sand grains or, if larger, to quickly bury themselves in the loose sand.

The infaunal communities of the sandy beaches of Santa Monica Bay have not been studied in detail, but data from studies conducted at beaches at Point Dume (Patterson 1974, Straughan 1982), El Segundo (MBC 1982b,c), Torrance (Straughan 1977b), and King Harbor (Straughan 1977a,b) are available. Bight-wide, sandy intertidal habitats support three slightly different communities separated along geographic lines (Straughan 1982). All sites between Point Mugu and Palos Verdes Peninsula are similar.

Hard-Bottom Sea Floor

Exposed bedrock is found nearshore along the Carillo and Malibu coasts from the Ventura-Los Angeles County line to Pulga Canyon and from Malaga Cove to Point Fermin on the Palos Verdes Shelf. Exposed bedrock is also found offshore, on the central shelf (Short Bank) of the Santa Monica Shelf and in both Santa Monica and Redondo Submarine Canyons. Inshore rocky bottoms are similar in composition to those on land nearby; however, the offshore bedrock generally consists of siliceous shales with mudstone, siltstone, sandstone, and schist (BLM 1975).

Stream deposition and the erosion of rocky shore have formed nearshore gravel beds off Malibu and along the Palos Verdes Shelf. These gravels are primarily rounded pebbles of igneous rock but include metamorphic and sedimentary rock. Other gravel beds surround the exposed bedrock areas of Short Bank (Shepard and MacDonald 1938, Terry *et al.* 1956, Bascom 1978) and in Santa Monica Submarine Canyon (Bascom 1978). These presumably resulted from the erosion of outcrops at lower sea level stands or from stream deposition at that time.

Anthropogenic hard-bottom substrates in the study area include municipal wastewater outfall pipes (three from Hyperion Treatment Plant and four from the Joint Water Pollution Control Plant), as well as smaller outfall structures for generating stations and the refinery. Other artificial hard-bottom structures include jetties, breakwaters, groins, and artificial reefs.

Because subtidal, hard-bottom habitats support algal growth and attract sportfisheries species, the California Department of Fish and Game (CDFG) has constructed 14 artificial reefs in Santa Monica Bay since 1958. The first five were constructed of degradable materials (streetcars and automobiles) and have since disappeared. Nine artificial reefs (constructed since 1962 out of quarry rock, concrete, pier pilings, tires, and marine vessels) are expected to remain for much longer (Lewis and McKee 1989).

Topography of the watershed and wasteshed

The terrestrial environment bordering Santa Monica Bay consists of two major regions: 1) the watershed and 2) the wasteshed (Figure 2-1). The watershed is the region of coastal land that comprises the natural drainage area of the Bay (i.e., the land from which surface waters drain into the ocean). The natural drainage and its potential to carry pollutants into Santa Monica Bay makes the watershed important as it pertains to the Bay's environmental quality. The wasteshed is that land area from which municipal wastes originate before being treated at municipal waste treatment facilities which discharge to the Bay and hence is not a natural physical region. Much of the surface runoff in the wasteshed is carried to the Los Angeles-Long Beach Harbor area east of the Palos Verdes Peninsula but some is carried into Santa Monica Bay. The surface area of the combined watershed and wasteshed of Santa Monica Bay is approximately 1,380 mi^2; the watershed drains about 414 mi^2 (SMBRP 1992).

The topography of the terrestrial environment bordering Santa Monica Bay is dominated by the Santa Monica Mountains, the Los Angeles Coastal Plain, and the Palos Verdes Peninsula. Mountain peaks in the Santa Monica Mountains are up to 3,111 ft high (on the western border of the natural drainage) and in the Palos Verdes Hills up to 1,480 ft (Reiter 1984). However, most of the plain is less than 500 ft above sea level (Terry *et al.* 1956, CLADPW 1982).

Historically, the Los Angeles River occasionally emptied into Santa Monica Bay at Ballona Creek instead of into San Pedro Bay at Long Beach. This resulted from changes in the river's course during unusually heavy storms and is known to have occurred in 1815-1825, 1862, and

VOL 12

1 5301

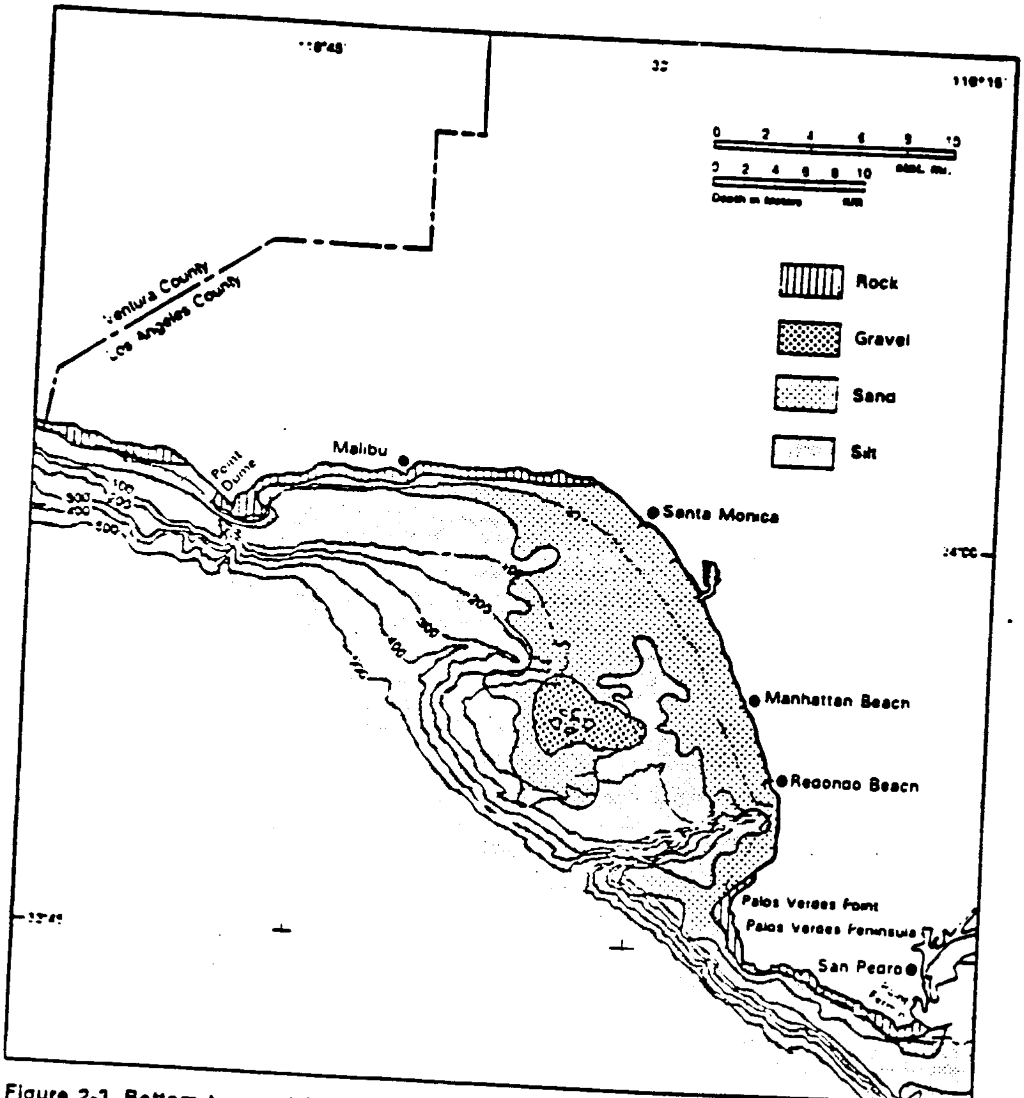

Figure 2-3. Bottom types of Santa Monica Bay (modified from MBC 1988).

Wind

Prevailing winds along the coast are from the west-northwest and wind speed is generally low throughout the year. At Santa Barbara Island, west of Santa Monica Bay, wind speed ranges from 6 to 8 mph in the fall to 10 to 12 mph during the spring, although gusts may reach 60 mph during the winter and spring (Kimura 1974). In summer sea breezes typically blow onshore in the morning as air over the land heats up, rises, and pulls cool air from the ocean (Miller and Hyslop 1983). At night offshore land breezes often develop as air over the land is pulled seaward as air over the warmer ocean rises.

During winter (but occasionally at other times) Santa Ana winds blow to the west off the deserts east of the Los Angeles Basin. These winds result from high pressure cells over the desert and enter the coastal zone through mountain passes. Santa Anas are very dry and hot as a result of compression as they drop in altitude, and gusts of 50 mph have been recorded. Santa Anas are responsible for dispersing dust and air-borne contaminants out over the ocean (Miller and Hyslop 1983).

OCEANOGRAPHY

Oceanographic conditions in the study area are largely a function of the California Current and other offshore currents, as modified by local topography and conditions.

Currents

Oceanic Currents

The California Current is a low-temperature, low-salinity, and nutrient-rich current that flows south along the California coast (Figure 2-4). It varies in velocity from year to year but is usually weakest in winter and spring (CLA,DPW and USEPA 1977). South of Point Conception, the California Current generally flows along the Patton Escarpment (100 mi offshore) and approaches the coast again near Cape Colnett, Baja California.

Off Baja California part of the California Current flows north into the Southern California Bight as the Southern California Countercurrent. Part of this countercurrent exits the Bight through the Santa Barbara Channel and rejoins the California Current while the rest flows south nearshore (CLA,DPW 1982). Beneath the surface water mass (i.e., from the surface to depths of about 820 ft) is a relatively high-temperature and high-salinity current called the California Undercurrent which flows to the north (CLA,DPW and USEPA 1977; Jackson 1986). This current surfaces nearshore north of Point Conception during the fall and winter and is known then as the Davidson Current.

Coastal Currents

Local currents are affected by local submarine topography, winds, and tides and are of two kinds: longshore currents which flow parallel to shore and cross-shore currents which move perpendicular to shore. Longshore currents are fastest near the surface; near-bottom they are slowed by seafloor friction. Off Palos Verdes and the seaward edge of Santa Monica Bay, longshore currents flow north at approximately 0.09 kn (CLA,DPW and USEPA 1977). However, surface currents with speeds up to 1.13 kn for several days have been measured on the Palos Verdes Shelf (SDWG 1988). Cross-shore currents flow shoreward or seaward near the surface and at depth; they are generally caused by surface wind forcing or by internal waves (Jackson 1986).

VOL 12

15303

1884 (Terry *et al.* 1956). When the Los Angeles River discharged through Ballona Creek, the natural drainage to Santa Monica Bay was much larger, including the San Fernando Valley and part of the San Gabriel Mountains. Because the Los Angeles River is now channelized, future discharges through the Ballona Creek are unlikely.

The area between Ballona Creek and present-day Beverly Hills was often a vast swamp (Johnston 1962, Reiter 1984); in fact, the Spanish word for swamp (*la cienega*) is given to a major boulevard in this region. During torrential rains in the winter of 1861-1862, the entire area from Los Angeles to the ocean, both toward San Pedro and toward Ballona, was a vast lake (Kuhn and Shepard 1981).

The natural drainage of the study area (Figure 2-1) follows the crest of the Santa Monica Mountains from the Ventura - Los Angeles County Line (and following a ridge to the sea in that area) to a point inland from Point Dume north of Lake Silverwood and from there east to Hollywood. From Hollywood it extends south and west across the Los Angeles plain to include the area east of Ballona Creek and north of the Baldwin Hills. South of Ballona Creek the natural drainage is a narrow coastal strip between Playa del Rey and the Palos Verdes Hills.

CLIMATE

Air Temperature

The climate of southern California is Mediterranean, characterized by warm, dry summers and mild, wet winters. Although less than half of the days of the year are cloudy, insolation (i.e., sunshine) is greatest from March to September. The sun heats the air, land, and water; in turn, the land and water heat the air. The average daily (24 hr) air temperature in the study area ranges from 45 to 72°F annually (SCCWRP 1973), being coldest in January and warmest in July. In summer the Los Angeles Coastal Plain is generally cooler than the nearby mountains and inland valleys due to the onshore flow of marine air (Miller and Hyslop 1983). Relative humidity is typically about 90% at night and about 60% during the day (Kimura 1974).

A temperature inversion often develops on the Los Angeles Coastal Plain during the summer. Cool coastal is air trapped beneath warm air at higher altitudes, resulting in hazy or smoggy air. Cool air over upwelling regions of the ocean often results in fog. During late spring and early summer, fog may deepen to several thousand yards, causing drizzles throughout the Coastal Plain (Miller and Hyslop 1983). At Los Angeles International Airport there are usually about 53 days of fog per year (Kimura 1974).

Rainfall

The average annual rainfall on the Coastal Plain is 12 to 13 in. but ranges from 4 to 25 in (SCCWRP 1973, Kimura 1974, Miller and Hyslop 1983). About 90% of the rainfall occurs between November and April (SCCWRP 1973). In winter cold-front storms typically come from the northwest; in summer tropical storms called chubascos occasionally come from the southeast. Most storms originate over the ocean as low pressure cells, but thunderstorms occasionally result from hot air rising over land (Kimura 1974, Miller and Hyslop 1983).

Surface currents in Santa Monica Bay are complex but those below the upper 100 ft flow north (Hickey 1988, pers. comm.). Surface currents along the Palos Verdes Shelf may flow northwest or south-southeast, at all depths and throughout the year. However, during the winter they tend to flow northwest and west-southwest below 150 ft; in summer they flow northeast and south-southeast near the surface (SCCWRP 1973).

Water sometimes enters Santa Monica Bay from the south, moving in a slow counterclockwise eddy. However, when the northward current is weakened, a clockwise gyre may develop. During these periods, a southward, longshore flow with speeds of 0.04 kn is induced (SCCWRP 1973, Hendricks 1980, CLA,DPW 1982). Recent studies suggest that the clockwise gyre may dominate on the shelf, except when it reverses for a few days at a time and inshore of the 70-ft isobath due to tidal action. The residence time of surface water (0-300 ft) in the Bay is estimated to be 3 to 4 days (Hickey 1988, pers. comm.).

Littoral Currents

Littoral currents move alongshore and adjacent to the shore, and are caused by breaking waves, as modified by shore topography. The littoral currents may move as much as 8 ft/sec and often transport beach sediments in a turbid layer which is denser than seawater and which may flow into submarine canyons as turbidity currents (Drake and Gorsline 1973). Point Dume and the offshore islands shelter much of Santa Monica Bay from most westerly and northerly storms. However, long period waves from southern storms may generate surf 10 to 15 ft high along the Malibu coast, reworking sediments to water depths of 250 ft (Haner and Gorsline 1978). On the Palos Verdes Shelf, storm waves can resuspend sediments to water depths of 150 ft (SDWG 1988).

Tides

Southern California has a mixed, semidiurnal tide, which is composed of two unequal high tides and two unequal low tides every 24 hr 50 min. In Santa Monica Bay the high and low tides generally differ by 3.7 ft, although spring tides may differ by 5.4 ft (NOS 1986). Tidal currents tend to flow onshore-offshore, but they achieve their greatest velocities alongshore (SCCWRP 1973). Down-canyon tidal flows in Santa Monica Submarine Canyon have been measured at 0.14 ft/sec and up-canyon velocities at 0.10 ft/sec (Hendricks 1980, CLA,DPW 1982). Similar flows probably occur in Dume and Redondo Submarine Canyons.

Upwelling

During prolonged northwesterly winds, nearshore surface water is transported offshore along coasts with a northwest-southeast orientation. In this process, known as upwelling, deep, oxygen-poor and nutrient-rich water comes to the surface to replace the surface water. In the study area upwelling is most likely to occur off the southwest portion of the Palos Verdes Shelf during the winter and spring (CLA,DPW and USEPA 1977).

Characteristics of Seawater

Natural seawater is characterized by a number of physical and chemical attributes, all of which vary seasonally as well as in irregular fashion. Key characteristics are described below, especially as they may be influenced by man's activities.

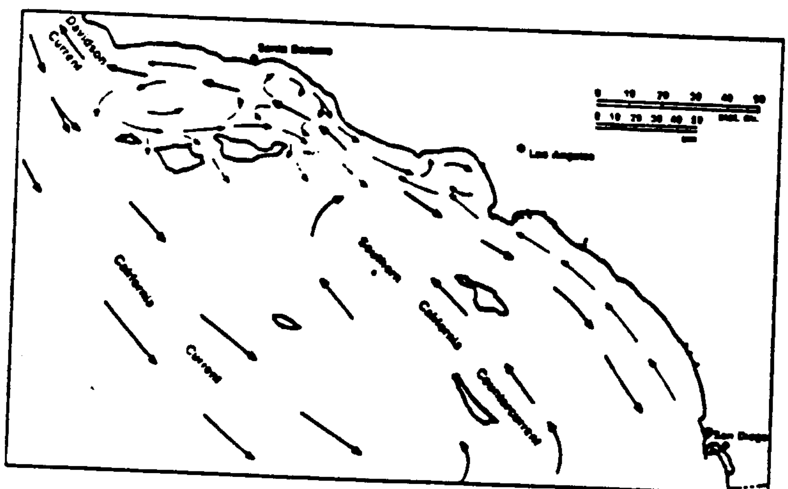

Figure 2-4. General ocean circulation of the Southern California Bight (modified from CLA,DPW and USEPA 1977).

Transparency to Light

As light penetrates the ocean it is reflected, absorbed, or scattered. The depth of light penetration is greatest in transparent waters and least in turbid waters. Water transparency (as measured by a standard Secchi disk) generally ranges from 20 to 50 ft in southern California. However, within a mile of stream deltas it may be less than 20 ft and off rocky areas it is often greater than 40 ft (AHF 1965, CLA,DPW and USEPA 1977). From 1956 to 1986 it ranged from 33 to 66 ft in Santa Monica Bay (Mearns 1987, pers. comm.).

Light penetration is especially important to photosynthesis (the process by which plants utilize carbon dioxide and water to produce, in the presence of light, organic matter and oxygen. Most photosynthesis occurs in the mixed layer, from the surface to water depths of about 33 ft. As light levels decrease photosynthesis decreases. The "compensation depth" refers to the depth at which light levels are so low that no net photosynthesis can occur; this depth marks the bottom of the "photic" zone.

Because inshore waters are generally more turbid, the photic zone may be less than 160 ft deep, whereas offshore it may extend deeper. Sunlight intersects the sea surface at a steeper angle in summer than in winter, this light penetrates more deeply in summer and the photic zone is deeper.

Hydrogen Ion Content (pH)

The pH of seawater over the shelf ranges from 7.5 to 8.6. High values result from photosynthesis which removes CO_2 from the water. Because photosynthesis decreases and net respiration increases with depth, CO_2 increases and hence pH decreases with depth (CLA,DPW and USEPA 1977).

Dissolved Oxygen

Oxygen is required for respiration (and thus life) of both plants and animals. As organic material decomposes, oxygen is used up, creating a biochemical oxygen demand (BOD). Dissolved oxygen (DO) levels are generally high near the surface as a result of input from the atmosphere and from photosynthesis; DO decreases with depth, as distance from the surface increases and photosynthesis ceases. The DO level near the sea surface is generally near saturation (approximately 5.5 ml/l), but saturation varies with temperature and salinity. At water depths of more than 200 ft, DO is usually about 2.8 ml/l, but is only 0.5 ml/l at depths of 1,640 ft along the slope of Santa Monica Bay. DO is virtually absent at the bottom of Santa Monica Basin (Emery 1960; BLM 1975; CLA,DPW and USEPA 1977; CLA,DPW 1982).

Inorganic Nonmetallic Materials/Nutrients

Nitrogen (ammonia, nitrite, nitrate), phosphate, and silicate are dissolved, inorganic materials which are required for photosynthesis and are called nutrients. Nutrients are especially important in the formation of amino acids (protein, nitrogen) and nucleic acids (phosphorous) as well as nonliving shells or tests (silicate).

Nutrient levels are generally low in the mixed layer and high in deeper water. This results from their utilization by phytoplankton in the photic zone and their regeneration by bacteria which are most abundant near the pycnocline. Nitrate is the predominant form of nitrogen found below the photic zone (Williams 1986).

Temperature

Horizontal differences in the temperature of seawater are due primarily to variations in the California Current and Countercurrent. Surface temperatures in the Southern California Bight range from about 52 to 73°F and are warmest (61 to 73°F) from July to December and coolest (52 to 63°F) from January to June (AHF 1965, CLA,DPW 1982; Bratkovich 1988, pers. comm.). Average annual surface water temperatures in Santa Monica Bay ranged from 60 to 65.8°F between 1956 and 1986 (Mearns 1987, pers. comm.).

Below 100 ft seasonal temperature patterns are different (Jackson 1986). At 200 ft temperatures range from 50 to 59°F and are warmest from October to March and coolest from April to September. At 500 ft temperatures are relatively constant at 47 to 50°F (AHF 1965, CLA,DPW and USEPA 1977).

Salinity

The major feature of seawater is the dissolved salts which produce its characteristic saltiness. Salinity is measured in parts per thousand (ppt), which refers to the amount of salt it contains. Most of the salt is common table salt, sodium chloride (NaCl); abundant ions in seawater include sodium (Na+), chloride (Cl-), sulfate (SO_4--), magnesium (Mg++), calcium (Ca++), potassium (K+), and bicarbonate (HCO_3-). Chloride comprises about 55% of the ions, sodium about 30%, and sulfate about 8%. The concentration of most of these ions is fairly constant and they are so abundant that even unusually high levels do not affect the overall salinity and hence are not considered contaminants.

Salinity in the California Current ranges from 33.5 to 34.1 ppt, whereas in the California Undercurrent it ranges from 33.4 to 34.6 ppt (CLA,DPW and USEPA 1977; Jackson 1986). The coastal waters of Santa Monica Bay are normally more saline during the summer due to evaporation of water and less saline in winter as a result of freshwater runoff. Salinity is usually less variable at greater depths.

Density and Stratification

The density of seawater is a function of its temperature and its salinity. Thus, layers of sharply different densities adjacent to one another (a pycnocline) can result from differences in temperature, salinity, or a combination of the two. If separated primarily by temperature, the pycnocline is also a thermocline; if separated primarily by salinity, it is also a halocline. Water above the pycnocline usually has little internal structure; it tends to be homogeneous and is called the mixed layer.

A pycnocline is a natural barrier to the exchange of water between the two layers. Wastewater is usually discharged below the pycnocline in order to prevent movement of the effluent into surface waters; except for oil and grease the plume is unlikely to reach the surface when the sea is stratified (CLA,DPW and USEPA 1977).

In Santa Monica Bay a thermocline often develops (from spring to fall) as a result of warm surface temperatures. In winter and spring there may also be a low-salinity lens at the surface which results from stream runoff. In summer a pycnocline occurs over the shelf at depths of about 35 ft When the surface temperature drops in the fall the density of the upper layer approaches that of the lower layer, the pycnocline breaks down. The mixed layer then extends into depths of 100 ft between December and March (Jackson 1986).

Event was in 1982-1983, with the previous large El Niño in 1957-1959. Events of lesser magnitude occurred in 1986-1987 and in 1991-1992 (Radovich 1961, Graham and White 1988, Kerr 1992).

During an El Niño marine organisms with more southern distributions occur in the Bight whereas cold water species become less abundant: pelagic red crabs were abundant offshore southern California in 1982 and 1983. During an El Niño the sport and commercial fisheries (and success) for pelagic species may increase dramatically.

In freshwater systems phytoplankton productivity is generally limited by the availability of phosphate. In the ocean, however, phytoplankton activity tends to be limited by the availability of nitrogen. Nutrients are replenished in the photic zone during upwelling or when the pycnocline breaks down in the winter; however, sewage and surface runoff may also add nitrogen and phosphate to local areas.

Trace Metals

Virtually all trace metals occur naturally in seawater. Among the more abundant are copper (Cu), manganese (Mn), zinc (Zn), cadmium (Cd), cobalt (Co), silver (Ag), nickel (Ni), and iron (Fe) (Williams 1986). Iron, manganese, and cobalt are abundant in the natural surface runoff from the Santa Monica Mountains (SCCWRP 1973).

Manganese and cobalt are typically more concentrated in surface waters than at depth, whereas the concentrations of cadmium, zinc, nickel, copper, and silver increase with depth. These patterns reflect both biological and chemical processes. For instance, iron is used by fish and other organisms to secure oxygen from the water and hence its concentration may be related to the abundance of organisms requiring it. Most trace metals are required for the growth of some organisms.

Organic Matter

Both particulate and dissolved organic compounds are found in seawater. The particulate phases are described as total particulate organic carbon, particulate organic nitrogen, and particulate organic phosphorus. Particulate organic materials are most abundant in the photic zone, less so with depth. Particulates adsorb trace metals and other contaminants; hence they are important in transporting these substances from the water column to the bottom (Williams 1986).

Dissolved organics include material from decaying organisms, their excretions and secretions, as well as synthetic materials produced by man. The major components are total dissolved organic carbon, dissolved organic nitrogen, and dissolved organic phosphorus. The concentrations of these components are high in the mixed layer and low at greater depths. For the most part materials are produced by phytoplankton in the photic zone and are broken down by bacteria at greater depths (Williams 1986).

El Niño Events

Every so often, with a quasiperiodicity of 3 to 5 years (Graham and White 1988), the oceanic environment of southern California changes dramatically as an El Niño Southern Oscillation (ENSO) event takes place. During an El Niño, the normal water mass off the California coast is replaced with water which is warmer, more saline, and lower in nutrients than usual. These conditions extend through the water column and may persist for months or years.

El Niños result from large-scale changes in the climate and oceanography of the Pacific Ocean as a whole. Normally tradewinds, which blow to the west north of the Equator, force water to pile up in the western Pacific. When the tradewinds weaken, seawater flows downhill (as a long-period wave) toward the eastern Pacific. When this wave encounters the Americas, it moves both north and south along the coast. Because currents in the North Pacific also decrease in strength, the south-flowing California Current is weakened and the warm-water mass from equatorial latitudes penetrates into the Southern California Bight. The most recent large El Niño

CHAPTER 3
THE BIOLOGICAL SETTING

TERRESTRIAL ENVIRONMENTS

Terrestrial organisms in the study area are largely warm-temperate species of the California Wildlife Region (Brown and Lawrence 1965). The only life zone in the watershed is the Upper Sonoran life zone (Grinnell 1935); although the altitude lies within the range normally classified as Lower Sonoran, the temperatures are cooler and humidity is higher along the coast than in areas of similar altitude elsewhere in southern California.

Habitats and Plant Communities

The Santa Monica Bay watershed and its surrounding area includes a variety of terrestrial habitats and plant communities (often regarded as habitats because of the nature of the physical structure they provide to the habitat). Many of these would have occurred prior to European contact but several have developed since that time, particularly with urbanization. The Santa Monica Mountains alone have more than 860 species of flowering plants (Ikeda *et al.* 1991); the more urbanized areas of the watershed have many additional species, most of which are introduced.

Thirteen terrestrial habitats are found in the Santa Monica watershed (Figure 3-1) (Mayer and Laudenslayer 1988). Nine of these occur throughout the watershed: Eucalyptus, Valley Foothill Riparian, Coastal Scrub, Annual Grassland, Fresh Emergent Wetland, Riverine, Lacustrine, Orchard-Vineyard, and Urban. The four remaining habitats (Valley Oak Woodland, Coastal Oak Woodland, Mixed Chaparral, and Chamise-Redshank Chaparral) are specific to the Santa Monica Mountains.

Three of the ubiquitous habitats (Fresh Emergent Wetlands, Riverine, and Lacustrine) are wetlands habitats, two (Eucalyptus and Annual Grassland) consist primarily of introduced species, two (Orchard-Vineyard and Urban) result from human development, and two (Valley Foothill Riparian and Coastal Scrub) are entirely native to the area (Mayer and Laudenslayer 1988).

Valley Oak Woodland

The Valley Oak Woodland occurs exclusively in the western part of the Santa Monica Mountain portion of the study area (Mayer and Laudenslayer 1988), particularly in the Upper Malibu Creek Drainage. This habitat is dominated by valley oak, a deciduous oak 50-115 ft tall. The trees may be sparsely distributed as in a savannah or more densely distributed with partially closed canopies. It is best developed on deep, well-drained alluvial soils in valley bottoms. The Valley Oak Woodland habitat usually merges with the Annual Grassland habitat or near streams with the Valley-Foothill Riparian vegetation.

There is generally little recruitment of young valley oaks to this habitat to replace the older oaks which are being destroyed by urban and agricultural development. Most surviving stands in the state are from 100 to 300 years old, some reaching 400 years old. Valley Oak Woodland is important to mammals such as the gray fox, western gray squirrel, and mule deer, and for birds such as the redtail hawk, European starling, and California quail (Mayer and Laudenslayer 1988). At Malibu Creek State Park grasses have been planted to associate with Valley Oak Woodland in an effort to expand the potential habitat for valley oak (Danielsen and Halvorson 1990).

Coastal Oak Woodland

The Coastal Oak Woodland occurs in the Santa Monica Mountains, but not immediately near the coast (Mayer and Laudenslayer 1988). This habitat is dominated by coast oak and California walnut; the oak is evergreen and the walnut is deciduous. In moist sites, the trees are dense and form a closed canopy 15-70 ft high; in dry areas they are more widely spaced, forming a savannah. The understory ranges from lush, shade-tolerant shrubs and ferns beneath closed canopies to annual grassland in dry areas; shrubs from neighboring chaparral and coastal scrub communities may contribute to the understory (Mayer and Laudenslayer 1988).

This habitat can be further divided into a number of subhabitats based on understory plants (Allen 1990). The Coastal Oak Woodland community is best developed on moderately to well-drained soils which are moderately deep and have low to medium fertility. Coastal oak woodlands consist of slow-growing, long-lived trees that require 60-80 years to regenerate large mature trees; most stands consist of medium to large trees with a few saplings. This community has experienced an increased frequency of fires in recent years but coast oak generally survives fires. Important vertebrate species in this community include California quail, western gray squirrel, and mule deer (Mayer and Laudenslayer 1988).

Eucalyptus

The Eucalyptus habitat occurs throughout the watershed and wasteshed in disturbed, agricultural, or urban sites (Mayer and Laudenslayer 1988). This habitat is usually dominated by blue gum, to a lesser extent by red gum. Eucalyptus, or gum trees, were introduced into California from Australia in 1856. The structure of the habitat ranges from thickets of a single species with no understory to scattered trees with a well-developed shrubby understory. They are planted in rows to provide wind breaks or in groves for hardwood harvesting. Gum trees typically stand 87 to 133 ft high, but some reach a height of 264 ft. Understory plants range from annual grassland species in groves to coastal scrub or chaparral species; near streams, riparian plants may occur in the understory. They are also planted near orchards and vineyards. The allelopathic nature of gum tree litter prevents many other plants from developing in the understory. Gum trees regenerate rapidly following fires, reproducing vegetatively as well as by seeds. Most gum trees achieve 70-90% of their height in their first 15 years. Crows, ravens, and barn owls are common in the Eucalyptus habitat; the bark litter provides habitat for southern alligator lizards, gopher snakes, and woodrats. The habitat does not occur above 2,100 ft altitude (Mayer and Laudenslayer 1988).

Valley Foothill Riparian

The Valley Foothill Riparian habitat occurs throughout the watershed and wasteshed, in valleys, coastal plains, and foothills; next to low velocity streams on gravelly or rocky soils; and in association with annual grassland or oak woodland (Mayer and Laudenslayer 1988). This habitat is dominated by Fremont cottonwood, California sycamore, and valley oak; California sycamore is dominant in coastal areas of the Santa Monica Mountains. White alder is the dominant subcanopy tree but many shrubs (e.g., wild grapes, willows, poison oak) and herbaceous plants occur in the understory. The dominant species are deciduous. The canopy is about 100 ft high and coverage is 20-80%. Cottonwood trees become large mature trees at 20-25 years. Willows generally dominate in early stages of succession and, where there are good flows of silt, may persist indefinitely. The Valley Foothill Riparian habitat is important to many species of mammals, birds, reptiles, and amphibians (Mayer and Laudenslayer 1988).

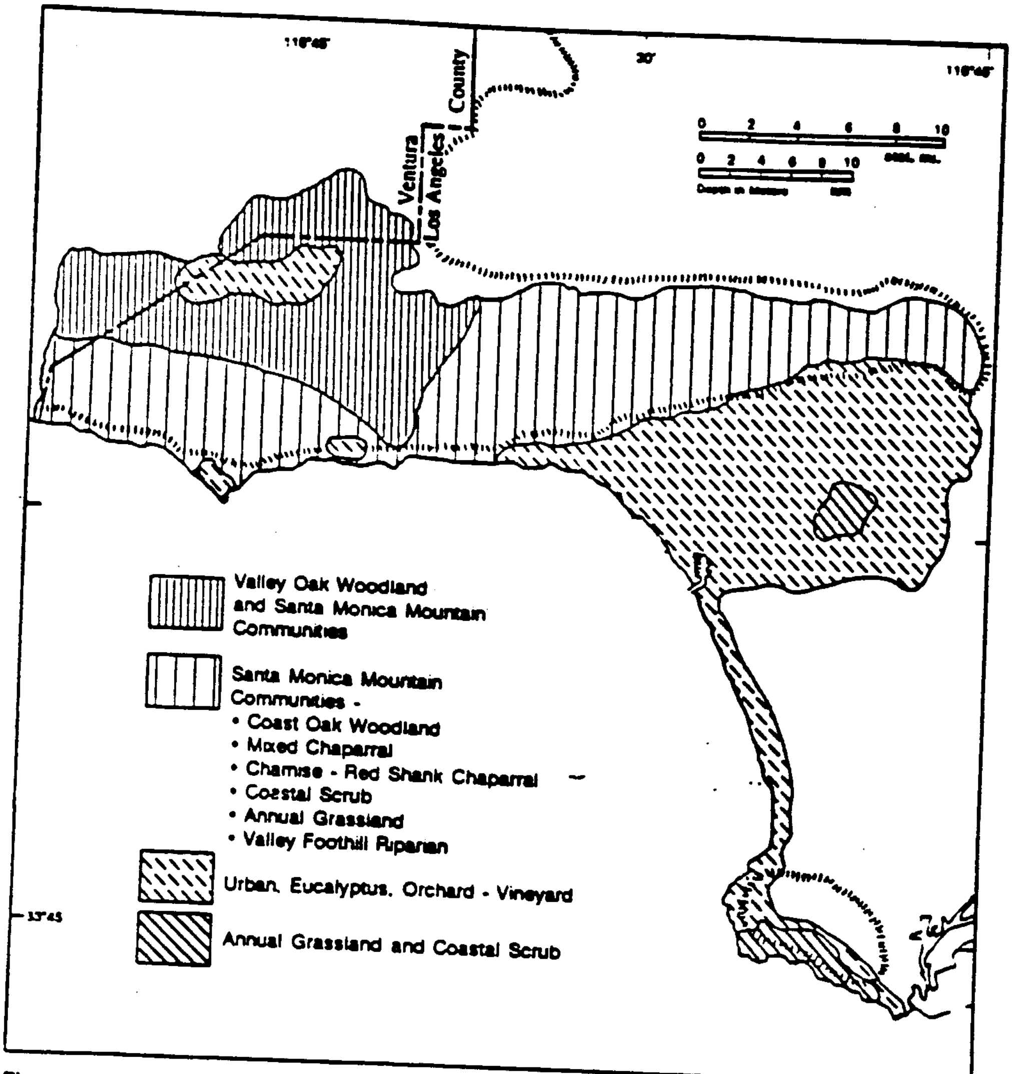

Figure 3-1. Major habitat areas of the Santa Monica Bay watershed.

VOL 12

15314

Annual Grassland

The Annual Grassland habitat occurs throughout the watershed and wasteshed. The habitat is found on flat plains to gently rolling hills. It consists of open grasslands dominated by annual grass and forb species (Mayer and Laudenslayer 1988). Most of the dominant species are introduced grasses (e.g., wild oats and red brome). Redstem filaree is a common forb in southern California annual grasslands and California poppy, the State Flower, is also found in this habitat. It often occurs as an understory in Valley Oak Woodlands and is found next to Coast Oak Woodland, Coastal Scrub, Valley Foothill Riparian, Fresh Emergent Wetlands, Orchard-Vineyard, and Eucalyptus habitats. Annual grasslands are generally found at lower elevations than Chamise-Redshank and Mixed Chaparral habitats. Seeds germinate following fall rains, grow slowly in winter but rapidly in spring as temperatures rise. During the summer the habitat can have a large amount of standing dead material if there is little grazing. The Annual Grassland habitat has replaced the pristine native grassland habitat in the area which was dominated by perennial bunchgrasses. Fall rains followed by extended dry periods encourage growth of deep-rooted forbs and grazing favors low-growing forbs. Important mammals in this habitat include black-tailed jackrabbit, California ground squirrel, and Botta's pocket gopher. Western meadowlark, turkey vulture, and American kestrel are common birds. Western fence lizard and western rattlesnake are important reptiles in this habitat (Mayer and Laudenslayer 1988).

Fresh Emergent Wetlands

The Fresh Emergent Wetlands habitat is found in localized areas throughout the watershed and wasteshed. It is dominated by erect, rooted water plants such as the perennial sedges, rushes, and cattails (Mayer and Laudenslayer 1988). The habitat is found on periodically flooded basins; thus the roots must do well in anaerobic silts and clays. This habitat naturally accumulates silt and over centuries is replaced by an upland community. It usually occurs in association with Riverine or Lacustrine habitats; its limit lies with the deepwater limit of emergent plants (usually at about a depth of 7 ft). This habitat is highly productive and provides food, cover, and water for many species of mammals, birds, reptiles, and amphibians, with some species utilizing the habitat for their entire life cycle. The endangered peregrine falcon utilize the habitat for feeding and roosting (Mayer and Laudenslayer 1988).

Riverine

The Riverine habitat consists of streams and rivers with intermittent or continually running water. This habitat occurs in a natural state primarily in the Santa Monica Mountains in the watershed; in the coastal plain the stream channels have been fixed as open concrete drainage channels with urban runoff rather than springwater constituting the stream flow. Most of the natural streams in the watershed are intermittent, with greatest flows in the winter. There are 28 stream drainage basins in the watershed (SMBRP 1992). Malibu Creek is the largest stream in the watershed and best represents this habitat. The habitat is usually found in association with Riparian, Lacustrine, and Fresh Emergent habitats. It usually arises at a spring in this area and runs down relatively steep canyons until the slope levels out, at which point the water becomes sluggish and may form pools (Mayer and Laudenslayer 1988). During this course, the floor of the stream changes from rocky to muddy; water temperature and turbidity increase and dissolved oxygen decreases down the stream course. In faster or upper-level streams, water moss and filamentous algae are attached to rocks, and stream insect larvae live on the underside of gravel in riffles or pools. In slower or lower-level streams mollusks and crustaceans replace the insects and emergent vegetation grows along the edge of the stream. Many insectivorous birds feed

VOL 12

1

5 3 / 5

Mixed Chaparral

The Mixed Chaparral habitat is only found in the Santa Monica Mountain portion of the watershed. It is dominated by shrubs with stiff evergreen leaves (Mayer and Laudenslayer 1988). It generally occurs above the coastal scrub habitat and occurs predominantly on moist coastal or north- and east-facing slopes with Chamise-Redshank Chaparral on drier, south- and west-facing slopes. It usually is found on steep slopes with thin, well-drained rocky, sandy, or gravelly soils; soils in this habitat are deeper than in the Chamise-Redshank Chaparral. Shrubs range in height from 3 to 13 ft, occasionally to 19 ft, and form an impenetrable thicket of 80% cover. Dominant species include scrub oak, ceanothus (wild lilacs), and manzanita, with many other shrubs (e.g., laurel sumac, sugarbush, birch-leaf mountain mahogany, and toyon) also included in the community. Leaf litter may accumulate beneath the shrubs for years until consumed during a fire. The community is fire-adapted with large rootbases. Following a fire, annuals and perennials dominate for 1-3 yr until seedlings and root-crown shoots appear; the shrub canopies do not overlap until 10-30 yr after a fire. Wildlife species found in mixed chaparral are also found in chamise-redshank chaparral and coastal scrub (Mayer and Laudenslayer 1988).

Chamise-Redshank Chaparral

Chamise-Redshank Chaparral is found in isolated stands in the Santa Monica Mountains (Mayer and Laudenslayer 1988). Most stands in the study area are almost exclusively dominated by chamise with some redshank occurring at higher elevations (Raven and Thompson 1966). It occurs on steep slopes with thin, coarse soil. These stands are 3-7 ft in height but can reach 10 ft (Mayer and Laudenslayer 1988). There is no overstory or understory and canopy cover can reach 80%. It occurs primarily on dry, south- and west-facing slopes above the coastal scrub habitat. Near the coast other shrubs (e.g., laurel sumac, toyon, and ceanothus) are also found in this community along with white sage, black sage, and California buckwheat. As with mixed chaparral, chamise-redshank chaparral is fire-adapted. Annuals and perennials dominate for 1-3 yr following a fire until chamise and associated plants sprout from seedlings and roots. Chamise canopies do not overlap until 3-15 yr after a fire. Wildlife found in this habitat are also found in mixed chaparral and coastal scrub (Mayer and Laudenslayer 1988).

Coastal Scrub

Coastal Scrub Habitat occurs on well-drained clay, gravelly, and rocky soils and was the dominant habitat of the Los Angeles Coastal Plain prior to urban development. At present it is found on undeveloped slopes of the Santa Monica Mountains adjacent to the ocean, in drier areas at higher levels, and in the Palos Verdes Hills (Jaeger and Smith 1966). It lies within 20 mi of the ocean between the coastal dune habitat and the mixed chaparral, chamise-redshank chaparral, and coastal oak woodland habitats of slightly higher elevations. It is typical of steep, dry, south-facing slopes with sandy to shale soils but also occurs on moderate slopes and stabilized dunes. This community consists of low to moderate-sized shrubs (to a height of 7 ft) with a canopy cover of up to 100%. The dominant species in the community varies with moisture; California sagebrush, California buckwheat, purple sage, and chaparral yucca generally dominate in the Santa Monica Bay watershed. The community is fire-adapted and takes about 10 yr to recover following a fire. Unburned stands can survive intact for up to 60 yr. The community can invade disturbed areas (Mayer and Laudenslayer 1988). Air pollution has reduced the cover by native species in some areas of southern California (Westman 1979). The California ground squirrel is probably the most abundant, obvious mammal (Reiter 1984). The California gnatcatcher, a species of concern, is found exclusively in this habitat and endangered peregrine falcons include this as an important habitat (Mayer and Laudenslayer 1988).

VOL 12 1 5 3 / 6

Conservancy was created at about the same time to acquire lands until the 70,000 acres necessary to complete the SMNRA could be completed; this acquisition is still in progress.

Endangered Species in the Watershed

Four species of flowering plants in the Santa Monica watershed are currently listed as rare, threatened, or endangered (Ikeda *et al.* 1991). The Santa Monica Mountains dudleya was listed as State Endangered in 1976. It is endemic to the Santa Monica Mountains where it has been found at less than 10 sites. It occurs on steep rocky areas along Malibu Creek. Lyon's pentachaeta has been listed by the California Native Plant Society. It occurs at less than 12 sites in the Santa Monica Mountains on the edge between annual grassland and chaparral communities. Conejo buckwheat was listed as State Rare in 1976. It occurs on dry rocky hillsides in coastal scrub and chaparral. Santa Susana tarweed was listed as State Rare in 1978. It grow on rocky outcrops in chaparral in the Santa Monica Mountains (Ikeda *et al.* 1991).

Federally endangered insect species in the study area include the Palos Verdes blue and El Segundo blue butterflies (CDFG 1992). Endangered birds in the watershed include American peregrine falcon (State and Federally Endangered), California gnatcatcher (Federally Proposed Endangered), and Belding's savannah sparrow (State Endangered).

Natural Variability

Fires

Many of the habitats in the Santa Monica Bay watershed are adapted to frequent fires. Plants in the chaparral and coastal scrub communities, in particular, have specialized methods by which to deal with what would ordinarily be a catastrophic event. Many perennial species, such as chamise, can resprout after the plant crown has been burned, and several species actually require that their seeds be exposed to the high temperatures of fires to germinate (Head 1989). Annual species have dispersal mechanisms which allow them to be transported long distances beyond the burned area (O'Leary 1989). Fire provides a means by which old growth and senescent plants are removed, making room for new individuals or new growth. The resulting ash, when carried by winter rains, provides nutrients to streams and coastal plains and wetlands (Faber *et al.* 1989). Fire also promotes greater diversity in the community, both among the plants and the animals which use them for food and shelter, by increasing the number of plant species available and providing more levels of habitat, such as open ground, opening-chaparral interfaces, and different age-class individuals. Fire also helps to maintain native plant communities by suppressing nonadapted, invasive, introduced plants (Wells 1990).

Drought

The climate of southern California is classified as Mediterranean, with mild, rainy winters and hot, dry summers. Near the coast, rainfall varies from about 10 to 20 in. per year, and temperatures range from highs of 68°F to 90°F in summer to lows of 37°F to 48°F, with infrequent frosts. Further inland, average rainfall is a little greater, up to 25 in. per year, and temperatures vary more, with summer highs up to 94°F (or over 100°F during a Santa Ana wind) and winters down to 29°F (Munz 1973). However, the distribution of rainfall, with most of it occurring in the cool, nongrowing season, requires that plants accomplish their warm-season growth during a period of little rainfall. Precipitation is also extremely variable from year to year, and periods of several consecutive years of below-normal rainfall result in extreme fire danger in the chaparral plant communities. Even within a normal-rainfall year, uneven distribution of the precipitation, with

VOL 12

1537

above this habitat and some water-associated birds are also found there (Mayer and Laudenslayer 1988).

Lacustrine

The Lacustrine habitat is found at several sites within the watershed and wasteshed. It consists of inland depressions or dammed streams that contain standing water and is often associated with riverine and fresh emergent wetlands habitats. The largest lakes in the watershed are Lake Sherwood and Malibu Lake. Light penetration is dependent on turbidity and oxygen levels may decrease with increasing depth. Dominant phytoplankton organisms consist of diatoms, desmids, and filamentous algae; other plants include duckweed and submerged algae and pondweeds. Rotifers, copepods, and cladocerans are important members of the zooplankton of lakes. Protozoa, hydras, snails, aquatic insects, and insect larvae also occur in lakes and ponds. Most lakes and ponds support fish populations (Mayer and Laudenslayer 1988).

Orchard-Vineyard

The Orchard-Vineyard habitat is sometimes found in rural areas of the watershed in the Santa Monica Mountains. It is an artificial, agricultural habitat that typically consists of a single tree (or in the case of grapes) vine species planted in rows with an open understory of low-growing grasses and herbaceous plants (Mayer and Laudenslayer 1988). In southern California dominant fruit and nut crops grown in orchards and vineyards include almonds, apples, apricots, avocados, dates, grapes, grapefruit, lemons, oranges, olives, and walnuts (Miller and Hyslop 1983). The habitat typically occurs in deep fertile soils and is sometimes irrigated. Individual orchards or vineyards may persist for about 40 yr, with replacement of orchard type resulting from a decline in market value or productivity. Deer, rabbit, and squirrels feed on orchard trees or their products (Mayer and Laudenslayer 1988).

Urban

The Urban habitat is found over much of the Santa Monica watershed south of the Santa Monica Mountains and over most of the wasteshed (Figure 3-1) (SMBRP 1992). It is also developed in the Thousand Oaks and Malibu areas and as residential areas near Point Dume and Topanga Canyon. Most of the habitat consists of single or multiple family residential areas but large areas of Santa Monica, Los Angeles, the Los Angeles Airport area, and El Segundo are put to commercial and industrial us (SMBRP 1992). Vegetation types include tree groves, street strips, shade trees and lawns, lawns, shrub cover, and demolition sites. Vegetation consists of a mixture of native and exotic species. Commercial and industrial areas often have little vegetation but nevertheless provide habitat for some species. Subhabitat types include downtown, urban residential, and suburbs. Rock dove, house sparrow, and European starling dominate the poorly vegetated downtown areas. Scrub jay, mockingbird, and house finch are the major birds in urban residential areas. Suburban areas approximate the natural environment and provide habitat to species from adjacent habitats. Air temperatures are generally warmer in urban areas and wind velocities lower, except where high-rise buildings are found (Mayer and Laudenslayer 1988).

Unique Areas and Habitats

Unique areas in the Santa Monica Mountains include the Santa Monica Mountains National Recreation Area (SMNRA) developed by Congress in 1978 to protect part of the mountains from further development (Ikeda *et al.* 1991). The Santa Monica Mountains

Wetlands are among the most productive ecosystems in the world. Productivity is related to several factors, including the efficient functioning of the grazing and detrital food chains. Additionally, periodic rise and fall of the tides and flooding in salt marshes bring nutrients from outside the system and keep the system oxygenated. Wetlands are now being recognized for their educational, recreational, and aesthetic values. Southern California wetlands are extensively used by bird watchers and other outdoor recreationists, and conservationist groups are taking increasingly important roles in their preservation and restoration.

Distribution

Ten brackish wetlands of varying size and state of naturalness are located along the edge of Santa Monica Bay: Trancas Lagoon, Zuma Beach Lagoon, Malibu Lagoon, Lower Topanga Canyon, Venice Canals, Ballona Lagoon, Oxford Flood Control Basin, Ballona Wetlands, Del Rey Lagoon, and El Segundo Dunes Wetlands (Figure 3-2). They range from small, seasonally-inundated river mouths, such as at Zuma Beach west of Point Dume, to the large Ballona Wetlands Complex at Marina Del Rey. A number of freshwater marshes occur within the watershed, such as Madrona Marsh (Torrance) and Upper Medea Creek (in the Malibu Creek drainage).

Ballona Wetlands Complex

Historically, the Los Angeles River occasionally emptied into Santa Monica Bay at Ballona Creek instead of into San Pedro Bay at Long Beach, as the river's course changed during unusually heavy storms that occurred between 1815 and 1825 and again in 1862 and 1884 (Terry *et al.* 1956). During that period, the drainage area of Ballona Creek (Los Angeles River) was considerably larger than at present, including the San Fernando Valley and part of the San Gabriel Mountains. The Los Angeles River is now channelized and future discharges through Ballona Creek are unlikely. The Venice Canals, Ballona Lagoon, Oxford Flood Control Basin, Ballona Wetlands, and Del Rey Lagoon are part of the historic Ballona Wetlands Complex.

The area between Ballona Creek and present-day Beverly Hills was often a vast swamp (Johnston 1962, Reiter 1984). During torrential rains in the winter of 1861-1862, the entire valley area from Los Angeles to the ocean, both towards San Pedro and toward Ballona, was a great lake (Kuhn and Shepard 1981). During periods when the Los Angeles River discharged into San Pedro Bay instead of into Santa Monica Bay, the areal extent of the Ballona wetlands was probably reduced, with greater marine influence.

In 1868 the Ballona Wetlands comprised 2,100 acres (Clark 1979). Development of Marina del Rey, the Venice canal system, and residential and commercial property, and the channelization of Ballona Creek reduced this area to less than 160 acres of habitat that can legitimately be called wetlands. Remnants of the Ballona Wetlands Complex include Ballona Lagoon, on the north side of the Marina channel; Del Rey Lagoon, to the south of Ballona Creek; Ballona Wetlands, the major marsh area, located north and south of Ballona Creek; Oxford Flood Control Channel on the north side of Marina del Rey; and the Venice Canals. The present remnant of the Ballona Wetlands Complex include mudflat, shallow subtidal, saltmarsh, brackish marsh, and freshwater marsh habitat (Schreiber 1981). Although estimates vary as to the total amount of extant habitat, about 10 to 15% of the original area (270 acres) can still be considered either degraded or nondegraded wetlands (Figure 3-3).

VOL 12

1 5 3 1 9

most occurring during only one or two storms rather than spread more evenly over the season, will affect how much of the available moisture is able to soak into the soil. Native vegetation is most affected by the worst conditions than by the average (Clark 1992). Prolonged drought may predispose plants to diseases and disorders caused by opportunistic parasites (Brooks 1992).

Native plants deal with drought conditions (annual or cyclical) in various ways. Many species have hard or waxy-coated leaves to prevent evaporation or white, shiny, or fuzz-covered leaves to reflect light. Some species (drought-deciduous) drop their leaves during the hottest period of the year, or turn their leaves to avoid the direct rays of the sun (Head 1989). Deep root systems and water-storage capabilities are also present in many species. Physiological mechanisms are also employed, such as resistance of xylem embolism (Davis *et al.* 1992).

Wet Periods

Periods of greater-than-normal precipitation may adversely affect plants which are adapted to low-moisture conditions. Soil oxygen may be lowered, affecting the root systems or promoting the growth of infecting disease organisms. The absence of fires which are required for germination of seeds of some species may result in a shift of dominance by some species within the plant community.

WETLANDS HABITATS

Background

The California Coastal Act of 1976 defines wetlands as "land within the coastal zone which may be covered periodically or permanently with shallow water and includes saltwater marshes, freshwater marshes, open or closed brackish water marshes, swamps, mudflats, and fens."

Wetlands generally occur where the slope of the land is sufficiently flat to retain water for some length of time. Freshwater wetlands usually occur along streams or in depressions which may fill with rainwater (vernal pool). Marine wetlands develop where streams enter the ocean across low, flat coasts; they are characterized by freshwater or saltwater marshes and channels. If stream flow is sufficient some salt marshes alternate between fresh and saltwater. Thus, the dominant natural factors which affect wetlands habitats bordering the sea are variable salinities and the tidal cycle which alternately exposes and covers it with water. Marshlands are depositional in nature; because wave forces are minor, fine silts and clays accumulate. Thus, regardless of man's impact they are slowly filling in with fine sediments by natural forces.

Importance

Historically, the ecological importance of wetlands was overlooked and wetlands were only considered useful for reclamation for more "constructive" purposes. However, this outlook has changed dramatically because the vital ecological roles that wetlands served have been documented. Wetlands mitigate flooding and recharge groundwater; provide feeding and breeding habitat for fish, waterfowl and other wildlife; filter pollutants from sewage and agricultural runoff; and stabilize the biosphere by using carbon dioxide and producing oxygen. Energy flow patterns involve the direct consumption of green plants, such as eelgrass, by grazers and the breakdown and consumption of detritus, or organic debris, by bacteria and other organisms. The patterns are complex and often intertwine.

the dominant saltmarsh plant; topographically it occurs lower than in other southern California saltmarshes with greater tidal influence. The saltmarsh is lacking in a low and middle marsh flora and has reduced the breeding, nursery, and foraging areas for fishes, birds, and reptiles.

There is a small pickleweed marsh at Malibu Lagoon, but this wetlands differs from the Ballona Wetlands Complex in that riparian woodland, with cottonwood and alder trees, and chaparral are found upstream (Dock and Schreiber 1981). Trancas Lagoon, Zuma Beach, and lower Topanga Canyon are less saline, and support a limited number of plant species. Their contributing creeks support riparian woodland species. El Segundo Dunes supports native dune species, but the native wetlands plants have been mostly replaced by invasive introduced species.

The endangered (state- and federally-listed) salt-marsh bird's beak, a low-growing annual, historically occurred in wetlands along the northern part of Santa Monica Bay. In other coastal wetlands of southern California and Baja California, it occurs at the landward edge of the salt marsh, where it is frequently disturbed. Introduced species often threaten to invade its habitat but no displacements have been documented (Zedler 1991).

Invertebrates

The shallow subtidal, marsh channel, and mudflat communities integrate the flow of energy through the wetlands. The marine invertebrates (primarily nematodes, annelids, crustaceans, and mollusks) in these environments recycle organics in the muds and are primary food sources for resident and transient fishes and shorebirds (Peterson 1975, Quammen 1980). Thus, the water and sediment quality and abundance of benthic invertebrates are likely to influence the distribution of higher trophic level organisms in the area.

The marine benthic invertebrate communities of the mudflats and tidal channels of the wetlands of Santa Monica Bay resemble those found in the sandy intertidal, but nematodes may be more abundant (Soule and Oguri 1985). Polychaetes, molluscs, and crustaceans dominate the invertebrate fauna of the Ballona Lagoon, however, oligochaetes are abundant in some places. Although the Ballona Wetlands are not well described, they are comparable to those of nearby Marina del Rey (Soule and Oguri 1987), Ballona Lagoon (Bakus 1975, Ford and Collier 1976), Playa Vista (Reish 1980), and other modified, shallow subtidal or mudflat embayments in southern California such as Sunset Bay, Anaheim Bay, and Upper Newport Bay. In these environments, combinations of physical and chemical stresses limit biological diversity, and community structure is dominated by hardy forms with life histories that are tolerant of the stressful conditions, whether natural or man-made (Kauwling and Reish 1975, McCall 1977, MBC and SCCWRP 1980, MBC and Marsh 1985, MBC 1986b). Several of the abundant species are indicators of organic enrichment and low dissolved oxygen. Ballona Lagoon may support the northern-most population of the fiddler crab on the west coast (Dorsey 1988, pers. comm.).

In the mid-1970s invertebrate assemblages of Ballona Lagoon were diverse and similar in species composition to those of the larger and more natural Tijuana Estuary, suggesting that the flora and fauna represented a reasonably natural and healthy assemblage of estuarine organisms. These conditions were attributed to adequate tidal exchange and flushing, despite the Lagoon's long and narrow configuration and restricted entrance (Ford and Collier 1976). In 1980-1982 the marine molluscan fauna of Ballona Lagoon was comparable in diversity and abundance to Mugu Lagoon and Mission Bay; the same species were present in all three saltmarshes, in approximately the same numbers (Ramirez 1981).

VOL 12

15323

Malibu Lagoon

Malibu Lagoon is located in the City of Malibu, west of the Malibu Pier and at the mouth of Malibu Creek. The full extent of the historical Malibu Lagoon-marsh system is unknown (Kraft 1978), but what remains probably represents only a small portion of the original marsh (CDPR 1978). In 1978, prior to restoration efforts, the natural resources consisted of 5 acres of open water, 10 acres of coastal saltmarsh, mudflats (area unknown), and 4 acres of riparian habitat. Most of the habitat reduction of the Malibu wetlands has resulted from the reclamation of habitat upcoast of Malibu Creek for mosquito control and housing developments such as Malibu colony (Kraft 1978).

Malibu Lagoon is a brackish water marsh, receiving most of its drainage from the Malibu Creek watershed with additional input from the Tapia Water Reclamation Facility (TWRF), located five miles upstream. The natural channel of Malibu Creek enters the ocean on the downcoast (southeast) side of Malibu Point and is normally open only during the winter rainy season. The sand bar which develops across the mouth is purposely breached by the Los Angeles County Department of Parks and Recreation for flood control purposes (CDPR 1978). As a result of the varying salinities, the species diversity is low compared to other coastal lagoons.

Water quality is a main concern in Malibu Lagoon. High nutrient loading makes the Lagoon susceptible to eutrophication, and coliform levels are frequently high due to various unidentified point and nonpoint sources of pollution, such as horse stables and septic tanks. The approved expansion of TWRF, which will increase the volume of freshwater input, may escalate the existing problems with the Lagoon entrance and water quality.

Biological Resources of Wetlands

Wetlands support a wide variety of plants and animals, and are populated by marine, estuarine, or freshwater organisms, depending upon the salinity of the water. Upstream wetlands are populated entirely by freshwater and terrestrial organisms. As a result of fine sediments and high organic content, wetlands support abundant bacteria (Pollock 1971). For the same reasons, oxygen concentrations in the sediment decrease rapidly with depth and reach zero within a few inches of the surface. Anaerobic bacteria in these zones produce hydrogen sulfide. Most of the Santa Monica Bay wetlands exhibit decreased biological diversity and productivity because of their degraded condition.

Plants

The present Ballona Wetlands Complex supports marine algae as well as marine and terrestrial flowering plants. Microalgae are abundant in the water column and on the sediments; the subtidal substrate (only in Basin D in Marina del Rey) supports eelgrass (Stephens *et al.* 1991) and sea lettuce occurs on mudflats. Immediately above the mudflats the saltmarsh plant assemblage consists of five species, dominated by one or more species of pickleweed. Upstream, the marsh grades into freshwater plant communities which include willows and freshwater marsh plants (Gustafson 1981). The higher areas of the wetlands and the adjacent sandy coastal strand and disturbed land contain 23 terrestrial plant species (Bakus 1975, Ford and Collier 1976).

Many marsh plant species which typify the pristine saltmarsh environments of southern California are absent from the Ballona Wetlands, possibly because of restricted water flow between the marsh and Ballona Creek proper (Gustafson 1981). Related factors (stagnation, salinity, and temperature fluctuations) have kept species density in the marsh low. Pickleweed is which occurred early in the century from Santa Barbara to San Diego, may also have contributed to their limited population size (Bent 1926). Since the clapper rail is a poor flyer, its natural immigration into Ballona is unlikely.

The same considerations probably also apply to the black rail, which occupies similar habitats (Grinnell *et al.* 1918). Early in the century the black-necked stilt bred at Playa del Rey (Willet 1933) and may have attempted to breed in the Ballona Wetlands during the summer of 1980 although no nests were found.

Mammals. Seventeen species of mammals are known to live in the wetlands complex and at least 21 more have occurred there in the past or forage in the area. Carnivores (including the introduced red fox), rodents, and rabbits are the most diverse groups (Friesen *et al.* 1981).

Endangered Species

Salt Marsh Bird's Beak. The salt marsh bird's beak was placed on the California and Federal Endangered Species Lists in 1978. It has suffered major population declines at all of the California coastal wetlands, and no longer occurs at any of the wetlands along Santa Monica Bay. The decline in numbers is due to loss of habitat (CNPS 1988).

Belding's Savannah Sparrow. The Belding's savannah sparrow depends on the upper saltmarsh habitat and is particularly abundant in areas dominated by pickleweed (Massey 1973, Zedler 1982), which it uses for foraging, breeding, and perching. This species is present year round in upper saltmarsh areas of the Ballona wetlands, but is limited to nesting territories between January and August (Dock and Schreiber 1981).

A beneficial, but short term, impact of placing dredge-spoil on the northern parcel of the Ballona wetlands during the construction of Marina del Rey was to increase the amount of suitable nesting habitat for Belding's savannah sparrows. Because of the long active breeding season and sensitivity to disturbance, human activity in this high marsh habitat may cause both habitat degradation and reproductive failure (Zedler 1982).

Territorial males have been observed on Playa del Rey and Ballona saltflats between 1973 and 1991, although there are no records of fledglings (Zembal 1992, pers. comm.). During the period from 1973 to 1987, the population was fairly stable, with 23 to 39 breeding pairs occurring in the wetlands each year (Table 3-1). Starting in 1990, the number of pairs started to decline, partly due to predation by introduced red foxes (Jurek 1992, pers. comm.) (Attempts have been made to trap and remove the foxes from the wetlands, but the program has encountered strong opposition from the animal-rights activists, to the extent that biologists were afraid to conduct surveys for fear of retaliation. Therefore, despite declining numbers of birds, surveys were not conducted in 1992.) The number of breeding pairs in the area may also be affected by changing habitat conditions, such as increased amounts of standing water during flooding and, in the case of the dredge spoil nesting site, a reduction in the quality and quantity of pickleweed habitat (Dock and Schreiber 1981).

California Least Tern. The California least tern is a summer visitor which breeds in southern California coastal habitat from late April to September. It builds its nests in shallow depressions in hard or soft dirt, dried mud, or sandy areas, usually on beaches or islands cleared of vegetation. The closest breeding site to any of the Bay wetlands is the Venice Beach site (Table 3-2).

VOL 12

15325

Nagano *et al.* (1981) identified 474 insect species from the Ballona Wetlands saltmarsh and estimated that as many as 1,200 may actually inhabit the region. On the basis of the presence of known indicator species, the Ballona region was characterized as a natural coastal saltmarsh and associated sand dune habitat. At least 10 of the species found have restricted coastal distributions, and destruction of Ballona Wetlands habitat could result in their elimination.

Vertebrates

Fishes. The Ballona Wetlands, primarily Ballona Lagoon, support a number of transient fish species but only nine resident species. The dominant species are the arrow goby, which lives commensally in burrows of other organisms in the intertidal zone; the mosquitofish, a freshwater species which was introduced to control mosquitos; and topsmelt, a pelagic marine species which moves in and out with the tides (Swift and Frantz 1981).

Marine lagoons and back bays in southern California serve as spawning and nursery grounds for resident species (such as several species of gobies, California killifish, Pacific staghorn sculpin, and possibly topsmelt) (Fitch and Lavenberg 1975) and as important nursery grounds for the California halibut (Haaker 1975). The importance of Ballona Lagoon and Marina del Rey to these species in the past is not known.

Rainbow trout (steelhead) and tidewater goby were present at Malibu Lagoon in the past, and those species might return there if the entrance to the ocean were kept open to improve water quality (WRA 1990). Topsmelt and gobies (and possibly other bay species) which occur in Marina del Rey probably also occur in the Oxford Flood Channel and the Venice Canals.

Amphibians and Reptiles. Three species of amphibians and six of reptiles are known from the Ballona Wetlands. Most of the amphibians are frogs and toads and most of the reptiles are lizards (MBC 1988). All are associated with freshwater areas in the wetlands.

Birds. Numerous terrestrial birds, shorebirds, and water fowl are found in the Ballona Wetlands Complex and Malibu Lagoon. However, diversity is greater at Malibu Lagoon because it is adjacent to riparian woodland and chaparral habitats. Most species in the Ballona Wetlands Complex are shore birds, perching birds, and waterfowl. Relatively few birds breed in the Ballona Wetlands Complex due to both human disturbances and limited habitat diversity (Dock and Schreiber 1981).

Two endangered species live and/or breed in the Ballona Wetlands: Belding's savannah sparrow and California least tern. The savannah sparrow is a year-round resident which forages and nests in pickleweed, while the least tern is present only during spring and summer, feeding in the shallow waters and nesting at nearby Venice Beach (Dock and Schreiber 1981, Atwood and Minsky 1983).

Two species of birds which have not been observed in the Ballona Wetlands in recent decades probably bred there early in the 19th century. The range of the light-footed clapper rail (a federally-listed endangered species) presently extends between the saltmarshes of northern Baja California and those of southern California. Clapper rail nesting was recorded in nearby Santa Monica marshlands early in the century (Grinnell and Miller 1944) and they have been found in various marshes in Los Angeles County (LFCRRT 1983). Their absence at Ballona may be a result of a lack of suitable nesting habitat, preferably cordgrass (Massey and Zembal 1979). Although it will nest in upper marsh areas, especially following flooding of lower marsh habitat, this habitat is generally lacking at Ballona. Overharvesting by museum collectors and hunters,

15328

Life zones are areas with distinct organisms with adaptations for special physical conditions (e.g., pressure, darkness). Life zone schemes usually divide the marine environment into pelagic (open-water) and benthic (bottom) environments, with these being further divided, usually by depth (Hedgpeth 1957, Allen and Smith 1988). Intertidal and estuarine environments are also included as separate categories (Hedgpeth 1957). Each of these environments can be divided into smaller habitat units, each characterized by particular physical attributes and a suite of specially adapted organisms.

The marine ecosystem is divided into the pelagic and benthic environments. The pelagic environment includes the entire water column from the surface to the bottom of the sea. Pelagic organisms typically meet their needs for food, space, and refuge in the water mass itself, with relatively little to no direct interaction with the underlying seafloor. Horizontally, the pelagic realm can be divided into two zones: neuritic and oceanic. The neuritic includes the water column that overlies the continental shelf. Oceanic zone includes all other open waters. The pelagic environment can be further divided vertically. Two life zones of the pelagic realm are represented in Santa Monica Bay: Epipelagic and Mesopelagic. The Epipelagic zone (euphotic zone) is part of the pelagic environment that is lighted; its lower boundary is the limit of light penetration and varies in depth with water clarity. The mesopelagic extends from the permanent thermocline and extends to about 1500 ft - the artificially defined deep boundary of the study area.

The benthic environment (Figure 3-4) has three major habitats based on substrate type (hard-bottom and soft-bottom) or the presence of kelp beds. Benthic communities generally show a change in composition along a gradient of water depth. The sublittoral zone (from shore to a depth of about 600 ft) is divided into inner shelf (5-100 ft), middle shelf (100-300 ft), and outer shelf (300-600 ft) zones (Allen 1982, Allen and Smith 1988); the mesobenthal zone extends from a depth of 600 to 1500 ft (the deepwater boundary of the study area) (Allen and Smith 1988). Kelp beds are only found in the inner shelf zone, where waters are warmer and with sufficient light for kelp growth. The term benthos is used variously to describe both the habitat and the organisms which live on or in the seafloor. Some organisms move about in the water column and feed or find refuge on the bottom; these are called demersal.

PELAGIC HABITATS

The pelagic habitat is the most obvious habitat in Santa Monica Bay, encompassing approximately 306 mi^2 (since it extends from the surface to depths of 1640 ft) and a total water volume of about 914 billion ft^3 (6,840 billion gal, using an average depth of 820 ft).

The pelagic environment varies on a fairly regular, seasonal basis as well as periodically. Temperature and phytoplankton production are two of the most important factors which affect the abundance of pelagic animals. Natural surface water temperatures in Santa Monica Bay range from 11.7°C to 22.0°C annually (EQA/MBC 1973). Seawater temperatures in the Bay are higher in late summer and fall and lower in the winter and spring. Stratification and increased light levels in spring and summer enhance phytoplankton production, which forms the basis for the pelagic food web and the bacteria which recycle waste products into nutrients.

Organisms of the pelagic habitat are planktonic or nektonic. Planktonic organisms are too small (or are otherwise unable) to swim against the prevailing currents and thus drift with the water mass. However, some are able to move vertically through the water, undertaking daily migrations to the surface (usually at night). Nektonic organisms are those which are large enough or strong enough to swim against prevailing currents; they can remain in one place or move to another at will. The largest of these (macronekton) are whales, sharks, and large fishes.

VOL 12

1 5 3 2 9

Least terns commonly utilize the open waters of Ballona Creek and, to a lesser extent, Ballona Lagoon to forage for food, principally northern anchovy, topsmelt, various surfperches, killifish, and mosquitofish (CLTRT 1980). Topsmelt, killifish, and mosquitofish are probably principal items in the tidal channels, creeks, and lagoons of the Ballona Wetlands, whereas northern anchovy is most important in offshore waters. Breeding success is partially dependent on food availability (Massey 1972).

Western Snowy Plover. Snowy plovers nest on beaches and salt flats which have some vegetation, and feed on mud flats in the wetlands. Historically, snowy plovers nested on the beaches at Malibu and on a stretch between Santa Monica and Redondo Beach (Page and Stenzel 1981). A few snowy plovers winter on the beaches of Santa Monica Bay (Page *et al.* 1986). However, nesting in the area has not been observed since 1949. The number of breeding birds in the U. S. in 1988-1989 (roughly 7900 birds) was about 20% lower than 10 years earlier (Page *et al.* 1991). This observed decline has raised concern for the future of this species, and the process of listing as threatened or endangered has been initiated.

Natural Variability

Although there is little information on the natural variability of wetlands plants and invertebrates in the area, seasonal and interannual variation would be expected under most conditions. Phytoplankton (and other seasonal plants) are most abundant in the spring and least abundant in winter. In addition, the aquatic and saltmarsh organisms would vary in abundance with regard to the relative influence of freshwater (runoff) and seawater, which may vary either seasonally or interannually.

Intertidal zones are used as classrooms for amateur and professional naturalists. Rocky tidepools, in particular, are visited by school classes and casual beach-goers, and may be heavily impacted during extreme low tides. Fisherman collect mussels for bait and some ethnic groups collect limpets and abalone for food, thereby depleting the shoreline of these species in some areas.

SANTA MONICA BAY HABITATS

The biological community and the physical environment function together as an ecological system or ecosystem (Odum 1959). The term ecosystem is usually applied to naturally defined systems to describe systems with unique physical and biological attributes. The biological environment of Santa Monica Bay is not a naturally defined ecosystem but rather an integral part of the larger Southern California Bight and California Current ecosystems; the study area is artificially defined here as the Santa Monica Bay ecosystem, with that understanding.

The following section includes a description of the plants and invertebrates found in most habitats. The marine vertebrates of Santa Monica Bay and their responses to human activities are discussed in Chapter 9. A complete list of scientific and common names of species used in this report are given in Appendix C.

Most marine organisms found in Santa Monica Bay and its watershed are temperate species with geographic ranges extending far beyond the immediate area. The majority are members of the San Diegan Province, which extends from about Point Conception, California, to Magdalena Bay, Baja California Sur, but some belong to the Oregonian Province, which ranges from southern Canada to northern Baja California (Hubbs 1974, Allen and Smith 1988).

Pelagic Organisms

Phytoplankton. The major plants of the pelagic realm are phytoplankton (blue-green algae, flagellates, and diatoms) and their primary production forms the basis of the pelagic marine food web. Phytoplankton are found most abundantly in the photic zone, both nearshore and well offshore. Dinoflagellates (some of which are responsible for "red tides") are characteristic of waters over most of the shelf in Santa Monica Bay, while diatoms are typically more abundant in colder water. During upwelling diatoms may dominate the phytoplankton community; when upwelling ceases, dinoflagellates become dominant again (Mullin 1986).

In general, phytoplankton abundance is greatest in spring when nutrients are abundant in the mixed layer and there is ample sunlight. However, blooms may occur in the fall when stratification breaks down and nutrients enter the photic zone from below. Most phytoplankton blooms in Santa Monica Bay result in response to local conditions such as surface runoff, upwelling, and sewage discharges that increase nutrient levels. Primary production in the study area ranges from 75 to 175 g carbon/m^2/yr; that of the Santa Barbara channel is approximately 142 g carbon/m^2/yr (Eppley and Holm-Hansen 1986).

Invertebrates. Smaller invertebrates comprise most of the zooplankton whereas larger invertebrates are often important members of the nekton. The most abundant animals of the pelagic environment are the zooplankton, which are small animals which drift with the currents. Zooplankton includes protozoa, crustaceans (copepods, euphausiids or krill, and mysid shrimps), pelagic snails, polychaete worms, arrow worms, comb-jellies, and jellyfish. Zooplankton are typically less than an inch in size, but some jellyfish are over 6 ft long (Beers 1986).

Most zooplankton are primary consumers and eat phytoplankton. In turn, they are consumed by larger, secondary consumers. However, many zooplankters are secondary consumers themselves. Zooplankton are found throughout the water column, although certain species are characteristic of various depths. Mysids are typical of shallow, nearshore waters while euphausiids are typical of middle and upper layers of deep offshore water. Many planktonic crustaceans undertake a daily vertical migration, swimming to the surface at night and to deeper waters during the day.

Most zooplankton species reproduce several times in a single year, the life span of individuals being measured in weeks or months. Eggs are usually broadcast into the water and develop through a variety of larval stages to mature adults.

Zooplankton abundances typically increase immediately following plankton blooms, especially in spring; in fact, predation by zooplankton contributes to a decline of phytoplankton. However, a decline in phytoplankton is primarily caused by depletion of nutrients. The volume of zooplankton in the surface waters of the Southern California Bight generally range from 90 to 300 *ml*/100 m^3 (Mullin 1986). In 1980 zooplankton (mostly copepod) volumes in Santa Monica Bay ranged from 100 to 1,300 *ml*/1,000 m^3 (Kleppel *et al.* 1982).

The eggs and larvae of many invertebrates are planktonic, even though the adult stages may not be. These meroplankton may last for only a short period (days to months) before the larvae become nektonic or settle to the bottom. The pelagic nekton includes larger mobile invertebrates such as squid and shrimp. The most important large nektonic invertebrate is the California market squid, although the pelagic red crab and the jumbo squid may be abundant locally during El Niño periods. Ocean shrimp feed in the water column at night but rest on the bottom during the day.

1 5332

Because many zooplankters migrate between deep water during the day and the surface at night, zooplankton abundance in surface waters varies between day and night. Larger species such as euphausiids and mysids are generally more abundant in the surface waters of the Bay at night than during the day. Smaller species such as calanoid copepods do not migrate as much and day-night differences are less pronounced.

Intertidal Habitats

Organisms

Plants. Plants in the rocky intertidal display vertical zonation, with distinct species assemblages at different tidal levels, although the patterns may be disrupted by grazing, by dominant attached invertebrates, or by trampling. Lichens dominate in the splash zone, whereas the upper intertidal flora includes green algae such as sea felt and sea lettuce, brown algae (rockweeds), and various red algae. The middle intertidal includes a more diverse algal assemblage with foliose, filamentous, and coralline red algae and brown algae. The lower intertidal zone has red and brown algae as well as surfgrass (Hedgpeth and Hinton 1961, Dawson 1966).

Few plants are found in the sandy intertidal, although one-celled algae may be abundant on beaches with fine particle sizes (Pollock 1971). Benthic diatoms sometimes form a brownish green layer on sands where wave action is not too great and green algae, such as sea felt and sea lettuce, may occur on protected beaches where there is little sand movement. On the mudflats of backbays, cordgrass forms dense stands at the lower tidal level, while pickleweed dominates the upper level.

Where conditions are favorable for dune formation, above the high-energy intertidal zone, the sand may be sparsely vegetated with salt-tolerant sand verbena, silver beachweed, beach primrose, beach morning glory, salt bush and salt grass. Many introduced exotic plant species, such as Hottentot fig and sea fig (both known as iceplant), and sea rocket have taken over much of the extant dunes in southern California (Munz 1964, 1973). The vegetative cover helps to stabilize the dunes but is fragile. Its disturbance by vehicles and foot traffic may lead to eventual loss of the dune system.

Invertebrates. On rocky shores, only shelled species can live at the highest zones; soft-bodied forms cannot tolerate exposure to the air for very long. The splash zone is best characterized by periwinkles, barnacles, limpets, and rock lice. Periwinkles and limpets graze on diatom films, barnacles filter-feed when the tide is in, and rock lice are scavengers.

In the upper intertidal zone, species diversity increases with additional species of snails (periwinkles, turbans, limpets), attached bivalves, chitons, hermit crabs, and striped shore crabs. The upper limit of this zone is marked by California mussels and Pacific goose (or gooseneck) barnacles both of which are filter feeders and which are preyed upon by ochre starfish. A variety of sea anemones, snails (including black abalone), sea slugs, octopus, polychaetes, barnacles, isopods, crabs, shrimp, and brittle stars is also found here.

The lower intertidal is very similar to the subtidal; sponges, sea anemones, polychaetes, snails, sea slugs, attached bivalves, octopus, bryozoans, crustaceans (amphipods, isopods, shrimp, hermit crabs, crabs), sea stars, brittle stars, sea cucumbers, sea urchins, and tunicates are all abundant (Hedgpeth and Hinton 1961).

The production of phytoplankton (and secondarily of zooplankton) in the water column provides the primary basis of the food web that supports most of the larger organisms in the Bay.

Natural Variability

Phytoplankton assemblages in Santa Monica Bay are relatively distinct from those elsewhere in the Bight. Dinoflagellate abundance is higher in the Bay than in other areas along the coast. This has been attributed to high concentrations of ammonium, a result of nutrient regeneration at the bottom of the relatively broad shelf or from anthropogenic inputs. In addition, maximum phytoplankton production is at shallower depths (mostly less than 30 ft) in Santa Monica Bay than in other coastal and offshore areas of the Bight (Mullin 1986); it is greatest nearshore and decreases offshore. The distribution of bacterioplankton abundance parallels that of the phytoplankton (Azam 1986).

Most of the variability of plankton in Santa Monica Bay is natural (SCCWRP 1973), and its abundance may vary by an order of magnitude at periods of several years. Thus, in 1979 the concentrations of chlorophyll (a measure of total phytoplankton abundance) were less than one-tenth those in 1975 (Eppley 1986). During El Niño periods, phytoplankton productivity drops as the thermocline deepens and the availability of naturally occurring nutrients decreases (McGowan 1984). Cool surface waters are generally from the productive California Current whereas warm surface waters are generally from the less productive southern waters which move into the area during an El Niño.

Phytoplankton abundance in the Bay also varies seasonally, as a result of variations in light levels and nutrient availability. Primary production may vary by a factor of three between seasons. In general, phytoplankton abundance and production increase in spring as the sun moves higher in the sky and as stratification of the water column (from warming of surface waters) traps nutrients in the mixed layer. However, as phytoplankters deplete the nutrients, they become less abundant; predation by zooplankton also contributes to this decrease. A bloom may also occur in the fall when stratification breaks down and nutrients enter the photic zone.

Both spring and fall blooms are less pronounced in southern California than to the north; most local phytoplankton blooms are the result of local nutrient conditions from runoff, upwelling, and sewage discharge (Eppley and Holm-Hansen 1986). Upwelling in the Bay, particularly along the southern Palos Verdes Shelf, may lead to phytoplankton blooms which are dominated by diatoms rather than dinoflagellates (Eppley and Holm-Hansen 1986, Mullin 1986). In 1980 diatom abundance was sometimes high over Santa Monica and Redondo Submarine Canyons, suggesting upwelling there (Kleppel *et al.* 1982).

"Red tides" (which are typically dominated by dinoflagellates) sometimes develop in nearshore areas when warm temperatures, high light levels, abundant nutrients, and a shallow pycnocline occur together (Mullin 1986). Localized red tides occur almost every year, extensive ones less frequently. A red tide which developed in Santa Monica Bay in 1945 extended from San Luis Obispo to Los Angeles Harbor (Sommer and Clark 1946).

Zooplankton abundance also varies with oceanic conditions; it is generally low at high temperatures and high at low temperatures. Zooplankton abundance generally increases during a phytoplankton bloom (as during the spring) and decreases as phytoplankton abundance decreases. The abundance of microzooplankton in Santa Monica Bay generally parallels primary productivity (Eppley and Holm-Hansen 1986).

VOL 12

15334

R0048639

Sandy beaches also provide foraging habitat for several species of shorebirds and nesting habitat for one endangered species, the California least tern. Western snowy plovers and willets are present on local beaches all year round; whimbrels, marbled godwits and sanderlings spend the winter only; and ruddy turnstones visit southern California beaches during spring and fall migrations (Garrett and Dunn 1981).

Marine Mammals. California sea lions sometimes haul out in rocky intertidal areas in Santa Monica Bay or rest on sandy beaches when sick or injured.

Importance

Beaches are the part of the marine ecosystem where the land meets the sea. As such, they present a unique and difficult environment for which a few species have become specially adapted. On sandy beaches, sand crabs and clams must cope with shifting sands (caused by waves) and with intermittent exposure to air during low tide. Species such as sand crabs and bean clams (also known as coquinas), move up and down with the tide, while others simply burrow deeper to avoid desiccation and predators. Pismo clams prefer the lower intertidal and are vulnerable only during the lowest tides. California grunion spawn in the sandy intertidal. All of these species are preyed upon at some time in their life cycle by other intertidal organisms, shorebirds, and humans.

Dunes provide protection for inland areas and serve as living and breeding areas for many species. Plants which have colonized dunes, in turn, act to stabilize the dunes, preventing them from blowing out during strong winds.

Rocky shores support a very different intertidal community. They provide points of attachment for algae which are primary producers and so are a source of algal as well as shell detritus. Rocky shores are the sole habitat for many species and they constitute nursery areas for the young of some fish and invertebrates.

Rare, Threatened, or Endangered species

California Least Tern. California least tern is a spring and summer visitor which breeds in southern California coastal habitat from late April to September. It builds its nests in shallow depressions in hard or soft dirt, dried mud, or sandy areas.

Historically, least tern nested on the upper reaches of sandy beaches along much of Southern California. As nesting habitat and suitable feeding grounds were lost and disturbance by humans increased (CLTRT 1980), terns made use of alternative sites (Dock and Schreiber 1981). California least terns formerly nested on salt- and mudflats at Playa del Rey in lieu of the larger and permanent site on Venice Beach. As a result of a program to protect least tern nesting grounds, the numbers of nesting pairs and fledglings at Venice Beach have almost tripled since 1984 (Table 3-2).

Breeding success of least terns varies greatly from colony to colony each year due to predation, unfavorable weather (CLTRT 1980), flooding (Dock and Schreiber 1981), and availability of food (Massey 1972). Least terns forage in the shallow, open waters of Ballona Creek, and to a lesser extent, Ballona Lagoon and Marina del Rey, principally for northern anchovy, topsmelt, surfperches, killifish, and mosquitofish (CLTRT 1980). Topsmelt, killifish, and mosquitofish are found in the tidal channels, creeks, and lagoons of the Ballona wetlands, whereas northern anchovy occurs in nearshore marine waters.

VOL 12

15335

The meiofauna, the smaller organisms of sandy beaches, is found in the upper sediment layers to a depth of several feet in coarse sand, to only 2 in. in fine sediment. Abundance is generally highest in coarse sands, but diversity is greater in fine sands. Similar species occur here as are found on the subtidal soft-bottom habitat.

The macrofauna of the sandy intertidal consists largely of polychaetes, bivalves, and crustaceans, the most obvious of which is the sand crab. This species is an important food for many surf zone fishes and is collected commercially for fishing bait. It filters particulate matter from the incoming waves but rapidly burrows deeper into the sand as the wave retreats.

The bloodworm is an infaunal polychaete which feeds on bacteria, microalgae, and meiofauna beneath the sand. Bean clams are abundant in some years; in other years they are rare. The pismo clam is a popular recreational species which is found on sandy beaches, and along with the little bean clam, extend subtidally. Populations of these two species appear to have declined over the past few years. The reasons are not clear, although recruitment has been very low, perhaps due to overfishing of parent stocks or habitat degradation (Shaw and Hassler 1989). The Pacific littleneck is found in coarse sand and gravel near rocky areas; this clam is also a popular recreational species. Although the status of this species is not known, it is subject to the same problems of overfishing and habitat degradation as Pismo and bean clams (Chew and Ma 1987). Amphipods are also important species on the intertidal sandy beach: beach hoppers (gammarid amphipods) live in burrows at low tide or under and around drift kelp (Hedgpeth and Hinton 1961). Further inland, on undisturbed, vegetated dunes, there are numerous species of insects, including the endangered El Segundo blue butterfly (WRA 1990).

Fishes. Rocky tidepool fishes are typically small and well-camouflaged. Woolly sculpin, opaleye, rockpool blenny, spotted kelpfish, and California clingfish are all found in the study area (Cross 1982a). The spotted kelpfish associates with turf algae, while the others are found where algae are not abundant. The rockpool blenny and California clingfish are most common in cobble areas whereas the woolly sculpin and opaleye are typical of fixed tidepools.

California grunion is a small, silvery fish, which deposits its eggs in the sandy intertidal zone. It spawns from late February to early September on the second night after a full moon, the so-called "grunion runs" of southern California beaches. Spawning occurs near the peak of the high tide during and just after high spring tides. Female grunion burrow tail-first into the sand and lay their eggs; males follow the females, wrap themselves around the females, and fertilize the eggs. They leave on succeeding waves and the eggs remain until the next spring tides two weeks later, when the eggs hatch and the larvae are carried out by waves. While buried on the beach, grunion eggs may be eaten by sand worms, isopods, flies, beetles and shorebirds (Fitch and Lavenberg 1971, USFWS 1985). Grunion may be caught (legally) by hand during the spawning season; they are taken incidentally in commercial nets along with other species (Fitch and Lavenberg 1971, USFWS 1985).

Several fishes live nearshore or in the surf zone. California corbina, barred surfperch, and shovelnose guitarfish all feed on sand crabs and are caught by sport fishermen. Surf fishermen often take California halibut as they move inshore to feed on grunion.

Shore Birds. Numerous shorebirds forage on crustaceans, mollusks, and polychaetes in the rocky intertidal zone. These include spotted sandpipers, willets, ruddy turnstones, black turnstones, surfbirds, wandering tattlers, black oystercatchers, Heermann's gulls, and western gulls (Jaeger and Smith 1966, MBC 1985). These species are most common locally during the winter; many migrate north in summer to breed.

Natural Variability

Under normal sea conditions, beaches exposed to wave surge erode or accrete in response to changing sea conditions. During winter storm events, beaches erode and sand is transported offshore. The resulting beach and nearshore profile are in equilibrium with the prevailing sea conditions. Typically, winter beaches are characterized by a steep beach face, relatively coarse sediment, and a sea cliff or winter berm (Anikouchine and Sternberg 1973). During summer much of the eroded sands is transported back to the beach by smaller waves (Bascom *et al* 1980) and the beach profile becomes less steep, with a smaller berm and finer sediments. During a severe storm, there may be insufficient sand on the beach to shape the equilibrium profile, and the upper beach dunes may be eroded to supply sand to the beach and nearshore zone. In winter 1982-83 there were four successive major storms with insufficient time between them for the beach to recover its stable protective profile (Armstrong 1991). Where the continental shelf is steep, waves cannot return sediment back to the beach after a severe storm and permanent erosion results (Woodell and Hollar 1991).

The coastline of Santa Monica Bay is naturally eroding because of the rise in sea level (more than 6 in. [15 cm] per century) (Woodell and Hollar 1991). The general long-term trend of shoreline erosion is very irregular and is punctuated by storm events, leading to a gradual, long-term trend of beach erosion. Major storm events during the last century which impacted Santa Monica Bay beaches occurred in 1905, 1915, 1926, 1931, 1939, 1941, 1952-53, 1957-58, 1972-73, 1077-78, 1982-83, and 1988. Recently, it has been recognized that these storms are associated with the El Niño-Southern Oscillation phenomenon.

Rocky intertidal habitats are subject to natural alteration by wave turbulence, inundation by sand, desiccation during hot, dry days, and freshwater dilution during rains. Storm surf damages these areas because they typically take the brunt of breaking waves; small cobbles are hurled about, damaging attached organisms. During winter the rocky intertidal is typically free of sand because beach sand is carried offshore; during summer, rocky intertidal areas may be covered with beach sand which is pushed ashore. Hot, dry weather subjects exposed organisms to desiccation and warms tide pools. During rain, attached organisms may be exposed to freshwater and tidepools may be affected by both freshwater and sediment carried in the runoff waters.

Thus, the abundance of intertidal organisms is expected to vary seasonally and interannually. Catastrophic destruction of individuals and habitat may occur at irregular intervals corresponding to major storms or dry periods. The natural variability of intertidal organisms in the Bay has not been quantified.

Soft-Bottom Habitats

The soft-bottom habitat is by far the most extensive benthic habitat in Santa Monica Bay. Most of the seafloor of the study area consists of unconsolidated (soft) sediments, which consist of mixtures of sand, silt, and clay (Figures 2-3, 3-4). Most of the energy entering this habitat is detrital fallout and phytoplankton from the water column, although detritus from surface runoff and sewage may be important.

Organisms

Plants. The few photosynthetic organisms that live on the soft-bottom habitat of the Bay include diatoms, blue-green algae, green algae, and flagellates which attach to sand grains or

VOL 12

15337

No studies have linked contamination of least tern food resources to reproductive success. However, since they prey on northern anchovy and topsmelt like the brown pelican, they may also have been impacted by the accumulation of chlorinated pesticides and PCBs in the 1970s.

Western Snowy Plover. The western snowy plover has recently been proposed for Federal threatened status (CDFG 1992). Its population has declined due to loss of beach nesting habitat in California (Garrett and Dunn 1981). Snowy plovers flock on the beach at Malibu and Hermosa Beach during winter but apparently do not nest there (Stenzel 1993, pers. comm.). The closest breeding colony is at Bolsa Chica in Orange County; other colonies nest at the Santa Clara River mouth, McGrath Lagoon and Mugu Lagoon in Ventura County, and some Channel Islands.

El Segundo Blue. The El Segundo blue is a subspecies of butterfly which inhabits (almost exclusively) dunes where its sole host plant, coastal wild buckwheat, is found (Emmel and Emmel 1973). It is presently limited to the dunes at the west end of LAX and Chevron USA's 1.6 acre butterfly preserve at the northwest corner of the refinery (Coonan 1992, pers. comm.). At one time the dunes encompassed 2,900 acres and included small seasonal pools and marshes; currently there are 338 acres of dunes, although potential enhancement sites are present within dunes owned by the airport and Chevron USA (WRA 1990). Attempts to protect the El Segundo blue from extinction have included protecting and propagating its host plant.

Wandering Skipper. The El Segundo Dunes are also inhabited by another rare butterfly, the wandering skipper. Wandering skipper larvae are restricted to one host plant, saltgrass. The decline in wandering skipper populations is due to loss of undisturbed beach dunes and coastal wetlands habitat (Zedler 1991). Thus, it is a valuable indicator of an ecosystem in continual decline. The wandering skipper has been a candidate for endangered status, and was listed in the Federal Register review of endangered or threatened invertebrate species (USFWS 1984).

Black Abalone. Black abalone are found in the intertidal and shallow subtidal of rocky shores from central Oregon to the southern tip of Baja California. Because they are large and easily noticed, they have been collected for food, beginning with the prehistoric coast-dwelling native Americans (Haaker *et al.* 1986). Indian middens along the southern California and Baja California contain great numbers of black abalone shells.

The black abalone population in southern California has been drastically reduced by commercial and sport harvesting as well as a mysterious "withering syndrome". Abalones also compete with sea urchins (which have increased along the coast) for the same food, brown algae. Collecting of black abalone has been banned in southern California from Palos Verdes Point to Dana Point and commercial harvesting is prohibited in Santa Monica Bay. The legal harvest size for black abalone is 5 in., but currently very few legal-sized animals are found in Santa Monica Bay (Harris 1992, pers. comm.).

Potential recovery strategies for black abalone include completely closing the fishery for up to 5 yr; continuing research on "withering syndrome" (evidence suggests that other abalone species may also be susceptible); and stricter enforcement of poaching regulations. Transplantion of larval or juvenile abalone onto Santa Monica Bay rocky beaches would not be practical until the cause of the withering syndrome is ascertained and until it can be demonstrated that transplantion actually works.

VOL 12

15338

Echinoderms (especially brittle stars) are also quite abundant and diverse. Brittle stars feed on detritus in the sediments or filter it from the water. Other less common invertebrate groups may be important at particular times or places. For instance, the spoonworm (an echiurid) is occasionally dense in some areas and is important in bioturbating sediments. Many benthic macrofaunal species have do not survive in contaminated areas, even though the sediment texture may be appropriate. Therefore, the benthic community composition differs with the degree of sediment pollution as well as with normal differences in sediment type.

Megafauna. The soft-bottom, invertebrate megafauna (excluding nektonic forms) of the Bay includes epibenthic sea stars, sea cucumbers, sand dollars, sea urchins, crabs, snails, and sea slugs. Being larger than the macrofauna, these species are less common and are spaced further apart. However, sand dollars and sea urchins often occur in very dense, single-species patches which limit the abundance of other species. Because they are larger, they often comprise the bulk of the biomass in an area. Most of these species feed on detritus and infaunal organisms. Sea cucumbers ingest sediments, sand dollars filter water, and sea urchins feed on detritus. However, moon snails, crabs, and the California sea slug are predatory.

Nektonic megafaunal species swim occasionally, but most spend much of their time on the bottom. Important invertebrate species include octopus, eastern Pacific bobtail (a squid), bay shrimp, ocean shrimp, and ridgeback rock shrimp.

Natural Variability

Sewage was discharged into the study area long before information on the infaunal communities of the area was available. The earliest large scale investigation of the infauna in the area was conducted (in 1952 to 1954) prior to operation of the HTP 5- or 7-mi outfalls. This study (Hartman 1956) did not sample sites off the Palos Verdes Peninsula, but included about 150 samples from the remaining portion of Santa Monica Bay. Six faunal assemblages were recognized, based mainly on physiographic differences in the habitat.

The above study was expanded into a survey of the entire Southern California Bight from 1957 to 1958 (CSWPCB 1959) which included stations on the Palos Verdes Shelf. Analyses of the data from this survey continued for years and these provide a background for impact studies (CSWQCB 1965, Jones 1969).

Historical information on the megafauna of Santa Monica Bay was not collected regularly nor is it comprehensive. The distribution of crabs and shrimp in the area are discussed by Wicksten (1984) on the basis of collections made prior to 1930. Qualitative comparisons of these data with those from 1958 to 1963 (Carlisle 1969) show little change in the species composition of Santa Monica Bay, but provide no information on abundance or fine scale distribution.

The abundance and distribution of individual species of the infauna and megafauna may vary seasonally and interannually, although most accounts of this are in studies concerned with human impacts. Most of this natural variability is difficult to separate from the variability associated with human impacts (Bernstein *et al.* 1984). However, any natural disturbance of the sediments or oceanographic changes, is likely to affect benthic soft-bottom invertebrate populations. For instance, a change in the species composition of the inshore megafauna assemblage of the Bight occurred after 1981, perhaps as a result of the 1982-1983 El Niño or because of severe winter storms in 1983 (SCCWRP 1936e). These events may also have been important in changing the composition of the infauna assemblages off Palos Verdes during this period (Swartz *et al.* 1986).

VOL 12

15339

R0048644

move about on the surface of the sediments. These are most abundant on the inner shelf, at depths of less than 30 ft, where sufficient light reaches the bottom (Round and Hickman 1971). A few green, filamentous red, and small brown algae attach to worm tubes and cobbles on the bottom; these have the same light requirements as the one-celled plants and only occur in shallow water.

Meiofauna. The meiofauna are the smallest (less than 0.5 mm in. one dimension) infauna. Meiofauna (organisms which live in the sediments) includes small organisms such as one-celled protozoans, small roundworms (nematodes), small polychaetes and oligochaetes, copepods, gastrotrichs, flatworms, kinorhynchs, and tardigrades. These organisms are dense in aerobic sediments throughout the year, feeding on bacteria, one-celled plants, detritus, and other meiofauna. The meiofauna of the Bay has not been well studied, but organically-enriched sediments generally have higher proportions of nematodes and oligochaetes than normal sediments.

Macrofauna. The invertebrate macrofauna which are less than about 0.5 in. in one dimension are the dominant members of the soft-bottom infauna. The soft-bottom habitat of the shelf supports an extremely diverse (numbers of different species) and abundant (numbers of individuals) infauna. As many as 1,200 infaunal species have been reported from Santa Monica Bay (Dorsey 1988). Samples from uncontaminated sediments along the 200-ft isobath in the Bight averaged 71 species and 423 individuals in 0.1 m^2 of bottom sediment. However, because these animals are usually quite small, the biomass is small averaging 7.0 g/0.1 m^2 (Word and Mearns 1979). These values vary with depth and sediment type.

The infauna is usually dominated, in numbers of species and numbers of individuals, by polychaete worms. Polychaetes are soft-bodied, and may be free moving or sedentary. The free-moving ones generally crawl along the surface or burrow through the soft sediments like earthworms; sedentary forms move, but usually within a tube which they construct in or on the sediments. Most soft-bottom polychaetes feed on the bottom, engulfing sediments and digesting off the attached bacteria, or filter feed on bits of organic detritus in the water. A few polychaetes are predatory, feeding on other infauna. Polychaetes are important constituents in the diet of many demersal fish and are important in reworking (bioturbating) the sediments.

Crustaceans are usually the second most diverse and abundant group of soft-bottom infauna. Among this group of animals, amphipods are the most common, but others such as cumaceans, isopods, and ostracods are also important. Some species of amphipods and all of the benthic cumaceans and ostracods burrow in the sediments; some amphipods live in tubes while others, hide among debris. All of these crustaceans brood their eggs and hence do not have pelagic larvae; the males of many amphipods, cumaceans, and ostracods migrate up into the water column at night. Some crustaceans filter plankton and detritus from the water column and others feed on meiofauna, diatoms, and detritus in or on the sediments. Still others scavenge on dead organisms. Amphipods are particularly important prey for many demersal fishes (Allen 1982).

Mollusks are usually the third most diverse and abundant group of soft-bottom macrofauna. Bivalves (clams, mussels, etc.), snails, and sea slugs make up most of the molluscan portion of the benthos. Most bivalves are infaunal but scallops and mussels are epifaunal. Clams generally filter the water for bacteria, phytoplankton, and detritus but some species engulf sediments as they burrow. Snails and sea slugs tend to scrape material from the sediments or hard surfaces, but many are predatory, preying largely on clams and other snails by drilling holes through their shells.

abalone feed on drift kelp while sea urchins graze on macrophytes and diatoms. Many of the small crustaceans (amphipods, isopods, shrimp) eat algae but crabs, shrimp, lobsters, snails, sea slugs, polychaetes, and sea stars are carnivorous or omnivorous.

Abalone, California spiny lobster, yellow rock crab, Pacific rock crab, red sea urchin, and Pacific purple urchin are fished recreationally in shallow water and spot shrimp in deep water.

Natural Variation

Natural variations in the plant and invertebrate populations of subtidal hard-bottom areas occurs seasonally (particularly in shallow water) and during El Niño periods but these have not been well documented in the Bay. Studies of artificial reefs in the Bay indicate that the plant and invertebrate assemblages on newly-exposed hard substrates undergo a succession in dominant species and area coverage of epifaunal growth with increasing time (Carlisle *et al.* 1964). A red tide which occurred from San Luis Obispo to the Los Angeles Harbor in 1945 killed California spiny lobster and sheep crab, both hard-bottom species (Sommer and Clark 1946).

Additional factors which affect the shallow habitat include turbidity, sea urchin predation, water movement, temperature, and inundation by sand. Changes in the biota of a shallow reef may be seasonal or long-term. Turbidity and sea urchin predation reduce the algal growth whereas the turbulence, scouring, and inundation by sand affects the suitability of the habitat for sessile and crevice-seeking species. Seasonal changes are caused by differences in light intensity and temperature, which affect photosynthesis and may trigger spawning in a variety of organisms.

Annual inundation by sand is common in shallow areas; it may smother the existing biota, resulting in a bare surface when the sand is gone. As a newly exposed hard surface appears, the process of succession, from small sessile forms to a dense cover of macroalgae and mussels begins. Thus, shallow reefs may be almost constantly in an early state of development.

Kelp Beds

Kelp beds are an extension of the hard-bottom habitat. However, most hard bottom in the Bay is of low relief and the presence of kelp extends this relief to the sea surface. Giant kelp is probably the best known of the macroalgae It generally grows on hard, subtidal bottoms at depths of 20 to 70 ft, where the water is clear (Abbott and Hollenberg 1976). More than other macroalgae, giant kelp becomes a part of the habitat, providing food, shelter, nursery, or a point of reference for invertebrates and fishes.

Giant kelp is harvested to produce compounds such as algin, which is used in the manufacture of ice cream, cosmetics, and many other commodities. Kelp beds are also important for sport fishing, commercial harvesting of abalone and sea urchins, and recreational diving (North and Hubbs 1968).

Giant kelp has a complex life history which is normally completed in 12 to 14 months (Neushul and Haxo 1968). The mature kelp plant (a sporophyte) produces spores which are shed into the water column. When the spores settle and survive, they develop into a microscopic plant (a gametophyte) which produces eggs and sperm. The eggs and sperm unite to form a young sporophyte which grows to become a mature kelp plant. Kelp may live for more than five years (North 1968) and may grow as much as 12 to 20 in. per day, making it among the fastest growing plants known.

VOL 12

15341

Hard-Bottom Habitats

Hard-bottom substrate includes natural hard bottom and artificial reefs and structures. Hard-bottom habitats have a diverse and abundant assemblage of organisms that are often unique to the habitat. Reefs provide forage, shelter, and nesting sites for many animals. Hard-bottom in the photic zone is generally dominated by algal growth whereas that in deep water lacks algae altogether. Nearshore reefs may also provide habitat for giant kelp, which in turn provides habitat an additional diverse assemblage of organisms. Because of the diverse and abundant assemblage of unique organisms, reefs are important sites for recreational diving and fishing. Artificial structures, such as outfall pipes, artificial reefs, jetties, groins, and piers also provide hard-bottom habitat in Santa Monica Bay.

The rocky subtidal bottom off the Palos Verdes Peninsula is composed of sedimentary strata. Shale boulders and shelves are often isolated by reaches of sand and cobble. Reefs are more diverse, with two to four times higher vertical relief on the western side of the peninsula. The eastern rocky subtidal (12-18 m depth) is characterized by greater water turbidity and associated bottom sediment derived from the Portuguese Bend landslide. Most rock substrate is covered by a 1-2 cm layer of fine grained material and the surrounding soft bottom channels may have up to 20 cm of this sediment (Stull, pers. comm. 1993).

Organisms

Plants. Although, hard bottoms support diatoms and other one-celled plants, they are distinguished for their growth of kelps and other macroalgae. Macroalgae are anchored to the bottom with a root-like structure called a holdfast and reproduce in a complex system which produces both spore and gamet stages. In the study area macroalgae are only abundant along the Carillo and Malibu coasts, the Palos Verdes Peninsula, and artificial structures along the shore.

The major plants of the rocky subtidal in Santa Monica Bay are red and brown algae. Typically, the red algae form a low turf or understory of coralline, foliose, and filamentous forms from shore to the edge of the photic zone. Brown algae are generally larger and form an overstory; locally the feather-boa kelp is dominant nearshore while giant kelp dominates deeper areas of a reef (Quast 1968).

Invertebrates. Hard-bottom invertebrates include sessile and motile forms. Sessile forms are firmly attached to the surface of the rocks whereas motile forms move about on the reef or swim near the reef. Most hard-bottom invertebrates have planktonic larvae, although some amphipods and isopods brood eggs and larvae; sea squirts and sea anemones also reproduce asexually to form colonies.

The most obvious forms on this habitat are sessile species: mussels, barnacles, sponges, sea anemones, sea fans, tube worms, and sea squirts. Date mussels and piddock clams actually burrow into the rocks. Most of the sessile invertebrates feed by filtering plankton and detritus from the passing water mass. They are generally less abundant where macroalgae cover is high but are the dominant organisms elsewhere.

Most of motile invertebrates hide in crevices in the habitat or are protectively colored. Large species include abalone and other snails, octopus, shrimp, lobsters, and crabs. Smaller species include polychaetes, bivalves, snails, amphipods, and isopods. A variety of small motile forms live in and among the bases of the relatively large sessile species. Among the motile forms,

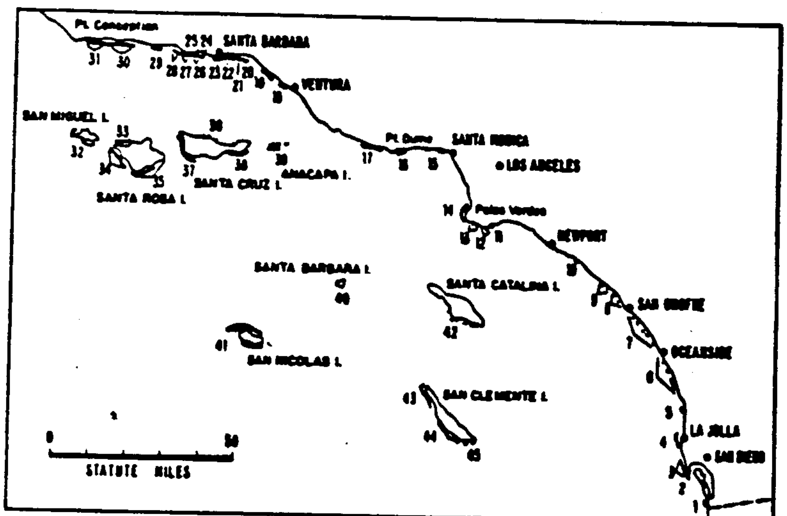

Figure 3-5. Kelp bed designations by the CDFG (CSWQCB 1964).

Mature giant kelp consists of a root-like holdfast, the stem-like stipes, and leaf-like blades. Gas-filled bladders at the base of each blade buoy up the plant, keeping the blades near the surface where light levels are maximal.

Giant kelp is found in the northeastern Pacific from Alaska to southern Baja California (Abbott and Hollenberg 1976). Not only are there replacement species along this latitudinal and temperature gradient, but within species there are strains which are adapted to particular temperature ranges. At present and in the recent past, giant kelp in Santa Monica Bay has been limited to rocky bottoms along Leo Carillo beach and the Malibu coast and along Palos Verdes Shelf (Figure 3-4).

The cover provided by California kelp beds provide protection and habitat for more of than 800 species of fishes and invertebrates, some of which are uniquely adapted for life in the beds. When kelp is absent from a reef, many of the associated invertebrates and fishes are also lacking.

Organisms

Plants. Many other algae associate with giant kelp, adding to the complexity and productivity of the habitat. These shrub or understory algae are similar to those found in other rocky bottoms at similar depths and include foliose, filamentous, and coralline red algae, smaller kelps and brown algae, and some green algae. In a dense bed, the canopy of kelp blades can actually limit the amount of light reaching the bottom so that understory algae (especially turf species) are less abundant. Feather-boa kelp is sometimes found on the inshore side of giant kelp, thus extending the bed shoreward (North 1976).

Invertebrates. The invertebrates found in kelp beds are similar to those found on hard-bottom environments without kelp. Because turf algae is often lacking, encrusting animals such as sponges, hydroids, sea fans, moss animals, and tunicates are more abundant. Pink abalone and California spiny lobster are often common in kelp beds, and red sea urchins and Pacific purple urchins are generally present. Several sponges, sea stars, and snails are unique to the holdfasts of giant kelp, as are file shells and warty sea cucumbers (Limbaugh 1955).

Kelp fronds become senile in about six months and individual blades deteriorate in one or two months; therefore, long-lived encrusting organisms like mussels and barnacles do not develop on them. However, some encrusting moss animals settle and form flat, white colonies that can completely cover a blade in three weeks. Broadtail isopods, carinate dovesnails, and kelp scallops are common on the stipes and many other invertebrates are found on the blades, though not exclusively (Limbaugh 1955).

Natural Variability

The history of kelp beds in the study area can be traced from records dating to 1911. Because kelp beds are licensed for harvesting each year they have been numbered by the California Department of Fish and Game (CDFG), which manages the resource (Figure 3-5). Beds 11, 12, 13, and 14 are located along the Palos Verdes Peninsula, between Point Fermin and Lunada Bay. Giant kelp has not been dense in this century along the sandy, central portion of Santa Monica Bay, although individual plants may have grounded there or grown on temporarily exposed rocks. Beds 15 and 16 are located between Santa Monica and Point Dume; Bed 16 is in the Mugu-Latigo Area of Special Biological Significance (CSWQCB 1979). In the early part of

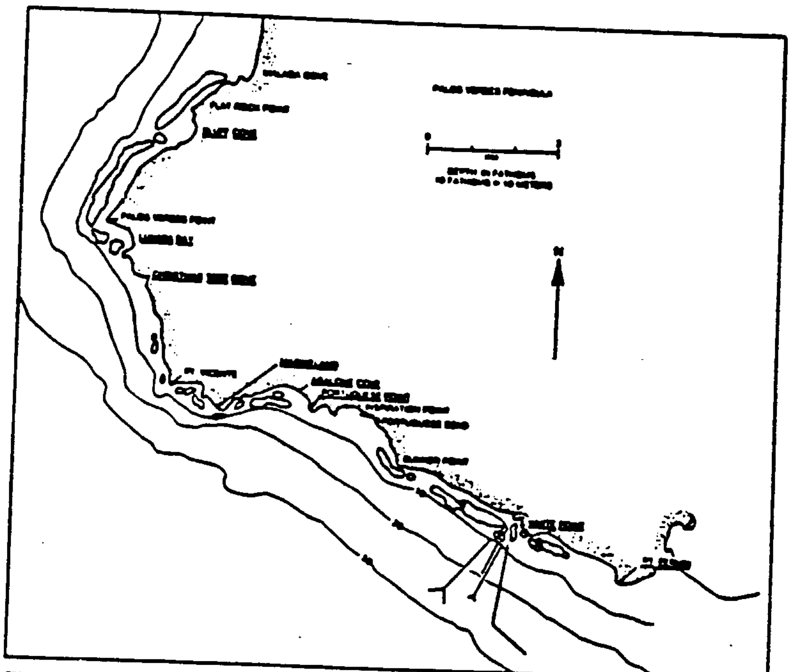

Figure 3-6. The kelp beds along Palos Verdes Peninsula in 1982 (MBC 1988)

this century, the Malibu coast beds extended from Point Dume to Santa Monica Canyon (Ulrey and Greeley 1928), but they now extend from Point Dume to Malibu.

From 1940 through 1974 the general trend in giant kelp was one of decline and appears to have been centered on the White Point outfall (North 1968). By 1959, following the strong El Niño Event of 1957 and 1958, kelp was almost completely gone; only small patches remained in Abalone Cove and at Portuguese Bend. By the fall of 1968 the last of these plants had perished (North 1970) and only transplanted kelp remained. Efforts to re-establish the Palos Verdes beds had begun in June 1967, initially with little success. During 1950-1960 as a result of increased urbanization, the marine environment became the disposal site for industrial and domestic waste. A decline in the size and number of productive kelp forests was documented during this time (Carter *et al.* 1985).

Between 1970 and 1977, the CDFG attempted to restart kelp at nine separate sites along the Palos Verdes Peninsula (Wilson *et al.* 1977). By 1975 kelp was thriving in Abalone Cove and was redeveloping in Bluff Cove (Figure 3-6). The total canopy area in 1982 was nearly what it was in the mid-1940s; it continued increasing, reaching a peak off Palos Verdes in mid-1987 which was 36% greater than recorded in 1911 (Neushul 1981). Kelp acreage was still high (617 acres) in early January 1988 (CDFG, unpubl. data), but as in 1983, storms in mid-January decimated the bed, severely reducing canopy cover. Storm decimation of the beds is a natural, ephemeral event with active regrowth following.

The history of Beds 15 and 16 in the western part of the Bay is not as well documented. Bed 15 (Figure 3-5) covered 182 acres in 1911 but has had a maximum canopy of 7 acres since 1935 (Neushul 1981). Between 1930 and 1980 the average cover was about 5 acres but kelp was often altogether absent (Harger 1983). Bed 16 in Paradise Cove is much larger and has been present continuously. In 1911 it covered 376 acres, but between 1959 and 1979 never exceeded 222 acres (Neushul 1981).

Causes of Natural Variability

The reasons for fluctuations in kelp bed canopy area and in health of the plants have been studied and argued for decades. Over-harvesting, recreational boating, waste discharge, storms, oil spills, turbidity, and warm water have all been identified as contributing to the disappearance or decline in kelp. To date no single cause has been identified and the luxuriant regrowth of kelp in areas from which it had disappeared has reassured many that declines are reversible. Many factors appear involved in the success or failure of any particular kelp bed, and neither natural nor contaminant related causes are of overwhelming importance.

Nutrient availability and storms seem to be the major natural factors which influence the health and survival of kelp. For a long time it was thought that warm summer temperatures and warm El Niño events caused the deterioration of giant kelp fronds. However, evidence indicates that lack of nutrients rather than warm temperature causes the summer degeneration (North 1983). The complicating factor is that in summer a density gradient (pycnocline) forms in nearshore waters, preventing nutrients (either natural or from sewage) from reaching surface waters. Thus, there may be both a yearly cycle in canopy extent and an irregular multi-year cycle which reflects El Niño influence.

Although low nutrient levels reduce canopy cover, they seldom result in the death of the plant. However, storms frequently do lead to complete loss of kelp. Whole beds may be uprooted during major storms and cast on or off shore. During the storms of winter 1987-1988 most kelp

VOL 12

1 5347

in the study area was lost. This repeated the 1983 winter storm decimation of beds in the study area (Wilson and Togstad 1983), and throughout southern California (Dayton and Tegner 1984) In both cases, high levels of growth followed.

Natural turbidity may also be important. Turbidity reduces light levels reaching the bottom and hence reduces plant growth. In addition, sediments settling to the bottom from turbid water may smother young plants or make the bottom unsuitable for settlement of sporophytes. Turbidity in near-bottom waters is greater in the eastern area of the peninsula primarily due to sediments from the Portuguese Bend landslide (Stull, pers. comm 1993). Since 1980 the landslide at Portuguese Bend has supplied more than seven times the suspended solids than the JWPCP outfall (SDWG 1988) and may have reduced kelp beds in the immediate area.

VOL 12

1

5348

Early Spanish and Mexican navigators had passed Santa Monica Bay, but did not land, possibly because they did not see the Indians' huts and the coves did not appear suitable for anchoring. Inland journeys of 1769 and 1774 also by-passed the coastal areas occupied by the Chumash, although they encountered some inland Gabrieleños settlements. Chumash villages were at the mouths of canyons (Robinson 1959); a Venturaño Chumash village named *Maliwu* was located near the present city of Malibu, which took its name from this village (Kroeber 1925, Johnston 1962). Gabrieleño villages were located throughout the Los Angeles Coastal Plain. Their villages were generally located on bluffs overlooking rivers or wetlands, some being located at Santa Monica (*Kuruvangna*), Los Angeles (*Wenot*), Culver City (*Sa'angna*), Redondo Beach (*Engnovangna*), and Palos Verdes Peninsula (*Masau*) (Kroeber 1925, Johnston 1962). In the late 1700s the Chumash Indians moved further inland using trails forged by explorers who had landed further north (Robinson 1959).

Little is known of the Venturaño Chumash, Fernandeño, or Gabrieleño Indians; their tribal names are unknown and their current names are derived from their later association with missions in the area San Buenaventura, San Fernando, and San Gabriel Mission (Kroeber 1925; Reiter 1984). Acorns were the staple food of all three tribes, but other plants and animals were also eaten. Coastal Chumash and Gabrieleños were skilled fishermen, the former using plank canoes and the latter using boats of made of rushes and tules. They fished for Pacific sardine, California halibut, lingcod, and tunas; hunted marine mammals such as dolphins, sea lions, seals, and sea otters; and gathered shellfish from the intertidal zone. In inland areas, they hunted deer, rabbits, and other small mammals (Johnston 1962). Indians made use of beach tar to waterproof their baskets and caulk their canoes.

SPANISH/MEXICAN PERIOD

The influx of Europeans in the late 1700s marked the beginning of the end of native Americans in the Los Angeles area. The Spanish occupation began in 1769 with the Portola expedition which founded Franciscan missions throughout California, the first being San Gabriel mission in 1771 (Josselyn *et al.* 1992). The missionaries encouraged the Indians to give up their traditional lifestyle and to live at the coastal missions but the stress of the mission routines and exposure to new diseases only hastened their demise. Some women practiced voluntary abortion rather than have their children grow up under such conditions (Robinson 1959). As the numbers of European and Mexican settlers increased, many natives deserted the area, and by 1852 there were approximately 3,700 "domesticated" Indians and 4,000 Europeans in southern California (Green 1980).

Several of the early explorers settled and purchased land in the Santa Monica Bay area. In 1775 Jose Bartolame arrived in Malibu with 240 colonists from Sonora, Mexico (Robinson 1959). He had a Spanish land grant for 13,000 acres which he called the Rancho Topanga Malibu Sequit and which was used primarily for cattle grazing. Bartolame cultivated a small area, planted a vineyard and cornfield, and built a mill, but after gold was discovered in the Sierra foothills in 1848, he sold Rancho Topanga. The three subsequent owners were a Frenchman, an Irishman, and a Puritan from New England who continued to raise cattle, the leading industry at the time.

In Santa Monica, Francisco Sepulveda purchased the majority of the land for cattle grazing (Robinson 1959). Other ranchos in the area included Rancho San Vicente y Santa Monica at Santa Monica, Rancho Rodeo de las Aguas at Beverly Hills, Rancho Ballona at Ballona Creek, and Rancho Sausal Redondo at Hermosa Beach (Josselyn *et al.* 1992).

CHAPTER 4

THE HUMAN POPULATION

During the last ice age (about 18,000 years ago) sea level was about 384 ft lower than at present (Nardin *et al.* 1981) and the continental shelf of Santa Monica Bay (which is presently submerged) would have been dry land and beach, probably backed by steep cliffs and rocky shores. Much of the land behind these cliffs was a broad, flat plain; Ballona Creek probably extended across this plain to enter what is now Redondo Submarine Canyon.

The land around Santa Monica Bay would have resembled that presently found near Monterey California, with forests of cypress and pine near the coast, brush and grasslands more inland, and riparian forests along the Ballona Creek drainage. In addition to the mammals and birds, which are still present, the area supported species which have since become extinct – mammoths, mastodons, giant ground sloths, sabertooth tigers, camels, and llamas.

Smoke from brush fires would have lingered in the valleys as "smog" and fallout from them would have contributed the same kind of "background" materials as they do today. The offshore oil seeps of today may have constituted tarpits near the mouth of Ballona Creek (at what is now Redondo Submarine Canyon). The sea was cooler and populated by marine life more typical of cooler waters than at present, and probably more abundant.

Sea level gradually rose, covering previously dry land, until the present sea level and coastline were attained about 3,000 years ago. Sandy beaches were the predominant shoreline during this period as the sea gradually progressed to higher levels across the plain; sea temperatures increased and the climate became warmer and drier.

THE NATIVE AMERICAN PERIOD

The earliest record of native Americans in the area is from about 6,000 years ago at Malaga Cove, although they were probably present much earlier (Reiter 1984). From 6,000 years ago to the 1700s, the area was populated largely by Indians with a hunting and gathering economy that emphasized plant foods such as seeds and acorns. Those living near the shore relied heavily on marine life for food.

Northern anchovy were more abundant, and large fishes, sea birds, and marine mammals which prey on anchovy may have been more abundant than at present (Soutar and Isaacs 1969). Hunting and fishing pressure increased with the native population and began to impact the plants and animals of the watershed, wetlands, and Bay. Some larger mammals may have been hunted to extinction and the food organisms along the shore were also probably impacted (Reiter 1984).

Although intermittent Spanish contact with the Indians occurred during the Cabrillo expedition of 1542 and the Vizcaino expedition of 1602, it was not until the late 1700s that the Venturaño Chumash, Gabrieleño, and Fernandeño Indians of the Santa Monica Bay watershed area had sustained contact with white men. The Gabrieleños lived from the Santa Monica Mountains south to the Aliso Creek Drainage in Orange County. The Fernandeños occupied the San Fernando Valley and the Santa Monica Mountains from the Topanga Canyon watershed east. The Venturaño Chumash were found west of the Topanga Canyon watershed to Ventura and inland to the Thousand Oaks area (Kroeber 1925). The entire Chumash population probably never exceeded 15,000 (Green 1980); less is known of the Gabrieleños, although their entire population was less than 5,000 in 1770 (Johnston 1962).

VOL 12

1 5350

selected San Pedro because it was better protected from winds, storms, and prevailing westerly swells (Marquez 1975).

By 1897 the population of Santa Monica had grown to approximately 2,000 people, twice that of 1875. With hopes of a shipping industry shattered, Santa Monica residents and entrepreneurs again tried to develop tourist and recreational opportunities. Since then, there has been opposition to large-scale industrial development (McQueen 1979).

1900 TO WORLD WAR II

The period from 1900 to 1920 was one of rapid population growth. Increases were especially pronounced between 1900 and 1905 when the population increased from 3,057 to 7,208 (136%), and again between 1910 and 1920 when it nearly doubled, from 8,700 to 15,000. These increases set the stage for dramatic regional growth and development between 1920 and World War II.

Establishment of the Douglas Aircraft Company (DAC) in the 1920s opened a new era for the Los Angeles area. Donald Douglas had moved to Santa Monica from the east coast to raise his children and to establish his own aircraft manufacturing company. With financing from David R. Davis, Douglas began work on an airplane which could fly coast to coast nonstop. With east coast associates, Douglas and his company received its first formal contract from the Navy in 1921. Douglas also secured the signatures of ten prominent Los Angeles businessmen on a $15,000 promissory note (Maynard 1962), and as the company grew, Douglas moved first to an abandoned movie studio in Santa Monica and in 1929 to Clover Field. The number of DAC employees increased from 20 in 1922 to 112 in 1924 (Maynard 1962) and at its wartime peak in 1944 DAC employed 160,000 persons in six plants. The firm manufactured 16% of all aircraft built in the U.S. between 1942 and 1945. Three of Douglas' plants closed in 1946, bringing employment down to 27,000, although there was an increase in sales during the Korean conflict in the 1950s. In the 1960s most of the company's operations were relocated to Long Beach.

The population of Santa Monica continued to grow substantially during this period, increasing from 15,000 to 37,000 between 1920 to 1930 (147%), from 37,500 to 53,000 (41%) between 1930 and 1940, and from 53,500 to 72,000 between 1940 and 1950 (35%) (USBC 1890-1970).

WORLD WAR II TO PRESENT

City of Santa Monica

The population of Santa Monica has increased dramatically since 1910 but the rate of increase was less after 1960 (Figure 4-1). In 1949 Santa Monica was characterized as a middle class community with a moderate degree of urbanization and little ethnic and social integration (McQueen 1979). Between 1950 and 1958, the population increased to 78,000, but residents were predominantly white, native-born American citizens. Ten percent of the population were foreign-born residents and 5% were non-white, predominantly black (90%) and Hispanic.

By 1990 the population of Santa Monica (including the City of Malibu) had increased to 98,388, 75% of whom were white, 14% Hispanic, 6.2% Asian, and 4.3% black. The median age of the residents was 37.9 years, significantly higher than the statewide median of 31.5. Santa Monica is home to a number of retired and senior citizens, 20.8% of whom are over 60 years old. Employment in Santa Monica increased dramatically between 1980 and 1990 (Figure 4-1) (MBC

VOL 12 15351

From the mid-1700s to the mid-1800s, inland vegetation was altered. Coastal scrub was converted to grassland as a result of burning and grazing (Johnston 1962). Smoke levels probably increased and bacteria from livestock entered streams draining to the sea. Without the Indians, intertidal organisms may have received a brief respite from fishing pressure, as the Europeans focused on fish, whales, and game. However, fishing and hunting pressure increased with firearms and better fishing methods, with marine mammals, seabirds, and water fowl probably the most affected (MBC 1988).

Although they occurred throughout history, major storms were first recorded in the 1800s. Storms from the southeast were common in the early 1800s and they often generated waves to 40 ft or higher (Kuhn and Shepard 1981).

EARLY STATEHOOD: 1850 TO 1899

In 1850, California became the 31st State. The collection of warm-water fish species in southern California in the 1850s suggest that El Niño events occurred during this time (Hubbs 1949). Extremely heavy rain fell in 1862 and from 1884 to 1891, causing the Los Angeles River to shift course between Ballona Creek and San Pedro (Kuhn and Shepard 1981). These storms probably affected beach erosion, offshore sedimentation, and coastal turbidity for months (MBC 1988).

Between 1864 and 1885 a whaling station was operated at Portuguese Bend (Sayers 1984) and by 1879 commercial and sport fishing had begun in Santa Monica Bay. Commercial landings at Los Angeles were dominated by pelagic and nearshore fishes (Jordan 1887).

Through the early 1870s the Santa Monica Bay region was largely open land used for cattle grazing, and very few Americans held land in the area. In 1872, 38,000 acres of Spanish Ranchos were purchased by New Englander Robert Baker, who hoped to develop a railroad terminus and shipping port. In 1875, when the local population was about 1,000, Baker sold two-thirds of his land to Senator John P. Jones of Nevada, who wanted to build a railroad to transport silver to ocean ports (Ingersoll 1908). Shortly thereafter the population began to grow, out of interest in Jones' plans and the emerging popularity of the area as an ocean resort. By 1877 the Comstock Crash forced Jones to sell the Los Angeles and Independence Railroad to Collis Huntington. The large ranchos were subdivided and sold to easterners and property values began to rise.

In 1878 the Southern Pacific Railroad dismantled the Santa Monica wharf, whereupon business declined. Santa Monica attempted to offset the loss of railroad and wharf resources by promoting its image as an ocean resort. This image was enhanced in 1886 with the construction of the luxurious Arcadia Hotel, which attracted people from all over the world. Santa Monica was also convenient for residents of Los Angeles and increasing numbers of people moved to Santa Monica and commuted to jobs in Los Angeles.

In 1891 Collis Huntington built a larger wharf in Santa Monica, intending to regain the shipping trade. Santa Monica and San Pedro vied for over five years as the location of a deep water port for the Los Angeles area, as the region had no natural harbor. The selected city would receive $3 million in federal funds to construct the new port. The Free Harbor League, an association of 400 members, supported San Pedro as the port site. Both public officials and private citizens feared that if located at Santa Monica, Collis Huntington and his Southern Pacific Railroad would dominate the port and form a monopoly. In 1897 the Army Board of Engineers

1988; SCAG 1991). In 1990 18.6% of the employed residents were in managerial, executive, and administrative positions (USBC 1990; CSM,PPD unpubl. data)

The income of Santa Monicans is also higher than the statewide average: in 1990 the mean household income in Santa Monica was $55,522, 20% higher than the state mean of $46,247. The number of housing units has increased at a slower rate than that of population or employment (Figure 4-1) (MBC 1988; SCAG 1991). Most Santa Monica residents rent; in 1990 only 26% of the 47,753 housing units in Santa Monica were owned by the occupant (USCB 1990; CSM,PPD unpubl. data). Rent control ordinances enacted in the 1980s have stabilized housing costs and apparently residents are reluctant to relocate from their current, low-cost homes.

Santa Monica continues to grow: the population is expected to increase 20% between 1990 and 2000 to approximately 104,683 persons (Figure 4-1) (USCB 1940, 1950, 1960, 1970; MBC 1988; SCAG 1991). A large percentage of residents continue to hold managerial, administrative and professional positions, but retail positions account for 13.6% of total employment (USCB 1990; CSM,PPD unpubl. data). The predominant land use is residential (61%), followed by commercial (22%), and industrial (6%) (Table 1-3) (SCAG 1992a). The tendency to keep industry to a minimum is still apparent: in 1991 9.8 million ft^2 were in commercial use and only 1.7 million ft^2 in industrial use (CSM 1991).

Education is important to the residents of Santa Monica: 87% are high school graduates and 70% have completed one or more years of college (USBC 1990; CSM,PPD unpubl. data).

Los Angeles County

In the past decade, many Los Angeles area businesses and industries have been bought by out-of-state and foreign companies. For example, in 1987 Pacific Southwest, Western, and Aircal airlines were taken over by U.S. Airgroup of Washington D.C., Delta of Atlanta, and American of Dallas, respectively. As of September 1992, 45.8% of the large downtown office buildings were foreign-owned (Cushman Realty Corp. 1992).

Trade is a major factor in this trend. The Ports of Los Angeles and Long Beach (located just outside the study area in San Pedro Bay) constitute the fastest growing major cargo center in the world. The value of import-export cargo going through the Ports increased from $35.4 billion in 1983 to $56.2 billion in 1985, and from $61.8 billion in 1986 to $1 trillion in 1990 (Leinberger 1988, Journal of Commerce 1990).

The population of Los Angeles County has increased rapidly since 1920 (Figure 4-2) (MBC 1988, SCAG 1991). As of 1990 Los Angeles County had a population of 8,863,164 (Figure 4-2), 57% of whom were white, 32% foreign-born, and approximately 11% black. Twenty-two percent of the residents were over 60 years (up from 13.3% in 1970) and the median age of 30.7 was very close to the statewide median of 31.5 years. Employment in the County has increased steadily, but at a lower rate in 1980-1990 than the population (Figure 4-2) (MBC 1988, SCAG 1991). The mean household income of Los Angeles County was $47,252, comparable to the statewide mean of $46,247 (USCB 1990).

The number of housing units in Los Angeles County has increased steadily since 1920, but at a much lower rate than either the population or employment (Figure 4-2) (MBC 1988, SCAG 1991). Los Angeles has a young homeowners market; 32% of households are headed by people under the age of 35, compared to 29% nationally. The national average for households with a college degree is 21%; Los Angeles is slightly higher with 24%. Managerial and

VOL 12

1 5353

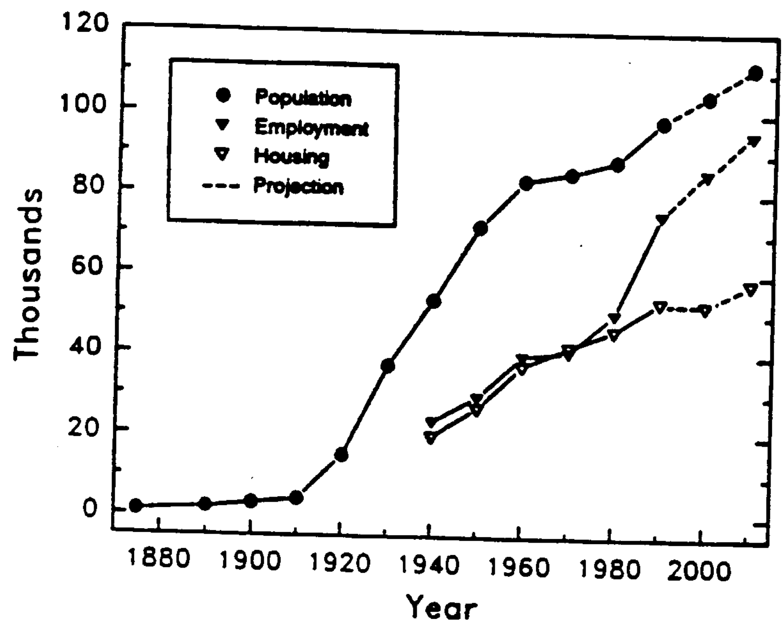

Figure 4-1. Population, housing, and employment trends in Santa Monica, 1875-2010 (data from MBC 1988; SCAG 1991; USBC, 1940, 1950, 1960, 1970, 1980, 1990).

professional positions are held by 27.5% of employed residents, while technical, administrative, and sales positions account for 32.3% (USCB 1990).

FUTURE PROJECTIONS

Housing in Los Angeles County is projected to increase by 879,538 units or 27.8% between 1990 and 2010, an increase which is close to the 28.3% increase projected for the population as a whole (Figure 4-2) (SCAG 1991). Housing in the Santa Monica Mountains area is projected to increase by 95.9% between 1984 and 2010. This increase is significantly higher than those projected for Central Los Angeles, Long Beach-Downey (10.5 and 21.9%, respectively), and for Los Angeles County as a whole (SCAG 1986).

The population of Los Angeles County is projected to increase by 2,514,032 or 28.3% between 1990 and 2010, an annual increase of 125,701 residents per year (Figure 4-2) (MBC 1988, SCAG 1991). The greatest increases will be in the Santa Monica Mountains and in East San Gabriel Valley, with increases of 84.3% and 56.8%, respectively. These projections are significantly higher than the 1.8 and 12.5% increases projected for Central Los Angeles and Long Beach-Downey (SCAG 1986).

The three basic components of population dynamics are births, deaths, and net migration. The first two components make up natural increases; net migration can be further separated into domestic migration (people moving to and from other parts of the nation) and foreign migration (including both legal and illegal immigration).

Immigration to California from elsewhere in the United States has eased due to the economy. In Los Angeles County there is an emigration of residents to surrounding counties. The major unknown is the rate of undocumented immigration from Mexico into southern California. In 1991 539,436 aliens were apprehended at the San Diego Zone of the Mexican border. The general rule is that for every apprehension at least two people enter the United States (Economic Development Corporation 1992).

Employment in Los Angeles County is projected to increase by approximately 1.2 million employees (25%) between 1990 and 2010 (Figure 4-2), a figure which is close to the projection of 26.2% for the City of Santa Monica (SCAG 1991). In recent years southern California has been shifting from a goods-producing, manufacturing economy into an information-based service economy. In 1991, the largest industry in the five-county Los Angeles area was business and management services (Calif. Employment Development Department 1992). The trend toward a service-based economy is expected to continue through the 1990s, then moderate between 2000 and 2010.

CHAPTER 5

POINT SOURCES OF CONTAMINATION

GENERAL CONSIDERATIONS

Numerous substances enter the waters of Santa Monica Bay via a variety of pathways. Some of these substances are neutral, some are beneficial, and some are detrimental to the Bay's environment. Some may not be particularly harmful alone but may have harmful synergistic effects when found with other substances. Those which have harmful effects on the ecosystem or on human health are generally considered to be contaminants or pollutants. "Pollutant" is often applied to contaminants resulting from human activities; these two terms are used interchangeably in this study. The effects of these contaminants on human health and on the ecosystem are discussed in subsequent chapters.

The point at which a body of water becomes contaminated differs for each contaminant and impact of concern (e.g., marine life, human health). The critical level for each contaminant is generally determined by scientific studies which test the toxicity or carcinogenicity of the contaminant against living organisms. Based on these studies regulations are made which restrict contaminant levels in input sources.

There is no single number or index by which the level of contamination of a water body can be measured; usually a water body is polluted in terms of some substances and perfectly normal as far as others go. The contamination of the body of water as a whole is determined by the diversity and levels of contaminants found but may also be determined by extremely high levels of specific substances alone. In general, unless a specific contaminant is extremely important (as with mercury in the Minimata disease of Japan; Eisler 1978), the degree of contamination of a body of water must be determined by comparison with other bodies of water with similar geographic and/or population settings.

Regulation of Contaminants

The U.S. Environmental Protection Agency (USEPA) has periodically issued ambient water quality criteria since 1969. The technical basis for water quality objectives are described in section 304(a) of the Federal Clean Water Act of 1977 and toxic pollutants are listed in section 307(a). The priority pollutant list includes about 126 substances and the list grows as more synthetic substances are developed and tested. Most of these substances are man-made compounds which have been shown to be toxic or carcinogenic, at least in laboratory animals. The EPA provides water quality criteria for 136 water contaminants; of these, 99 (73%) are priority pollutants and 50 (37%) are carcinogens. The remaining priority pollutants have not been studied sufficiently to define water quality criteria and standards at present (OWRS 1987).

The California Ocean Plan sets water quality objectives for contaminants discharged into the ocean off California from point and nonpoint sources. The plan sets criteria that apply to all discharges to the ocean off California excluding enclosed bays and estuaries (which are covered by the Enclosed Bays and Estuaries Policy) and thermal pollution (which is covered by the Thermal Plan). State-adopted numerical objectives have been set for 23 toxic materials and apply to all ocean discharges. Effluent limits have also been set for six other constituents or properties common in publicly-owned treatment works and industrial discharges but for which effluent guidelines were not established in sections 301, 302, 304, or 306 of the Federal Clean Water Act (CSWRCB 1990).

VOL 12

1537

The agencies which regulate contaminants in the study area and the pertinent regulations are described in SCAG (1988). In general, the U.S. Environmental Protection Agency (EPA) provides guidelines for water and air quality and human health. State agencies such as the California State Water Resources Control Board (CSWRCB), Regional Water Quality Control Board, Los Angeles Region (RWQCB,LAR); California Air Resources Board (CARB), and California Department of Health Services (CDHS) implement regulations prescribed in California law. Other state and federal agencies including the South Coast Air Quality Management District and the U.S. Food and Drug Administration, as well as city and county agencies also play important roles in regulating contamination in and around the Bay.

Physical/Chemical Processes

Most contaminants enter the marine environment by way of the water column. Once in the ocean the movement of contaminants is dictated by water turbulence, the direction and strength of currents, and the presence (or absence) of a pycnocline. The presence of a density gradient in the water column (pycnocline) restricts upward mixing of wastewater effluent and downward mixing of material discharged to the surface. The HTP and JWPCP sewage outfalls are located near the edge of the continental shelf, at the 200-ft depth contour. The HTP sludge outfall, which was inactivated in 1987, is located in about 300 ft of water, near the head of the Santa Monica Submarine Canyon. The configuration and location of these outfalls were designed to maximize dispersion and minimize transport of contaminants to the water surface or to the beach.

Drainage channels, on the other hand, provide a different input pathway, discharging into surface waters adjacent to the shoreline. Flow from these channels tend to form a freshwater surface layer, or lens, that is resistant to mixing with the underlying water.

The dilution and dispersion of dissolved or colloidal pollutants is entirely a function of the mixing and advection of water masses. Nutrients such as ammonia and phosphate are highly soluble and can be used to trace the dissolved component of sewage effluent plumes in the early stages of mixing. Dissolved contaminants can become associated with or transformed into particulates by the processes of sorption precipitation, and ion exchange. Sorption occurs more readily on fine-grained silts and clays than on coarse, sandy sediments. Fine suspended organic particles such as living or dead plankton and sewage particles have high sorption capacities, especially for dissolved organic contaminants. Trace metals absorb onto organic particles and iron or manganese oxyhydroxide phases, which form in oxygenated marine environments and coat the surfaces of particles.

The pathways followed by particle-bound contaminants are a function of particle density and current strength. Fine particles are easily transported by relatively slow currents; therefore they are easily dispersed. Studies of the distribution of suspended particulate material near the HTP 5-mi outfall indicate that the sewage plume rises rapidly from the discharge depth of 200 ft to about 66 ft below the water surface (Kolpack 1979). The initial direction of transport is toward the shoreline southeast of the outfall for most of the year, with wave action dispersing the plume over a large part of the Santa Monica shelf. Subsequent transport offshore occurs in well-defined zones near the sea surface.

Coarse-grained or dense particles are more resistant to transport. Sand accumulates on beaches because it is resistant to the wave energies that erode fine material. Similarly, coarse-grained material, which is resistent to turbulence and currents, accumulated near the HTP sludge outfall (Bascom *et al.* 1980). The settling of a particle onto bottom sediments does not mean that its journey is over. Stronger currents can rework the sediments, resuspending material and

VOL 12

1 5358

transporting it until the current velocity diminishes and the particles once again are deposited. Current velocities necessary for sediment resuspension in the vicinity of the JWPCP outfalls are often met (Hendricks 1976).

Water depth determines the susceptibility of sediments to resuspension by storm waves. Storm waves introduce energy that is proportional to their frequency and size. Although shallow water sediments are most affected, severe coastal storms can resuspend accumulated contaminant-laden particles from greater depths. Chemical concentrations in vertical sediment profiles on the Palos Verdes Shelf indicate that surface sediment losses in the nearshore region were induced or accelerated by several severe storms (Stull *et al.* 1986a). Recent studies have indicated that DDT-laden sediments are periodically resuspended in relatively shallow shelf areas, transported and redeposited elsewhere along the shelf (Hendricks 1987).

The accumulation rate and the physical mixing of surface sediments also influence the fate of particle-borne contaminants. The accumulation rate is a function of the rate of supply from both natural and anthropogenic sources and current velocities at the sediment-water interface. Mixing of the surface sediments can result from the activities of benthic organisms, a process called bioturbation. Both sediment accumulation and mixing act to bury freshly settled particles, thereby minimizing the potential for resuspension. Because benthic mixing derives from the activity of organisms, it is either absent or reduced in sediments with low abundances of benthic organisms. In a recent 301(h) waiver application (LACSD 1988), it is argued that decreases in solids discharged from the JWPCP outfalls could increase contaminant levels in surface sediments on the Palos Verdes Shelf by causing the recent depositional conditions (which have buried large amounts of DDT) to return to the (presumably historical) erosional environment. In this scenario the contaminated subsurface sediments from historical discharges would replace the less contaminated sediments from more recent discharges and would be available for resuspension. The combination of reduced sediment accumulation rate and enhanced benthic mixing (greater densities of organisms which resulted from decreased levels of contamination in surface sediments) were identified as the primary determinants of DDT distribution along the 200-ft depth contour on the Palos Verdes Shelf.

Several processes enhance the size of particles and thus the speed at which they sink through the water column. Flocculation is aggregation of colloidal material as freshwater mixes with seawater; differences in ionic strength (electrical charge) between fresh and salt water cause changes in the charges of the colloids and they attach to one another. Coagulation is the aggregation of particles brought about by physical contact. The higher the concentration of particles, the greater the chances of collision, and the greater the possibility of particle aggregation. Coagulation is probably an important process in the vicinity of sewage outfalls and storm drains where the concentration of particles, particularly particulates rich in organic matter, is high.

Pollutants can be incorporated into biologically produced particles such as fecal pellets, which are relatively large and sink quickly. It has been suggested that vertical transport by fecal pellets is an important mechanism for transporting particles to the sediments.

The behavior of oil spills illustrates the complex array of pathways and processes followed by a single kind of waste. Crude oil consists of a variety of organic compounds, a small fraction of which are soluble in water. The lighter, less dense fraction floats to the water surface, where it may be incorporated into particles (including organisms) and sink; volatilized into the atmosphere; or degraded by exposure to sunlight. Denser materials aggregate into tar balls that sink to the bottom, where they are subject to erosion, burial by accumulating sediments, or degradation by organisms. Oil and grease in sewage effluent tend to rise to the water surface and undergo similar processes.

Biological/Chemical Processes

Biological processes further complicate the fates of contaminants. Organisms can store contaminants, or can transform and decompose them through their metabolic processes. The microbially mediated degradation of organic matter is an oxidative process that transforms it into basic inorganic components (i.e., carbon dioxide, water, ammonia, orthophosphate). Biodegradation can also be a less drastic process that changes an organic contaminant to a more oxidized form that may be more or less toxic than the original compound. The chemical form of a contaminant can also be changed by the process of biotransformation, whereby a pollutant form is altered by an organism to make it less toxic to that organism. Biological processes also affect the fate of contaminants indirectly by altering environmental parameters. Degradation of organic matter lowers the pH (increasing the acidity), reduces the oxygen concentration and redox potential, and produces chemicals such as ammonia and sulfide that can impact aquatic life and interact with contaminants.

Degradation of Organic Matter

Many types of microorganisms derive energy by degrading organic matter, which also triggers changes in pH and redox potential in the environment. Marine aquatic systems are well-buffered by the presence of carbonate alkalinity, and relatively small changes in pH typically accompany organic matter degradation (seldom decreasing below a pH of 7). Changes in redox potential are more extreme. The degradation (i.e., oxidation) of organic matter by microorganisms requires the concurrent reduction of an electron acceptor, which in most environments is oxygen. If organic loading is sufficient and available oxygen has been consumed, nitrate, sulfate, and carbon dioxide are utilized sequentially as electron acceptors, producing reduced forms of these chemicals. The change in redox potential that accompanies organic matter degradation can change the oxidation state of some metals. Iron and manganese, which are present as insoluble oxyhydroxides under well-oxygenated conditions, are much more soluble in their reduced form. Moreover, metals that are sorbed to the surfaces of iron and manganese oxyhydroxides under well-oxygenated conditions may become mobilized as the phase undergoes dissolution in reducing environments. The reduction of sulfate is a particularly important process because sulfide is the degradation product. Many metals react with sulfide and precipitate as metal sulfides.

Bioaccumulation

The uptake and retention of chemical contaminants by organisms is called bioaccumulation. Chemical properties that make a particular contaminant more prone to bioaccumulation (i.e., that increase its solubility in fatty tissue) were described in the section on Chemical Properties and Behavior. Characteristics of organisms that result in high bioaccumulation potential include: 1) having a high fat content, 2) living on or near the bottom sediments, 3) filter-feeding on organic particles, and 4) being high on the food chain. Examples of such organisms include demersal fish (e.g., Dover sole), mussels and clams (filter feeders), and seals (high in fat and the top carnivore). Greater accumulation of a contaminant by organisms higher on the food chain is termed biomagnification. The accumulation of contaminants by the biota may result in biological effects to contaminated organisms or their predators.

Studies of the spatial distribution of hazardous substances in mussel tissues indicate that elevated concentrations of silver and chromium are found in the vicinity of the JWPCP and HTP outfalls, while elevated concentrations of lead and PCB are more widespread. Interpretation of fish bioaccumulation patterns indicates that the JWPCP and HTP outfalls may be major sources of PCB, but elevated tissue concentrations of PCB are found far from these outfalls because fish are mobile. The highest concentration of DDT in fish tissue occurs near the JWPCP outfall, a documented historical source. Spatial and temporal patterns in contaminant bioaccumulation in Santa Monica Bay are described in greater detail in Chapter 12.

Biotransformation of Contaminants

Microorganisms are responsible for most of the biotransformation or biodegradation of contaminants that occurs in the environment. Highly chlorinated hydrocarbons like PCB and DDT are relatively resistant to degradation, but are slowly degraded over time. DDT, a major contaminant in Santa Monica Bay, is slowly degraded to DDD and DDE. Measurements in sediments on the Palos Verde Shelf, described in Chapter 9, indicate that degradation of DDT is more rapid in shallow water than in deep water, as indicated by a comparison of DDE/DDT ratios. The redox potential may influence the rate of contaminant degradation. The degradation of anthracene and naphthalene (PAH) is not observed in sediments in the absence of oxygen. Under toxic conditions, these lower molecular weight PAH compounds are more susceptible to degradation than higher molecular weight PAH compounds.

The microbial synthesis of methylmercury is a good example of the process of biotransformation. The microbial synthesis of methylmercury and other organometallic compounds has advantages for cellular elimination because nonpolar compounds are more easily transferred across the cell membrane (Wood and Wang 1983). Unfortunately, these compounds are more easily bioaccumulated by higher organisms for similar structural reasons.

Sources of Contamination

Contaminants entering Santa Monica Bay may originate on land, in the air, or at sea outside of the Bay itself. The ultimate source of a contaminant, as used here, refers to the place at which it is introduced into the system that carries it to the ocean. The proximal source of a contaminant is the point or pathway by which it actually enters Santa Monica Bay. The ultimate source of most lead in the local environment was the leaded gasoline used in automobiles. After combustion, some lead entered the atmosphere and eventually landed on the ocean surface as aerial fallout -- a proximal source. Other lead particles adhered to material on streets and driveways and eventually entered Santa Monica Bay with storm runoff -- another proximal source.

The variety of ultimate sources of contaminants found in Santa Monica Bay is great, (Table 5-1) and it would be nearly impossible to identify all the possible sources for all the possible contaminants in the Bay. Knowledge of ultimate sources is especially important when source control programs are at issue, whereas knowledge of proximal sources helps to explain the distribution of contaminants in the Bay. There are two general kinds of proximal sources -- point sources and nonpoint sources -- although the distinction is sometimes difficult to make.

A point or discrete source is an identifiable place at which substances enter the receiving waters (usually continuously) and at which water quality samples can be taken repeatedly; it is usually a pipe or open drain built specifically to carry the waste material. Point sources include outfalls for municipal wastewater discharges, power plant cooling water discharges, and industrial waste effluent. All point sources which discharge to the Bay are issued National Pollutant

VOL 12

15361

Table 5-1. Ultimate sources of contaminants found in Santa Monica Bay.

Trace Metals:	
Dissipative decay of products containing the contaminant. Combustion of coal, residual oil, distillate oil, gasoline, and other fossil fuels.	
Cadmium:	Oil and gasoline combustion, batteries, pigments, plastics, synthetics, plating, galvanized pipe, photoelectric cells
Copper:	Oil and gasoline combustion, paint, electrical, building, automobiles, manufacturing, antifouling paint, pipes, roofing insecticides
Chromium:	Oil and gasoline combustion, Chemical industrial (Chromite, chromic acid, sodium dichromate), pigment, plating, protective coating
Lead:	Oil and gasoline combustion, paint, antifouling paint, lead metal, storage batteries, pigments, lead arsenate
Mercury:	Oil and gasoline combustion, industrial catalysts, agriculture, dental preparations, thermometers, barometers, electrical, paints, antifouling paint, pharmaceuticals, batteries
Nickel:	Stainless and heat-resistant steel, alloys, cast iron, electroplating, catalysts batteries, protective coating
Selenium:	Electronics, photographic uses, catalyst
Silver:	Chemical industry, electronics, plating, alloys
Tin:	Antifouling paint, pewter, plating, alloys
Zinc:	Oil and gasoline combustion, alloys, paint, pigment, plating, batteries, auto parts
Inorganic, Non-metallic Constituents:	
Chlorine:	Antifouling agent for generating stations, disinfectant
Phosphate:	Fertilizer, detergent
Nitrogen:	Fertilizer, refrigeration
Pesticides:	
DDT:	Montrose Chemical Corp., Torrance (past) agricultural application to: grains, vegetables, small fruits, grapes, nuts
Chlordane:	Private and industrial application to structures and vegetation; primary use for termite control
BHC/lindane:	Agricultural application to vegetables, grapes
Aldrin:	Agricultural application to vegetables
Dieldrin:	Agricultural application to vegetables, small fruits, hay
Endrin:	Agricultural application to cereals, vegetables
Heptachlor:	Agricultural application to vegetables, hay
Toxaphene:	Agricultural application to vegetables, grains, cereals
PCBs:	
Direct discharge from production facilities into holding reservoirs, receiving waters, municipal sewerage	
Decay of products releasing the contaminant to the environment: transformers (approx. 2150 lbs each); capacitors (approx. 25 lbs each); antifouling paint; plasticizers; lubricants; heat transfer fluids; hydraulic fluids; wax extenders; fluid in vacuum pumps; and compressors	
Other Organic Compounds:	
PAH:	Crude oil, fuel oil, crankcase oil; combustion releases contaminated soot which falls back on land
Phenol:	Phenolic resin, fuel-oil sludge inhibitor, solvent, rubber chemicals
Detergent:	Emulsifier, soap
BOD:	Organic material including human and animal waste and food refuse

Discharge Elimination System (NPDES) permits by the Regional Water Quality Control Board with the concurrence of the U.S. Environmental Protection Agency.

A nonpoint or diffuse source is widespread, changing, or not identifiable; as such it may be difficult to sample. Nonpoint sources include aerial fallout, surface runoff, advective transport, ocean dumping, and boating and shipping activities. Aerial fallout and advection are clearly diffuse, whereas surface runoff and ocean dumping have some discrete aspects. Offshore petroleum activities which may occur in the area in the future also have point and nonpoint aspects. Offshore oil production platforms, for example, are required to have NPDES permits for the discharge of treated sewage, drilling muds, and cuttings; however, deckwash from a moving work boat is diffuse.

The Clean Water Act considers storm drains to be a nonpoint source of contaminants even though the effluent from a single drain can be sampled repeatedly. However, many channels drain to the Bay, resulting in a diffuse input of contaminants along the shore after a storm. At present, storm water is not treated and there are no facilities for storing it for later treatment. The operating and regulatory agencies have only limited power to control what is discharged into the drainage system upstream and little or no power to enforce effluent limitations or water quality objectives.

Los Angeles County and 89 cities in the Santa Monica Bay watershed have received NPDES permits requiring them to control pollution from urban runoff. In addition, industrial facilities and construction sites also receive general stormwater discharge permits. Operators and regulators must encourage source control programs (Best Management Practices) which reduce the likelihood of contaminants entering the system.

There are seven facilities in the study area with NPDES-permitted point discharges: three municipal waste treatment plants; three coastal generating stations; and one oil refinery (Figure 5-1). With the exception of the Joint Water Pollution Control Plant (JWPCP) outfalls at White Point on the Palos Verdes Peninsula, and the Tapia Water Reclamation Facility (TWRF) on Malibu Creek, these facilities discharge offshore in the south-central part of the Bay between Playa del Rey and Redondo Beach.

POINT SOURCES

Municipal Wastewater Treatment Plants

Municipal wastewater in the Los Angeles region includes sewered wastes from domestic, commercial, and industrial sources. Storm water runoff is collected in a separate system, although some infiltrates into sewers during exceptionally heavy rains. Residential sewage contains a variety of household cleaners and detergents; oil, grease, and solvents; food wastes; and enteric bacteria from human fecal waste. Commercial and industrial wastes include oils and grease, metals, and a variety of synthetic organic substances. About a 100 gal of sewage per capita per day is discharged into the study area (Barletta and Webber 1986; CLA,DPW 1988; Stull 1988, pers. comm.). Human fecal waste is produced at the rate of about 75 g (dry weight) – just under one-sixth of a pound – of solids per person per day (Bascom 1977).

Municipal wastes are collected by an extensive network of main and feeder sewers which drain into central treatment plants. The level of treatment which is attained can vary widely. Raw sewage (i.e., untreated sewage) is ordinarily not discharged to the ocean or any stream discharging into the ocean. Sewage is initially subjected to preliminary treatment, which consists

VOL 12

1 5363

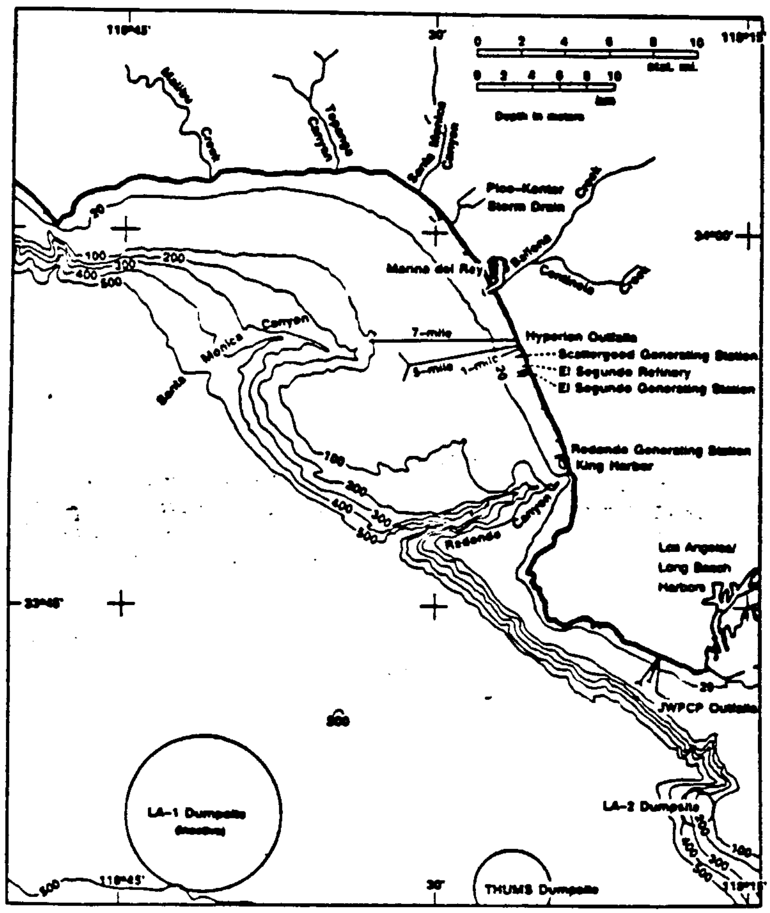

Figure 5-1. Major point and nonpoint sources in the Santa Monica Bay area.

VOL 12

1 5364

R0048669

of screening, comminution (pulverization), and grit removal. Primary treatment consists of the removal of much of the suspended solids by sedimentation but not colloidal and dissolved matter. It does not include biological oxidation and usually consists of clarification with or without chemical treatment. At the end of this stage substantially all floating and settleable solids have been removed (Rogers *et al.* 1981).

Secondary treatment is defined by the U.S. EPA in terms of BOD-5, suspended solids, and pH, and is primarily a biological process (e.g., activated sludge) followed by settling that produces an effluent very low in solids, BOD, and sludge (Dorsey 1993, pers. comm.). Tertiary treatment (advanced waste treatment) includes the removal of nutrients (e.g., nitrogen and phosphorus compounds) and most of the remaining suspended solids. Finally, the effluent may be subjected to disinfection, whereby the effluent is treated with a disinfectant (e.g., chlorine or sulfur dioxide) to kill bacteria and viruses (Rogers *et al.* 1981, Dorsey 1993, pers. comm.).

The Clean Water Act (Public Law 92-500) of 1972 requires all domestic wastewater dischargers in the nation to achieve a minimum of secondary treatment. The effluent may have no more than 30 *mg/l* of biological oxygen demand (BOD) and of total suspended solids (TSS) (CLA,BE 1977). However, in 1977 Congress amended the Clean Water Act to add section 301(h) which provides for a NPDES permit with modified secondary treatment requirements (i.e., less than secondary). At present the Los Angeles County Sanitation Districts (LACSD) have been granted an evidentiary hearing after being denied a 301(h) waiver for the JWPCP discharge and judgment is pending. Hyperion Treatment Plant was denied a waiver and is presently upgrading their treatment to full secondary treatment, which is scheduled to be in place by 1998. Although full secondary treatment has not been attained by these dischargers, the quality of discharged wastewaters has improved greatly in recent years. This is the result of more stringent regulations with better enforcement; improved waste treatment technology and facilities; and better source control through education and enforcement.

Two municipal wastewater treatment plants discharge directly into Santa Monica Bay: Hyperion Treatment Plant (HTP) and Joint Water Pollution Control Plant (JWPCP). The Tapia Water Reclamation Facility (TWRF) discharges tertiary-treated wastewater into Malibu Creek.

Hyperion Treatment Plant

At one time raw sewage from the City of Los Angeles was used, untreated, for irrigation. The first ocean outfall was completed in 1894 and discharged across the beach near the present site of HTP. In 1907 a new outfall was constructed which discharged at a water depth of 16 ft. After the Los Angeles-Owens River Aqueduct was completed in 1913, much of the San Fernando Valley was annexed to the City of Los Angeles. Because of population growth and storm overflows in the 1920s, a screening plant and a new submarine outfall was built at HTP in 1925. In 1943, because of nearshore odors, discoloration, grease, and high levels of the bacteria E. coli (Dorsey 1993, pers. comm), the State Board of Health quarantined about 10 mi of beach from Hermosa Beach to Venice Beach. Soon an upgraded HTP was designed to implement full secondary treatment, with a high-rate activated sludge system, digestion, and sludge-drying facilities. HTP was placed on-line in 1950 and began discharging 193 mgd of chlorinated, secondary effluent through a 12-ft diameter concrete pipe one mile offshore, at a water depth of 50 ft (WSED 1982, CLA,DPW 1987; Dorsey 1988, 1993, pers. comm.).

Continued growth and the threat of beach contamination resulted in the construction of a 12-ft diameter pipe which discharges 5 mi offshore at a water depth of 190 ft. This pipe, built in 1959 and in full service by 1960, has a Y-shaped end with 83 diffuser ports (WSED 1982;

VOL 12 15365

Dorsey 1993, pers. comm.). HTP was also modified at this time to provide 100 mgd of activated-sludge, secondary treatment, and up to 420 mgd of primary treatment.

Beginning in 1950 an effort was made to recycle digested solids as fertilizer but this resulted in air pollution and was uneconomical to operate. The excess solids which could not be processed were discharged into nearshore shallow waters and created a water pollution problem. To rectify this, a 7-mi long 20 in diameter sludge pipe was constructed to discharge at the head of Santa Monica Canyon to a depth of 320 ft (WSED 1982). This pipe became operational in 1957 (Carlisle 1969, SCCWRP 1986b, CLA,DPW 1987) but use was discontinued in November 1987 (CLA,BE 1977; CLA 1987). At that time about 80% of the dewatered sludge was being transported to a landfill with the remaining 20% being treated by Chemfix, a chemical fixation process whereby the sludge is mixed with lime and silicate to produce a clay-like product (CLA 1987; Crosse 1988, pers. comm.).

By 1989, all sludge, now referred to as biosolids, was being recycled; none went to landfills. Presently, about 1,100-1,200 wet tons per day of biosolids are used as follows:

14% Dehydrated and combusted in HTP's cogeneration facility (Hyperion Energy Recovery System - HERS)

31% Directly injected into agricultural fields for crops not used for human consumption

39% Composted along with bulking materials (e.g., farm wastes, some green trimmings from the City) to produce a soil amendment for agriculture and horticulture

16% Chemically stabilized with lime and silicate to produce part of a clay-like substance used for covering landfills (Dorsey 1993, pers. comm.)

In 1988 HTP increased secondary treatment to 165 mgd from 90 mgd in 1985 (CLA,DPW 1988). This increase in secondary treatment is a direct result of the replacement of the air delivery system with a fine-bubble diffuser system, chemical addition to enhance capture of solids during the primary treatment phase, and development of innovative operating parameters which produced a high rate, secondary treatment operation (Dorsey 1993, pers. comm.) The improvements in the quality of effluent can be attributed to the Hyperion Interim Improvement Plan of 1986. The plan set compliance limitations which were revised in 1991 for BOD, total suspended solids, oil and grease, and settleable solids (CLA,DPW 1991). To achieve the 1991 levels, upgrades in chemical addition and aeration resulted in a 35% reduction of BOD in primary effluent, which allowed for an increase of up to 200 mgd of secondary effluent treatment (CLA,DPW 1991). HTP continues to decrease mass emissions of constituents in effluent discharged from the 5-mile pipe and in 1992 reached the 1998 mandated limitations for all constituents except BOD (Dorsey 1993, pers. comm.). The Hyperion Full Secondary Expansion Program is expected to be fully operational by 1998.

Influent Waters. As of 1990 the City of Los Angeles was treating wastewater of 3.5 million people over an area of 600 mi^2 (Figure 5-2). Most waste is processed at HTP but waste from San Pedro, Wilmington, and Terminal Island is processed at the Terminal Island Treatment Plant and discharged into outer Los Angeles Harbor (Barletta and Webber 1986). The wasteshed of HTP is about 480 mi^2.

VOL 12

1 5366

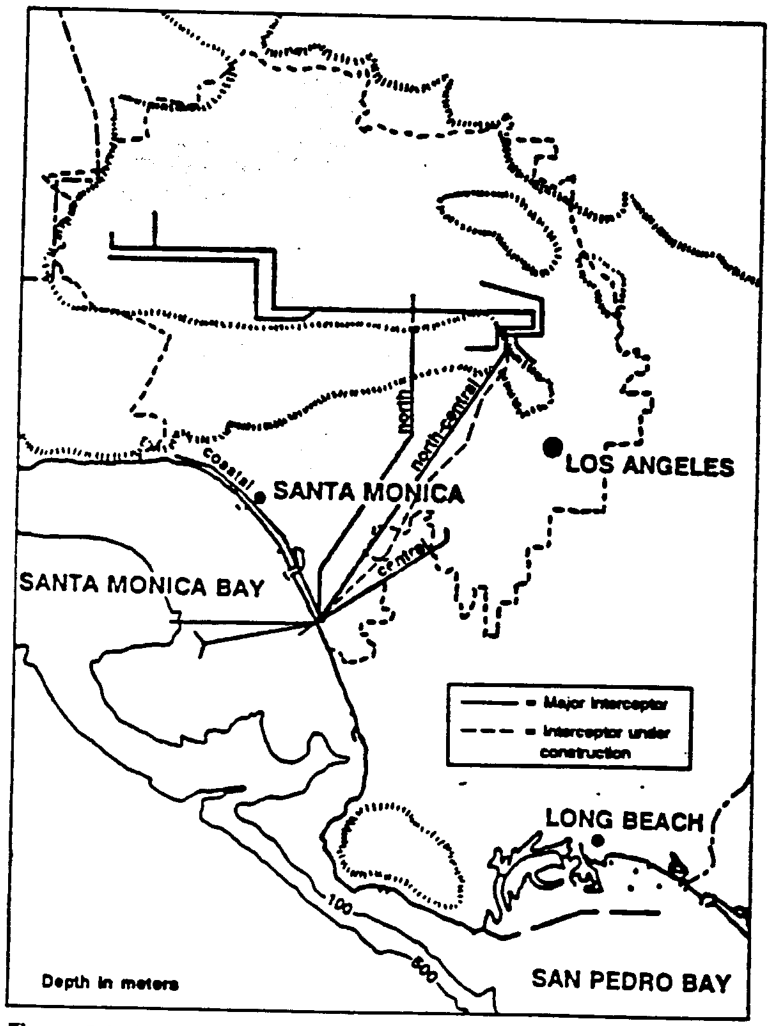

Figure 5-2. HTP watershed and influent collector lines (modified from CLA,DPW 1987 and 1993).

VOL 12

1 53567

HTP is supplied via four main collector lines (Figure 5-2). A new main sewer pipe, the North Outfall Replacement Sewer (NORS), was completed late in 1992 and is expected to be fully on-line by spring of 1993. When NORS goes on-line, the North Outfall Sewer (NOS) will be refurbished (Figure 5-2) (Dorsey 1993, pers. comm.). The influent sewage delivered by the present four tributary lines has remained fairly consistent since 1975, fluctuating annually due to wet and dry years. Influent sewage flow generally increases during heavy rainfall periods as surface runoff enters the system (Dorsey 1988, pers. comm.). About 85% of the influent sewage is domestic and about 15% is industrial (Crosse 1988, pers. comm.). Approximately 52% comes from the north collector, 35% from the north-central, and 6 to 7% each from the coastal and central collectors. Most constituents (i.e., potential contaminants) are also from the north outfall, followed by the north-central collector (CLA,DPW 1988).

In 1986 the total influent averaged 1.26 g/l of solids, about 75% dissolved and 25% suspended. The north-central line was the major contributor of phenols, cadmium, total chromium, nickel, sulfate, total identifiable chlorinated hydrocarbons (TICH), total pesticides, heptachlor, and lindane. The coastal line contributed most of the chloride, magnesium, and sodium, probably a result of saltwater intrusion into the outfall (CLA,DPW 1988).

Treatment. In 1991 HTP processed about 349 mgd of wastewater. Presently 60% of the flow receives secondary treatment and sludge digestion (CLA,DPW 1991; Dorsey 1993, pers. comm.). The influent is initially treated with chemicals to enhance the capture of solids and to control odors; the raw sewage is then screened and grit is removed. Next it is sent to primary settling tanks and from there to the secondary treatment system. In the secondary treatment system the primary effluent is pumped to aeration basins where oxygen and activated (biological) sludge are added to reduce the amount of organic matter. After four hours this effluent is pumped to secondary clarifiers which allow the activated sludge to settle out and be recycled. Of the secondary effluent, 30-40 mgd are recycled within the plant (mainly in the HERS process). The remaining effluent is blended with primary effluent and discharged from the 5-mile outfall (Dorsey 1993, pers. comm.). Most volatile organics are lost to the air during secondary treatment and metals (particularly chromium and copper) concentrations are reduced by adsorption to the particulates which are removed during treatment (Young 1978; Dorsey 1988, pers. comm.).

Mass emissions of most constituents have decreased in recent years due to improved chemical treatment and an increase in secondary treatment from 100 mgd in 1986 to 200 mgd in 1991. HTP expects to provide full secondary treatment by 1998, a project that is expected to cost $1.1 billion (CLA,DPW 1987; Biagi 1988, pers. comm.). The Hyperion Energy Recovery System (HERS) became fully operational in 1989 producing over 100 million kwhs of electricity and up to 28,000 tons of steam used for the energy recovery system (CLA,DPW 1988, 1989, 1990, 1991). By 1991 it produced 146 million kwhs, an increase of approximately 45% from 1988. Increases in the amount of electricity and energy recovery were due to improvements in on-line availability of turbines, generators, and the retrofitting of new gas burners into all of the combustion trains (CLA,DPW 1991).

Volumes Discharged. The volume of wastewater discharged from HTP has generally increased since 1950, when 193 mgd was discharged (Dorsey 1988, pers. comm.). During the first 6 years of operation, the combined flow from the 5- and 7-mile outfalls ranged from 261 to 283 mgd (Carlisle 1969); between 1974 and 1987 the combined flow averaged 371 mgd. During this period, flow from the 7-mile sludge pipe averaged 1.2% of the combined flow (Mitchell and McDermott 1975; Schafer 1976, 1977, 1978, 1980, 1982, 1984; SCCWRP 1986a; CLA,DPW 1987, 1988).

From 1987 to 1992 the total volume discharge from the 5-mile effluent pipe decreased from 375 mgd to 298 mgd (Figure 5-3 and Appendix D). In 1989 the flow increased slightly to 365 mgd then continued to decrease to the current level of 298 mgd in 1992. The average flow between 1988 and 1992 was 339 mgd, which is approximately 10 percent lower then the 1974-1987 period.

5-mile Effluent. The 5-mi outfall discharges a nonchlorinated mixture of primary and secondary effluent. This effluent is usually discharged by pumping during daily peak periods or storm flow; however, during low flow periods it is usually discharged by gravity (Dorsey 1988, pers. comm.). From 1974 to 1987 an average of 367 mgd of effluent was discharged from this outfall. This compares with an average discharge of 343 mgd for the period 1987 to 1992, a decrease of approximately 07% over the previous 13 year period (Figure 5-3 and Appendix D).

The lowest mass emission values for BOD, TSS, settleable solids, and oil and grease were recorded in the period 1987 to 1992 (Figure 5-4 and Appendix D). Peak values for these constituents reported in 1985 were caused by hydraulic overloading, increased influent flow, and construction at HTP, which resulted in a temporary reduction in the number of primary tanks in operation (SCCWRP 1986a; Dorsey 1988, pers. comm.).

Nitrate nitrogen was measured at 141 MT in 1974, however, no measurements were taken for the period 1975 through 1984. Levels for the remaining 8 year period ranged from a reported high of 273 MT in 1989 to a low of 110 MT in 1992, a decrease of approximately 60% (Figure 5-4 and Appendix D).

From 1974-1988, phenols decreased 96% from a high of 28 MT (Figure 5-4 and Appendix D). Mass emissions for phenols have remained relatively constant averaging 0.8 MT for the 5 year period 1988-1992. Mass emissions for cyanide have remained within a fairly consistent range from 14.0 to 6.6 MT since 1984, compared with a range of 94.2 to 25.0 MT in the preceding 10 year period.

Mass emissions for organic nitrogen, total phosphorus and detergents (MBAS) remained constant from 1975 through 1987. Levels for phosphorus elevated to 6,180 MT in 1985 but declined from there to the 1992 value of 2,530 MT. MBAS stabilized at approximately 1,500 MT in 1987, the last year measurements were available. Although ammonia nitrogen levels have fluctuated since 1974, the general trend indicates a gradual increase in mass emissions for this constituent, from a low in 1974 of 6,501, to the present high of 12,203 MT (Figure 5-4 and Appendix D).

In general, from 1974 to 1992 mass emissions of trace metals from the 5-mile outfall declined, with some metals displaying periods of fluctuation (Figure 5-4 and Appendix D). Overall, discharges of trace metals declined during the 1974-1992 period by the following percentages: silver (66%), arsenic (47%), cadmium (99%), chromium (97%), copper (82%), mercury (99%), nickel (92%), lead (96%), and zinc (69%) (Appendix D).

Total DDTs and PCBs were measured by different methods from 1974 to 1979 than from methods used during 1980 to 1987, therefore, reported values for the two periods may not be comparable. During the earlier period values were generally higher; however, DDT levels dropped sharply after 1976 and PCBs after 1978 (Figure 5-4). Since 1987, mass emissions for DDTs and PCBs have remained under the detection limits with the exception of trace amounts of DDT measured in 1991 (Figure 5-4 and Appendix D). The decline of DDTs and PCBs is credited to prohibitions placed on their use and production during the 1970s.

VOL 12

15372

R0048677

7-mile Effluent. Between 1974 and its discontinuation in November 1987, the 7-mi pipe discharged an average of 4.4 mgd of a mix of secondary effluent and digested sewage sludge. Annual mass emissions and concentrations of total suspended solids (TSS) averaged 50,030 MT from 1974 to 1985 while those of oil and grease averaged 2,687 MT (CLA,DPW 1988). TSS and oil and grease levels peaked in 1975 and were relatively constant since 1979 (Mitchell and McDermott 1975; Schafer 1976, 1977, 1978, 1980, 1982, 1984; CLA,DPW 1988). BOD was not reported because no limits were set, but levels in sludge were generally high (Dorsey 1988, pers. comm.).

A complete scan of EPA priority pollutants in sludge from the 7-mi outfall in 1978 identified three volatile organics (1,2-trans-dichloroethylene; ethylbenzene; toluene) and two extractable organics (4-nitrophenol; phenol) which exceeded 10 ppb, the EPA mandated quantification limit (Young 1978).

Sludge Removal. Since the termination of the 7-mile sludge outfall in 1987, sludge wastes have been relegated to land disposal locations, for land applications, nonconsumption agriculture, chemical fixation for cover material at landfills, HERS, or landfill. All sludge is anaerobically digested and dewatered by centrifuge with polymer conditioning to 20% solids (CLA,DPW 1988). Quality assurance measures have been implemented by HTP to regulate and monitor contamination levels of sludge. Materials found hazardous must be disposed at an alternate disposal site that meets with California State codes regarding the disposal of contaminated material.

In November of 1987, all sludge was hauled to landfill sites for disposal, the most economical and flexible method of disposal at the time. By 1988 alternatives for sludge (biosolids) disposal resulted in 181 metric tons per day (MT/d) used for land application, 181 MT/d for cover material, (chemical fixation), 181 MT/d for HERS, and 590 MT/d relegated to landfill disposal, for a total of 1,134 MT/d. By 1989 biosolids disposal at landfills was halted. Disposal at alternative sites in 1992 accounted for 100% of all material with 31% for land applications, 39% for city composting, 16% for chemical solidification, and 14% for use by HERS, accounting for approximately 1,100-1,200 wet tons per day (Dorsey 1993, pers. comm.)

1-mile Effluent. Power outages or mechanical failures (which are usually associated with periods of heavy storm flow) occasionally cause effluent pumps to malfunction. When pump failure occurs, part of the 5-mile effluent is diverted to the 1-mile outfall. Since 1988 overflows into the 1-mile outfall have occurred 25 times, ranging from a high of 8 in 1988 to none in 1992 with an average of 5 bypasses per year (CLA,DPW 1988-1991). Such diversions to the 1-mile outfall are now rare, but when the need to divert occurs, the flow is split between the 1- and 5-mile outfalls with primary/secondary blend discharging to the 5-mile, and chlorinated secondary to the 1-mile (Dorsey 1993, pers. comm.).

Storm overflows. Increased inflow and infiltration into the North Outfall Treatment Facility during rainstorms occasionally necessitates discharges into Ballona Creek, although the facility can store about 1.1 million gal before this occurs. Such overflows presently receive primary sedimentation, two stages of screening, and chlorination at 40 *mg/l* (Crosse 1988, pers. comm.). The chlorination results in at least a four-order of magnitude bacterial kill (Crosse 1988, pers. comm.; Dorsey 1988, pers. comm.). However, there have been overflows in the past consisting of raw sewage (Sowby 1988, pers. comm.).

Ninety-four incidents of overflow discharges into Ballona Creek (and other storm drains) were recorded between 1965 and 1992 (Appendix H); none occurred in 1968, 1972, 1973, 1975, 1976, 1989, or 1991. Between 1965 and 1987, the average overflow lasted approximately 5.8 hr and discharged average of 4.6 million gal (Crosse 1988, pers. comm.). Between the years 1988 and 1991, three wastewater overflows entered Ballona Creek discharging an average of 3.4 million gal (Appendix H). On three consecutive days of heavy rain in February 1992, overflow discharges totaled 66 million gals with the average overflow lasting 9.2 hours (CLA,DPW, unpubl. data).

The primary reason for these overflows is the inability of the old NOS line to handle excessive water during storms. The new NORS line, completed in 1992 and due on-line in 1993, will be able to handle a total system flow to HTP of approximately 850 mgd (Figure 5-2). Presently HTP is unable to handle flows over 680 mgd, but interim projects scheduled for completion by spring of 1993 will enable the plant to receive system-wide flows to 850 mgd (Dorsey 1993, pers. comm.)

Permit Requirements. From 1979 to 1987 HTP discharges were subject to the requirements of an NPDES permit issued in 1979 that had expired in 1984. In 1987 a new permit was issued which established discharge limitations for 27 constituents in the 5- and 1-mile effluent and the 7-mile sludge discharge, which was terminated in 1987. Because the EPA could not sanction the discharge of sludge, standards specific to sludge were not set in the NPDES permit; therefore, the sludge discharge was subjected to full secondary treatment standards (Dorsey 1988, pers. comm.). The constituents included BOD (5-day), suspended solids, oil and grease, settleable solids, turbidity, toxicity concentration (chronic and acute), arsenic, cadmium, chromium (hexavalent), copper, lead, mercury, nickel, silver, zinc, cyanide, total chlorine (residual), ammonia (N), nonchlorinated phenolic compounds, chlorinated phenolic compounds, aldrin and dieldrin, chlordane and related compounds, DDT and derivatives, endrin, HCH, PCBs, and toxaphene. These limitations generally included 6-month median values and daily maximum values. The same limitations were set on gross constituents (total suspended solids, settleable solids, BOD, oil and grease, turbidity, and toxicity) as well as limitations on residual chlorine for all three outfalls (RWQCB,LAR 1987).

In 1991 limitations on BOD, suspended solids, oil and grease, and settleable solids for the 5-mile pipe were revised to comply with a consent decree between the EPA, Region IX, and the RWQCB, LAR. HTP is currently in compliance with the permit scheduling to reach full secondary treatment by 1998.

Compliance with standards. During the past eight years the number of noncompliance with the 1-mi effluent limit has decreased. In 1985 the effluent exceeded the daily maximum discharge limits on occasion for five parameters: fecal coliform, residual chlorine, beta-radiation, chromium, and toxicity. The 7-day mean limits on fecal coliform were also exceeded. In 1986 the daily discharge limits were exceeded for three constituents. Beta-radiation levels were too high for the year, residual chlorine during five months, and fecal coliform during one month. In 1987 the daily limits of residual chlorine were exceeded in two months and the six-month median for beta-radiation was exceeded for the year (RWQCB,LAR 1988). From 1988 to 1992 compliance with NPDES permit requirements were met for all overflows through the 1-mile effluent outfall (Dorsey 1993, pers. comm.)

The 5-mile effluent has been well within compliance with all standards established in HTP's NPDES permit since 1987. Presently all effluent constituents are meeting the standards for full secondary effluent that will be required in 1998 (Dorsey 1993, pers. comm.)

VOL 12 1 5 3 7 4

Proposed Improvements. By 1998, HTP must be at full secondary treatment to comply with current NPDES regulations. In 1986, in order to comply with these regulations, HTP began the Interim Improvement Program to ensure that the highest quality of effluent was being discharged by the time the secondary treatment program was operational (CLA,DPW 1991). Recent improvements include a fifth pump in the effluent pumping plant and new maintenance facilities. Current construction includes a fully enclosed truck loading station to control odors, an intermediate pump station between primary and secondary systems, a cryogenic oxygen system and new secondary reactors and clarifiers for phase 1, and new headworks now in start-up (CLA,DPW 1991; Dorsey 1993, pers. comm.).

Proposed projects that will help HTP reach full secondary treatment by 1998 and increase the amount of effluent flow include; a dewatering centrifuge and anaerobic digester expansion for phase 1 and 1a respectively, medium and high pressure gas compressors, steam dryer for sludge dehydration, waste activated sludge thickening, and the expansion of cogeneration facilities to remain completely self sufficient. With current projects in construction and the proposal of future work HTP expects to be in full compliances of the 1987 consent decree to discharge full secondary treatment effluent.

Joint Water Pollution Control Plant

Until the 1920s most of the communities in Los Angeles County not serviced by HTP used cesspools and septic tanks. In the late 1920s the County Sanitation Districts were formed and White Point on the Palos Verdes Peninsula was selected as an ocean outfall site, partly because of its distance from the popular beaches of Santa Monica Bay.

The first Joint Disposal Plant was completed in 1928 and effluent was discharged into Dominguez Slough which flowed into Los Angeles Harbor. The ocean disposal of wastewater onto the Palos Verdes Shelf began in 1937 through a 5-ft diameter pipe; a 6-ft diameter pipe was added in 1947 (Rawn 1965). These outfalls discharged at water depths of 110 and 160 ft, respectively, and the initial flows were about 14 mgd each. A 7.5-ft diameter outfall, ending in a Y-shaped multiport diffuser at a water depth of 200 ft, was completed in 1956; in 1966 a 10-ft diameter pipe with a dog-legged, multi-port diffuser discharging at a 200 ft depth was added. The two diffusers are approximately 1.9 mi offshore (RWQCB,LAR 1977; Stull *et al.* 1986a).

Influent waters. The Los Angeles County Sanitation Districts Joint Outfall System (LACSD,JOS) presently treats the wastewater of 5 million people and more than 70,000 businesses and industries in a service area of approximately 583 mi^2 (Figure 5-5) (Stull 1993, pers. comm.). Approximately 30% of the influent sewage is treated to tertiary standards in upstream water reclamation plants and 70% is treated at the JWPCP in Carson (Horvath 1988, pers. comm.). The JWPCP provides advanced primary and partial secondary treatment for about 330 mgd of wastewater (Stull 1993, pers. comm.). About 15% of the influent sewage is industrial and about 85% domestic (Horvath 1988, pers. comm.).

Treatment. In 1983 the JWPCP began operating new secondary treatment facilities and by 1985 was treating an average of 179 mgd (SCCWRP 1986a). The wastewater was screened and grit removed prior to receiving advanced primary treatment, which included the addition of a polymer to remove suspended solids. Sixty percent of the effluent received pure oxygen secondary treatment while the rest was screened to remove grease and floatables. The combined flow was chlorinated and discharged. About 25% of the resulting sludge was sold as a soil amendment and the rest was hauled to the Puente Hills landfill (Stahl and Horvath 1988). Air disposal (via anaerobic digestion of sludge and subsequent combustion of the gas for energy

VOL 12

1 5 3 7 5

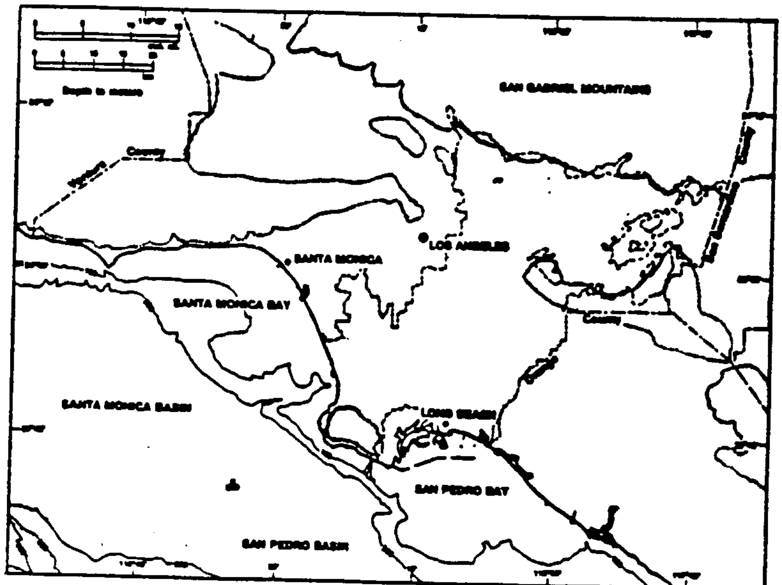

Figure 5-5. JWPCP watershed (modified from LACSD map G-m-450).

VOL 12

15376

production) increased from 26 to 35% between 1973 and 1985 (Horvath 1988, pers. comm.; Stull and Haydock 1988).

Volumes Discharged. From 1937 to 1970 the volume of municipal waste discharged from the JWPCP increased in approximate proportion to the population growth in its service area; it has remained relatively constant since 1970 (Figure 5-6 and Apppendix D) (Stull *et al.* 1986; Stull and Haydock 1988). From 1974 to 1987 JWPCP discharged an average of 356 mgd of effluent, with a peak flow of 382 mgd in 1989. In 1991 flow dropped by 12% to 330 mgd, the lowest recorded since 1977. This drop coincided with water conservation measures in response to the drought, as well as the economic recession (Stull 1993, pers. comm.). Projected flow for 1992 was 333 mgd, lower than the 1977 average flow. Data on flow for 1991 and 1992 suggest that drought conditions continued to impact the volume of final effluent (Appendix D).

In 1977 about 67% of the total effluent was discharged from the dog-leg outfall and 33% from the Y-shaped diffuser (RWQCB,LAR 1977). The 72-in. diameter outfall, which discharges at 160 ft depth, is on standby and may be used during heavy rains to provide hydraulic relief. The 60-in. diameter outfall which discharges at 110 ft depth is also on stand-by for extreme emergencies, although it has not been used in years (Stull 1993, pers. comm.).

In addition to the two main and two emergency ocean outfalls, JWPCP has 11 other discharge points; Harbor Lake, Dominguez Channel, Los Angeles River, and the Pacific ocean nearshore zone, used for extreme emergency relief (RWQCB,LAR 1991).

Effluent. The JWPCP improved effluent quality substantially between 1971 and 1981, partly through better source control and partly as a result of advanced technology – the use of polymers to help settle particulates, better sludge dewatering, and better screening techniques (Stull *et al.* 1986b).

Mass emissions recorded in the period 1987 to 1992 for BOD, TSS, settleable solids, and oil and grease were the lowest reported since 1974 (Figure 5-7 and Appendix D). From 1974-1992, phenols decreased 81%, from 1,582 to less than 300 MT. Cyanide levels declined 98% from a high of 206 in 1974 to 3 MT 1992. Although detergents (MBAS) fluctuated over the 19 year period, the overall trend declined (Figure 5-7 and Appendix D).

Mass emissions of organic nitrogen, total phosphorus, and ammonia nitrogen remained constant from 1974 to 1992, displaying little variability between years with 1992 values slightly lower than those in 1974 (Figure 5-7 and Appendix D).

In general, from 1974 to 1992 mass emissions of trace metals from the JWPCP outfall declined. Few metals displayed periods of high fluctuation; e.g., silver peaked in 1979 at 9.6, compared with a current value in 1992 of less than 2 MT; arsenic levels rose to 9.7 in 1984 before dropping to 1.9 MT in 1992 (Figure 5-7 and Appendix D). Overall, discharges of trace metals declined during the 1974-1992 period by the following percentages: silver (68%), arsenic (84%), cadmium (98%), chromium (98%), copper (95%), mercury (80%), nickel (87%), lead (98%), and zinc (95%) (Appendix D).

Total DDTs and PCBs were measured by different methods during 1974 to 1979 than from methods used 1980 to 1987, therefore, reported values for the two periods may not be comparable. During the earlier period values were generally higher; however, PCB levels dropped sharply after 1974 and to non detectable levels by 1987 where they have remained through 1992 (Figure 5-7 and Appendix D). DDTs experienced a more gradual decline and were further reduced

when the primary source (the Montrose Chemical Corporation) was identified and prohibited from dumping processing wastes into the JWPCP system (Chartrand 1988) (Figure 5-7 and Appendix D).

Permit Requirements. In 1991 the Regional Water Quality Control Board, Los Angeles Region (RWQCB,LAR), adopted a new NPDES permit for JWPCP which established discharge limitations (in concentrations) for 86 constituents. These include all of the major wastewater constituents, aquatic life toxicants, non-carcinogens, and carcinogens included in the 1990 California Ocean Plan, plus BOD. Many of the limits are more stringent than the Ocean Plan, and are based on either previous performance or practical quantitation limits. Limits for major constituents and aquatic life toxicants are provided for both concentrations and mass emissions, and are expressed for various time periods (e.g., 30-day, 7-day, daily, instantaneous, in various combinations) (Stull 1993, pers. comm.). The permit also includes limits and provisions for receiving waters established by the 1990 California Ocean Plan, which also sets limitations regarding secondary treatment of effluent.

Compliance with Standards. In the period 1983-1987 JWPCP effluent was in compliance with the California Ocean Plan limits except that daily concentration limits for suspended solids and chlorine were exceeded in 1983 and pH and turbidity in 1984 (RWQCB,LAR 1988). Presently JWPCP is unable to comply with these limitations regarding secondary treatment of effluent and until the 301(h) variance is resolved, or full secondary treatment is reached, must operate on interim limits set in a 1988 cease and desist order issued by the Board for secondary treatment. JWPCP's application for a variance to section 301(h) was denied in 1990 by the EPA Region IX, subsequently JWPCP requested and was granted a challenge to the denial. Dates for the challenge hearing are still pending (RWQCB,LAR 1991; Stull 1993, pers. comm.) A lawsuit was also filed in District Court by EPA seeking resolution of the secondary treatment issue (Stull 1993, pers. comm.).

Proposed Improvements. By 1995 LACSD will have finished construction of their sludge dehydration and thermal processing facilities (RWQCB,LAR 1988). Expansion is estimated to handle all sludge currently hauled off site to landfills, approximately 240 dry tons per day, and will be used for the energy recovery facility to generate electricity.

Tapia Water Reclamation Facility

The Las Virgenes Municipal Water District (LVMWD) was formed in 1958 and by 1965 construction of TWRF was completed with up to 500,000 gpd capacity. TWRF's capacity was expanded to 2 mgd after construction of sewer trunk lines were completed. Expansion in 1972 increased capacity to 8 mgd of effluent with solids handling capabilities of 4 mgd and at this time TWRF installed facilities to allow for water reclamation. Between 1972 and 1982 TWRF underwent area-wide facility upgrades, from the expansion to 8 mgd of hydraulic capacity, to the design and completion in 1982 of Rancho Las Virgenes with a capacity to handle 8 mgd of dewatered sludge. In 1984 filtration systems were installed and 1989 expansions allowed TWRF to increase capacity to 10 mgd. In 1991 construction began at TWRF and Rancho Las Virgenes that will allow for the handling of 16.1 mgd of influent and dewatered sludge (Gamble, 1992, pers. comm.).

In the past discharge of effluent to Malibu Creek was through percolation beds. The beds were removed from service after the installation of on site filters, however, periodic discharge to the percolation beds is required in summer months by CDFG to maintain the creek flow necessary to sustain fish populations in (RWQCB,LAR 1989).

Treatment. TWRF currently provides primary, secondary, and tertiary treatment of wastewater. Primary treatment includes coarse screening, grit removal, and primary sedimentation using rectangular clarifiers. Secondary treatment employs activated sludge with single-stage nitrification followed by secondary clarification. For tertiary treatment, coagulation chemicals are added and the water is flocculated, filtered, chlorinated and dechlorinated (RWQCB,LAR 1989). Tertiary treated wastewater is reclaimed and used for irrigation, dust control and fire suppression.

Sludge is currently being treated by aerobic digestion, screened, and either pumped to land injection farms, or dewatered in belt presses and hauled to landfills. Solids collected from coarse screening, grit removal, and sludge screening are hauled to landfills. Additional sludge incurred from expansion will undergo composting for use in landscape related activities.

Volumes Discharged. Flow from TWRF has averaged 2.7 mgd since 1974 with a maximum of 4.5 mgd discharged in 1978 (Figure 5-8, Appendix D). Over the last five years, flow has averaged 2.5 mgd. The trend of the previous five years has been fairly stable, though declining. This decline coincides with drought periods and subsequent water conservation measures.

Effluent. Emissions of total suspended solids, phosphorus, BOD, total nitrogen, detergent, chromium, copper, nickel, and zinc have generally been low but have erratic variation (Figure 5-9 and Appendix D). Copper emissions have increased slightly in recent years but appears to be part of this variation.

Permit Requirements. TWRF is subject to discharge requirements established in a 1985 NPDES permit, revised in 1989.

Wastewater discharge is limited to tertiary treated water with 30-day mean and daily maximum limits set for six constituents: BOD, suspended solids, oil and grease, residual chlorine, settleable solids, and turbidity. Eighteen other constituents, as well as EPA priority pollutants, are monitored and reported on a regular basis. Because Malibu Creek has relatively low dilution and is subject to human contact, discharged wastewater must be completely pathogen free (RWQCB,LAR 1989).

Proposed Improvements. By 1993-1994 TWRF is projected to be complete, with the capabilities to treat and discharge 16.1 mgd. Improvements in the plant consist primarily of expansion and upgrades to the current facility.

Industrial Dischargers

Industrial dischargers include three power generating stations; Scattergood, El Segundo, and Redondo, and the El Segundo Refinery.

The power generating stations use seawater from Santa Monica Bay to cool steam condensers. Cool seawater is pumped into the station, circulated through noncontact heat exchangers, and discharged at elevated temperatures. In addition to increased temperatures, the once-through cooling water may include treated wastewater which is nonhazardous as defined by state and federal regulations. The wastewater may include water-side boiler tube cleaning wastes, cooling water blowdown, and various low-volume wastes consisting of fireside boiler tube wash water, water purification wastes, boiler and evaporator blowdown, in-plant floor drainage, and rainfall runoff. Chlorine is also injected into the once-through cooling system (condensers) periodically to control biological growth (RWQCB,LAR 1985a,b,c; Karapetian 1988, pers. comm.).

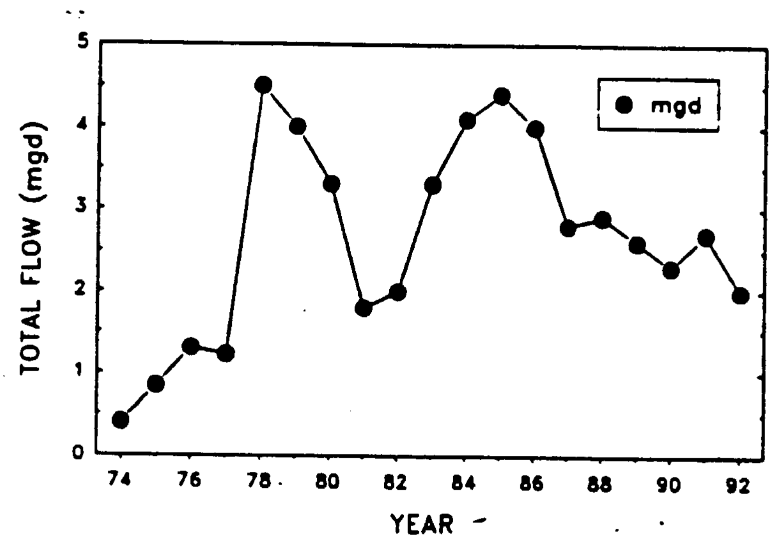

Figure 5-8. Average flow from TWRF 1974-1992. (Whitbeck 1992, pers. comm.)

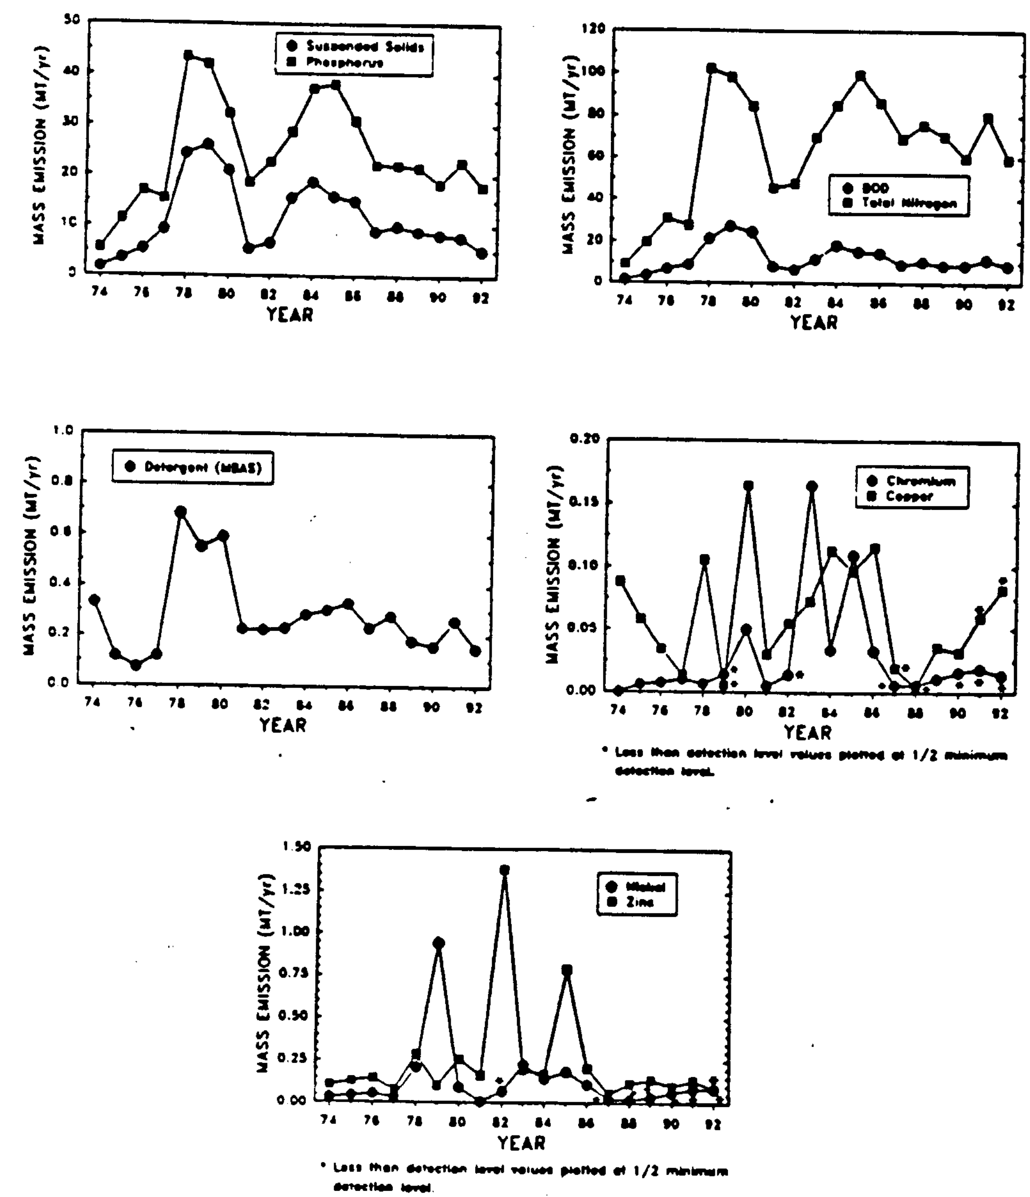

Figure 5-9. Annual mass emission rates of selected contaminates from TWRF 1974-1992. (Whitbeck 1992, pers. comm.)

VOL 12

1 5384

R0048689

In addition, the following wastes could be discharged along with the once-through cooling water: wastewater from laboratory drains, metal cleaning wastes, treated wastewater from fuel pipeline hydrostatic testing, treated sanitary wastes, treated oil wastes, and groundwater. These wastes are held in settling basins before they are discharged to the ocean; residues from the basins are land disposed (RWQCB,LAR 1985a,b,c; Karapetian 1988, pers. comm.).

The growth of marine biofouling organisms in the discharge and intake conduits is periodically removed by recirculating a portion of the cooling water to achieve higher temperatures. These "heat treatments" kill fouling organisms as well as some fish and other nekton resident in the cooling water structures. Heat treatments are conducted every five to eight weeks and last two to four hours (RWQCB,LAR 1985a; Karapetian 1988, pers. comm.). Routine operation of generating station cooling systems may impinge and entrain a variety of marine organisms.

NPDES permits for generating stations limit constituents, as instantaneous and daily maximum or minimum levels or six-month median values. The regulated constituents include physical characteristics, metals, nonmetallic inorganics, toxicity, and radioactivity (RWQCB,LAR 1985a,b,c; 1991).

Concentration levels are measured in the discharged cooling water. However, because this water is unfiltered seawater, the same constituents are also found in the seawater entering the intake conduit. Calculations of mass emissions using cooling water flow and final discharge concentrations give unrealistically high values for these constituents. Therefore, the mass emissions given in the following sections are based on concentrations and flow from the retention basin discharge before it enters the cooling water effluent and reflects the mass emissions actually discharged by the plant itself. Chlorine is the only constituent added directly to the cooling water at another site in the system (Alcaino 1988, pers. comm.; Schumann 1988, pers. comm.). An earlier study of the cooling water discharge of power generating stations in southern California indicated that the transit through the plant increased intake (background) levels of trace metals by 0.21 ppb or less for each metal examined (Young *et al.* 1977). Thus the contribution of the cooling water discharge alone to trace metal concentrations appears to be very low.

Scattergood Generating Station

The Scattergood Generating Station (SGS) in Playa del Rey is owned and operated by the City of Los Angeles, Department of Water and Power. It consists of three fossil-fueled, steam-electric generating units and has been in operation since 1958 (LCMR,IRC 1979; RWQCB,LAR 1985a). The cooling water intake is located about 1,600 ft offshore, at a depth of 18 ft below the surface. The discharge to Santa Monica Bay is 1,200 ft offshore at a depth of 15 ft below the water surface (LCMR,IRC 1979; RWQCB,LAR 1985a; Karapetian 1988, pers. comm.).

Effluent. The maximum flow from Scattergood is about 500 mgd with the average flow about 322 mgd (RWQCB,LAR 1985a). For the last five years the flow from the retention basins to the cooling water averaged 0.16 mgd (CLA, DWP 1992, unpubl. data). The temperature of the discharge averages 80.7°F in winter and 82.4°F in summer. During normal operations the temperature differential is approximately 20°F. The maximum allowable discharge temperature during a heat treatment is 135°F, and averages approximately 120°F. Flow during heat treatments is about 75% of that during normal operations, with 50% being recirculated within the station. The difference between intake and discharge temperatures can range from 35 to 85°F. The flow from other in-plant waste streams accounts for less than 0.05% of the total discharge (RWQCB,LAR 1985a; Karapetian 1988, pers. comm.).

VOL 12

1 5385

Since 1987 Scattergood discharged an average of 1.6 MT of total suspended solids, and 0.32 MT of oil and grease to the once-through cooling water. Mass emissions of chromium and zinc have been measured in trace amounts during the 1988-1992 period (CLA,DWP 1992, unpubl. data). Emissions over the past five years have remained fairly consistent.

Permit requirements. The NPDES permit for the SGS discharge no longer includes limits for suspended solids, oil and grease, or BOD. Based on five years of monitoring data, limits for these constituents were determined by the RWQCB to be unnecessary (Karapetian 1988, pers. comm.).

El Segundo Generating Station

The El Segundo Generating Station in El Segundo is operated by the Southern California Edison Company (SCE) and consists of four stem-electric generating units. Units 1 and 2 have been in operation since 1955-1956 and Units 3 and 4 since 1963-1964 (LCMR and IRC 1979). Cooling waters for the two pairs of units have separate intake and discharge structures. Water for Units 1 and 2 is drawn from a water depth of 20 ft at the end of a conduit which extends 2,600 ft offshore and is discharged 1,900 ft offshore at a depth of 16 ft. Cooling water for Units 3 and 4 is drawn at a depth of 16 ft at the end of a conduit which extends 2,600 ft offshore and is discharged 2,100 ft offshore at a depth of 16 ft (LCMR,IRC 1979).

Effluent. From 1985 to 1987 the average flow through all units was 370 mgd; the flow through Units 1 and 2 averaged 106 mgd and through Units 3 and 4, 264 mgd. Discharge temperatures averaged 80°F for Units 1 and 2 and 85°F for Units 3 and 4 (Hertel 1988, pers. comm.). The average flow from the retention basins to the cooling water of all units was about 0.16 mgd in 1987 (Alcaino 1988, pers. comm.). The maximum temperature during a heat treatment is 125°F with the maximum difference between intake and discharge temperature during a heat treatment is 73.2°F (RWQCB,LAR 1985b).

Since 1989 emissions have averaged 3.4 MT of TSS and 1.7 MT of oil and grease. In 1991 the El Segundo Generating Station discharged about 4.8 MT of TSS, and 1.6 MT of oil and grease from the retention basin to the cooling water. Total flow from the El Segundo wastewater treatment plant in 1992 averaged less than 1 mgd, discharging approximately .07 MT of BOD, .09 MT of TSS, .03 MT of oil and grease, and 4,527 l/yr. of settleable solids (SCE 1992, unpubl. data).

Permit Requirements. Southern California Edison operates the El Segundo generating station under a NPDES permit issued in 1984, amended in 1985, and amended again in 1990 to include the objectives stated in the revised California Ocean Plan of 1988. Discharge limits for metal cleaning wastes, low volume wastes, and wastewater from treatment facilities must meet 30-day mean and daily maximum for: BOD, suspended solids, oil and grease, settleable solids, total copper, and total iron (RWQCB,LAR 1990).

Redondo Generating Station

The Redondo Generating Station, located in King Harbor, is operated by SCE and consists at present of four steam-electric generating units. Units 5 and 6 have been in operation since the early 1950s, and Units 7 and 8 since mid-1960. Units 1 to 4 went on-line in 1940 but were withdrawn from service in November 1986 (Curtis 1988, pers. comm.).

VOL 12

Cooling water for the two pairs of units are drawn and discharged in separate cooling water systems. Cooling water for Units 5 and 6 is drawn into two intake conduits at a water depth of 20 ft within King Harbor and discharged at a depth of 25 ft, north of the Harbor and 1,600 ft offshore. Cooling water for Units 7 and 8 is drawn at a depth of 20 ft from a conduit extending 1,000 ft offshore at the entrance to King Harbor and discharged within the Harbor at a depth of 20 ft (RWQCB,LAR 1985c).

Effluent. From 1985 through 1987 the average flow through Units 5 and 6 was 227 mgd and through Units 7 and 8, 530 mgd. The average flow in 1987 from the retention basins to the cooling water of all units was about 1.2 mgd (Alcaino 1988, pers. comm.). The average discharge temperature for Units 5 and 6 was 85.7°F and that for Units 7 and 8, 83°F (Hertel 1988, pers. comm.). The maximum temperature during a heat treatment is 125°F, which represents an increase of 68.5°F, over intake temperatures (RWQCB,LAR 1985C).

In 1992 the Redondo Generating Station discharged about 3.4 MT of oil and grease, and 6.7 MT of total suspended solids to the cooling water from the on site retention basin, a decrease of 85-90% from 1990. An average of 74 MT of suspended solids and 32.8 MT of oil and grease have been discharged during the period 1988-1992 (SCE 1992, unpubl. data).

Permit Requirements. Redondo Beach Generating Station is currently operating under an NPDES permit issued in 1984, amended in 1985, and amended again in 1990 to include the objectives stated in the revised California Ocean Plan of 1988. Limits on effluent constituents for metal cleaning, and low volume wastes are set with a 30-day mean and daily maximum for suspended solids, oil and grease, total copper, and total iron (RWQCB,LAR 1990).

1

El Segundo Refinery

Chevron USA's El Segundo Refinery has been in operation since 1911 and now manufactures various petroleum products, including gasoline, jet fuel, kerosene, solvent, coke, fuel oil, liquified petroleum gases, and propylene polymer. The refinery occasionally uses benzene and toluene in its processes, but these petroleum derivatives are manufactured elsewhere. Manufacturing processes used at the refinery include distillation, catalytic cracking, alkylation, isomerization, coking, catalytic reforming, hydrogenation, sulfur recovery, and blending. The refinery has a maximum production capacity of about 405,000 barrels per day, although the average production is about 240,000-290,000 barrels per day (RWQCB,LAR 1984; Chevron USA 1988, pers. comm.).

5387

Since the early 1970s the El Segundo Refinery has discharged treated wastewater through an outfall 500 ft offshore of the beach at Grand Avenue at a depth of approximately 20 ft (RWQCB,LAR 1984; Chevron USA 1988, pers. comm.). This discharge consisted of non-contact cooling water bleed-off, petroleum processing wastewater, treated boiler water, shallow recovery well groundwater, and stormwater runoff. All petroleum processing wastewater and shallow recovery well groundwater had been treated at an Effluent Treatment Plant (ETP) on the facility before being discharged.

In early 1993, Chevron announced plans to extend its wastewater pipeline two-thirds of a mile from the beach, effectively removing the last industrial discharger from the nearshore environment. The construction, which involves revamping an unused series of pipelines that stretch from the refinery to a tanker mooring, is expected to be completed within a year (LA Times 1993). The discharged effluent will still be processed through the ETP with treatment consisting of both primary and secondary processes including dissolved air flotation units, an equalization basin, and activated sludge (biological) units. Stormwater runoff is discharged after treatment in oil/water separators and induced air flotation units; if necessary, this can also be routed to the ETP for biological treatment. About 90% of this runoff may contain oil or other spilled contaminants (RWQCB,LAR 1984; Coonan 1993, pers. comm.).

Three tanks and an induced air floatation unit were constructed in 1988 as part of the Effluent Diversion Project to increase the residence time of the effluent during treatment. Two of the tanks have 7,140,000 gal capacities and one has a capacity of 2,940,000 gal (Chevron USA 1988, pers. comm.; Coonan 1993, pers. comm.).

Effluent. The refinery discharges 6 to 7 mgd of treated wastewater, with maximum discharges of up to 20 mgd and dry-weather flows of about 6.2 mgd (RWQCB,LAR 1984; Chevron USA 1988, pers. comm.; Dorsey 1988; Coonan 1993, pers. comm.). The most abundant constituents in the discharge are COD, BOD, and TSS, with average annual mass emissions of 1,760, 123, and 105 MT, respectively.

Permit Requirements. Chevron's NPDES permit limits a number of effluent constituents and includes 6-month medians, 30-day averages, and daily maximums for both dry and wet weather discharges. The regulated constituents include physical characteristics, metals, nonmetallic inorganics, organics, and toxicity (RWQCB,LAR 1984; Coonan 1993, pers. comm.). Settleable solids and turbidity do not have permit limitations but are monitored nevertheless (Chevron USA 1987; Coonan 1993, pers. comm.).

CHAPTER 6
NONPOINT SOURCES OF CONTAMINATION

While most of the contaminants found in Santa Monica Bay probably came from point sources and urban runoff (a nonpoint source), other nonpoint sources may also be a major factor. These include marine vessel activities, oil and hazardous material spills, dredging, ocean dumpsites, historically deposited sediments, advection, and aerial fallout.

MARINE VESSEL ACTIVITY

Small Craft Boating and Harbors

Although boats berthed elsewhere use Santa Monica Bay, most small boat traffic is concentrated in Marina del Rey and King Harbor. Marinas act as collecting basins for a variety of substances, including raw and chemically treated sewage, fish wastes, antifouling paint additives, oil and grease, wash water, and trash as well as surface runoff. During ebb tides or storms these contaminants enter the Bay through harbor entrances and porous breakwaters and jetties.

Marina del Rey

Marina del Rey was constructed between 1958 and 1962 from Ballona Wetlands. It includes about 403 acres of waterways (navigation channels and small craft berthing basins) and a similar amount of land-based support facilities. About one-third of the land is used by the Los Angeles County Department of Small Craft Harbors and two-thirds is leased to private entities (Soule and Oguri 1977).

About 6,000 boats can be harbored at Marina del Rey and hundreds more are in dry storage nearby: the number of boats berthed there increased from 5,500 in 1973 to 5,800 (SCCWRP 1973, Soule and Oguri 1992). The Marina includes four dry docks and two fuel docks (LACHP 1988, pers. comm.; MDRHMI 1988, pers. comm.). In addition to storm drains which empty directly into the Marina, tidal action carries storm water from Ballona Creek and Ballona Lagoon into Marina del Rey.

King Harbor

King Harbor was constructed between 1962 and 1968 (CCC 1987; Pitzer 1988, pers. comm.) and lies along the open coast between Hermosa Beach and the head of Redondo Canyon. It is surrounded by a porous breakwater which parallels the coast.

King Harbor includes about 110 acres of waterways and three small craft berthing basins. It has one fuel dock, two fishing piers, and berths for about 1,600 small boats (Straughan 1977a; Clemens 1988, pers. comm.; Pitzer 1988, pers. comm.). In 1973 there were about 1,400 boats in the harbor (SCCWRP 1973). Contaminants also enter King Harbor from surface runoff and the cooling water discharge of the Redondo Generating Station.

Commercial/Naval Shipping Activities

During the late 1800s Santa Monica served as the City of Los Angeles' deep water port. At present most commercial and naval shipping activities occur outside Santa Monica Bay, in the shipping lanes offshore, and in nearby Los Angeles and Long Beach Harbors (Figure 6-1).

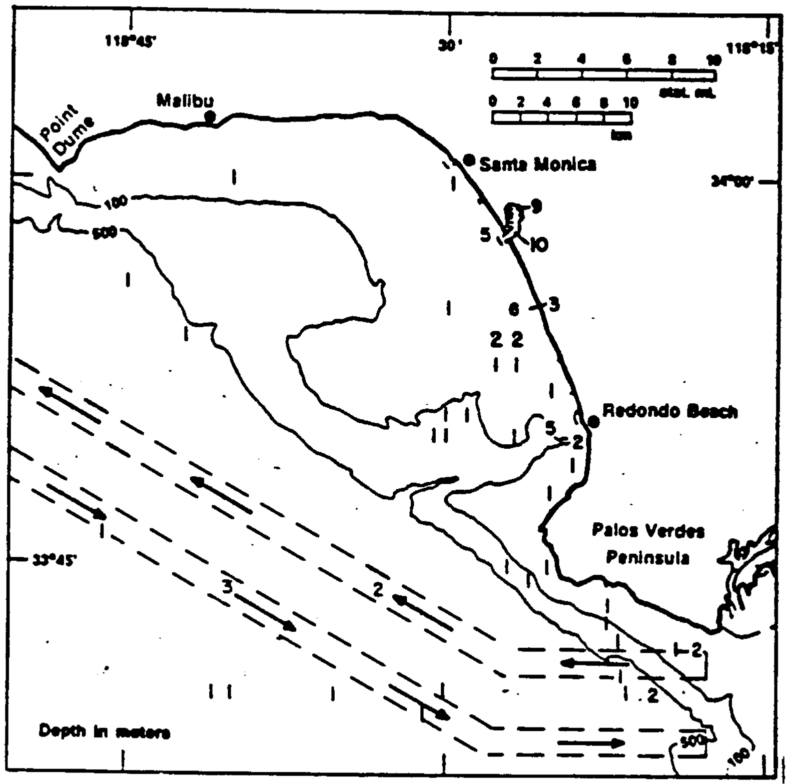

Figure 6-1. Shipping lanes and reported vessel spills (1973-1987 and 1991) in or near Santa Monica Bay area. (Numbers indicate number of spills; U.S. Coast Guard, Dept. Trans., unpubl. data).

VOL 12

1 5390

R0048695

The entrance to Los Angeles Harbor is about 2.5 mi east of Point Fermin. In 1990, 7,013 vessels arrived at the Los Angeles-Long Beach Harbors, with over 1,000 of these tankers. Over 10,000 are expected to arrive in the year 2000 (USACOE/LAHD 1992). It is not known how many of these vessels pass by Santa Monica Bay, but it can be assumed that several thousand pass the Bay during the year. The coastwise shipping lane extends west of Point Fermin for 8.9 mi before turning northwest and running parallel to the 500-m isobath of Santa Monica Bay; it generally lies about 3.4 mi offshore of Santa Monica Bay (Figure 6-1).

Chevron USA maintains three submerged pipelines which extend from shore to a three-berth offshore tanker mooring facility in 42 to 66 ft of water. For the most part, these pipes transport crude oil and refined products (mostly gasoline and jet fuel) to tankers moored in the area (Chevron USA 1988, pers. comm.); refined product is occasionally off-loaded to the refinery.

Oil tankers cross the Bay from the coastal shipping lane to the moorings at a frequency of 10 to 20 tankers per month (O'Reilly 1988). In 1980 and 1985, about 305 and 310 vessels arrived at the moorings respectively (MMS,POCSR 1983). About 200 tankers arrived in 1986 but only 92 in 1987.

Trace Contamination from Marine Vessels

Trace pollutants from marine vessels include antifouling bottom paints, anticorrosion anodes, and fuel residues. Formerly, antifouling paints included copper, with trace amounts of mercury, arsenic, and PCBs; primers may contain zinc, chromium, and lead (SCCWRP 1973). In recent years tributyl tin (TBT) has been used in bottom paints as an antifouling agent. TBT is lethal (especially to mollusks) at parts per trillion levels. In 1984, 50 to 75% of pleasure craft used TBT paints and this percentage was probably higher for larger vessels (Soule and Oguri 1987). TBT-based paints are now banned on vessels less than 82 ft long that are not made of aluminum (CSG,MAP 1988).

Although its use is now restricted, much of the TBT paint from earlier applications has been sloughed, sanded, or scraped off boat bottoms, and may form a reservoir in the sediments of harbors and marinas. Because recreational vessels spend more time in port than large vessels and because their hulls are often scraped while in the water, small craft harbors may represent an important source of TBT (Soule and Oguri 1987).

In 1973 90% of the sail and power craft in Marina del Rey used sacrificial zinc anodes to control galvanic corrosion; some cadmium was also used. Each boat uses an estimated 4 to 5 kg/yr for this purpose (SCCWRP 1973). If similar usage rates occur today, the two marinas contribute about 30 to 38 MT of zinc per year to Santa Monica Bay.

Most of the fuel sold to recreational vessels is leaded gasoline (Bender 1988, pers. comm.). In 1973 it was estimated that the use of leaded fuel by vessels in Marina del Rey contributed about 0.55 MT/yr of lead to the environment (SCCWRP 1973). Spillage of oil and combustion of fuel by small craft introduced PAHs to the harbors. Higher than background levels of benzo(a)pyrene have been found in King Harbor (Puffer 1988, pers. comm.).

In 1971 the estimated mass emission of mercury to the Southern California Bight from vessel-related sources (bottom-paint) was greater than the total estimated mass emission of mercury from the municipal wastewater and surface runoff combined. The estimated PCB and copper emissions from this source were about half of the combined emission for wastewater and runoff. Hence, vessel-related contaminants may be a significant contaminant source (SCCWRP

VOL 12

1539 1

1973). At present the concentration of PCBs in antifouling paints is low but higher levels were found in older paints. Thus, the sediments in harbors may represent a reservoir which can release PCBs during dredging operations (Young and Heesen 1976).

OIL AND HAZARDOUS MATERIALS SPILLS

Potential Sources of Spills

The potential sources for spills and contamination from oil and other hazardous materials in the Santa Monica Bay area include small craft boating and harbors, commercial shipping activities, refinery transfer activities, offshore oil and gas operations, natural oil seeps, underground contamination at Los Angeles International Airport and El Segundo refinery, and accidents on land which could move into the Bay through its tributaries. Spills can be highly variable in size, and consist of very different substances. They are unpredictable, and are usually caused by unexpected problems or equipment failures. They can cause little or no problems to major damage, coating miles of shoreline. A spill on the order of the Exxon Valdez could impact an area from the Mexican Border to the Central coast. Spills in the watershed can move through drainage systems to reach wetlands, the intertidal communities, and finally the ocean. Spills on the ocean can evaporate into the air, coat the surface, suspend by emulsion into the water column, or sink to the bottom, depending on the properties of the substance spilled. Petroleum products may separate into different constituents, each reacting differently.

Boating and Commercial Shipping Spills

The U.S. Coast Guard lists at least 82 vessel spills in Santa Monica Bay between 1973 and 1987, with an average of 6 spills per year; the locations of 37 more spills were questionable (Appendix E) (U.S. Coast Guard, unpubl. data). The spills listed were almost exclusively of petroleum products, including automotive and aviation gasoline and jet fuel; 31% of the spills were fuel oil, 17% crude oil, and 17% miscellaneous oil products. Spills totalling just under 2,000 gal were recorded during this period; the median amount spilled was 2 gal and only two spills were greater than 100 gal. A tanker offshore El Segundo in 1977 spilled 1,000 gal of crude oil, most of which was recovered. In 1973, 370 gal of clarified oil were spilled from a recreational vessel in Marina del Rey.

In 59 of the 82 instances the vessel causing the spill was identified; 51% of these were recreational vessels, 29% tankers, and 14% fishing vessels. Twenty-four spills occurred in or near Marina del Rey, 17 were off El Segundo and Hermosa Beach, and 12 were in the commercial shipping lanes (Figure 6-1). More than 50% of these spills took place from 1973 to 1979.

In the past there have been occasional small spills and leaks at Chevron's offshore terminal, with only two larger spills. A tanker leak of crude oil in December 1980 was cleaned up and caused no apparent harm to beaches or marine life (Chevron 1988, pers. comm.).

In March 1991 a transport vessel's anchor snagged the offshore mooring complex at the Chevron El Segundo Refinery, resulting in a spill of 9,240 gals of a diesel oil/naphthalene mixture (MBC 1991a). At the time of the accident, an approaching low pressure weather front produced strong winds from the south-southeast, driving the floating oil to the north-northeast where it contacted the shore at Malibu. Beaches were closed to swimmers for a few days at Malibu and El Segundo during this period (Appendix I).

VOL 12

15392

VOL 12

Offshore Oil and Gas Operations

Offshore oil and gas operations generate contaminants from a variety of point and nonpoint sources. Crude oil may be leaked in small amounts during exploration and production drilling or spilled in large amounts in a blowout, a tanker accident, or a rupture of a submerged pipeline. Refined petroleum products may be leaked or spilled during routine transfer operations and in tanker accidents or pipe ruptures.

Trace metals and other synthetic compounds are found in drilling muds and a variety of metals, combustion by-products, and other substances resulting from the operation of heavy gasoline- and diesel-powered machinery on boats and platforms. Domestic wastes generated at drilling platforms and aboard work vessels are treated in self-contained treatment plants and discharged overboard. Although operators in the Federal Outer Continental Shelf (OCS) dispose of drilling muds and cuttings at sea under a general permit, those from State Lands operations must be barged ashore for land disposal.

At present the major oil and gas operation in Santa Monica Bay is tanker traffic to and from Chevron USA's refinery in El Segundo, the largest refinery in California with a capacity of 405,000 barrels/day. The refinery does not treat Federal OCS production. In the past spills or leaks occurred about once a year during offloading or onloading at the offshore terminal.

1

Although oil and gas reserves are believed to occur on the Santa Monica Shelf, oil and gas development in or near Santa Monica Bay has been limited. It is estimated that the 40 tracts within the Bay have about 70 million barrels of oil and 90 billion ft^3 of gas.

By 1983 several lease plans had been considered which could affect Santa Monica Bay. Several alternatives were described in the draft Environmental Impact Statement (EIS) for the southern California lease offering, describing different drilling scenarios as well as potential risks (MMS,POCSR 1983; MBC 1988). However, by June of 1990, Federal OCS lease sale 95 was canceled. In addition, no leasing will occur in any other areas offshore of California before the year 2000. In the Santa Barbara area, 87 tracts will be offered for lease before January 1996, adjacent to areas currently in production (MMS,OCSNC 91). It is not clear what impact this new activity in the Santa Barbara area would have for the Santa Monica Bay.

5393

Natural Oil Seeps

Two natural oil seeps are known from Santa Monica Bay. One, with three seepage zones, is located about 2.3 mi off Redondo Beach, near the head of the Redondo Submarine Canyon; the other has two seepage zones and is located about 4.6 mi off Manhattan Beach. It is estimated that an average of about 10 barrels (420 gal) of oil from the seeps reach the surface each day; additional oil probably does not surface, either deteriorating or forming tar balls underwater. The daily flow (to the surface) is estimated to range from 2 to 18 barrels (84 to 756 gal) per day, but may be several times this amount during and after local earthquakes.

In calm weather surface oil slicks several miles long have been observed; in windy conditions the slicks dissipate rapidly. Surface oil generally drifts northward, towards shore, reaching the beaches from Redondo Beach to Malibu in 1 to 2 days. In 1971, 18 to 836 oil globules were found in a 2,500 ft^2 area of sand along Redondo Beach and Manhattan Beach; about 86% of these deposits originated from natural oil seeps (Marconsult 1971). More recent studies suggest that about 75% of the tar on Santa Monica beaches is from the Santa Barbara Channel (Hartman and Hammond 1981).

Natural oil from the vicinity of the La Brea Tar Pits also seeps into the Ballona Creek drainage system, contributing to contamination of the Creek and the Bay, especially during periods of low flow (Mitchell 1988, pers. comm.).

At least two accumulations of refined petroleum products have been identified adjacent to the shores of Santa Monica Bay. Although there is no evidence that any of these products have seeped into the Bay, their proximity to it has raised concern by the general public and regulatory agencies.

El Segundo Refinery

During its first 77 years of operation, a variety of oil and refined products had leaked into the ground beneath the El Segundo Refinery (Chevron USA), from surface spills, storage tanks, and leaking pipes. The refinery is located atop sand dunes, under which three aquifers or subterranean layers of groundwater are located in sand beds separated by relatively impervious layers of clay. The removal of drinking water from the aquifers has caused seawater intrusion (Waters 1988).

For several years, Chevron contractors drilled numerous delineation wells to identify the size and nature of the contaminated pool located in the aquifers. The results indicated that the pool contained about 252 million gal, primarily crude oil, gasoline, and jet fuel. Most of the petroleum contaminants had accumulated in the uppermost of three aquifers. Trace amounts had been found in the middle aquifer while the lowermost aquifers (the only one from which drinking water is extracted) appeared uncontaminated. Having identified the nature of the pool, Chevron began a program to recover as much of the pool as possible. 1988 estimates indicated that 50 to 70% of the materials could be recovered over the next 20 years (Waters 1988).

Los Angeles International Airport (LAX)

During the years LAX has been operating, jet fuel has leaked into the ground beneath the airport from underground pipes or from the 500,000 gal storage tanks. Initial investigations indicated that the contamination extended to a depth of 60 ft and included the uppermost aquifer (which is brackish from saltwater intrusion), but the full extent of contamination is unknown (Kelley 1988).

Since the initial reports, LAXFUEL, a nonprofit consortium of 50 commercial airlines serving 98% of airline operations at LAX, has initiated investigations to characterize the extent of contamination. Phase I and II groundwater investigations were completed between 1989 and 1991. A free-hydrocarbon recovery system was approved by the RWQCB and installed in September of 1991. Since that time, approximately 10,000 gals of free-hydrocarbon product has been recovered. LAXFUEL is currently modernizing and upgrading its bulk storage facility, and conducting Phase III groundwater contamination investigations (Speelmans 1992, pers. comm.).

Impacts of Spills

Impacts of oil or other hazardous material spills can reach all areas of the environment. Birds and marine mammals can be affected by a surface oil slick, by bioaccumulation in the food chain, or by direct toxicity from chemical spills. As spilled contaminants disperse through the water column, they can affect plankton, both plant and animal, as well as fish. They can also have toxic effects on kelp and other algal species which provide habitat for many animals in the Bay. When an oil spill sinks it coats the bottom and it can smother benthic communities that live in the

VOL 12

15394

sand and mud. Oil that washes up on the beaches or the intertidal zone can coat and smother species that dominate those areas. The California grunion, a fish that spawns on sandy beaches could be heavily impacted if a spill occurred during spawning season. Land spills, as well as ocean spills, could move into biologically sensitive wetlands, which are nursery areas for many species. Many of these areas do not have adequate baseline (pre-spill) information to determine the impacts on the communities and populations if a spill did occur (Lees 1992).

Following the 1991 spill at the Chevron USA offshore terminal, there were no observed impacts to California grunion spawning, sand crab populations, and the Santa Monica Bay artificial reef at Malibu (where the spill contacted the shore) nor were petroleum hydrocarbons found in beach sand; however, there was some mortality of mussels, spiny mole crabs, and possibly smooth turban snails (MBC 1991a).

In addition to the biological effects, there are aesthetic and economic effects for the human population. Large areas could be closed for recreational activities such as fishing, swimming, surfing, diving and sunbathing. This has an extended effect on businesses that depend on these activities. The fumes of a spill occurring, or moving ashore, in a heavily populated area could also result in health effects. Toxic materials could accumulate in sportfish species, and also cause residual health problems.

Risk of Future Spills

Current plans for oil and gas lease activity appear not to add any increased risk for future spills. However, if exploration and drilling resume, the risk will increase.

Commercial shipping is expected to increase for the near future. Los Angeles/Long Beach Harbors are expanding berthing facilities in their 2020 Plan to meet expected increases. In 1990, 7,013 vessels arrived at both ports, with over 1,000 of these tankers. Over 10,000 are expected to arrive in the year 2000 (USACOE/LAHD 1992). This will mean more traffic in the shipping lanes, with potential spills or accidents more frequent. It is not clear what number of these vessels transit the shipping lanes offshore of Santa Monica Bay.

The number of tankers loading and unloading at the El Segundo refinery has been steady for a number of years, however, Chevron recently received a permit to tanker from Santa Barbara to Santa Monica Bay. Currently none of these tankers has had a major spill, but should one occur, it could have a significant impact in the bay as evidenced by the Huntington Beach spill in 1990.

Prevention and Response to Oil and Hazardous Materials Spills

In 1990, the State of California passed the Lampert/Keene/Seestrand Oil Act (SB2240) in response to the Exxon Valdez and American Trader oil spills. The result of this law was to create an Oil Spill Prevention and Response (OSPR) group in the California Department of Fish and Game (CDFG). The goal of the Act is to increase inspection of facilities, transportation equipment and vessels, and to promulgate regulations defining these needs. This will provide for behavioral changes to increase preventative procedures and increase the ability to respond to a spill.

The law states that every oil plant, transporter, and vessel in state waters have contingency plans, preventative methodology, and containment equipment on hand in case of a spill. This must include a list of contacts for reporting and assistance and identification of rescue and rehabilitation groups. A Response Unit must be created to assist in a spill, if needed. OSPR

VOL 12

15395

provides for Natural Resources Damage Assessment methodology to be applied to determine what impacts occur during a spill, and to provide help with remediation efforts after the event. One function of OSPR is to identify sensitive biological areas that would be most affected by a spill, and provide this information to maximize efforts to keep these areas from being impacted.

The Santa Monica Bay is within two of the OSPR response areas. One extends from San Luis Obispo to Point Dume, with the OSPR Coordinator stationed in Santa Barbara. The other extends from Point Dume to Dana Point, with the OSPR Coordinator stationed in Long Beach (John Grant 1992, pers. comm.).

In addition to California legislation, the U.S. government passed the Oil Pollution Act of 1990 (OPA 90), which addresses spill prevention and response and contains requirements similar to California's SB2240. In addition, federal regulations are also being written to cover marine transfer facilities, bulk cargo carriers for oil landings in the ocean and mobile facilities, e.g., pipelines, railroad transport, and tank trucks. These are expected to be released in 1993, and will only cover specific types of oil and facilities. The regulations covering other types of hazardous materials have not yet been written.

The U.S. Coast Guard, Long Beach, has created a Port Area Committee, which is making contingency plans for the local area. These plans are pre-designed responses to spills of any size and type, from small up to the worst case scenario (Exxon Valdez size). The plans designate response actions and responsibilities for management, so implementation can be as rapid as possible.

A more general set of regulations exist under MARPOL, issued by the International Maritime Organization of the United Nations, effective in 1983. Regulation 26, Annex 1, MARPOL requires response plans for all ships of 400 Gross Tons (GT) or greater and bulk oil carriers of 150 GT or greater, and will be in effect in 1995 for existing ships. The regulation is presently in effect for ships under construction (Panagakos 1992, pers. comm.).

Local agencies, primarily fire departments, respond to spills occurring on land. They are trained in containment and response procedures and maintain a list of agencies to notify in case of storm drain contamination. Local laws are in effect requiring businesses to provide hazardous material inventories to response agencies, and also require containment methodology and response plans to be present on site. A regular inspection program provides enforcement of this legislation. Inspection and response programs are also undertaken by interested groups, e.g., Ballona Creek Task Force.

DREDGING

Dredged sediments are the only materials that may be dumped into the Southern California Bight in large quantities, however, they must meet Ocean Dumping Act requirements (USEPA 1988). The Army Corp of Engineers, RWQCB,LAR and the EPA regulate and manage all dredging and oceanic dumping.

Dredging is necessitated by the accumulation of sediments around harbor entrances which pose potential navigation hazards to vessels. Removal of this material has typically been done by hopper dredges, clam shell dredges or dragging. Dredged material can be used for beach replenishment, landfill in harbors, dumped at oceanic dumpsites, or disposed in sanitary landfill sites. Disposal of dredge material must meet specific criteria for each disposal type. Beach replenishment material must undergo chemical analysis and meet grain size limitations for the

VOL 12

1 5396

R0048701

location of disposal. Ocean dump site material has to undergo chronic and acute toxicity analysis as well as chemical analysis for trace constituents and heavy metals (USEPA 1988).

Historical Dredging in Santa Monica Bay

Net sediment transport in Santa Monica Bay is to the south in the northern part of the Bay and to the north in the southern portion of the Bay with the accumulation of the majority of materials at the head of the Redondo Submarine Canyon (Woodel and Holler 1991). Two areas of concern in sediment buildup are the Marina del Rey entrance channel and King Harbor.

King Harbor is uniquely situated along the coast at the head of the Redondo Submarine Canyon. Sediment transport and accumulation around King Harbor varies with seasonal, tidal and long shore current patterns. In general, transport of sediments is downcoast with accumulation on the upcoast side of the Redondo breakwater. Sediments transported around the breakwater are deposited at the head of the Redondo Submarine Canyon where they move down and off the nearshore shelf (Terry *et al.* 1956).

Between 1960 and 1963 the original Ballona Wetlands was dredged to create Marina del Rey Harbor and was, at that time, the largest dredging project on the West Coast removing approximately 10.1 million yds^3 of dredged material. Since that time, occasional dredging is necessary due to sediment deposition in the entrance channel of Marina del Rey. This deposition is partially due to the position of a breakwater off shore and parallel to the coast which creates an area of calm water inside the breakwater that facilitates the build up of sediment. Urban run-off from Ballona Creek also deposits material at the mouth of the harbor entrance. Dredge activities since 1969 have produced 664,080 yds^3 of material, ranging from 298,000 yds^3 in 1969, to 17,000 yds^3 in 1992 (Woodel and Hollar 1991, Chang 1992, pers. comm.). Dredge spoils from 1969 to 1987 dredge operations were disposed on the beach directly down coast of the Harbor entrance. Records were not available to determine if any chemical analyses were done for the 1981 and 1987 activities.

Present Dredge Sites

King Harbor was dredged in 1990 for the removal of accumulated sediments inside the Harbor following storm activities. In 1990, 156,000 yds^3 of material was dredged and used for beach replenishment 0.5 mi south of the Harbor. No chemistry data are available for this project because it was deemed clean and met all grain size criteria for disposal (Chow 1992, pers. comm.). All earlier dredging activities at King Harbor were similar to the 1990 dredging operations (Chow 1992, pers. comm.).

In 1992 approximately 17,000 yds^3 were dragged from the entrance of Marina del Rey Harbor to downcoast of the entrance, where long shore currents transported the material downcoast. Beach and LA-2 dumpsite disposal were not viable alternatives due to high levels of lead and heavy metal contamination which probably originated in run-off from Ballona Creek (Chang 1992, pers. comm.). Future dredging activities will be handled by dragging, as needed, until appropriate disposal sites can be found or measured contamination levels are below EPA regulations (Chang 1992, pers. comm.).

OCEAN DUMP SITES

The dumping of unwanted material at sea has been practiced for centuries and has been regulated by federal law since 1886, originally to prevent navigational obstructions. EPA permitted ocean dumpsites are point sources in the sense that only specified amounts of specific materials can be disposed in a prescribed area. In practice, however, every load is not carefully monitored, and the kind and amount of material dumped may differ from what is permitted. In addition, "short-dumping" (i.e., dumping before the vessel reaches the designated site to save vessel time and money) of materials may be common. Accurate records of dumping activities at dumpsites are generally lacking.

Illegal dumping has occurred in the study area, but quantification of the kinds and amounts of materials dumped is almost impossible. The California Salvage Company illegally dumped industrial wastes off White Point on the Palos Verdes Peninsula on two occasions in 1968, but it is not known what or how much waste was dumped in the area (Chartrand *et al.* 1985).

Historical Dumping

Industrial wastes have been dumped into San Pedro Channel since the 1930s and continued more or less unregulated until 1967. Between 1967 and 1972 dredge spoils, oil refinery wastes, chemical wastes, filter cake, oil drilling wastes, refuse and garbage, radioactive wastes, and military explosives were dumped at 17 regulated dumpsites off Southern California (Figure 6-2). In 1972 the Marine Protection, Research, and Sanctuaries Act (Ocean Dumping Act) was enacted to regulate ocean dumping more closely and the disposal of hazardous materials (chemicals, munitions, bacteriological agents, etc.) at any offshore site was forbidden (Chartrand *et al.* 1985).

Prior to 1973 industrial wastes were dumped at a site (LA-1) in the San Pedro Channel, approximately 10 mi northwest of Santa Catalina Island in 2,500 ft of water (Figure 5-1). Between 1947 and 1960 the California Salvage Company dumped about 125 million gal of caustic and acid wastes from oil refineries and 2,000 to 3,000 gpd of acid sludge from the Montrose Chemical Company. This sludge contained DDT and it is estimated that over the years between 348 and 696 MT of DDT were dumped. Because of new oil refinery methods the total volume dropped from 1.2 million gal per month to 210,000 gal per month in 1961. Approximately 3 million gal of refinery wastes were dumped between 1961 and 1972 (Chartrand *et al.* 1985).

In 1961 the RWQCB,LAR began regulating ocean dumping, requiring that wastes be in containers which were perforated just before they were dumped. Between 1965 and 1972 about 0.8 million gal of aluminum chloride and 0.3 million gal of cyanide were dumped in the ocean. Solvents and acid wastes, beryllium, cesium, bromine, and film-processing materials were also included (Chartrand *et al.* 1985).

Between 1961 and 1964 the Pacific Ocean Disposal Company also dumped liquid and solid wastes at LA-1. Most liquid wastes were pumped directly overboard, but some liquid and the solid wastes were in containers. About 1.6 million gal of sodium hydroxide and 0.1 million gal of calcium fluoride were dumped; polymer acid sludge, acid wastes, nitric-hydrofluoric acid, paint and lacquer, and hydrolyzed aluminum chloride solution were also present (Chartrand *et al.* 1985).

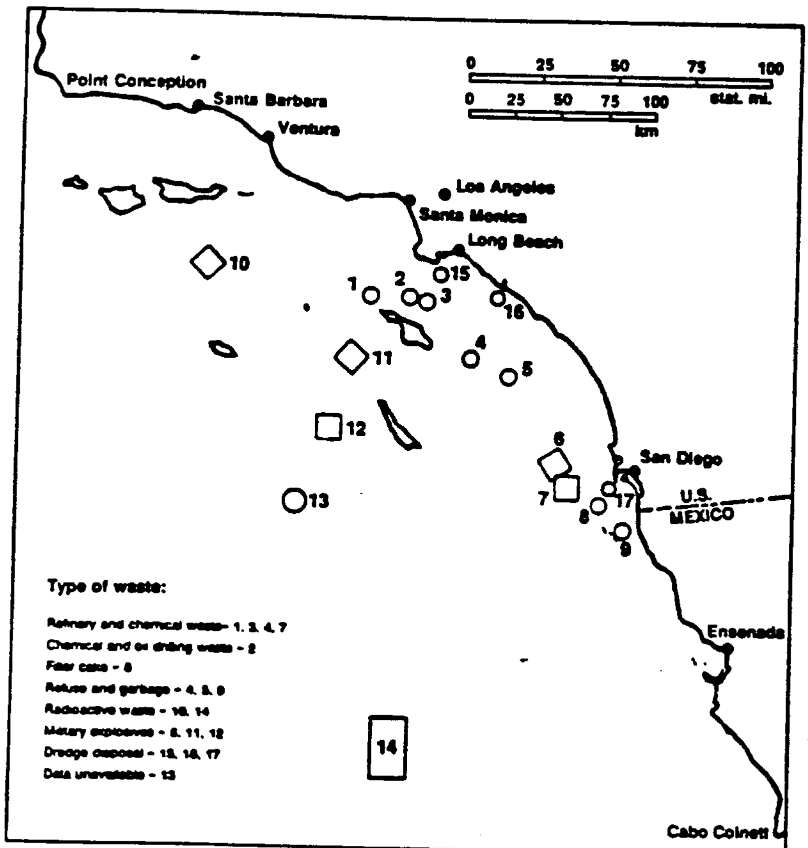

Figure 6-2. Designated ocean dumping sites in the Southern California Bight, 1931-1978 (modified from Chartrand *et al.* 1985).

The Texaco Humble Union Mobile Standard (THUMS) dumpsite is a 3 mi diameter circular site near the center of the San Pedro Basin at a water depth of 2,910 ft (Figure 5-1). The closest edge is approximately 8 mi from the study area. This site was designated by the EPA in 1985, for a period of three years, for the disposal of drilling muds and cuttings from THUMS' production operations in Long Beach Harbor. The drilling muds are similar to those approved by the EPA under a blanket permit for disposal in Outer Continental Shelf (OCS) waters (Chartrand *et al.* 1985). The THUMS dumpsite was in use for about one year (1986-1987), during which time about 50,000 barrels of drilling muds and cuttings were pumped from a barge as a slurry. THUMS did not reapply for an extension to the permit, allowing the site to become inactive (Otott 1988, 1992, pers. comm.).

LA-2 Dumpsite

At present there is one permitted dumpsite near, but outside of the study area (Figure 5-1) (Chartrand *et al.* 1985). This site may contribute to contamination of the Bay via advection but no estimates have been made of the amounts of material which might have moved toward shore.

The LA-2 dumpsite is a 1.1 mi diameter circle at a water depth of 600 ft, about 1.5 mi south of the study area (Figure 5-1). The site was given interim status by the EPA in 1977 for the ocean disposal of dredged materials (Rote 1985). Fine sediments which might be contaminated are tested in a laboratory bioassay before they can be dumped in the ocean, and if found to be toxic, are land-disposed.

The material dumped at LA-2 originates from maintenance and construction dredging in Los Angeles and Long Beach Harbors, which have multi-year permits for the disposal of dredged sediments. From 1978 to 1988 the U.S. Army Corps of Engineers issued permits for the disposal of 2.1 million yd^3 of dredged material at LA-2, but only 1.6 million yd^3 had been dumped. An average of about 180,000 yd^3 of material was dumped each year (USEPA 1988, Welch 1992, pers. comm.).

In 1989 SCCWRP estimated the quantity of material dumped and inputs of trace contaminants contained in disposed dredged material from 1984 to 1988. Six permit applications for dumping dredged material into LA-2, involving a total of 386,000 yd^3 were examined. Chemical data were available for only one dredge activity of 46,000 yd^3. It was assumed that the volume of dredged material discharged was equal to the amount permitted to be dumped in the application. Mass emission values were calculated from the available chemistry data and the total amount of sediments discharged. Due to the small size of the database it was difficult to determine exact mass emissions rates but a general trend can be distinguished. In general, the concentrations of contaminants in dredged materials is one-half to one-sixteenth those in municipal wastewater effluent. Although only limited chemical analysis of dredged materials has been conducted, dredge materials can reintroduce trace levels of constituents into the environment (SCCWRP 1989).

From January 1989 to March 1991 the LA-2 dumpsite was closed to dumping activities while an EIS was completed by the EPA (Cotter 1992, pers comm.). In March 1991, the LA-2 site was reopened under a new designation which allowed for continued dumping over a five year period. During this time potential environmental impacts will be monitored using current meter arrays, satellite imaging, and analysis of fisheries data. Continued use of the LA-2 dumpsite at the end of the five year period will be based on the environmental findings from this monitoring program. In the event EPA closes the LA-2 site, an alternative site must be designated within two years (Cotter 1992, pers. comm.). The EPA holds the final approval over permitting and can

VOL 12

15400

reassign the disposal of dredge material to land fills, beach restoration, and alternative ocean dump sites as needed (USEPA 1988).

Currently the Port of Long Beach has a five month contract ending in April 1993 for the disposal of approximately 710,000 yd^3 of dredged material at the LA-2 site. Other dredge contracts are planned for the Los Angeles and Port of Long Beach Harbors but anticipated dredged amounts are unknown at this time (Cotter 1992, pers. comm.).

ADVECTION

Advection is the transport of material by ocean currents. Prevailing currents not only disperse contaminants which are discharged into the Bay, but bring contaminants into the Bay from other areas. However, current patterns in the study area are complex and not well-known and very little effort has been expended in estimating the mass balance between contaminants entering and those leaving the Bay.

In general, water enters and exits at the seaward edge of the study area, along the 500-m isobath. Surface water generally enters from off Ventura County or Redondo Canyon and leaves at the same places or to the south, offshore of the Palos Verdes Peninsula. Recent studies suggest that a clockwise gyre is dominant seaward of the 20-m isobath (Hickey 1988, pers. comm.), but a counterclockwise gyre has been observed in Santa Monica Bay. Surface currents generally flow south off the Palos Verdes Peninsula, while below 90 m, water enters the study area from the south.

Oil slicks, contaminants in the surface microlayer, and other floatables are likely to be transported into the Bay by wind-generated currents and waves. Tar from the Santa Monica Channel is carried into the Bay by advection (Hartman and Hammond 1981). Contaminants form the Los Angeles-Long Beach Harbor may enter the Bay from the south, in the subsurface current which flows north along the Palos Verdes Shelf.

The sediments at nearby ocean dumpsites may constitute reservoirs of contaminants which, if resuspended, could be transported into the Bay in deep currents. However, the general pattern is for fine sediments to move offshore and into basins where they are deposited. Thus, the likelihood of significant amounts of contaminants moving against that natural gradient is remote.

Sea Surface Microlayer

Many anthropogenic substances, such as trace metals, chlorinated and petroleum hydrocarbons, and plastics, accumulate in the sea surface microlayer. Little information exists on the distribution of contaminants in the microlayer in Santa Monica Bay because effective sampling methods have only recently been developed (SCCWRP 1986d, Cross *et al.* 1988).

In general, trace metal and PAH concentrations in the microlayer are higher by orders of magnitude in inshore areas of harbors than in offshore areas (SCCWRP 1986d, Cross *et al.* 1988). Chlorinated hydrocarbons were not detected in offshore areas but occurred in low levels at King Harbor. Benzo(a)pyrene, a carcinogenic and mutagenic PAH, has been found in the microlayer of King Harbor (Puffer 1988, pers. comm.).

The dominant trace metals in the particulate phase of the microlayer in King Harbor were iron, manganese, and zinc with concentrations of 1,105; 20; and 12 $\mu g/l$. The most important

VOL 12 15401

metals in the dissolved phase at King Harbor were copper, zinc, and manganese with concentrations of 4.14, 3.44, and 2.97 µg/l; at White Point these were iron, zinc, and copper with concentrations of 4.48, 3.93, and 2.08 µg/l (SCCWRP 1986d).

Oil and grease concentrations in the microlayer were 1.04 µ/l on the Palos Verdes Shelf at White Point. Total PAH levels were 2.65 µ/l at King Harbor and 0.59 µ/l at White Point. Total DDT occurred at 11 µ/l at White Point (SCCWRP 1986d).

Water Column

Most contaminants enter the ocean dissolved in or carried by water. However, their concentrations are affected by circulation rates and patterns and are often low; rapid dilution of point discharges makes concentrations even lower. Impacts are usually observed only in biota carried along with the water mass and exposed for longer periods.

Debris

Natural and anthropogenic debris are most visible at the surface of the sea and at the shore. The distribution of debris is generally determined by wind or currents, and is not necessarily related to its origin. No estimates are available on the relative contributions of marine versus terrestrial sources, but tons of debris are removed annually from the shoreline of Santa Monica Bay. Much of this material, such as kelp, is natural and is removed for aesthetic reasons. Natural debris is eventually decomposed or consumed whereas man-made refuse, especially plastic, is persistent.

Ever increasing amounts of plastic debris are found at sea and on the shore. The average daily production of solid waste in Los Angeles County has increased from 10 lb per person in 1980 to 12 lb per person in 1988 (MBC 1988). Although data are not available, trends in the marine environment probably parallel those of land disposal.

Heat

In enclosed areas the addition of heated ocean water by power generating stations can cause severe impacts. In open coastal waters, waste heat seldom creates environmental problems. Waste heat from the three generating stations in Santa Monica Bay is detectable only in the nearshore surface waters between Dockweiler Beach and the Redondo Submarine Canyon (Figure 6-3).

The Thermal Plan prohibits a surface temperature elevation of more than 4°F above ambient following initial dilution and local power plants comply with this limitation (EQA/MBC 1973, IRC 1973). Areas of Santa Monica Bay which are affected by waste heat are actually smaller today than in 1973 because the availability of hydroelectric power from the Pacific Northwest has allowed most local power plants to operate below peak loadings. Two of the Redondo Generating Station's 8 units are now out of service, reducing the total potential for thermal pollution of the Bay.

Turbidity

Coastal waters are frequently murky, as a result of phyto- and zooplankton or of fine sediment suspended by nearshore turbulence. This natural phenomenon is often visible from the beach after a storm, when nearshore waters are brown, and offshore waters blue or blue-green.

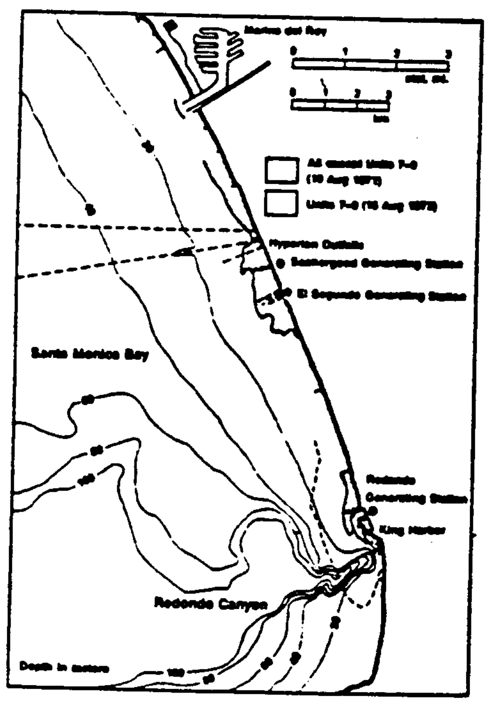

Figure 6-3. Maximum extent of 1F° above ambient thermal field from the Scattergood, El Segundo, and Redondo Generating Stations, August 1971 (Eliason and Foote 1972, EQA/MBC 1973).

VOL 12

15403

R0048708

Both plankton and suspended sediments interfere with light penetration into seawater and restrict growth of seafloor plants.

Within a mile of shore, turbidity usually limits light penetration to less than 20 ft off sandy beaches and 20 to 40 ft off rocky shores (SCCWRP 1973). Off landslide areas at Portuguese Bend on the Palos Verdes Peninsula, turbidity is higher and light penetration less. Seaward of the surfzone, turbidity declines and light penetration increases.

Around the HTP 5-mile outfall the turbid plume caused by outfall particulates seldom reaches the surface; it usually remains below the thermocline, at depths of 65 to 100 ft (Kolpack 1979). Turbidity is highest near the ends of the outfalls but is rapidly reduced by dilution. Initially the plume moves southeast and toward shore, where it mixes with natural nearshore turbidity; it is then transported seaward by tidal currents.

Currents on the Palos Verdes Shelf are complex but primarily move along shore and toward the northwest. In the late 1970's, the turbidity plume from JWPCP outfalls rose to within 45 ft of the surface, and extended westward to Palos Verdes Point (Sweeney and Kaplan 1980). This plume most affected light transmission near-bottom, where it formed a flocculent particle layer (Meistrell and Montagne 1983).

Water transparency in the study area generally increased between 1956 and 1979 (Mearns 1980); a trend which continued off Palos Verdes through 1985 (Stull *et al.* 1987). Additional studies would be needed to determine whether the increase in water transparency was a function of water temperature or the decrease in particulates discharged.

Metals

Trace metals in the water column are found in two phases: dissolved and particulate. In the open ocean most metals are predominantly present in dissolved form, but in nearshore waters more are associated with particulates. Dissolved metals in marine waters are generally very low, even adjacent to outfalls (Katz and Kaplan 1981). Dissolved cadmium levels near the JWPCP outfall were about the same as those at control sites but chromium was elevated two-fold, nickel four-fold, and copper six-fold near the JWPCP outfalls (Young and Jan 1975).

Over 90% of the metals in wastewater of the study area associated with particles (Young and Jan 1975). Ninety percent of the particles in the HTP 5-mile effluent and 75% in the JWPCP effluent remain suspended for at least 3 hr and travel 6 mi or more before settling (Herring and Abati 1978). Metals concentrations on suspended particulates near JWPCP were elevated 8 (cadmium) to 65 (chromium) times over background levels. The average enrichment (over background) of mercury on particulate matter near the JWPCP outfall was 36-fold. When the HTP 7-mile outfall was in operation, mercury enrichment ranged from 36 to 191 times, averaging 49.

The concentration of organotin compounds (tri-, di-, and monbutlytin) have been measured in seawater from both Marina del Rey and King Harbor. In King Harbor, total organotin levels ranged from 0.171 to 0.480 ppb, with tributyl tin (TBT) levels between 0.021 and 0.060 ppb (Stallard *et al.* 1986). TBT and total organotins were both higher in Marina del Rey water, TBT reaching 0.470 ppb (Soule and Oguri 1987). Dissolved tin compounds were not detected outside of enclosed marinas.

VOL 12 15404

Inorganic Nonmetallic Nutrients

Nutrients are introduced to the photic zone in runoff, via upwelling and destratification of the water column, and by sewage disposal. They stimulate plant growth and are generally beneficial, although excessive algal growth can have deleterious effects. Nutrients in the water column are linked with those in sediments by cyclic chemical transformations. Nitrogen is found in numerous forms including ammonia, nitrate, organic nitrogen, and nitrogen gas (Valiela 1984). After advection and upwelling, sewage was the most important source of these materials.

Nitrogen is never available for long in the open ocean. Nitrate, nitrite, and ammonia uptake by plants is swift and prevents their accumulation in surface water. Both nearshore and offshore ammonium inputs were clearly visible along the HTP 5-mile outfall in Santa Monica Bay (Figure 6-4) (Eppley *et al.* 1979). Inshore, near the El Segundo Refinery outfall, surface waters showed elevated ammonium on 7 of 10 cruises between 1975 and August 1977. Elevated levels have not been measured there since August 1977 and even the highest observed levels pose no hazard to exposed organisms (Eppley 1986).

Toxic substances such as chlorine, sulfide, cyanide, and asbestos fibers are introduced with both sewage and runoff waters and by fallout or in solution from the air. Chlorine is generally introduced only as residual chlorine in sewage following its application as a disinfectant and is present in wastewater as chloramines. At present, HTP does not routinely chlorinate its 5-mile effluent (nor did it chlorinate its sludge), although it chlorinates overflows discharged through the 1-mile outfall. JWPCP routinely chlorinated its effluent from 1972 to 1985 during cold months when the thermocline is absent and year-round since September 1985 (Ackerman 1988, pers. comm.; Weisman 1992, pers. comm.). The discharge limit for chloramine is 0.3 mg/l - typically it is <0.1 mg/l (the detection limit) (Stull 1993, pers. comm.).

The three generating stations in the Bay use chlorine to control biofouling growth in cooling systems, but under normal circumstances none is discharged into the Bay. It is not known whether significant levels of by-products of chlorination, such as chloramines and bromamines, occur in this effluent.

Data on dissolved sulfides and cyanide are not available from the study area. Asbestos has not been monitored sufficiently in the study area to establish either distribution or input levels (MBC 1988).

Organic Contaminants

Contrary to popular belief, all organic materials are not contaminants. The input of natural, terrestrial organic material via rivers predates man's influence and is an essential part of the normal nutrient cycle. However, man has controlled the input of organics to the sea by diverting them to drainage channels or sewage waste streams. Basic measures of organic loading in waters and sediments include biochemical oxygen demand (BOD), chemical oxygen demand (COD), and organic carbon. These quantify organic matter in terms of oxidation demand or carbon content. In open water such as the study area, dissolved and particulate organic materials almost never depress available oxygen below levels safe for marine organisms on the continental shelf. Particulate organic material may, however, be present to excess.

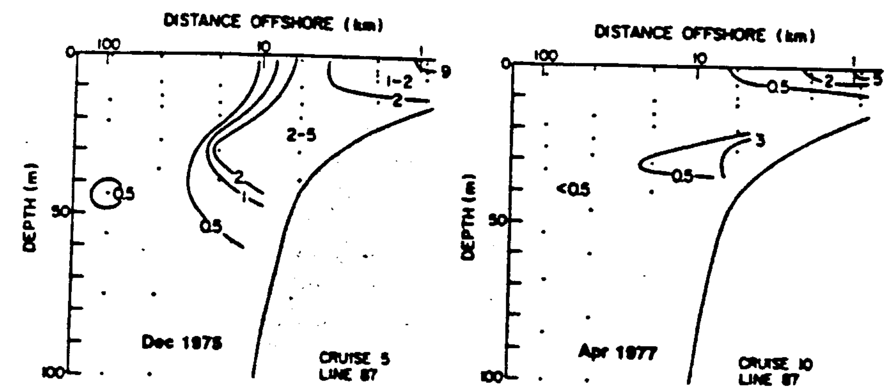

Figure 6-4. Concentrations of ammonium in ug-atoms/l from shore through mid-Santa Monica Bay parallel to the HTP outfalls in December 1975 and April 1977 (Eppley et al. 1979).

VOL 12

Biological Pathogens

Bacteria, viruses, and protozoans are introduced into marine waters at sewage outfalls, bathing beaches, and storm drains. To minimize pathogens, sewage effluents which are discharged nearshore are treated (i.e., disinfected) with chlorine. Once introduced into the marine environment, pathogens are found both free in the water column and on particulates. Biological pathogens are discussed in more detail in Chapter 11.

AERIAL FALLOUT

Aerial fallout is a diffuse and potentially large source of contaminants which also derive from other sources. However, it is probably the least controllable source and possibly the most difficult to quantify. Relatively few studies have been conducted to assess the kinds and amounts of contaminants which enter the ocean via this path. Trace metals, chlorinated hydrocarbons, and PAHs (SCCWRP 1973, 1986a) have been identified in aerial fallout to the study area.

During the late 1960s zinc, lead, and manganese were the most abundant trace metals in rainfall in southern California. Bight-wide, it was estimated that the mass emissions of lead, mercury, and manganese in aerial fallout actually exceeded those from discrete sources. However, given the smaller area and the presence of two major sewage discharges, this is not likely to be true for Santa Monica Bay and the Palos Verdes Shelf. The mass emissions of copper and zinc in aerial fallout in the Bight were about the same as from discrete sources and those of iron and nickel were less (SCCWRP 1973). Levels of lead in aerial fallout were greater in the vicinity of Los Angeles than on the offshore islands.

Bight-wide, dry-weather fallout emissions of DDT and PCB in 1973-1974 were lower than those from municipal wastewater, about 1,300 and 1,500 kg/yr, respectively (SCCWRP 1973, Young and Heesen 1976). The highest fluxes of dry-weather aerial fallout of DDT in the Bight were at Santa Monica and Point Fermin where averages were estimated at 0.665 and 0.575 $\mu g/m^2$ per day, respectively. For comparison, Point Dume and Palos Verdes Point averaged 0.280 and 0.155 $\mu g/m^2$ per day, respectively (Young *et al.* 1976b). Based on the area of the present study and average fluxes at the four sites, the mass emission of DDT to Santa Monica Bay during that period was about 113 kg/yr.

Dry-weather PCB fluxes in 1974 were 0.650, 0.500, 0.190, and 0.052 $\mu g/m^2$ per day at Santa Monica, Point Fermin, Point Dume, and Palos Verdes Point, respectively (Young *et al.* 1976b). The mass emission to Santa Monica Bay during this period is estimated at 94 kg/yr.

DDT was manufactured at the Montrose Chemical Plant in Torrance; until 1972, Montrose disposed of DDT process wastes at the Palos Verdes Landfill on the Palos Verdes Peninsula. The flux of DDT from the air near the plant and landfill were 31 and 16 times higher, respectively, at Santa Monica, whereas the flux of Aroclor 1254 was about twice as great at the Montrose plant as at Santa Monica (Young *et al.* 1976b). The flux of both DDT and PCB to Santa Monica Bay was twice as high during Santa Ana wind conditions as during normal dry weather (Young and Heesen 1976). In 1986 chlorinated hydrocarbons in the sea surface microlayer were higher near Los Angeles than further offshore (SCCWRP 1986d), possibly reflecting aerial fallout.

Brush fires create pulses of trace metals to the atmosphere by mobilizing metals deposited on foliage. In 1975 smoke from a large brushfire in the Angeles National Forest was carried out over Santa Monica Bay and the aerial fallout of most metals increased. The fluxes of

1 5407

manganese, iron, and chromium were 6 to 8 times higher than normal; the area directly beneath the smoke cloud had by far the highest levels (Young and Jan 1975).

Airplanes departing Los Angeles International Airport fly directly over Santa Monica Bay. The combustion of jet fuel and gasoline probably contribute to the aerial fallout in this region. PAH and other hydrocarbons may be especially high in fallout below this air corridor although this has not been quantified. In addition, airplanes experiencing difficulties have been known to dump fuel over the ocean before attempting to land.

CHAPTER 7
URBAN RUNOFF

Urban runoff is probably the most important of nonpoint sources of contamination to Santa Monica Bay and has been the focus of much public, political, and scientific attention during the past five years. Surface runoff (consisting of stormwater and nuisance water) is transported to the Bay via the watershed's drainage channels (i.e., natural creeks and open or enclosed storm drains). Because surface runoff from urban areas generally transports more contaminants than natural creeks, surface runoff is generally called urban runoff.

In many parts of the country, the storm drain and sewer systems are combined into a single system. However, in southern California the storm drain system is separated from the sewage system because storms are infrequent and heavy in flow. Because urban runoff is not treated it may now be the most significant source of contamination to Santa Monica Bay. Surface runoff is discharged to the ocean via about 80 storm drains. Because there are so many drains and because the flow varies with the time of year, it has been difficult to quantify the kinds and amounts of total contamination.

Surface runoff probably constitutes an important source of trace metals, pesticides, and coliform bacteria. As the quality of sewage effluent has improved over the years, the relative contribution by storm drains has increased, even if its absolute contribution has remained the same.

DRAINAGES TO THE BAY

Drainage Area

The total natural drainage area of Santa Monica Bay comprises about 414 mi^2 (SMBRP 1992). In the north part of the Bay, the natural drainage follows the crest of the Santa Monica Mountains from just west of the Los Angeles-Ventura County Line to Hollywood; a small crest separates the drainage west of Point Dume from that to the east (Figure 7-1). From the Santa Monica Mountains it extends south to Ballona Creek and the Baldwin Hills and east to downtown Los Angeles. South of Ballona Creek, the natural drainage is a narrow coastal strip from Playa del Rey to Point Fermin on the Palos Verdes Hills.

Inland, urban runoff from most of the wasteshed of Santa Monica Bay (i.e., the area with sewer lines leading to Hyperion Treatment Plant and the Joint Water Pollution Control Plant) flows into the Los Angeles River, San Gabriel River, and Dominguez Channel, all of which drain into Los Angeles and Long Beach Harbors (Figure 2-1). Hence, while most of the sewage from the metropolitan area of Los Angeles County discharges into Santa Monica Bay, most of the urban runoff from the same area discharges into Los Angeles-Long Beach Harbor in San Pedro Bay.

Drainage Channels

Numerous storm drains (pipes or open channels) empty onto or across the beaches of the study area (Figure 7-1). There are at least 10 between the Los Angeles-Ventura County Line and Point Dume (Terry *et al.* 1956) and 68 between Big Rock Beach (east of Malibu) and Point Fermin; 37 of these are maintained by the Los Angeles County, Department of Public Works (LAC,DPW) and 31 by other organizations (LAC,DPW 1985). Along the Malibu and Palos Verdes coasts there are many small drains which collect runoff from a single street, parking lot, or small arroyo. Presently LAC,DPW is in the process of mapping drainage channels maintained by the cities in the study area (Hildebrand 1993, pers. comm.).

VOL 12

15410

R0048715

Of the major drainage channels in the area, Ballona Creek (including Centinela Creek and Sepulveda Channel) is channelized; Pico-Kenter and Santa Monica Canyon are partially enclosed storm drains; while Malibu Creek and Topanga Canyon are natural creeks. Ballona Creek drains about 90 mi^2 and Malibu Creek drains about 103 mi^2 (LAC,DPW unpubl. data).

The water quality of Marina del Rey is influenced by point source and nonpoint source discharges which enter either the Marina or adjacent contiguous waters (Soule *et al.* 1992). Ballona Creek, Ballona Lagoon, and the Oxford Flood Control Basin collect runoff from urban areas which enters the Marina as a result of tidal exchange or storm water runoff (Soule *et al.* 1992). Oxford Street flood control channel is one of the smaller drainage channels in the watershed, however, it is important because it drains into the Marina through a tide gate. Although Ballona Creek flood control channel carries a much larger volume of water from a larger area than Oxford Street basin, Ballona Creek seems to have less of an impact on the Marina (Soule *et al.* 1992). Heavy wet weather flow will carry much of the debris into Santa Monica Bay, but during dry weather low flow, debris will enter the Marina on rising tides.

RUNOFF FLOW RATES

Surface runoff has two major components: rainfall and nuisance water (street runoff from domestic activities, irrigation water, and commercial and industrial discharges). In the dry season, from May to October, surface runoff consists primarily of nuisance water. In the wet months, from November to April, most of the surface runoff is from rainfall.

Annual Flow

The average surface runoff flow to Santa Monica Bay from all storm drains and creeks has been estimated at 143 to 153 mgd (NRC,COWT 1984; Garber and Wada 1988). However, flow rates vary widely by season, by year, and during a storm due to the amount of rainfall. Ballona Creek and Malibu Creek are the major channels in the drainage with gauging stations. However, because the gauging stations are located upstream, they do not measure the entire flow from either creek (Figure 7-1). Hence, the absolute flows are actually larger than indicated below. Santa Monica Creek and Sepulveda Channel also have gauging stations (Engineering Science 1987) but flow rates are not measured on a regular basis at these locations. The Topanga Canyon gauging station was destroyed during a storm in 1992 and at present there are no plans to replace this station (Hildebrand 1993, pers. comm.).

In normal (i.e., dry) years the annual flow in Ballona Creek is typically 2 to 10 times greater than that in Malibu Creek whereas in wet years the two flows are more comparable (Figure 7-2). For instance, in 1984 (a dry year), the Ballona Creek mean annual flow was 19 mgd whereas that of Malibu was 12 mgd (MBC 1988). Similarly, in the dry years of 1988 to 1991, the mean annual flow from Ballona Creek was 24 mgd whereas that of Malibu Creek was 10 mgd (LAC,DPW, unpub. data). In contrast, in 1983 (a very wet year) the flow in Ballona Creek was 81 mgd while that in Malibu Creek was 82 mgd. However, in some wet years the flow from Malibu Creek is higher than that of Ballona Creek. For instance, in 1969 the Malibu Creek flow was about 1.5 times that of Ballona Creek. Similarly, in 1992 (January to September) the average daily flow in Malibu Creek was almost twice that of Ballona Creek (LAC,DPW unpubl. data).

Flow rates for Topanga Creek were only available for 1989 (a dry year). Flows averaged 0.2 mgd in Topanga Creek while flows averaged 6 mgd and 15 mgd in Malibu and Ballona, respectively (LAC,DPW unpubl. data).

VOL 12

1541

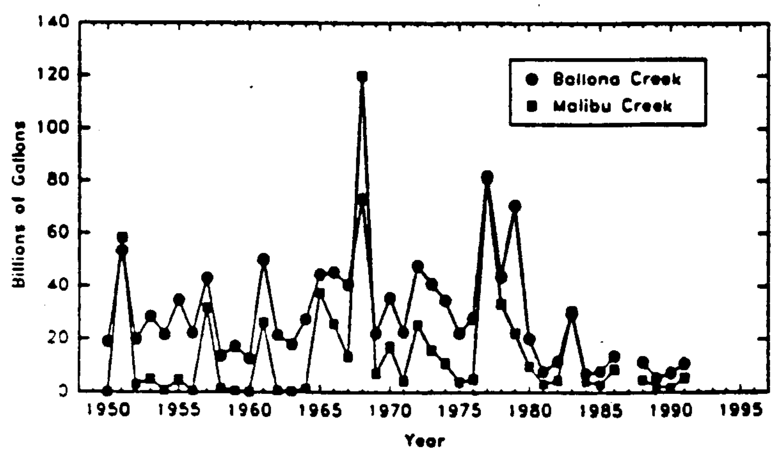

Figure 7-2. Annual flow from Ballona and Malibu Creeks for 1950-1991 (LAC,DPW unpubl. data).

Seasonal Flow

In addition to annual variation in flow there is seasonal variation between wet-weather (storm) and dry-weather months. In water year 1971-1972, wet- and dry-weather flows were estimated on the basis of instantaneous volumetric flows which were extrapolated to seasonal and annual flows for Ballona Creek, Pico-Kenter Storm Drain, and Malibu Creek (SCCWRP 1973). The annual flow during that period in Ballona Creek was about 10 times that of the Pico-Kenter Storm Drain or Malibu Creek, although only dry-weather flow was reported for Malibu Creek. In Ballona Creek wet-weather flow was 1.7 times greater than dry-weather flow, but in Pico-Kenter Storm Drain wet-weather flow was about 33% of dry-weather flow (SCCWRP 1973).

Based upon 1983 gauging station records, about 48% of the total flow in Ballona Creek and about 64% of it in Malibu Creek occurred during January and March. In 1984 about 39% of the total runoff in Ballona Creek was in December (LAC,DPW, unpubl. data). In 1991, 22% of the flow in Ballona Creek occurred in December and 65% occurred from January to March; however, in Malibu Creek about 15% occurred in December and 81% in January through March. Based on 1992 gauging station data for January through September, 86% of the total flow in Ballona Creek and about 88% in Malibu Creek occurred during January through March.

Storm Flows

Surface runoff is highest during and following storms and hence is usually highest during the winter. About 70% of the surface runoff in southern California occurs during storms (NRC, COWT 1984). During a storm in 1986, the peak flow in Ballona Creek was 275 times the dry weather flow (Schafer and Gosset 1988a).

CONSTITUENTS OF URBAN RUNOFF

Surface runoff carries large quantities of sediment, debris, and dissolved materials to the ocean. Many of these constituents are characteristic of natural runoff and do not pose a problem to the environment. However, some contaminants are potentially a threat to human health, impact the marine habitat, or affect the aesthetic qualities of the Bay. Three categories of pollutants found in stormwater/urban runoff are of concern in Santa Monica Bay because of their potential impact on the marine environment and human health. These include toxic compounds, biological pathogens, and litter. Naturally occurring nutrients and sediment from construction activities may also impact enclosed bodies of water such as wetlands or streams.

Existing monitoring programs conducted by LAC,DPW include regular dry weather and storm sampling at Ballona Creek, Pico-Kenter Drain, Malibu Creek, Santa Monica Canyon Channel, Topanga Canyon, and Dume Creek (Hildebrand 1993, pers. comm.). Several one-time studies have also examined levels of constituents in urban runoff from the area (LAC,OCAO 1981; Schafer and Gosset 1988b; UCLA and WCC 1992).

Sediment

Sediment naturally enters runoff during storms when rainwater flows over open areas. During the periods when the Los Angeles River discharged into Santa Monica Bay via Ballona Creek, storms probably transported large quantities of sediment to the Bay from the enlarged watershed area. However, even in the absence of a connection with the Los Angeles River, more sediment would have been transported in Ballona Creek prior to the construction of flood control channels during the early [illegible] of the 20th century (Terry *et al.* 1956) because the land in the drainage was less developed. Suspended sediments have not been measured in all surface runoff entering Santa Monica Bay, but aerial photographs of runoff plumes suggest that emissions are substantial, especially in natural drainages along the Malibu coast (Mitchell 1987, pers. comm.).

Mass emissions of silt are still highest in Ballona Creek. In water year 1971-1972, mass emissions of silt from Ballona Creek, Malibu Creek, and Pico-Kenter Storm Drain were estimated at 10,800, 1,000, and 700 MT, respectively. About 93% of the silt from Ballona Creek and about 71% from Pico-Kenter was discharged during storm flows (SCCWRP 1973). Sources of this silt include dust blown into the watershed by winds and sediments from upstream construction sites.

The soil in terrestrial areas adjacent to the Oxford Street flood control channel is highly contaminated with trace metals, pesticides and PCBs accumulated from earlier dumping or from World War II industrial contamination (Soule *et al.* 1992). During rainstorms, excavated soils erode and become suspended carrying pollutants into Marina del Rey harbor (Soule *et al.* 1992).

Naturally Occurring Dissolved Constituents

Naturally occurring compounds and metals dominate the dissolved solids in surface runoff. These constituents are abundant in surface runoff in both developed and undeveloped areas and are not considered to be harmful. Naturally occurring dissolved solids in surface runoff include calcium carbonate, bicarbonate, sulfate, chloride, calcium, sodium, magnesium, organic carbon, potassium, nitrate, nitrite, ammonia, iron, flouride, barium, and manganese, with traces of other metals. These constituents form the background environment to which contaminants or pollutants from human activities are added. Nevertheless some human activities in the watershed may increase concentrations and emissions of some of theses constituents.

From 1962 to 1982 the overall most abundant constituents from the five major drainage channels in the watershed were calcium carbonate, chloride, calcium, barium, and boron (Garber and Wada 1988). In 1983-1984 and 1989-1990 the major constituents of the surface runoff from Malibu Creek, Santa Monica Canyon, Pico-Kenter Storm Drain, Ballona Creek, and Centinela Creek were calcium carbonate, bicarbonate, sulfate, chloride, and calcium (Tables 7-1, 7-2) (LAC,DPW unpubl. data). The most abundant metallic ions were calcium, sodium, magnesium, and potassium. Dominant metals include iron, boron, and barium; abundant nonmetallic, inorganic constituents were chlorides and nitrates.

Constituent levels differ somewhat between drainage channels. In 1971-1972 mass emissions of most constituents were 5 to 10 times greater in Ballona Creek than in the Pico-Kenter storm drain or Malibu Creek (SCCWRP 1973). In 1983-1984 total dissolved solids (TDS) and the major constituents (calcium carbonate, bicarbonate, and sulfate) in surface runoff of Ballona and Malibu Creeks were comparable (MBC 1988). In 1989 mass emissions of constituents in surface runoff were generally higher in Ballona Creek than in Malibu Creek (Table 7-3) (M. Stenstrom, Univ. Calif., Los Angeles, unpubl. data; LAC,DPW, unpubl. data). This was due in part to a flow in Ballona Creek that was more than twice that of Malibu Creek. Sulfate was dominant in both creeks but chloride, calcium, and sodium followed in Ballona Creek whereas in Malibu Creek, the order of the last three constituents was reversed (i.e., sodium, calcium, and chloride).

Contaminants

Constituents of concern in urban runoff are generally the same as are limited in NPDES permits for point source discharges. Toxic compounds include organic chemicals and trace metals can be directly toxic to marine organisms or can accumulate in the tissues of marine

organisms and thus potentially cause adverse effects to the organisms or make them unfit for human consumption.

Contaminant levels in urban runoff are generally low, however, the more general categories of BOD and oil and grease as well as nutrients such as nitrates, ammonia, and phosphates are often abundant. For instance, in 1983-1984 mass emissions of contaminants (estimated from average concentrations in major channels) of BOD, oil and grease, ammonia, and phosphates were 1,514; 664; 277; and 201 MT/year, respectively (Table 7-4)(NRC,COWT 1984; LAC,DPW, unpubl. data). These constituents come from both natural and anthropogenic sources.

Trace metals are generally the next most abundant chemical contaminants. From 1962 to 1982 the major trace metal contaminants discharged to the Bay in urban runoff were zinc, lead, nickel, total chromium, copper, arsenic, selenium and mercury, with average mass emissions of 72.3, 17.9, 14.2, 12.4, 11.7, 2.9, 2.2, and 0.09 MT/year (Garber and Wada 1988). In 1983-1984 mass emissions of the dominant trace metals (estimated from average concentrations in major channels) contributed by urban runoff from major drainage channels in the watershed were 14.4, 11.5, and 10.6 MT/year for zinc, nickel, and hexavalent chromium, respectively (Table 7-4)(NRC,COWT 1984; LAC,DPW, unpubl. data). The dominant chlorinated hydrocarbons were total DDT, endosulfan, and endrin with estimated mass emissions of 31, 24, and 18 kg/year. A previous estimate of mass emissions based on the same flow but using constituent concentrations obtained from the Pico-Kenter Storm Drain during dry weather conditions produced somewhat different values (Table 7-4). Total dissolved solids, chloride, sodium, COD, calcium, BOD, potassium, boron, zinc, lead, and cadmium had higher values while sulfates, magnesium, oil and grease, nitrates, phosphates, manganese, nickel, chromium, copper, and silver were lower (NRC,COWT 1984).

As with other constituents, contaminant levels differ between drainage channels. In 1971-1972 mass emissions of most contaminants were 5 to 10 times greater in Ballona Creek than in the Pico-Kenter or Malibu discharges (SCCWRP 1973). In 1983-1984 Ballona Creek was higher in ammonia, oil and grease, and BOD while Malibu Creek was higher in phosphates, nitrates, and sulfates (Table 7-3)(LAC,DPW unpubl. data). In 1989 constituents that were more than 10 times higher in Ballona Creek than in Malibu were TOC, nitrates (M. Stenstrom, Univ. Calif., Los Angeles, unpubl. data; LAC,DPW, unpubl. data). Levels of phosphates and lead were higher in Malibu Creek. Pesticides were only measured in Ballona Creek and these were dominated by total DDT and lindane (MBC 1988).

In 1980 dry-weather flow from Pico-Kenter Storm Drain was scanned for the presence of about 600 compounds; 250 were subjected to Ames testing for possible mutagenic properties. Although some components were mutagenic, no specific mutagen was identified. Possible mutagens found in the discharge were petroleum products; phthalate esters from thinners, lacquers, and varnishes; and automobile coolant (ethylene glycol esters and propylene glycol) (LAC,OCAO 1981; NRC,COWT 1984). Mutagenic organic substances have also been found in other stormwater samples of the Los Angeles area (Garber and Wada 1988).

Biological Pathogens

Urban runoff also contributes bacteria and viruses to the marine environment. Pathogenic (disease-causing) forms may pose potential health risks to swimmers and waders. Indicators of potential human contamination include total coliform, fecal coliform, fecal streptococcus, and enterococcus bacteria. The concentrations of these bacteria is measured to indicate possible presence of pathogens of concern to humans (Greenberg *et al.* 1985). Pathogenic agents which

*Based on mean concentrations at the Pico-Kenter Storm Drain during October 1980 and the estimated total surface runoff flow to Santa Monica Bay (NRC,COWT 1984).

**Based on average mean concentrations for Malibu Creek, Santa Monica Canyon, Pico-Kenter Storm Drain, Ballona Creek, and Centinela Creek during 1983 (a wet year) and 1984 (a dry year). (MBC 1988).

***Estimated average annual flow of surface runoff to Santa Monica Bay (NRC,COWT 1984) survive in seawater include viruses (hepatitis A and polio myletis), bacteria (*Staphylococcus, Salmonella,* and *Vibrio*), and a fungus (*Candida albicans*) (Kim 1975, Morris and Kim 1975, Dufour and Cabelli 1983).

Enteric bacteria are introduced via runoff in all drainage channels in the watershed. Enteric bacteria from Santa Monica Mountain streams (including Malibu Creek) and urban storm drains (including Ballona Creek) could pose a health risk to swimmers and waders in those areas.

In 1980 total coliform counts in dry-weather flow were highest in Centinela Creek while fecal coliform counts were highest in Pico-Kenter Storm Drain; lowest counts of both were in Ballona Creek (LAC,DPW unpubl. data). In 1983-1984 average concentrations of total coliform was highest in Ballona Creek; fecal coliform and fecal streptococcus was highest in Pico-Kenter Storm Drain.

In 1989 average concentrations of total coliform were more than 10 times higher in Ballona Creek than in Malibu Creek (Table 7-2)(LAC,DPW, unpubl. data). Average concentrations of total coliform, fecal streptococcus, and fecal coliform were highest in Pico-Kenter Storm Drain; the second highest concentrations were found in Centinela Creek.

Dry-weather coliform counts from the surf zone near storm drains during 1985-1987 were greatest near the Pico-Kenter and Pulgas Canyon Storm Drains. Elevated counts occurred throughout the surf zone of the Bay after storms but particularly near storm drains. The highest counts were off the Pico-Kenter Storm Drain and Ballona Creek (both sides); however, high counts were also found between Pulgas Canyon and HTP and off Torrance south of King Harbor (MBC 1988). Storms or extreme high tides carry fecal material washed off the jetties, such as dog, bird, and human feces, into the Marina (Soule *et al.* 1992).

Litter

Litter enters the Bay with surface runoff, via ocean currents, and as a result deliberate or accidental disposal into the ocean or onto beaches (Pruter 1987). Most is aesthetically unpleasing and some litter may represent a physical hazard; however, some may provide food and habitat for marine life. Plastics and metals degrade slowly and may persist indefinitely.

Creeks receive a large amount of debris such as yard clippings, Christmas trees, fast food plastic containers, waste motor oil, and aluminum cans. Trash and debris significantly affect the aesthetic quality of the seashore and may cause the death of fish, birds, and marine mammals that become entangled in or attempt to consume items of litter.

INFLUENCE OF STORMS ON CONTAMINANT LEVELS

The major constituents in dry- and wet-weather flows differ considerably. In general, suspended and settleable solids are greater during storms while dissolved solids (mostly salts) are greater in dry weather. Calcium, magnesium, sodium, potassium, hexavalent chromium, calcium carbonate, bicarbonate, nitrate, chloride, fluoride, and endosulfan have greater dry-weather mass emissions. The mass emissions of most metals, ammonia, phosphates, TOC, BOD, COD, oil and grease, heptachlor epoxide, and lindane are greater in wet weather. Thus, most of the annual input of metals and organics to the ocean occurs in storm flows whereas most salts enter in dry-weather flows (LAC,DPW unpubl. data). Salts can generally dissolve in a small amount of water whereas a sizeable flow is required to suspend and carry silt and organics.

Highest concentrations generally occur in channels with the greatest flows also making them the greatest sources of mass emissions (Schafer and Gossett 1988). Highest contaminant concentrations occurred near the peak flows and not at the first increase in flow (Schafer and Gossett 1988b).

High mass emissions generally occurred in months when flows were highest (Figure 7-3). In 1991 mass emissions of lead and oil and grease were highest in March when the flow was highest in both Ballona and Malibu Creek. In 1992 flows in Malibu Creek and Ballona Creek were highest in February and decreased in March. In general, mass emissions of lead and oil and grease varied in respect to flow, with highest emissions in February and decreasing at the same rate as flow in March and April. Mass emissions of lead were extremely high in January 1989 in both Ballona Creek and Malibu Creek when flow was relatively low. This may be the result of heavy rains that occurred in December 1988, prior to sampling. These high values in lead may also be due to a spike or illegal discharge, or an error in sample analysis, however, concentrations were high in all drainage channels during that time. During dry periods mass emissions showed little to no variation from month to month.

Runoff Dynamics During a Storm

The first storm of the season (or any storm which follows a dry period of several weeks or more) that significantly increases stream flow generally creates an immediate pulse in the concentrations of contaminants which accumulated in streets, gutters, and channels during dry weather, low-flow conditions (Engineering-Science 1987, MBC 1988). The highest contaminant concentrations occur near the peak flows, not at the first increase in flow (Schafer and Gossett 1988b). During a storm in 1986, peak flows in Ballona Creek occurred 24 hr after the rainfall began but concentrations of most constituents were highest 13 hr after the beginning of the storm (when flow was 40% of the peak flow). Maximum concentrations of the constituents at 13 hr were greater than the minimum levels (which generally occurred 24-42 hr after the storm began) by the following multipliers: DDT, 1,360; lead, 261; total suspended solids, 192; total pesticides, 162; chromium, 110; cadmium, 29; zinc, 26; nickel, 19; and oil and grease, 17 (Schafer and Gossett 1988b).

Comparison with other Watersheds

Compared to other drainage channels in Ventura and Los Angeles Counties, Ballona Creek stormwater had the highest levels of oil and grease, DDT, and trace metals in runoff samples from the first storm after the dry season in 1986 (Schafer and Gossett 1988b). Both the Los Angeles River and Ballona Creek had the highest mass emissions of the contaminants examined; this was the result of both having the highest flow and highest mean contaminant concentrations. Ballona Creek had both higher concentrations and higher mass emissions of DDT than the Los Angeles River (Table 7-5) and other locations sampled within the Southern California bight (Schafer and Gossett 1988b). Concentrations of oil and grease and trace metals, except copper and chromium, were higher in Ballona Creek than in the Los Angeles River but the higher flow at the Los Angeles River resulted in higher mass emissions there (Schafer and Gossett 1988b).

SOURCES OF CONTAMINANTS

Potential sources of contaminants in runoff include household and industrial wastes, accidental spills, sewer overflows, septic tank leaks, illegal and illicit connections, excess runoff and chemicals from landscape irrigation, rubbish, used crankcase oil, grease, food by-products,

wash water, debris discarded on the street, animal droppings, and settled air pollutants. Street runoff carries the metal, rubber, and oil residues from highways, while garden runoff carries pesticides (Soule *et al.* 1992).

Enteric bacteria in Malibu Creek may also come from the TWRF, which has discharged into the creek since the late 1970s. As of 1987, about 90% of the treated effluent is recycled and sold during the summer but in the winter, most is discharged into Malibu Creek. The effluent received advanced secondary from the late 1970s to 1984 and has received tertiary treatment since then. The effluent has been below NPDES limits for coliform about 99% of the time. However, since the effluent is dechlorinated (after disinfection with chlorine) before being discharged to the creek, it is possible that regrowth may occur (Colbaugh 1988, pers. comm.). Coliform bacteria in Malibu Lagoon and Malibu Creek may be from this source but may also be from soil, lower animal wastes, septic tanks in the drainage, or from waterfowl (Sowby 1988, pers. comm.).

Most of the residential area along the coast west of Palisades is unsewered and sewage is disposed of in septic tanks. Tanks that are in disrepair may leak and may contaminate the ocean. High coliform counts have been noted in the area after storms. Many residents in the area do not believe that a new sewer system is necessary because septic tank problems have been less common in recent years. The coliform contamination in this area may also be from pets, wildlife, and birds (Stewart 1987).

CONTRIBUTION OF CONTAMINANTS BY LAND USE

Pollutant loadings are affected by various factors such as rainfall pattern, land use, and area of the drainage basin. There are 28 separate drainage basins within the Santa Monica Bay watershed (Figure 7-4). Each drainage area is unique due to topography and land use: the largest drainage areas are Ballona and Malibu Creek. Major types of land use include residential (single-family and multi-family), commercial, public, light industrial, other urban, and open areas (Figure 7-5). Open space is the primary land use in the Santa Monica Bay watershed with 57% of the total watershed area; it is followed by single-family and multi-family residential at 26% and 7%, respectively. Commercial and light industrial uses constitute the remaining 10% of the total watershed area (UCLA and WCC 1992).

The type of land use strongly influences the pollutant load: the more impervious area, the greater the runoff (UCLA and WCC 1992). The dominant form of land use, open space, has no impervious surface area whereas commercial land use has the highest (92%) impervious surface area. Thus, more runoff per unit area will result from commercial areas than from open areas. In single-family residential areas, an average of 35% of the surface is impervious. Since more land in the Santa Monica Bay watershed is devoted to residential use than commercial, residential accounts for a greater percentage of runoff pollutants (SMBRP 1992).

Among measured attributes, levels of TSS and COD were the highest in runoff from land-use areas in the Santa Monica Bay drainage basin, with TSS the dominant constituent (Table 7-6) (UCLA and WCC 1992). Oil and grease were the dominant constituent in runoff from multi-family residential, commercial, public, light industrial, and other urban areas; BOD in single-family residential areas and TKN in open areas. Single-family residential areas contribute the highest percentage of BOD, COD, total phosphorus, soluble phosphorus, TKN, nitrite and nitrate, copper, lead, and zinc. Open areas contribute the highest percentage of total suspended solids and multi-family residential areas contribute the highest percentage of oil and grease.

VOL 12

15427

Single-family residential areas contributed approximately 50% of the annual load of the oxygen demand, and nutrient pollutants (Table 7-6). All other land use types contributed mostly to oil and grease; the largest contributors are from multi-family and commercial areas. The greatest percentage of copper, lead, and zinc is also from single family residential areas. TSS predominantly comes from open areas.

REGULATION OF CONTAMINANTS IN URBAN RUNOFF

Because there is no means of treating surface runoff at present, source control is the only way to reduce the levels of contamination in urban runoff.

NPDES Permits

In June 1990, the California Regional Water Quality Control Board, Los Angeles Region issued a NPDES permit for stormwater and urban runoff to the County of Los Angeles as principal permittee, and the cities in the Santa Monica Bay Watershed as co-permittees (Appendix F). The permit requires Los Angeles County and the 85 cities in the County to control pollution from urban runoff. To address the distinct problems associated with the control of stormwater/urban runoff pollution, a new approach has been initiated in the Santa Monica Bay watershed.

General Stormwater Discharge Permits

General stormwater discharge permits for industrial facilities and construction sites were issued by the State Water Resources Control Board in the summer of 1992. These stormwater/urban runoff permits provide a new regulatory framework which is considered practical and adaptable to the Los Angeles County drainage system's distinct structure. Programs developed under current stormwater permits emphasize pollution control through best management practices (BMPs) as opposed to conventional technology-driven water quality standards.

Best Management Practices

Studies conducted by the SMBRP have shown that land use practices are among the most identifiable causes of stormwater/urban runoff pollution. It is widely recognized that the elimination of diffuse "nonpoint" sources ultimately depends on successfully changing the long-standing habits and practices of people at work and in their communities. Therefore, among potentially effective BMP's, priority should be given to implementation of new land-use practices and to nonstructural control measures, in particular, public education and involvement programs.

Ozone Treatment

One potential technique for the treatment of urban runoff is to construct catch basins at the mouths of drainage channels and to treat runoff by ozone disinfection prior to discharging into the Bay. Ozone is used by the drinking water industry as an alternative to chlorine, and a pilot study demonstrating ozone disinfection was conducted for the SMBRP on the Kenter Canyon Storm Drain System in Santa Monica. Results showed that ozone was an effective dry-weather storm drain disinfectant (Greene 1992).

CHAPTER 8

IMPACTS - TERRESTRIAL, INTERTIDAL, AND WETLANDS HABITATS

TERRESTRIAL HABITATS

The native habitats of the Santa Monica Bay watershed have been greatly modified by the arrival of humans into the area. Native Americans used the natural resources such as plants and animals for shelter and food; they even practiced some fire control vegetation management. However, the impact was small compared to that from the first Europeans. Following California's statehood, some plant communities were more impacted than others. The first to be modified were the relatively flat native grasslands and the riparian areas along streams and rivers. Changes began with cattle grazing, clearing for fields, and damming of streams. Later, residential and commercial development, channelization of rivers and streams, introduction of non-native plant and animal species and production and use of toxic chemicals for industry and agriculture have all had their impact on native habitats.

About half of the area of the Santa Monica Bay watershed has been modified from native plant communities for agricultural and urban use (Figure 7-5). The impacts of development go beyond the actual area being used, as air and water carry material into previously pristine areas, and urban populations look for recreational locations away from the everyday congestion of the urban setting.

The growth of agriculture and trade resulted in the introduction of non-native species from Europe and other parts of the Americas for use as crops, other food, or for transportation. Many introductions were accidental (e.g., rats), but some were nonagricultural but concomitant with human civilization (e.g., cats). It will never be known how many native species were driven to extinction by introduced species taking over habitats or by the destruction of small or unique habitats. It is known that most of the native perennial bunch grasses are gone, along with many other annuals, insects, birds and mammals. At present there is concern about the remaining native habitats and steps are being taken to reduce the pressure from increasing population, to protect and restore native plant communities.

In southern California, the practice of fire suppression to prevent destruction of property has resulted in thick chaparral stands which have not burned for many years near populated areas. These stands are extremely susceptible to natural or man-induced fires, especially during Santa Ana wind conditions. Because of the accumulation of fuel, fires in these stands can burn extremely fast and hot. Urban sprawl has continued to intrude into these habitats, making control of fires necessary, but more difficult. The California Department of Parks and Recreation's policy now considers fire to be a natural element of the environment, and has begun prescribed burning in some units of the State Park System (Wells 1990). Other landholders, such as the Nature Conservancy, are taking similar steps.

Since they usually occur in the dry, hot season, large and severe fires can lead to widespread flooding, accompanied by high sediment loads in runoff from heavy winter rains. When combined with other man-made disturbances of the earth, such as road building and housing construction, flooding can result in destruction of property and loss of life.

Remediation

The Conservation/Open Space Element of Los Angeles County's General Plan (revised in 1979) includes the need "to protect...watershed, streams, and riparian vegetation to minimize water pollution, soil erosion, and sedimentation, maintain natural habitats, and to aid in ground water recharge." There are 65 significant ecological items in this element that are identified in a report entitled "Land Capability/Suitability Study, Los Angeles County General Plan Revision Program 1976" (Faber *et al.* 1989).

INTERTIDAL HABITATS

Impacts

Reduction of Sand Sources

Prior to the construction of flood control structures, heavy rains carried abundant sediment to the coast (Woodell and Hollar 1991). However, development in the Los Angeles basin has included measures to decrease the risk of flooding, along with water retention and diversion for agricultural and domestic use. Flood-control projects have reduced the rate and volume of flood runoff and its sediment load. As a result, some beaches downcoast of major streams or storm drains eroded; the sand which is lost offshore during high-wave events is not replenished naturally. Erosion now threatens coastal structures and beaches with less sand are less attractive for recreational activities.

Historically, the major sources of beach sand for Santa Monica Bay were bluff erosion and creeks and rivers which emptied into it: Calleguas, Malibu, Topanga and Ballona Creeks, and, occasionally, the Los Angeles River. Sand is lost to the system offshore and by longshore transport into Redondo Submarine Canyon. Estimates of transport rates vary, but in the 1960s a net transport of 246,000 yd^3/yr (188,000 m^3/yr) to the south was considered reasonable. Completion of the King Harbor North Breakwater has disrupted the loss to Redondo Submarine Canyon somewhat, although sediment still enters the Canyon from the south (Woodell and Hollar 1991). The development of housing and recreation facilities atop dunes has further reduced the amount of available sand (Casali *et al.* 1991).

Construction and beach renourishment projects have resulted in a coastal zone which is fairly stable, but which shows little resemblance to the beaches prior to man's intervention. The reduction of sand loss down Redondo Submarine Canyon, the construction of Marina del Rey and King Harbor, and the many piers and groins, have combined with beach nourishment to yield 14 miles of beaches which are now several hundred feet wider than they were previously (Woodell and Hollar 1991).

Groin, Jetty, and Pier Construction

One of the fundamental problems in the coastal zone is sand management: sand often erodes from desirable locations (for recreation and storm protection) and accumulates where it is not wanted (in harbor entrances, passes and inlets). The groins and jetties which are built to protect harbor entrances or to control erosion also affect longshore sediment transport. Sand accumulates on the upcurrent side of a structure perpendicular to the shoreline and erodes on the downcurrent side (Anikouchine and Sternberg 1973).

Structural methods of shoreline protection in the past, include the construction of more than 50 groins and jetties on Santa Monica Bay beaches. Many were specifically intended to help sand accumulate (Woodell and Hollar 1991).

Beach Nourishment

The primary nonstructural method of beach protection is beach nourishment, which often has only short-term success unless other measures are taken concurrently. Beach nourishment is only feasible (i.e., cost effective) where there is a nearby sand source. Most beach nourishment projects are initiated in response to navigational requirements to dredge and remove sand from harbor entrances.

Efforts to rebuild eroding beaches was begun in 1938 when nearly 1.8 million yd^3 of material from nearby dunes was placed onto the beaches (Shaw 1980). Since then more than 30 million yd^3 of material have been placed in the littoral zone (Woodell *et al.* 1990).

Almost 17 million yd^3 of material has been placed on Dockweiler State Beach since 1938 from the construction of the original Hyperion Treatment Plant. Since 1960 Dockweiler has also received more than 10 million yd^3 of material from construction and by-pass operations at Marina del Rey.

Dockweiler Beach is presently being nourished with sand from nearby dunes. In 1992, lead and other metals levels in sediments from Marina del Rey were found to be too high for beach nourishment. Materials dredged from the Marina were dumped offshore, to be distributed by longshore currents (Chang 1992, pers. comm.). More than 1.3 million yd^3 of sand from offshore sources have been deposited on Venice Beach and almost 2.6 million yd^3 on Redondo and Torrance Beaches (Woodell and Hollar 1991).

Especially large storms may even cause erosion of sand dunes. By replacing sand to the eroded dune, both beach and dune are nourished and maintained. Dune maintenance can stabilize a beach even where sand is lost to longshore transport (Walther 1991).

Urban Runoff

Urban runoff is a major source of contaminants which impacts intertidal marine organisms. Contaminants in seafood organisms can be transferred to man and result in adverse health effects. Filter-feeding intertidal organisms have a particularly high potential for bioaccumulating pesticides such as DDT, complex chlorinated hydrocarbons such as PCBs, and organometallic compounds such as methylmercury. In addition, most intertidal organisms are invertebrates and are less able than vertebrates to transform organic and metal contaminants to less toxic forms. Bacteria are discharged onto beaches from storm drains during periods of high flow, necessitating beach closures for short periods of time to protect human health.

Municipal Wastewater Discharges. Intertidal habitats are not exposed directly to contaminants discharged offshore, but they are exposed indirectly with every tidal cycle. Floatable materials from municipal effluent may reach the intertidal zone during onshore winds. Of particular concern are oily materials which rise to the surface, bearing lipid soluble contaminants (Word *et al.* 1984). These accumulate at the sea surface along with contamination from spills, boat bilge pumping, storm drain runoff, and natural oil seeps.

VOL 12

15431

R0048736

The potential impacts of floatable materials on intertidal biota have not been examined from a community standpoint, although some air-water interface contaminant data are available (SCCWRP 1986d). The susceptibility of intertidal communities can be inferred from tissue toxicant concentrations in the California mussel; trace metals, DDT, and PCB levels were higher along the Palos Verdes Peninsula and near Marina del Rey than elsewhere in the study area.

Rocky intertidal communities in the Bay have not been well studied. Although intertidal algal distributions are adequately described. Data are available from prior to (Couch 1915, Goodman 1935), during (Dawson 1959, 1965; Widdowson 1971), and after (Thom and Widdowson 1978; Harris 1980, 1983) the period of peak contaminant discharge into the Bay. Reductions in algal cover and diversity on the Palos Verdes Peninsula were attributed to effluent from the JWPCP outfalls (Tetra Tech 1984). Algal communities impacted by sewage effluent resemble early successional stages and are dominated by opportunistic species with high reproductive potential (Murray and Littler 1978). Widdowson (1971), however, indicated that exposure to treated wastewater was less damaging than either human use (trampling) or exposure to air pollution. Although the exact cause is uncertain, a decrease in intertidal algae on the Palos Verdes Peninsula may have been related to direct treated wastewater exposure (Littler and Murray 1975) because the community has recovered with declining JWPCP mass emissions.

Thermal Discharges. The rocky intertidal biota on the breakwater at King Harbor is exposed to the thermal discharge from Redondo Generating Station. Studies indicate that the main determinant of community structure is tidal height, (EQA/MBC 1973; Straughan 1977a,c) although some data suggest a slight compression of the vertical zonation with organisms being found at lower than normal tidal heights (Straughan 1977a).

Marine Vessel Spills. The effects of oil spills from marine vessel traffic in the Bay have not been well studied. However, because spills are likely to encounter the beach, they may affect the eggs and newly hatched larvae of California grunion. Benzo(a)pyrene, (a PAH found in oil spills, industrial discharges, and aerial fallout), caused decreased hatching success and larval deformities in California grunion eggs collected from Redondo Beach. Such impacts would be detrimental to the survival of the fish if they occurred (Winkler *et al.* 1983). Benzo(a)pyrene does not cause tumors in marine fishes, but it does cause stress and makes them less resistant to parasites (Puffer 1988, pers. comm.). A spill of diesel and naphthalene offshore of El Segundo in 1991 did not affect intertidal organisms at Malibu, where it came ashore (MBC 1991a), and grunion were later observed to spawn normally on the Malibu coast.

Litter. Beach litter is both an aesthetic and an ecological problem. Birds may entangle themselves or ingest harmful substances and objects, and litter may smother organisms on beaches and in tidepools. Sharp objects are also dangerous to humans engaged in recreational activities. About 2,200 MT of litter were collected from beaches between San Pedro and the Los Angeles-Ventura County line excluding Santa Monica Beach from 1 July 1987 to 30 June 1988 by the Los Angeles County Department of Beaches and Harbors. About 690 MT were collected from Cabrillo Beach to Manhattan Beach; 681 MT from El Segundo to Venice; and 826 MT from Will Rogers State Beach to the Ventura-Los Angeles County border (Schumaker 1988, pers. comm.). From 1987 to 1992, an annual average of 3,400 MT of litter was collected from beaches in Santa Monica Bay excluding Santa Monica Beach (Isbitsky 1992, pers. comm.). Ten to 12 MT of litter are picked up from Santa Monica Beach each year (Rogers 1992, pers. comm.).

Contaminated Sediments Used in Beach Nourishment. Dockweiler Beach received more than 0.6 million yd^3 of material dredged from Marina del Ray during its construction. Heavy metals and other contaminants are known to be high in Marina del Rey sediments (Stallard *et al.*

VOL 12

15432

1986; Chang 1992, pers. comm.) and after USACE tests showed that heavy metal values were too high in Marina del Rey sediments for beach nourishment, the materials were disposed of nearshore.

Other Activities. The value of beaches for recreation and relaxation has resulted in the destruction and degradation of intertidal and dune ecosystems. Beach visitors walk on vegetation and intertidal organisms and leave litter which must be removed. Drift kelp is removed for aesthetic reasons, thus, interrupting the natural degradation of kelp and its reintroduction into the marine environment as a food for filter feeders. Beach hoppers (or sand fleas) depend on the salty dampness of the normal beach; they burrow into the sand under piles of seaweed during the day and come out at night to scavenge food. Beach isopods and kelp flies also help recycle decaying kelp and dead animals. Human foraging for edible intertidal organisms such as abalone, limpets, mussels, clams, and sea urchins may eliminate juvenile stages, leaving no individuals to grow to adulthood and reproduce.

Dunes are a fragile ecosystem which is easily disturbed by vehicle and foot traffic. Repeated disturbance kills the low-growing plants by exposing the fine root system to drying wind and sun. When vegetation is removed, the sand is exposed and becomes susceptible to transport further inland by strong winds. In addition to the direct loss of habitat, the dunes can no longer supply sand to eroding beaches or protect inland areas. Human intrusion also interrupts shorebird foraging and nesting. Inadvertent and deliberate disturbance of nesting and feeding of chicks and crushing or removal of eggs and nestlings has had a major impact on California least tern and Western snowy plover populations (Page and Stenzel 1981).

Remediation

Beach Profile Surveys

Beach profile surveys have been conducted sporadically by Los Angeles County Coastal Studies Division to study specific problem areas; they have not been used to study long-term, regional trends. However, a program is now underway to compare three recent surveys with several historical surveys, in light of the many erosion events and beach nourishments projects which have been conducted (Woodell and Hollar 1991).

California State Mussel Watch Program

The California State Mussel Watch Program has monitored contaminants in intertidal invertebrates near Santa Monica Bay beaches on an intermittent basis, a more consistent approach and thorough sampling program is needed to track patterns and trends of contaminants.

California Least Tern Habitat Restoration

California least terns nest on sandy beaches, however, they must be protected from human disturbance and introduced predators. The protected site at Venice Beach has been very successful, but additional space is needed to enhance continued population growth. An additional beach nesting site near the Ballona Wetlands complex was suggested to help the population expand by attracting first-time nesters.

In 1991, with funds from the SMBRP and USEPA, a 3.5 acre site with extant native vegetation was prepared on Dockweiler State Beach. A temporary enclosure fence was erected and plans were made for a permanent fence for the 1993 breeding season. Decoys and audio recordings of least tern calls were used to attract birds to the site. Although no terns nested on the site in 1992, there were several landings. The first year was considered to be a trial and plans now call to eventually expand the site to 5 acres (Baird 1992, pers. comm.). A California least tern nesting island at the west end of the Ballona Wetlands is also planned as part of the mitigation associated with the development of Playa Vista by Maguire-Thomas Partners.

Western snowy plover

The Western snowy plover is a threatened species (CDFG 1992) and restoration projects have been started. Snowy plovers have many of the same nesting habitat requirements as least terns, and restoration projects may target both species (Yoder 1993, pers. comm.).

Black Abalone Recovery Program

The black abalone population has decreased dramatically in Santa Monica Bay, probably as a result of extensive poaching, although the increase in sea urchin (which feed on the same resource, algae) population and "withering disease" may also have contributed. A recovery program could include planting young black abalone on rocky shores.

El Segundo Dunes Reserve

Dunes are a rapidly disappearing habitat which support a unique community of plants and animals. The remnant El Segundo Dunes are home to 11 threatened species, including the El Segundo blue, a Federal- and State-listed endangered butterfly. Restoration of the El Segundo Dunes and creation of a Dunes Habitat Preserve would halt the spread of invasive species and avoid further extinction of native species.

The dunes at the west end of Los Angeles International Airport (LAX) (most of which are owned by the airport) are the subject of a proposed El Segundo Dunes restoration program (WRA 1990). At present the vegetation is dominated by iceplant and acacia and the major goal is to reintroduce native vegetation. The area is inaccessible to the public (which should help) but an irrigation system would have to be installed and the non-native plants removed (WRA 1990).

Chevron USA maintains a 1.6-acre El Segundo blue butterfly preserve at the northwest corner of the El Segundo refinery (This site is not contiguous with the proposed El Segundo Dunes mitigation project west of LAX). The El Segundo blue recovery program involves ensuring that the butterfly's host plant, coastal wild buckwheat, is present and protecting the habitat from human intrusion.

The El Segundo Dunes fall under the jurisdiction of several entities: LAX owns 277 acres, 43 acres of which are relatively undisturbed; the Los Angeles Department of Water and Power owns 55 acres of right-of-way property; Chevron USA owns 1.6 acres, which have been set aside as a butterfly preserve; and the City of Manhattan Beach owns 4 acres.

VOL 12

15434

WETLANDS HABITATS

Impacts

Wetlands in Santa Monica Bay are threatened by the proximity of the large human population and its impact on the physical, chemical and biological characteristics of the wetlands. Specific factors are stream alteration, dredging and filling, modified water flow patterns, drought, urban runoff, sewage disposal, boating and shipping, encroaching housing and commercial development, introduced species, and the increased use of natural habitats for recreation.

Wetlands have been used as waterways and have been modified by dredging and filling for harbors and marinas. In several areas, the wetlands had been diked and used for duck hunting, oil production, and reclaimed water discharge by sewage processing facilities. More recently, the margins have been developed for residential and commercial purposes.

Development and Habitat Reduction

Most of the wetlands of Santa Monica Bay have already been highly modified by draining, dredging, filling, diking, and channelization to provide sites for port and harbor facilities, housing and commercial development, and farming. They have also been degraded by urban runoff, introduction of non-native species, and human disturbance, resulting in losses in biological diversity, productivity, and wetlands function. The loss of wetlands habitat is not unique to Santa Monica Bay.

Between the late 1800s and mid-1960s much of the wetlands of Los Angeles and Orange Counties was "reclaimed," with resulting losses in biological diversity, productivity, and function. Seventy-five percent of the coastal estuaries and wetlands in southern California have been destroyed or severely altered since 1900. Two-thirds of the 28 sizeable estuaries once found in southern California have been dredged or filled (CCZCC 1975).

Freshwater wetlands have also suffered: streams have been channelized and dammed and water appropriated to supply distant cities. Current water policy considers unused water to be a waste, thus from as far away as the San Joaquin-Sacramento River delta and the lower Colorado River water is transported to southern California for domestic and agricultural uses. Wetlands associated with those systems have been impacted by changes in water level and seasonal flow, as well as by damming, channelization, expanded agriculture, and livestock grazing. For example, about 3,000 acres (1,200 ha) of riparian vegetation are being lost along the lower Colorado River each year (Manci 1989). Water diversions have seriously impacted the commercial and sport freshwater fisheries in central California because of water draw-downs and salinization of a large part of the formerly freshwater delta (Rozengurt and Haydock 1991).

Ballona Wetlands Complex. In 1868 the Ballona Wetlands Complex covered as much as 2,100 acres (Clark 1979). By 1894, the area had been reduced to approximately 1,535 acres, from the present-day community of Venice on the north, southwest through La Ballona, inland to Machado and south to present-day Culver Boulevard (Figure 8-1). The area consisted of a broad marsh behind a long sand spit, with a narrow, ephemeral opening to the sea. The opening probably closed to the ocean during spring and summer, leaving a brackish lagoon until high winter inflow washed out the spit and exposed the marsh to tidal waters (Swift and Frantz 1981).

By about 1930 the major lagoons of the Ballona Wetlands had been drained and converted for agricultural use, oil and gas development, and to control and abate mosquitos and

VOL 12

1

5436

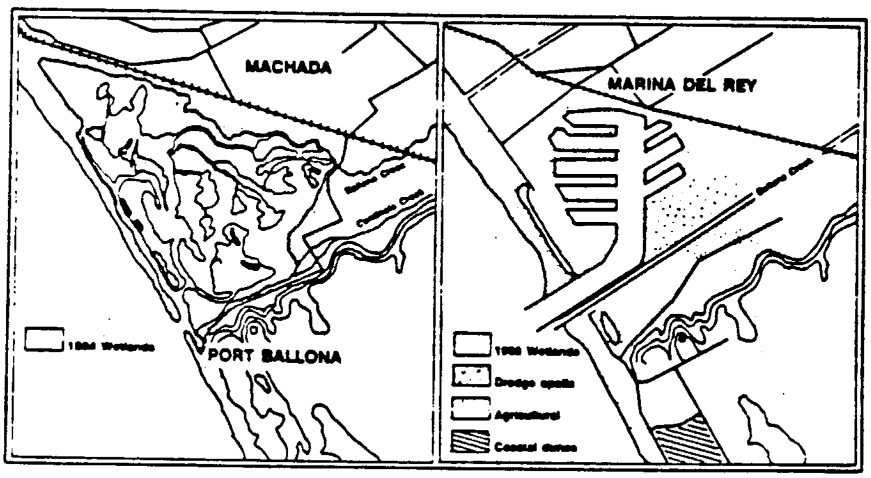

Figure 8-1. The Ballona Wetlands region in 1894 and 1988.

black gnats (Soule and Oguri 1977). From the 1930s to the 1950s roads and levees were built to access oil drilling pads and in the early 1960s, further reduction of the habitat resulted from dredging of Marina del Rey (Soule *et al.* 1992). Four-to 5-ft of dredge spoils were placed on northern section of wetlands that had been previously used for agriculture (Friesen *et al.* 1981).

By 1938 Ballona Creek, which was the principal freshwater source for the Ballona Wetlands Complex, was completely channelized as a flood control measure (Clark 1979). Channelization reduced the inflow of fresh water and nutrients to the marsh ecosystem and allowed the natural inlet to be blocked by sediments within two years. It also altered the natural salinity and depth regimes of the wetlands, leading to more-saline water and a deeper and more defined channel (Swift and Frantz 1981).

Introduced plants have become established in the Complex, altering the ecological balance and use of the marsh by native biota. Introduced species account for 40% (130 of 235) of all plant species in the saltmarsh area (Gustafson 1981) and much of the terrain is vegetated by introduced species such as gum (eucalyptus) trees and iceplant which are detrimental to the habitat as a whole and out-compete native species. Because of the continued disturbance, weedy species cover approximately 15% of the saltmarsh. A restoration project in progress at Ballona Lagoon, includes planting native salt marsh vegetation and removal of introduced species (Weiss 1993, pers. comm).

Malibu Lagoon. The full extent of the historical Malibu Lagoon-marsh system is unknown (Kraft 1978), but what remains probably represents only a small portion of the original marsh (CDPR 1978). In 1978, the natural resources consisted of 5 acres of open water, 10 acres of coastal saltmarsh, 4 acres of riparian habitat and mudflats (unknown). Most habitat reduction of the Malibu wetlands has resulted from the reclamation of habitat upcoast of Malibu Creek for mosquito control and houses (Kraft 1978).

The natural channel of Malibu Creek enters the ocean downcoast of Malibu Point. The sand bar which develops across the mouth is purposely breached by the Los Angeles County Department of Beaches for flood control purposes (CDPR 1978).

Urban Runoff

Significant quantities of floating trash and other urban debris are carried into Santa Monica Bay by way of Ballona Creek (Metz 1978) and much of it accumulates in the Ballona Wetlands Complex (Schreiber 1981). Debris and trash can temporarily limit light availability in the water column and cover saltmarsh habitat; styrofoam and plastic bags may be ingested by fish and birds.

During dry weather the low volume "nuisance" water brings grass clippings, motor oil, household pesticides, and drainage from roadway drips and accidental spills down-channel. When this flow reaches the tidal prism, debris and contaminants are deposited inside of the Marina jetty.

During wet weather, runoff carries bacteria into the wetlands and Marina del Rey and waters are considered unsafe for body contact during and for a few days following a storm (Soule *et al.* 1992). The sand bar at the entrance to the Marina may reduce circulation and flushing within, prolonging the period of contamination. Increased flow in Ballona Creek tends to carry the debris and contaminants as well as occasional sewage overflows from the HTP North Outfall Facility into Santa Monica Bay proper (Soule and Oguri 1986, 1987). As a result, sediments at the mouth of the Ballona Creek are more contaminated than those elsewhere in the vicinity of Marina del Rey (Soule and Oguri 1987). Stagnation and high nutrient input from urban runoff periodically cause algal blooms in Ballona Lagoon (Soule and Oguri 1977).

Organic enrichment due to wastewater overflows may account for low benthic community species diversity at the mouth of Ballona Creek, where the fauna is dominated by high numbers of nematode worms and the polychaete *Capitella capitata* (Soule and Oguri 1987). These organisms are highly opportunistic and characteristic of unstable, stressed environments, whether natural or anthropogenic. However, this area is also subject to excessive scour during storms, deposition during dry weather, and fluctuating salinity and temperature. The abundance of nematodes and *Capitella capitata* may also result from these natural perturbations. The benthic community in Ballona Lagoon is also affected by high organics, poor circulation, and storm run-off from the Venice canals.

The Oxford Flood Control Basin Marina del Rey are impacted by trace metals, pesticides and PCBs, apparently from sediments eroded during storms. Adjacent terrestrial areas are contaminated from earlier dumping and World War II industrial activities. Recent construction excavation may have exposed soils to erosion, as suggested by the increase in percentage of fine sediments in the Marina following heavy rainfall (Soule *et al.* 1992)

Many of the substances such as PCBs, pesticides, and heavy metals in urban runoff are toxic to marine organisms. Small amounts of several trace metals have been detected in the Marina, but these have been determined by the National Oceanographic and Atmospheric Administration (NOAA) to have low environmental effects. Concentrations of other metals (e.g., nickel and TBT) have been high in the past but are less concentrated now; concentrations of lead and zinc increase following heavy rainfall and decline during dry weather, indicating terrestrial sources. Copper concentrations have increased even during dry periods, suggesting its increased use as an antifoulant since the ban on TBT. Pesticides such as chlordane continue to be detected at high environmental effects levels (NOAA 1991b). The highest concentrations of chlordane have been at the mouth of the entrance channel, indicating that it has come from Ballona Lagoon (where there are many wooden structures which may have been treated for termite control). Levels were also high in the Oxford Flood Control Basin. Levels of DDT appear to be decreasing but still exceed the low environmental effects level at some locations in the Marina. Its metabolite DDE has increased in fish taken at the Fisherman's Village fish docks in the Marina's Main Channel (Soule *et al.* 1992)

Toxic materials may occur both in sediments and in the water column. Studies to determine levels of trace metals and organics in the marine environment are conducted by California State Mussel Watch (CSMW) primarily using California and bay (blue) mussels. Marina del Rey is the only CSMW site in northern Santa Monica Bay, but in 1981-1982, levels of PCBs in resident bay mussels from Marina del Rey were relatively high (1,000 ppb), indicating local PCB sources. Mussel transplant studies conducted in 1980 and in 1985-1986 also revealed high PCB levels (1,800 ppb in 1980 and 2,500 in 1985) in Marina del Rey (CSWRCB 1982, 1988). Marina del Rey mussels also had one of the highest lead concentrations measured in California (49 ppm), and had elevated zinc (340 ppm in 1980 and 833 ppm in 1986) and copper (13 ppm in 1980 and 112 ppm in 1986) concentrations as well. The lead concentration in Marina del Rey mussels was over 50 times those typically measured at uncontaminated coastal sites. Contaminants originating or accumulating in the Marina may flush into the Ballona Wetlands under normal conditions or from the wetlands into the Marina during wet periods.

VOL 12

1 5 3 8

Transplanted and resident mussel tissues also had elevated concentrations of chlordane and dieldrin; total chlordane was the highest (780 ppb in transplants and 480 ppb in resident mussels) detected in the CSMW surveys. These data suggest a local source of the pesticide, because total chlordane in mussels from Palos Verdes was generally less than 50 ppb and from reference areas less than 10 ppb. The concentration of dieldrin was 91 ppb in 1980 transplant studies at Marina del Rey, although lower concentrations were measured in resident mussels from Marina del Rey (19 ppb) and the Palos Verdes Peninsula (6.5 to 11 ppb).

Marine Vessel Activity

Marina del Rey. The development of Marina del Rey drastically altered the original lagoon habitat. The shoreline was changed from natural muddy intertidal habitat to vertical concrete walls, although a small beach remains at the end of Basin D (Stephens *et al.* 1991). The Marina is, therefore, a wetlands only with respect to the shallow subtidal habitat which supports wetlands fish (and eelgrass in Basin D, prior to 1992). The amount of shallow bottom habitat was decreased by dredging (to 20 ft in the Main Channel and about 16 ft in the basins) and water circulation between the harbor and the ocean was increased. This alteration of habitat has no doubt decreased the abundance of lagoon species such as the arrow goby and California killifish, although this change has not been documented. It has probably also reduced the amount of nursery habitat for California halibut. Juveniles of this species generally develop in warmwater lagoons and hence the development of the Marina may have resulted in fewer adult halibut in the Bay.

The abundances of fish larvae and benthic-feeding fishes have declined in Marina del Rey since 1984. This may be the result of post-El Niño cooling but may also be related to TBT concentrations in the Marina. TBT is used as a biocide in antifouling paint and is more toxic to larvae than to adults (Soule and Oguri 1987). Since the use of TBT on small boats was banned in 1988, levels of TBT in the Marina have decreased three fold (Soule *et al.* 1992). Habitat disturbance may be responsible for the disappearance of the eelgrass beds from Basin D in 1991 (Soule *et al.* 1992)

Ballona Wetlands and Lagoon. The fish fauna of the remaining natural Ballona wetlands is less speciose and less diverse than coastal embayments such as Anaheim Bay (Lane and Hill 1975) and Newport Bay (Horn and Allen 1981), probably because only the shallow tidal channel habitat is present. In addition, flood gates and the shallow Ballona Creek Flood Control Channel separate the marsh from deeper water, interrupting the continuum from shallow marsh to the Bay. The limited number of flatfish collected in the Ballona wetlands suggest that it plays a limited nursery ground role compared to other southern California wetlands (Zedler 1982). The absence of goby eggs indicated that the Ballona wetlands are not even an important nursery for resident estuarine species, although Ballona Lagoon may be important nursery habitat for California killifish and topsmelt (Ford and Collier 1976).

TBT is present at some sites in Marina del Rey and Ballona Creek at levels (i.e., above 0.05 ppb) which are potentially toxic to mollusk larvae (Alzieu 1986). The reduction in mussel populations and crustaceans in Marina del Rey may be the result of TBT. Chronic exposure to and bioaccumulation of even low levels of TBT may have lethal or sublethal effects (Soule and Oguri 1987).

The degree to which TBT may impact shorebirds which forage on mollusks, crustaceans, polychaetes, or fish is unknown. However, reduction in the quality or quantity of these food

VOL 12

15439

resources could indirectly impact populations of waterbirds and shorebirds in the vicinity of Marina del Rey.

In 1988, unhatched eggs of California least terns from the Venice Beach nesting site had high levels of selenium, cadmium, and lead (Collins 1992); relatively high levels of lead have also been found in least tern feathers (Boardman and Collins 1992). Potentially dangerous levels of organochlorines, including DDT and its metabolites have also been found in least tern eggs and feathers (Boardman 1988). These levels are sufficiently high to cause concern for terns and other threatened species. California least terns feed on northern anchovy and topsmelt and they may be impacted by the accumulation of chlorinated pesticides and PCBs in the same way as the brown pelican.

Other Human Activities

Regulation of discharge of sewage by boats in the Marina has helped to reduce the levels of bacteria which are of concern to public health. There are occasional peaks of bacterial counts during dry weather, but overall, violations of Los Angeles County Department of Health Services standards were reduced in 1992 as compared to previous years (Soule *et al.* 1992).

Horse traffic, off-road vehicles, and human foot traffic have been noted in the Ballona wetlands, and these can cause lasting impacts by impeding or accelerating drainage and by altering elevations, thus affecting species abundance and composition (Zedler 1982). Noise from off-road vehicles or humans and domestic pets (Kraft 1978, Schreiber 1981) may affect locally breeding species such as the California least tern and Belding's savannah sparrow.

Insects in the Ballona Wetlands may also be affected by horse, human, and off-road traffic which compacts the soil, crushes insects, and destroys vegetation. The spread of introduced iceplant crowds out native plants required by some insects, while pesticides may eradicate native insects (Nagano *et al.* 1981).

Remediation

At present, the California Resources Agency (California Department of Fish and Game, Department of Foresty, etc.) is preparing a State Wetlands Conservation Plan (SWCP) through a cooperative, multi-organizational planning process. A draft outline was completed in 1992. The SWCP will identify and inventory wetlands and develop a state strategy for their protection and restoration. A regional wetlands agreement would take into consideration the special conditions of Santa Monica Bay wetlands resources.

The Santa Monica Bay Restoration Project funded a project to map and inventory all wetlands of the Santa Monica Bay watershed, and the report was produced in 1992 (Josselyn *et al.* 1992). The wetlands were evaluated and several sites were recommended for restoration, acquisition, creation, and/or best management practices (BMPs). Next priorities for these activities will be determined and an overall approach for protecting and enhancing wetlands resources of Santa Monica Bay will be adopted.

In 1990, the Port of Los Angeles (POLA) developed a Local Wetlands Mitigation Program, identifying 13 potential wetlands mitigation sites in the Los Angeles area (WRA 1990). Nine of the sites are in the coastal zone of Santa Monica Bay and one is in the watershed (Figure 8-2). One additional coastal site and one other watershed site were identified in the draft SMBRP Wetlands Inventory and Restoration Potential (Josselyn *et al.* 1992).

VOL 12

15441

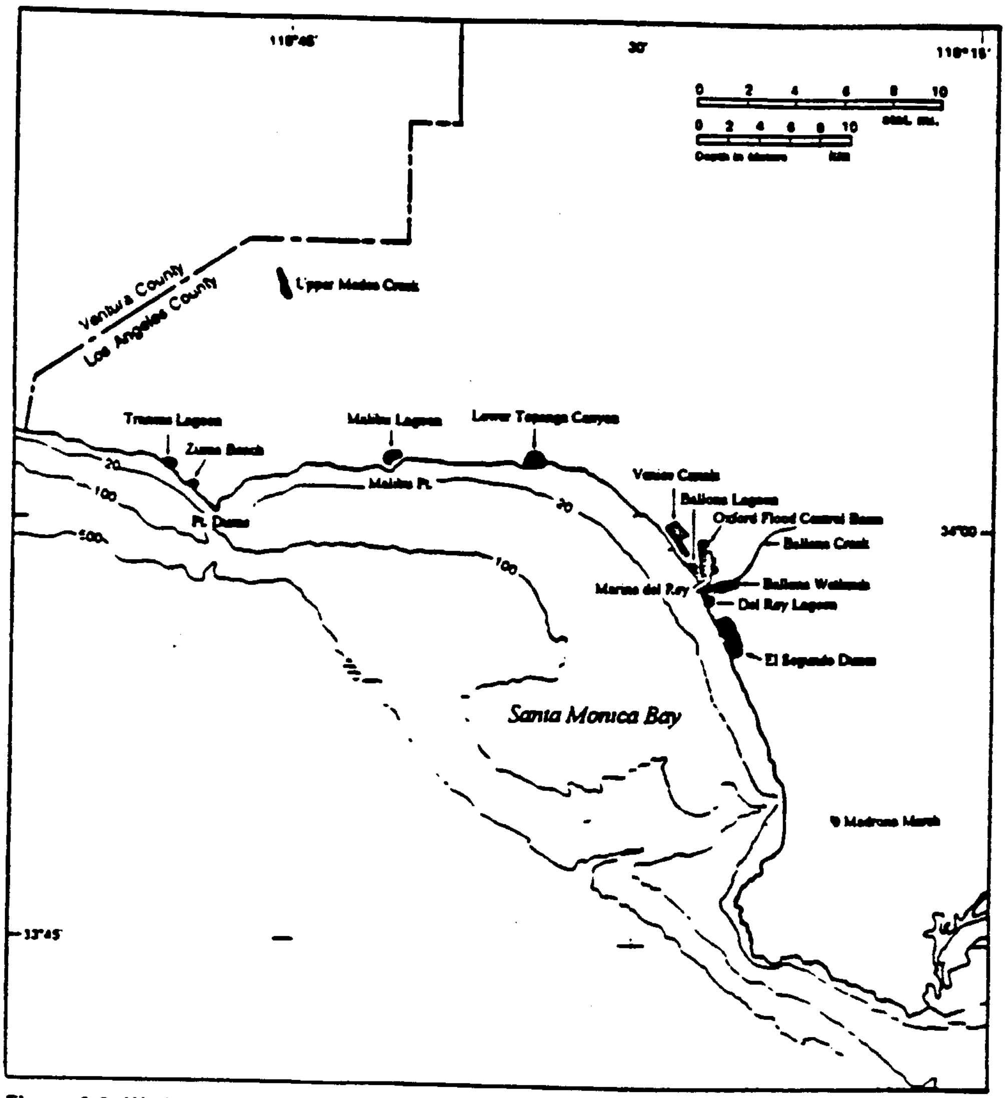

Figure 8-2. Wetlands of Santa Monica Bay study area.

Jurisdiction and Concerned Groups

Government. Many agencies maintain control over the wetlands in Santa Monica Bay, among them the U.S. Army Corps of Engineers (USACE), U.S. Environmental Protection Agency (USEPA), California Environmental Protection Agency (CalEPA), California Resources Agency, U.S. Fish and Wildlife Service, U.S. National Marine Fisheries Service, U.S. Soil Conservation Service, California State Department of Fish and Game, California Coastal Commission, California State Water Resources Control Board, Los Angeles Regional Water Quality Control Board, City of Los Angeles, Los Angeles Department of Parks and Recreation, and Topanga-Las Virgenes Resources Conservation District (TLVRCD).

The ecologic problems of wetlands involve numerous issues (habitat protection, point and nonpoint sources of pollution, land-use planning and resource management) which are too complex for any single agency to handle. Congress has enacted several programs to deal with wetlands, but the responsibility has often been relegated to the state level. In the face of budgetary shortfalls, the emphasis has been on eliminating duplication of effort and the EPA has become a facilitator rather than a manager or administrator of water pollution policies (Imperial *et al.* 1991). Under the National Estuary Program (NEP) the EPA identifies estuaries that are threatened by pollution, development, or overuse, and facilitates the preparation of comprehensive conservation and management plans (CCMP). The plans are implemented by the states using federal Coastal Zone Management (CZM) funding and are administered by the National Oceanographic and Atmospheric Administration (NOAA).

Private. The 16 acres of Ballona Lagoon is owned by several private individuals but is under the jurisdiction of the City of Los Angeles. Del Rey Lagoon (1 acre) is owned by the City of Los Angeles and Summa Corporation; Venice Canals (12 acres) are owned by the City of Los Angeles; Ballona Wetlands (232 acres) are owned largely by Maguire Thomas Partners; and El Segundo Dunes Wetlands habitat (less than 1 acre) is owned by the Los Angeles International Airport. Malibu Lagoon (36.1 acres) and lower Topanga Canyon (less than 1 acre) are owned by the California Department of Parks and Recreation.

Responsible agencies include the Soil Conservation Service, Topanga-Las Virgenes Resources Conservation District (TLVRCD), California Coastal Conservancy, and the California Coastal Commission. Oxford Flood Control Basin (10.5 acres) is controlled by Los Angeles County, Department of Public Works and the Zuma Beach Wetlands is controlled by the Los Angeles County Department of Beaches and Harbors. Trancas Lagoon (2 acres) is partly privately owned and restoration plans include expanding the Lagoon to the north of Pacific Coast Highway. The eight-acre Madrona Marsh has been designated as a significant ecological area by the County of Los Angeles and is owned by the City of Torrance. The proposed Upper Medea Creek restoration area (about 43 acres of riparian habitat along 2.2 mi of Medea Creek) is a tributary of Malibu Creek; much of the property along the creek is privately owned.

On-Going or Proposed Projects

Maguire Thomas Partners-Playa Vista Ballona Wetlands Project. In 1982 the California Department of Fish and Game conducted a Los Angeles County Local Coastal Plan status determination of the Ballona wetlands pursuant to Section 30411 of the California Coastal Act 1976. Purposes of the determination were to 1) define historical wetlands and their present status; 2) identify restoration within the area; 3) and assess the feasibility of restoring and enhancing

VOL 12

1542

wetlands. Their study area included the major marsh area and former agricultural parcels nearby. Their results indicated:

> "...that of the 510 acres within the study area, 478 acres were historically wetlands and 32 were historically uplands. ...of the 478 acres of historic wetlands, 151 acres are presently viably functioning wetlands. Of these 151 acres, 65 acres are essentially non-degraded and 86 are degraded. Additionally, 327 acres of historic wetlands have been so severely degraded that they no longer function viably as wetlands. Of these 327 acres, 51 acres are feasibly restorable and 276 acres may not be feasibly restored...(CDFG 1982)."

In 1984, Friends of Ballona Wetlands successfully challenged certification of a land-use plan by the California Coastal Commission (CCC) to allow the building of a roadway across the Ballona Wetlands and building of a residential development and golf course within the Wetlands. A settlement agreement was reached with the Commission and Maguire Thomas-Playa Vista (subsequent owners of the property) which downscaled the commercial development and eliminated development in contiguous wetlands, increased wetlands acreage through restoration, and restored mid-tidal flow.

Restoration of Ballona Wetlands was proposed in the Ballona Wetlands Habitat Management Plan (NAS 1986), prepared for the City of Los Angeles as part of the Local Coastal Program for the Ballona Wetlands. The plan included wetlands restoration and an interpretive and controlled access program. Under the plan, the Audubon Society would receive ownership of the property from Howard Hughes Properties and would manage restoration efforts with funds provided by them. This plan was later dropped and the property was sold to Maguire Thomas Partners (MTP), who acquired additional developable acreage through payment of $85 million and 70 acres in a land swap with the State of California; 60 acres were set aside for the wetlands (LA Times, 14 Sep 1991).

MTP developed a new plan, (agreed to by the Friends of Ballona Wetlands), to develop part of the property as Playa Vista, a residential-marina complex. The plan includes restoration of the saltwater marsh south of Ballona Creek, through restoration of tidal flow (the mid-tide plan developed by the National Audubon Society), dune restoration, creation of a freshwater marsh and riparian corridor upstream, and fish habitat enhancement in the proposed marina. A second enhancement plan - to reestablish full tidal action to all areas of the salt marsh - was proposed which would require the participation of other parties interested in receiving mitigation credits for tidal wetlands. In 1990 MTP applied for a permit for the first phase of the project (creation of the freshwater wetlands) and the permit was granted in 1991. However, it has not yet been signed by MTP-PV, although the draft EIR was recently submitted.

Ballona Lagoon. The California State Coastal Conservancy (CSCC) and the Ballona Lagoon Marine Preserve have been instrumental in assembling an enhancement plan for Ballona Lagoon which emphasizes improved water quality by enhancing circulation. Planting of native vegetation, fencing, and litter clean-up, along with reduced algal growth due to increased tidal exchange, would improve the aesthetics of the area (WRA 1990, Josselyn *et al.* 1992).

The City of Los Angeles, local landowners and the CSCC have approved a plan to develop Ballona Lagoon as the Ballona Lagoon Marine Preserve. The plan includes dredging, grading, bank replanting, sediment and oil and grease traps, and provisions for public access. Dredging would enhance the habitat for marine fish which are prey for the endangered California

VOL 12 15443

least tem. At present, adoption and implementation of the plan depends on assignment of the CEQA documents to either the City or the CSCC.

Some small enhancement projects are underway at Ballona Lagoon. Removal of debris and bank improvement has taken place at the southeast end of the Lagoon, and several property owners have removed exotic plant species and replaced them with native vegetation (Holderman 1992, pers. comm.). The Summa Corporation (which owns about a third of the Lagoon) has agreed to create a deep pool by dredging at the north end, although the project is pending because the private owners have not agreed to the plan for the other two-thirds of the Lagoon.

Other Projects. The Port of Los Angeles has investigated the potential for restoration of Del Rey Lagoon. Increased tidal flow would improve water quality, although local residents may object to the regular exposure of tidal flats. Improved tidal flow would increase the potential for flooding in the surrounding urban area. Pet waste control measures and banning the feeding of domesticated ducks would have to be enforced.

In 1990 the Oxford Flood Control Basin Task Force determined that enhancement possibilities for the Oxford Flood Basin were limited because of poor water quality, conflict with flood control uses of the basin, and limited wildlife potential.

Rehabilitation of the Venice Canals is currently being undertaken by the City of Los Angeles and work is due to be completed in 1993 (Josselyn *et al.* 1992).

The Malibu wetlands are within Los Angeles County Significant Ecological Area No. 5. The California Department of Parks and Recreation (CDPR) and others are developing a comprehensive plan for the Malibu Creek watershed which would include recommendations for the restoration of Malibu Lagoon (Michel 1992, 1993, pers. comm.). Enhancement of Malibu Lagoon as a brackish water marsh would probably include regulation of freshwater flow by retention or release from the Tapia Water Reclamation Plant and control of biological pollutants by the elimination of point and nonpoint sources. Tidal flushing is unlikely, as the flow volume is seldom sufficiently great to keep the mouth of the creek open to the ocean (WRA 1990).

Several projects have already begun at Malibu Lagoon, with funding from the CDPR and EPA. The tidewater goby was reintroduced into Malibu Lagoon in 1990, and has survived. Under EPA's Near Coastal Waters program, with funding from CalTrans as mitigation for construction of a replacement bridge across the Lagoon, a section of stream bank in the upper reaches of the Lagoon will be recontoured and revegetated to provide more goby habitat.

The CCSC wants to investigate effects of salinity changes on resident organisms; the effects of contamination from septic tanks on both water quality and organisms; and the effects of the water level in the Lagoon on the water table. At present, the CDPR breaches the berm to allow water to escape whenever the level in the Lagoon rises above 3.5 ft to avoid possible interaction with septic systems at the Malibu Colony. The long-term fate of the tidewater goby may depend, however, on restoration of a natural pattern of opening of the berm only during high-flow periods (Manion 1992, pers. comm.).

Wetlands which were linked to Malibu Lagoon historically but are not in the jurisdiction of the CDPR are found in the City of Malibu. The City has applied for grant funding to enhance or restore several small areas along with the larger Lagoon project (Manion 1992, pers. comm.).

CHAPTER 9

IMPACTS - MARINE INVERTEBRATES

PELAGIC RESOURCES

Because phytoplankton constitute the primary basis of the marine food web, impacts to the plankton populations of the Bay could seriously alter the abundance of other species.

Municipal Wastewater Discharges

In 1957 and 1959 the abundance of phytoplankton and zooplankton were higher within 2.2 mi of the HTP and JWPCP outfalls than at reference stations. When regular discharges ceased from the 1-mi outfall and began at the 5-mi outfall in the early 1960s, plankton abundance in Santa Monica Bay decreased in general, but the center of greatest abundance moved offshore (Figure 9-1). Because the 5-mi pipe discharges beneath the thermocline, nutrient enrichment of surface waters and phytoplankton enhancement only occurs when the wastefield surfaces (SCCWRP 1973).

In 1980 phytoplankton abundance and composition near the 5-mi outfall were not different from those at reference sites in the Bay. However, zooplankton were more abundant (the copepod (*Calanus pacificus* was dominant) near the discharge, but it is not known whether the increased abundance was due to population growth, entrainment, or migration (Kleppel *et al.* 1982).

Generating Station Impacts

The use of coastal water to cool electric generating stations contributes to losses of plankton (including larval stages of fish and invertebrates) and adult members of nearshore communities (Stephens *et al.* 1983). The mortality rate of plankton passing through the San Onofre Nuclear Generating Station was estimated at about 30% (USAEC 1973), that of zooplankton entrained at the Huntington Beach Generating Station was estimated at 28%. Intermittent chlorine injections (to prevent the accumulation of microbial slime inside of the pipes) temporally reduces photosynthesis by about 90%. Presumably the entrainment and chlorine treatment have a similar effect at Redondo, Scattergood, and El Segundo Generating Stations.

Refinery Impacts

High concentrations of ammonium were associated with a relatively consistent dinoflagellate bloom near the El Segundo Refinery discharge from 1975 to 1977. Ammonium levels and dinoflagellate abundance both decreased after 1977, but is not certain whether effluent from the El Segundo Refinery was actually responsible for conditions leading to this bloom (Eppley 1986).

Oil Spill Impacts

Oil slicks may cause a short-term reduction of light penetration and hence reduce photosynthesis in certain areas. These effects would last for a few days (Eppley 1986).

Urban Runoff Impacts

Storm runoff plumes can also enhance phytoplankton levels if the runoff contains elevated levels of nutrients. However, if suspended sediment concentrations are high, light penetration may

VOL 12 1 5446

be reduced, leading to low photosynthesis and phytoplankton levels (Eppley 1986). Phytoplankton abundance in Santa Monica Bay increased dramatically in 1969, a year with exceptionally high surface runoff (SCCWRP 1973).

SOFT BOTTOM SEDIMENTS

Most contaminants are more concentrated and more readily measured in sediments than in the water column. Because contaminants usually bind to the surface of particulates, absolute levels are generally higher in fine sediments (which have a larger surface area per unit weight). Most studies of sediment concentrations in the study area have been near the HTP and JWPCP wastewater outfalls.

Contaminants in ocean sediments generally concentrate near point sources, whereas materials entering by way of aerial fallout are evenly distributed over the entire area. Once introduced, contaminants may be moved long distances with fine particles; most materials introduced into Santa Monica Bay are ultimately moved into offshore basins. Both the spatial and temporal distribution of contaminants are important and are described below.

Distribution by Contaminants

Treated wastewater discharges are the major source of toxic trace metals to the Southern California Bight (Young *et al.* 1978a). Cadmium, chromium, copper, lead, mercury, nickel, silver, and zinc are most commonly studied. To assess man's impact on levels of metals, they must be measured at a reference site far from known inputs. In 1977 SCCWRP sampled and analyzed sediments from 71 sites in the Southern California Bight at water depths of about 200 ft, the depth at which most wastewater outfalls are located. On the basis of chemical and biological measurements, 29 of these sites were selected as reference stations (Word and Mearns 1979).

In 1985 levels were reexamined (Thompson *et al.* 1987) at 13 of the 1977 references sites to evaluate changes over time. There was no consistent trend in metals concentrations at these reference stations, some having increased and some having decreased: except for silver, most values were in the same general range in 1985 as they were in 1977.

Analysis of undisturbed core samples has also been used to estimate background metals levels (SCCWRP 1973, Galloway 1979). In this technique, a deep core of sediments is collected and sectioned horizontally and analyzed separately. Since sediment age increases with depth in the core, levels prior to human influence can then be determined.

Trace metal levels in surface sediments near the HTP and JWPCP outfalls are higher than levels found by Galloway (1979) in core-base sediments, but have generally decreased since 1985 (Table 9-1). In 1991 trace metals from near the 5-mi outfall were 0.8 to 9.6 times higher than core-base levels; those near the 7-mi outfall were 4 to 120 times higher and those near the JWPCP outfall (in 1990) were 11 to 81 times higher. Cadmium was the most enriched at all outfalls.

Elevated levels are not necessarily toxic to the local organisms. Ranges of toxicity have been developed by the National Oceanographic and Atmospheric Administration (NOAA) (Long and Morgan 1990) using data from spiked sediment bioassays, sediment-water equilibrium partitioning, the co-occurrence of fauna and contaminants in the field, and background levels. The resulting toxicity ranges are as follow: from threshold to the tenth percentile of effects is called the Effects Range-Low (ER-L), followed by the Effects Range-Medium (ER-M) and an Apparent

Effects Threshold (AET). The National Research Council has also developed threshold toxic levels based on data from USEPA, the U.S. Geological Survey, and other sources (NRC 1989).

Mercury

In 1990, mercury levels were highest near the HTP 7-mile and JWPCP outfalls and surrounding areas (Figure 9-2). Mercury concentrations were also elevated (up to 1.2 ppm) in Marina del Rey (Soule *et al.* 1992), (Table 9-1).

In 1972 mercury levels in sediments were elevated as much as 100-fold over background levels (Eganhouse *et al.* 1976), the average enrichment on the Palos Verdes Shelf being 23-fold (Hershelman *et al.* 1981). In 1972 the highest levels in Santa Monica Bay proper were within 0.6 mi of HTP's 5-mi outfall, where they were elevated 14-fold, and near Redondo Submarine Canyon, where they were 18 times background. Concentrations in most of Santa Monica Bay were lower in 1990 than in 1970 except immediately adjacent to the outfalls. Mercury concentrations decreased approximately 50% near the 7-mi outfall between 1990 and 1991, from almost three times the effects levels to less than twice the effects levels (Table 9-1). Concentrations are still higher near the 7-mi outfall than near the 5-mi outfall.

On the Palos Verdes Shelf sediment mercury levels declined 46% at 100-ft stations, 38% at 200-ft stations, and increased 3% at depths cf 500 ft between 1973 and 1979, suggesting down-slope and offshore movement of contaminants (Stull and Baird 1985). Pre-1974 values may not be as accurate as recent values and the decrease may have been greater (Stull 1988, pers. comm.). Mercury levels on the Palos Verdes Shelf in 1990 were less than half those in 1972 except at the JWPCP outfalls. Concentrations deceased with distance north of the outfall and were below 1 ppm on most of the Palos Verdes Shelf the level at which effects are seen, (Table 9-1, Figure 9-2).

Cadmium

In 1986 cadmium concentrations exceeded 5 ppm (the level at which effects may occur) at stations close to the 5-mi outfall and in the 7-mi sludge field. They exceeded the average Bay value of 2.8 ppm in an ellipse about one mile wide and 2 mi long which included both outfalls. In 1990 and 1991 the ellipse of elevated levels was still centered on the 5- and 7-mile outfalls but its areal extent was smaller than in 1986 (Figure 9-3). Cadmium concentrations at the 7-mile outfall have been slowly decreasing since 1985 and were below the NRC threshold toxic level in 1991, although still above other effects levels (Table 9-1).

In 1977 cadmium levels off Palos Verdes exceeded average Bight values by about 36-fold (Hershelman *et al.* 1981). Between 1974 and 1980 concentrations and the area of very high concentrations both decreased. This trend continued, with an 48% decline in sediment cadmium concentrations near the JWPCP outfalls between 1980 and 1985 (LACSD, unpubl. data). The general trend of decreasing cadmium levels on the Palos Verdes Shelf appears to have continued into 1990, although at some shallow sites levels were higher in 1990 than in 1980. The highest levels on the Palos Verdes Shelf are near the JWPCP outfalls, but concentrations were above the NRC threshold toxic level of 31 ppm at only one sampling station (Figure 9-3).

Cadmium concentrations in Marina del Rey in 1991 were generally below 1 ppm, although they ranged as high as 5.5 ppm (Table 9-1).

VOL 12

15451

Lead

In 1986, the concentrations of lead in sediments Bight-wide along the 200-ft isobath, averaged 32 ppm, five times background level (Word and Mearns 1979). In 1990 most levels in the Bay were below 20 ppm (Figure 9-4). In 1986 and 1990 the most concentrated lead values were in the Bay at the end of the 7-mi outfall. Elevated lead levels extended northwest of the 7-mi outfall (Figure 9-4) in both 1990 and 1991, although levels were only above effects levels near the 7-mi outfall (Table 9-1). In the Bay levels were lower overall and the area of elevated levels was smaller than in 1986.

Most sites in Marina del Rey in 1991 contained more than 100 ppm lead, over 10 times the levels in most of Santa Monica Bay (168 ppm in May, 152 ppm in October) and the highest levels exceeded toxic thresholds (Table 9-1). The average lead concentrations in Marina del Rey in 1991 were higher than average from 1984 to 1991 (Soule *et al.* 1992). Lead levels in Marina del Rey also generally increased between 1977 and 1987, a 3-fold increase in the entrance channel and a 10-fold increase at the mouth of Ballona Creek (Soule and Oguri 1987).

Lead concentrations in sediments near the JWPCP outfalls decreased by 59% between 1980 and 1985 (LACSD, unpubl. data), continuing the trend from 1974 to 1980 (Stull and Baird 1985), although values were still 23 times background at stations nearest the outfalls (Swartz *et al.* 1986; LACSD, unpubl. data). Vertical profiles of Palos Verdes Shelf sediments along the 200-ft isobath also show declines from earlier levels (Figure 9-5) (Stull *et al.* 1986a). Sediment lead concentrations decreased substantially on the Palos Verdes Shelf to below 100 ppm in 1990 except in sediments nearest the JWPCP outfalls (Figure 9-4). Highest concentration in 1990 was 237 ppm compared to 449 ppm in 1980 and 594 ppm in 1974. However, concentrations on much of the Palos Verdes Shelf remain above theoretical effect concentrations (Table 9-1).

The general trend over time appears to be a decline in sediment levels throughout the study area, except in Marina del Rey. This is probably a result of a decline in mass emissions from wastewater treatment plants and in aerial fallout. Nearshore sediments are gradually being cleansed of lead by resuspension and offshore transport.

Other Metals

Generally, the distributions of other metals are similar to those of mercury, cadmium, and lead. In 1990 copper concentrations were 5 to 10 times higher near the JWPCP outfalls than on the rest of the Palos Verdes Shelf; arsenic, chromium, and zinc were 4 times higher and nickel and silver, 2 times higher (LACSD unpubl. data). Copper concentrations are relatively high in Marina del Rey, but appear to be decreasing near the HTP and JWPCP outfalls (Table 9-1).

A notable exception to this pattern is that of the organic forms of tin, particularly tributyl tin (TBT). TBT has been used in the production of textiles, plastics, paints, fungicides, bactericides, and rodenticides since 1925 and in anti-fouling boat paint in the 1960s (Sax and Lewis 1987, Soule and Oguri 1987). However, because TBT is toxic to marine life it has been banned from use on vessels less than 50 ft long.

Present levels of TBT are linked to historical use on pleasure craft berthed in marinas. TBT values in Marina del Rey have decreased three orders of magnitude from 1,070 ppm in 1987 to 0.53 ppm in 1991 (Soule *et al.* 1992).

Inorganic Nonmetallic Substances

Sediments act as a regeneration point for water column nutrients and as a sink for water column toxicants. Elemental nutrients (nitrogen, phosphorus, silicon) and toxicants (sulphur, chlorine) undergo changes in chemical form and distribution which may be further modified by man's activities. Inorganic nonmetallic substances may be essential parts of the marine system, but may be contaminants if especially excessive.

Organics Indicators

Total organic carbon (TOC) and organic nitrogen are measures of the amount of organic matter in sediments. In 1985, Bight-wide reference sites contained 0.2 to 1.5% TOC (Thompson *et al.* 1987), whereas in Santa Monica Bay, TOC was 6.4% at HTP's 7-mi outfall and 0.8% at the 5-mi outfall (CLA, DPW 1986). In the same year, values in Marina del Rey ranged between 1.0 and 10.1% and were highest at the mouth of Ballona Creek (Soule and Oguri 1986).

In 1990, TOC in Santa Monica Bay was again highest (4.7%) at HTP's 7-mi outfall with levels of 1.3 to 1.7% to the northwest, while most of the Bay sediments contained less than 1% (CLA, DPW, unpubl. data). After the termination of sludge disposal from the 7-mile outfall, TOC in the sludge field decreased from approximately 10% in 1986 to 8.5% in 1990 (SCCWRP 1992). On the Palos Verdes Shelf, levels were highest (5 to 8%) offshore of the outfalls, and decreased to 1 to 2% to the north. Levels in Marina del Rey in 1991 were generally 2 to 4% (Soule *et al.* 1992).

Treated sewage is a major source of nitrogen and elevated nitrogen values in sediments can be used to trace the transport and deposition of wastewater particulates. In 1977 organic nitrogen in sediments along the 200-ft isobath in the Southern California Bight averaged 0.11%, compared to the background level of 0.08%. The highest levels were in the vicinity of the HTP 5-mi (0.11%) and the JWPCP outfalls (0.81%) (Word and Mearns 1979), but in 1990 organic nitrogen levels were half the 1977 level near the JWPCP outfalls (Stull 1993, pers. comm.).

After termination of sludge disposal, organic nitrogen in the 7-mi sludge field decreased, from approximately 1.0% in 1986 to 0.08% in 1990 (SCCWRP 1992). Sediment levels of organic nitrogen also decreased on the Palos Verdes Shelf between 1971 and 1990. The highest levels (up to 0.4%) in 1990 were near the JWPCP outfalls, while most of the Shelf had levels below 0.2%. Organic nitrogen levels in Marina del Rey in 1991 were generally 0.1 to 0.2% (Soule *et al.* 1992).

Oil and Grease

In 1991, the highest levels of oil and grease in Santa Monica Bay were at the 7-mile outfall (4,400 ppm) and in 45 m of water off El Segundo (4,760 ppm) (CLA, DPW, unpubl. data). Levels higher than 400 ppm extended northwest and southeast of the 7-mile outfall while most sediments in the Bay contained less than 300 ppm. In 1989 and 1990 levels were even higher near the 7-mile outfall, 17,300 and 16,300 ppm, respectively.

The abundance of oil and grease near El Segundo in 1991 may have been due to a Chevron oil spill in March 1991, as levels in 1989 and 1990 were near average.

Oil and grease levels were high in Marina del Rey in 1991, as much as 8,700 ppm, although they were between 1000 and 2000 ppm in most areas (Soule *et al.* 1992). Oil and grease levels have always been high in Marina del Rey in the past, presumably from boating activities. In 1977 and 1978 values ranged from 1,000 to 7,000 ppm; in 1984 from 200 to 5,000 ppm; and in 1985 and 1987, up to 20,700 ppm. In 1987 concentrations within the Marina ranged from 1,000 to 4,250 ppm; the higher concentrations were near the mouth of Ballona Creek, suggesting runoff as the source (Soule and Oguri 1987).

In 1980, concentrations of oil and grease were 20,600 ppm at the JWPCP outfalls, but decreased to 1,020 ppm northward (Swartz *et al.* 1986). By 1983 concentrations had decreased to 6,860 ppm at the outfalls and to the north, around Palos Verdes Point, to 610 ppm. In those same years values at a reference site in northern Santa Monica Bay were 338 and 516 ppm, respectively.

PCBs

Polychlorinated biphenyls (PCBs) are among the most persistent and toxic of synthetic organic compounds. Over 200 congeners of PCB and a variety of mixtures have been produced; Aroclor 1254 was the most widely used locally. The manufacture of PCBs was limited in 1970 and their use restricted in 1972 to closed systems; manufacture of new PCBs was banned altogether in 1976.

PCBs are still concentrated in the sediments near municipal outfalls and in harbors, even though input levels have decreased with time (CSWRCB 1983). In 1976 it was estimated that 6 MT of Aroclor 1254 alone occurred on the 19 mi^2 of shelf surrounding the JWPCP outfalls (Young *et al.* 1976a).

In 1985, reference areas outside the study area had an average PCB concentration of 17.5 ppb – more than twice the average of 7.2 ppb in 1977 (Thompson *et al.* 1987), although the high levels have been attributed to a more refined analytical technique (Stull 1993, pers. comm.) In 1977 concentrations of PCBs in sediments from the 200-ft isobath of the Palos Verdes Shelf averaged 3,120 ppb, 69% which was Aroclor 1254. Concentrations of 10,890 ppb (60% 1254) were found near the JWPCP outfalls, but levels of both total and 1254 declined westward to 109 ppb (83% 1254) off Rocky Point (Word and Mearns 1979). By 1985, most of the Palos Verdes Shelf had PCB levels of less than 2,000 ppb. The highest levels (4,880 ppb) were again found offshore and to the north of the JWPCP outfalls (Stull 1988, pers. comm.). In 1990 PCB levels on most of the Palos Verdes Shelf were below 500 ppb, however, near the outfalls levels were 2,000 to 4,000 ppb, and up to 11,000 ppb in areas immediately adjacent (Figure 9-6).

In 1977, sediments contained an average of 157 ppb PCBs (81% 1254) in the vicinity of the HTP outfalls and along the 200-ft isobath. Levels were highest (up to 513 ppb, 80% 1254) near the outfalls; these values were four times the background off Point Dume (Word and Mearns 1979). In 1975 PCB concentrations as high as 10,000 ppb were measured in the sludge field below the 7-mi outfall.

By 1989 and 1990 PCB levels were below detection levels (20 ppb), in much of Santa Monica Bay, although in 1989 they were detected in a small area north and west of the 7-mi outfall. In 1990 levels were higher than in 1985 in an area near and southwest of the discharge (Figure 9-6). In 1991 the area of detected PCBs was larger than in 1990 in the same locations. Essentially all PCBs detected from 1989 to 1991 in Santa Monica Bay were Aroclor 1254.

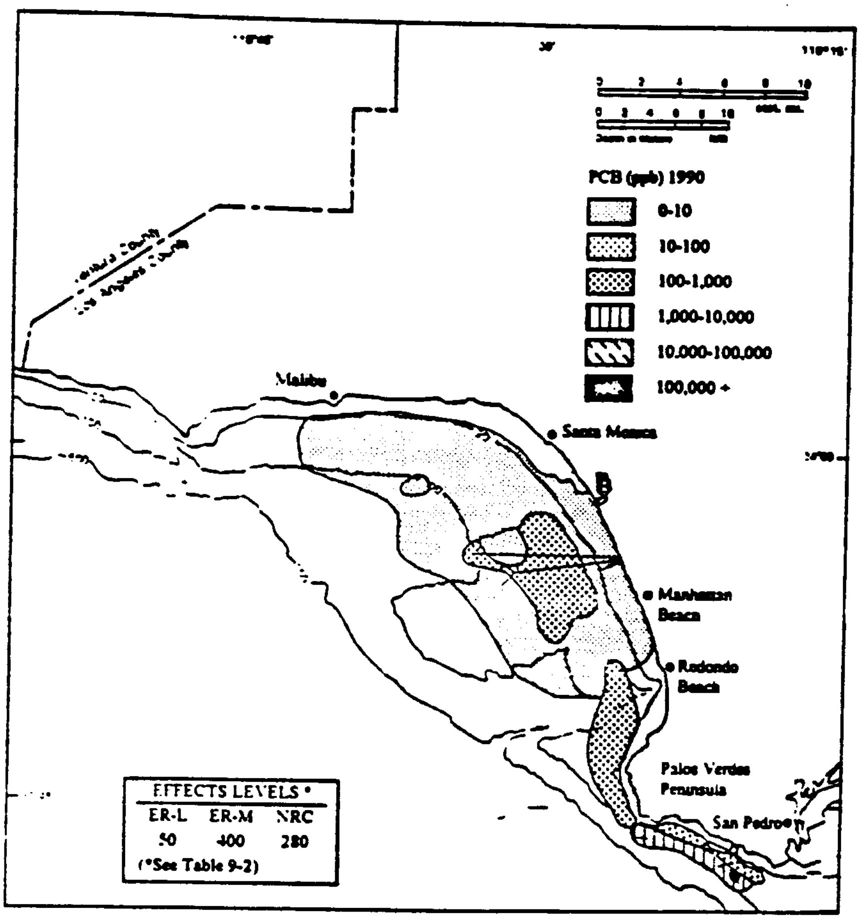

Figure 9-6. PCB concentrations in surface sediments of Santa Monica Bay and Palos Verdes Shelf, 1990. Map contours contain areas of measurement. (Soule et al. 1992; CLA,DPW unpubl. data; LACSD unpubl. data).

VOL 12

1 5457

In 1989 PCB concentrations were high (up to 330 ppb) in Marina del Rey where they previously had not been detected (Soule *et al.* 1992). Areas of high concentration varied between surveys, but were below detection levels by 1991. These PCBs may have been introduced at the result of grading projects in areas which were contaminated by industrial activity during World War II. Levels were up to six times toxic thresholds in May 1991 (Table 9-2).

The recent appearance of PCBs in Marina del Rey, and the increase in sediment concentrations from 1989 to 1990, and 1990 to 1991 indicate an upstream, historical source of PCBs.

DDT

Large amounts of DDT processing wastes were discharged through the JWPCP outfalls, resulting in especially high concentrations of DDT, DDD and DDE on the Palos Verdes Shelf. An estimated 1,700 MT of DDT were discharged between 1953 and 1970 – about 291 kg/day in 1970. The discharge of DDT processing wastes ceased in 1971, although DDT was manufactured until 1982.

In 1972 an estimated 200 MT of total DDT i.e., (DDT, DDD, and DDE) were contained in the upper foot of sediments in a 19 mi^2 zone around the JWPCP outfalls and 300 MT more on the surrounding shelf. In some places concentrations exceeded 200,000 ppb, the highest in shallow water northwest of the outfalls (MacGregor 1976, Young *et al.* 1976b).

Between 1971 and 1973 the concentration of DDT in surface sediments near the JWPCP outfalls ranged from 50,000 to over 200,000 ppb, however, in 1982 they averaged about 19,000 ppb. By 1985 most surface sediments on the Palos Verdes Shelf contained less than 10,000 ppb, although adjacent to the JWPCP outfalls, levels were as high as 65,000 ppb (Stull 1988, pers. comm.). Peak DDT levels (375,000 ppb) in 1985, were 12 in. below the surface (Figure 9-7), indicating that the heavy loading of the late 1960s and early 1970s has been buried.

By 1990 DDT levels on the Palos Verdes Shelf (Figure 9-8) had decreased somewhat, though not substantially since 1985. The highest concentrations are near the JWPCP outfalls, (up to 138,000 ppb), 10 times those on the shelf generally, and 100 times those to the north (CLA, DPW unpubl. data; LACSD unpubl. data).

In 1985 concentrations of DDT around the HTP outfalls decreased to the north and increased to the south, although levels near the 5- and 7-mi outfalls were higher than in the surrounding area. Values in Redondo Submarine Canyon are intermediate between those in Santa Monica Bay and the JWPCP area, suggesting that DDT has moved from the Palos Verdes Shelf into and across Redondo Submarine Canyon, and has mingled with inputs from HTP. In 1982 the mass emission rate from JWPCP was only 15 times that from HTP, yet the sediments off Palos Verdes contained 200 to 300 times more DDT than those around the HTP outfalls (Brown *et al.* 1984a).

DDT levels in Santa Monica Bay in 1990 and 1991 indicate that areas of high concentrations are slowly shrinking (Figure 9-8). Most of the "total" DDT found in Santa Monica Bay from 1988 to 1991 was DDE. DDT has only been detected twice since 1998: near the 5-mi outfall in 1988 and inshore of the 5-mi outfall in 1990, indicating that most DDT has degraded to the less toxic DDE (NRC 1989).

VOL 12

15461

R0048766

Total DDT in Marina del Rey is above low effects levels (Table 9-2). Maximum levels decreased between 1990 and 1991, but increased between May 1991 and October 1991 after the spring rains, indicating upstream sources of DDT. The presence of DDT as well as DDE and DDD also suggests continued input (Soule *et al.* 1992).

In 1977 background sediment DDT levels averaged 30 ppb along the Bight-wide, 200-ft isobath (Word and Mearns 1979). When these same stations were resampled in 1985, the average DDT concentration had declined to 19.4 ppb (Thompson *et al.* 1987). In 100 ft of water DDT averaged 9.1 ppb, while in 500 ft of water it averaged 30.1 ppb, suggesting that DDT has moved offshore with time. Although levels in most of Santa Monica Bay have decreased with time, they remain above background levels.

Since 1971 mass emissions of DDT to the study area have decreased and degraded to DDD and DDE and moved offshore. Because contaminated sediments can be resuspended by storms and bioturbation, leading to the bioaccumulation of previously buried DDT or DDE, DDT continues to be of concern.

Other Pesticides

After DDT was banned, other pesticides were used and many of these are now found in the marine environment. Among the most common are aldrin, dieldrin, endrin, endosulfan, heptachlor, and isomers of BHC. In 1986, the concentrations of most of these in the vicinity of the HTP outfalls were less than 9 ppb. Gamma BHC, heptachlor epoxide, and endosulfan were most concentrated near the HTP 5-mi outfall, alpha BHC along the shelf break off Malibu, and dieldrin in Redondo Submarine Canyon. By 1991 most of these compounds were not detected in Santa Monica Bay, although 266 to 718 ppb of Beta BHC were found along the 45-m isobath.

Chlordane is a persistent insecticide which was used extensively in termite control until it was banned in 1988. Chlordane is high in Marina del Rey and may be increasing suggesting that it is continually being introduced (Soule *et al.* 1992). In 1991 all levels exceeded effects levels in Marina del Rey (Table 9-2).

PAHs

Polycyclic (or polynuclear) aromatic hydrocarbons (PAHs) are related compounds which are present in crude oil and refined products and are released during combustion. Some are also released during the burning of non-petroleum substances in brush and forest fires. Concern about PAHs in the environment is fairly recent and their local abundance and distribution is not well known.

In 1984, the concentration of PAHs near the JWPCP outfalls was 560 ppb, at the HTP outfalls 370 ppb (Malins *et al.* 1987). In 1985 among sediments from 24 river mouths, harbors, and outfalls between Santa Monica Bay and San Diego, the least contaminated sample contained 150 ppb of PAHs. Sediments from the HTP 5-mi outfall contained 393 ppb PAHs, those from the 7-mi outfall 11,317 ppb, and those near the JWPCP outfalls 7,902 ppb (Anderson and Gossett 1986).

In 1985, 43 "reference" sites between Point Conception and San Diego averaged 32 ppb PAHs. Sites close to Los Angeles generally included 4 to 6 compounds, those further away only 1 or 2 compounds. A site in 100 ft of water west of Point Dume was one of the most contaminated, with 147 ppb PAHs (Thompson *et al.* 1987).

In 1987 sediment PAH at HTP 7-mile outfall were 20,000 ppb, higher than found in sites in Long Beach, Los Angeles, or San Diego harbors where values ranged from 4,700 to 12,100 ppb (SCCWRP 1989). Since the termination of sludge disposal at the 7-mi outfall, PAHs in the sludge field have decreased 50%, from approximately 10,000 to 5000 ppb (SCCWRP 1992).

In a nationwide survey, the highest levels of total PAH in California were found in San Diego Harbor (7,300 ppb) followed by San Francisco Bay (4,700 ppb) and San Pedro Bay (2,400 ppb) (NOAA 1991a). Sediment levels near Palos Verdes, in Santa Monica Bay, and in Marina del Rey were 1,100; 1,300; and 320 ppb, respectively.

Contaminated Sediments as Point Sources

Areas on Palos Verdes Shelf near HTP 5- and 7-mile outfalls, and in Marina del Rey sediments are sufficiently contaminated to be considered point sources of contamination themselves.

Most contaminants are more concentrated on the Palos Verdes Shelf than in Santa Monica Bay; they are especially high to the northwest and offshore of the JWPCP outfalls, and decrease with distance toward Redondo Submarine Canyon. Although DDT levels are decreasing in Santa Monica Bay, they remain elevated on the Palos Verdes Shelf. Lead concentrations have decreased, but are now higher in Marina del Rey than at the JWPCP outfalls.

Palos Verdes Shelf

Contaminated sediments deposited on the Palos Verdes Shelf in the recent past may be a primary source of contamination to Santa Monica Bay and of DDT and PCBs for the entire Southern California Bight (Mearns *et al.* 1991, SCCWRP *et al.* 1992). High levels of DDT, PCB, lead, and other trace metals accumulated near the JWPCP outfalls prior to the 1970s. The primary field of contaminated sediments in 1972 was about 19 mi^2 upcoast of the JWPCP outfalls (MacGregor 1976, Young *et al.* 1976a).

Although DDT levels were highest near the sediment surface in 1972, peak levels were about 6 in. below the sediment surface in 1981, and about 12 in. below the surface in 1987 (Figure 9-7) (SDWG 1988). Away from the outfalls (at Point Vicente) levels of DDT were shallower, 6 in. below the sediment surface in 1981 and 7 in. in 1987 (SDWG 1988). Lead shows a similar pattern: peak concentrations about 12 in. below the sediment surface near the outfall and about 2 in. below the surface 15 km upcoast of the outfalls (Figure 9-5) (Stull *et al.* 1986a, SDWG 1988).

Despite the burial, in 1990 DDT and PCB levels in white croaker and yellow rock crab tissue were still much higher on the Palos Verdes Shelf than at other locations in Santa Monica Bay indicating that the sediments are a source of contamination (SCCWRP *et al.* 1992). Bioturbation (the burrowing activities of infauna) may bring some of this contamination to the surface. In addition, some of these infauna may be preyed upon by fishes and larger invertebrates, thus introducing contamination into the food chain. Erosion especially at the edges of the field, may also remobilize the contaminants (SDWG 1988).

Recovery at the 7-Mile Outfall

Sludge from HTP was discharged from the 7-mile outfall from 1957 to 1987 resulting in a 20 mi^2 area of elevated contaminant concentrations centered along the axis of the upper part of Santa Monica Submarine Canyon. The sludge field was 50-100 cm deep (SCCWRP 1987)

VOL 12

1 5463

R0048768

during the period of active sludge disposal. Sediments in the Canyon were characterized by extremely high organics and sulfides. By August 1990, the concentrations of most contaminants in the sludge field had decreased (SCCWRP 1992). DDT levels, on the other hand, decreased considerably at a nearby site although not in the sludge field.

Sulfide levels decreased rapidly within nine months after disposal abatement but remained higher than background levels. Organic carbon levels decreased 23%, nitrogen 29%, PCBs and PAHs about 49%, and trace metals 53 to 59%. In 1990 approximately 1 cm of clean sediment was found on the surface of the accumulated sludge. Based on the evidence of 1.5 yr of pre-abatement and 3 yr of post-abatement data recovery of the sludge field is estimated to take at least ten years, except for sulfide concentrations which may approach background by the end of 1994 (SCCWRP 1992).

Marina del Rey

Concentrations of the insecticide chlordane in Marina del Rey Harbor are as much as 100 times the "low effects" range (Soule *et al.* 1992). Although banned, chlordane continues to enter the Marina, either from continued use or from leaching from previously treated structures. DDT levels in Marina del Rey are sufficiently high to potentially impact larval and juvenile organisms. PCBs were found in the Marina between the October 1989 and May 1991, but were not detected in October 1991 (Soule *et al.* 1992).

Nickel concentrations are below low effects levels at most stations in the Marina while copper, lead, and zinc levels have fluctuated. Lead and zinc increase after heavy rainfalls, indicating terrestrial sources (Soule *et al.* 1992), lead levels in Marina del Rey are among the highest in Southern California (Mearns *et al.* 1991). Average copper levels in Marina del Rey have increased between October 1990 and October 1991, possibly because of copper based antifouling paint (Soule *et al.* 1992).

SOFT-BOTTOM BIOTA

Municipal Wastewater Discharges

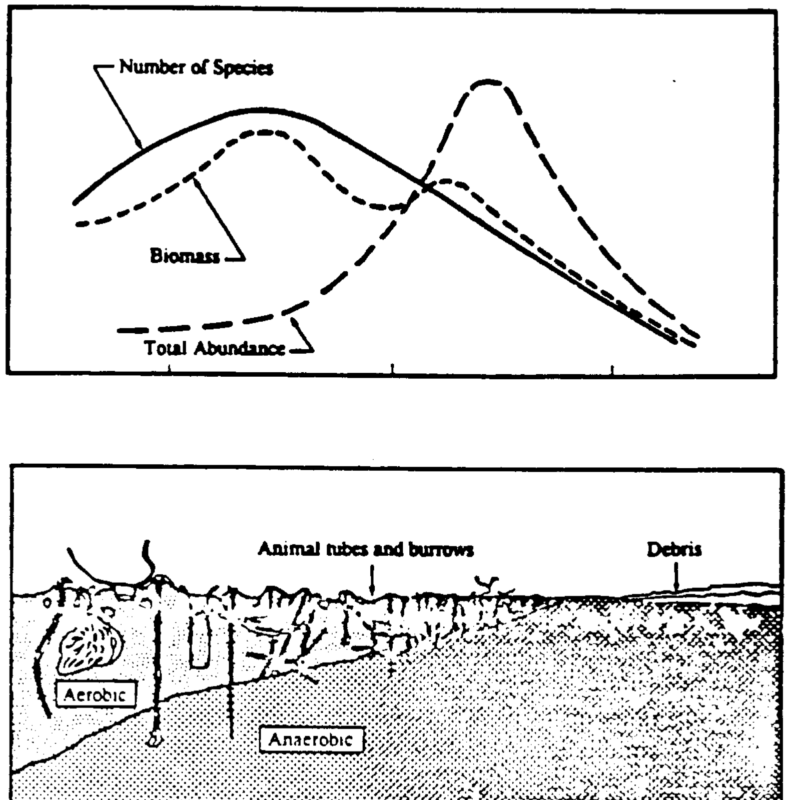
Macrofauna

Large wastewater discharges into the sea have created "hotspots" of contamination and ecological imbalance, which generally expand with time as the discharge continues. They may contract if the discharge is stopped, its quality is improved, or if contaminated sediments are resuspended and flushed from the area. There is little evidence that wastewater effluent has approached shore in Santa Monica Bay since the discharge from HTP's 1-mi outfall was discontinued in 1960.

Early benthic investigations detected altered physical conditions in infaunal communities near outfalls in Santa Monica Bay. In 1957 the bottom near the JWPCP outfall was "foul" and lacked several important animal groups (Hartman 1959). As early as 1952, it was noted that infaunal community structure near the HTP 1-mi outfall was altered (Hartman 1956). Within 0.3 mi of the outfall was an impoverished zone, which was followed by an area of pollution-tolerant populations at 0.3 to 1.9 mi, and a zone of enrichment at 1.9 to 4.5 mi. High diversity and low density of species was noted at 4.5 to 7.9 mi and an unaffected bottom beyond 8 mi. This description exemplifies the benthic enrichment gradient described by Pearson and Rosenberg (1978) (Figure 9-9).

VOL 12

15465



NORMAL	TRANSITION	POLLUTED	GROSSLY POLLUTED
Normal Infauna	Increased Abundance	Pollution Indicator Species	No Macrofauna

Figure 9-9. Generalized changes in fauna, sediment structure, and benthic community parameters along an organic enrichment gradient (Pearson and Rosenberg 1978).

The HTP 5-mi outfall became operational in 1961 and an area of impacted infauna began to develop around the discharge point. The 7-mi outfall became operational in 1957, and a degraded bottom community, (which corresponded to Hartman's 1952-1954 impoverished zone) developed. The affected area increased in the 1960s and 1970s, although the net trend has been downward (Hartman 1956, Tetra Tech 1981, Dorsey 1988). In 1985 an area of 11.5 mi^2 around the 5-mi and 7-mi outfalls supported an affected bottom community (Dorsey 1988), which corresponded to the first three zones observed by Hartman around the 1-mi outfall in 1952 to 1954. Thus, in the 31 years from 1954 to 1985, the area of bottom affected by the discharges declined by more than half, from 25 to 12 mi^2.

In 1977 the infaunal community in the study area was most degraded near the JWPCP outfalls and the HTP 7-mi outfall (Figure 9-10), as measured by the infaunal trophic index which evaluates the relative abundance of different infaunal assemblages (Bascom 1978). The general distribution of degraded and altered communities is very similar to that of many contaminants, including DDT and PCBs (Figures 9-6 and 9-8).

Comprehensive investigations of the infauna near the JWPCP outfalls were undertaken in 1972 and have continued to date. The infaunal community is most severely affected along a gradient of organic enrichment extending northwest of the outfalls along the Palos Verdes Shelf. In 1980 to 1981 the abundance and biomass of infauna were low about 2.5 mi north of the outfall, although at or slightly above 1977 reference station values. Diversity and numbers of species were also very low up to 2.5 mi north of the outfall.

The densities of the dominant species of infauna changed along a gradient extending 7 mi northwest of the outfalls at a depth of 200 ft (Tetra Tech 1984). The polychaete worms *Capitella* and *Schistomeringos*, which are indicators of degraded or polluted conditions, were most abundant near the outfall, while the clam *Parvilucina* (an indicator of mild pollution) and the polychaetes *Mediomastus* and *Tharyx* and the ostracod *Euphilomedes* (indicators of organically enriched, but not degraded areas) (Word *et al.* 1977) were more abundant away from the outfall.

Once the discharge of wastewater is stopped, the benthos recovers fairly quickly (Vesco and Gillard 1980). When regular discharge through the HTP 1-mi outfall was discontinued in 1961, the infauna in the area began to recover almost at once. Based on data collected between 1983 and 1987, the infauna near the 1-mi outfall can no longer be distinguished from that at similar depths elsewhere in the Bay (Dorsey 1988). HTP's 1-mi outfall was in a shallow, high-energy environment; recovery in deeper water (where most present outfalls are located) may proceed much more slowly (Smith 1988, pers. comm.).

HTP stopped disposing of sludge via the 7-mi outfall in November 1987. Quarterly sampling to determine the rate and direction of benthic recovery around the outfall was initiated in February 1986 (1.5 yr prior to termination) and continued until August 1990.

In 1986 indicator taxa such as the polychate *Capitella capitata* were most abundant in the contaminated area on the periphery of the sludge field, while sites in the sludge field near the outfall terminus were characterized by unusual polychaete taxa, such as *Ophryotrocha* spp., which are found only in highly contaminated areas (SCCWRP 1987).

After the termination of sludge discharge, the abundance of *Ophryotrocha* spp., initially increased, but they were nearly absent by August 1990 (SCCWRP 1992). Although *Capitella capitata* was only present in low abundance in the sludge field during discharge, it became the most abundance in this area within a year after discharge termination. By 1990 *Capitella capitata*

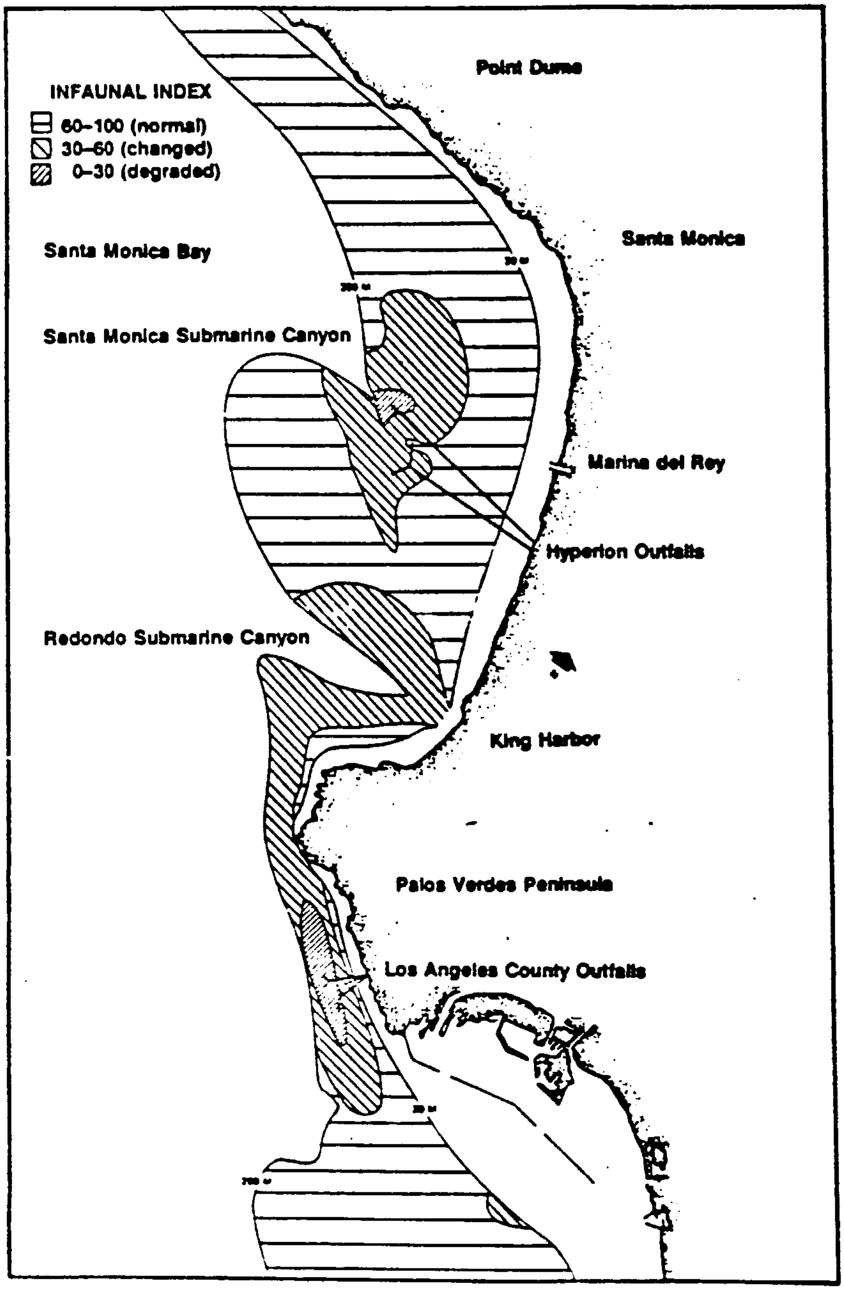


Figure 9-10. Location of normal, changed, and degraded areas in the study area as defined by changes in infaunal index, 1977 (Bascom 1978)

VOL 12

15467

abundance had decreased in all areas. Decreasing abundance of these two species indicates the gradual recovery of the sludge field. However, *Amphiodia urtica* an indicator of uncontaminated conditions and a species abundant in reference sites, to date have not become abundant in any of the contaminated areas (SCCWRP 1989).

Recovery also occurs when the discharge of pollutants is reduced, but not stopped. Between 1971 and 1981 the quality of the JWPCP effluent improved markedly and so did the infaunal community (Stull *et al.* 1986b), which is still recovering (Stull 1988, pers. comm.). Both the number of species and the Shannon Wiener diversity increased from 1972-1991, indicating general improvement in the Palos Verdes benthos (Stull 1992 pers. comm.).

Recovery of benthic assemblages was especially apparent following the reduction in input of DDT, PCBs, solids, trace metals, and various other contaminants from the JWPCP outfalls. Since 1972 the benthic community has become less characterized by pollution indicator species, has become more diverse, and has supported increasing abundances of microcrustaceans and echinoderms (Word and Striplin 1980) which were absent previously (SCCWRP 1973).

Recovery continued between 1980 and 1983; stations near the JWPCP outfall went from major degradation in 1980 to moderate degradation in 1983, changes which were attributed to improvements in the quality of the JWPCP effluent. However, natural environmental changes associated with the strong El Niño event of 1982-1983 may have also been involved (Swartz *et al.* 1986). The strong storms of that time period presumably resuspended contaminated surface sediments, especially near headlands such as the Palos Verdes Peninsula.

In 1973 large numbers of spoonworm *Listriolobus pelodes* settled on the Palos Verdes Shelf and by 1975 the center of the population was near the outfalls. The population declined by 1977 and the worms had all but disappeared by 1980 (Stull *et al.* 1986c). Although it is not certain whether their occurrence was due to chance or to the local environmental conditions, they had an important impact on the benthic community. Spoonworms form U-shaped burrows in the sediments, and their burrowing, feeding, and respiratory activities rework and aerate the sediments. On the one hand this bioturbation may improve physical, chemical, and biological characteristics of the sediments generally but it also exposes buried contaminants to the water column.

The areal extent of black sediments rich in hydrogen sulfide decreased during the spoonworm period, and the abundance of pollution-tolerant polychaetes, *Capitella capitata* and *Schistomeringos*, decreased as well. However, following the collapse of the spoonworm population, neither the species abundances nor the sediments returned to their previous states. The net improvement in sediment conditions during the period of high spoonworm density may have resulted from increased oxygenation of the surface sediments and a consequent decrease in free sulfide. Free sediment sulfide has been found to be the abiotic variable most strongly correlated with the infaunal community at outfall depths on the Palos Verdes Shelf (Greene and Smith 1975).

In 1989-1990 the numbers of species were lowest immediately adjacent to the HTP outfalls, but increased rapidly with distance from these disturbed areas; abundance was moderate around the 5-mi and high at the 7-mile outfall (CLA,DPW 1991). Diversity was lowest at the 7-mile outfall and increased with distance from the area, whereas it was moderate around the 5-mile outfall. Abundance and numbers of species were highest south of the outfalls at Short Bank, a habitat characterized by low-lying rock outcrops and heterogenous sediments.

Classification analysis of recent summer macrofauna data indicated five broad macrofaunal assemblages, which formed site groups associated with depth and proximity to the outfalls (Figure 9-11). Around the 5-mile outfall, two subgroups were delimited. One subgroup consisted of stations adjacent to the outfall, the other subgroup consisted of stations further from the outfall and represented macrofauna which are transitional between outfall and natural conditions (CLA,DPW 1991). The site group nearest the 7-mi sludge field was characterized by large numbers of individuals and low numbers of species, including several opportunistic, pollution-tolerant species.

Macrofauna assemblages also vary in composition along a strong depth gradient (from inner-shelf to upper-slope) and along natural sediment gradients, and with distance from the two outfalls, representing an environmental stress gradient (CLA,DPW 1991). Diversity and composition of the assemblages away from the outfalls were typical for southern California shelf communities.

The fluctuations in the size of the area impacted by the outfalls may result from the increase in numbers (species and individuals) of opportunistic species which respond quickly to small physical and chemical changes in the environment (CLA,DPW 1991). There are fewer opportunistic species around the 5-mi outfall, and species that were common away from it, (e.g., *Pectinaria californiensis*), have become common at the outfall. Pollution sensitive species such as *Amphiodia urtica*, however, are still sparse near the outfall but have invaded transitional areas between the outfalls and unaffected areas. During the period of sludge disposal, the polychate *Ophytrocha* dominated the field, but since about 1987, the abundance of this polychaete has diminished to nearly zero (CLA,DPW 1991).

Thus, in general, the abundances of opportunistic species are approaching background levels and overall diversity is incre ng. The area around the 5-mi outfall now supports a relatively natural composition of macrofauna, although sediments in the old sludge field are populated with a mix of "natural" and opportunistic species (CLA,DPW 1991).

The "degraded" area also persists around the JWPCP outfalls, although it is much smaller (in areal extent) than it was previously. The "changed" area has also contracted, gradually receding eastward on the Palos Verdes Shelf.

Megafauna

At water depths of 200 ft on the Palos Verdes Shelf, white sea urchins and other large echinoderms were uncommon (low population densities) between 1972 and 1979 compared to reference areas at the same depth (Word and Striplin 1980). Major megafaunal species were absent within several miles of the JWPCP outfalls in 1973, although they were present elsewhere in Santa Monica Bay (Mearns and Greene 1974). The diversity and abundance of echinoderms as a group were depressed near the JWPCP outfalls between 1971 and 1976 (Allen and Voglin 1976) and total invertebrate megafaunal biomass on the Shelf was only half that at stations in Santa Monica Bay between 1977 and 1982 (Moore *et al.* 1982). However, densities of the ridgeback rock shrimp were greatly enhanced.

In 1982 megafaunal biomass was about equal at sites on the Palos Verdes Shelf and at control sites in northern Santa Monica Bay (Table 9-3): however, in the vicinity of the HTP outfalls it was 3 to 4 times higher than at the reference sites (Cross 1982a). Between 1984 and 1986 enhanced biomass was most apparent south of the 5-mi outfall: while at the outfall itself the

biomass was slightly lower than at the northern Santa Monica Bay control site (Johnson and Roney 1988).

By 1982 echinoderms (which had previously been lacking), were collected in the vicinity of the JWPCP outfalls, indicating a major change in the community structure since the early 1970s. Classification analysis of trawl-collected megafauna from throughout the Southern California Bight between 1971 and 1985 indicated that 1980 was a turning point on the Palos Verdes Shelf (SCCWRP 1986e). Prior to 1980 samples from Palos Verdes Shelf were separated from the "normal" mainland shelf group; whereas after 1980 samples from the Palos Verdes Shelf were grouped along with "normal" samples. Samples collected from depths of 120 to 520 ft in Santa Monica Bay, including those from near the HTP outfalls, were grouped with the reference stations during all years.

In 1989 and 1990 megafaunal communities exhibited a pronounced relationship to the HTP outfalls. Near the 5-mi outfall, diversity and the mean number of species were reduced (Figure 9-12)(CLA,DPW 1991). Spiny sand stars were most abundant at the outfall sites, possibly due to the abundance of prey whose populations were enhanced by organic enrichment. White sea urchins were present at offshore sites but not in the vicinity of the outfalls; in laboratory studies, both these species prefer clean sediments over contaminated sediments (Anderson et al. 1988).

During pre-abatement sampling at the 7-mi outfall, ridgeback rock shrimp and white sea urchin were the most abundant megafaunal invertebrates collected (SCCWRP 1989). Megafaunal species collected at the 300 ft depth contour differed between contaminated sites and the reference sites (SCCWRP 1989). In 1986-1987 (during active sludge discharge) the most abundant megafaunal species at the contaminated sites was the California sand star (SCCWRP 1989). Following discontinuation of sludge disposal the abundance of California sand star decreased below reference levels (SCCWRP 1989). White sea urchin was formerly most abundant at the reference sites and did not usually occur at the contaminated sites, it has not returned following sludge termination (SCCWRP 1989).

Industrial Discharge Impacts

Macrofauna

The shallow, subtidal bottom between Redondo Beach and El Segundo have been surveyed in connection with NPDES permits for three generating stations and the El Segundo Refinery industrial discharge. No effluent impact on the infauna has been demonstrated around either the El Segundo or Scattergood Generating Station discharges (IRC 1979, 1981, MBC 1991b); thermal effects and NPDES monitoring studies at the Redondo Generating Station have not indicated any effects of the discharge other than increased bottom turbulence (EQA/MBC 1973, MBC 1982a).

Turbulence associated with the discharge plume results in coarser bottom material near the discharge structure, and coarse sediments are inhabited by a somewhat different benthic community. Coarsening has also been observed at the intake structure, where mussel and barnacle shell fragments are flushed out during heat treatment of the conduits. These minor changes are only noticeable within 300 ft of the structures. Metals dissolved from the condenser tubes and chlorine used to control growth of clams and barnacles within the cooling water system do not have detectable effects on bottom communities.

1 5473

Infaunal sampling at El Segundo and Scattergood Generating Stations in 1991 indicated no effects from the discharge (MBC 1991b). Abundance and species richness have been greatest at stations along the 20-ft and 30-ft isobaths upcoast of the Scattergood Generating Station. Infaunal abundance and species richness patterns were closely associated with sediment grain size, suggesting that the sediments are the most important factor, but that the impact is not ecologically significant (MBC 1991b). Abundance, species richness, and diversity all generally decreased with increasing distance from the El Segundo Refinery discharge in 1990, indicating enhancement, if anything, due to the discharge (MBC 1990).

Megafauna

Diver-observed and trawl-caught megafauna along the 30-ft isobath were no different near the El Segundo Generating Station than away from it (IRC 1979, 1981). At water depths of 65 ft off Redondo Beach, white sea urchins were less abundant near the power plant discharge than in trawls taken off Manhattan Beach (MBC 1986a); however, few other species showed such a pattern.

Marine Vessel Activity Impacts

The soft benthos of Marina del Rey appears to have been impacted by marine vessel-related contaminants, in particular TBT from antifouling paints. Many mollusk species are virtually absent or are less abundant in areas where TBT levels are high than they would normally be expected (Soule and Oguri 1986, 1987).

HARD BOTTOM HABITATS

Municipal Wastewater Discharges

Treated wastewater can affect nearby rocky habitat through sedimentation, turbidity, and the toxicity of its metal and chlorinated organic components. In 1958 algal cover in rocky areas exposed to the JWPCP effluent was fairly normal at water depths of 10 and 33 ft, but almost no algae were found below 33 ft (CSWQCB 1964). In 1969 almost no algae were found at water depths of 50 to 75 ft from 2 mi upcoast to 2 mi downcoast of the outfalls and more than 0.4 in. of fine organic-rich sediment covered rock surfaces 1.3 mi upcoast of the discharge (Grigg and Kiwala 1970).

It appears that the area affected by the outfalls tripled between 1954 and 1969 and in 1966 the algal community at depths of 20 to 100 ft off Palos Verdes Point (8 mi upcoast of the JWPCP outfall) was modified as a result of exposure to wastewater (Strachan and Koski 1969). Partial recovery of the subtidal algal community (which coincided with decreases in the emission of particulates and toxicants from the JWPCP outfalls) was reported later (Grigg 1978, Meistrell and Montagne 1983), but significant increases in algal cover and diversity only occurred at sites farthest from the outfall (e.g., Palos Verdes Point). Algal populations and community structure near the outfalls were still impacted (Tetra Tech 1984).

In 1977 concentrations of metals and chlorinated hydrocarbons in the flocculent, near-bottom particulate layer off Palos Verdes Point were elevated above ambient. A concentration gradient (more metals and organics in this layer nearer the JWPCP outfalls) indicated that the outfalls were the source. Both positive and negative responses were noted: some populations apparently benefitted from outfall-derived nutrients, but overall the richness of the fauna increased as mass emission rates decreased. Exposed epifauna may have been affected indirectly by reductions in the availability of algal food and by the floc layer directly. By 1977, significant improvements had been observed compared to conditions in 1969, the greatest recovery being at Long and Palos Verdes Points (Grigg 1978).

The mass emissions of suspended solids from JWPCP in the 1990s is less than one-fifth the 1970 level, and it is no longer the source of particulates described by Grigg and Kiwala (1970) or Grigg (1978). Since 1978, the Portuguese Bend landslide, (located 3.5 miles west of the JWPCP outfall system), has been more active than before and through the 1980s, an average of 200,000 MT per year of slide debris were dislodged (City of Rancho Palos Verdes 1986), over five times that of JWPCP (Stull, pers. comm. 1993). The landslide sediments are released at the shoreline; whereas solids from JWPCP are discharged 2 to 4 km offshore in 60 m of water. Thus, while the rocky subtidal community of Palos Verdes Peninsula continues to be impacted by turbidity and sedimentation, the landslide has replaced JWPCP as the source of particulates. Reductions in mass emissions of trace constituents coincided with significant recovery of eastern sites from the 1970s to the mid-1980s (Stull, pers. comm. 1993).

The HTP outfall conduit provides additional hard-bottom substrate for both plants and animals to colonize, thereby creating positive impacts. Inshore portions of the 5- and 7-mi conduits are dominated by gorgonian corals and strawberry anemones, and the ballast rock provides crevices for cryptic species (Allen *et al.* 1976). In deeper water, low-relief rocky bottom near the shelf break has been examined with remote camera (Moore and Mearns 1980) and the hard substrates of the HTP outfalls by submersible (Allen *et al.* 1976). Plumose anemone was dominant on the pipe, however, it was not seen on the deep, low-relief rock bottom, despite its presence at equal depths elsewhere. The reasons for this and other differences between the communities in the two areas are not known, but may be related to the waste discharge. Although the outfall pipe supports a diverse and abundant epifauna, it is not the same as that of nearby natural rock areas.

The conduit does provide a habitat which attracts many fish and invertebrates, thereby making them popular sport fishing locations. Many species of rockfish are common near the 5-mi outfall terminus.

Industrial Discharge Impacts

No effects from the Redondo Generating Station effluent have been noted on rocky subtidal invertebrates in King Harbor. The widespread distribution of open coast algae in the harbor indicates good water circulation, which is at least partially due to the generating station intake and discharge (Straughan 1977).

Marine Vessel Activity Impacts

The substrate of groins, breakwaters, and jetties in shallow water near Marina del Rey may be subjected to the toxic effects of TBT on mussels, clams, and snails (Soule and Oguri 1986, 1987). TBT has been used in boat bottom-paint and because of its toxicity to mollusks, Marina del Rey has fewer species of mollusks than other areas where there are fewer marine vessels.

Fishery Impacts

Commercial fishing in the study area for California spiny lobster, rock crabs, and red sea urchin occurs primarily west of Malibu Point and south of Palos Verdes Point. Lobsters can only

VOL 12 15475

be fished from mid-October to mid-March (Schultze 1986), and commercial catches of lobster from the Bay have declined since 1955 (MBC 1985). However, total catch decreased in the early 1970s on the Palos Verdes Shelf and increased in the 1980s. Rock crab catches from this area were especially low in 1971, peaked in 1975, and have decreased since then. The red sea urchin fishery began on a large scale in 1976 and by 1981 had already been overharvested (Stull *et al.* 1987). It is not certain whether these fluctuations were due to natural causes, overfishing, loss of habitat (e.g., surfgrass nursery grounds for lobster), or pollution.

Recreational fishing for California spiny lobster, rock crabs, pink abalone, and rock scallop also occurs in the Bay, primarily by divers. The impact of this fishery has not been described, but the construction of artificial reefs in the Bay was intended to increase their habitat and thus fishing success.

ARTIFICIAL REEFS

A large number of unique and popular plants and animals utilize the hard-bottom, reef habitat. However, hard bottom is lacking in most of the study area and artificial reefs have been constructed to provide hard-bottom habitat. Originally, the justification for construction of artificial reefs was to enhance recreational fishing and diving, however, in recent years artificial reefs have also been used as mitigation for marine resources lost in coastal development projects (Wilson *et al.* 1990, Johnson *et al.* 1992).

Most of the nearshore area of Santa Monica Bay proper consists of sandy bottom and is devoid of natural reefs. Since 1958 the California Department of Fish and Game (CDFG) has constructed 14 artificial reefs in Santa Monica Bay. Five of the early reefs were constructed of streetcars, automobiles, and other degradable materials and have since disappeared. However, nine artificial reefs remain in the nearshore subtidal area from Malibu to Torrance Beach (Figure 9-13) (Lewis and McKee 1989). These are named as follows: Malibu, Topanga, Santa Monica, Santa Monica Bay, Marina del Rey Reef 1, Marina del Rey Reef 2, Hermosa Beach, Redondo Beach, and Palawan. Most are composed of quarry rock but Palawan Artificial Reef off Torrance Beach consists of the sunken liberty ship *Palawan* (Lewis and McKee 1989).

KELP BEDS

Wastewater discharges are thought to have contributed to the loss of giant kelp (*Macrocystis pyrifera*) near Los Angeles and San Diego (North and Schafer 1964). Kelp plants have been shown to be sensitive to many of the contaminants introduced by man, and although there are other sources, most of these in the study area are from treated wastewater (CSWQCB 1964). Aside from the coincidence that the Palos Verdes kelp beds began to degenerate shortly after the White Point discharge became operational in 1937 and spread outward from the outfall, there is a strong relationship between mass emissions through the JWPCP outfalls and kelp canopy coverage on the Palos Verdes Peninsula. Conversely, between 1974 and 1987 mass emissions of total suspended solids in the JWPCP effluent decreased by 72%, while the area of kelp coverage increased.

Kelp coverage along Palos Verdes has generally increased since the mid-1970s (Figure 9-14), although in 1983 and 1988 it suffered losses of 90% and 95%, respectively, due to extremely severe winter storms. Other beds in southern California suffered similar losses. Recovery of giant kelp was rapid at Palos Verdes: the surface canopy in 1989 was four times that in 1978. Between 1989 and 1992, kelp coverage has declined because of increased grazing pressure from expanding sea urchin populations. Some areas are essentially devoid of vegetation

VOL 12 1 5478

because of sea urchins, although this appears to be a natural episodic event, unrelated to the discharge of treated wastewaters (Stull, pers. comm. 1993).

Toxic materials in wastewaters may harm kelp, but the accumulation of particulates on rock surfaces probably has the greatest impact. The small, young plants (sporophytes) which are contacted by the particulates are not only more sensitive than adults to toxic materials, but they do not settle and grow on rocks covered with a particulate film. In areas of heavy particle concentration the few sporophytes which settle are often on ridges which bottom currents sweep clear of sediment. Normally rocks in a well-developed kelp bed support large numbers of small sporophytes, which do not grow to maturity because the existing canopy keeps light levels too low for active photosynthesis. When adult plants die back because of summer nutrient limitations or are torn up by storms, light penetrates to the bottom and the sporophytes grow.

Turbidity and light reduction may also result from wastewater discharge and may affect kelp. Even though this would not prevent settlement of sporophytes, it might prevent their growth by reducing bottom light levels. At present there is not enough evidence to distinguish between these two effects, or to establish the role of toxic materials in kelp growth and survival in the study area. The strong relationship between JWPCP mass emissions and kelp die-off strongly suggests wastewater involvement, but it does not indicate which constituent is responsible.

CHAPTER 10

MARINE VERTEBRATE RESOURCES

The marine vertebrates of Santa Monica Bay are important to the general public, especially to commercial and recreational fishermen as well as to recreational SCUBA divers. In the past, fish diseases have been an obvious indicator of contaminated areas. Sea birds, shore birds, and waterfowl are some of the most obvious members of the Santa Monica Bay fauna, and are important scavengers and foragers throughout the Bay. They are aesthetically and recreationally pleasing, and have shown some of the most striking responses to marine contamination. Marine mammals are important to Bay tourists, particularly whale watchers and party-boat fishermen; being near the top of the food web, they often accumulate high levels of contaminants.

FISHES

Distribution by Habitat

Pelagic

The most obvious and abundant pelagic nekton in the study area are bony fishes, species which typically school and are often migratory. Most pelagic fishes feed on copepods when small, on shrimp-like prey when larger, and on other fish as adults.

The dominant pelagic fishes in the study area are chub (or Pacific) mackerel, jack mackerel, northern anchovy, and Pacific sardine. These species make up most of the commercial wetfish fishery catch, the dominant commercial fishery in southern California. Oceanic species such as swordfish are important in the driftnet fishery and northern anchovy are caught in the bait fishery.

Some pelagic sport fishes such as yellowtail and Pacific barracuda are migratory species which move into the Bay in summer, and may be especially abundant during an El Niño period. Chub mackerel and Pacific bonito are commonly taken from piers and jetties as well as charter and private boats. In the 1980s chub mackerel and Pacific bonito accounted for about 27 and 13%, respectively, of the sport catch in the Bay proper, and 31 and 18% of that of the Palos Verdes Shelf (MBC 1985, Stull *et al.* 1987). Chub mackerel, Pacific barracuda, and Pacific bonito accounted for 29, 7, and 7%, respectively, of the recreational fish catch of Santa Monica Bay in 1991-1992 (MBC, in prep.).

Many neritic species occur in the Bay, including queenfish, jacksmelt, and topsmelt in shallow depths and shortbelly rockfish along the outer shelf. White seabass are important in the commercial set gillnet fishery (which will end in 1994) others are taken by recreational fishermen.

The deeper waters of the Bay support northern and Mexican lampfish, California smoothtongue, and Pacific hake. These species migrate between the surface waters at night and the deepwater mesopelagic zone below 300 ft during the day.

Many species are temporary members of the pelagic community. Vermilion rockfish, bocaccio, and sablefish feed in the water column at night but rest on or remain near the bottom during the day. White croaker and white seaperch school in the water column but feed on the bottom.

The eggs and larvae (ichthyoplankton) of many bony fishes are planktonic, even though the adult stages may not be. The planktonic stage lasts for a few weeks to months before the larvae transform into nektonic or demersal juveniles. Ichthyoplankton are of particular concern because of their relationship to the abundance of adults in particular fishing grounds. The most abundant fish larvae in an area are typically those of the most abundant adult species, but this is not always the case.

Sharks are the dominant cartilaginous fishes in the pelagic environment of Santa Monica Bay, with blue shark the most abundant, although thresher sharks, basking sharks, and others are seen occasionally. Most sharks feed on adult fish and squid but basking sharks feed on juvenile fish and euphausiids.

Soft-bottom

The soft-bottom habitat supports an abundant and diverse assemblage of demersal fishes which swim occasionally, but spend much of their time on the bottom. Flatfishes, rockfishes, sculpins, combfishes, and eelpouts make up most of the soft-bottom fish fauna. Different basic assemblages are found on the inner, the middle, and the outer shelf (SCCWRP 1973, Fay *et al.* 1978, Allen 1982). The inner shelf assemblage is dominated by speckled sanddab, the middle shelf by stripetail rockfish, and the outer shelf by slender sole (Allen 1982).

California halibut, California scorpionfish, barred sand bass, and white croaker are fished by sport fishermen. In the 1980s barred sand bass accounted for 8% of the sport fish catch off the Palos Verdes Shelf and 6% of that of the Bay proper (MBC 1985, Stull *et al.* 1987). In 1991-1992 they accounted for 11% of the recreational fish catch from piers, private boats, and commercial passenger fishing vessels (MBC, in prep.). Sablefish, Dover sole, and English sole are important in commercial fisheries to the north, although they are not fished in Santa Monica Bay.

Hard-bottom

The hard-bottom fish assemblage differs in composition with depth. Common shallow water families include the sea basses, surfperches, rockfishes, kelpfishes, sculpins, damselfishes, and wrasses. Important species locally include kelp bass, brown rockfish, pile perch, black perch, white seaperch, rubberlip seaperch, señorita, and opaleye (Carlisle *et al.* 1964; Stephens *et al.* 1984b; MBC 1987a; Dorsey 1988, pers. comm.). In deeper water, vermilion rockfish, bocaccio, cowcod, and flag rockfish dominate (Allen *et al.* 1976, Moore and Mearns 1980). Because these species occur off-bottom they are readily observed by divers or remote cameras; however, hard-bottom species such as kelpfishes, sculpins, and pipefishes are cryptic and hence difficult to see.

Hard-bottom fishes are pursued by divers on the Malibu and Palos Verdes Shelves and by anglers from shore, piers, and private or party boats. Because outfall pipes constitute hard substrate, party boat fishing is sometimes conducted along their length. Rockfishes and kelp bass are the most important hard-bottom sport fish in the Bay, rockfishes in deep water and kelp bass in shallow water. In the 1980s, rockfishes and kelp bass accounted for 43 and 6%, respectively, of the sport catch in the Bay proper and 17 and 10% of that of the Palos Verdes Shelf (Mearns 1977; MBC 1985, Stull *et al.* 1987). In 1991-1992 more kelp bass than rockfishes were taken by recreational anglers in Santa Monica Bay; kelp bass and rockfishes comprised 9 and 6%, respectively, of the catch during that period (MBC, in prep.).

Kelp-bed

The vertical complexity of kelp beds attracts many fishes which use the beds for schooling, shelter, and foraging. Kelp bass, black perch, rubberlip seaperch, opaleye, kelp rockfish, and olive rockfish are common in kelp holdfast zones. Yellowtail, white sea bass, rubberlip seaperch, halfmoon, and halfblind goby have been observed in the stipe region of the bed. Fishes of the kelp canopy include the topsmelt, kelp pipefish, kelp perch, giant kelpfish, kelp clingfish, and kelp gunnel.

Opaleye and halfmoon feed primarily on algae, whereas kelp bass, yellowtail, and white seabass eat fish and squid. The remaining species feed largely on crustaceans such as amphipods, copepods, mysids, crabs, and shrimp. The kelp bass is important in the sport fishery, comprising 10 and 6% of the catch of the Palos Verdes Shelf and Santa Monica Bay, respectively (MBC 1985, Stull *et al.* 1987). In 1991-1992 they comprised 9% of the recreational fish catch from Santa Monica Bay.

Natural Variability

The fish populations in Santa Monica Bay vary in size as a result of major climatological events and minor oceanographic and biological events. The species composition in fish assemblages also varies for similar reasons; although the effects of these natural events have only been described qualitatively.

The abundance of fish scales in sediments from basins off southern California indicates that populations of pelagic species have fluctuated greatly during the last 1,800 years (Figure 10-1) (Soutar and Isaacs 1969). Pacific sardine abundance has ranged from periods of high abundance lasting 20 to 200 years to periods of low abundance averaging 80 years in duration. Population peaks in the past were about twice those of the present century. However, fluctuations during the 19th century were similar in magnitude to those during this century: the low abundance of sardines since the 1940s is similar to that of the period between 1865 and 1885 (Soutar and Isaacs 1974).

Northern anchovy and Pacific hake populations did not crash as severely as did the Pacific sardine, but they have fluctuated greatly. The abundance of northern anchovy peaked about 1,500 years ago and has declined gradually since. Pacific hake has peak abundances about every 300 years, the last being about 250 years ago (Soutar and Isaacs 1969).

The abundance of these pelagic fishes combined was greater from 1900 to 1925 than anytime since (Soutar and Isaacs 1974). These long term changes may be related to variations in the California Current. During El Niño periods, warm-water species either recruit to the Bay from the south as larvae or move into the Bay as adults. Many species move into the area from their more typical habitat off Mexico (Radovich 1961, Mearns 1988).

Pelagic, warm-water, and migratory sport fish abundance increased in Santa Monica Bay during the 1957-1959 El Niño (Mearns *et al.* 1976). During the El Niños of 1978 and 1982-1983, several species of warm-water reef fishes recruited into King Harbor where they are still abundant (Stephens 1988, *pers. comm.*). Similarly, during 1985-1986 the shallow, demersal fish assemblage of the Palos Verdes Shelf had more warm-water species than it did in 1972-1973, a period of cold water (MBC 1987b).

VOL 12

15482

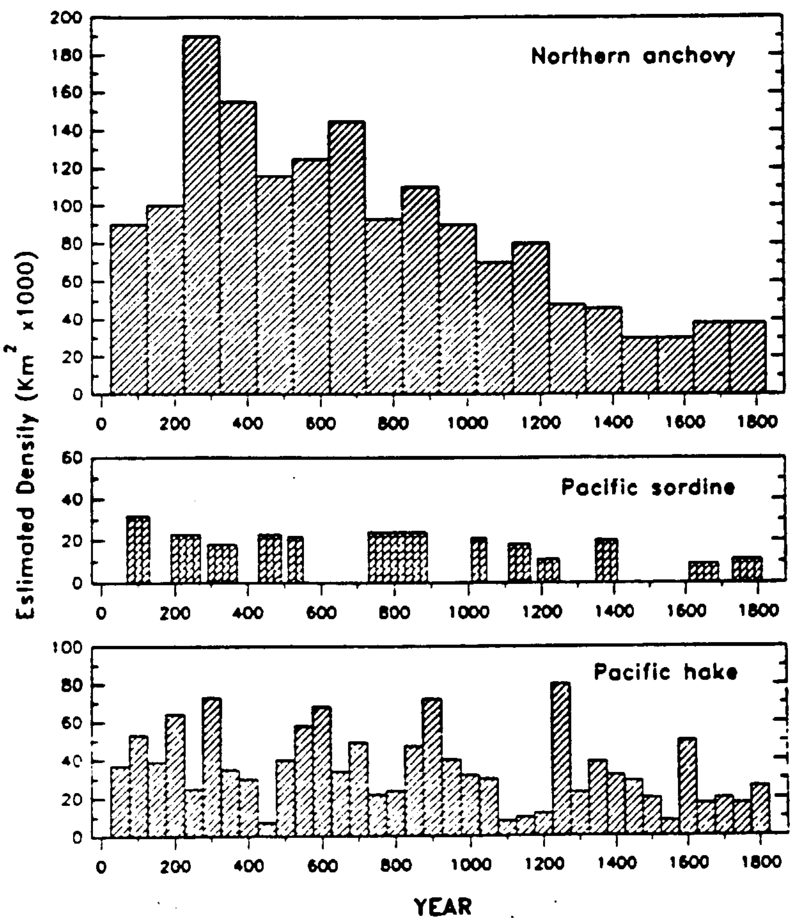

Figure 10-1. Minimum population estimates (based on scale abundance) in Santa Barbara Basin during the past 2,000 years for a) northern anchovy, b) Pacific sardine, and c) Pacific hake (Soutar and Isaacs 1969).

Cold water species are negatively affected during an El Niño event. The abundance of demersal fish in Santa Monica Bay was about one-third of normal during the 1957-1959 El Niño. This decrease coincided with the initiation of sludge discharge into Santa Monica Submarine Canyon (Carlisle 1969). Although the potential effect of sludge disposal cannot be discounted, the abundance of demersal fish did increase immediately after the El Niño.

During the 1982-1983 El Niño, many cool water soft-bottom species moved to deeper water in Santa Monica Bay (Love *et al.* 1986). Several coastal species disappeared from Marina del Rey, (presumably moving into the Bay proper) and these did not return until the water was cooler in 1986 (Soule and Oguri 1987). Apparently some cool-water species also recruited poorly during this period, possibly due to a decrease in zooplankton abundance (Love *et al.* 1986).

The development of kelp beds on the Palos Verdes Shelf during the late 1970s had little effect on the rocky-bottom fish fauna in general, but the abundance of kelp bass increased (Stephens *et al.* 1984b). Extreme wave turbulence destroys reef and kelp bed habitats and disrupts inshore sandy bottoms. Artificial rocky reefs in King Harbor were lost during a major storm of January 1988 (Stephens 1988, pers. comm.). Turbidity from storm runoff and landslides may linger for weeks or months, making the area unsuitable for many fish (Allen 1982). The movement of sand into tidepools during the summer reduces the amount of habitat for intertidal fishes.

Although a red tide in 1945 (from San Luis Obispo to Los Angeles Harbor) killed sharks, stingrays, and California halibut (Sommer and Clark 1946), no other red tides have caused major fish kills along the California coast in recent years (Bongersma-Sanders 1957).

Recruitment of juveniles to the Bay is not necessarily related to local spawning, primarily because most fishes have planktonic larvae. The coastal current regime during a spawning event may act to retain larvae spawned in the Bay, may carry them away, or may import larvae from outside the Bay.

Impacts

Municipal Discharge Impacts

Population Changes. The effects of wastewater discharges on the fishes of Santa Monica Bay were first studied after the discharge of sludge was initiated at the HTP 7-mi outfall in 1957. The abundance of most small, trawl-caught fishes in Santa Monica Bay declined in 1959, but returned to previous levels between 1960 and 1963 (Carlisle 1969). The decline probably resulted from poor recruitment of cool-water fishes during the El Niño Event of 1957-1959 (Mearns *et al.* 1976). Speckled sanddab appeared to be attracted to the 7-mi outfall, but yellowchin sculpin, California tonguefish, as well as the speckled sanddab were absent in the area near the terminus of the 5-mi outfall (Carlisle 1969).

From 1957 to 1975 the abundance and diversity of demersal fish were low around the 5- and 7-mi outfalls (Mearns *et al.* 1974, Allen and Voglin 1976, Mearns *et al.* 1976), but from 1976 to 1979 species richness, biomass, and individual fish size were greater in the sludge field than in reference areas. Underwater cameras showed that Pacific electric ray, white croaker, and shiner perch were abundant in the sludge field, the latter two apparently feeding in the sludge (Bascom *et al.* 1980). From 1984 to 1986 fish biomass was higher and fish abundance was generally high near the outfall stations while white croaker dominated the fish abundance near both outfalls although not in other offshore areas of the Bay (Johnson and Roney, 1988).

By the late 1980s, the number of fish per trawl in the contaminated zone near HTP 7-mi outfall were still below reference levels (SCCWRP 1989) and white croaker and Dover sole were the most abundant species collected (SCCWRP 1989). Immediately following termination of the sludge discharge fewer white croaker were collected at the contaminated sites, but sludge did not appear to impact fish communities at water depths of 200 m (SCCWRP 1989). The number of fish per trawl have not indicated any trends toward recovery.

Five demersal fish assemblages were described in Santa Monica Bay in 1989-1990 (Figure 10-2) (CLA,DPW 1991). The three offshore assemblages consisted of northern, mixed, and outfall site-groups; the two nearshore assemblages were separated by seasonal differences. Mean numbers of species and individuals were highest along the 60-m isobath, depressed in the vicinity of the outfalls, and lowest nearshore.

Flatfishes were the most abundant group; hornyhead turbot was the most widely distributed, California lizardfish the most abundant species near the outfalls. Contaminated sediments near HTP's 5-mi and terminated 7-mi outfalls may exclude, depress, or enhance the abundance of certain species (CLA,DPW 1991).

The distribution of fish species in Santa Monica Bay is also related to distribution of their prey. Changes in the composition of the benthic infauna can result in a change in the composition of demersal fish assemblages (Cross *et al.* 1985, MBC 1987b). Crustaceans (the preferred prey of most common demersal fish) are uncommon near the outfall sites. Fish that feed predominantly on benthic and epibenthic crustaceans are rare or absent from outfall sites (CLA,DPW 1991). Hornyhead turbot and English sole, on the other hand, feed primarily on infaunal polychaetes and mollusks (Allen 1982). Infauna near the outfalls were dominated by these invertebrates, thus those fish species were dominant there.

Between 1970 and 1976 the fauna of the Palos Verdes Shelf was more severely affected by wastewater discharge than that near the HTP outfalls. The abundance and diversity of demersal fish were low near the JWPCP discharges on the 200-ft isobath and were severely depressed at a depth of 450 ft, 0.6 to 1.2 mi northwest of the outfalls. Although fish biomass was enhanced at a depth of 450 ft near the discharge; hornyhead turbot, California tonguefish, plainfin midshipman, and yellowchin sculpin were rare or absent whereas white croaker, shiner perch, and curlfin sole were unusually abundant (Mearns *et al.* 1976, Allen 1982).

By 1985 and 1986 the demersal fish assemblage had changed from that characteristic of the early 1970s and some of the differences appeared to be related to improved effluent quality. Previously rare or uncommon species such as hornyhead turbot, California tonguefish, yellowchin sculpin, and plainfin midshipman were common whereas previously abundant species such as white croaker, shiner perch, and curlfin sole were absent or rare (MBC 1987b). Some of these shifts appear to be related to food availability; e.g., several species which fed on gammarid amphipods were absent when amphipods were uncommon during the mid-1970s whereas fish species which fed upon polychaetes were abundant when polychaetes were dominant (Allen 1982, Cross *et al.* 1985, MBC 1987a).

From 1988 to 1990 the fish fauna of the Palos Verdes Shelf changed little (LACSD 1992). At first, bigmouth sole was the most common species and slender sole the most abundant; in 1991 plainfin midshipman was the most abundant and most common species. Larvae of the most abundant species had settled on the Palos Verdes Shelf and thus most species were represented by several age-classes (LACSD 1992). Some species that feed on benthic microcrustaceans continue to be less abundant near the outfalls, but California tonguefish has been consistently

1 5486

more abundant. Curlfin sole and shiner perch were abundant near the outfall in the early 1970s and were described as being "discharge-associated" (Allen 1982), but they are now rare or absent (LACSD 1992); whereas several species that were absent in the early 1970s are now present (Stull 1992 pers. comm.).

The HTP 5- and 7-mi outfalls function as artificial reefs, attracting many rocky bottom fishes. Schools and aggregations of fishes near the conduit in deep water may simply orient to the pipes, and may feed there. In shallow water, the ballast rock provides cover for rockfishes; shortbelly rockfish, vermilion rockfish, cowcod, and bocaccio are most common along deeper portions of the pipes (Allen *et al.* 1976).

Wastewater-related changes in intertidal fish populations have not been documented, although changes in the algae assemblage probably affect some fishes. Human disturbance has probably reduced intertidal fish populations throughout southern California (Cross 1982b).

Diseases and Abnormalities. Diseases and abnormalities in marine organisms have been related to pollution throughout the world (Sindermann 1979, Sindermann *et al.* 1980, Mix 1986). Diseases and abnormalities in marine organisms from southern California have been documented since the 1950s (Mearns and Sherwood 1977), although careful evaluations of the cause and effect relationships were not conducted until the early 1970s. Since then, many studies have surveyed the prevalence (i.e., percentage of a population affected) and geographic distribution of fish diseases and abnormalities. The major abnormalities that may be related to pollution in Santa Monica Bay include fin erosion, epidermal tumors, oral papillomas, and microscopic liver abnormalities.

Fin Erosion. Fin erosion is an obvious abnormality and has been linked to degraded marine environments throughout the world. It is characterized by the degeneration or absence of fins (Mearns and Sherwood 1974), but the causes are complex and may include chemical contamination, low dissolved oxygen, and secondary bacterial invasion (Sindermann *et al.* 1980). Although little is known about how the disease affects survival rates, it is less common in fish more than three years old (Cross 1985).

In 1969 to 1972 fin erosion in Dover sole was exceptionally high (42%) on the Palos Verdes Shelf and declined sharply both upcoast and downcoast from that area (Mearns and Sherwood 1974). The overall prevalence in Santa Monica Bay was 6%, but it was greater than 10% near the HTP outfalls and less than 2% elsewhere.

Fin erosion was found in 33 of 151 species (22%) from the study area and prevalence was 5% or greater in seven species: Dover sole (30%), greenstriped rockfish (14%), rex sole (13%), barred sand bass (9%), greenblotched rockfish (6%), and vermilion rockfish (5%) (Mearns and Sherwood 1977). The prevalence pattern of fin erosion in five species was similar to that in Dover sole: it peaked on the Palos Verdes Shelf (11 to 39%) and declined both upcoast and downcoast from that area (Sherwood 1978). Mearns and Sherwood (1974, 1977) and Sherwood (1978) concluded that fin erosion in fishes on the Palos Verdes Shelf is probably a result of the JWPCP effluent.

From 1971 to 1983, fin erosion was found in 29 fish species near the JWPCP outfalls: approximately 90% of all individuals with fin erosion were Dover sole (Cross 1985). The prevalence of fin erosion in Dover sole declined with increasing distance from the outfalls along both the 200- and 450-ft isobath. Within 0.6 mi of the outfalls prevalence was approximately 30%, whereas 14.4 mi from the outfalls it was close to 0.0%. The prevalence of fin erosion in Dover sole exhibited a fairly steady decline from 1971 to 1983. Values within 5.4 mi of the outfalls ranged from 51 to 81% in 1971-1972, and declined to less than 10% by 1983. The number of fish species with fin erosion near the JWPCP outfalls also declined, from 18 in 1971 to just 6 in 1983 (Cross 1985). Cross (1985) also concluded that this abnormality was the result of exposure to sediment contaminants. Fin erosion in Dover sole on the Palos Verdes Shelf was even lower (0.7%) in 1988. Within 0.6 mi of the outfall about 1.1% of the fish have the condition (Stull 1988, pers. comm.).

The extent of fin erosion has also declined over the years (Stull 1992, pers. comm.). In the 1970s most fins were completely lost, whereas in the 1980s and 1990s only a small section of the mid-dorsal fin was afflicted.

Fin erosion has been found in fishes from many other areas of the United States. Between 1967 and 1971 in Raritan, Lower, and Sandy Hook Bays (New York City), relatively high levels of fin erosion were found in four species bluefish 24%; summer flounder 16%; weakfish 11%; and winter flounder 8% (Mahoney *et al.* 1973). This condition was limited to inner portions of the New York Bight and was thought to be caused by bacteria in conjunction with environmental stress from chemical contamination (Mahoney *et al.* 1973). Fin erosion was found in two of 22 fish species from the highly contaminated Duwamish River in Puget Sound: 8% of the starry flounder and 0.5% of English sole. The abnormalities were attributed to an interaction of the genetic constitution of the organisms with multiple environmental variables, (such as chemical contaminants and physical factors), and mechanical injury (Wellings *et al.* 1976).

These studies confirm those from southern California which suggest that high prevalences of fin erosion are found only in highly contaminated areas, i.e., that the disease is induced by pollution. They also suggest that not all species are equally susceptible to fin erosion, although the reasons for different susceptibilities is not known.

Epidermal Tumors. Epidermal tumors appear as nodular growths on the skin and are most prevalent in flatfishes less than 3 years old. They have been found in several flatfish species on the west coasts of both Canada and the United States but have not been found in any species on the east coast of either country (Stich *et al.* 1977). They are thought to be caused by a unicellular parasite or a virus (Cross 1988). Epidermal tumors are frequently prevalent near urbanized areas (Sindermann 1979). Individuals with epidermal tumors exhibit reduced growth, increased mortality, and failure to participate in normal seasonal migrations (Stich *et al.* 1976, Campana 1983, Cross 1986).

Of 151 species examined from southern California between 1972 and 1975, only Dover sole was consistently affected with tumors (Mearns and Sherwood 1977). Tumors were most prevalent in Dover sole less than 120 mm standard length (SL) (Mearns and Sherwood 1977); 8% in Santa Monica and San Pedro Bays and about 5% on the Palos Verdes Shelf. Dover sole <120 mm SL were 34 times more abundant on the Palos Verdes Shelf than in Santa Monica Bay. Epidermal tumors were not seen in fish (fewer than 25 specimens) from Dana Point and Santa Catalina Island.

From 1969 to 1972, the prevalence of epidermal tumors in all size classes of Dover sole was highest (>2%) off Port Hueneme and in San Pedro Bay and ranged from 1 to 2% at other sites, (Mearns and Sherwood 1974, Sherwood and Mearns 1976).

Museum specimens from southern California as early as 1946 revealed that diseased Dover sole were found in relatively uncontaminated areas far from the Southern California Bight (Mearns and Sherwood 1976). Mearns and Sherwood (1977) concluded that epidermal

VOL 12

15488

papillomas are not related to discharges from southern California outfalls. The prevalence in juvenile fish was similar throughout the area; because juvenile fish were more abundant on the Palos Verdes Shelf, more juvenile fish with tumors were found there.

From 1971 to 1983, epidermal tumors were found in 15 species near the JWPCP outfalls (Cross 1988). Dover sole accounted for 93% of all individuals with tumors, largely fish less than 120 mm SL. The prevalence of the tumors decreased with increasing distance from the outfalls. The maximum prevalence (3.3%) was at a water depth of 200 ft within 0.6 mi of the outfalls; prevalence was less than 0.6% 14.4 mi from the outfalls. The prevalence of tumors within 5.4 mi of the outfalls declined temporally in the mid-1970s, but appeared to increase in the early 1980s (within 1.8 mi from the outfalls). The number of fish species with epidermal tumors near the JWPCP outfalls declined from 6 in 1971 to 1 in 1976 and remained at one or two through 1983.

In 1988 the prevalence of epidermal tumors near the JWPCP outfalls was 1.1% for small fish and 0.1% for large fish (Stull 1988, pers. comm.). In 1991, 2.1% of all Dover sole had epidermal tumors; 87% were <120 mm SL (Stull 1992, pers. comm.). Cross (1988) concluded that these epidermal tumors in Dover sole were directly related to the chemical contaminants in the sediments.

In 1986 2.8% of the Dover sole near the HTP 7-mi outfall had epidermal tumors, compared to an incidence rate of 1.5% in northern Santa Monica Bay (Johnson and Roney 1988), rates similar to those from this area in 1971 and 1972 (Mearns and Sherwood 1974). Epidermal tumors were not observed on fishes collected in 1987 to 1989 (CLA,DPW 1991).

Epidermal tumors have been found in young flatfishes from contaminated and uncontaminated areas on the west coasts of Canada and the United States. The highest prevalences (15 to 59%) in English sole were from contaminated areas near Vancouver, British Columbia; Bellingham, Everett, Seattle, and Aberdeen, Washington; and San Francisco, California (Cooper and Keller 1969, Stich *et al.* 1977). A prevalence of 54% was found in starry flounder from Bellingham, Washington. The prevalence of epidermal tumors in fishes from uncontaminated areas has generally been less than 1%, but a few high values have been observed: 30% in sand sole from the Queen Charlotte Islands, British Columbia; 23% in rock sole from the Bering Sea, Alaska; and 15% in flathead sole from the San Juan Islands, Washington (Miller and Wellings 1971, Stich *et al.* 1977, McCain *et al.* 1978). Thus, epidermal tumors may be unrelated to human pollution.

Oral Papillomas. Oral papillomas on fish from southern California were first reported in white croaker collected in 1956 within 1.4 mi from the HTP 1-mi outfall in Santa Monica Bay (Russell and Kotin 1957). The prevalence of oral papillomas in fish near the outfalls was approximately 3%, whereas none were found in fish from a reference area 48 mi away, suggesting that the papillomas may have resulted from exposure to a contaminant.

Between 1970 and 1976, the prevalence of oral papillomas in white croaker was less than 1% in Santa Monica Bay and on the Palos Verdes Shelf, less than 5% in San Pedro Bay, and 0% south of Oceanside (Mearns and Sherwood 1977). The prevalence of this disorder continues to be relatively low up to the present (Cross 1988, pers. comm.). Because of the low prevalence rates and their wide distribution, they do not appear to be related to municipal wastewater discharges (Mearns and Sherwood 1977).

Microscopic Liver Abnormalities. No microscopic abnormalities were found in livers of Dover sole from Dana Point in 1976, but those from the Palos Verdes Shelf had fatty vacuolations of cells, structural disarray, cellular degeneration, and increases in the numbers and sizes of melanin macrophage centers (Pierce *et al.* 1977). There was no evidence that the observed abnormalities were caused by pathogens or parasites and the authors suggested that they may have resulted from exposure to the chlorinated hydrocarbons DDT or PCBs.

From 1983 to 1984 Rosenthal *et al.* (1984) studied microscopic liver abnormalities in fishes from nine locations in southern California; yellowchin sculpin, California tonguefish, Pacific sanddab, longspine combfish, and California scorpionfish. Abnormalities were found in most fishes, but they were no more prevalent in contaminated areas than in reference areas. The prevalence of cellular vacuolation and hypertrophy (increased size) in California tonguefish was significantly different among locations. The authors concluded that liver abnormalities may be the result of widespread chlorinated hydrocarbon contamination.

In 1984 Malins *et al.* (1986) examined microscopic abnormalities in white croaker, hornyhead turbot, and California tonguefish from the HTP and JWPCP outfalls, Los Angeles Harbor, and Dana Point. Only in Los Angeles Harbor was the prevalence of one or more of the 11 abnormalities in white croaker substantially higher than at Dana Point. The prevalence of abnormalities in hornyhead turbot near the outfalls was similar to that at Dana Point. The prevalence of abnormalities in California tonguefish was similar near the outfalls and in Los Angeles Harbor.

The most serious liver abnormalities evaluated by Malins *et al.* (1986) included tumors and pretumorous conditions. Liver tumors were found in only three white croakers from the HTP outfalls (4%) and from Los Angeles Harbor (3%); pretumorous conditions were found in one white croaker from Los Angeles Harbor (2%).

Microscopic liver abnormalities are relatively widespread in fishes in contaminated and uncontaminated areas in the Southern California Bight. If they are the result of human contamination, it is unlikely that they can be related to specific sources. They may be related primarily to natural stresses, such as temperature, dissolved oxygen, and food availability.

Liver tumors and pretumorous conditions are also prevalent in fishes from other contaminated areas in the United States. The prevalences of tumors and pretumorous conditions in English sole frequently exceed 5 and 15%, respectively, in highly contaminated areas of Puget Sound (Malins *et al.* 1984, 1985a,b; Krahn *et al.* 1986; Becker *et al.* 1987). The highest (32 and 52%) prevalence in Puget Sound were in an area contaminated with creosote (Malins *et al.* 1985a,b). In Boston Harbor, the prevalence of liver tumors and pretumorous conditions in winter flounder collected near a major sewer outfall were 8% (Murchelano and Wolke 1985).

Other Conditions. Studies around Santa Monica Bay have indicated that fishes from contaminated areas may have impaired reproduction and chromosomal abnormalities (Cross and Hose 1988). Reproductive success in white croaker from San Pedro Bay was significantly less ($P \leq 0.05$) than at Dana Point. [Impaired reproduction was indicated by increased early oocyte destruction, lower batch fecundities, and lower fertilization rates.] Concentrations of total DDT and PCBs in liver and gonads were significantly higher ($P \leq 0.001$) in fish from San Pedro Bay than fish from Dana Point. These contaminants may have been partly or wholly responsible for the impaired reproduction in fish from Santa Monica Bay (Cross and Hose 1988).

VOL 12 15490

Hose *et al.* (1987) evaluated circulating erythrocyte micronuclei in the blood of fish from contaminated and reference areas in and near Santa Monica Bay. The frequency of micronuclei in kelp bass was 11 times higher at contaminated sites than at the reference site; micronuclei frequencies in white croaker were four times higher at the contaminated site than at the reference site. Although the frequency of micronuclei may be partly a function of blood cell kinetics, temperature, life history stage, and sex differences, the results also suggest a relationship between contaminant exposure and genotoxicity in fishes.

Industrial Discharge Impacts

As seawater is circulated through the cooling system of generating stations, planktonic larvae are entrained and some are killed. Studies in 1979-1980 estimated that about 3.4 billion fish larvae are entrained in the Redondo Generating Station each year. White croaker was the most abundant species overall, accounting for about 36% of the larvae, but the dominant species varies throughout the year (Connally *et al.* 1982). On the basis of average flows, about 2 billion and 1 billion larvae would have been entrained at the El Segundo and Scattergood Generating Stations, respectively.

The cooling water conduits function as artificial reefs. Intake conduits of the El Segundo and Redondo Generating Stations attract rocky-bottom and schooling species; the former utilize the riprap around the pipes for cover and the latter use the pipes as a point of reference (Helvey and Smith 1985). Both juveniles and adults are sucked into the conduits and killed by impingement on protective screens, by the physical habitat, or, by elevated temperatures during heat treatments. The most abundant species taken are nearshore pelagic or schooling demersal species. Between 1978 and 1980 approximately 71,000 fish/year were estimated to have been impinged at Redondo Generating Station, about 78,000/year at El Segundo Generating Station, and about 48,000/year at Scattergood Generating Station (Herbinson 1981, Damron 1988, pers. comm.). Queenfish accounted for about 48% of those at Redondo and 45% at El Segundo (Herbinson 1981); queenfish were the most abundant species impinged at Scattergood in 1986-1987 but surfperches were often dominant in the past (Damron 1988, pers. comm.). The numbers of fish impinged at all three stations has decreased since this period (Herbinson 1988, pers. comm.).

Fish impingement losses at Redondo Generating Station were the lowest in 1988 and 1989 since 1978, although they climbed again in 1990 and 1991 (MBC 1991b). In 1991 over 21,000 fish were impinged at Redondo Generating Station; blacksmith and white croaker accounted for 37% and 17% of the total (MBC 1991b). The decrease in 1988 and 1989 was due to a reduction in the number of circulating pumps in operation, which results in a lower current velocity at the intake (MBC 1991b).

Approximately 30,000 fish were impinged during heat treatments in 1991 at Scattergood and El Segundo Generating Stations (MBC 1991c). Over 90% of the fish impinged at El Segundo occur during heat treatments (Curtis 1992, pers. comm.). Blacksmith was the most abundant fish impinged at El Segundo whereas white croaker was most abundant at Scattergood (MBC 1991c). About 99% of the fish near generating station intakes are expected to survive for at least 5 years: a 10-fold increase in intake volume would reduce this to 82% (SCE 1982).

Urban Runoff Impacts

The potential impacts of surface runoff on fishes has not been studied specifically. The input of freshwater to inshore zones would cause fishes that cannot tolerate low salinities to move

VOL 12

15491

offshore temporarily. Turbidity from suspended sediments in stormwater may linger for days or weeks, and could cause decreased visibility and respiratory problems (Allen 1982). Contaminant effects are not known.

Marine Vessel and Harbor Development Impacts

The abundances of fish larvae and benthic-feeding fishes in Marina del Rey have decreased since 1984. These changes are probably the result of post-El Niño cooling but could be related to TBT concentrations in the Marina. TBT was used as a biocide in boat antifouling paint and is known to be more toxic to larvae than to adults (Soule and Oguri 1987).

The development of Marina del Rey drastically altered the original lagoon habitat. The amount of shallow bottom habitat was reduced whereas water exchange between the harbor and the ocean was increased. The abundance of lagoon species such as the arrow goby and California killifish undoubtedly decreased. The amount of habitat suitable as a nursery ground for California halibut was reduced. Juvenile halibut utilize warm-water lagoons for development (Kramer 1988, pers. comm.) and thus the development of the Marina may have resulted in fewer adult halibut in Santa Monica Bay. The construction of rock breakwaters and jetties at King Harbor and Marina del Rey provide habitat for many species (Stephens and Zerba 1981), thus benefitting rocky bottom fishes.

Commercial Fisheries. Sport and commercial catches are reported by block to the California Department of Fish and Game (Figure 10-3). Pelagic species have been the major component of the commercial purse seine and gillnet fisheries of southern California, however, those methods are prohibited in most of Santa Monica Bay (Figure 10-4). Commercial fishing for pelagic fish outside of the study area could impact sport fishing in the Bay.

Between 1934 and 1950 Pacific sardine accounted for over 50% of the annual commercial catch in the Bight. When the sardine population collapsed, the commercial fishery shifted first to jack mackerel and then, after 1969, to the northern anchovy. The crash of the Pacific sardine population appears to have been the result of a long-term population fluctuation pattern (Figure 10-1; Soutar and Isaacs 1969), although it may have been aggravated by intense fishing pressure (Browning 1980).

A moratorium on fishing for Pacific sardine and chub mackerel was implemented in the mid-1970s. By 1975 the chub mackerel population had recovered and by 1985 it was the major fishery in California, 83% from southern California in 1985 (CDFG 1986, 1987). Chub mackerel has been important in the catch from the Palos Verdes Shelf and Santa Monica Bay since 1978 (MBC 1985, Stull *et al.* 1987).

From 1969 to 1983 northern anchovy was generally the dominant fish in the southern California catch: prior to 1978 it accounted for about 90% of the wetfish fishery, but for only 42% since then (Stull *et al.* 1987). In part this shift reflects a poor market for anchovy and a better one for other pelagic species (CDFG 1987).

Gillnet fishing has increased in importance in California, although it is not allowed in the inner part of Santa Monica Bay. California halibut is fished on the Shelf west of Malibu Point and from Palos Verdes Point to Point Fermin. Halibut gillnets are set at depths less than 120 ft for California halibut (Vojkovich 1988, pers. comm.), and in 1986-1987 the CDFG observed about 34 sets per year in the Malibu Point-Point Dume area and about 22 sets per year in the Palos Verdes Point-Point Fermin area (McCormick 1988, pers. comm.). These observations represent about 1

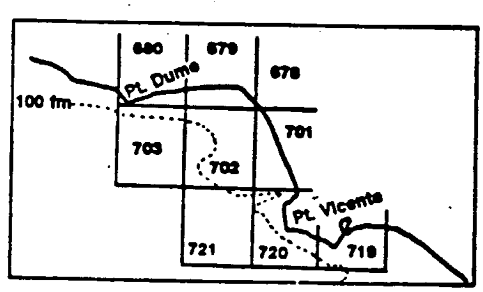

Figure 10-3. CDFG fish catch blocks for Santa Monica Bay (CDFG, unpubl. data).

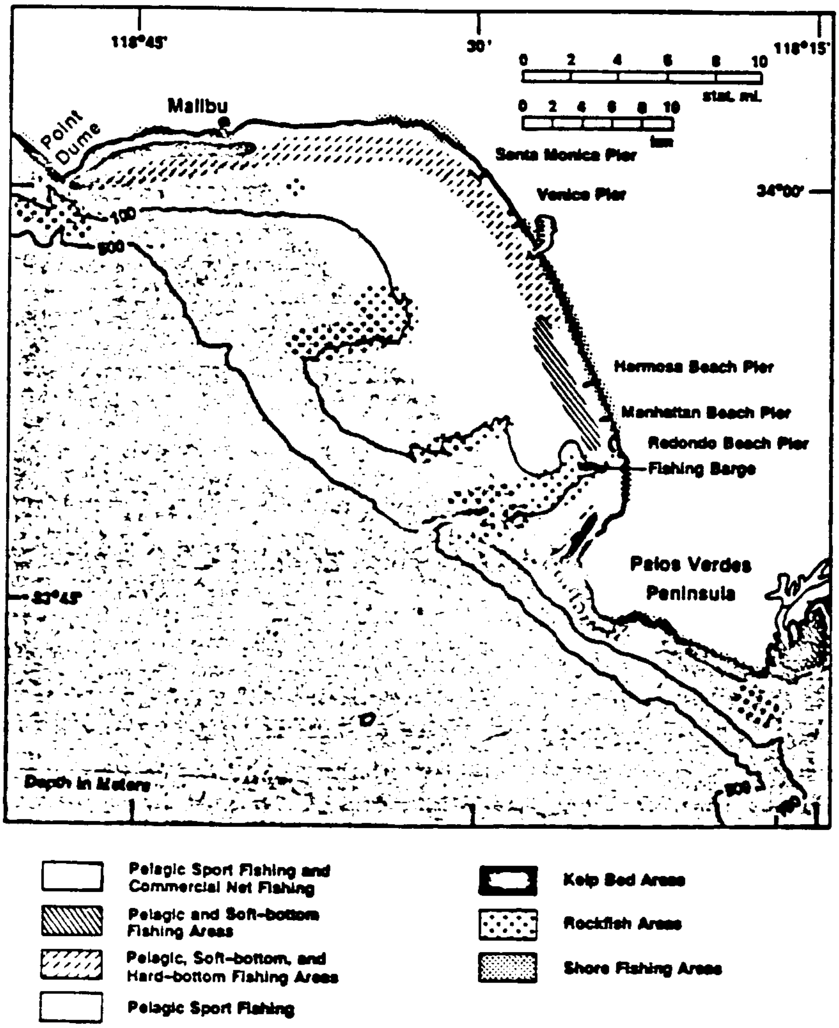

Figure 10-4. Fishing areas in and near Santa Monica Bay (based on Squire and Smith 1977, MBC 1988).

to 2% of the total fishing effort (Vojkovich 1988, pers. comm.); the actual fishing effort is probably 50 to 100 times greater. The annual catch of California halibut from southern California decreased 1976 to 1978, but has generally increased since then with a peak in 1985. In 1986 the minimum mesh size for gillnets was increased and a moratorium on the issuance of new permits for set gill nets and trammel nets was implemented (CDFG 1987).

White croaker are targeted with set gillnet on the Palos Verdes Shelf; the catch is sold fresh, primarily to ethnic markets in Los Angeles. Drift gillnet fishing for swordfish and pelagic sharks has not been observed in the study area (Vojkovich 1988, pers. comm.). The closures to net fishing in most of the Bay protect resident fishes from overfishing. However, commercial gillnetting for California halibut, (along with the recreational fishery and reduced nursery grounds), probably limits the halibut population in the Bay by intercepting adult halibut moving in from other areas.

Sport Fisheries. Sport anglers fish from beaches, piers and jetties, private boats, and commercial passenger fishing vessels (CPFV or party boats); divers use spears or their hands in shallow water to harvest fish and invertebrates (Squire and Smith 1977). Between 1981 and 1984 an average of 11,100,750 fish was taken per year in the Southern California Bight by an average of 1,551,000 sport fishermen (NFSP 1984, 1985).

Between 1985 and 1991 an average of 390,414 fish was taken from CPFVs in the study area. CPFV catches within Santa Monica Bay have dropped compared to previous years (Figure 10-5) (CDFG, unpubl. data), due in part to a shift in the fishery from deepwater to pelagic species following the 1982 El Niño (Gregory 1993, pers. comm.). The 1982-1983 El Niño provided exceptionally good sport fishing in the Bight (CDFG 1986) and in 1984 the catch was four times that in 1982. Chub mackerel, rockfishes, and Pacific bonito dominated the catches during these years (NFSP 1984, 1985).

The total sportfish catch has decreased in most of the study area since 1982, although it increased between Ocean Park and Redondo Beach reflecting the sport fishing near piers, jetties, and wastewater and generating stations outfalls (CDFG, unpubl. data). In 1973 nearly one-third of the entire catch of 3.7 million fish in the Southern California Bight was taken within 12.5 mi of the largest wastewater outfalls. Outfalls appeared to receive about 10 times more fishing pressure than the rest of the coast (Mearns 1977).

Most sport fishing in Santa Monica Bay is conducted nearshore or along the edges of submarine canyons and the Shelf (Figure 10-4). The area from Point Dume to Playa del Rey is fished for California halibut, kelp bass, barred sand bass, rockfishes, chub mackerel, Pacific bonito, white seabass, and Pacific barracuda. The area from Playa del Rey to Hermosa Beach is fished for Pacific bonito, California halibut, and Pacific barracuda. Vermilion rockfish, bocaccio, and chilipepper are taken along Redondo Submarine Canyon; along the shelf off Hermosa Beach; and in Santa Monica Submarine Canyon. Vermilion rockfish, olive rockfish, and bocaccio are caught off Point Dume (Squire and Smith 1977). The sport fishes most frequently caught in Santa Monica Bay in 1987 were Pacific bonito, chub mackerel, and barred sand bass (CDFG, unpubl. data). In addition to these species, the rockfish complex and kelp bass are also important on the Palos Verdes Shelf (Stull *et al.* 1987).

The sport catch per angler in Santa Monica Bay fell during World War II and did not reach pre-war levels until the early 1960s, except in 1957 (the largest on record) which was probably a result of the El Niño that year. The catch per unit effort (CPUE) peaked again in 1971-1972, decreased 1976-1977, peaked in 1979, and fell in 1982-1983, during another El Niño. CPUE has

VOL 12 15495

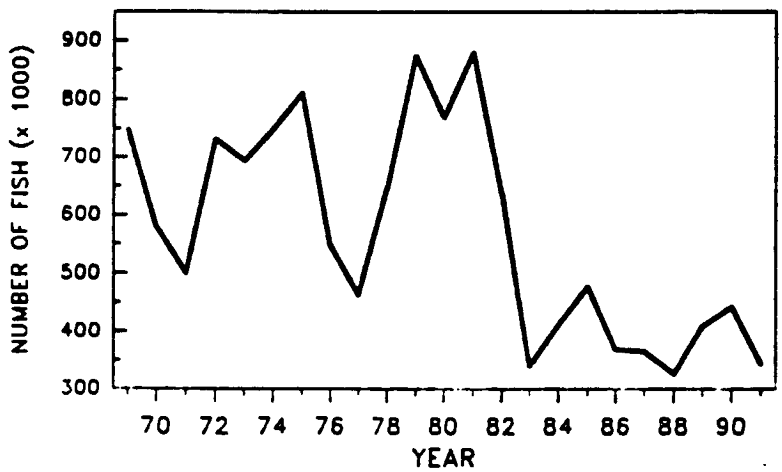

Figure 10-5. Total number of fish caught from commercial passenger fishing vessels for Santa Monica Bay and Palos Verdes Peninsula from 1969-1991 (CDFG, unpubl. data).

remained fairly low since 1982-1983; even the peak in 1989-1990 was low compared to catches prior to 1982 (Figure 10-6) (CDFG 1992, unpubl. data).

Fishing effort increases during an El Niño because the pelagic species which enter the area are highly prized. However, CPUE in Santa Monica Bay is usually greater during periods of cool, turbid water, when resident rockfishes dominate the catch. The general increase in CPUE from the 1940s to 1976 may have been a function of cooler water, but probably also reflects improvements in fishing gear and knowledge of fishing areas. Recent decreases reflect overfishing and oceanographic conditions (MBC 1985).

Total catch and CPUE along the Palos Verdes Shelf peaked in the late 1970s, but dropped to previous levels during the 1980s. From 1980 to 1985, catches of chub mackerel, California sheephead, kelp bass, barred sand bass, yellowtail, California scorpionfish, ocean whitefish, and Pacific bonito from the Shelf were greater than the 50-year average; whereas catches of California halibut, lingcod, white seabass, and rockfishes were lower than the average.

The catch of white croaker declined after 1985 when the California Department of Health Services (CDHS) posted warnings that it was contaminated with DDT and PCBs. The decline in California halibut catch may reflect the elimination of its estuarine nursery grounds (Stull *et al.* 1987) or the harvest of adults in the commercial fishery. Lingcod is a cool-water species which may have been excluded by the El Niño Event of the early 1980s.

Although pollution is often perceived as causing the decrease in sportfish abundance, this has not been demonstrated with certainty. Changes in the sport catch in Santa Monica Bay during 1957-1963 could not be linked to the HTP wastewater discharge (Carlisle 1969): the reduced catch of white croaker on the Palos Verdes Shelf in 1985 was related to CDHS-posted warnings (Stull *et al.* 1987). There has not been a fish kill in the Bay that can be attributed to pollution. Sublethal contamination would presumably affect fish behavior and lead to increased mortality by predators; however, diseased fish did not appear especially susceptible to predation by spiny dogfish or sablefish (SCCWRP 1974).

SEA BIRDS

Distribution by Habitat

Some seabirds feed in the pelagic realm and rest on land, but loons, grebes, scoters, California brown pelicans, gulls, and jaegers rest on the sea surface throughout the Bay. Shearwaters, fulmars, petrels, murres, puffins, and auklets are more oceanic and frequent the outer reaches of the Bay. California brown pelicans and terns (including the endangered California least tern) dive into the water from the air to catch fish; cormorants, murres, puffins, and auklets dive from the sea surface to pursue fish and zooplankton beneath the surface. Bonaparte's gulls congregate on the surface during the winter and feed on particulates and zooplankton.

Natural Variability

The abundance of seabirds, shorebirds, and waterfowl in Santa Monica Bay are highly seasonal. Bird diversity and abundance increase during the winter when migratory species arrive and decrease during the summer when they depart, leaving only resident species. Few species nest along the shores of the Bay; most use the Bay as either a stop over during migrations or for foraging.

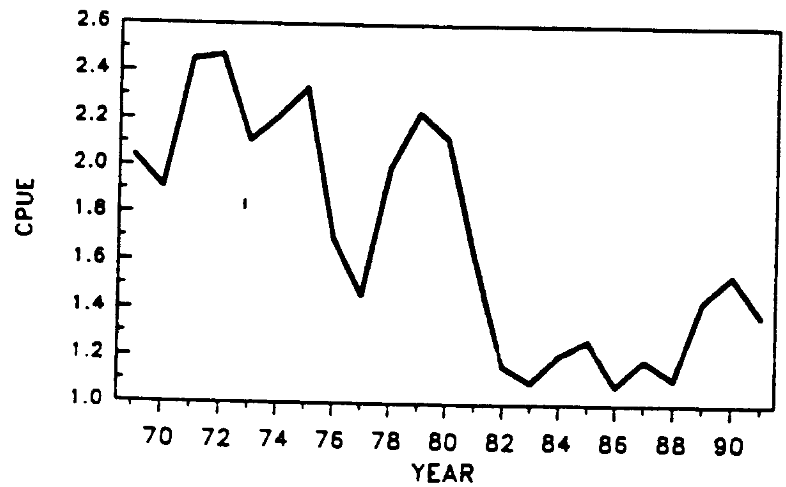

Figure 10-6. Catch per unit effort for commercial passenger fishing vessels for Santa Monica Bay and Palos Verdes Peninsula from 1969-1991. CPUE = numbers of fish divided by angler hours. (CDFG, unpubl. data).

Impacts

Municipal Discharge Impacts

Bonaparte's gulls and other species have been observed feeding near the JWPCP outfalls in winter, but the primary interaction of most seabirds with municipal wastewater is indirect via consumption of contaminated prey. DDT and PCBs increase in concentration up the food chain (i.e., they are biomagnified), being accumulated first in phyto- and zooplankton, then in northern anchovy, other fish, and finally in seabirds.

California brown pelicans nest on West Anacapa Island, Scorpion Rock (Santa Cruz Island), Santa Barbara Island, and Los Coronado Islands - all well removed from Santa Monica Bay. During the 1950s the reproductive success of brown pelicans declined and excessive eggshell thinning appeared to be the primary cause of reproductive failure (Risebrough *et al.* 1971). Research indicated that their eggshells were 26% thinner in 1962 than previously. By 1969 the eggshell thickness had decreased to 50% of pre-1943 values (Anderson and Hickey 1970).

Eggshell thinning was found to be a physiological response to high levels of DDT. Out of 300 eggs examined at the Anacapa breeding colony in 1969, only 12 were intact and DDE residues averaged 43 ppm (wet weight). Eggshell thinning results from DDE inhibition of an enzyme needed to transport calcium ions from the blood to the developing egg (Miller *et al.* 1975). DDT may also depress estrogen levels in birds, resulting in late breeding or the inability to lay more eggs if early clutches are destroyed (Peakall 1970).

In 1971 the use of DDT and the disposal of production wastes into sewers were banned (USEPA 1983). This resulted in a sharp decline of DDT input into coastal waters, and residual levels in the marine food web decreased substantially following the initiation of landfill disposal (Anderson *et al.* 1975, Risebrough *et al.* 1976, Ohlendorf *et al.* 1978, Risebrough *et al.* 1979). Ocean disposal of total DDT compounds decreased from 2,177 kg/year in 1971, to 721 kg/year in 1979 (Schafer 1980), to 50 kg/year in 1985 (SCCWRP 1986a) to 30 in 1987 (Stull 1988, pers. comm.). At the same time eggshell contamination and thinning were reduced (Anderson 1977), and by 1974, reproductive success of the California brown pelican had stabilized, although it was still lower than previously. Productivity has increased substantially since 1969, with peaks in 1975 and 1985 (Table 10-1) (Gustafson, in prep.).

Since California least tern feed upon similar fishes as the brown pelican (northern anchovy and topsmelt), they may also have been impacted by the accumulation of chlorinated pesticides and PCBs.

Other Impacts

Diving birds such as cormorants and scoters are occasionally impinged in generating station cooling waters (Curtis 1988, pers. comm.); however, this is a minor source of mortality to the species.

TBT may impact shorebirds which forage on mollusks, crustaceans, polychaetes, or fish by reducing the quality or quantity of these food resources in the vicinity of Marina del Rey; however, no studies have attempted to establish this connection.

Although human disturbances do not constitute a population-level impact at present, they could adversely affect brown pelican productivity. Such disturbances include deliberate mutilation,

accidental hooking by commercial and sport fishermen, drowning in gillnets, disruption of nesting habitats by photographers and educational groups (Schreiber 1976, Anderson and Keith 1980), noise from aircraft and boats (Evans *et al.* 1979, Cooper and Jehl 1980, Jehl and Cooper 1980), and oil spills (Holmes and Cronshaw 1977). Population-level impacts could also result from overfishing of northern anchovy, the brown pelican's primary food source.

MARINE MAMMALS

Distribution by Habitat

California sea lions and northern elephant seals have been observed in outer parts of Santa Monica Bay (Bonnell *et al.* 1981, Dohl *et al.* 1981). California sea lions are common, and forage beneath the surface and in kelp beds for fishes and invertebrates.

Four species of baleen whales and eight species of toothed whales have been observed in the Bay. Gray whales, bottlenose dolphins, common dolphins, and Pacific white-sided dolphins are the most common species (Dohl *et al.* 1981; Shulman 1988, pers. comm.), and most sightings are within 9 mi of Point Dume or Point Vicente (Bonnell *et al.* 1981). Southerly migrating gray whales pass the Bay from December to February enroute to calving lagoons in Baja California; northerly migrating whales pass by the Bay from February to May enroute to feeding grounds in the Bering Sea (Dohl *et al.* 1981, Poole 1984). Although most gray whales cross the outer part of the Bay, juveniles have been seen north within 2 mi of shore from March to May (Figure 10-7).

Natural Variability

Because of their long lifespans and low reproductive potential, natural population changes in marine mammals generally occur slowly. Prior to human influence, food availability and disease were probably the major influences on marine mammal abundance.

Most strandings in Santa Monica Bay are of single animals. Autopsies of stranded animals indicate various causes of death, including parasites (in the liver, pancreas, and brain); cirrhosis of the liver and lung diseases (Ridgway and Johnston 1965; Ridgway and Daily 1972; Cowan *et al.* 1986; LACMNH, unpubl. data); traumatic injury such as boat propeller and gunshot wounds (Woodhouse 1984, Cowan *et al.* 1986); and entanglement with fishing gear (LACMNH, unpubl. data; NMFS, unpubl. data).

Impacts

Contaminant Impacts

Specimens of marine mammals (washed ashore in southern California) often have elevated levels of DDT and PCBs; in general, small nearshore species such as the California sea lion, common dolphin, and bottlenose dolphin have the highest levels (Britt and Howard 1983, Schafer *et al.* 1984). However, although the stranded marine mammals often have high tissue burdens of pesticides and PCB, data are insufficient to show a cause-and-effect relationship between the contaminant load and the stranding death.

Gray whales generally avoid embayments such as Santa Monica Bay because of the high turbidity due to runoff or waste discharges (Dohl *et al.* 1981). However, since gray whales seldom

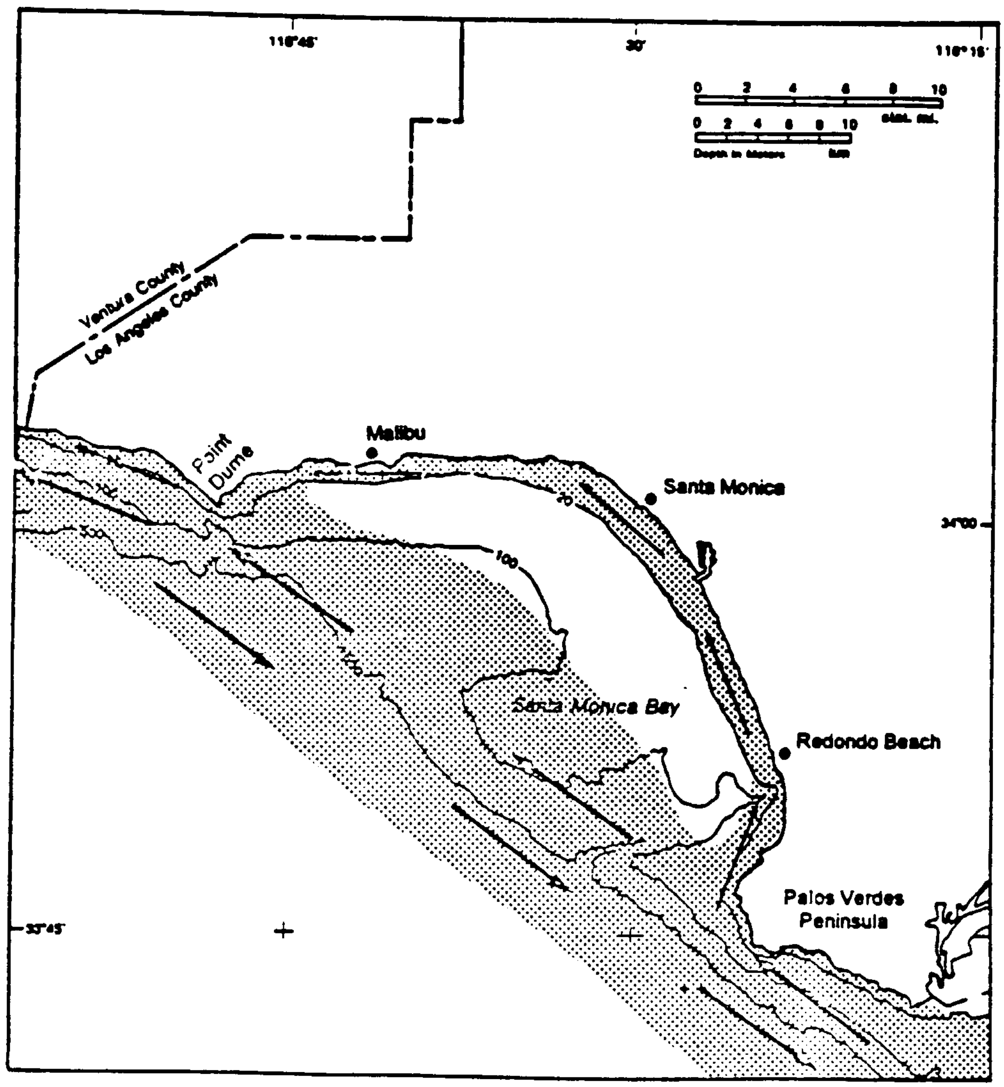

Figure 10-7. Generalized gray whale migration routes in the Santa Monica Bay area (modified from MBC 1988)

VOL 12

1 5502

feed during their migration, the bioaccumulation of contaminants from Santa Monica Bay is not likely.

Marine vessels and harbors

Marine mammals frequently interact directly with marine vessels. Marine vessels may collide with or harrass them. Vessel collisions are rare, (although many go unreported) but are the most detrimental impact of the encounters, since impacts may kill the animal. The most recent (reported) local collision was on 12 March 1988 when a tanker collided with one or two animals offshore the Palos Verdes Peninsula (Lewis 1988, pers. comm.).

Gray whales are frequently harassed by boaters who do not follow NMFS guidelines for whale watching. Human actions which interrupt whale behavior constitute "harassment" under the Marine Mammal Protection Act and the Endangered Species Act. Although violators can be prosecuted, enforcement is difficult and harassment hard to prove. Because of intensive local whale watching and concern that gray whales may be changing migrating habits as a result, the present guidelines may become official NMFS regulations in the near future (Jozwiak 1988, pers. comm.).

Vessel engine noise may cause short-term stress to individuals, although gray whales may have acclimated to human activity (BLM 1981). When approached by vessels whales often change their swimming course, and some researchers have suggested that the gray whale migration corridors are farther offshore than in previous years (Dohl *et al.* 1981, Reilly 1984, Shulman 1986).

Gray whales react more to cavitating propellers and sudden changes in engine speeds (Richardson *et al.* 1983) than to constant engine speeds (Dahlheim *et al.* 1984). Responses may include changing course, and/or altering swimming, diving and breathing patterns until the sound source is out of its hearing range (Malme *et al.* 1983, Richardson *et al.* 1983).

Fisheries Impacts

Marine mammals are occasionally caught in set gillnets. Since gillnetting became legal in the 1970s in southern California, California sea lions, common dolphin, bottlenose dolphin, and gray whales have been caught incidentally (NMFS, unpubl. data). The rate and number of entanglements of nontarget species are uncertain because: 1) fishermen may not report entanglements; 2) dead animals cut loose from the nets may not strand; and 3) the cause of death is not always possible to determine. Most deaths occur where gillnetting occurs, whereas strandings occur throughout the Bay because of the currents. There is no evidence that these entanglements have impacted any marine mammal populations (Lecky 1985).

In Santa Monica Bay gillnets are set along headlands between Point Dume and Malibu and from Palos Verdes Point to Point Fermin. From 1986 to 1988, at least six gray whales were caught in set gillnets; three near Point Dume and three along the Palos Verdes Peninsula. Four of the six were released by biologists or lifeguards; the outcomes of the other two were not determined.

Between 1983 and 1987 five gray whales which stranded in Santa Monica Bay either had gillnet around them or evidence which suggested that the cause of death was by gillnet (NMFS Stranding Network, unpubl. data).

Sea lions have been observed eating "hooked" sportfish and live bait used for chumming; there is also evidence that the catch rate slowed or stopped when sea lions were present (Scholl 1983). Partyboat operators are permitted to use nonlethal means (seal bombs or acoustical deterrents) to keep sea lions from interfering with fishing operations (Hanan 1988, pers. comm.).

Endangered Vertebrate Species

California brown pelican, California least tern, and Belding's savannah sparrow (of salt marshes) are federally-protected under the Endangered Species Act of 1973. The gray whale is a federally-protected marine mammal under the Marine Mammal Protection Act of 1972 and the Endangered Species Act of 1973.

CHAPTER 11

SWIMMING-RELATED HEALTH HAZARDS

The health risks of swimming in Santa Monica Bay derive from sources common to swimming in any body of water, such as drowning, ripcurrents, shark attacks, jellyfish stings, and injuries due to diving into shallow water. Drowning and diving injuries are typically associated with swimming anywhere, whereas ripcurrents, shark attacks, and jellyfish stings are generally limited to the ocean. In addition, biological pathogens and hazardous chemicals that are associated with large human populations and/or specific human activities may also pose a risk in certain areas. Because Santa Monica Bay lies adjacent to the largest population center on the West Coast, swimmers in the Bay are potentially exposed to biological pathogens and hazardous chemicals from urban runoff, accidental spills, and permitted municipal and industrial wastewater discharges.

Concern about the health risks of swimming in Santa Monica Bay has increased because of beach closures due to sewage spills and storm drain runoff. Thus, contamination of the Bay by microbial pathogens (i.e., bacteria and viruses) and toxic chemicals is recognized as a potential threat to human health. Articles in the press, which have increased public, scientific, and government awareness, may have fostered misconceptions about the magnitude of health risks by assigning causal roles to specific pollutants, specific sources, and specific human activities. However, a comprehensive study of the human health risks associated with Santa Monica Bay has not yet been performed.

This chapter first presents information on hazardous chemicals, then on microbial pathogens, and finally discusses public health approaches.

HAZARDOUS CHEMICALS

Bathers in Santa Monica Bay may be exposed to a variety of harmful chemicals resulting from improper disposal of household toxins; illegal disposal of motor oil, antifreeze, and battery acid into storm drains; and industrial discharges both into and "upstream" of the Bay. Depending on the nature of the contaminant, the duration of exposure, and the concentration at the point of contact, organic solvents and toxic chemicals may produce acute and long-term health effects such as sore throats, conjunctivitis, gastrointestinal illness, caustic burns, and even cancer. However, etiological relationships between chemical contamination and human health are difficult to establish because of the uncertainties in dose responses, contaminant sources and distribution patterns, differences between acute and long-term exposure, possible synergistic interactions of different compounds, and the long latency (possibly years) between exposure and subsequent disease, especially for cancer. Thus, very few studies have attempted to link human illness with chemical contamination of marine waters.

Hazardous Chemical Spills

Numerous chemical spills have occurred in the Santa Monica Bay watershed during the past several years. Some of these reached storm drains or creeks and were subsequently discharged to the ocean. Although such spills occasionally resulted in public health warnings, only one verified report of a chemical spill between 1986 and 1992 caused beach closures in Santa Monica Bay (Appendix I). On 16 March 1991, 9,240 gal of diesel oil mixed with naphthalene spilled from a tanker off the Chevron USA refinery at El Segundo (MBC 1991a). The spill resulted in beach closures at Surfrider Beach in Malibu on 24 March and between Imperial Highway and Grand Avenue on 29 March (LACDHS, unpubl. data).

Exposure Routes

Human health risks from chemical contamination may develop via several exposure routes. Direct water contact routes include absorption of contaminants through the skin, ingestion of contaminants along with seawater, and inhalation of volatilized contaminants (Brown *et al.* 1984). Exposure routes from contact with sediments include dermal absorption and ingestion of contaminated sediments.

Direct contact with contaminated seawater and/or sediments may occur during swimming, diving, wading, fishing barefoot, or playing in the surf zone. Dermal absorption and inhalation are potentially important routes for volatile organic compounds. While inadvertent ingestion of small quantities of seawater is likely to occur during any swimming activity, ingestion of sediments is unlikely to be significant except in children that exhibit pica behavior (i.e., abnormally high rate of soil ingestion).

BIOLOGICAL PATHOGENS

Direct water-contact activities (swimming, surfing, and skin-diving, etc.) and the consumption of raw molluscan shellfish are the major routes for the transmission of infectious diseases to man from the marine environment. Certain microorganisms native to the marine environment (for example, the genus *Vibrio*) occasionally cause human infections via both transmission routes (MBC 1988). Although pathogens from marine fauna may pose a human health risk, pathogens in the fecal wastes of ill persons and carriers are of most concern in the United States.

Such pathogens have accounted for most illnesses, resulted in the development of water quality standards, and led to the development of control technologies. These pathogens reach marine waters from municipal wastewater discharges, urban runoff, boat wastes, and swimmers. In small urban populations (less than about 40,000 people), the abundance of pathogens in the wastewater discharge varies with the numbers of ill or carrier individuals in the population, but in areas adjacent to large population centers, such as Los Angeles, the pathogen density remains fairly constant (McGee 1993 pers. comm.). In addition to pathogens derived from human wastes, the fecal matter of other vertebrates, particularly mammals, may also pose a threat to human health. Most biological pathogens are thought to be species specific (Atlas 1984), but the relative human health risk from pathogens derived from non-human sources is unknown.

Pathogens

Pathogenic bacteria, viruses, fungi, and protozoa all may occur in the nearshore waters of Santa Monica Bay and all could have adverse effects on swimmers. Pathogenic bacteria that have been found in the Bay include *Pseudomonas*, *Enterobacter/Citrobacter*, *Streptococcus*, *Escherichia coli*, *Klebsiella*, and marine *Vibrio* (Cabelli in MBC 1988). These pathogens cause a variety of human illnesses, ranging from skin infections, gastroenteritis, upper respiratory problems, and wound infections to pericarditis and spinal meningitis (Cabelli 1982).

Viral agents in recreational ocean waters have also been suspected of causing human illness (Cabelli *et al.* 1979, 1982; Gerba *et al.* 1979, 1985). Human-specific viruses such as hepatitis A, poliovirus, and Norwalk virus (which is suspected of causing gastroenteritis), have been found in marine waters (CDC 1987). Enteric human viruses are especially suspect in marine waters that receive municipal waste because they commonly escape secondary sewage treatment (Edmond *et al.* 1978) and because many persist for prolonged periods in the environment (Akin

VOL 12 1 5506

R0048811

et al. 1971, Gerba and Schaiberger 1975, Melniek and Gerba 1980, Rao and Melniek 1986), thus increasing the potential for human exposure. However, no appropriate epidemiological study to discern a viral etiology in human illness has been conducted. Parasitic pathogens, such as *Cryptosporodium*, *Giardia*, and certain yeasts may also cause human illnesses (Atlas 1984).

Diseases

Numerous bacterial and viral pathogens have been recovered from human fecal wastes and municipal wastewater and potentially all of them could be transmitted back to man via contaminated shellfish and recreational waters. Because of the difficulty in conducting epidemiological studies, there is little, if any, evidence that these routes are significant in the transmission of infectious disease in the U.S. at present. There are, however, three exceptions: infectious hepatitis caused by hepatitis A virus; acute gastroenteritis caused by the Norwalk-like viruses; and pharyngo-conjunctivitis caused by adenovirus types 3 and 4 (Cabelli 1983a).

The most frequently reported waterborne disease in outbreak and epidemiological studies is acute gastroenteritis. Of the biological indicators examined in epidemiological studies conducted by the EPA, enterococcus levels in the water correlated best (r=0.75) with the rates of swimming-associated gastroenteritis (USEPA 1986). This relationship was recommended by the EPA as the marine recreational water quality criterion. The EPA also recommended a guideline of a geometric mean of 35 enterococci/100 ml, a value that corresponds to a predicted illness rate of about 19 cases of acute gastroenteritis per 1,000 swimmers (USEPA 1986).

Indicator Organisms

With the exception of areas adjacent to undisinfected waste discharges, human bacterial pathogens and enteric viruses are generally rare in the marine environment, which makes their enumeration and subsequent risk analysis difficult. Thus, to study the distribution and density of biological pathogens, researchers have used "indicator" organisms, which can be associated with the pathogens and may be more abundant. The indicators are easily-counted bacteria that are part of the normal intestinal flora of humans and some other animals. The rationale for their use is that their concentration in the environment is an indication of possible human fecal contamination and, hence, the potential for human disease (Atlas 1984).

Biotypes

At the turn of the century three bacterial species (*Escherichia coli*, *Streptococcus faecalis*, and *Clostridium perfringens*) were suggested as fecal indicators of water quality (Cabelli in MBC 1988). Each of these is found in human feces and none has appreciable extrafecal sources, although all three are found in the fecal wastes of other vertebrates. Because of procedural problems, each indicator system has been expanded to include biotypes that include non-fecal species.

The *E. coli* system was expanded to "total coliforms," which also includes three other genera, *Enterobacter*, *Citrobacter*, and *Klebsiella*. Although those organisms are not always found in human feces, they are usually abundant in sewage, presumably because they multiply there (Dufour 1976). The total coliform system was subsequently replaced with the "fecal coliform" system, more properly called thermotolerant coliforms because only those coliforms that ferment lactose at 44.5°C (as opposed to 35.0°C for total coliforms) are counted. Thermotolerant coliforms include *E. coli*, a portion of the *Klebsiella* biotype, and some extrafecal types (Dufour 1976).

The *Streptococcus faecalis* system was expanded to include *S. mitis* and *S. salivarius*, which are part of the oral flora; *S. equinus* and *S. bovis*, which are found primarily in the feces of mammals other than humans; and *S. faecalis* and *S. faecium*, which are found in the wastes of humans and other endotherms (Greenberg *et al.* 1992).

Because of the difficulties in discerning sources of contamination using specific biotypes, the ratio of fecal coliforms to fecal streptococci has also been used. A ratio greater than four indicates human fecal contamination, whereas a ratio less than 0.7 indicates contamination from non-human sources (Greenberg *et al.* 1992). Although this system has value in specific circumstances, differences between the two groups in terms of variable survival rates, responses to disinfection, and enumeration techniques limit its usefulness (Greenberg *et al.* 1992).

The enterococcus system is a sub-group of the fecal streptococci that is composed of *S. faecalis*, *S. faecium*, *S. avium*, and *S. gallinarum* (Greenberg *et al.* 1992). The enterococci group has proven to be a valuable indicator of fecal contamination in both fresh- and salt-water systems (Greenberg *et al.* 1992) and both enterococci and fecal coliform have been evaluated as indicators of gastroenteritis at public beaches (Cabelli *et al.* 1983, Dufour 1976). The best correlation between indicator concentration and general and acute gastrointestinal symptoms was seen for enterococci (Fattal *et al.* 1983), a relationship that is consistent with the observation that, with regard to their survival in seawater, fecal streptococci resemble the viruses more than the coliforms do. Current concepts of pathogenic risk from contact with bacteria-contaminated marine water are based on the indicator enterococcus (Cabelli *et al.* 1982).

Longevity

Viruses appear to be more resistant to environmental stress than bacterial indicators (Keswick *et al.* 1985) and they generally survive longer than human enteric bacteria in seawater and shellfish (Akin *et al.* 1971, Morris and Kim 1975, Gerba and Schaiberger 1975, Morris *et al.* 1976, Melniek and Gerba 1980, Rao and Melniek 1986). Mussels and other shellfish effectively concentrate bacteria and viruses and they have been used to examine pathogen die-off rates in seawater. Morris *et al.* (1976) found that viruses survived longer than total coliform bacteria in tissues of mussels near the Hyperion Treatment Plant (HTP) and Joint Water Pollution Control Plant (JWPCP) outfalls in 1975-1976 and enteroviruses have been detected in mussels collected from Ballona Creek and Marina del Rey (Morris and Kim 1975), which probably reflects the better survival of viruses than coliform bacteria in the ocean and shellfish.

Greater survival in the marine environment is also true of the Norwalk virus and of F male-specific coliphage, a virus that infects *E. coli* bacteria that have produced F pili. F male-specific coliphage survive chlorination and natural salinity better than either coliforms or enterococci (Cabelli in MBC 1988). Because of this, F-male specific coliphage has been suggested as an indicator of human fecal contamination (Cabelli in MBC 1988). However, Gold *et al.* (1990, 1991, 1992) found that F-male specific coliphage was a poor indicator of human enteric viruses in Santa Monica Bay.

Because many viruses appear to survive longer in seawater than bacterial indicators of fecal pollution, viruses may be present in sufficient number to produce illness after the indicators become undetectable. Thus, the potential health risks from human enteric viruses may be greater than that predicted by the bacterial indicators. This emphasizes the need for more sensitive indicators for human fecal contamination, particularly for known pathogens.

California Ocean Plan Bacterial Standards

To limit the risk of human infection from biological pathogens from municipal sewage, the California Ocean Plan (COP) has instituted the following objectives for bacterial indicators for shoreline and nearshore areas (CSWRCB 1990):

1) Water samples from each sampling station shall have a total coliform density of less than 1,000 cfu (colony forming units) per 100 ml, provided that not more than 20% of the samples at any station, in any 30-day period exceed 1,000 cfu/100 ml; and providing further that no single sample, when verified by a repeat sample taken within 48 hours exceed 10,000 cfu/100 ml.

2) Water samples for fecal coliform densities are based on a minimum of not less than five samples for any 30-day period per sampling station. For fecal coliform, geometric means shall not exceed 200 cfu/100 ml and less than 10% of the total samples during any 60-day period shall exceed 400 cfu/100 ml.

The COP also states that in waters where shellfish may be harvested for human consumption, the median total coliform density shall not exceed 70 cfu/100 ml, and not more than 10% of the samples shall exceed 230 cfu/100 ml (CSWRCB 1990).

Although enterococcus density standards have not been developed, California has adopted the following enterococcus guidelines for shoreline and nearshore stations when the total or fecal standards have been exceeded: a geometric mean of 24 cfu/100 ml for any 30 day period and a geometric mean of 12 cfu/100 ml for any six-month period, based on at least five samples per month (CSWRCB 1990). If a shore station consistently exceeds one of these bacterial objectives, the COP requires a sanitary survey to determine the source of the contamination. However, the protocol for such a survey has not been developed.

Sources and Distribution of Biological Pathogens

Fecal waste is the primary source of most human-specific biological pathogens, and several sources of fecal wastes could lead to infectious disease among users of the Bay. These include treated wastewater discharges, urban runoff, sewage spills into storm drains, small boat waste discharges, bathers, and marine fauna. Although the risk of disease from human fecal contamination is paramount, it is important to emphasize that the relative importance of pathogens from non-human sources is not known.

Wastewater from sewage treatment facilities may be a potentially large source of human fecal contamination to bathers in Santa Monica Bay. Treated wastewater is discharged directly to the Bay from both the HTP and the JWPCP outfalls, which discharge offshore, and indirectly from the Tapia water reclamation facility (TWRF), which discharges into Malibu Lagoon via Malibu Creek. The relative importance of the offshore sources and their impact on the health of bathers depends upon the transport of associated pathogens shoreward to bathing beaches. Both HTP and JWPCP regularly monitor bacterial indicators at offshore, nearshore, and shoreline sites throughout the Bay and in the past 10 years there has been no evidence from microbial indicators that sewage from the effluents has reached the beach. Occasionally high bacterial counts at shoreline stations is a result of other sources of contamination, such as storm drains, shorebirds, and bathers.

Hyperion Treatment Plant

HTP began monitoring total coliform levels at shoreline stations near the 1-mi outfall in the 1940s. Between 1947 and 1959 total coliform levels along shore decreased dramatically (Figure 11-1), due to improved treatment and because the 1-mi outfall was extended to 5 mi offshore in 1957 (WSED 1982, Garber and Wada 1988). Increases in bacterial densities at shoreline stations between 1959 and 1974 were probably due to urban runoff via storm drains, especially those in the north with large drainage basins (MBC 1988).

The present HTP monitoring program was initiated in 1974 and is focused on recreational waters of Santa Monica Bay. HTP monitors 17 shoreline stations between Topanga and Torrance Beaches (Figure 11-2), 11 nearshore stations located 1,000 ft from shore, and several stations along Ballona Creek and at the Pico-Kenter Storm Drain in the city of Santa Monica. Shoreline samples are collected and analyzed daily for total coliforms and enterococci and at least five times per month for fecal coliforms. Nearshore samples are analyzed for all three indicators four or five times per month (CLA,DPW 1992). In addition to the shoreline and nearshore stations, HTP also monitors bacterial densities associated with plume tracking and microlayer investigations.

The results of the present monitoring program indicate that levels of indicator bacteria (and presumably microbial pathogens) continue to decline in the receiving waters. All nearshore samples have been in compliance with indicator bacterial levels since 1987, suggesting that HTP's 5-mi outfall is not the source of occasionally high bacterial counts in the Bay. This trend is due primarily to improved treatment: new digesters, chemical additives (ferric chloride and polymer), sludge dewatering, and an increase in the amount of flow receiving secondary treatment. The trend should continue as the plant is scheduled for full secondary treatment by 1998 (CLA,DPW 1992).

Although densities of bacterial indicators are generally low at nearshore stations, water quality limits have been exceeded in recent years at several shoreline sites, most frequently those near storm drains. Thus, the major sources of bacterial contamination at the surf zone appear to be urban runoff, sewage overflows to storm drains, and marina activities, rather than the HTP effluent.

Joint Water Pollution Control Plant

JWPCP regularly monitors bacterial indicators in the nearshore waters of the Palos Verdes Peninsula. Between 1972 and 1982 total coliform counts were made at seven shoreline and five nearshore stations near White Point (Figure 11-3). Over that period, total coliform counts decreased at all stations except one, and those high values were attributed to a colony of California sea lions. The decrease in coliform levels is attributed to improvements in treatment (Figure 11-4).

Because elevated subsurface counts had been measured during previous interruptions in chlorination (Stull 1992, pers. comm.), the chlorination facilities and procedures at JWPCP were modified in 1987 and 1988 to meet more stringent requirements. Chlorine dosage was increased and from 1988 to 1990 a backup chlorination station was constructed for use on primary effluent when the main facility was inoperative. In 1991 another standby disinfection facility was constructed for use in the secondary waste treatment system.

Figure 11-1. Temporal trend in total coliform bacteria at Santa Monica Bay shoreline. Values are mean of annual geometric mean in mpn/100 ml (Garber and Wada 1988).

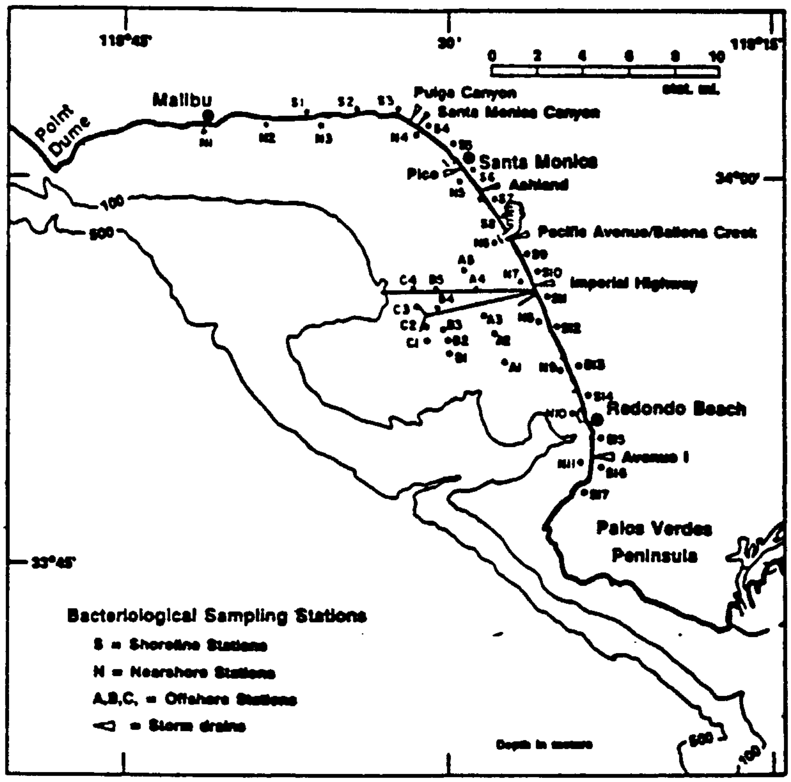

Figure 11-2. HTP bacteriological sampling stations in Santa Monica Bay.

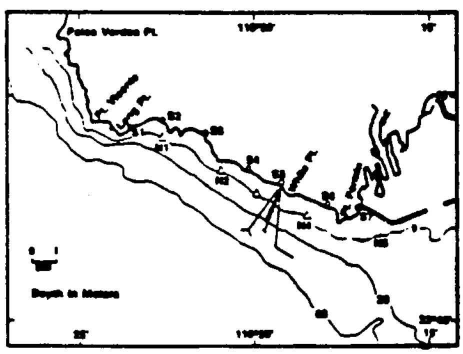

Figure 11-3. JWPCP shoreline (S) and nearshore (N) bacteriological stations on the Palos Verdes Shelf.

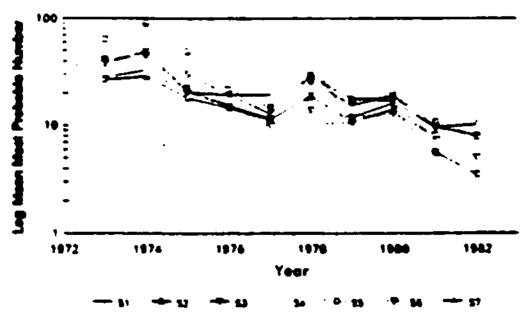

Figure 11-4. Temporal trends in total coliform bacteria densities at Palos Verdes shoreline stations 1972-1982. Values are log mean mpn/100 ml (modified from LACSD, unpubl. data).

These improvements resulted in further decreases in bacterial densities at both shoreline and nearshore stations. In 1991 total coliform densities exceeded 1,000 cfu/100 ml on less than 0.6% of the sampling days at the seven shoreline stations (Stull 1992, pers. comm.). No surface or subsurface coliform limits were exceeded at the nearshore stations, although near-bottom samples occasionally exceeded the limits at some stations. Since total coliform counts have been continuously lower than standards for fecal coliform, fecal coliform measurements have not been required since 1988. JWPCP began monitoring enterococcus levels in December 1991, and all counts since then have been at or near detection limits at all stations.

Although chlorination appears to have reduced levels of indicator bacteria at both shoreline and nearshore stations, the efficacy of chlorination in reducing viral concentrations has never been determined. Furthermore, the potential for toxic effects on marine life from extensive chlorination has not been adequately addressed (Gold 1993 pers. comm.).

Urban Runoff

More than 68 storm drains discharge into Santa Monica Bay between Ventura County and Point Fermin. The majority of these storm drains convey appreciable run-off to the Bay only intermittently, but during periods of heavy rainfall they may carry high concentrations of biological pathogens as well as chemical contaminants from a variety of residential and industrial sources. Although storm drains may constitute point sources at the site of entry into the Bay, the contaminants that they convey derive from a variety of non-point sources, making monitoring and regulation of storm drain effluents difficult. Bacterial pathogens may be transported to the Bay when stormwater overflows into sewage lines, causing sewage to flow into the storm drain system. These overflows cause the most extensive human fecal contamination of Santa Monica Bay. However, high indicator bacteria levels and human enteric viruses have been found in storm drains even during dry weather (CLA,DPW 1988, 1990, 1991, 1992; Gold *et al.* 1990, 1991, 1992). Because most storm drains in the Bay discharge directly into the surf zone, and because of the high levels of contamination that have been found in storm drain runoff, surf zone areas near storm drains are considered high risk areas to swimmers, especially during rain storms.

Dry-weather Flow. Monitoring recently conducted by HTP indicates that high levels of indicator bacteria in the Bay are usually associated with flowing storm drains (CLA,DPW 1988, 1990, 1991, and 1992). For example, since at least 1987 indicator levels at Stations S3, S6, S11, and S16 (Figure 11-2) have exceeded one or more of the Ocean Plan standards. Each of these stations is adjacent to a storm drain: Station S3 is just north of the Pulga Storm Drain; Station S6 is midway between the Pico-Kenter and Ashland Storm Drains; Station S11 is just south of the Imperial Storm Drain; and Station S16 is just south of the Avenue I Storm Drain. High counts have also been recorded at Station S9, which is adjacent to Marina Del Rey and Ballona Creek, and at Stations S14 and S15, which are adjacent to King Harbor in Redondo Beach (CLA,DPW 1988, 1989, 1990, 1991, and 1992). When high levels of bacterial indicators were recorded at the shoreline stations, low levels were recorded at nearshore stations, suggesting that the HTP outfall was not the source of bacterial contamination at the shoreline.

Because high levels of indicator bacteria in the Bay are consistently found near storm drains, the Santa Monica Bay Restoration Project (SMBRP) conducted a series of studies to assess storm drain contamination of the Bay (Gold *et al.* 1990, 1991, 1992). These studies examined storm drain runoff at several sites throughout Santa Monica Bay and they provide the most recent analysis of dry-weather biological contamination from urban runoff.

VOL 12

1 5 5 / 5

The first study was conducted over a period of nine weeks during August and September 1989. Samples were collected at the Pico-Kenter and Ashland Storm Drains in the city of Santa Monica, which have had high densities of indicator bacteria in the past (CLA,DPW 1987, 1988, 1989, 1990, 1991, 1992). At each site, samples were taken from inside the drains and from the surf zone at several sites at ankle and chest depths. These samples were analyzed for total and fecal coliforms and enterococcus densities. Human enteric viruses and F-male specific coliphage densities were analyzed in samples taken from the storm drains. In addition, viral seeding experiments were conducted to determine the effectiveness (i.e., percent of recovery) of the enumeration methods and to test for possible toxic effects of the storm drain effluent on the viruses (Gold *et al.* 1992). In 1990 and 1991, the sampling program was expanded to include the Pico-Kenter Storm Drain; the Herondo Storm Drains, which are located just north of King Harbor in Redondo Beach; and several sites within Malibu Lagoon (Gold *et al.* 1991, 1992). Ankle and chest-deep samples were taken only near the Pico-Kenter Storm Drain. The 1991 study was also designed to evaluate the effectiveness of the 600-ft pipeline extension at the Pico-Kenter Storm Drain, which was completed in August 1991, in dispersing the effluent beyond the surf zone. The densities of bacterial indicators were evaluated on whether they exceeded "excessive limits" or "levels of concern," which were defined as 1,000 cfu/100 ml for total coliform, 200 cfu/100 ml for fecal coliform, and 24 cfu/100 ml for enterococcus (Gold *et al.* 1990, 1991, 1992).

In 1989, 1990, and 1991 all three bacterial indicators exceeded levels of concern in virtually all samples taken from the Pico-Kenter Storm Drain (Figures 11-5 and 11-6). In general, densities of bacterial indicators decreased with depth and distance along the shoreline. In 1989 most surf zone samples taken 10 yd from the storm drain exceeded limits on 100% of the sampling days, but chest-depth samples exceeded limits much less frequently (Figure 11-5, Gold *et al.* 1990). The geometric means of bacterial densities further demonstrate the decrease in the concentrations of bacterial indicators with distance from the storm drain (Figure 11-7). Pico-Kenter Storm Drain samples in 1989 had mean bacterial levels nearly one-hundred times greater than levels of concern, but levels of all three indicators in ankle-deep water were approximately one order of magnitude lower than storm drain samples and levels in chest-deep water were approximately two orders of magnitude lower. Bacterial densities in 1989 also exceeded levels of concern at a station 150 yd from the storm drain. However, during the 1989 sampling, HTP recorded bacteria levels below levels of concern at Station S6, 200 yd south of Pico-Kenter (CLA,DPW 1990), suggesting that the extent of bacterial contamination may be limited to within 150 to 200 yd from the storm drain.

Densities of all three bacterial indicators in 1991 were three to five times higher in the Pico-Kenter drain than the Herondo drain, and one to two orders of magnitude higher than at Malibu Lagoon. In the Pico-Kenter Storm Drain, densities of all three indicators exceeded levels of concern in all 13 samples. However, in the surf zone, levels of concern were infrequently exceeded at the ankle- or chest-deep stations. The results from the 1991 dispersion study were very different from that conducted in 1990 (Gold *et al.* 1991, 1992), in which bacterial levels of concern were frequently exceeded at ankle and chest-deep stations up to 100 yd from the drain (Figure 11-6). Furthermore, for all three indicators, at nearly every surf zone station, the geometric means in 1991 were significantly lower than the means in 1990. Thus, the 600-ft extension to the Pico-Kenter Storm Drain, when functioning properly, appears to be effective in reducing the densities of indicator bacteria in the surf zone, where the potential for human exposure is greatest (Gold *et al.* 1992).

The distribution pattern in and around the Ashland Storm Drain was similar to that seen at Pico Kenter: levels of concern for all three bacterial indicators were exceeded in nearly 100% of the 15 storm drain samples and least frequently at the chest-depth stations (Figure 11-8).

VOL 12

1

5520

Bacterial densities at ankle-depth were not as high as those at the Pico-Kenter site, but all three indicators exceeded levels of concern in most samples.

Human enteric viruses were found in both the Pico-Kenter and Herondo Storm Drains (Gold *et al.* 1990, 1992). However, no viruses were detected in any of the samples taken from the Ashland Storm Drain, even in the seeded samples (recovery of spiked viruses was 0%), suggesting that there were significant interferences in the collection or identification processes (Gold *et al.* 1990, 1992). Thus, the lack of viruses in the Ashland Storm Drain is not evidence of their absence. The presence of enteric viruses in the Pico-Kenter and Herondo Storm Drains indicates that human fecal waste was present in the runoff during the majority of the sampling period. The viruses were identified as Coxsackie B, which can cause gastroenteritis and on rare occasions, pericarditis and meningitis (Gold *et al.* 1992). Possible sources of the human fecal contamination detected in the storm drains include leaky sewer lines, overflows from blocked sewers, illegal inputs, or the local homeless population (Gold *et al.* 1992).

At all sites in Malibu Lagoon, the mean densities of all three bacterial indicators exceeded levels of concern. Densities were especially high in Malibu Creek, upstream of the main Lagoon. Furthermore, enteric viruses were found at all three sampling sites in the Lagoon, suggesting the presence of human fecal contamination. TWRF discharges tertiary-treated waste water into Malibu Creek approximately 6 mi upstream from the Lagoon and is a potential source of fecal contamination. However, levels of bacterial indicators in samples taken from the facility's effluent were very low during the study period and remained so throughout 1992 (LVMWD unpubl. data). Thus, the plant does not appear to be a direct source of fecal contamination, which confirms indications in 1987 when only a single human enteric virus was detected in TWRF's effluent during 25 days of sampling (James M. Montgomery Engineers 1988). Possible sources of human fecal input to Malibu Lagoon include the Malibu Colony Septic system, campers, picnickers, temporary residents, and illegal discharges from mobile homes or recreational vehicles (Gold *et al.* 1992).

The density of F-male specific coliphage was monitored to examine its usefulness as an indicator of human enteric viruses in marine waters polluted with human sewage. Coliphage densities were ten times higher at the Pico-Kenter Storm Drain than at the Ashland Storm Drain in 1989, but the data were extremely variable and there was not enough information available on human fecal inputs to explain the higher density at Pico-Kenter (Gold *et al.* 1990). Furthermore, there was no correlation between the densities of coliphage and bacterial indicators, nor between coliphage densities and the presence of enteric viruses. Thus, F-male specific coliphage is apparently a poor predictor of the presence or absence of human enteric viruses.

The ongoing monitoring studies conducted by HTP, JWPCP, and TWRF and the studies conducted by Gold *et al.* (1990, 1991, 1992) have established that the largest potential threat to swimmers in Santa Monica Bay from human pathogens is from urban runoff, particularly at the Pico-Kenter and Herondo Storm Drains and in the Malibu Creek/Malibu Lagoon drainage system, where the presence of human fecal contamination has been detected. Although there are several areas of potential fecal input into these drainage systems, it is important to emphasize that the source or sources of the sewage has not been determined conclusively at any site. Furthermore, an epidemiological study, which would evaluate the impact of human sewage on swimmers, has not been conducted in Santa Monica Bay. The first step in reducing the potential for human health risks associated with swimming in waters contaminated with fecal waste is to carry out a sanitary survey, which would identify and reduce or eliminate the sources of fecal contamination. However, until the criteria and methods for such studies are developed, the public should continue to be informed about the potential risks of swimming in contaminated areas.

VOL 12

1552I

Wet-weather flow. Because of the relationship among wet weather, storm drains, and high bacterial counts, regulatory agencies distinguish between wet- and dry-weather sampling; HTP has defined wet weather as the day of rain plus the two subsequent days. Bacterial monitoring studies conducted by HTP from July 1989 through June 1990 (CLA,DPW 1991) indicate that total coliform, fecal coliform, and enterococcus densities all increase during wet weather, especially at stations closest to storm drains (Figure 11-9). For example, in 1989-1990, densities of all three indicators were highest during wet weather at Station S3, which is adjacent to the Pico-Kenter Storm Drain, and at Stations S8 and S9, which are on either side of Marina Del Rey and Ballona Creek (Figure 11-2).

The effect of runoff on the densities of bacterial indicators in the Bay can be demonstrated by examining wet-weather vs. dry-weather days in which bacterial indicator standards were exceeded. For instance, between July 1989 and June 1990, total coliform levels exceeded standards on at least one day at every HTP station (Table 11-1, CLA,DPW 1991). Levels were particularly high between the Pulga Canyon Storm Drain and the Imperial Highway Storm Drain (Stations S3 through S11, Figure 11-2), an area that drains a large portion of Los Angeles County (Figure 7-1), and on either side of King Harbor in Redondo Beach (Stations S14 and S15). Fecal coliform and enterococcus levels were also higher during wet weather, but the difference between wet- and dry-weather days for fecal coliform and enterococcus were much less than that for total coliform. Although high levels of any one of these indicators by themselves is not necessarily indicative of fecal contamination, high levels of all three indicators at a single location suggests human fecal input.

The extent of contamination around a storm drain depends on local rainfall, runoff from the surrounding area, and the interval between storms. For example, densities of all three bacterial indicators were highest during periods of peak rainfall in Los Angeles between July 1989 and June 1990 (Figure 11-10) (CLA,DPW 1991). Bacterial densities are usually highest during the first few months of the rainy season and tend to decrease as the season progresses. This pattern is known as the "first flush" and it assumes that coliform-bearing materials accumulate throughout the dry season. For the same reason, bacterial densities may also be particularly high during the first few hours of a rain that follows an extended dry period. Densities of bacterial indicators (and presumably human pathogens) may remain high for three or four days following the initial runoff (Figure 11-11), during which time swimmers are at greatest risk (CLA,DPW 1991).

Sewage Spills and Overflows

When sewage spills in Santa Monica Bay occur, they are usually a result of heavy rainfall or construction near sewer lines. Spills have lasted anywhere from an hour to several days and they may carry large volumes of sewage to the Bay through local storm drains. Although overflows cannot be predicted, there is usually enough time to warn the public about impacted areas and thus minimize exposure to potential pathogens.

Unusually high inflow and/or infiltration occasionally requires the North Outfall Treatment Facility of HTP to discharge into Ballona Creek or other storm drains. In the past some of these overflows have consisted of raw, untreated sewage (Sowby 1988, pers. comm.), but normally the sewage receives primary sedimentation, two stages of screening, and chlorination at a concentration of 40 mg/l (Crosse 1988, pers. comm.; Dorsey 1988, pers. comm.). A new sewer line and associated upgrades, which will virtually eliminate these discharges, are scheduled for completion in 1993-1994 (CLA,DPW 1992).

5525

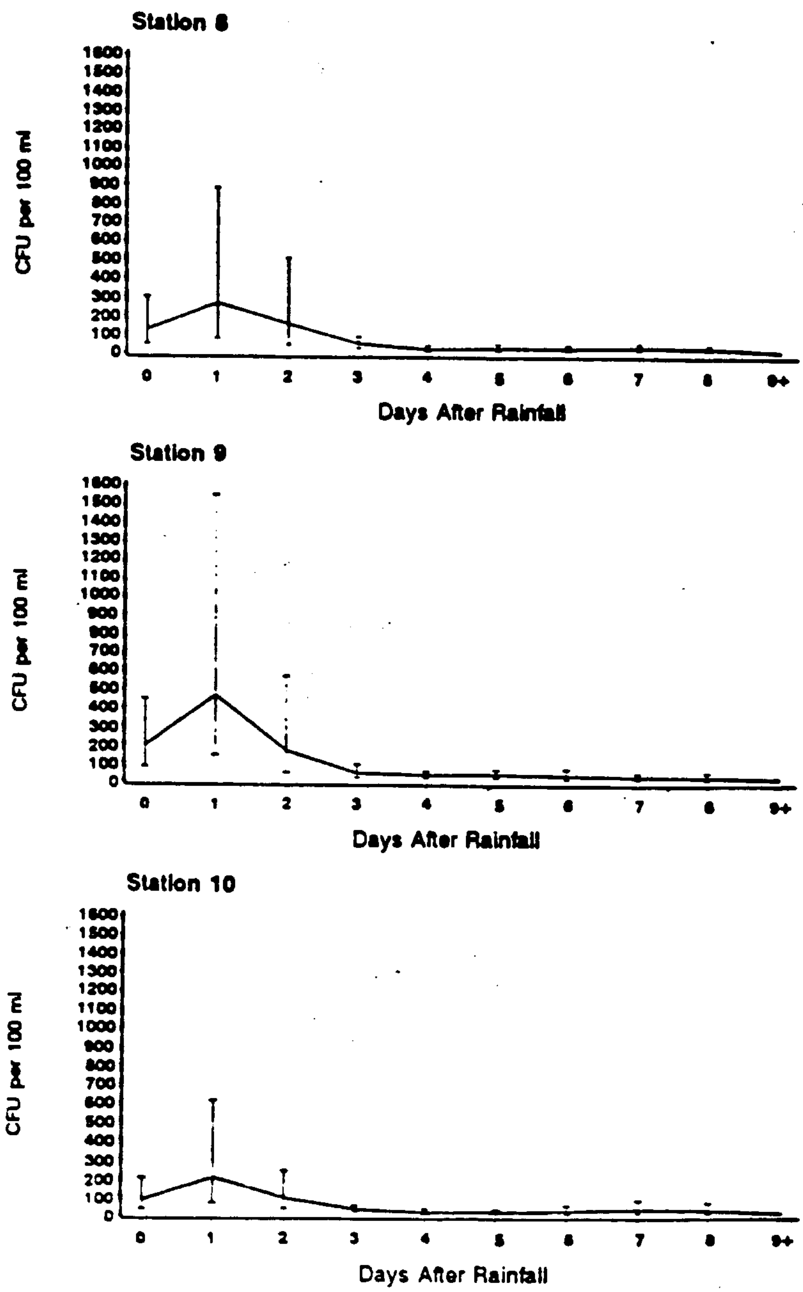

Figure 11-11. Bacterial counts on the days following rain at HTP shoreline stations S8, S9, and S10 (CLA,DPW 1991).

Between January 1987 and September 1992, at least 26 sewage overflows were recorded that resulted in beach closures (Appendix I). Most of these were the result of excess storm water in collector lines leading to HTP, although, some sewage has been released from septic tanks and coastal restaurants. The largest of the spills occurred on 10 February 1992 when heavy rains caused the discharge of over 66 million gallons of partially treated sewage into Santa Monica Bay. Because of the high bacterial levels, beaches were closed along the entire Los Angeles County coast for 11 days (Appendix I).

Small Boat Wastes

The overboard discharge of wastes from boats, particularly those berthed in the marinas, may present a risk of infectious disease to people that use recreational resources in the immediate vicinity. However, because of the small numbers of individuals who contribute to this source and their intermittent nature, the risks are not predictable by fecal indicators or pathogen levels in the water. Therefore, the conventional water quality guidelines and standards do not apply. The recognized solution is to restrict body-contact activities in the immediate vicinity of marinas and to enforce regulations that prohibit sewage discharges from boats. However, since enforcement is often difficult, education of recreational boat users about the potential hazards of sewage discharge is also essential.

Bathers

At least two epidemiological studies have related swimming-associated illness and bather density in areas of poor water exchange (Fattal *et al.* 1986, Calderone and Dufour, pers. comm.). Although there appears to be a health risk to swimmers from other bathers in the area, the extent of the risk is unpredictable and not amenable to usual control technology. The levels of *Staphylococcus aureus*, a potential human pathogen that has been found to be a good predictor of illness in freshwater, correlate well with bather density and could be used to identify such situations (Fattal *et al.* 1986, Calderone and Dufour 1988, pers. comm.). However, the link between *S. aeureus* density and illness has not been established in marine waters.

Marine Fauna

Fecal wastes from marine mammals, water fowl, and shorebirds may contain bacteria (notably *Salmonella*) pathogenic to humans. Although the infectious dose for *Salmonella* is very high, heavy contamination of the water could produce disease among swimmers or consumers of shellfish. The impacts on swimmers of pathogens from non-human sources has not been examined, except for swimmer's or clam-digger's itch, a problem caused by a bird shistosome (MBC 1988). Because bacterial indicators originate from several sources other than human feces and because most viruses are thought to be species-specific (Atlas 1984), water contaminated with non-human feces would probably have to markedly exceed bacterial indicator limits before a significant risk of human illness would result.

VOL 12

Public Health Approaches

Beach Closures and Warnings

Santa Monica Bay beaches are closed when high indicator bacteria levels are linked to sewage spills or when there are other health-risk concerns.

Santa Monica Bay beaches were closed to swimmers 39 times from January 1987 through September 1992 (Appendix I). Beach closures ranged from three in 1990 to 10 in 1987, with eight from January through September 1992. Most closures lasted from one to three days, but the longest closure lasted for 42 days in 1987, due to high densities of bacterial indicators that apparently resulted from an excessive bird population at Marina del Rey Beach.

Most closures were for a small segment of the beach, usually near a storm drain, but some extended beyond the study area. Three closures during this period extended from the Ventura-Los Angeles County Line to the Long Beach City border; these closures occurred on 22 and 31 October, 1987, and on 10 February, 1992, and lasted for 6, 12, and 11 days, respectively. These closures were due to sewage discharges of 2.7, 4.1, and 66.1 million gal, respectively from the North Outfall Treatment Facility resulting from heavy rains.

Epidemiology

To assess the potential risk to human health from swimming in Santa Monica Bay, it would be necessary to conduct an epidemiological study, which would evaluate the impact of pathogenic organisms or toxic chemicals on swimmers. However, such a study has not been conducted for Santa Monica Bay. Adequate chemical data are lacking for intertidal and shallow subtidal areas near storm drains and sewage overflow points, which are the primary areas of concern in the Bay other than possible unknown spill sites. However, as a result of the ongoing monitoring conducted by HTP, JWPCP, and TWRF and recent studies by Gold *et al.* (1990, 1991, 1992), there appears to be sufficient evidence from biological data that an epidemiological study is warranted. Such a study has been designed and proposed by Dr. Robert Haile and it has been approved and recommended for implementation by the Santa Monica Bay Restoration Project Management Committee (Gold 1993 pers. comm.).

The first step in reducing the potential for human health risks associated with swimming in waters contaminated with fecal waste is to carry out a sanitary survey, which would identify and reduce or eliminate the sources of fecal contamination. However, until the criteria and methods for such studies are developed, the public should continue to be informed about the potential risks of swimming in contaminated areas.

Risk Analysis

Procedure. Health risks to swimmers from microbial contamination in Santa Monica Bay was predicted according to the method of Cabelli *et al.* (1983b) in 1988 (MBC 1988). This analysis was based on sewage-contaminated waters which, considering the results of Gold *et al.* (1990, 1991, 1992), appears to be a valid, conservative risk assessment (Gold 1993 pers. comm.). Sampling days were first segregated into two groups, wet and dry, based on the mean enterococcus levels for the 17 shoreline stations sampled by HTP. The risk of acute gastroenteritis was estimated for wet and dry days using enterococcus data. Values of enterococci-based risks were evaluated for multiple stations to describe spatial patterns of contamination and risk.

The Cabelli method for evaluating risk is based on a regression equation between enterococcus density in swimming water and the rate of swimming-associated cases of acute gastroenteritis (Cabelli 1983b). "Swimming" is defined as the exposure of upper-body orifices to the water and illness rates are predicted from measurements of enterococcus levels in bathing water. The log to the base 10 of the median enterococcus level (median number per 100 ml) is entered into the regression equation obtained from epidemiological studies that were conducted at other locations:

$$Y = 12.17 \text{ (log Median)} + 0.02$$

where:

Y = the predicted number of illnesses/1000 swimmers.

If the geometric mean of enterococcus counts from at least ten days is used to represent enterococcus levels, the predicted rate is equivalent to the illness rate that would not be exceeded on half the days during the swimming season. From a public health point of view, this is not a protective prediction. When there are sufficient data points, the 90th percentile enterococcus level can, with some mathematical reservations, be entered into the equation to obtain an approximation of the predicted illness rate that will not be exceeded on 90% of the days during the time period represented.

Cabelli calculated the risk of swimming-associated acute gastroenteritis from the illness-indicator relationship in the above equation (MBC 1988) using the 50th and 90th percentile enterococcus levels for each shoreline station during wet and dry weather (Table 11-2). The values in Table 11-2 may be viewed as the predicted swimming-associated rates of gastroenteritis that would not be exceeded on 50% and 90% of the days, respectively. During dry weather, the predicted 50th percentile rates for all stations were less than that accepted by the EPA enterococcus guidelines; this was also true for most of the stations during wet weather.

Assumptions and Uncertainties. Most of the uncertainty in microbial risk assessment is related to the sources of the indicators, particularly those that are unpredictable or not related to human fecal contamination. Enterococci or coliforms reaching the beaches of Santa Monica Bay could derive from several sources, including off-shore municipal wastewater outfalls, sewage spills, urban runoff, discharges from pleasure boats, marine and shore fauna, and the bathers themselves.

Untreated discharges from pleasure craft and fecal contamination from bathers may pose a risk of swimming-associated illness, but these discharges are small relative to the number of contributing individuals. Therefore, the risk may not be predictable using bacterial indicator guidelines.

One major uncertainty in calculating risk from stormwater runoff results from the occurrence of indicator bacteria unrelated to human fecal inputs, notably those from the feces of other endotherms. These extraneous bacteria confound the relationship between the indicator and actual pathogens. For stormwater discharges that contain nonhuman fecal wastes but little of human origin, the risk of illness may be markedly overstated by the enterococcus or coliform levels in the water. However, since the survival rate of some human enteric viruses may be greater than that of the indicator bacteria, health risks may be understated in some areas.

a Defined from log-probability plot (MBC 1988) by day of the 17-station GM enterococcus levels. Cut-off of 5.5 CFU/100 mL.

b Includes spills and unexplained events leading to 17-station GMs in excess of 5.5.

c Predicted from equation (Cabelli 1980). Swimming-associated acute gastroenteritis (AGI) rate/1,000 persons:

$$y = 12.17 \log x + 0.2$$

where:

y = predicted swimming-associated rate for acute gastroenteritis
x = GM enterococcus level/100 mL.

d Assumes, with reservations, that the equation developed from GMs can be used with 50th and 90th percentile values. 90th percentile rate can be thought of as the rate which will not be exceeded on 90% of the days during bathing season.

VOL 12 1 5530

Finally, it must be realized that recreational water quality criteria may not apply under certain conditions such as unusually high levels of illness in the population whose wastes potentially contaminate the resource.

Recreational Water Quality Standards

As noted above, viruses survive longer in seawater and shellfish than do human enteric bacteria, which suggests that the risk of swimming-associated illness may be greater than suggested by the indicators. However, because of the problems in identifying an etiological relationship between water-borne pathogens and human illness and because of the lack of a mechanism for swimming-associated illness surveillance, there has never been a reported outbreak of a specific illnesses associated with swimming in Santa Monica Bay.

Cabelli (in MBC 1988) suggested that a predicted illness rate of 17 to 18 cases of swimming-associated gastroenteritis per 1,000 swimmers corresponds to a dry-weather recreational water quality standard of a 90 percentile limit of 25 to 30 enterococci/100 ml. A somewhat crude interpretation of this limit is that this is the rate that will not be exceeded on more than 10 percent of the days during the swimming season. The decision as to whether this risk is acceptable or not is properly one of policy.

With regard to Santa Monica Bay, the predicted rate probably overstates the actual one to the extent that the sources of enterococci are often non-human wastes. Even if a worst case situation is assumed (i.e., all the enterococci derive from human fecal sources), the predicted rates are appreciably less than those accepted by the USEPA guideline and the corresponding enterococcus limits are attainable. Moreover, the implementation of these limits as interim guidelines or standards should provide an impetus for the conduct of the monitoring, research, and epidemiological programs needed to better assess and manage risks.

A better operating procedure for dealing with events leading to unusually high enterococcus levels that are linked with high total or fecal coliform levels at multiple stations is needed. The response to sewage spills in the absence of stormwater runoff is a relatively simple problem; the potentially affected beaches are temporarily closed until the bacterial standard is achieved. At present there is no epidemiological database regarding the risk of swimming-associated illness from biological pathogens; this information is needed. In addition, an indicator system that is more reflective of human fecal wastes or sewage than the present system is needed. Until these are available, the current practice of issuing health advisories concerning swimming at beaches near storm drains after rainfall should continue. Based on recent studies by Gold *et al.* (1990, 1991, 1992) and ongoing monitoring by HTP (CLA,DPW 1987, 1988, 1990, 1991, 1992), bathers should stay at least 200 yards away from storm drains during dry weather and refrain from swimming during and immediately (two to three days) after rain storms.

VOL 12

CHAPTER 12
HEALTH HAZARDS OF SEAFOOD CONSUMPTION

Marine environments adjacent to heavily populated urban areas may be exposed to a variety of chemical contaminants from anthropogenic sources, including pesticides such as dichlorodiphenyltrichloroethane (DDT), polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), chlordane, dieldrin, as well as heavy metals such as arsenic, mercury, silver, selenium, and lead. Marine organisms living in impacted areas may also be exposed to the same contaminants through direct water contact soon after discharge from a point source, or through contact with sediments in which contaminants have accumulated over time. Human health may in turn be at risk if animals exposed to contaminants are consumed. The contaminants that pose the greatest risk to human health from consumption of seafood are those that "biomagnify" or increase "up the food chain." The degree of accumulation in aquatic organisms depends on the type of food chain, on the availability and persistence of the contaminant in the environment, and especially on the physical and chemical properties of the contaminant. The most extensively studied and tractable contaminants in Santa Monica Bay are heavy metals, PCBs, and DDT and its by-products.

CONTAMINANTS OF CONCERN AND DISEASES

Many trace metals are important in animal nutrition, where, as micronutrients, they play an essential role in tissue metabolism and growth. The essential trace metals include cobalt, copper, chromium, iron, manganese, nickel, molybdenum, selenium, tin, and zinc (Rand and Petrocelli 1985). However, the optimum concentration range for trace metals is usually very narrow and severe imbalances in their availability can contribute to poor health, retarded growth, and death. Some non-essential trace metals, such as lead, cadmium, and mercury, also can be toxic at concentrations commonly found in marine sediments and natural waters.

15532

Uptake of metals in invertebrates and fishes can occur through contact with contaminated sediments and waters or through ingestion of contaminated food. Heavy concentrations of trace metals in the environment can pose a health risk to humans that eat seafood from the contaminated area. The mechanisms of accumulation and storage of trace metals in aquatic animals are diverse, varying with chemical form of the metal, mode of uptake, and animal species (Luoma 1983). However, many aquatic animals are able to excrete a higher than normal proportion of their metal intake under contaminated conditions and thus maintain trace metal concentrations in the body at a normal level (Phillips 1980). A major exception to this pattern is mercury, which is readily bioaccumulated when it is in the organic form of methylmercury (Phillips 1980). Thus, the idea of bioaccumulation, where the highest trophic levels contain the highest toxin concentrations, does not hold for most heavy metals (Rand and Petrocelli 1985). For this reason, sediments generally contain higher concentrations of heavy metals than are present in aquatic organisms.

PCBs are a class of synthetic chlorinated organic chemicals that were used in many industrial products (e.g., hydraulic fluids, plasticizers, adhesives, and paper coatings) from 1929 to 1971. Beginning in 1970, their use was voluntarily restricted by the Monsanto Chemical Company to closed electrical systems in the mid-1970s (Cordle *et al.* 1978). Because of their toxic properties, a partial ban was imposed on PCB use and manufacture in 1976 [Section 6(e) of the Toxic Substance Control Act (TSCA)]. In 1979, TSCA regulations were finalized to prohibit their use in heat transfer systems used for the manufacture of food, drugs, and cosmetics. After 1 July 1984, PCBs were no longer allowed for use in electrical equipment. After distribution in the Santa

Monica Bay environment from stormwater, and sewage inputs, PCBs may be absorbed and accumulated by seafood organisms. Consumption of fish and shellfish (including freshwater species) represents the major pathway of human exposure to PCBs today.

Although PCBs have low toxicity in short-term exposures, they are of public health concern because of their persistence and their long-term toxic effects in humans and other animals (Calabrese and Sorenson 1977; Kurzel and Cetrulo 1981; Rogan *et al.* 1986). The low short-term toxicity of PCBs means that a massive dose would be required to cause death or other severe health effects from short-term exposures. Such extreme doses are unlikely to occur under environmental conditions. However, a series of smaller doses over a long period of time (e.g., decades) may cause toxic effects on skin and liver tissue, including liver cancer. A variety of reproductive effects of PCBs have been demonstrated in humans and other animals (e.g., mink, chickens, monkeys, rats). For example, in Michigan and North Carolina infants born to women that were heavy consumers of PCB-contaminated fish exhibited a reduced size at birth, poor muscle tone, and behavioral deficiencies (Jacobson *et al.* 1985, Rogan *et al.* 1986). Because PCBs are lipophilic, long-term exposure to PCBs may result in high concentrations in breast milk (Schwartz *et al.* 1983; Jacobson *et al.* 1984; Humphrey 1987, 1988). Recently, the Los Angeles County Health Department, the California Department of Health Services, and the Office of Environmental Health Assessment conducted a comprehensive study of concentrations of PCBs, DDT, dioxin, and dibenzofurans in breast milk of women in Los Angeles County. The report from this study is currently being prepared.

In the 1960s and early 1970s, the Montrose Chemical Company dumped tons of the insecticide DDT into the Palos Verdes Shelf via the JWPCP outfalls (Chartrand 1988). Although DDT has been banned in the U.S. since 1972, high levels are still found in the sediments near the JWPCP outfall (NOAA 1991a), which themselves now act as source of DDT contamination for demersal organisms. Like PCBs, DDT and related compounds are readily accumulated in animal tissues and tend to persist once uptake has occurred. Although there is some concern that DDT and related compounds may cause premature birth in humans (Kurzel and Cetrulo 1981), the evidence for potential toxic effects in humans concerns primarily liver and pancreatic cancer (Garabrant *et al.* 1992). USEPA (1985) concluded that DDT, DDD, DDE, and dicofol, a DDT-related pesticide, are probable carcinogens (cancer-causing chemicals) based on evidence from experiments with rats, mice, and other animals. The extent to which these substances are carcinogenic to humans remains unknown because appropriate epidemiologic data for calculating carcinogenic potency are lacking. As with PCBs, DDT and related chemicals may occur in high concentrations in breast milk of females that consume large amounts of DDT-contaminated fish, but appropriate studies to show health effects in infants are not yet available. Nonetheless, Rogan *et al.* (1986) demonstrated a positive correlation between DDE concentration in breast milk and slow reflexes in infants.

SOURCES OF CONTAMINANTS

The contaminants that may be taken up by animals in Santa Monica Bay originate from many potential sources. Sewage treatment facilities discharge an enormous volume of wastewater to the Bay. Although all sewage that enters the Bay, aside from occasional leaks and overflows, has undergone primary, secondary, or tertiary treatment, sewage outfalls historically have been considered the principal sources of contaminants to the Bay. However, with improvements in effluent quality during the past two decades, sediments near the outfalls that were previously exposed to contaminants may now be the principal source of many contaminants. Other sources include coastal generating stations, oil refineries, and storm drains, which deliver a variety of

VOL 12 1 5533

contaminants, particularly during periods of heavy rainfall or sewage overflows. The specific constituents originating from these sources are discussed in Chapter 5.

DISTRIBUTION OF CONTAMINANTS IN MARINE ORGANISMS

The amount of a contaminant that is bioaccumulated by an organism depends on several factors, including the chemical characteristics of the contaminant, its concentration in the marine environment, and the characteristics of the organism. For example, the chemicals that have the highest potential for bioaccumulation are least soluble in water. Such compounds are highly soluble in fats and oils and tend to be retained in tissues once they enter organisms. These same chemicals generally have a high affinity for organic particles and tend to concentrate in bottom sediments. Chemicals with a high potential for bioaccumulation include pesticides such as DDT, complex chlorinated hydrocarbons such as PCBs, and organo-metallic compounds such as methylmercury. Highly soluble or volatile compounds such as chloroform have a very low potential for bioaccumulation, even when highly concentrated.

Organisms with a high bioaccumulation potential generally have characteristics such as 1) high fat content, 2) live on or near the bottom sediments, 3) filter-feed on organic particles, and 4) are high on a food chain (i.e., top carnivores). Examples of such organisms include Dover sole and other flatfish species (demersal fishes), mussels and clams (filter feeders), and seals (high fat and top carnivores).

Invertebrates

Except for mussels, contaminant levels in invertebrates from Santa Monica Bay have not been well studied. Data on mussel contamination levels have been generated primarily by the California State Mussel Watch (SMW) Program, a periodic assessment that has been conducted since 1977 by the State Water Resources Control Board (SWRCB). The program uses both blue (= bay) and California mussels to assess spatial and temporal trends in the contamination of native and transplanted organisms. Mussels are good indicators of environmental contamination because they are filter feeders, and therefore ingest small organic particles and associated contaminants. Mussels are also attached to a substrate and as such provide a better indication of localized conditions than motile organisms, such as fishes.

Other invertebrates that have been assessed for tissue contamination include yellow rock crab, ridgeback rock shrimp (= ridgeback prawn), black abalone, California spiny lobster, and giant rock scallop; species names are listed in Appendix C.

Spatial Patterns

Metals. In 1979, the SMW Program conducted an intensive survey of resident intertidal mussels in Santa Monica Bay. The distributions of metals in mussels showed distinct patterns that related to metal sources and to fate processes in the Bay. For example, the mussels at Royal Palms, on the Palos Verdes Peninsula, had the highest tissue levels of silver in the study area (about 6 times those at Point Dume); intermediate and relatively constant levels of tissue silver were measured at locations in central and southern Santa Monica Bay (Figure 12-1). The high silver levels in Royal Palms mussels probably resulted from contamination from the JWPCP outfalls.

In contrast, lead contamination of mussels had a very different pattern in the Bay, with the highest concentrations being measured along the central inshore Bay from Playa del Rey to

VOL 12 15534

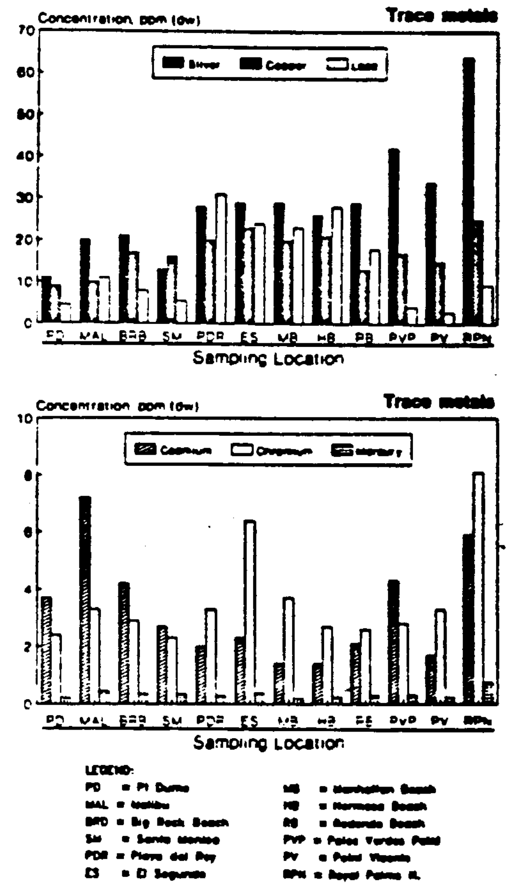

Figure 12-1. Regional variations in concentrations of trace metals in resident sea mussels (*Mytilus* spp.) from Santa Monica Bay, 1979 (CSWRCB 1982).

VOL 12

1 5535

Redondo Beach. This pattern suggests that the major lead sources were probably urban surface runoff and marinas. One of the highest lead concentrations measured in resident mussels (49 ppm at Marina del Rey) was about 50 times the lead concentrations typically found at uncontaminated coastal sites.

Brown *et al.* (1986) and Thompson *et al.* (1987a) measured hepatopancreatic concentrations in ridgeback rock shrimp and found that copper, zinc, and cadmium had very different spatial patterns (Figure 12-2). Concentrations of copper and zinc in shrimp from Santa Monica Bay were less than, or similar to, concentrations of these metals in shrimp from adjacent coastal areas. In contrast, cadmium was highly elevated in shrimp from northern and central Bay sites, but not in shrimp from the Palos Verdes Shelf, possibly reflecting the high degree of cadmium complexing with organic matter near that outfall (MBC 1988).

Analyses of edible tissue of six invertebrate species collected near the JWPCP outfalls from 1974 to 1976 indicated that most metals, including those of greatest concern relative to human health (lead, mercury, and cadmium), were not substantially elevated above reference areas (Jan *et al.* 1977). For most of the species and metals tested, the concentrations in outfall organisms ranged from 1 to 3 times the control levels. The only metal showing substantial bioaccumulation in outfall organisms was chromium, which was elevated about 10 times reference levels in edible tissues of scallops and abalone. These data suggest relatively minor bioaccumulation of metals in these species, since sediment metal concentrations near the outfalls were elevated from 16 to 36 times control areas.

Organic Compounds. Resident mussels from a few sites in Santa Monica Bay have been analyzed for tissue concentrations of organic chemicals. From 1932 to 1983, mussels from Royal Palms on the Palos Verdes Peninsula contained about 1,400 ppb total DDT (Ladd *et al.* 1984). This value was over 6 times the total DDT concentration in mussels from a reference area off Oceanside and over 140 times the levels at northern California reference sites such as Trinidad Head. High DDT levels have also been reported for giant rock scallop, black abalone, and California spiny lobster collected from the Palos Verdes Peninsula (Young *et al.* 1978). Most of the total DDT present in animal tissues is in the form of DDE, with lesser amounts of DDD and very small amounts of DDT, suggesting that there has not been a recent input of the parent compound. Most pesticides other than DDT (e.g., chlordane, endrin, aldrin, endosulfan, heptachlor, and toxaphene) do not have elevated concentrations in animals from Santa Monica Bay (SCCWRP 1992, CSWRCB unpubl. data).

Data for ridgeback rock shrimp collected in 1982 (Brown *et al.* 1986) and 1985 (Thompson *et al.* 1987a) indicate widespread DDT contamination in this species throughout the Southern California Bight (Figure 12-3). In particular, shrimp from Santa Monica Bay displayed highly elevated tissue levels when compared with adjacent coastal areas. The highest mean DDT concentration (49,000 ppb) was measured in shrimp from near the JWPCP outfall at White Point (Figure 12-3), which were over 370 times the mean DDT concentration in shrimp from Imperial Beach. Shrimp from Malibu and HTP outfall areas also had high DDT concentrations in hepatopancreas tissue, with mean values exceeding 10,000 ppb (Figure 12-3). These data suggest that, in addition to the large source of DDT near the JWPCP outfall, the HTP outfall or perhaps other sources such as runoff from the Malibu watershed, may have contributed to the DDT contamination in northern Santa Monica Bay.

The historically high levels of contaminants in sediments and animal tissue at the Palos Verdes Peninsula prompted the Santa Monica Bay Restoration Project (SMBRP) to conduct a study on the distribution of PCBs and DDT in yellow rock crab to assess the extent of

VOL 12

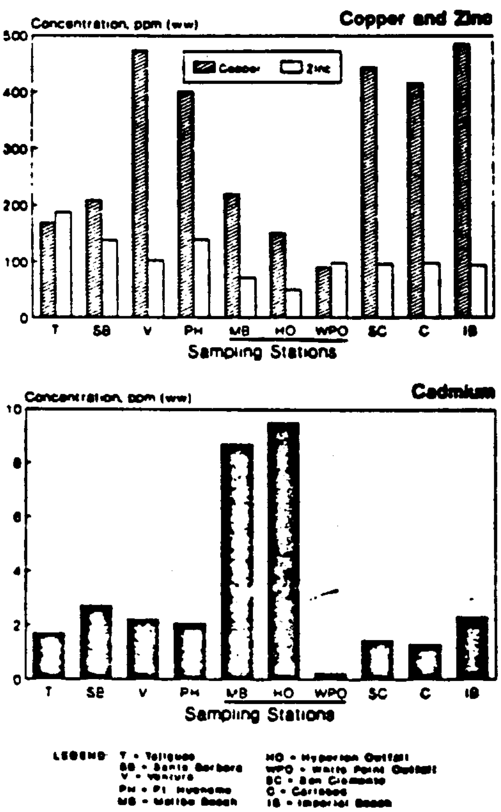

Figure 12-2. Regional variations in concentrations of trace metals in hepatopancreas of ridgeback rock shrimp (*Sicyonia ingentis*) from the Southern California Bight, 1982-1985 (Brown *et al.* 9186, Thompson, unpubl. data).

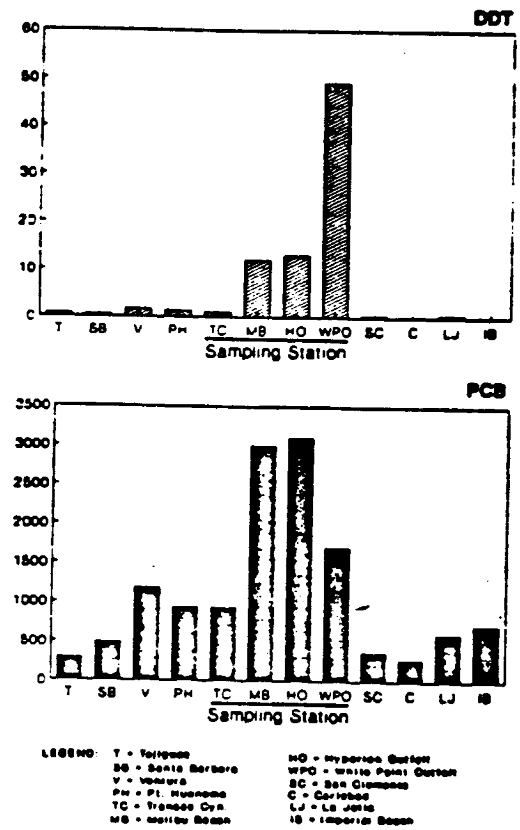

Figure 12-3. Regional variations in concentrations of DDT and PCB in hepatopancreas of ridgeback rock shrimp (*Sicyonia ingentis*) from the Southern California Bight, 1983-1985 (Brown *et al.* 9186, Thompson, unpubl. data).

contamination in the animals near the JWPCP outfall (SCCWRP *et al.* 1992). The mean DDT concentration in the muscle of yellow rock crab taken from White Point in 1990 (31 ppb) was an order of magnitude greater than from crabs collected at Dana Point (Figure 12-4). Over 90% of the total DDT at both sites was in the form of DDE, suggesting that there has been no recent input of the parent compound, but that sediments near the outfall are still contaminated with DDT by-products. PCB levels (Figure 12-5) were about three times higher in yellow rock crab taken from White Point (9.1 ppb) than those from Dana Point (2.7 ppb) (SCCWRP *et al.* 1992).

In mussels, the spatial distribution of PCBs is similar to that seen for DDT and its constituents. In 1990, PCB concentrations were 150 ppb in mussels from Royal Palms, while tissue levels at Oceanside were 54 ppb (CSWRCB unpubl. data). Levels at Santa Monica (65 ppb) and Malibu (70 ppb) were similar to those at Oceanside and other sites in southern California (CSWRCB unpubl. data). In contrast, ridgeback rock shrimp hepatopancreatic PCB contamination was highest in northern and central Santa Monica Bay near Malibu Beach and the HTP outfall, where concentrations exceeded 3,000 ppb in 1983-1985 (Figure 12-3; Brown *et al.* 1986, Thompson unpubl. data). The PCB levels in Santa Monica Bay shrimp were about 10 times the levels at Tajiguas, the most northerly site sampled. Brown *et al.* (1986) found similar patterns of hepatopancreatic concentrations of PCBs and DDT in armed box crabs from Santa Monica Bay. The most likely source of PCB contamination in northern Santa Monica Bay is effluent from the HTP outfall.

Temporal Trends

Metals. Data from the SMW Program indicate temporal trends in contaminant levels because the same sites have been sampled through time with consistent methods. The only SMW site in Santa Monica Bay with good temporal data is at Royal Palms, on the Palos Verdes Peninsula. Royal Palms mussel tissue show a substantial decline in lead contamination since 1977 and evidence of lower chromium levels (Figure 12-6). However, copper, silver and cadmium display no apparent declines during the period of 1977 to 1983. With the exception of copper, all of the metal levels in Royal Palms mussels remain considerably higher than those measured at Oceanside, a relatively uncontaminated downcoast site. Data collected in 1990 show that lead concentrations at Royal Palms have continued to decrcase, but concentrations of other metals in 1990 were similar to those in 1982-1983 (CSWRCB unpubl. data).

Recently, SCCWRP (1992) analyzed HTP monitoring data to determine the effects of sludge that had been discharged through HTP's 7-mi outfall since 1957. Sludge discharge was terminated in November, 1987, and data collected since that time was used to assess the impacts of sludge discharge on contaminant levels in marine organisms in the impacted area and the recovery of organisms following sludge discharge cessation. This summary provides a good database for analyzing recent temporal trends in contamination levels near the outfall.

SCCWRP (1992) analyzed tissues of ridgeback rock shrimp and Dover sole from the 100-m isobath at a "contaminated" site surrounding the discharge, a reference site approximately 10 km west of the discharge, and a transition zone between the two areas. The concentrations of trace metals in hepatopancreas tissue in ridgeback rock shrimp from contaminated sites changed very little from 1986 through 1988 (Figure 12-7; SCCWRP 1992). Copper and silver concentrations decreased slightly after sludge termination, but zinc and cadmium showed no appreciable changes. Although sludge abatement had little effect on metals contamination, concentrations of all metals in shrimp tissue from the outfall area were similar to those from animals taken elsewhere on the southern California mainland shelf (SCWWRP 1992).

VOL 12

1 5543

Organic Compounds. Levels of DDT and PCBs in mussels collected from the Palos Verdes Peninsula have declined substantially since 1971 (Figure 12-8). In 1982-83, concentrations of PCBs and DDT were only about 12% and 7%, respectively, of the concentrations measured in 1971. Concentrations of both contaminants from mussels collected in 1990 (CSWRCB unpubl. data) were similar to those in 1982-1983 (Ladd *et al.* 1984). Thus, PCB and DDE levels in Palos Verdes mussels have remained fairly constant since about 1977.

The decrease in DDT and PCB levels at Palos Verdes is also evident in yellow rock crab body burden levels. Heesen and McDermott (1974) showed widespread DDT contamination of yellow crab muscle in 1971 and 1972. Total DDT concentrations were highest in crabs from the Palos Verdes Shelf, ranging from 500 to 2,100 ppb in edible tissue (Heesen and McDermott 1974). In 1990, mean DDT levels in yellow rock crab taken from White Point averaged 31 ppb (SCCWRP 1992). Thus, it appears that DDT levels in crabs from the Palos Verdes Peninsula have greatly decreased in the last 15 or 20 years.

PCB contamination of crabs was much more uniform throughout the Bay in the early 1970s. The overall range was 400 to 1,900 ppb PCBs in 1972, with maximum concentrations in crabs from central Santa Monica Bay near the HTP 5-mi outfall (Heesen and McDermott 1974). By 1990, PCB levels had decreased greatly, with a mean value of 9.1 ppb in yellow rock crab taken at White Point (SCCWRP 1992).

In 1986-1987 SCCWRP (1992) found that concentrations of PCBs in shrimp hepatopancreas from the contaminated areas near HTP's 7-mi outfall were high compared to levels in animals from the reference site (Figure 12-9). PCB levels decreased in shrimp from the impacted area in 1987, and by 1990 levels were similar to those of the reference site (Figure 12-9). This trend correlates well with levels of PCBs in the sediments in the study area (SCCWRP 1990). Although the data are somewhat variable, it appears that sludge abatement in 1987 eliminated, or at least decreased, a potentially large source of PCBs to Santa Monica Bay, which subsequently reduced PCB uptake in shrimp near the 7-mi outfall.

In contrast to PCB levels, the concentration of DDT in ridgeback rock shrimp hepatopancreas did not decrease from 1986 to 1990 (Figure 12-10) (SCCWRP 1992). However, with the exception of 1988, DDT levels from 1986 through 1990 remained below 1,000 ppb in animals taken near the outfall terminus. These values are much lower than those collected in 1983-1985, when hepatopancreas levels were greater than 10,000 ppb (Brown *et al.* 1986, Thompson *et al.* 1987a). The high DDT values in 1988 are difficult to explain, but higher values at the reference site suggest that previously contaminated sediments may be periodically exposed through tectonic activity or storms, or that sources other than the 7-mi outfall are present, such as urban runoff through local storm drains.

Fishes

Studies of fish contamination in Santa Monica Bay have emphasized contaminants in edible muscle and liver tissue. The edible muscle tissue is important because it represents the contaminants that could be passed on to humans. However, liver body-burden levels are indicative of the total range of contaminants entering the fish because of the role the liver plays in regulation and storage of toxic chemicals (Fowler 1982). Consideration of contaminants in both edible muscle and liver tissue can therefore provide an assessment of the potential human health impacts as well as the health of fishes.

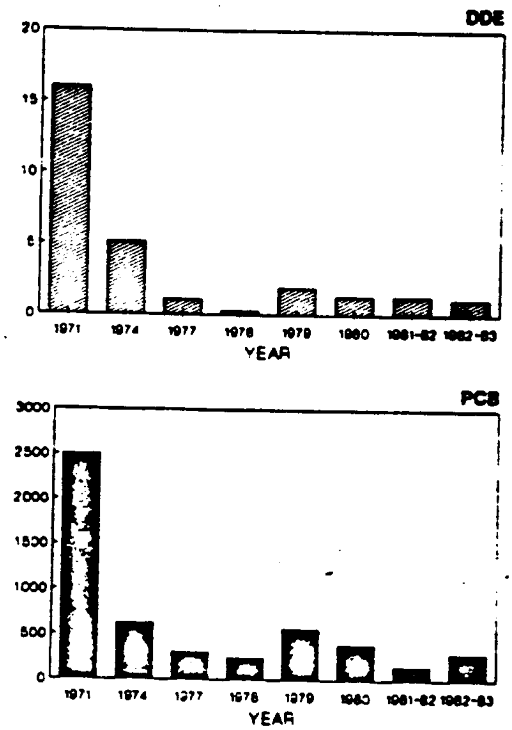

Figure 12-8. Temporal variation in concentrations of DDE and PCB in resident mussels at Royal Palms State Beach on the Palos Verdes Peninsula, 1971-1983 (Stephenson *et al.* 1980, Ladd *et al.* 1984).

Demersal fishes are preferred as indicators of contamination because they live in close contact with bottom sediments, often feed on benthic organisms, and are not generally migratory. Contaminants in fishes with these characteristics can be related to localized sources with confidence.

Spatial Patterns

Metals. In general, metals concentrations in edible muscle and liver tissue in fishes from Santa Monica Bay have not been elevated substantially above the levels observed in fishes from reference areas such as the Santa Barbara Channel, Santa Catalina Island, Point Dume, and Dana Point (DeGoeij *et al.* 1974, McDermott *et al.* 1976, Sherwood *et al.* 1978, Young *et al.* 1978, Young *et al.* 1980, Jenkins *et al.* 1982, Brown *et al.* 1986). Brown *et al.* (1986) and Thompson (unpubl. data) found that liver concentrations of copper, cadmium, and zinc were frequently lower in fish near the HTP and JWPCP outfalls than in fish from a number of relatively uncontaminated reference areas along the California coast (Figure 12-11). The low levels near the outfalls may result from reduced availability of the metals as a result of complexing with organic sewage material or from the inhibitory effects of organic contaminants on the retention of metals.

Organic Compounds. Most studies of organic compounds in fishes from Santa Monica Bay have dealt with PCBs and DDT and its by-products in muscle and liver tissue, although a few have considered other organic contaminants, primarily EPA priority pollutants (Young and Heesen 1977; Gossett *et al.* 1982, Gossett *et al.* 1983a, b; Malins *et al.* 1987). An early (1971 to 1972) study of DDT in Santa Monica Bay in Dover sole (Young *et al.* 1976a) found that concentrations of DDT were highest near the JWPCP (White's Point) outfalls and rapidly declined both upcoast and downcoast from that location (Figure 12-12). Values in Santa Monica Bay were 2 to 36 times higher than the value observed at Point Dume. A similar pattern was also seen for DDT levels in livers of several demersal species in 1982 and 1985 (Brown *et al.* 1986, Thompson *et al.* 1987a). These studies show the DDT discharged in the 1960s and 1970s into the Palos Verdes sediments continues to bioaccumulate in the tissues of fishes that inhabit the area.

The distribution of PCBs in Santa Monica Bay fishes is also usually highest at Palos Verdes, but fishes from other areas in the Bay often contain elevated levels. In 1982 and 1985, Brown *et al.* (1986) and Thompson *et al.* (1987a) found that liver concentrations of PCBs were highest near the JWPCP and HTP outfalls in four demersal fishes: Pacific sanddab, California scorpionfish, yellowchin sculpin, and longspine combfish. Although values generally declined both upcoast and downcoast from these two locations, unusually high concentrations in Pacific sanddab were found at Point Dume and Imperial Beach. Concentrations in Pacific sanddab from Santa Monica Bay ranged from 0.4 to 1.4 times the value at Point Dume. Concentrations in California scorpionfish from Santa Monica Bay ranged from 3 to 4 times the value at Dana Point. The more uniform distribution pattern of PCBs in the Bay reflects the numerous sources of this contaminant.

In 1991, the Office of Environmental Health Hazard Assessment (OEHHA) and the Department of Health Services (DHS) conducted a comprehensive study of chemical contaminants in fishes collected in southern California (Pollock *et al.* 1991). This report provides an excellent database for examining the distribution of contaminants in local fishes. Several fish species from twelve sites in Santa Monica Bay were included in this study. DDT and PCB levels in fish caught at stations in Santa Monica Bay and at Dana Point (reference) were examined for Pacific bonito, chub mackerel, California halibut, kelp bass, California scorpionfish, several species of surfperches, queenfish, and white croaker (Table 12-1).

VOL 12

1 5551

The distribution and concentrations of contaminants in the fishes examined depends on the mobility, feeding habits, and metabolism of individual species (Table 12-1). For instance, Pacific bonito and chub mackerel are biologically similar in that they are pelagic fishes that migrate over a large area of the ocean (Eschmeyer *et al.* 1983). DDT and PCB levels are low in Pacific bonito and chub mackerel from all sites and it does not appear that contaminant concentrations in these fishes are site specific (Pollock *et al.* 1991). Kelp bass had high DDT levels at White Point and slightly high levels at Palos Verdes-Northwest, but levels were low in kelp bass caught throughout the rest of Santa Monica Bay. California halibut is a demersal ambusher (Allen 1982) that might be expected to have high contaminant levels due to its close contact with sediments and its trophic position. However, DDT levels were very low in California halibut at all sites where it was collected, possibly reflecting the consistently low lipid concentrations found in this species (Pollock *et al.* 1991) or because adults primarily feed on pelagic, non-resident northern anchovy (Allen 1982). California scorpionfish and the surfperches had elevated DDT levels at most stations on the Palos Verdes Peninsula, but levels generally were low throughout Santa Monica Bay.

The most elevated DDT levels were found in queenfish and white croaker (Table 12-1) (Pollock *et al.* 1991). Site-specific DDT levels for both species were almost always the highest levels found for all fishes analyzed. Similar to other species with elevated contaminant levels, the highest DDT concentrations in white croaker and queenfish were found at stations on the Palos Verdes Peninsula. White croaker from Point Vicente and White Point had the highest DDT levels of any fishes in the study area, with mean concentrations of 2,641 and 2,099 ppb, respectively. In addition to high DDT levels in fishes from Palos Verdes, contaminated white croaker and queenfish were also found in northern Santa Monica Bay at Point Dume, Malibu Pier, Malibu, and Santa Monica Pier.

PCB levels in fishes analyzed by Pollock *et al.* (1991) were low for most species (Table 12-1). However, PCB levels in queenfish and white croaker were markedly elevated compared to the other fishes analyzed. Levels were particularly high in queenfish from Malibu Pier and in white croaker from Point Dume and Malibu and from Point Vicente and White Point. The HTP and JWPCP outfalls are the most likely sources of PCBs in northern Santa Monica Bay and Palos Verdes, respectively, but the more uniform distribution of PCBs (compared to DDT) in fishes throughout the Bay suggests that there are probably several sources of this contaminant.

It should be mentioned that the levels of chlordane were very low in most fishes throughout the study area (Pollock *et al.* 1991). Only white croaker, surfperches, California corbina, and queenfish had total chlordane levels above the method detection limit.

In 1992, the SMBRP conducted a study on the contamination of seafood in Santa Monica Bay (SCCWRP *et al.* 1992). Although not a risk assessment, the study was designed to provide information for management decisions regarding subsistence, recreational, and commercial fisheries in the area. White croaker was most extensively analyzed because of the historically high levels of chlorinated hydrocarbons found in this species (Table 12-1) and because it is one of the most commonly caught seafood species in Santa Monica Bay (Wine 1979). White croaker were collected from 11 sites along the southern California coast in September 1990 and tissue composites were analyzed for lead, selenium, and several chlorinated hydrocarbons including PCBs, DDT, and chlordane.

The distribution of PCBs in white croaker tissue (Figure 12-13) (SCCWRP *et al.* 1992) suggest that the most heavily contaminated area in 1990 was off the Palos Verdes Peninsula. At all three Palos Verdes stations (Palos Verdes North, South, and White Point), the mean

VOL 12

1 5552

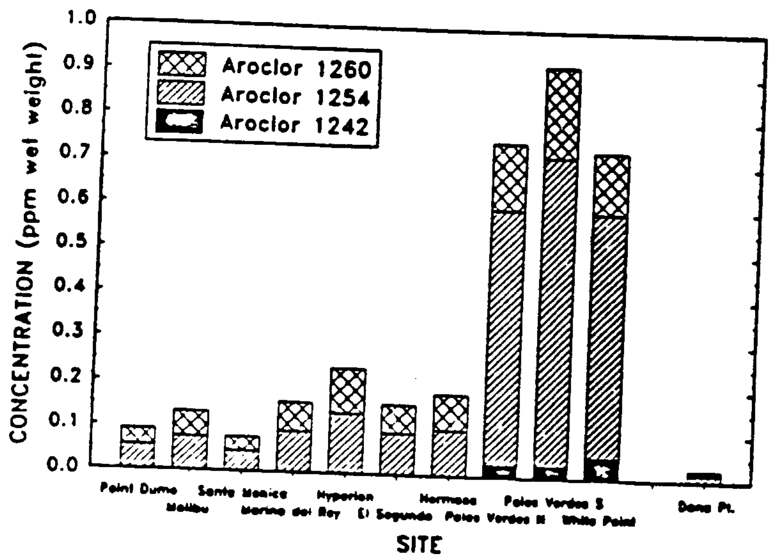

Figure 12-13. Mean concentrations of total PCB (Aroclors 1242 + 1245 + 1262) in composites of muscle tissue of white croaker (*Genyonemus lineatus*) collected from coastal sites in southern California, 1990 (SCCWRP *et al.* 1992)

concentration of total PCBs was two to three times higher than at any other station in Santa Monica Bay and more than 30 times higher than the Dana Point reference site. This is similar to the DDT distribution pattern in white croaker tissue in which DDT levels in fish collected from the Palos Verdes sites were as much as 85 times higher than those collected from Santa Monica Bay. Thus, in 1990 the distribution of PCBs and DDT in white croaker were highly elevated in fish taken from Palos Verdes, but in contrast to the 1987 survey (Pollock *et al.* 1991) contaminant levels were not elevated in white croaker from northern Santa Monica Bay. Both these studies confirmed the results of Young *et al.* (1976a) and Gossett *et al.* (1983b), that the JWPCP outfall area is the primary source of DDT and PCB contamination in fishes in the Southern California Bight.

Temporal Trends

Metals. The temporal distribution of metals in Santa Monica Bay fishes has not been extensively studied, and long term trends are available for only a few species. One of the best surveys in recent years was conducted by SCCWRP (1992) for Dover sole near the HTP outfall to study the effects of sludge abatement in 1987. Concentrations of zinc, copper, cadmium, and silver were all low at "contaminated" sites near the outfall from 1986 through 1988 and only silver concentration decreased following sludge abatement (Figure 12-14). The concentrations of all metals analyzed in dover sole were equal to or less than the southern California average of the mainland shelf (SCCWRP 1992).

Organic Compounds. In general, the concentrations of DDT and PCBs in the muscle tissue of fishes collected in Santa Monica Bay and off the Palos Verdes Peninsula have decreased over the last 20 years (McDermott-Ehrlich *et al.* 1977, 1978; Sherwood *et al.* 1978; Smokler *et al.* 1979; LACSD 1988; Young *et al.* 1988b, Pollock *et al.* 1991, SCCWRP *et al.* 1992). Because of the historically high levels of these contaminants found in white croaker, and because of the extensive database that exists for this species, the temporal changes in DDT and PCB levels in white croaker are outlined below.

Between 1980 and 1990, DDT levels in white croaker from Santa Monica Bay have decreased or remained relatively constant, with the highest levels measured in 1981 from fish taken at Malibu (Figure 12-15) (SCCWRP *et al.* 1992). However, off the Palos Verdes Shelf, DDT levels have been consistently the highest of anywhere in the Southern California Bight (NOAA 1991b). Since the dumping of DDT was terminated in 1971-1972, the concentration of this contaminant in sediments surrounding the JWPCP outfall has declined (NOAA 1991a). The change in DDT levels in Palos Verdes sediments reflects the bioaccumulation in white croaker. For instance, in 1971, the mean DDT concentration in white croaker from the Palos Verdes Shelf averaged 39,000 ppb (Young *et al.* 1978), but had decreased to 7,629 ppb by 1980 (Schafer *et al.* 1984). There was no apparent change in DDT levels between 1981 and 1987 (Pollock *et al.* 1991). In 1990, DDT levels from white croaker collected at three sites on the Palos Verdes Peninsula averaged 11,580 ppb (Pollock *et al.* 1991), which was a significant increase from 1987 levels. This increase may have resulted from shifting sediments off the Palos Verdes Shelf, which could have exposed old reservoirs of DDT or possibly to differences in the biological condition of the fish at the time of analysis. Since PCBs and DDT tend to accumulate in the fatty tissue, differences in reproductive condition or annual migrations of white croaker may have contributed to the apparent increase from 1987 to 1990, but it is unlikely that there has been any "new" source of DDT to the area.

PCB levels in white croaker from Malibu and Point Dume have decreased since 1987, which may reflect the termination of sludge disposal from the HTP outfall in 1987 (SCCWRP 1992). However, PCB levels in white croaker at other locations throughout Santa Monica Bay have

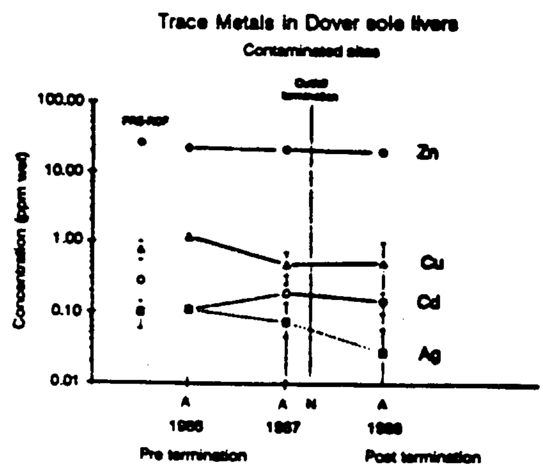

Figure 12-14. Concentrations of trace metals in liver tissue of Dover sole (*Microstomus pacificus*) from contaminated sites near the HTP 7-mile outfall, 1986-1988 (SCCWRP 1992).

VOL 12

1 5557

R0048862

changed little since 1981. On the Palos Verdes Shelf, PCB levels decreased markedly in white croaker tissue from 1975, when the average concentration was 2,780 ppb (Young *et al.* 1978), to 1980 when tissue levels averaged 383 ppb (Figure 12-16) (Schafer *et al.* 1982). These results reflect the decrease of PCB in Palos Verdes sediments (NOAA 1991a). In 1987, PCB levels in white croaker muscle (Pollock *et al.* 1991) were similar to those in 1980, but by 1990 levels at several locations had increased to approximately 1,500 ppb (SCCWRP *et al.* 1992). It is unlikely that there has been any recent input of PCBs through the JWPCP outfalls, but the apparent increase in white croaker PCB levels from 1987 through 1990 may have been due to seasonal differences in lipid content of white croaker or perhaps to the shifting of sediments on the Palos Verdes Shelf, which may have exposed old beds of the contaminant. The fact that PCB levels have not decreased since the early 1980s reflects the persistence of this contaminant over time and suggests that the Palos Verdes sediments act as a source.

SEAFOOD CONSUMPTION

Because of the persistence of contaminants in some fishes caught in Santa Monica Bay and the Palos Verdes Shelf, and because of the growing public concern over the consumption of seafood from the area, the SMBRP funded a seafood consumption study, which was conducted in 1991 and 1992 (MBC in prep.) to determine the amount and type of seafood that is being eaten from the Bay. The last seafood consumption study of Santa Monica Bay was conducted in 1980 (Puffer *et al.* 1981, 1982). However, since that time the health risks of consuming seafood from the Bay may have changed due to changes in seafood availability, species preference, and ethnic composition of the fishing population.

Recreational Fish Catch

In the 1992 study (MBC in prep.), surveyors identified 72 seafood species that were caught by recreational anglers during the summers of 1991 and 1992. The species caught in greatest abundance were chub mackerel, barred sand bass, kelp bass, white croaker, and Pacific barracuda. Chub mackerel was the most abundant fish caught from piers, private boats, and party boats, accounting for 51.9, 24.0, and 23.3% of the total catch, respectively. Of the fish caught from piers, white croaker was the second most abundant species, accounting for 18.2% of the total catch, followed by jacksmelt, and surfperches. Barred sand bass was the second most abundant species caught from party boats, accounting for 20.2% of the total, followed by kelp bass (16.4%) and Pacific barracuda (13.2%). Of the species caught from private boats, white croaker was the second most abundant species (16.6%) followed by barred sand bass (8.8%), kelp bass (8.5%), and Pacific barracuda (5.9%). Much fewer species were caught by beach anglers, but of these, sea mussels and Pacific purple urchin together accounted for nearly 90% of the total catch.

Demographic Profile of Santa Monica Bay Anglers

The demographic profile of the anglers that catch and consume seafood species from the Bay is used to determine the relative risks of different ethnic groups of eating contaminated seafood. In 1980, Puffer *et al.* (1981, 1982) found that the anglers in the Los Angeles area consisted mainly of caucasians (42%), followed by blacks (24%), Mexican-Americans (16%), Oriental/Samoans (13%), and "others" (5%). Of these 88% were male, primarily between the ages of 18 and 40. Similar to 1980, the majority (44%) of the anglers in 1991 and 1992 were white. However, the second most abundant anglers were hispanic (25%), followed by blacks (10%); Filipinos, Koreans, Chinese, Vietnamese, and "others" each accounted for less than 7% of the

VOL 12

1 5558

R0048863

total fishing population in the Bay. In 1991 and 1992, 86% of the anglers were male and most were between the ages of 25 and 45.

Seafood Consumption Rates

The health risks of consuming contaminated seafood from the Bay depends on the frequency and magnitude of food consumed and on the level of contaminants present in the consumed species. In the 1980 seafood consumption study, Puffer *et al.* (1981) found that, of the species caught by recreational anglers, California halibut, Pacific bonito, chub mackerel (listed as Pacific mackerel in Puffer *et al.* 1991, 1982), and opaleye were consumed the most. On average, anglers consumed 4.3, 1.9, 1.1, and 0.5 kg/person/month, respectively. White croaker was the fifth most abundantly consumed species, with anglers consuming an average of 0.4 kg of white croaker per person per month (Puffer *et al.* 1981).

The surveys conducted in 1991 and 1992 (MBC in prep.) suggest that the consumption habits of recreational anglers that fish in the Santa Monica Bay area have changed little in the last 10 years and that the differences that do exist probably reflect species availability. In 1991 and 1992, the species that anglers consumed the most were chub mackerel, Pacific barracuda, barred sand bass, and Pacific bonito. The "other" group, which consisted of Middle Easterners, Samoans, and Cambodians had the highest consumption rates, followed by blacks and Filipinos. However, the "other" group consumed virtually no white croaker, whereas blacks and Filipinos consumed the most.

Health Warning Awareness. To determine the effectiveness of health warnings posted by the Department of Health Services concerning the consumption of fish from Santa Monica Bay, recreational anglers in Santa Monica Bay were asked whether they were aware of the health warnings, and if so, what effect have they had on seafood consumption (MBC in prep.). Of the 925 individuals questioned in the 1991 and 1992 surveys, nearly 50% said that they were not aware of the health warnings (Table 12-2). Of the anglers that were aware of the warnings (468 individuals), 46% (217 individuals) said they had stopped eating some fish, 25% (115 individuals) said they ate less of all fish, 19% (87 individuals) said they stopped eating all fish, and 10% (49 individuals) said they ate less of some fish.

RISK ASSESSMENT

Approach

The first step in the risk assessment process is to define toxic hazards posed by the chemical contaminants in selected seafoods of Santa Monica Bay. The hazard and dose-response assessments result in the choice of the critical health effects on which to base the subsequent steps in the risk analysis. For example, the health effect of concern may be selected because it is the most severe adverse effect identified in the hazard assessment. Because cancer is a severe disease that may be initiated by relatively low levels of exposure to toxic chemicals, it is usually the health effect chosen for evaluating risks of any potentially cancer-causing chemical.

Contaminants of Concern

Information on concentrations of toxic chemicals in tissues of invertebrates and fishes of Santa Monica Bay was presented in previous chapters. The contaminants of greatest concern

Table 12-2. Responses of recreational anglers to seafood consumption warnings posted in Santa Monica Bay, 1991-1992 (MBC in prep).

Warnings Effect	Racial/Ethnic Category									
	Black	Korean	Filipino	Vietnamese	Chinese	Hispanic	Japanese	White	Other	Total

VOL 12

1 5560

relative to potential human health effects are DDT and PCBs. These contaminants exhibit the following characteristics (MBC 1988):

- High persistence in the aquatic environment
- High bioaccumulation potential
- Suspected as potential cause of cancer in humans based on mammalian bioassays
- Known sources of contaminant within Santa Monica Bay
- High concentrations in previous samples of both fish and invertebrates from various locations within the Bay.

Based on the data presented earlier, concentrations of metals in samples of fish muscle tissue from Santa Monica Bay are not sufficiently high to pose a problem. Chlordane and selected metals (lead, silver, cadmium, chromium, and mercury) in shellfish may pose a human health hazard, but data for edible tissues of harvested species are very limited. Therefore, subsequent steps in this risk assessment focus on PCBs and DDT (and related compounds).

Chemical Intake from Seafood Consumption

Because the seafood consumption study of Santa Monica Bay (MBC in prep.) has not yet been completed and because catch/consumption patterns undoubtedly vary over time, precise estimates of exposure to contaminated seafood have not yet been made. However, two studies (MBC 1988, Pollock *et al.* 1991) have analyzed the potential risks of eating seafood from Santa Monica Bay. In MBC (1988), a range of estimates of consumption was used to derive a range of contaminant doses for each of the selected seafood species and geographic locations. Risk estimates presented in a later section are related to a range of consumption values.

The calculated doses of total DDT and total PCBs from consumption of contaminated seafood correspond to selected consumption rates as follows (MBC 1988): a low estimate equal to the national average consumption of estuarine fish and shellfish (6.5 g/d = about 2 meals/mo), the 90th percentile value for each species [85.2 g/d = 22 meals/mo for white croaker, 334 g/d = 88 meals/mo for Pacific bonito; Puffer *et al.* 1981, 1982], and the 90th percentile value for all species combined (225 g/d = 59 meals/mo). The average serving of fish was assumed to be 0.25 lb (= 114 g). These consumption values were selected only for illustration purposes, and to develop the relationships between risk and consumption presented below. Estimates of average per capita consumption of fish and shellfish by the U.S. population generally range from 6.5 to 20.4 g/day (Pastorok 1988). Most estimates include fish and shellfish (mollusks and crustaceans) in marine, estuarine, and fresh waters, but marine species form the bulk of consumed items. Most estimates also include commercially harvested fisheries products. Also, estimates of average U.S. consumption do not account for subpopulations in coastal areas that may consume large quantities (>20 g/day) of locally caught fish or shellfish.

Risk Characterization

Estimates of excess cancer risk associated with long-term consumption of seafood from Santa Monica Bay (MBC 1988) were derived from estimates of toxic potencies for the selected contaminants (i.e., PCBs, total DDT) and chemical intake by sport fish consumers. It should be noted that consumption of fish and shellfish (including commercial products) is the major route of exposure of humans to PCBs (USFDA 1984, Humphrey 1987). In contrast, exposure of humans to DDT and related compounds occurs through a variety of foods and, in some subpopulations (e.g., farmers, pesticide applicators), through use of pesticides. When interpreting the risk estimates presented below, remember that they represent approximate (order of magnitude) estimates of a plausible upper limit to lifetime cancer risk for the specific chemicals and exposure conditions (i.e., a selected seafood species, harvest location, and consumption rate). The real health risks may be much lower than those shown. Because an individual's chance of having cancer is influenced by factors other than PCB and DDT exposure via seafood consumption (e.g., cigarette smoking, hereditary factors), the risk estimates presented below represent additional risks associated only with the exposure route of concern (i.e., ingestion of seafood from Santa Monica Bay).

Cancer Risk Estimates

The potential upper-limit risks of cancer associated with consuming selected seafood species from some areas of Santa Monica Bay (MBC 1988) are shown in Figures 12-17 and 12-18. The plausible-upper-limit risk is shown as a function of consumption rate to illustrate the relative importance of consumption rate and to allow evaluation of risks based on various consumption rates. Each shaded area in the figure is based on the range of total concentration of PCBs and DDT (including DDD and DDE) in muscle tissue for the species and locations noted. Data on contaminant concentrations in edible fish tissue were available for several locations (Figures 12-17 and 12-18), including frequently used fishing piers and several offshore areas Santa Monica Bay; a party boat fishery; the Palos Verdes Peninsula (PV); trawl transects T-3 and T-5 within 5 km of the JWPCP outfall sampled by Los Angeles County Sanitation District; and the JWPCP outfall area (WP), which may not normally be used by recreational anglers. Each shaded area (Figures 12-17 and 12-18) represents information for two or more locations with the same general range of risk (i.e., high, medium, or low). A separate line is not shown for each location because the risk estimates are not precise and individual replicate data to test for statistical differences among areas were not available.

To interpret Figures 12-17 and 12-18, choose a consumption level (on the horizontal axis) that corresponds to the average frequency of the seafood species in the diet. The consumption rate is the average consumption rate for a 70-year lifetime, but exposures for less than 70 years can easily be calculated. For example, if it is assumed that the seafood of interest is eaten once per month (i.e., one 0.25-lb serving per month) for only 7 years, then the average lifetime (70 years) consumption rate is one-tenth (7 divided by 70) the short-term rate, or 0.025 lb/month. Find the region of the shaded area for the fishing location of interest that corresponds to the consumption rate selected. Then read the range of risk estimates (on the vertical axis) that corresponds to the selected consumption rate and harvest area. Comparisons with health risks from other foods and common activities can be made using Figure 12-19 (also refer to the section, Comparison of Santa Monica Seafood Risks with Other Risks).

Based on the risk analysis by PTI in MBC (1988), consumption of seafood from the JWPCP outfall area and the surrounding areas of the Palos Verdes Peninsula poses the greatest risk of cancer from total DDT and PCBs combined. Total DDT accounted for more than about 35% of the total cancer risk associated with total DDT and PCBs in white croaker at only the Palos Verdes Peninsula area. Consumption of white croaker from areas offshore of Hermosa Beach also posed a relatively high risk. Cancer risks associated with consuming white croaker from offshore Santa Monica Bay (Figure 12-17) were moderate relative to other study areas; nevertheless, they were about the same as risks associated with the consumption of white croaker representing the average contamination at six Los Angeles Harbor sites combined (including party boat samples

All risk estimates were taken from Wilson and Crouch (1987) except: peanut butter, English sole, trout, steak (Pastorok et al. 1986); sidestream cigarette smoke (Papanek 1988, pers. comm.); white croaker and bonito (present study).

Average annual risk estimates from Wilson and Crouch (1987) were multiplied times the uncertainty factor given by the authors to convert them to upper-limit estimates and by a factor of 70 years to convert them to lifetime risks. Data were not available to calculate cancer risk estimates associated with swimming in Santa Monica Bay.

5565

analyzed by Gossett *et al.* (1983a)]. Marina del Rey and the Venice and Redondo Piers also presented moderate risk levels relative to other areas. The lowest risk levels for croaker occurred at the Malibu/Santa Monica Piers, which exhibited risk estimates slightly lower than the control areas at Orange County and Dana Point.

The relative risk of consuming Santa Monica Bay seafood as estimated by PTI in MBC (1988) is similar to that estimated by Pollock *et al.* (1991). For instance, Pollock *et al.* (1991) estimated that the excess lifetime risk of consuming white croaker from White Point was 1 in 1,000 (1.0×10^{-3}), which is the same as that estimated by MBC 1988 (Figure 12-17). However, the two risk assessments cannot be compared directly because of differences in PCB and DDT contaminant levels, the PCB carcinogenic potency factors, and theoretical seafood consumption rates.

Pollock *et al.* (1991) developed site-specific recommendations for seafood consumed from several areas in Santa Monica Bay and the Palos Verdes Shelf (Table 12-3), and species-specific recommendations for the most frequently caught and consumed fishes in the area (Table 12-4); recommendations were based on contaminant levels in fishes collected in 1987 (Pollock *et al.* 1991), where one meal consists of six oz (170 g) of fish. The recommendations are meant to provide guidance to anglers as an indication of how often to fish in an area and how often to eat a specific fish species caught at a site (Pollock *et al.* 1991).

Summary of Assumptions and Uncertainties

Faced with the many uncertainties and assumptions in risk assessment, an estimate of the plausible upper-limit to cancer risk was derived above to evaluate potential human health effects related to consumption of contaminated fish. A similar approach is commonly used by EPA and other agencies as the basis for environmental regulations. This ensures that health risks will not be underestimated. Although the absolute risk may often be overestimated by as much as 1,000 times (or even 10,000 times in some circumstances), the plausible-upper-limit approach is appropriate to ensure adequate protection of human health. Assumptions inherent in this risk assessment are summarized in MBC (1988).

Because of the differences in habitat, feeding habits, and trophic position, white croaker and Pacific bonito were selected in MBC (1988) to represent a wide range in assessing the health risks associated with consuming seafood from the Bay. White croaker are probably more indicative of specific areas of the Bay because of their limited movements and benthic feeding habits. In contrast, Pacific bonito are highly mobile species. Consequently, major differences in contamination of white croaker among areas are found, whereas little spatial variation in contamination of Pacific bonito is expected.

In the analyses on which Figures 12-17, 12-18, and 12-19 were based, the effect of cooking on contaminant concentrations was not taken into account. The effect of cooking on the ultimate health risk from a mixture of chemicals (including any transformation or degradation products produced by heating) is not completely understood. Some studies have shown decreases in concentrations of lipid-soluble organic compounds such as DDT and PCBs following pan-frying, broiling, or baking of fish fillets (Smith *et al.* 1973; Skea *et al.* 1981; Puffer and Gossett 1983).

Because of the limitations of risk assessment, emphasis should be placed on relative risk comparisons. For example, comparisons among fishing areas are valuable for developing perspectives for environmental advisories such as guidance on choices of fishing location and

1 5568

target species by individual anglers. Statistical differences in PCB and DDT concentrations in fish tissue among fishing areas were demonstrated by Gossett *et al.* (1983a). Nevertheless, caution should be exercised in interpreting upper-limit risk estimates presented in Figures 12-17 and 12-18. Contaminant concentration differences on the order of those between Hermosa Beach and the JWPCP outfall area or between the Redondo Piers and the offshore Santa Monica Bay station are likely to be nonsignificant. Thus, risk estimates for these pairs of areas (and other pairs of areas differing by a similar magnitude of contamination) in Figure 12-17 should be considered as roughly equal.

Comparison of Santa Monica Bay Seafood Risks with Other Risks

Are Santa Monica Bay seafoods hazardous to your health? Although this question is on the minds of many scientists, environmental managers, and anglers, it is impossible to provide a simple answer. The answer to this question depends on five factors: 1) the location of interest (e.g., outer bay vs. the outfall areas vs. fishing piers), 2) the species of interest (open-water species vs. bottom species), 3) the chemicals responsible for contamination, 4) seafood consumption rate, and 5) the risk level considered "acceptable" or tolerable by an agency or the individual consumer. Despite our best efforts, society will never achieve a world of "zero-risk," especially relative to food quality (e.g., see Ames 1983).

Despite the limitation of this assessment (many of which are inherent in any risk assessment), the data are adequate to support the conclusion that significant risks of potential health effects may result from relatively high consumption of bottomfish and lipid-rich species harvested from certain locations within the study area. Concentrations of total DDT and PCBs in fish from within the study area are clearly elevated above "background" concentrations at control sites.

To aid interpretation of the risk estimates presented above, health risks from consumption of other foods and from other common activities are presented in Figure 12-19 [based mainly on data in Pastorok *et al.* (1986) and Wilson and Crouch (1987)]. Against a background of an average lifetime risk on the order of 2 to 3 in 10 (20 to 30%) per individual for all cancers from all causes, an additional lifetime cancer risk of one in a million or less is generally considered tolerable by environmental regulatory agencies (Travis *et al.* 1987). An additional lifetime cancer risk above about one in a thousand is generally considered unacceptable. Risk levels on the order of one in ten thousand to one in one-hundred thousand have often led to development of environmental regulations on chemical releases and exposure of humans. Regulatory decisions regarding contamination of food products have sometimes been based on risk levels up to 1 in 1,000 to 1 in 100.

Although the potential health risks of eating fish from Santa Monica Bay are high in some cases (Table 12-4), other foods and activities may pose substantial risks (greater than 1 in 1,000). Considering that the usable protein content of Santa Monica Bay fish, steak, and peanut butter are roughly similar, substitution of the latter two protein sources for locally harvested fish may not substantially reduce cancer risk.

CHAPTER 13
SUMMARY, STATUS AND TRENDS

The information presented in Chapters 1 through 12 describes in detail the sources of contamination to and the nature of developments in the study area; the distribution of contaminants and developments in space and time; and the actual impacts which are known or suspected to have resulted from the contamination, development, and use of Santa Monica Bay.

This chapter emphasizes the major trends of concern and those issues which have given rise to the Action Plan Elements being developed by the Santa Monica Bay Restoration Project (Table 13-1). Like the body of the report, this chapter includes three major topics (sources, distribution, and impacts of contamination) which are arranged in that order. The sources of contaminants will be addressed by Action Plan Elements IA, IB, and ID of Table 13-1. These elements deal with mass emissions, pollution prevention, and municipal and industrial discharges.

POINT SOURCES

Point sources relate primarily to Action Plan Element ID of Table 13-1, Municipal and Industrial Discharges. Seven facilities operate point sources of contamination and potential impacts to Santa Monica Bay under NPDES permits.

Generating Stations

The three generating stations use seawater to cool condensers, discharging it back to the Bay at somewhat elevated temperatures. Redondo, Scattergood, and El Segundo Generating Stations have all been operating for more than 20 years. No long-term, widespread impacts have been attributed to the thermal waste from them, individually or collectively. The small amounts of contaminants which originate in the plant are generally well below the NPDES-permitted limitations and do not constitute a threat to the local biota.

Each year a seemingly large number of plankton (one to two billion) are entrained into the cooling water flow, where they are usually assumed to suffer in excess of 99% mortality. However, despite the large numbers, there is no indication that these losses have affected the local population size even though individual units at the plants have been operating for 20 to 40 years. White croaker generally suffer the greatest entrainment losses and yet they are also among the most abundant offshore species.

Adult fishes are also impinged and killed on protective screens across the intake conduit. These losses, as much as 78,000 individuals per year at El Segundo, also seem high; but the most commonly impinged species - queenfish - is also among the most common species offshore; thus no population-level impact can be ascribed to the stations.

Oil Refinery

Chevron USA operates an NPDES-permitted ocean outfall from its El Segundo refinery which discharges an average of about 8 million gallons of wastewater to the Bay each day. Chevron's on-site treatment facility became operational in the 1970s and has been upgraded several times since then. At present operational wastes are fully treated before being discharged; storm runoff is treated in oil/water separators with induced air flotation units.

VOL 12

1 5571

The most abundant constituents in the present effluent are COD, BOD, and TSS, with annual mass emissions of about 1,800, 125, and 100 MT, respectively. The effluent has only exceeded permitted limitations on three occasions in the last 7 years. At present the wastewater outfall discharges in about 20 ft of water, less than 200 ft from shore. However, Chevron is in the process of relocating the outfall to a point 3,500 ft from shore in approximately 60 ft of water.

Wastewater Treatment Plants

Hyperion Treatment Plant (HTP) and Joint Water Pollution Control Plant (JWPCP) are among the four largest municipal wastewater treatment plants in southern California; both discharge treated domestic sewage to the study area. In the past these discharges were unquestionably the major point sources of contamination to Santa Monica Bay. However, effluent concentrations and mass emissions from both facilities have declined significantly since the early 1970s, following the creation of the USEPA and enactment of the Clean Water Act.

Hyperion Treatment Plant

HTP treats wastewater from most of the City of Los Angeles' 3.5 million persons and tens of thousands of businesses and industries.

The flow from HTP's 5-mile outfall has generally increased over the years, from about 200 million gallons per day (mgd) in 1950 to over 400 mgd in 1983. However, the flow has declined steadily since 1983, to just under 300 mgd in 1992 (Figure 13-1). Between 1974 and 1987 (when it was discontinued) an average of 4.4 mgd of mixed secondary effluent and digested sewage sludge was discharged to the head of Santa Monica Submarine Canyon through HTP's 7-mile outfall.

Mass emissions of key organics indicators (suspended solids, BOD, and settleable solids) through the 5-mile outfall also increased steadily through the mid-1980s, peaked in 1985 and have declined since then (Figure 13-2). The mass emission of BOD, for example, was about 140,000 metric tons (MT) in 1985 but has been below 50,000 MT since 1988.

Mass emissions of nutrients were relatively stable from the mid-1970s to the mid-1980s, at which time they decreased sightly (Figure 13-2). The increase in ammonia is attributed to treatment improvements, digestion which converts nitrates to ammonia.

Mass emissions of most trace metals declined between 1974 and 1986, although the annual variability was great (Figure 13-2). Since 1988 mass emissions have been consistently low, in some cases not detectable.

The mass emissions of DDT and PCBs declined dramatically in the late 1970s, displaying a 3-5 year lag behind legislative source control which limited their use and manufacture (Figure 13-2). Mass emissions have been very low (sometimes undetected) since 1982.

The general decline in the mass emissions of most contaminants between 1974 and 1986-87 reflect source control of various sorts; the dramatic decreases in 1987-1988 coincide with better solids removal (suspended and settleable solids) to which the contaminants bind.

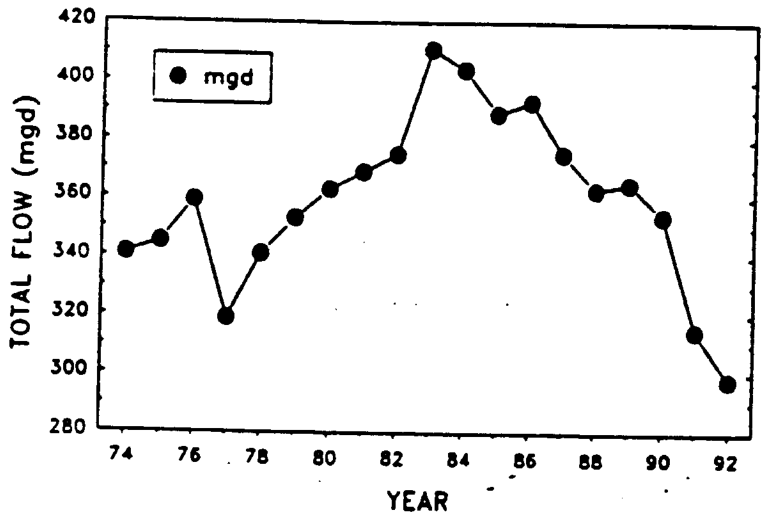

Figure 13-1. Average flow from the HTP 5-mile outfall, 1974-1992. (Data from Mitchell and McDermott 1975; Schafer 1976, 1977, 1978, 1980, 1982, 1984; SCCWRP 1986c; CLA,DPW 1987, 1988, 1989, 1990, 1991, 1992).

VOL 12

1 5574

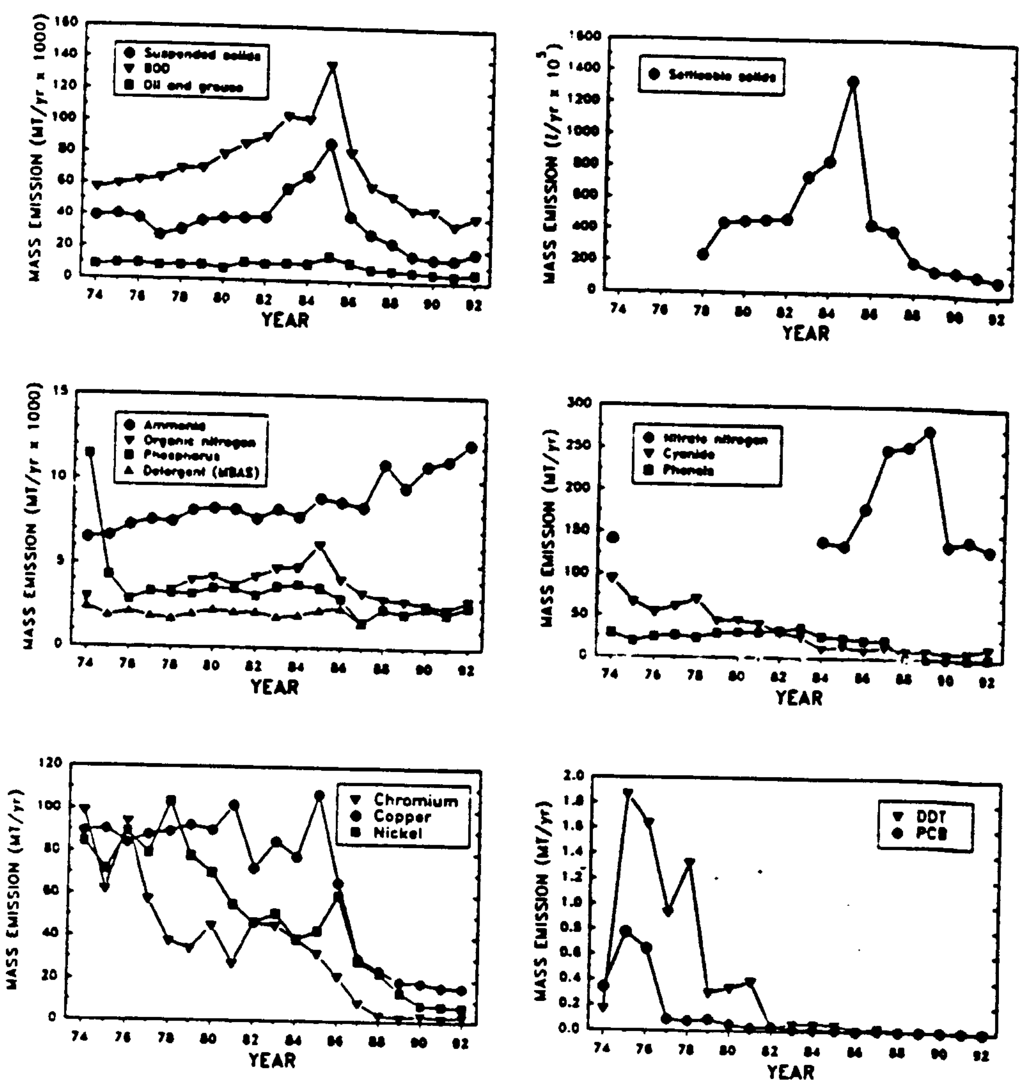

Figure 13-2. Annual mass emission rates of selected contaminates discharged from HTP 5-mile outfall from 1974-1992. (Data from Mitchell and McDermott 1975; Schafer 1976, 1977, 1978, 1980, 1982, 1984; SCCWRP 1986c; CLA,DPW 1987, 1988, 1989, 1990, 1991, 1992).

Joint Water Pollution Control Plant

(JWPCP) treats wastewater from a population of about 5 million people and 70,000 businesses and industries, most of Los Angeles county which is not serviced by HTP.

Flow from JWPCP to the Palos Verdes Shelf generally increased from about 340 mgd in the mid-1970s to about 370 mgd in the late 1980s (Figure 13-3). In 1991 and 1992 the flow declined and averaged 330 mgd.

Mass emissions of key organics indicators (suspended solids, BOD, and settleable solids) from JWPCP decreased steadily from 1974 to 1982, exhibited a spike in 1983, and continued to decline (although not as quickly as earlier) from 1984 to 1990. Mass emissions increased slightly in 1991 and 1992 (Figure 13-4).

Mass emissions of ammonia remained almost unchanged from 1974 to 1992, whereas organic nitrogen and phosphorus declined steadily from the mid-1970s to 1985, and have been stable since then (Figure 13-4).

Mass emissions of most trace metals declined steadily between 1974 and the late 1980s. There are indications that the mass emission rates have reached a plateau and will not decline more without major changes in the treatment process (Figure 13-4).

The mass emissions of DDT from JWPCP decreased 80% between 1974 and 1975, reflecting a lag with respect to the cessation of its disposal to the treatment system in 1971 (Figure 13-4). DDT levels have been very low since 1985 and often are not detected. The mass emissions of PCBs declined steadily between 1974 and 1985 and have also been very low (sometimes undetected) since then.

The very gradual, but steady, decline in mass emissions of most contaminants from JWPCP in the last 20 years reflect better source control as well as improved treatment technology, especially solids removal.

Tapia Water Reclamation Facility (TWRF)

TWRF provides primary, secondary, and tertiary treatment for as much as 10 mgd. Sludge is treated by aerobic digestion and either pumped to land-injection farms, or dewatered and disposed at land-fills.

TWRF's NPDES permit allows only tertiary-treated and completely pathogen-free wastewater to be discharged to Malibu Creek. The flow to Malibu Creek has averaged 2.7 mgd since 1974 and 2.5 mgd over the last five years.

NONPOINT SOURCES OF CONTAMINANTS

Nonpoint sources relate primarily to Action Plan Element I-A and I-B of Table 13-1, mass emission and pollution prevention measures. Nonpoint sources of contamination are, by definition, diffuse, unpredictable, and difficult to quantify. In the past runoff was strictly considered a nonpoint source, However, recent legislation now treats storm drains as point sources in the sense that they require NPDES permits. Although effluent does enter the receiving waters at a single point, they will always be nonpoint in the sense that contaminants enter the storm drain in a diffuse, irregular, and unpredictable (i.e. nonpoint) manner.

VOL 12

1 5577

Marine Vessel Activities

Contaminants which enter the waters of Santa Monica Bay through the operation of marine vessels includes oil and refined petroleum products; antifouling paint additives (zinc, chromium, copper, mercury, arsenic, PCBs, and tributyl tin); trace metals from sacrificial anodes; lead from leaded marine fuel; PAHs from the combustion of fuel; and human enteric wastes.

The most remarkable fact about this potential contamination is that it is nonpoint and virtually impossible to quantify. Except for the enteric bacteria which result from illegal discharges of holding tanks or toilets, most derive from normal operation of the source vessels. Stricter enforcement of regulations will help reduce the input, as will careful evaluation of the use and effects of specific substances. Thus, TBT was banned from use on small vessels which are moored in confined marinas for long periods of time. TBT is still being released as old paint is scraped or sloughed off, but new sources are not being added.

Oil and Hazardous Materials Spills

This section relates directly to Action Plan Element IE, prevention of and response to oil and hazardous waste spills to Santa Monica Bay. Because there are no large, commercial ports and few large commercial vessels in the study area, the risk of oil spills from tankers or ruptured fuel tanks in the study is relatively low.

Spills are required to be reported to the US Coast Guard, which recorded an average of 6 spills per year from 1973 to 1987. These totaled less than 2,000 gal, and were primarily fuel oil and crude oil. The largest spill in that period of time was 1,000 gal of crude oil from a tanker offshore El Segundo and most of it was recovered. In 1991 approximately 9,000 gal of diesel-based cutting oil spilled from a ruptured pipeline off El Segundo; some of this product reached shore in Malibu, although no serious impacts were reported.

For comparison, it has been estimated that an average of about 10 barrels (420 gal) of oil from natural submarine oil seeps off Redondo Beach and Manhattan Beach reach the surface each day. Additional amounts do not reach the surface, either deteriorating or forming tarballs.

In 1990, the Lampert/Keene/Seestrand Oil Act (SB2240) was passed. Among other things the Act established an Oil Spill Prevention and Response (OSPR) group within the California Department of Fish and Game. OSPR is now engaged in establishing baseline data and enforcing development of contingency plans by every oil facility, transporter, and vessel in State waters.

Dredging and Dumpsites

The dumping of unwanted and hazardous waste materials at sea has been largely prohibited since 1972, although some illegal activities have taken place since then. However, none of the 15 formerly permitted dumpsites in southern California is in the study area. It is virtually impossible to estimate what kinds and amounts of materials have accumulated on-bottom, much less what fraction may some day be resuspended or dissolved and enter the ecosystem.

At present dredged materials from Los Angeles and Long Beach Harbors are dumped at a permitted site (LA-2) which is just outside the study area. From 1978 to 1988 an average of about 180,000 cubic yards per year of dredged material was disposed of at LA-2. LA-2 was recently re-opened for use, but no contaminated materials will be permitted to be dumped.

Theoretically materials from LA-2 could move into Santa Monica Bay, but no estimates have been made of this potential.

Aerial Fallout

Aerial fallout is probably the most diffuse contaminant source and the most difficult to quantify. Studies in the 1960s and 1970s indicated that the mass emissions of lead, mercury, and manganese from aerial fallout might exceed those from point sources. However, only a few studies of aerial fallout have been conducted locally in the last 15 years.

Knowledge of the emission rates in aerial fallout is academic, however, since the only way to regulate aerial fallout is by the application of source control measures at the site(s) where the contaminants enter the atmosphere. The levels of lead in aerial fallout undoubtedly decreased after the use of leaded gasoline was restricted, just as the mass emissions of DDT to Santa Monica Bay decreased after DDT process wastes were no longer disposed of at landfills on Palos Verdes Peninsula.

Storm and Urban Runoff

Material in this section relates to Action Plan Element IC of Table 13-1, comprehensive stormwater and urban runoff management program. Unlike some metropolitan areas, the City and County of Los Angeles have separate sewage and storm drain systems. The sewage system is too small to handle the uncommon, but sometimes torrential rains, although storm runoff does infiltrate and overload the sewage system on occasion. Overflows of sewage caused by storm runoff may result in raw, untreated sewage entering Santa Monica Bay through storm drains.

Legislation now treats storm drains as point sources (the effluent does enter at a single point), but they will always be nonpoint in the sense that contaminants enter the storm drain in a diffuse, irregular, and unpredictable (i.e. nonpoint) manner. Thus, until the flow in major storm drains is retained and treated, there is no effective way to control contaminant levels except by upstream source control – i.e. policing all sites where contaminants enter the drainage.

The kinds and amounts of contamination in storm/urban run-off to Santa Monica Bay were estimated for the major drainages in 1983, 1984, and 1989 (Table 13-2). However, it is not possible to accurately extrapolate the results of just a few surveys (usually conducted during periods of high runoff) to the many small drains and various flow conditions which prevail through the year and study area.

Above all else, these studies confirm that many contaminants remain high in storm/urban runoff. Thus, as wastewater treatment becomes more effective and mass emissions decrease from them, the relative contribution of contaminants via runoff have become greater, even though the absolute amounts have not increased.

Storm/urban runoff is somewhat unique in that it contributes indicator bacteria to the nearshore of Santa Monica Bay (Table 13-2). Bacteria from HTP and JWPCP do not ordinarily reach shore, where the potential threat to humans engaged in direct body-contact activities is greatest. However, numerous studies have confirmed that bacteria are abundant in stormwater and are most concentrated in the vicinity of stormdrains and the mouths of streams to the Bay.

Note: Mass emissions for 1989 was calculated by adding monthly mass emissions. When parameter was not detected during a particular month, half the minimum detection level was used. Selenium, aldrin, lindane, dieldrin, Heptachlor, heptachlorepoxide, Endosulfan, and Endrin were all not detected at Ballona Creek and not analyzed at Malibu in 1989.

BOD was not analyzed throughout 1989 at Malibu.

Data not available for DDE, DDD, and DDT in 1989.

* TOC - Total Organic Carbon

** BOD - Biochemical Oxygen Demand

As in the case of aerial fallout, the only effective way to reduce contaminant input via storm/urban runoff is to impose stricter upstream source control measures. While the upstream sources of some contaminants have been identified (at least generally) the exact upstream sources of bacterial contamination have not.

DISTRIBUTION OF CONTAMINANTS

This section contains material which relates to Action Plan Element I-F of Table 13-1, remediation of contaminated sediments. Most contaminants reach Santa Monica Bay in an aqueous medium; a few are dissolved in water but most are attached to particulates which are suspended in water. Once in the Bay the organic or inorganic particulates are re-distributed to some extent, but tend to settle out of suspension and accumulate on-bottom according to two basic criteria: close to their point of entry, and in depositional environments (quiet water where contaminant-bearing particulates settle out of suspension). The so-called "hotspots" of contamination reflect these criteria.

In Santa Monica Bay hotspots are found in the vicinity the HTP and JWPCP outfalls, in embayments such as Marina del Rey, King Harbor, and Ballona Lagoon, and (temporarily) at the mouths of streams and stormdrains. Hotspots began to develop around wastewater outfalls as soon as the outfalls became operational: in 1937 at the JWPCP outfalls on the Palos Verdes Shelf; in 1951 at the HTP 5-mile outfall; and in 1957 at the HTP 7-mile sludge outfall to Santa Monica Submarine Canyon.

Especially high levels of DDT and PCBs were discharged through the JWPCP outfalls until the mid-1970s, several years after the discharge of process wastes to the sewage system was discontinued. However, JWPCP has continued to discharge less-than-secondary treated effluent since then and solids in the (cleaner) effluent have settled out of suspension to cover the highly contaminated sediments. DDT and PCB levels are now highest 6 to 12 inches beneath the sediment surface and are almost undetectable at the surface. While this may have temporarily sequestered the contaminants and kept them from being incorporated into the food web, they remain in the area and are potentially available to be resuspended and reintroduced into the ecosystem.

Fortunately, hotspots of chemical degradation can and do recover once the input of contaminants is curtailed or reduced. This has been observed world-wide and in the study area, as the contaminated sediments are resuspended (through bioturbation or water motion) and are carried by ocean currents out of the area.

In 1987 HTP ceased discharging sludge into Santa Monica Submarine Canyon and in 1988 the sludge field was as much as 140 cm (4.6 ft) deep. Indicators of organic enrichment and contaminant levels were elevated over an area of 20 mi^2 However, sediment sulfide levels decreased within nine months after the discharge was terminated and were only slightly above background values. Within a year organic carbon values decreased 23%, nitrogen 29%, PCBs and PAHs about 48%, and trace metals from 53 to 59%. DDT concentrations actually increased, however, perhaps as surface materials were removed, exposing underlying deposits. By 1990 1 cm of cleaner sediment had covered the sludge.

The mouths of streams and storm drains into Santa Monica Bay constitute point sources which probably create temporary hotspots of contamination. Although appropriate time-series studies have not been conducted just offshore of drains to confirm this, it is expected that the hotspots would only last (in the Bay itself) for a few days after the input has ceased. The concentrations of organic and inorganic substances (for example, oil and grease from roads and parking lots) would be reduced through dilution and dispersion, aided by the stream flow itself as well as the wave energy and currents in the nearshore environment. The reduction in bacterial concentrations would accelerate because of the natural die-off of the organisms in seawater.

Marina del Rey, King Harbor, and Ballona Lagoon are not only depositional locales, but include the mouths of streams or drains which discharge runoff. Thus contamination levels are affected by both criteria for hotspots. Fortunately, they are all relatively small and contaminated sediments can (theoretically) be dealt with readily; in fact some accumulations of toxic substances have probably been removed during maintenance dredging at Marina del Rey and King Harbor.

Contaminant levels in Marina del Rey have fluctuated in recent years, possibly because they derive from nonpoint, and therefore unregulated, sources. Even though its use is banned, for example, the insecticide chlordane is highly concentrated; it may be leeching out of previously treated wooden structure. The limited exchange with the Bay proper reduces the likelihood that existing levels will be reduced by dilution or dispersion.

HABITAT IMPACTS

The impacts summarized in this section provide information which relates to Action Plan Elements IIIA-IIID of Table 13-1, to restore, protect, and manage habitats and watersheds.

Subtidal Benthos

Infaunal assemblages were used to evaluate the "health" of the seafloor even before analytical chemistry was used to monitor contaminant levels directly. Both scientists and lay persons are usually more interested in the effects of pollution on the living resources than in the chemical concentrations themselves. Because the contaminants can be passed up the food web to humans, there is also an indirect concern for their own well-being.

The infaunal assemblages which have inhabited the sediments around HTP and JWPCP outfalls reflect the contamination levels in those sediments. They also reflect the improvements in sediment quality which have taken place during the last 20 years.

As early as 1952 the area around HTP's 1-mi outfall supported infaunal assemblages which were progressively degraded with proximity to the discharge. The assemblage was unaffected 8 mi from it; enrichment characterized the infauna at 1.9 to 4.5 mi away; and within 0.3 mi of the outfall was an impoverished zone. In 1957, the bottom near JWPCP outfalls on the Palos Verdes Shelf was described as "foul" and lacking several important animal groups.

In 1977 benthic communities throughout the study area were characterized using the "Infaunal Index" as being normal, changed, or degraded (Figure 13-5). Eighteen and a half mi^2 of bottom surrounding the HTP outfalls were considered changed, and within this area, 1.2 mi^2 (around the HTP 7-mile outfall) were considered degraded; no degraded communities were observed near the 5-mi outfall. Approximately 33 mi^2 around the JWPCP outfalls on the Palos Verdes Shelf and extending north past Redondo Submarine Canyon were changed, 3.5 mi^2 immediately adjacent to the outfalls were degraded.

By 1991 only 9 mi^2 of bottom in the vicinity of the HTP outfalls were considered "affected" and less than 1 mi^2 next to the (now unused) 7-mile sludge outfall was considered degraded. These represent a 50% reduction in the total area affected by HTP effluents; by 1991 diversity of

VOL 12

VOL 12

1 5583

R0048888

the infauna had improved throughout the area, just since 1985. All these improvements are attributed to the reduction of mass emissions from HTP: abatement of sludge disposal from the 7-mile outfall, and improved effluent quality from the 5-mile outfall.

Demersal Fish Assemblages

Between 1957 and 1975 the abundance and diversity of demersal fishes were low near both HTP outfalls, but from 1976 to 1979 species richness, biomass, and the size of individual fish were all greater in the 7-mile sludge field than in reference areas. From 1984 to 1986 biomass and abundance were generally high near the outfalls and white croaker was the dominant species, although it was not elsewhere in the Bay. In 1989 and 1990 the numbers of species and individuals were both depressed in the vicinity of the outfalls.

Although the above community-wide measures do not indicate clear recovery at either outfall, examination of individual species suggests that replacement often takes place according to individual species prey preferences. Crustaceans (which are the preferred prey of most common demersal fish) are uncommon near outfalls and so also are species which feed on them. Hornyhead turbot and English sole feed primarily on infaunal polychaetes and mollusks, which dominate near outfalls, and those fish species are also often dominant near outfalls.

Between 1970 and 1976 the abundance and diversity of demersal fishes near the JWPCP outfalls on the Palos Verdes Shelf were severely depressed, however, by 1985 and 1986 the assemblage was showing marked signs of recovery. Previously rare or uncommon species were becoming common while previously abundant species (indicators of outfalls) were becoming less common. These changes coincided with improvement in JWPCP's effluent quality and in changes in the availability of infaunal prey (crustaceans vs. polychaetes) which the fish consumed.

Beaches and Rocky Intertidal Habitats

Prior to development, the coast between Santa Monica and the Palos Verdes Peninsula consisted primarily of sand dunes and sandy beaches, which were moved around by air and water currents. Beach sand is naturally moved offshore by longshore currents; sediment needed to replenish the beach sand lost down submarine canyons was replenished by rivers and creeks flowing into Santa Monica Bay. Dunes behind the beach also supplied sand and provided a buffer between the shoreline and inland development.

The development of coastal structures impacted longshore sediment transport and channelization of drainages reduced the sediment input. These factors, along with rising sea level, have combined to redistribute the available material and erode local beaches to the point that recreation and coastal development are threatened.

Beach nourishment has ameliorated the condition in some places: more than 30 million yd^3 of material have been placed on beaches in Santa Monica Bay since 1938, much excavated from nearby dunes and construction projects or dredged from Marina del Rey. Recently, however, sediments in Marina del Rey were found to be too contaminated with lead and other metals for beach nourishment. Therefore, dredged material has been dumped offshore, to be distributed by longshore currents. Shoreline erosion and accretion continue to be studied in search for methods to protect and restore the beaches of Santa Monica Bay.

Beaches provide habitat for certain species which are of special concern specifically because of the loss of habitat in southern California. The Federal government lists the California

VOL 12

1 5584

least tern and the El Segundo Blue (butterfly) as endangered and the Western snowy plover as threatened. California least terns and Western snowy plovers both nest on beaches and salt flats which have been heavily developed and used for recreation. The El Segundo Blue is severely imperiled, as it is restricted to sand dunes where its host plant is found. Other species are being studied because their numbers are declining: the wandering skipper butterfly is another dune inhabitant and the black abalone is found on rocky shores.

Projects underway to protect the California least tern include providing appropriate and undisturbed nesting habitat near suitable foraging areas. One such site at Venice Beach has been very successful, even though it is located on a well used beach. Other potential nesting sites are being identified to further expand the least tern population, including one in the Ballona Wetlands and one at Dockweiler Beach. No projects have been implemented or proposed for Western snowy plover; however, since its nesting requirements are similar to those of the California least tern, future restoration projects may be designed for both.

Efforts to protect the El Segundo Blue have included preserving a small dune area near the western end of LAX and maintaining the population of the butterfly's host plant, the coastal wild buckwheat. Restoration of additional dunes and halting the spread of invasive plants (which displace the buckwheat) will help survival of this species.

More than 50 million people visit the beaches of Santa Monica Bay each year. The beaches between Santa Monica and Redondo Beach receive the heaviest use, as they are most accessible to inland populations. Beaches and rocky intertidal tidepools are used as classrooms by students and naturalists; they also provide bait for fishermen and food for some ethnic groups.

As human use of the beaches and waters of Santa Monica Bay increases, so does trash and the need for beach clean-up, including (unfortunately) the removal of natural debris such as drift kelp which is a natural part of the marine nutrient cycle. The increase in the user population has also meant more marine vessel spills and greater contamination from urban runoff. Floatable materials may impact intertidal species such as California grunion which lay their eggs on beaches. Contaminants may also find their way into the food web, potentially impacting the entire ecosystem.

Kelp Beds

Kelp beds along the Palos Verdes Peninsula began to decrease in size shortly after the first JWPCP outfall became operational in 1937; degeneration began near the outfall site at White Point and spread outward from there. There has been a strong inverse relationship between kelp coverage and mass emissions of total suspended solids (TSS) from JWPCP, and when TSS levels declined between 1974 and 1987, kelp coverage increased. However, the impact of large, destructive storms cannot be discounted as a major factor, as was clear in 1983 and 1988 (Figure 13-6).

Wetlands

Wetlands are covered periodically or permanently with shallow water, and include freshwater, saltwater and brackish water marshes, swamps, and mudflats. Marine wetlands develop where streams enter the ocean across a low, flat coasts and are modified by variable salinities and the tidal cycle. Wetlands help mitigate flooding, filter and recharge groundwater, and provide feeding and breeding habitat for fish and waterfowl. In the past, wetlands were

VOL 12

1 5585

VOL 12

1 5586

R0048891

considered useful only for more "constructive" purposes. Recently the ecological role and importance of wetlands has been recognized.

Ten brackish wetlands occur along the edge of Santa Monica Bay, the largest of which are the Ballona Wetlands Complex (Ballona Wetlands, Ballona Lagoon, Del Rey Lagoon, Oxford Flood Control Basin, and the Venice Canals) and Malibu Lagoon. At one time the Ballona Complex comprised 2,100 acres of wetlands. The development of Marina del Rey, the Venice Canals, and other residential and commercial properties; the draining for agricultural use and to control insect pests; and the channelization of Ballona Creek have reduced the wetlands to less than 160 acres. The 40-acre Malibu Lagoon, at the mouth of Malibu Creek, is also a remnant of a previously larger system. Most wetlands in the study area have reduced biological diversity and productivity because of their degraded condition.

Restricted water flow, which results in poor water quality (high levels of nutrients and/or contaminants), is the main concern at most sites. Additional adverse impacts include the lack of shallow water habitat, disruption of upstream flow, introduction of non-native plants and animals, debris and bacteria from urban runoff, human recreational over-use, and the presence of domestic pets.

The wetlands of Santa Monica Bay support a variety of marine and terrestrial biota; however, many of the species characteristic of pristine saltmarshes of southern California are lacking. Vegetation is often sparse and includes or is dominated by introduced species which have little functional value. The salt-marsh bird's beak (a Federally- and State-listed plant) is no longer found in the area. Belding's savannah sparrow (a State-listed endangered species) is a year-round resident of saltmarshes, foraging and nesting in pickleweed, a dominant plant of the upper marsh. The population of this sparrow was low but stable until 1990, when it began to decline, in part because of predation by introduced red foxes. Attempts to remove the foxes have met with limited success. Other "listed" birds which have not been seen for some time (due to the absence of cordgrass) are the light-footed clapper rail (Federally- and State-listed endangered) and the black rail (State-listed as threatened). The black-necked stilt, a species of concern, has not nested recently in the local wetlands.

Animal communities in the sediments, lagoons, and channels of local wetlands are also less diverse than in the past and some of the most abundant invertebrates found now are indicators of stressed conditions. Some fish species (for example rainbow trout) no longer occur although the tidewater goby was recently reintroduced to its original habitat at Malibu Lagoon. California least tern (State- and Federally-listed) forage in the waters of several of the Bay wetlands.

Although several plans have been developed to preserve and restore the wetlands of Santa Monica Bay, prior attempts have often been confused by the complex issues and often conflicting goals of the regulatory agencies. The extant wetlands have been inventoried (for the Santa Monica Bay Restoration Project) to serve as a basis for a general approach to protection and enhancement. The Port of Los Angeles has developed a Local Wetland Mitigation Program which identifies those wetlands available for mitigation projects. Successful implementation of any of the plans will depend on dedicated individuals and adequate funding.

Restoration at Malibu Lagoon has begun with the regulation of freshwater flow and reintroduction of the tidewater goby. Future plans include reduction of nutrient inputs, recontouring and revegetation of the intertidal habitat, and restoration of former wetlands in the City of Malibu. Rehabilitation of the Venice Canals has also begun and plans have been approved

VOL 12

1

5587

to enhance Ballona Lagoon, including removal of debris and exotic vegetation and replacement with native species. Construction of the Playa Vista residential-marina complex depends on development of plans to restore the Ballona Wetlands. The plans are to include: restoration of tidal flow; construction of saltwater marsh, dunes, a freshwater marsh, and a riparian corridor; and fish habitat enhancement in the proposed marina. Suggestions for enhancement of Del Rey Lagoon include increased tidal flow to achieve better water quality.

SWIMMING RISKS

The material summarized below relates to Action Plan Element IIB of Table 13-1, concern for the human health risks associated with swimming in Santa Monica Bay. Concern about the health risks from hazardous chemicals and biological pathogens to swimmers in Santa Monica Bay derives primarily because beaches have been closured due to sewage spills and storm drain runoff. There are no documented (verified) cases of disease or illness which were caused by microbial pathogens or toxic chemicals in the Bay.

Bathers in Santa Monica Bay may be exposed to a variety of harmful chemicals which may produce acute and long-term health effects. However, because etiological relationships between chemical contamination and human health are difficult to establish, health risk analyses of swimming in Santa Monica Bay have focused primarily on biological pathogens.

Pathogenic bacteria that have been found in the Bay include *Pseudomonas*, *Enterobacter/Citrobacter*, *Streptococcus*, *Escherichia coli*, *Klebsiella*, and marine *Vibrio*. These can cause human illnesses ranging from skin infections, gastroenteritis, upper respiratory problems, and wound infections, to pericarditis and spinal meningitis. Human-specific viruses such as hepatitis A, poliovirus, and Norwalk virus have also been found in marine waters and recently Coxsackie B viruses were found in storm drains that discharge to Santa Monica Bay.

The primary source of most human-specific biological pathogens is human fecal waste from treated wastewater discharges, urban runoff, sewage spills, small boat waste discharges, and the bathers themselves. The risk of disease from human fecal contamination is paramount; the relative importance of pathogens from non-human sources is not known.

There has been no evidence (microbial indicator) that the waste fields from HTP or JWPCP have reached shore in the past 10 years, a result of improved treatment and offshore discharges. The largest source of bacterial pathogens to nearshore bathers in Santa Monica Bay is probably urban runoff via storm drains and stormwater overflows into sewage lines (which force untreated sewage back into storm drains, then to the Bay). Because most storm drains discharge directly into the surf zone and because high indicator bacteria counts have been found in storm drain runoff, the surf zone near storm drains is a high risk area, especially during rain storms.

High indicator bacteria levels and human enteric viruses have also been found in storm drains during dry weather. Recent studies in Santa Monica Bay provide evidence of dry-weather biological contamination of urban runoff. Samples from the Pico-Kenter, Ashland, and Herondo Storm Drains and Malibu Lagoon were analyzed for densities of "indicator" bacteria (total and fecal coliforms and enterococcus) and human enteric viruses. Samples were taken variously from inside the drains and from the nearby surf zone at ankle and chest depths. Densities of bacterial indicators were classified as exceeding "excessive limits" or "levels of concern".

In 1989, 1990, and 1991 all three bacterial indicators exceeded levels of concern in generally decreased with water depth and distance from the Drain (Figure 13-7). In 1989 bacterial counts from Pico-Kenter were nearly one-hundred times greater than levels of concern.

All three indicator levels were approximately one order of magnitude lower in ankle-deep water than in storm drains and two orders of magnitude lower in chest-deep water than in the drains. A similar pattern was seen at the Ashland Storm Drain. Bacterial densities were markedly lower in the surf zone, but levels of concern were frequently exceeded up to distances of 150 yd from the Pico-Kenter Drain. In 1989 HTP recorded bacteria levels below levels of concern at a station 200 yd south of Pico-Kenter, suggesting that bacterial contamination may be limited to within 150 to 200 yd from the Storm Drain.

Bacterial densities near Pico-Kenter were much lower in 1991 than in 1990 (Figure 13-7), suggesting that the 600-ft extension to the Drain (which was added in August 1990) reduces bacterial densities in the surf zone.

Human enteric viruses were found in the Pico-Kenter and Herondo Storm Drains and in Malibu Lagoon, indicating that human fecal waste was present in the runoff even during dry weather. Possible sources of the human fecal contamination include leaky sewer lines and septic systems; overflows from blocked sewers; campers, picnickers, or the local homeless population; and illegal discharges from mobile homes or recreational vehicles.

The extent of contamination around storm drains depends on local rainfall, runoff from the surrounding area, and the interval between storms. Densities of all three bacterial indicators were highest during periods of peak rainfall in Los Angeles between July 1989 and June 1990 (Figure 13-8). Bacterial densities are usually highest during the first few months of the rainy season and during the first few hours of a single storm and tend to decrease thereafter.

These ongoing studies have established that the largest potential threat to swimmers in the Bay is from human pathogens in urban runoff, especially at the Pico-Kenter and Herondo Storm Drains and in the Malibu Creek/Malibu Lagoon drainage system.

To assess the potential swimming risk quantitatively it is necessary to conduct an epidemiological study and there appears to be sufficient evidence from biological data to warrant one. Such a study has not been conducted for Santa Monica Bay, although one has been designed and proposed by Dr. Robert Haile, and approved and recommended by the Santa Monica Bay Restoration Project Management Committee.

CONTAMINATED SEAFOOD

The material summarized below relates to Action Plan Element IIA of Table 13-1, concern that seafood collected from Santa Monica Bay is safe to consume.

Marine environments adjacent to heavily populated areas may contain many chemical contaminants. Organisms (including humans) may contact these contaminants through direct water contact or through contact with contaminated sediments. Human health may be at risk through direct contact and by consuming contaminated species. The most extensively studied and tractable contaminants in Santa Monica Bay are heavy metals, PCBs, and DDT and its derivatives.

Historically wastewater outfalls were the principal source of contaminants to the Bay. Recent improvements in effluent quality may have changed this: the sediments contaminated

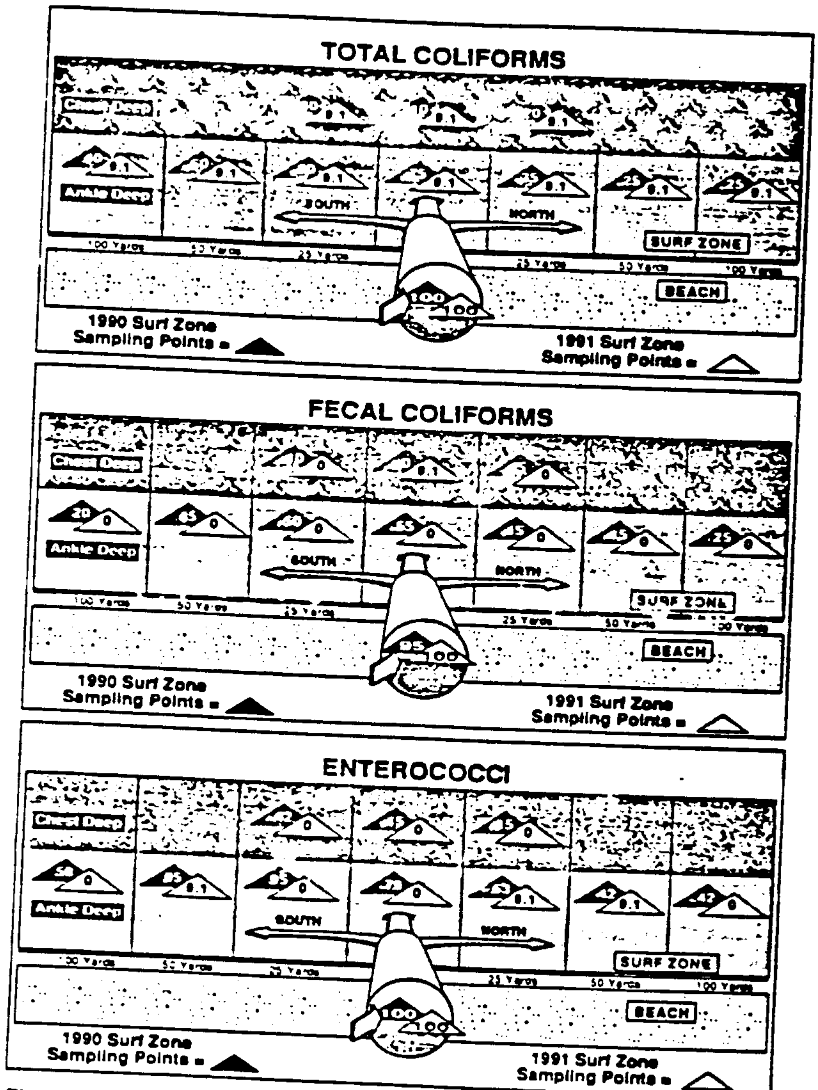

Figure 13-7. Percentage of sampling days where excessive levels of bacterial indicators were exceeded near the Pico-Kenter Storm Drain in 1990 and 1991 (excessive levels: total coliforms = 1,000 cfu/100 ml, fecal coliforms = 200 cfu/100 ml, enterococci = 24 cfu/100 ml). (Gold et al. 1992).

VOL 12

1 5591

previously may now constitute a principal source of contaminants along with urban runoff via storm drains, particularly during periods of heavy rainfall or sewage overflows.

In general, metal levels in edible tissue of fishes and invertebrates from near the JWPCP and HTP outfalls in the last ten years have not been substantially elevated over those at reference sites elsewhere in southern California. Since sediments near the outfalls often contain high metal concentrations, actual bioaccumulation and biomagnification of metals in the species studied appear to be minor. Thus seafood consumption does not appear to pose an appreciable health risk from metals contamination.

Organic contaminants such as PCBs and DDT (and DDD and DDE) present the greatest risk to individuals that consume seafood from Santa Monica Bay. High levels of these contaminants in the sediments around the JWPCP and HTP outfalls reflect the massive discharges that occurred in the 1960s and early 1970s. Over the past 25 years several species (especially filter-feeding invertebrates and demersal fishes) from contaminated areas have exhibited very high body-burden levels of PCBs and DDT. Body-burden levels in the late 1970s were much lower than those in the late 1960s, reflecting the ban on dumping these contaminants in the early 1970s.

Body-burden levels of PCBs and DDT have been about the same (at particular sites) throughout the Bay since about 1982, reflecting the persistence of these contaminants over time and suggesting that historically contaminated sediments now constitute a source. The PCBs and DDT discharged to the Palos Verdes Shelf in the 1960s and 1970s continue to bioaccumulate in the tissues of fishes and invertebrates in area.

Because of the persistence of PCBs and DDT in fishes from the Palos Verdes Shelf and northern Santa Monica Bay, the Office of Environmental Health Hazard Assessment (OEHHA) conducted a comprehensive study and risk assessment in 1991. OEHHA measured body burden levels of several contaminants (including PCBs and DDT) in fishes from the Bay and assessed the potential health hazards of consuming the contaminated species.

White croaker is generally the most contaminated fish in the Bay, especially those from highly-contaminated areas such as the Palos Verdes Shelf. The theoretical excess lifetime cancer risk from consumption of white croaker from the Palos Verdes Shelf is approximately 1 in 1,000, based on a theoretical consumption rate of about one 6 oz (170 g) meal per week (23 g/day). Other relatively contaminated species are California corbina, queenfish, surfperches, and California scorpionfish. Pacific bonito, chub mackerel, Pacific sanddab, Pacific barracuda, opaleye, halfmoon, and halibut are less contaminated.

OEHHA also developed (on the basis of 1987 data) site-specific recommendations for seafood consumption from areas of Santa Monica Bay and the Palos Verdes Shelf (Table 13-3) and species-specific recommendations for the most frequently caught and consumed fishes (Table 13-4). OEHHA points out that the inclusion of seafood in the diet is strongly encouraged as a general recommendation. Tables 13-3 and 13-4 reference fishes caught locally and are meant to indicate how often to fish an area and how often to eat specific species from each site.

A recent SMBRP-funded study to determine seafood consumption patterns of anglers that fish in Santa Monica Bay will describe consumption patterns by ethnic group and will identify those groups that are most at risk from consuming contaminated seafood from the Bay. The report will also report angler consumption rates, which may be used to calculate actual health risks rather than those formulated from theoretical consumption rates.

Table 13-3. Site-specific seafood consumption recommendations for several locations in Santa Monica Bay, based on 1987 contaminant levels (Pollock *et al.* 1991).

Site	Fish Species	Recommendation*
Marina Del Rey Redondo Beach Santa Monica Pier Venice Pier Venice Beach Dana Point	All species	No Restrictions
Redondo Pier	California corbina	One meal every two weeks
Malibu Pier	Queenfish	One meal a month
Short Bank	White croaker	One meal every two weeks
Malibu Point Dume Point Vicente Palos Verdes-Northwest	White croaker	Do not consume
White Point	White croaker	Do not consume
	California scorpionfish Rockfishes Kelp bass	One meal every two weeks+

* One meal is about six ounces (170 g).

APPENDIX A

List of Acronyms

Appendix A. List of Acronyms. Santa Monica Bay Characterization Study, 1993.

AHF	University of Southern California, Allan Hancock Foundation
BHC	Benzene hexachloride
BLM	United States Department of Interior, Bureau of Land Management
BMPS	Best Management Practices
BOD	Biochemical oxygen demand
CalCOFI	California Cooperative Oceanic Fisheries Investigations
CCC	California Coastal Commission
CCMP	Comprehensive Conservation and Management Plan
CDFG	California Department of Fish and Game
CDFG,MRO	California Department of Fish and Game, Marine Resources Division
CDFG,OSPR	California Department of Fish and Game, Oil Spill Prevention and Response
CDHS	California Department of Health Services
CDPR	California Department of Parks and Recreation
CEG	Coastal Ecology Group
CEPA	California Environmental Protection Agency
CEQA	California Environmental Quality Act
CFR	Code of Federal Regulations
CLA,BE	City of Los Angeles, Bureau of Engineering
CLA,DA	City of Los Angeles, Department of Airports
CLA,DPW	City of Los Angeles, Department of Public Works
CLA,DWP	City of Los Angeles, Department of Water and Power
CLA,EMD	City of Los Angeles, Environmental Monitoring Division
CLTRT	California Least Tern Recovery Team
CNPS	California Native Plant Society
COD	Chemical oxygen demand
CPFV	Commercial Passenger Fishing Vessel
CPUE	Catch per unit effort
CRWQB,LAR	California Regional Water Quality Control Board, Los Angeles Region
CSCC	California State Coastal Conservancy

WSED	Wastewater Systems Engineering Division
ww	Wet weight

APPENDIX B

Glossary

VOL 12

1 5649

VOL 12

1 5550

208 PLANNING	Authorized under Section 208 of the 1972 amendments to the Federal Water Pollution Control Act to control non-point source pollution.
AEROBIC	Living, active, or occurring only in the presence of oxygen.
ALDRIN	A cyclodiene insecticide which is extremely toxic from skin absorption.
ALGAE	A group of chiefly aquatic nonvascular plants which lack flowers and produce organic compounds by the process of photosynthesis. Includes one-celled algae such diatoms and dinoflagellates as well as multicellular seaweeds and kelps.
AMPHIPOD	A small (most are well under an inch long) shrimp-like crustacean of the order Amphipoda. Sand fleas are a common example.
ANAEROBIC	Living, active, or occurring in the absence of oxygen. Some bacteria live only in the absence of oxygen and in the course of normal respiration produce the hydrogen sulfide which is characteristic of anoxic sediments.
ANNELID	Any of a phylum (Annelida) of segmented worms, including polychaetes.
ANOXIC	Lacking oxygen; said of water or sediment.
ANTHROPOGENIC	Made or caused by man; said of substances such as DDT or effects such as elevated water temperatures.
AQUIFER	An underground rock, sand, or gravel formation that yields water.
AROMATIC	A class of (often persistent) organic compounds characterized by at least one benzene ring.
ASSEMBLAGE	A group of species that occur together. See Community.
ADVECTION	The horizontal movement of air.
BACTERIOPLANKTON	Planktonic bacteria
BAITFISH	Small, schooling pelagic fish (such as anchovy) which are preyed upon by larger game fish and hence are used as bait by sport fishermen.
BENEFICIAL USE	Water protected under the Porter-Cologne Act including domestic, municipal, agricultural and industrial water; power generation; recreation; navigation; and preservation of fish, wildlife, and aquatic resources.
BENTHIC	Living on or in the sea floor.

BENTHOS	The bottom of the ocean; also, collectively, the biota living on or in the bottom.
BEST MANAGEMENT	Steps by which water quality is protected, usually from nonpoint sources such as agriculture, construction, mining, logging or urban runoff. These steps can also be applied to point source waste discharges.
BIOACCUMULATION	The accumulation of a substance (usually a contaminant) in the tissues of an organism.
BIOASSAY	A test which measures the lethal or sub-lethal effects of a substance (or composite mixture) on living organisms or tissues.
BIOCHEMICAL OXYGEN DEMAND (BOD)	The amount of oxygen used by organic matter in water. High levels of BOD can remove oxygen needed to support fish and aquatic life.
BIODEGRADATION	A biochemical (i.e. conducted by living organisms) process by which complex substances are broken down into simpler ones; said especially of toxic substances which are detoxified by the process.
BIOMAGNIFICATION	The accumulation of a substance (usually a contaminant) at greater tissue concentrations in successively higher-level consumers with increasingly higher contaminant levels as prey are consumed up the food chain.
BIOMASS	The weight of living tissue, of an organism or a group of organisms. Often includes the weight of non-living material (such as a snail's shell) which was produced by the organism(s).
BIOTA	The plants and animals found in a particular environment.
BIOTURBATION	Disruption of sediment caused by animal activity.
BIVALVE	A mollusk having two shells hinged together, as the oyster, clam, or mussel.
CARBON DIOXIDE (CO2)	A colorless, odorless, incombustible gas present in the atmosphere and formed during respiration.
CARCINOGENIC	Having the capacity to cause cancer.
CATCH PER UNIT EFFORT (CPUE)	The numbers or pounds of organisms which are collected in a standard sampling or fishing effort.
CETACEAN	Whales, dolphins, and porpoises, all of which are sometimes placed in the order Cetacea.
CHLORDANE	An insecticide and fumigant (for termites) which is toxic by ingestion, inhalation, and skin absorption.
CHLORINATED HYDROCARBONS	Organic compounds that contain chlorine and have toxic properties in varying amounts; pesticides and solvents such as DDT, DDD, DDE, and PCB.

Appendix B (Cont).

CHLOROPHYLL	The pigment which makes most plants green and enables them to produce organic substances in the process of photosynthesis.
CLEAN WATER ACT	The federal water quality control law governing surface waters establishing water quality objectives, waste discharge standards, and the NPDES permit process; also called the Federal Water Pollution Control Act, amended.
CLEAN WATER GRANT	Apportioned under Clean Water Act for upgrading or constructing publicly-owned and operated sewage treatment facilities.
COLIFORM	Relating to, resembling, or being the colon bacillus bacteria.
COMMUNITY	All plants and animals living in a particular place or habitat and which interact with one another. Some scientists use the term assemblage to denote a community when interactions among the species cannot be defined.
CONDUCTIVITY	A measure of salinity in water determined by conduction of electricity; generally related to the chloride ion concentration (or chlorinity).
CONTAMINANT	An unnatural (man-made) substance found in the environment or a naturally occurring substance or compound which is found in unnaturally high concentrations; a health hazard; a pollutant.
CORALLINE	Consisting of or containing deposits of calcium carbonate which would include any of the various corallike animals or calcareous algae.
CRUSTACEAN	An animal belonging to a class or phylum of organisms (Crustacea) which have a hard exoskeleton and jointed legs and body; includes crabs, lobster, amphipods, and shrimp.
CUBIC FEET PER SECOND (cfs)	The flow of water past a given point over time at the equivalent of 449 gal/min or 1.98 acre-ft/day.
DBCP (dibromochloropropane)	A pesticide and fungicide extensively used until banned in 1977 as a suspected carcinogen.
DDT (dichlorodiphenyl-trichloroethane)	A toxic insecticide banned in 1970 but still widely found in water and fish samples.
DEMERSAL	On or near the sea floor.
DETRITUS	Fine, disaggregated particles of inorganic and organic material (i.e. dead plant and animal matter), either in suspension on settled on the bottom of a water body. Forms the basis of an extensive food web in the ocean.
DIATOM	Any of a class (Bacillariophyceae) of minute planktonic unicellular or colonial algae with silicified skeletons.

VOL 12

15552

Appendix B (Cont).

DIELDRIN	An insecticide toxic by ingestion, inhalation, and skin absorption. It is carcinogenic. Its use is now restricted to nonagricultural applications.
DINOFLAGELLATES	Important plantlike elements of plankton having two flagella.
DIOXIN	2,3,7,8-tetrachlorodibenzo-p-dioxin, a contaminant of a herbicide, banned by the FDA for most purposes after ten years of use. It was also a contaminant in defoliants used in Vietnam (agent orange). It is a carcinogen, a teratogen, and a mutagen.
DISINFECTION	Process where effluent is treated with a disinfectant (e.g. chlorine) to kill bacteria and viruses.
DISSOLVED OXYGEN (DO)	Oxygen (parts per million) which is dissolved in water; the source of most oxygen used by plants and animals in their normal respiration. The dissolved oxygen in seawater replenished by exchange with the air or produced by plants during photosynthesis.
DIVERSITY	A parameter of ecological communities which describes the relationship between the number of species and their abundance.
ECHINODERM	An invertebrate animal having radial symmetry and belonging to the phylum Echinodermata. Includes starfish and sea urchins.
ECOSYSTEM	The sum of all plants, animals, and non-living components of a particular defined area. A given kelp bed may be viewed as an ecosystem, but it is also part of the larger coastal or Bay ecosystem.
EFFLUENT	The material which flows out of a pipe or facility into a water body (or another larger pipe). Wastewater which has undergone treatment to remove pollutants.
EL NIÑO	An aperiodic change in the oceanic climate of the Pacific whereby warm, low-nutrient water flows east along the Equator, north along the west coast of North America and south along South America. The condition lasts for several months or 2-3 years, causing a change in the biota and climate of an area.
EMBAYMENT	A body of water forming an indentation of the shoreline, larger than a cove but smaller than a gulf.
ENDOSULFAN	An insecticide which is toxic by ingestion, inhalation, and skin absorption. Use is restricted.
ENDRIN	A stereoisomer of dieldrin, used as an insecticide to control crop insects and mites. It is a carcinogen, and toxic by inhalation and skin absorption.
ENTERIC	Relating to the intestines.
ENTEROCOCCUS	Any of a genus (*Streptococcus*) of nonmotile, usually parasitic, gram-positive bacteria occurring in the intestine that divide only in one plane and which occur in pairs or chains.

EPIBIOTA	Organisms living on the surface of the seafloor.
EPIDERMAL TUMORS	Tumors located in the outer, nonvascular, layer of the skin.
EPIFAUNA	Benthic animal living on the surface of bottom material.
EROSION	Deterioration of earth or rock by water, glaciers, winds, and waves.
ERYTHROCYTE	One of the red cells of the blood.
ESTUARY	The coastal portion of a river mouth where the fresh, river water mixes with the saltwater of the ocean. The degree of mixing and layering (fresh water tends to float on top of the sea water) depends on tidal conditions, river flow, and local currents. Estuaries typically support a biota which can tolerate varying salinities and therefore differ from marine and freshwater biotas.
EUPHAUSIID	Any of an order (Euphausiacea) of usually luminescent, shrimp-like crustaceans which are important components of plankton; also known as krill.
EUTROPHIC	Describing a situation in which excess nutrients have led to excessive plant growth; when the plants die and decompose, dissolved oxygen is used up, making the water uninhabitable by animals. Erosion, sewage discharges, fertilizers and detergents speed the process.
FAUNA	The animal life of a community, habitat, or ecosystem.
FECAL COLOFORM (bacteria)	A class of bacteria which are found in the intestinal tracts of mammals, including man. Fecal coliform bacteria are not dangerous themselves, but their abundance is measured in water as an indication of raw sewage and thus the potential for the presence of pathogenic organisms.
FEDERAL WATER POLLUTION CONTROL ACT, as amended	Original title of Clean Water Act.
FLOOD CONTROL BASIN	An area to temporarily hold water to prevent flooding of lands downstream.
FLORA	The plant life of a community, habitat, or ecosystem.
FOLIOSE	Describes having leaves of a specified number or type, or a thin leaflike stratum or layer.
FORB	Any herb that is not a grass or grasslike.
FOOD WEB	A symbolic description of the interdependence of the organisms of a community, based on who eats whom.
GENOTOXIC	Any substance that is toxic to a specific plant or animal as a group.
GEOCHRONOLOGICAL	Relating to the chronology of the earth as indicated by geological data.

VOL 12

15654

GEOSTROPHIC	Current flow resulting from the deflective forces caused by the rotation of the earth.
GILLNET	A curtainlike net, suspended vertically in the water for the purpose of entrapping fish by their gills.
GROIN	A small jetty extending from the shore to prevent beach erosion.
GROUNDWATER	Water in the spaces between soil and rock particles; water under the subsurface from which wells and springs are fed.
HABITAT	A particular place or environment which supports a particular assemblage of organisms. Most habitats are described in terms of physical parameters such as sediment type and water depth, but the concept also includes chemical attributes of the water column and living components (a mussel, for example, provides a place for other organisms to attach).
HAZARDOUS WASTE	A waste or combination of wastes, which may cause or contribute to death or serious illness or pose a potential hazard to human health or the environment.
HEPATOPANCREAS	A glandular organ of a crustacean that combines the digestive functions of the vertebrate liver and pancreas.
HEPTACHLOR	A persistent cyclodiene chlorinated hydrocarbon insecticide, toxic by ingestion, inhalation, and skin absorption. Use has been restricted and discontinued except for termite control.
HEPTACHLOREPOXIDE	Insecticide, a degradation product of heptachlor.
HERBICIDE	A substance which is capable of killing or stunting the growth of plants.
HERBIVORE	An animal that eats plants.
HYDROCARBON	An organic compound composed of the elements hydrogen and carbon; natural gas, coal, and petroleum are important naturally occurring hydrocarbons.
INDICATOR	An organism or ecological community so strictly associated with particular environmental conditions that its presence is indicative of the existence of these conditions.
INDIGENOUS	Native, or belonging to a particular region or local ecosystem; said of plants and animals as well as of humans.
INFAUNA	Collectively, the invertebrates that live in, beneath, and just at the surface of unconsolidated soft sediments.
INSECTICIDE	A substance which is capable of killing insects, either by direct application or by ingestion.
INSOLATION	Solar radiation.

VOL 12

15555

Appendix B (Cont).

INTERTIDAL	That portion of the shore or structures in the ocean which is between high and low tide levels; the substrate and organisms in the intertidal are alternately covered by seawater and exposed to the air.
KILOGRAM (kg)	A standard metric unit of weight (mass) equivalent to 1,000 grams or about 2.2 pounds.
KILOMETER (km)	A standard metric unit of length (distance) equivalent to 1,000 meters or about 0.6 mile.
LARVA	A young or juvenile stage (of some species) which differs in basic body form from that of the adult; the plural is larvae.
LINDANE	A pesticide (hexachlorocyclohexane) consisting chiefly of the gamma isomer of BHC, which is toxic by ingestion, inhalation, and skin absorption. Its use is restricted.
LIPID	Substances that are soluble in nonpolar organic solvents and includes fats and oils; along with proteins and carbohydrates are major structural components of living cells.
LITER (*l*)	A standard metric unit of volume, equivalent to 1,000 cubic centimeters or 0.26 gal.
MEIOFAUNA	Very small (less than about 0.5 mm) organisms found in sediments.
MEROPLANKTON	Planktonic eggs and larvae of invertebrates and fish.
METABOLISM	The sum total of all chemical processes which go on in an organism and give it life; the major kinds of metabolism include the breakdown of some substance and the synthesis of others.
METER (m)	A standard metric unit of length or distance, the equivalent of about 3.3 feet or 1.1 yard.
METRIC TON (MT)	A standard metric unit of weight (mass), the equivalent of 1,000 kilograms, 2,200 pounds, or 1.1 English tons.
MICROGRAM (μg)	A metric unit of weight which equals one millionth of a gram.
MICROLAYER (Sea Surface)	The very thin, upper surface layer of the ocean, at which organic substances, toxicants, and pathogens accumulate at greater concentrations than in the water column itself.
MILLIGRAM (mg)	A metric unit of weight which equals one thousandth of a gram.
MILLIGRAMS PER LITER (mg/*l*)	Concentration of a substance in water equaling 0.001 g in 1,000 *ml* of water. Approximate equivalent - parts per million.
MILLION GALLONS PER DAY (mgd)	Measure of water or wastewater flow equal to about 0.5 cubic feet per second or 3.78 million liters per day.

VOL 12

1 5556

Appendix B (Cont).

MOLLUSC(K)	An invertebrate animal which belongs to the phylum Mollusca and which has an unsegmented body and usually with a hard outer shell. Includes clams, mussels, snails, chitons, squid, and nudibranchs.
NATIONAL POLLUTANT DISCHARGE ELIMINATION SYSTEM (NPDES)	Standards for waste discharges from point sources to surface waters (rivers, lakes, bays, oceans, etc.) controlled by state or federal agencies under provisions of Clean Water Act.
NEKTON	Free-swimming aquatic animals, independent of wave and current action.
NEMATODE	Elongated cylindrical worms (round worms) of the phylum Nematoda parasitic in animals or plants or free-living in soil sediments or water.
NEOPLASM	A tumor-like area of (abnormal) cell growth; a new growth of tissue serving no physiological function.
NERITIC	Relating to the region of shallow water (over the continental shelf) adjoining the seacoast.
NITRATE	Ion containing nitrogen and oxygen; its excess in water will stimulate the growth of algae.
NONPOINT SOURCE	A widespread, diffuse, or unidentifiable source of contaminants that comes from more than one point which cannot be controlled or easily monitored; it therefore does not involve an NPDES permit.
NUISANCE WATER	A component of surface runoff which includes street runoff from domestic washdown and irrigation water but not rainfall.
NUTRIENTS	Elements necessary for plant growth. Nitrogen and phosphorous are the most common. Excess nutrients in surface waters stimulate plant and algae growth.
OLIGOCHAETE	An annelid worm of the class Oligochaeta; these are more common on land (e.g. earthworms) than in the sea.
OMNIVORE	A consumer which eats many types of foods, including both plants and animals.
ORGANIC	In the chemical sense, a compound that contains one or more atoms of the element carbon (not applied to simple carbon compounds such as carbon dioxide or cyanide); more generally, produced by, derived from, or having to do with organisms.
PAPILLOMA	A benign tumor due to overgrowth of the epithelial tissue on papillae of vascular connective tissue.
PARTS PER BILLION (ppb)	Number of units per billion units. (e.g. μg/kg)
PARTS PER MILLION (ppm)	Number of units per million units. (e.g. mg/kg)
PELAGIC	Of, in, or pertaining to the water column as opposed to the bottom of the ocean.

1 5557

PERCOLATION	Movement of water through rock or soil.
PESTICIDE	Any substance which is used to control (usually by killing) pests, including insecticides, herbicides, algicides etc.
pH	A measure of the acidity or alkalinity of a fluid which ranges from 1 to 14. A pH of 7.0 is neutral, while 3 is very acidic and 12 is very alkaline (basic).
PHENOL	Aromatic organic compounds in which one or more hydroxy groups are attached directly to the benzene ring.
PHYTOPLANKTON	Small (generally one-celled) drifting plants including blue-green algae, flagellates and diatoms.
PINNIPEDS	A seal or sea lion, both of which are sometimes placed in the order or suborder Pinnipedia.
PLANKTON	Generally relatively small organisms which drift passively with currents, and are unable to swim against them.
POINT SOURCE	A single source from which contaminants enter the receiving water body; usually a discharge pipe or structure which is regulated under an NPDES permit.
POLLUTANT	In general, the same as a contaminant, i.e. some substance present in an environment at unnatural concentrations or levels. Some persons define a pollutant as a contaminant which has an adverse impact on the environment or which comes from an anthropogenic source.
POLYCHAETE	An annelid worm of the class Polychaeta; these are found only in the ocean.
POLYCHLORINATED BIPHENYLS (PCBs)	An extremely toxic group of industrial chemicals used in capacitors, transformers, and carbonless paper. Manufacture of this product was banned in 1976 and its use discouraged.
PORTER-COLOGNE WATER QUALITY CONTROL ACT	1970 California law defining water rights and pollution control programs.
PRELIMINARY TREATMENT	Initial stage of sewage treatment which includes screening, pulverization, and grit removal.
PRIMARY TREATMENT	Sewage treatment which includes the removal of much of the suspended solids by sedimentation but not colloidal and dissolved matter. It does not include biological oxidation and usually consists of clarification with or without chemical treatment.
PRIMARY CONSUMER	Animals that eat plants.
RAW SEWAGE	Untreated sewage.
REGIONAL WATER QUALITY CONTROL BOARDS	Nine regional boards in California that plan and enforce water quality standards within their boundaries.

VOL 12

1 5558

RESIDENCE TIME	The estimated, average time that a water parcel spends in a confined or semi-confined region before being exchanged with the open ocean.
RESPIRATION	The collective metabolic processes by which an organism converts stored chemical energy into physical energy in order to remain alive; involves the use of oxygen and the production of carbon dioxide.
RIPARIAN	Area next to a river; bank of a stream.
RUNOFF	Water that is not absorbed into the ground and hence which flows into streams or other bodies of water, or into a drain or sewer.
SALINITY	The standard measure of the "saltiness" of seawater, measured as the weight of salts (primarily sodium chloride) per unit of water and expressed as parts per thousand or grams per liter. The salinity of normal seawater is between 33 and 35 ppt.
SEAWATER INTRUSION	A condition that occurs when seawater enters an aquifer near the coast, generally resulting from the removal of freshwater via wells.
SECONDARY CONSUMER	Animals that eat other animals, particularly primary consumers.
SECONDARY TREATMENT	Sewage treatment that includes the reduction of organic material and solids by bacterial decomposition; about 85% of the BOD and suspended solids are removed. It consists primarily of clarification followed by a biological process to produce sludge.
SEDIMENTATION	Deposition or settlement of suspended matter in water, wastewater, or other liquids.
SESSILE	Permanently attached, not free to move about.
SHELLFISH	Molluscs (such as oysters, clams, and abalone) and crustaceans (such as crab and lobster) which have a hard outer shell or exoskeleton and are of sport or commercial interest.
SLUDGE	The solid material which settles, or is precipitated, out of sewage during the treatment process.
SPOROPHYTE	A young plant developed from a spore
STATE WATER RESOURCES CONTROL BOARD	State agency responsible for water rights and pollution control.
STRATIFIED	Occurring in distinct layers, separated by a sharp difference in some parameter. In the ocean, where the layers are of different densities, the boundary is called a pycnocline. If the difference is in temperature, the sharp difference, the pycnocline, is also a thermocline; if in salinity, it is also a halocline. Freshwater tends to float on top of saltwater and warm water on top of cold water.

VOL 12

1 5559

Appendix B (Cont).

SUCCESSION	Unidirectional change in the composition of an ecosystem or ecological community as the competing organisms modify the environment.
SUSPENDED SOLIDS	Organic and inorganic material which is in suspension in seawater or in a waste effluent.
SYNERGISTIC	Having the capacity to work together such that the total effect is greater than the sum of the individual effects.
TEMPERATE	The region between the Tropic of Cancer and the Arctic Circle or between the tropic of Capricorn and the Antarctic Circle; the biota associated with this region.
TERTIARY TREATMENT	Sewage treatment that includes the removal of nutrients (e.g. nitrogen and pholphorus compounds) and most of the remaining suspended solids.
THERMOCLINE	A boundary layer in a thermally stratified body of water that separates upper, warmer, less dense water from lower, colder, denser water.
TOTAL DISSOLVED SOLIDS (TDS)	Solids that are able to pass through a filter but which remain following evaporation; generally consist of salts.
TOXAPHENE	A chlorinated camphene insecticide, toxic by ingestion, inhalation, and skin absorption. Most uses are prohibited; widely used and persistent; used on cotton, tomatoes, and many field crops.
TOXIC	Lethal or damaging to humans or other living animals such as plants, pets, fish, and wildlife.
TRACE METAL	Metallic elements such as cadmium, chromium, lead, nickel, silver, and zinc which occur naturally in "trace" amounts in ocean water. They are of concern because 1) their concentrations may be increased through man's activities; 2) they do not degrade; 3) their concentration may be biomagnified through the food chain; and 4) they may be toxic at high concentrations, even though many are required for the normal functioning of organisms.
TRACER	A chemical (or bacterium) used to track the transport and fate of contaminants from a particular source.
TUNICATE	Any marine chordate having a saclike body enclosed in a thick membrane or tunic.
TURBIDITY	Water cloudiness; determined by the amount of material (living and non-living) which is suspended in a parcel of water. High turbidity reduces the penetration of light.
WASTE DISCHARGE REQUIREMENTS	Waste discharge conditions adversely affecting waters of state and regulated by the Regional Water Quality Control Board and sometimes the State Water Resources Control Board.
WASTEWATER RECLAMATION	A process where pollutants are removed so that the water can be reused.
WASTESHED	The land area encompassing the service area of a municipal wastewater treatment plan.

15560

Appendix B (Cont).

WASTEWATER	Sewage; a combination of water-carried wastes and liquid from industrial plants, residences, and commercial buildings.
WATERSHED	The total land from which rain water drains into a particular stream, drain, or body of water; the drainage basin.
WETFISH	Fish that are packed in a can first and then cooked; pelagic wetfish in southern California include small schooling species such as Pacific sardine, northern anchovy, chub (=Pacific) mackerel, and jack mackerel, all of which are harvested by purse seine.
WETLANDS	A collective term which describes areas where permanently or frequently wet conditions produce particular plant and animal communities; includes saltmarshes, freshwater marshes, and tidal mudflat habitats.
ZOOPLANKTON	Small drifting animals. See plankton.

APPENDIX C

List of Common and Scientific Names.

Appendix C. List of Common and Scientific Names. Santa Monica Bay Characterization Study.

Common Name	Scientific Name
abalone	*Haliotis spp.*
American kestrel	*Falco sparverius*
amphipod	Amphipoda
anemone	Anthozoa
annelid	Annelida
armed box crab	*Mursia gaudichaudii*
arrow goby	*Clevelandia ios*
arrow worms	Chaetognatha
auklet	Alcidae, unid.
barnacle	*Balanus spp.*
barnacle	*Chthamalus spp.*
barnacle	Cirripedia
barred sand bass	*Paralabrax nebulifer*
barred surfperch	*Amphistichus argenteus*
basking shark	*Cetorhinus maximus*
bat ray	*Myliobatis californica*
bay shrimp	*Crangon spp.*
beach bloodworm	*Euzonus mucronata*
beach hopper	Talitridae
beach morning glory	*Convolvulus soldanella*
beach primrose	*Camissonia (Oenothera) cheiranthifolia*
bean clam	*Donax gouldi*
Belding's savannah sparrow	*Passerculus sandwichensis beldingi*
bigmouth sole	*Hippoglossina stomata*
black abalone	*Haliotis cracherodii*
black oystercatcher	*Haematopus bachmani*
black perch	*Embiotoca jacksoni*
black rail	*Laterallus jamaicensis*
black turnstone	*Arenaria melanocephala*
blacksmelt	*Bathylagus spp.*
blackspotted bay shrimp	*Crangon nigromaculata*
blacktail jackrabbit	*Lepus californicus*
black-necked stilt	*Himantopus mexicanus*
blood worm	*Glycera dibranchiata*
blue shark	*Prionace glauca*
blue whale	*Balaenoptera musculus*
blue (= bay) mussel	*Mytilus edulis*
bluefish	*Pomatomus saltatrix*
bocaccio	*Sebastes paucispinis*
Bonaparte's gull	*Larus philadelphia*
Botta's (valley) pocket gopher	*Thomomys bottae*
bottlenose dolphin	*Tursiops truncatus*
brittle star	*Amphiodia urtica*
brittle star	Ophiuroidea, unid.
broadtail isopod	*Paracerceis spp.*
brokenspine brittle star	*Ophiura lutkeni*
brown algae	Phaeophyta
brown pelican	*Pelecanus occidentalis occidentalis*
brown rockfish	*Sebastes auriculatus*
bryozoan	Ectoprocta
cabezon	*Scorpaenichthys marmoratus*
California brown pelican	*Pelecanus occidentalis californicus*
California buckwheat	*Eriogonum fasciculatum*
California clingfish	*Gobiesox rhessodon*
California corbina	*Menticirrhus undulatus*

VOL 12

Appendix C (Cont).

Common Name	Scientific Name
California gnatcatcher	*Polioptila californica*
California ground squirrel	*Spermophilus (= citellus) beecheyi*
California grunion	*Leuresthes tenuis*
California gull	*Larus californicus*
California halibut	*Paralichthys californicus*
California killifish	*Fundulus parvipinnis*
California least tern	*Sterna antillarum browni*
California lizardfish	*Synodus lucioceps*
California mussel	*Mytilus californianus*
California poppy	*Eschscholzia californica*
California sagebrush	*Artemisia californica*
California sandstar	*Astropecten verrilli*
California scorpionfish	*Scorpaena guttata*
California sea cucumber	*Parastichopus californicus*
California sea lion	*Zalophus californianus*
California sea slug	*Pleurobranchaea californiensis*
California sheephead	*Semicossyphus pulcher*
California smoothtongue	*Leuroglossus stilbius*
California spiny lobster	*Panulirus interruptus*
California tonguefish	*Symphurus atricauda*
carinate (= keeled) dovesnail	*Alia carinata*
cattail	*Typha latifolia*
chaparral candle yucca	*Yucca whipplei*
chilipepper	*Sebastes goodei*
chiton	Polyplacophora
chub (= Pacific) mackerel	*Scomber japonicus*
cladoceran	Cladocera
comb jellies	Ctenophora
common dolphin	*Delphinus delphis*
common murre	*Uria aalge*
conejo buckwheat	*Eriogonum crocatum*
copepod	*Calanus pacificus*
cordgrass	*Spartina foliosa*
cormorant	*Phalacrocorax spp.*
cowcod	*Sebastes levis*
crustacean	Crustacea
cumacean	Cumacea
curlfin sole	*Pleuronichthys decurrens*
Dall's porpoise	*Phocoenoides dalli*
damselfish	Pomacentridae, unid.
date mussel	*Lithophaga spp.*
diatoms	Bacilliophycea
Dover sole	*Microstomus pacificus*
dudleya	*Dudleya cymosa marcescens*
eastern brown pelican	*Pelecanus occidentalis carolinensis*
eastern Pacific bobtail squid	*Rossia pacifica*
echinoderm	Echinodermata
eelgrass	*Zostera marina*
El Segundo blue butterfly	*Euphilotes battoides allyni*
encrusting bryozoan	*Membranipora spp.*
English sole	*Pleuronectes (= Parophrys) vetulus*
euphausiid	Euphausiacea, unid.
fantail sole	*Xystreurys liolepis*
feather-boa kelp	*Egregia menziesii*
fine-lined lucine (clam)	*Parvilucina tenuisculpta*
flag rockfish	*Sebastes rubrivinctus*
flathead sole	*Hippoglossoides elassodon*
fragile sea urchin	*Allocentrotus fragilis*
frog	*Hylidae and Ranidae*
giant kelp	*Macrocystis angustifolia Macrocystis pyrifera*

VOL 12

15664

R0048969

Appendix C (Cont).

Common Name	Scientific Name
giant rock scallop	*Crassidoma gigantea*
gigantic plumose anemone	*Metridium gignteum*
Gould beanclam (coquina)	*Donax gouldii*
gray sandstar	*Luidia foliolata*
gray whale	*Eschrichtius robustus*
grebe	Podicipedidae, unid.
greenblotched rockfish	*Sebastes rosenblatti*
greenling	Hexagrammidae, unid.
greenstriped rockfish	*Sebastes elongatus*
Gulf sanddab	*Citharichthys fragilis*
gull	*Larus spp.*
halfblind goby	*Lethops connectens*
halfmoon	*Medialuna californiensis*
harbor porpoise	*Phocoena phocoena*
harbor seal	*Phoca vitulina*
Heermann's gull	*Larus heermanni*
hermit crab	Paguridea
hornyhead turbot	*Pleuronichthys verticalis*
Hottentot fig	*Mesembryanthemum edule*
ice cream cone worm	*Pectinaria californiensis*
ice plant	*Mesembryanthemum spp.*
jack mackerel	*Trachurus symmetricus*
jacksmelt	*Atherinopsis californiensis*
jaeger	*Stercorarius spp.*
jellyfish	Scyphozoa
kelp	*Macrocystis spp., Egregia menziesii*
kelp bass	*Paralabrax clathratus*
kelp clingfish	*Rimicola muscarum*
kelp flies	Coelopidae
kelp gunnel	*Ulvicola sanctaerosae*
kelp perch	*Brachyistius frenatus*
kelp pipefish	*Syngnathus californiensis*
kelp rockfish	*Sebastes atrovirens*
kelp scallop	*Leptopecten latiauratus*
kelpfishes	*Gibbonsia spp.*
krill	Euphausiacea
large beach hopper	*Megalorchestia californiana*
laurel sumac	*Rhus larina*
light-footed clapper rail	*Rallus longirostris levipes*
limpets	*Acmaea spp.*
lingcod	*Ophiodon elongatus*
lizard	*Iguanidae, Scincidae, Teiidae, and Anguidae*
longspine combfish	*Zaniolepis latipinnis*
loon	*Gavia spp.*
Lyon's pentachaeta	*Pentachaeta lyonii*
marbled godwit	*Limosa fedoa*
Memphill fileclam (file shell)	*Limatula hemphilli*
Mexican fiddler	*Uca crenulata*
Mexican lampfish	*Triphiturus mexicanus*
minke whale	*Balaenoptera acutorostrata*
mollusk	Mollusca
moonsnail	Naticidae, unid.
mysid	Mysidae, unid.
mysid shrimp	Mysidacea
nematode	Nematoda
nematode	Nematoda, unid.
northern anchovy	*Engraulis mordax*
northern elephant seal	*Mirounga angustirostris*
northern fulmar	*Fulmarus glacialis*
northern lampfish	*Stenobrachius leucopsarus*

VOL 12

1 5565

Appendix C (Cont).

Common Name	Scientific Name
northern right whale dolphin	*Lissodelphis borealis*
ocean shrimp	*Pandalus jordani*
ocean whitefish	*Caulolatilus princeps*
ochre starfish	*Pisaster ochraceus*
octopuses	*Octopus spp.*
olive rockfish	*Sebastes serranoides*
opaleye	*Girella nigricans*
ostracod	*Euphilomedes spp.*
ostracod	Ostracoda
Pacific argentine	*Argentina sialis*
Pacific barracuda	*Sphyraena argentea*
Pacific bonito	*Sarda chiliensis*
Pacific electric ray	*Torpedo californica*
Pacific goose barnacle	*Pollicipes polymerus*
Pacific hake	*Merlucclus productus*
Pacific littleneck	*Protothaca staminea*
Pacific purple urchin	*Strongylocentrotus purpuratus*
Pacific rock crab	*Cancer antennarius*
Pacific sand dollar	*Dendraster excentricus*
Pacific sanddab	*Citharichthys sordidus*
Pacific sardine	*Sardinops sagax*
Pacific spiny brittle star	*Ophiothrix spiculata*
Pacific staghorn sculpin	*Leptocottus armatus*
Pacific white-sided dolphin	*Lagenorhynchus obliquidens*
Palos Verdes blue butterfly	*Euphilotes battoides allyni*
pelagic red crab	*Pleuroncodes planipes*
pelagic snail	*Janthina spp.*
peregrine falcon (American)	*Falco peregrinus anatum*
periwinkle	*Littorina spp.*
pickleweed	*Salicornia spp.*
pickleweed	*Salicornia virginica*
piddock clam	Pholadidae, unid.
pile perch	*Rhacochilus (= Damalichthys) vacca*
pink abalone	*Haliotis corrugata*
pink seaperch	*zalembius rosaceus*
pipefish	Syngnathidae, unid.
pismo clam	*Tivela stultorum*
plainfin midshipman	*Porichthys notatus*
polychaete	*Capitella capitata*
polychaete	*Mediomastus*
polychaete	*Schistomeringos*
polychaete	*Tharyx spp.*
polychaete worms	Polychaeta, unid.
puffin	*Fratercula spp.*
pygmy sperm whale	*Kogia breviceps*
queenfish	*Seriphus politus*
rainbow (= steelhead) trout	*Oncorhynchus mykiss (formerly Salmo gairdneri)*
red algae	Rhodophyta
red fox	*Vulpes fulva*
red sea urchin	*Strongylocentrotus franciscanus*
rex sole	*Errex (= Glyptocephalus) zachirus*
ridgeback rock shrimp (= ridgeback prawn)	*Sicyonia ingentis*
rock crab	*Cancer spp.*
rock lice	*Ligia spp.*
rockfish	*Sebastes spp.*
rockpool blenny	*Hypsoblennius gilberti*
rockweed	*Pelvetia spp.*
rotifer	Rotifera
roundworm	Nematoda, unid.
rubberlip seaperch	*Rhacochilus toxotes*

VOL 12

1 5666

Appendix C (Cont).

Common Name	Scientific Name
ruddy turnstone	*Arenaria interpres*
sablefish	*Anoplopoma fimbria*
salt bush	*Atriplex spp.*
salt grass	*Distichlis spicata*
saltmarsh bird's beak	*Cordylanthus maritimus ssp. maritimus*
sand crab	*Emerita analoga*
sand flea	Talitridae
sand sole	*Psettichthys melanostictus*
sand verbena	*Abronia maritima*
sanderling	*Calidris alba*
sandflat elbow crab	*Heterocrypta occidentalis*
Santa Susana tarweed	*Hemizonia minthornii*
scale insect	*Haliaspis spartina*
scoter	*Melanitta spp.*
sculpin	Cottidae, unid.
sea bass	Serranidae, unid.
sea cucumber	Holothuroidea
sea fan	Gorgonacea, unid.
sea felt	*Enteromorpha spp.*
sea fig	*Mesembryanthemum chilense*
sea lettuce	*Ulva spp.*
sea moss	Bryozoan, unid.
sea rocket	*Cakile maritima*
sea slug	Nudibranchia
sea squirt	Ascidiacea, unid.
sea star (sand star)	*Astropecten armatus, A. verrilli*
sea urchin	*Strongylocentrotus spp.*
senorita	*Oxyjulis californica*
shark	*Elasmobranchiomorphi* (= *Chondrichthyes, Elasmobranchii*)
shearwater	*Puffinus spp.*
sheep crab	*Loxorhynchus grandis*
shiner perch	*Cymatogaster aggregata*
shortbelly rockfish	*Sebastes jordani*
shortfin pilot whale	*Globicephala macrorhynchus*
shovelnose guitarfish	*Rhinobatos productus*
shrimp	Natantia
silky axinopsid (clam)	*Axinopsida serricata arvilucina*
silver beachweed	*Ambrosia (Franseria) chamissonis*
slender sole	*Eopsetta (= Lyopsetta) exilis*
small beach hopper	*Traskorchestia traskiana*
speckled sanddab	*Citharichthys stigmaeus*
sperm whale	*Physeter macrocephalus*
spider crab	*Podochela lobifrons*
spiny dogfish	*Squalus acanthias*
spiny sandstar	Astropecten armatus
sponge	Porifera
spoonworm	*Listriolobus pelodes*
spot shrimp (= spot prawn)	*Pandalus platyceros*
spotted kelpfish	*Gibbonsia elegans*
spotted sandpiper	*Actitus macularia*
squid	Teuthoidea
starry flounder	*Platichthys stellatus*
stingray	Dasyatididae, unid.
storm-petrel	*Oceanodroma spp.*
striped shore crab	*Pachygrapsus crassipes*
stripetail rockfish	*Sebastes saxicola*
summer flounder	*Paralichthys dentatus*
surfbird	*Aphriza virgata*
surfgrass	*Phyllospadix spp.*

Appendix C (Cont).

Common Name	Scientific Name
swordfish	*Xiphias gladius*
tern	*Sterna spp.*
thresher shark	*Alopias vulpinus*
tidewater goby	*Eucyclogobius newberryi*
toad	*Pelobatidae and Bufonidae*
topsmelt	*Atherinops affinis*
toyon	*Heteromeles arbutifolia*
tuberculate pear crab	*Pyromaia tuberculata*
tule	*Scirpus spp.*
tunicate	Ascidiacea
turban	*Tegula spp.*
turkey vulture	*Cathartes aura*
vermilion rockfish	*Sebastes miniatus*
walleye surfperch	*Hyperprosopon argenteum*
wandering skipper	*Panoquina errans*
wandering tattler	*Heteroscelus incanus*
warty sea cucumber	*Parastichopus parvimensis*
weakfish	*Cynoscion regalis*
western fence lizard	*Sceloporus occidentalis*
western gull	*Larus occidentalis*
western meadowlark	*Sturnella neglecta*
western mosquitofish	*Gambusia affinis*
western snowy plover	*Charadrius alexandrinus nivosus*
western sycamore	*Platanus racemosa*
western (southern Pacific) rattlesnake	*Crotalus viridis helleri*
whale	Cetacea
whimbrel	*Numenius phaeopus*
white alder	*Alnus rhombifolia*
white croaker	*Genyonemus lineatus*
white sea bass	*Atractoscion nobilis*
white sea urchin	*Lytechinus pictus (= L. anamesus)*
white seaperch	*Phanerodon furcatus*
wild buckwheat	*Eriogonum parvifolium*
wild lilac	*Ceanothus spp.*
willet	*Catoptrophorus semipalmatus*
willow	*Salix spp.*
winter flounder	*Pleuronectes (= Pseudopleuronectes) americanus*
woolly sculpin	*Clinocottus analis*
wrasse	Labridae, unid.
yellow rock crab	*Cancer anthonyi*
yellowchin sculpin	*Icelinus quadriseriatus*
yellowtail	*Seriola lalandi*

a. For Total PCB, the average concentration for January to September was 4.72; for October to December, 29.1.
b. For Chlorinated hydrocarbons Project values: Analyses of two 1-week composite samples of each effluent.
c. Project value for DDT based on 52 weekly composites.
d. MBAS is Methylene blue active substances.
e. Less than values calculated at 1/2 minimum detection level.
f. Mass emissions for 1992 are extrapolated to 12 months based on January to October data.

APPENDIX F

National Pollutant Discharge Elimination System Permits.

VOL 12

STATE OF CALIFORNIA
CALIFORNIA REGIONAL WATER QUALITY CONTROL BOARD
LOS ANGELES REGION

ORDER No. 90-079

NPDES NO. CA0061654 (CI 6948)

WASTE DISCHARGE REQUIREMENTS
STORMWATER/URBAN RUNOFF DISCHARGE
for
LOS ANGELES COUNTY
and
CO-PERMITTEES

15685

The California Regional Water Quality Control Board, Los Angeles, (Regional Board) finds :

1. The County of Los Angeles, in cooperation with the following cities : Agoura Hills, Beverly Hills, Culver City, El Segundo, Hermosa Beach, Inglewood, Los Angeles, Manhattan Beach, Rancho Palos Verdes, Redondo Beach, Rolling Hills Estates, Rolling Hills, Santa Monica, Torrance, West Hollywood, and Westlake Village, has submitted a report of waste discharge (NPDES permit application) dated March 15, 1990 for issuance of waste discharge requirements for the County of Los Angeles and other cities tributary to Los Angeles County (excluding Antelope Valley) under the National Pollutant Discharge Elimination System. (NPDES Permit No. CA0061654).

2. The discharges consist of surface runoff generated from various land uses in all the hydrologic drainage basins which discharge into water courses flowing into water bodies in Los Angeles County. The quality of these discharges varies considerably and is affected by land use, basin hydrology and geology, season, and the frequency and duration of storm events. The constituents of concern and significance in these discharges are: total and fecal coliform and enterococci bacteria, total suspended solids, biochemical oxygen demand, oil and grease, heavy metals, nutrients, polychlorinated biphenyls, polycyclic aromatic hydrocarbons, pesticides and herbicides, and petroleum hydrocarbons.

3. The objective of this permit is to develop a timely, comprehensive, and cost-effective stormwater pollution control program to minimize pollutants in urban runoff/stormwater discharges to water bodies in Los Angeles County.

4. Due to the complexity and networking of drainage facilities within and tributary to Los Angeles County, the county and adjacent areas discharging storm water into Los Angeles County are divided and prioritized into five drainage basins for the implementation of the permit. The owners/operators of all facilities impacting stormwater quality will be ultimately a party to these waste discharge requirements. The County of Los Angeles together with the cities identified above, the initial parties filing for the system-wide permit, are 'Permittees', with the County of Los Angeles as the 'Principal Permittee' and the rest as 'Co-Permittees'. All other cities and recognized entities such as Caltrans, college/university campuses, hospitals, parks, agricultural areas, real estate developments and waste disposal facilities identified in this Order, are designated 'Co-Participants'. A 'Co-Participant' will be a 'Co-Permittee' upon becoming an active party to the permit.

   Attachments 1 and 2 show, respectively, the list of cities and a partial list of entities designated as Co-Participants for this permit. The list of entities will be revised as necessary.

5. The County of Los Angeles, as the 'Principal Permittee', will obtain the cooperation of 'Co-Participants' to become 'Co-Permittees'. The Regional Board has the discretion and authority to require non-cooperating cities and/or entities to become 'Co-Permittees' or obtain individual stormwater discharge permits, pursuant to 40 CFR 122.26 (a).

6. Los Angeles County as the 'Principal Permittee' is the permit coordinator responsible for general administration of this Order, and coordinating cooperation by 'Co-Permittees', including but not limited to the implementation of local self-monitoring programs and Best Management Practices, and the preparation and submittal of reports required by this Order.

7. Los Angeles County obtains its authority to :

   - control pollutants in stormwater discharge
   - prohibit illegal discharges and control spills
   - require compliance and carry out inspections

of drainage facilities in the County of Los Angeles from the Los Angeles County Flood Control Act and various county ordinances which address industrial wastes and waste discharges within the unincorporated areas of Los Angeles County and contract cities. 'Co-Permittees' with the status of incorporated cities have various forms of legal authority in place, such as charters, State Code provisions for General Law cities, city ordinances and applicable portions of Municipal Codes and the State Water Code, to regulate stormwater/urban runoff discharges.

8. The division and prioritization of Los Angeles County and adjacent areas into five drainage basins for program implementation are based on hydrological characteristics of the watersheds, perceived importance and beneficial uses of water bodies, and the existence of an adequate infrastructure for program implementation. The five drainage basins are :

I	:	Santa Monica Bay Drainage Basin
II	:	Upstream Los Angeles River Drainage Basin, to and including Sycamore Canyon Channel (San Fernando Valley);
III	:	Upper San Gabriel River (San Gabriel Valley) Drainage Basin.
IV	:	Lower Los Angeles River Drainage Basin
V	:	Lower San Gabriel River Drainage Basin; and Santa Clarita Valley Basin.

Attachment 3 shows a map of Los Angeles County with the boundary delineations of the five drainage basins.

Attachment 4 shows Co-Participant cities in Los Angeles County (and their respective populations).

[Note: Detailed maps of the Los Angeles County storm drain system with boundary delineations of drainage basins are available for review at the Regional Board Office.]

9. A number of studies on stormwater/urban runoff pollution in the permit areas has been conducted by agencies such as the City of Los Angeles, the Southern California Coastal Water Research Project and the Southern California Association of Governments. These studies indicate stormwater/urban runoff contributes significantly to the deterioration of the quality of water bodies in Los Angeles County.

The University of California at Los Angeles, under the sponsorship of the Santa Monica Bay Restoration Project, is currently compiling and summarizing data and information on stormwater/urban runoff discharges for the Santa Monica Bay watershed.

10. The Los Angeles County Department of Public Works has an active surface water quality monitoring program in the permit area, comprising twenty-eight monitoring stations located at principal storm drains and water conservation facilities. The Surface Water Quality Monitoring Program comprises the collection and analysis of dry weather water samples for general minerals, pesticides, total petroleum hydrocarbons, heavy metals and bacteria (total and fecal coliform, KF streptococci and enterococci). Volatile organic constituents are tested semi-annually at selected stations. Stormwater runoff is monitored three to four times annually at twenty-one stations for minerals, pesticides, heavy metals (total and dissolved), bacteria, total and organic suspended solids, oil and grease, biochemical oxygen demand, total organic carbon and volatile organics.

11. The Los Angeles County Department of Public Works and some cities have on-going activities that reduce stormwater/urban runoff pollutant loads. These activities include periodic catch-basin cleaning and street sweeping, public information on proper disposal of household hazardous waste, and emergency responses to reports of illegal dumping, illicit disposal, illegal connections, and industrial waste spills. The Los Angeles County Department of Public Works also participates and coordinates action with local, State, and Federal agencies responding to spills and illegal dumping reports that threaten surface waters.

12. The Regional Board currently regulates industrial process and point source non-process wastewater and stormwater discharges to storm drain systems through NPDES permits. Point source discharges including stormwater will continue to be regulated by the Regional Board. An information system will be developed and maintained to update pollutant loadings to designated

drainage facilities and water bodies from permitted point source discharges.

13. The State Water Resources Control Board (State Board) adopted a Water Quality Control Policy for the Enclosed Bays and Estuaries of California on May 16, 1974. The policy provides that the discharge of industrial process waters to enclosed bays and estuaries shall be prohibited. Storm water and urban runoff are not considered industrial process waters for the purpose of that policy.

14. The State Board adopted a revised Water Quality Control Plan for Ocean waters of California (Ocean Plan) on March 22, 1990, which amended the Plan adopted on September 22, 1988. The Plan contains water quality objectives for the coastal waters of California.

15. The Regional Board adopted a revised Water Quality Control Plan for the Los Angeles River Basin (Basin Plan) on November 27, 1978. The Basin Plan incorporates the Ocean Plan, and contains water quality objectives for the basin, including the beneficial uses of water bodies.

16. The beneficial uses of water bodies in Los Angeles County and their tributary streams include contact water recreation, non-contact water recreation, wildlife habitat, preservation of rare and endangered species, marine habitat, estuarine habitat, fish migration, fish spawning, industrial service and process supply, agricultural water supply, shellfish harvesting, navigation, commercial and sport fishing, and groundwater recharge.

17. Section 405 of the Water Quality Act of 1987 added Section 402(p) to the Clean Water Act of 1972 to require the Environmental Protection Agency (EPA) to establish regulations for stormwater/urban runoff discharge under the National Pollutant Discharge Elimination System (NPDES).

18. The Federal Clean Water Act allows EPA to delegate its NPDES permitting authority to States with an approved environmental regulatory program. The State of California is one of the delegated States. The Porter-Cologne Act (State Water Code) authorizes the State Board, through its Regional Boards, to regulate and control the discharge of pollutants into waters of the state and tributaries thereto.

19. Although Water Code Section 13263 (a) requires that waste discharge requirements issued by Regional Boards shall include provisions to implement water quality based objectives, numerical water quality standards

VOL 12

15689

are not provided in this Order. Information is not available to establish appropriate numerical limits, and determine locations where permittees shall be made accountable. The requirements in this Order will provide the necessary information while concurrently achieving reductions in pollutant loads to water bodies from stormwater/urban runoff discharges. Numerical water quality objectives will be developed by Board staff for consideration in the permit renewal process and utilized for the evaluation of Best Management Practices.

20. Due to the significance of the Los Angeles County Stormwater/Urban Runoff Program, the Regional Board, in recognition of the need for public involvement and participation in the development and implementation of an effective program will conduct at a minimum an annual workshop, prior to approving plans submitted by Permittees, to solicit comments and to inform the public of the progress of the program. Comments presented will be referred to Los Angeles County for response.

21. Stormwater/urban runoff discharges to drainage facilities that cross County boundaries and Regional Board jurisdictions, and which are regulated under NPDES permits, are the regulatory responsibility of those agencies issuing the permits.

22. The issuance of waste discharge requirements for this discharge is exempt from the provisions of the California Environmental Quality Act (CEQA); Chapter 3 (commencing with Section 21100) of Division 13 of the Public Resources Code in accordance with Water Code Section 13389.

The Board has notified the Permittees and interested agencies and persons of its intent to issue waste discharge requirements for this discharge and has provided them with an opportunity to submit their written views and recommendations.

The Board, in a public hearing, heard and considered all comments pertaining to the discharge and to the tentative requirements.

This Order shall serve as a National Pollutant Discharge Elimination System permit pursuant to Section 402 of the Federal Clean Water Act, or amendments thereto, and shall take effect at the end of ten days from the date of its adoption provided the Regional Administrator, EPA, has no objections.

IT IS HEREBY ORDERED that the Permittees, in order to meet the provisions contained in Division 7 of the California Water Code and regulations adopted thereunder, and the provisions of the Clean Water Act as amended and regulations and guidelines adopted thereunder, shall comply with the following:

1.0 COMPLIANCE

1.1 The Permittees and Co-Permittees shall comply with the requirements contained in this Order according to the following schedule:

	DRAINAGE BASIN	STARTING DATE FOR COMPLIANCE WITH REQUIREMENTS
I.	Santa Monica Bay	July 1, 1990
II.	Upper Los Angeles River (San Fernando Valley)	July 1, 1992
III.	Upper San Gabriel River (San Gabriel Valley)	July 1, 1992
IV.	Lower Los Angeles River	July 1, 1993
V.	Lower San Gabriel River and Santa Clarita Valley	July 1, 1993

2.0 REQUIREMENTS - YEAR 1

2.1 For each Drainage Basin, prepare and submit to the Regional Board within 12 months of the starting date for compliance, according to the schedule under 1.1:

2.1.1 Water quality data and flow data from 1980 to the present to facilitate identification of sources of pollutants present in discharges from the prioritized drainage basin. "Drainage areas" in the drainage basin are to be reported and the "drainage areas" associated with each drainage basin clearly identified.

For purposes of stormwater/urban runoff, a "drainage area" is defined as a subdivision of a drainage basin which is unique in land use patterns, and pollutant characteristics and loadings.

2.1.2 The 90th percentile value for the water quality parameters, (i) Total Suspended Solids (TSS), and (ii) Oil and Grease, from the data set of all wet weather samples collected from 1980 to the present. These data will be used to establish guidance for early action control of stormwater pollution.

The 90th percentile for a given water quality parameter is defined as the concentration value exceeded in ten percent of the samples of the reference data set.

2.1.3 Additional information of a qualitative nature that would contribute to isolating and identifying sources of problems. Such information should include but not be limited to visual observations of factors exacerbating stormwater contamination, principal land use classifications and Standard Industrial Code (SIC) categories of facilities in "drainage areas", and a description of soils, dumps, landfills, waste disposal sites and Resource Conservation and Recovery Act (RCRA) facilities associated with each area.

2.1.4 Monthly precipitation data from rain gauge stations, relevant to the drainage basin, for the years 1980 to the present, and an estimate of the area of impervious surfaces (including paved areas and building roofs) within each "drainage area".

2.1.5 Documentation of existing procedures to detect and address illegal discharges and illicit disposal practices.

2.1.6 Documentation of existing practices and improvement plans to control pollutants in stormwater/urban runoff from construction sites.

2.1.7 Documentation of existing stormwater/urban runoff management practices and existing Best Management Practices (BMPs) for the control of pollutants in discharges from residential, commercial and industrial areas.

For purposes of this permit, a Best Management Practice is defined as a stormwater quality management practice that has been demonstrated to reduce stormwater/urban runoff constituents of concern in studies in the United States and elsewhere, or a stormwater/urban runoff quality management practice that can significantly control stormwater/urban runoff pollution.

2.1.8 Plan with schedule of implementation, for approval by the Executive Officer, of early action BMPs.

For purposes of this permit, an early action BMP is defined as an existing stormwater/urban runoff quality management practice that is optimized to the maximum extent practicable (MEP) in efficiency for the control of stormwater runoff pollution, such as improving the frequency of storm drain catchment basin cleaning or the stricter enforcement of existing regulations, or a BMP that is not specific to stormwater/urban runoff constituents or "drainage area" in its constituent removal capacity and can be applied on a system-wide basis, such as public outreach and educational programs.

For purposes of this permit, maximum extent practicable means to the maximum extent possible, taking into account equitable considerations of synergistic, additive and competing factors, including but not limited to gravity of the problem, fiscal feasibility, public health risks, societal concern, and social benefits.

The Principal-Permittee, in the submittal of plans and schedules to the Executive Officer, shall demonstrate that public input has been obtained.

For purposes of this permit, public input is demonstrated by, (i) disseminating the notice of availability of plans for review and comment, to the public at large, environmental groups, Federal, State and local officials and other interested parties, and (ii) addressing concerns expressed by the public.

The Board may modify the plans in response to public input received at the Board during its comment/review period. Permittees are required to implement the original or modified plan on approval by the Executive Officer.

2.1.9 A workplan for the development of a stormwater/urban runoff monitoring program, for approval by the Executive Officer, to include but not be limited to the following information :

- listing of constituents and parameters to be monitored and the rationale for their choice.
- listing of monitoring locations and the rationale for their choice.
- listing of sampling methodology of choice and frequency of sampling for both wet weather and dry weather flow.
- supplementary information that influences the design of the monitoring plan.

VOL 12

15693

CA0061654

The Principal-Permittee, in the submittal of the workplan to the Executive Officer, shall demonstrate that public input has been obtained.

2.1.10 Documentation that each Permittee, individually and/or jointly, through the establishment of a joint powers authority or a stormwater utility, possesses adequate legal authority to operate and manage stormwater/urban runoff quality management programs, and/or plans to obtain the necessary legal authority to regulate illegal discharges and illicit disposal practices into storm drains, and to prosecute violators.

3.0 REQUIREMENTS - YEAR 2

3.1 For each Drainage Basin, prepare and submit to the Regional Board, for approval by the Executive Officer, within 24 months of the starting date of compliance, according to the schedule under 1.1:

3.1.1 A monitoring program based on the approved workplan. This program shall be designed to:

- detect accurately the constituents and parameters of concern, in discharges indicated in the workplan, and to identify their possible sources.
- identify illegal dischargers and/or locations of illicit disposal practices.

Monitoring reports for this program shall be submitted according to the format and frequency to be approved by the Executive Officer.

3.1.2 Plan with schedule of implementation for additional BMPs, judged appropriate for each city or drainage basin, to control pollutants from residential, commercial and industrial sites to the maximum extent practicable.

Both structural and non-structural BMP measures are to be evaluated at the MEP standard. Examples of non-structural measures include catch basin cleaning, street sweeping and public education, while controls such as detention/retention basins, first flush diversions, grassy swales and porous pavements are examples of structural measures.

3.1.3 Plan with schedule of implementation of procedures to detect and eliminate illegal discharges and illicit disposal practices.

3.1.4 Plan with schedule of implementation of measures to control pollutants in surface runoff from construction sites.

The Principal Permittee, in the submittal of plans and schedules (items 3.1.2, 3.1.3, and 3.1.4) to the Executive Officer shall demonstrate that public input has been obtained. The Board may modify the plans in response to public input received at the Board during its comment/review period. Permittees are required to implement the original or modified plans on approval by the Executive Officer.

3.2 Evidence of satisfactory progress of implementation of plan and schedule for early action BMPs.

3.3 Evidence of all requisite legal authority to regulate illegal discharges and illicit disposal practices to drainage facilities, and to prosecute violators.

4.0 REQUIREMENTS - YEAR 3

4.1 For each Drainage Basin, submit to the Regional Board, within 36 months of the starting date of compliance, according to the schedule under 1.1, the following:

4.1.1 Evidence of satisfactory progress of implementation of plan and schedule for early action BMPs and additional BMPs.

4.1.2 Evidence of implementation and progress of procedures to detect and eliminate illegal discharges and eliminate illicit disposal practices.

4.1.3 Evidence of implementation and progress of measures to control pollutants in surface runoff from construction sites.

5.0 EXPIRATION AND RENEWAL

5.1 This Order expires on June 18, 1995.

5.2 The Permittees shall file a report of waste discharge (ROWD), not later than 180 days before the expiration date, as application for reissuance of waste discharge requirements. This report of waste discharge shall include but not be limited to the following:

5.2.1 Summary of the results of the monitoring program.

5.2.2 Summary of BMPs implemented and evaluations of their effectiveness.

5.2.3 Summary of procedures implemented to detect illegal discharges and illicit disposal practices and an evaluation of their effectiveness.

5.2.4 Summary of measures implemented to control pollutants in surface runoff from construction sites and an evaluation of their effectiveness.

5.2.5 Evaluation of the need for additional BMPs, source control, and/or structural control measures.

5.2.6 Proposed plan of stormwater/urban runoff quality management activities that will be undertaken during the term of the next permit.

I, Robert P. Ghirelli, Executive Officer, do hereby certify that the foregoing is a full, true, and correct copy of an order adopted by the California Regional Water Quality Control Board, Los Angeles Region, on June 18, 1990.

ROBERT P. GHIRELLI, D.Env.
Executive Officer

APPENDIX I

Los Angeles County Beach Closures 1986-1992.

Appendix I. Los Angeles County beach closures, 1986-1992 (LAC,DHS unpubl. data).

LOS ANGELES COUNTY BEACH CLOSURES 1986 - 1992

Date Closed	No. of Days	Location	Cause
03/20/86	2	Redondo Pier to ¼ mile southward.	Sewage discharge under Redondo Pier.
09/26/87	2	Temescal Storm Drain to Sunset Storm Drain.	Sewage discharge due to sewage pump failure.
10/07/87	1	100 yds. north and south of Santa Monica Canyon Storm Drain.	Sewage discharge due to blocked sewer line. 100 gallons.
10/22/87	6	½ mile north of Sunset Storm Drain to ½ mile south of the Bel Air Bay Club.	Sewage discharge due to pump failure.
10/22/87	6	Ventura County border to Long Beach City border.	Sewage discharge at North Outfall Treatment Facility, due to heavy rains. 2.7M gallons.
10/22/87	42	Marina Del Rey Beach.	Excessive bird population leading to elevated bacterial levels.
10/30/87	13	Temescal Storm Drain to Sunset Storm Drain.	Unknown.
10/31/87	12	Ventura County border to Long Beach City border.	Sewage discharge at North Outfall Treatment Facility, due to heavy rains. 4.11M gallons.
11/25/87	5	Temescal Storm Drain to Sunset Storm Drain.	Unknown.
12/01/87	3	Temescal Storm Drain to Sunset Storm Drain.	Sewage discharge due to unknown sewer system failure. Approximately 2K gallons.
12/30/87	3	Pulga Canyon Storm Drain to Santa Monica Canyon Storm Drain.	Unknown.
06/03/88	1	¼ mile either side of Pulga Storm Drain.	Sewage discharge due to sewage pump failure.
07/06/88	1	¼ mile either side of Sunset Storm Drain.	Sewage discharge due to line blockage.
09/15/88	2	Santa Monica Pier south to Pico/Kenter Storm Drain.	Suspected sewage discharge from Santa Monica Pier Storm Drain.
10/07/88	1	Pico/Kenter Storm Drain to ¾ miles southward.	Possible diesel fuel flow from Pico/Kenter Storm Drain.
11/10/88	3	Venice Pier to Grand Ave. Storm Drain.	Sewage discharge into Ballona Creek due to sewer line blockage.
12/12/88	3	Sunset Storm Drain to Temescal Storm Drain.	Sewage discharge due to sewage pump failure.

VOL 12

Appendix I (Cont.)

LOS ANGELES COUNTY BEACH CLOSURES
1988 - 1992

Date Closed	No. of Days	Location	Cause
01/23/89	3	200 yds. north and south of Santa Monica Pier.	Small sewage discharge under Santa Monica Pier.
03/06/89	3	King Harbor south ¼ mile to Ainsworth Court.	Sewage discharge due to restaurant sewer line blockage.
05/02/89	2	Venice Pier to Imperial Ave. Storm Drain.	Sewage discharge into Ballona Creek due to sewage pump failure. 100K gallons.
09/26/89	3	¼ mile either side of Ashland Storm Drain.	Sewage discharge of unknown origin into Ashland storm drain. Est. less than 500 gallons.
11/20/89	1	½ mile either side of Pulga Storm Drain.	Sewage discharge due to pump failure caused by tripped circuit breaker. Est. 1.5K gallons.
12/13/89	2	Sunset Storm Drain to Temescal Storm Drain.	Sewage discharge due to pump failure caused by faulty air check valve at pump station 639. Approximately 6.5K gallons.
02/17/90	4	Entire Los Angeles County coastline from Topanga Canyon Storm Drain to Palos Verdes Point.	Discharge of primary treated sewage from North Outfall Treatment Facility, due to heavy rains. Approximately 7.6M gallons.
9/19/90	9	Santa Monica Pier south to Ashland storm drain. Reopened Ashland to Hart St. on 9/21/90.	Possibly caused by construction on the Pico/Kenter storm drain. Release of accumulated debris. Not sewage related.
12/10/90	4	King Harbor south to Pearl Street extended (appx. ¼ mi. north and south of Redondo Pier)	Small sewage leak from 12" main.
02/28/91	14	Topanga Canyon Blvd. south to Palos Verdes Point. Closure reduced to Marina Del Rey entrance channel south to the El Segundo city line and Marina Del Rey on 3/5/91.	Discharge of 2.31M gallons partially treated sewage at the North Outfall Treatment Facility due to heavy rains.
03/01/91	13	Topanga Canyon to the Ventura County border. Closure reduced to Topanga Canyon to Malibu Creek on 3/6/91.	Washout of private sewage treatment systems due to heavy rains.
03/24/91	1	Surfrider Beach, Malibu.	Diesel fuel spill.
03/29/91	2	Grand Ave. north to Imperial Highway.	Diesel fuel spill.

VOL 12

1 5711

Appendix I (Cont.)

LOS ANGELES COUNTY BEACH CLOSURES
1988 - 1992

Date Closed	No. of Days	Location	Cause
11/21/91	4	Imperial Highway storm drain, one mile north and south.	Sewer line break at Hyperion Treatment plant resulting in flow of sewage into Imperial Hwy. storm drain and 2K gallons of sewage into ocean. Partially reopened 11/22/91.
02/10/92	11	Entire L.A. County coastline, from Ventura County of Long Beach City.	Discharge of 66.12M gal. partially treated sewage at the North Outfall Treatment Facility due to heavy rains. Partially reopened 2/19/92 from MDR entrance channel to Cabrillo Beach.
05/02/92	3	Dockweiler Beach, ½ mile north to 1 mile south of Marina Del Rey entrance channel and Marina Del Rey Beach.	High Bacteria counts detected in Ballona Creek, most likely caused by a small sewage discharge which occurred when a contractor accidently drilled into a sewer line. This coincided with civil disturbances in Los Angeles and as a precautionary measure beaches were closed.
05/16/92	1	Redondo Beach Pier, south to Ruby St. (appx. ¼ mile).	Leaking sewer line under the Redondo Beach Pier. Quantity unknown.
07/29/92	1	Redondo Beach Pier, south to Ruby St. (appx. ¼ mile).	Leaking sewer line under the Redondo Beach Pier. Quantity 50 - 75 gallons.
08/15/92	3	Rose Ave. south to Imperial Highway (appx. 4 miles).	High bacteria counts originating from sewage in upper Ballona Creek, source unknown. Coastline reopened 8/18/92 and Marina Del Rey Beach reopened 8/19/92.
08/17/92	3	Redondo Beach Pier, south to Knobhill Ave. (appx. ¾ mile)	Leaking sewer line under the Redondo Bch. Pier due to vandalism. Amount and duration unknown.

APPENDIX B

EXECUTIVE SUMMARY

The Pico-Kenter Canyon storm drain has become the archetype for assessing the problems and possible solutions that can be associated with many of the urban storm drains in the Santa Monica Bay region. While known events of chemical contamination are few, the drain has long been known to be contaminated with indicator bacteria such as Total and Fecal Coliforms. More recently, the consistent identification of Human Enteric Viruses, F-male Specific Coliphage, and high densities of Enterococcus bacteria have indicated that a potentially serious public health threat exists. The City of Santa Monica, with the assistance of the Santa Monica Bay Restoration Project (SMBRP), the United States Environmental Protection Agency (EPA), and the UCLA Laboratory of Biomedical and Environmental Sciences (LBES), recently completed an evaluation of ozone for the treatment of dry-weather storm drain flows. The primary goals of this study were to establish if ozone could be used to disinfect the water that typically flows from the Pico-Kenter storm drain and determine if some known hazardous chemical contaminants were present at significant levels.

Recently, ozone has become renowned in the drinking water industry as an alternative to chlorine that rapidly disinfects water while forming few halogenated by-products. This study demonstrated that ozone was an effective disinfectant, reducing bacterial and viral populations by 3-5 log (99.9 to 99.999% of the microbes killed or inactivated). In many of the 438 effluent samples, coliform concentrations were sufficiently reduced to qualify the water for reclamation projects such as landscape irrigation along the Santa Monica Freeway, suggesting a possible useful role for the treated effluent. Ozonation by-products (aldehydes) were detected in the plant effluent at low (<100 PPB) concentrations. No significant increases in halogenated by-products, or mutagenicity, were observed following ozone disinfection. During a test of the ozonation process, twelve organic chemicals were added to the influent water and the effluent monitored. While some refractory compounds passed through the pilot facility intact, the concentrations of most were reduced.

In comparison to State Ocean Plan Water Quality Objectives and Federal Drinking Water Maximum Contaminant Levels, the primary hazardous chemical constituents in the influent storm drain water were metals (primarily copper and lead) and polynuclear aromatic hydrocarbons (PAHs). While lead levels were significantly above both standards, the concentration of copper was well under drinking water standards. The mean observed level of six major PAHs were approximately equal to their proposed phase V drinking water MCL standard (100-400 ng/L or PPTr). Isolated samples were found to contain organic contaminants, such as ortho-xylene and the pesticide chlordane. This did not appear to be a pervasive problem and can be attributed to isolated events that cannot be anticipated and will only be prevented through an informed and concerned public.

VOL 12

15719

While the metal content of the water cannot be reduced using ozone, this study found that high concentrations of some organics, including PAHs, can be reduced during the ozonation process. This remediation probably occurs by oxidation and hydroxylation to less hazardous forms. Irregardless of further ozonation investigations, additional more sensitive and definitive PAH analyses are warranted in future studies of the storm drain water and sediments.

Based on the results of this investigation, the City of Santa Monica is investigating construction of a disinfection facility that would reclaim high quality water for landscape irrigation, use low quality for sewer flushing, and disinfect the remainder prior to releasing it into the Santa Monica Bay. Construction of the proposed facility would be encouraged by the support of the Santa Monica Bay Restoration Project in goal definition and consensus building among the member and non-member agencies.

Summary Conclusions

1) Ozone at moderate doses (10-20 mg/L) was an extremely effective disinfectant of dry-weather storm drain flows.

2) Bacterial and viral levels were reduced 3-5 log (99.9% to 99.999% of the microbes killed or deactivated).

3) Much of the effluent was sufficiently disinfected to meet the landscape irrigation standard of 23 coliforms per 100 ml.

4) Based on California Ocean Plan Water Quality Objectives, heavy metals and polynuclear aromatic hydrocarbons appear to be the primary contaminants of concern in the pilot plant effluent.

5) While ozone disinfection by-products were detected (aldehydes), their concentration was low and, in contrast to what would be expected from disinfection by chlorination, no increase in mutagenicity was observed following ozonation.

Summary Recommendations

1) The SMBRP should encourage further evaluation of the ozone disinfection process, by promoting the City of Santa Monica in its effort to design and construct a full scale facility.

2) Since construction and operation of the proposed facility will require interagency consent and permitting, the City of Santa Monica solicits the continued assistance of the SMBRP in consensus building, policy direction, and technical support.

3) Further investigations into the use of the ozone technology should include provisions for the evaluation of Advanced Oxidation Processes (AOPs), using hydrogen peroxide and ozone, for the control of organic pollutants such as PAHs.

INTRODUCTION

In contrast to the success achieved in controlling point sources of water pollution, storm drains and other non-point sources of pollution remain a significant threat to the environmental and public health of our national waterways (GAO 1990 and Water-2000 1991). The popular perception of these conveyances is expressed by the antiquated, but still prevalent, descriptive phrase "storm sewers", suggesting a pipe that conveys wastewater to a treatment facility that purifies the water into a non-polluting effluent. However the Civil Engineer knows, and the public is being educated to the fact, that storm drains are only tubes meant to rapidly convey rainfall to a nearby lake, river, or bay, without significant treatment to remove the pollutants that maybe present.

Rain falling in urban areas becomes contaminated by scavenging pollutants such as Polynuclear Aromatic Hydrocarbons (PAHs) even before reaching the ground (Tsai et al, 1991). The runoff is further contaminated by passing through fields or lawns that contain fertilizers, pesticides, and decaying organic matter. Urban areas are also significant sources of additional pollutants including construction site suspended solids, transportation-derived metals, particulates, oils and previously deposited aerial fallout. Even hazardous substances, which may be present at outdoor storage and manufacturing facilities, find their way into storm drain water. While urban runoff, groundwater infiltration, and National Pollutant Discharge Elimination System (NPDES) permitted facilities, produce a steady stream of contaminated water, spills and illegal releases of hazardous chemicals continue to regularly occur with potentially disastrous implications (SCAG 1988). Additional sources of urban storm drain pollutants include illegal sewer and floor drain connections, sanitary sewer overflows, swimming pool drainage, lawn over-watering, human and pet fecal matter, vehicular and structural washdown, leaking cooling systems, and automotive repair shop off-site drainage.

A second aspect of the storm drain pollution problem, is attempting to economically deal with the volume of water that must be conveyed. In many regions of the United States, precipitation is evenly spaced throughout the year and undeveloped land is relatively affordable. In these areas, management practices, such as open spaces and park-like detention basins, can help to detain water on-site, provide additional area for infiltration, and reduce the stormwater pollutant loading (Davenport 1990). Unfortunately, in Southern California rainfall and runoff are observed on one or two dozen days each winter and the large percentage of impervious surface assures that a immense volume of water must be processed in an exceedingly short time. Furthermore, the high value of land in Southern California ensures that little open space remains for the installation of treatment or detention facilities, especially when usage is limited to few dozen days per year and the adjacent developed areas might become susceptible to periodic flooding.

VOL 12 1572/

The City of Santa Monica, California, located just west of Los Angeles, is an extreme example of a populated urban community with a resident population of 86,900 (1990 census), a significantly larger business population, and a surface area of only 8.147 square miles. Santa Monica was founded in 1875 and is mainly zoned for residential and commercial use, with confined industrial areas. The municipal infrastructure is well developed and most of the storm drain system was constructed prior to 1960. Since then, numerous multistory buildings, parking lots, roofs, roadways and other impervious surfaces have been added, covering an estimated 70% of the total municipal surface area and exceeding the drainage capacity of the system. Eight, of the fourteen storm drains in the City, discharge onto municipal beaches, while the remaining six drains pass through adjacent portions of Los Angeles before entering Santa Monica Bay. Although originally constructed to seasonally empty into the ocean, accretion of beach sand has resulted in some drains discharging directly onto public beaches where trash and other debris accumulates and ponding occurs. Several of these areas have been identified as major sources of biological and chemical contamination during both wet (rainy) and dry-weather conditions. While incidents of chemical contamination are few, the drainage water often contains high levels of indicator organisms that pollute the adjacent marine environment and are associated with human and animal fecal input (PLC 1988).

The Kenter Canyon, Pico Boulevard, and Santa Monica Freeway or Caltrans (California Department of Transportation) storm drains all terminate under Pico Boulevard at The Promenade, entering a concrete lined channel before spilling onto the beach. The latter two are completely within the City of Santa Monica and join approximately one kilometer upstream of the beach, but have significantly different source characteristics and should be considered independently. The Kenter Canyon Storm drain enters Santa Monica along its northeast boundary, after having drained canyon, suburban and commercial areas of Los Angeles City. Two thirds of the total Kenter Canyon drainage area of 6.28 square miles is in the City of Los Angeles. Approximately one third of the total City of Santa Monica area is discharged at the combined three drain outlet. While the California Department of Transportation is responsible for the Santa Monica Freeway drain, the Pico and Kenter Canyon drains are maintained and operated by the Los Angeles County and City Departments of Public Works and City of Santa Monica Department of General Services.

The dry and wet weather flow, from the Pico-Kenter Canyon storm drain outfall, primarily consists of water conveyed by the Kenter Canyon storm drain. During dry weather, the Pico and Caltrans drains usually contain little water and the flow is generally less than a few thousand gallons per day. In contrast, the Kenter Canyon Storm drain has a dry-weather flow estimated at between one hundred thousand and three million gallons per day (SCCWRP 1973), most of which enters Santa Monica from the upper drainage basin. Low flows during this study were normally estimated at between one and three hundred thousand gallons per day (70-210 GPM). During a significant storm, this stream swells to an estimated hundred million gallons per day, fills the enclosed 10 by 12 foot Kenter Canyon storm drain, and lifts manhole covers.

For decades, the effluent from the mouth of the Kenter Canyon storm drain has formed large ponds on the beach, where young children would play away from the surf, and wildlife would find a source of freshwater. Over a dozen years ago, the outfall became suspect as a source of carcinogens which may have affected the health of lifeguards stationed near it. Since then, the Pico-Kenter has become one of the most heavily investigated storm drains in the country. The beach adjacent to it is now posted to warn bathers to avoid the area and storm drain water in general.

While the evidence of chronic chemical contamination is mixed, it appears that few recognized hazardous contaminants are present in significant concentrations (PCR 1988). Among those that are present, most are found in low concentrations and at levels that are comparable to other storm drains (SCAG 1988b). Assuming a five fold initial dilution, and comparing the mean values reported in State of the Bay report (SCAG 1988b) with the 1990 California Ocean Plan, several pesticides exceeded the water quality objectives given in the Plan. In particular, the DDT, DDE, and DDD group was several hundred times above the 1990 objectives. The endrin and endosulfan (including heptachlor) groups also exceeded objectives by 6 to 20 times. Copper was determined to be at about six times the water quality objectives while lead, chromium, zinc, and nickel were all slightly above their respective goals. Significant spills of hydrocarbons, probably vehicular fuels, were observed in the outfall in September 1980, December 1985, and September 1986, and caused beach closures and the posting of warning signs (PCR 1988).

The problem of microbial contamination in the Pico-Kenter effluent is more clear than that of chemical contamination and has warranted significant attention from various agencies and advocacy groups. Biological standards are based on the enumeration of benign indicators, such as enterococcus and total and fecal coliform bacteria, because of the difficulty in estimating the number of human pathogenic (disease causing) organisms, such as enteric viruses. Unfortunately, as was extensively reviewed in the State of the Bay report (1988b), all of the standard indicators have sources other than human fecal material. The California Ocean Plan standards for total coliform organisms can be summarized as 1,000 bacteria per 100 ml of water, yet this group of microbes are common constituents of soil and vegetation and are prevalent in the urban runoff found in storm drains. The criterion for fecal coliform and enterococcus bacteria are 200 and 24 organisms per 100 ml. respectively. Both of these groups are prevalent in the intestinal tract of endotherms and would be anticipated in the runoff from communities with large pet populations or where birds bathe and roost, as is observed in the beach ponds below the Pico-Kenter outfall. Not surprisingly, the Pico-Kenter outfall, even with ocean dilution, frequently exceeds the standards for these indicator bacteria. However, due to the prevalence of non-human sources, the presence of these indicator bacteria in storm drain effluent has been minimalized and not used as evidence of a public health threat for exposure to pathogenic organisms. The recent detection of human enteric virus in the mouth of the Kenter Canyon storm drain (Gold et al. 1990), indicates that a defined public health threat may indeed exist and that the storm drain low-flow may warrant treatment to control human pathogenic organisms.

In response to concerns for the public and environmental health, the City of Santa Monica has participated on commissions and undertaken studies and projects, with the goal of reducing exposure to contaminated storm drain effluents. The Cities of Santa Monica and Los Angeles have joined with Los Angeles County in directing the combined Pico-Kenter dry-weather effluent through a by-pass pipe, 600 feet into the ocean in an effort to reduce the exposure of terrestrial organisms to contaminants. As part of this project, the Consortium has also installed hydrocarbon sensors that warn authorities in case of a significant fuel spills. The Cities have begun construction of a temporary diversion to pump the dry-weather flow into a sanitary sewer for eventual treatment at the Hyperion Sewage Treatment Facility. The City of Santa Monica also commissioned a treatment orientated preliminary assessment for the Pico, Caltrans, and Kenter Canyon Storm Drains which concluded that chlorination could be successfully used to disinfect the dry weather flow (JMM 1987). However, chlorine is a hazardous chemical with significant storage and transportation risks. In addition, the chlorine gas disinfection process, requires long contact times, forms many carcinogenic disinfection by-products, and ocean release of the chlorinated water would require a dechlorination step. Furthermore, the proposed facility would have been placed on a heavily used public beach, adjacent to resort hotels, and would probably have encountered significant resistance from local environmental and neighborhood advocacy groups.

Recently, ozone has become renowned in the drinking water industry as an alternative to chlorine, that rapidly disinfects water while forming few halogenated, and toxicologically potent, by-products (Tate 1991). Unlike chlorine, ozone is generated from air or oxygen at the time of use and does not require the storage or transport of hazardous chemicals. During an emergency, electrical generation of ozone terminates and the ozone rapidly reverts back to oxygen. The process of ozonating water is easily monitored using off gas and effluent monitors, so that the dosage can be instantaneously increased to meet the challenge of contaminated material entering the treatment stream. The dissolved ozone residual in the plant effluent, rapidly degrades and introduces little environmental hazard. Off-gas ozone is rapidly returned to oxygen by passage through a heated metal catalyst.

VOL 12

15724

The City of Santa Monica, with the assistance of the Santa Monica Bay Restoration Project (SMBRP), the United States Environmental Protection Agency (EPA), and the University of California Laboratory of Biomedical and Environmental Sciences (LBES), recently completed an evaluation of an ozonation pilot plant for the treatment of dry-weather storm drain flows. The major goal of this study was to determine if ozone could be used to disinfect the water that typically flows from the Pico-Kenter Canyon storm drain. Unlike drinking water, the storm drain effluent is high in suspended solids and organic carbon, factors that might be expected to significantly reduce the efficacy of ozone disinfection. Secondarily, this study was also intended to develop a comprehensive and long-term analysis of chemical constituents in both the influent and treated water and their variability. This information could then be used to determine if construction of a full scale facility was warranted, which pollutants would be amenable to treatment at the proposed plant, and what process train the facility should incorporate.

METHODS

A. Location, Design and Operation of the Ozone Pilot Plant

This project was facilitated, by the placement of the Santa Monica Municipal Bus Yard over the Kenter Canyon storm drain near the corner of 5th Street and Olympic Boulevard in Santa Monica. This facility provided security, utilities, and supportive staff that assisted in maintenance activities. Operation of the pilot plant began in November 1989 and continued through December of 1990, but was intermittent during June, July, and August due to organic contamination that was eventually traced to the rupture of a sanitary sewer into an upstream catch basin. Sampling was occasionally suspended due to plant modifications or monitoring device failures. Generally three sample runs were conducted during each day of operation. Each run consisted of an influent/effluent sample pair with the treated sample collected after a time delay sufficient to allow the influent sample plug to reach the effluent port. This time delay was equivalent to the contactor tower volume (12 gallons) divided by the flow rate (1- 6 GPM) which yielded delays of 2 to 12 minutes. Feed gas flow ranged from 2-18 Standard Cubic Feet per hour (SCFH) with an ozone concentrations of up to 4.5%. Effluent dissolved ozone residuals of up to 10 mg/L (PPM) were observed. Although dosages of up to 40 mg/L (PPM) ozone were delivered, operation was generally in the 5-20 PPM range.

In general, all materials exposed to ozone were constructed of either stainless steel, polyvinyl chloride (PVC), borosilicate glass, or teflon. Swagelock® fittings and valves were utilized for lines smaller than ½ inch, while PVC valves were used on the water lines. Most of the samples were collected with the flow design shown in figure 1 and the schematic plant configuration shown in figure 2. The daily operating schedule commenced with provision of compressed gas and warming up of the ozone generation and monitoring systems. Compressed air was prepared using a Dayton Speedaire® oil-less air compressor (model 3Z852) equipped with aftercooler, air filter, and relief valve. Later in the study, standard cylinders of industrial grade compressed oxygen were obtained from the Liquid Air Corporation. The use of compressed oxygen, rather than air, doubled the ozone production in the influent gas and effectively doubled the applied dose, but does not significantly influence the disinfection process or basic treatment parameters. For all but the largest ozone facilities, generation from air is more economical than first separating oxygen from air. The submersible pump (Goulds #3885) was secured in a large plastic housing, with 1.5 mm aluminum mesh screen, lowered into the storm drain, upstream of a temporary weir, and the screened water pumped to the surface and into a 110 gallon polyethylene holding tank. Once the level in the tank reached the return overflow, water was pumped through an Ace-50 swimming pool-type pump through an RMC-145 flow meter (1-9 GPM) and into the top of the contactor tower.

VOL 1 2

1 5 7 2 6

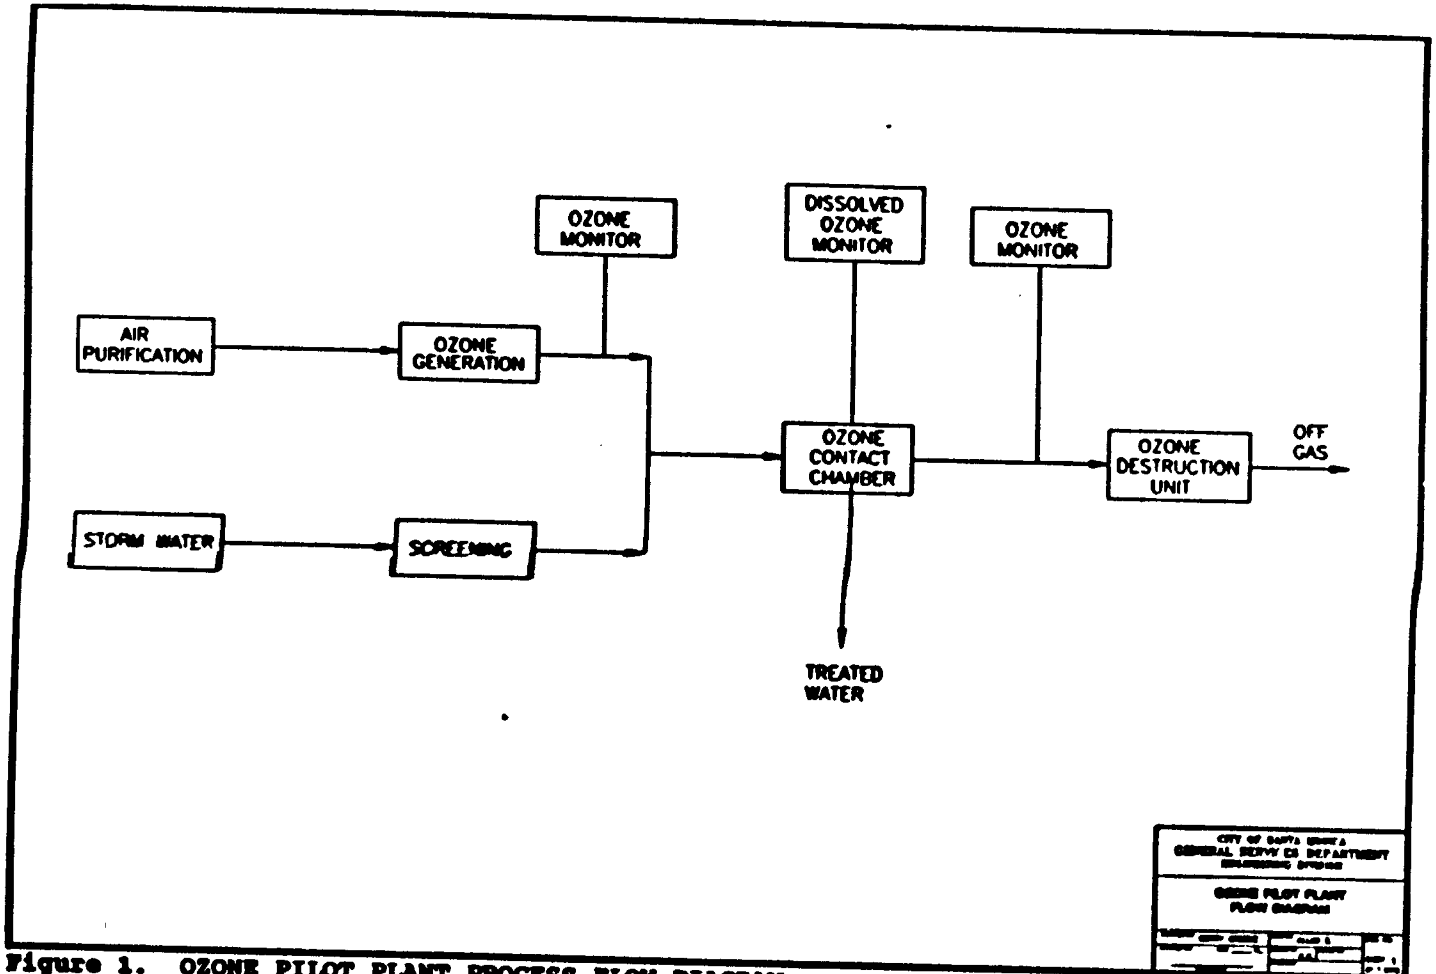

Figure 1. OZONE PILOT PLANT PROCESS FLOW DIAGRAM.

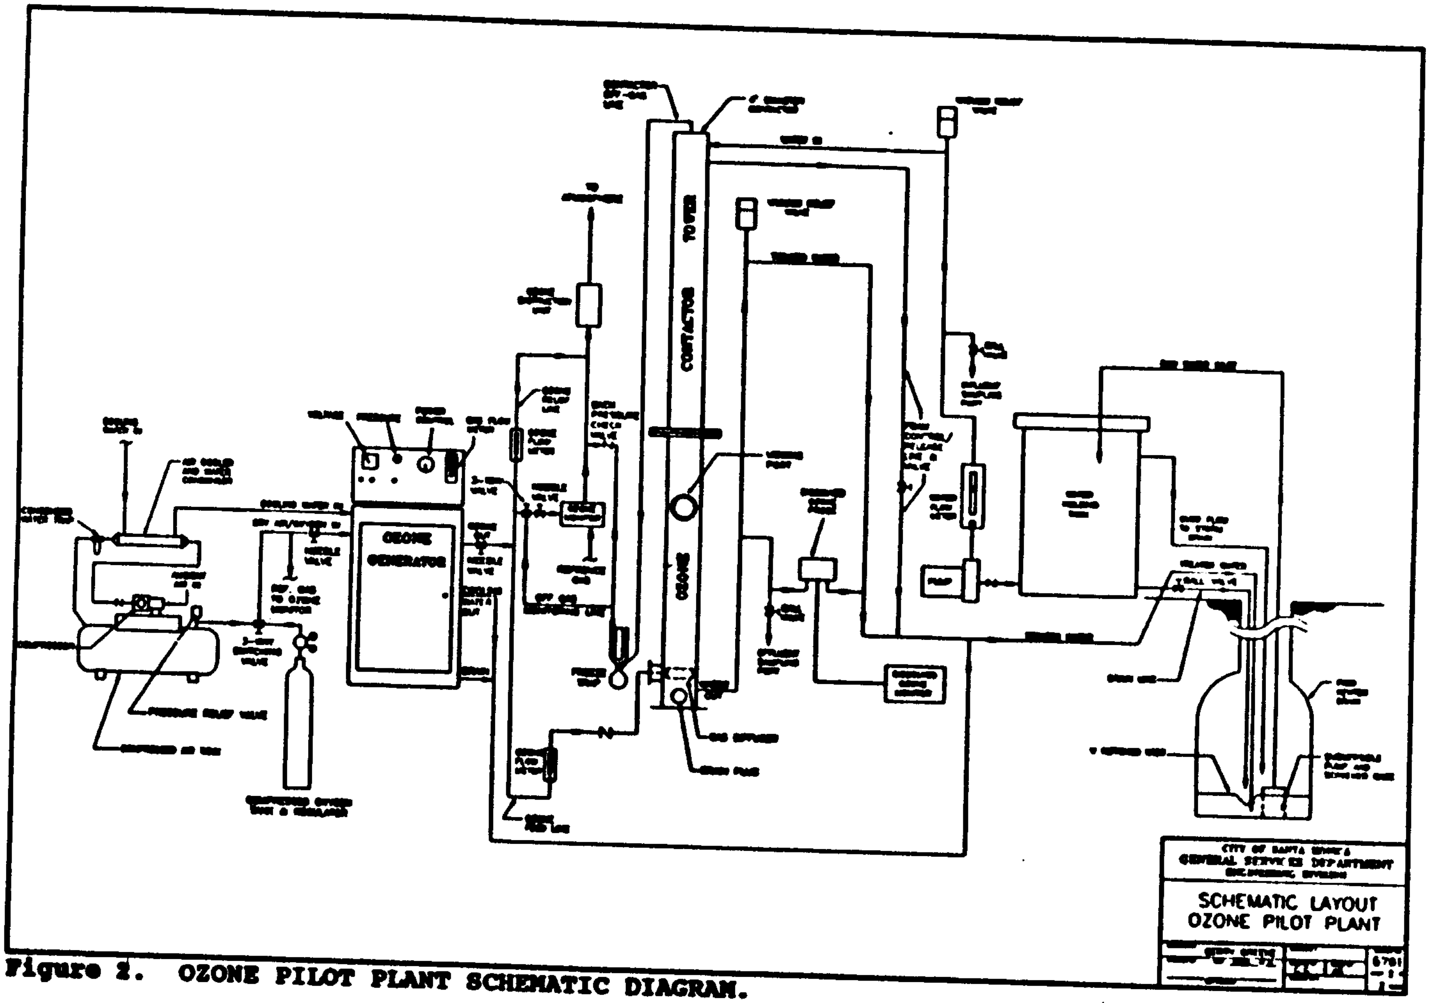

Figure 2. OZONE PILOT PLANT SCHEMATIC DIAGRAM.

The contactor tower, ozone generator, and flow meters were generously supplied by the Hankin Ozone Company of Scarborough, Canada and San Francisco, California. The stainless steel contactor tower was composed of two section with a 10 cm inside diameter and total height of 6 meters. The gas flow meters were rotameter type and calibrated to deliver the specified flow (1-18 scfh) with the 6 meter water head pressure. The ozone generator was a Hankin dual Ozotec® lab unit with cabinet. The bulk of the feed-gas leaving the ozone generator was passed through the flow meter and into the bottom of the contactor tower through a cylindrical ceramic diffuser (bubbler) to increase transfer efficiency. A side stream from the generator could be passed through a 3-way valve to a PCI HC® ozone gas monitor, which determines ozone concentration on the basis of UV light absorbance. After the flows of water and gas were initiated, the process was monitored and allowed to stabilize for at least 15 minutes prior to each sample collection. Samples were taken as influent/effluent pairs, with an appropriate delay for flow through the treatment train. The delay was determined based on the assumption that the influent water would travel through the tower as a plug. An Orbisphere dissolved ozone probe was installed adjacent to the effluent sampling port and operated based on the manufacturer's instructions. During each sampling period, the dissolved ozone residual was recorded twice. Following treatment, the pilot plant effluent was returned to the storm drain downstream of the weir.

The tower off-gas was passed through a water vapor trap, a check valve, and then the remaining ozone was catalytically reverted to oxygen by passage through a Carulite® 200 (Carus Corp.) manganese dioxide ozone kill unit. The water vapor trap was a Dewar type condenser (Ace glass # 5964-14), with Claisen adapter (Ace Glass # 5055-10), and 50 ml boiling flask. It was utilized, as described below, to prevent water vapor from passing into the ozone gas monitor. Prior to pilot plant installation, the vapor trap was tested in a by-pass loop between the generator and gas monitor to insure that the device would not directly influence ozone concentration. No difference in ozone gas concentration was observed after passage through the trap. During normal operation, the trap condenser was filled with a dry-ice/butanol mixture and the contactor tower off-gas passed in through the adapter side arm. While water, and sloughed off ice crystals, collected in the boiling flask, the off-gas would pass through the condenser where the water vapor would freeze out. Between the vapor trap and back pressure/check valve, a "T" led to the three-way valve and into the ozone gas monitor. During the sample run time delay, the 3-way valve was switched between influent and off-gas lines, the flow rate adjusted, and the ozone concentrations recorded. Normally, both ozone feed- and off-gas concentrations were measured twice per sample. The difference between these two values was used to calculate the absorbed or consumed ozone dose. If foam was noted in the vapor trap, holding tank or influent sampling port, sampling was generally suspended and the tower either drained or the top of

VOL 12 1 5729

the tower "skimmed" via a foam release line and valve. When foam was present, the tower was observed to pressurize and water would be forced out, shortening the contact time and interfering with dosage estimation.

At the conclusion of each sampling day, the ozone generator was turned off, the ozone off-gas concentration allowed to fall to background, and the tower and holding tanks drained. The submersible pump and screen were then removed from the drain and the screen cleaned. The ozone generator, flow meters, and monitors were maintained as per manufacturers recommendations. On several occasions the tower was not promptly drained and the check valves failed. The ozone unit would then require extensively cleaning, after which it would take several days for the full ozone generating potential to return. This is probably associated with water vapor in the generator dielectric and illustrates the need for dry feed gas. The catalyst in the off-gas kill unit was also noted to "combust" organics when, during an incidental test of a sensor, water contaminated with gasoline (50-100 PPM) passed through the contactor tower and began reacting in, and melting, the plexiglass kill unit. During spiking tests, when the influent water was artificially contaminated, the effluent was collected in barrels and subsequently passed through a carbon filter (organics spiking tests), or chlorinated and dechlorinated (virus spikes), prior to release back to the drain. Following the summer 1990 sewage shut down, the ozone transfer efficiently was observed to be greatly reduced and the diffuser was eventually found to be contaminated with organic matter. The diffuser was subsequently cleaned in concentrated sulfuric acid and found to operate more efficiently then during earlier parts of the project.

B. Sampling Design

The sampling design basically followed that given in the Project Quality Assurance Plan which was approved by Kent Kitchingman of the EPA in November of 1989. Most of the deviations from the proposed plan were related to the additional analyses that were undertaken at the request of the project review board. Some changes were the result of concerns with the external certified laboratory analyses and are more fully elaborated in appendix A (Quality Control and Assurance Report). The basic goal of the analytical design was to identify those water quality and disinfection parameters which most substantially influenced the treatment process. In particular, we were concerned with those parameters which could be effectively monitored and controlled in a full-scale automated facility. The secondary goal was to identify known hazardous chemicals, in both the plant influent and effluent, and determine if they would constrain future operations or induce significant public health or environmental harm.

VOL 12 15730

Because the storm drain environment can be subjected to relatively small plugs of contaminants moving through the system, this study analyzed pre- and post-ozonation sample pairs, with an appropriate contact-time delay between them. The analyses were split into physical, biological, and chemical groupings. The physical analyses were performed at the pilot plant site and at the University of California Los Angeles (UCLA) Laboratory of Biomedical and Environmental Sciences (LBES). Biological analyses were performed at the site and at a certified contract laboratory. Chemical analyses were undertaken at UCLA and at the certified laboratory. While the intent of using both research and contract labs was to insure the quality of the results from the University labs, several difficulties arose in interpreting the contract laboratory results, which are elaborated in appendix A. Since this study was primarily concerned with disinfection, the staff utilized the minimal media Most Probable Number (MPN) method to analyze each of the 438 sample pairs for the number of total and fecal coliform organisms. The certified lab performed 48 duplicate coliform analyses and all of the Enterococcus analyses.

While the analytical chemical methods were chosen to provide a thorough screen of emissions into the Santa Monica Bay, the individual analyses were selected for specific secondary purposes. The concentrations of the individual metal analytes, including sodium, calcium, and magnesium, were critical to evaluating the potential usefulness of the water for reclamation. The formation of hexavalent chromium during ozone treatment was a concern of the SMBRP steering committee. Total Organic Carbon (TOC) can be correlated to bacterial counts and may be a indicator of sanitary contamination. Chlorinated pesticides, like DDT, have previously been detected in this drain and were a likely source of health or environmental risk that could be compared to previously published data. Volatile organic analysis was used to screen for gasoline components and previously reported chlorinated solvents, but also estimated the concentration of short chain aldehydes, a known ozonation by-product. The semi-volatile, or base-neutral acid extractable (method 625), analysis was included to screen for heavier hydrocarbons, such as polynuclear aromatic hydrocarbons (PAHs), and other significant, but non-traditional contaminants.

C. Analytical Methods

The analytical methods followed those given in the Project Quality Assurance (QA) Plan which was approved by Kent Kitchingman of the EPA and the other project officers in November of 1989. Following the validation described in appendix A, the duplicate sample spiking concentrations were reduced in several of the methods, in order to facilitate interpretation of the analytical results at the low contaminant levels observed during this study.

The analyses can be split into process, physical, chemical and biological groups. Among the process analyses, were the various flowmeters and ozone monitors previously described. Rotameter-type flowmeters were checked daily for accumulations of oil or debris that would inhibit free travel of the metering ball, and cleaned as needed. Water and gas flow rates were always verified immediately prior to, during, and following each sampling run. The gas and water ozone monitors were both solid state and self calibrating. The monitors were maintained as recommended by their manufacturers and repaired when indicated by the monitor or by questionable performance. The gas monitor generally failed catastrophically, while the dissolved ozone monitor failed both catastrophically and occasionally by degraded performance over the matter of a few hours. During occasions of degraded performance, the collected samples were discarded and repeated after repairs were completed.

The physical analyses included temperature, pH, conductance, turbidity, settleable solids, suspended solids, dissolved solids and total solids. The measurement of conductance was initiated in mid-January, 1990, using an ICM model 71250 portable, temperature correcting, conductivity meter and the analysis conformed to EPA Method 120.1 (EPA 1983). Fresh calibration standards were prepared monthly and the unit calibrated before each analysis. The measurement was taken within 15 minutes of sample collection, from the one liter samples used for pH, temperature, settleable solids and turbidity analyses, which were collected in polycarbonate graduated cylinders. The measurement of pH was initiated using a pocket meter, but by January, analyses were being made using a portable ICM model 41250 unit. Commercial prepared temperature corrected buffer solutions were used to calibrate the unit before each sample. Measurement was made within 15 minutes of sample collection, from the 1 liter sample, and conformed with EPA method 150.1 (EPA 1983). Temperature was measured using a standard glass laboratory thermometer that was checked weekly against a precision thermometer. Measurement was made within 15 minutes of sample collection from the 1 liter sample and conformed to EPA method 170.1 (EPA 1983), except that the thermometer was not mercury filled. This deviation did not appear to influence the results.

Turbidity measurements began in early January 1990 and were made using a Monitek model 21PE Nephelometer. The unit was calibrated between samples and the initial measurement was made within 15 minutes of sample collection. Influent samples exceeding 100 NTU were diluted until the desired working range was reached. The corresponding effluent sample was then identically diluted. Although method 180.1 was followed, two notable analytical difficulties arose. First the 1-10 and 10-100 NTU scales did not completely overlap i.e. a sample could read greater than 10 units on the lower scale, but less than 10 on the higher range. Careful analysis of standards indicated that both scales were in error by about 10% on a 10 NTU sample, with the error decreasing to 0% for values below 8 and above 15 NTU. Analyses that were observed to be within this range, were estimated from the readings on one or the other scale and the paired sample measured on the same scale. The second problem related to effluent samples which were observed to form gas bubbles on the wall of the turbidity cuvette. After "bumping" the bubbles free, the turbidity was found to be lower. It appeared that micro bubbles of dissolved ozone/oxygen aggregated or came out of solution during the delay between repeated sample analysis. Unfortunately, it is unknown whether the reduction in turbidity is due to aggregation of micro bubbles or settling of suspended material. Both of these difficulties are not expected to effect a full scale treatment facility and only trivially corrupt the results of this analysis.

After the completion of the above physical test, the remainder of the 1 liter samples were used to determine the quantity of settleable solids in poly carbonate Immhoff cones as per EPA method 160.5. It should be noted that occasionally material would settle on the walls of the cone, but not fall to the bottom. Usually a rapid rotation of the cone would cause much of the material to dislodge and fall downward for inclusion in the measurement.

The analysis for total solids (total residue, Method 160.3), dissolved solids (filterable residue, method 160.1) and suspended solids (non-filterable residue, method 160.2) followed basic EPA methodology except that the volume in the latter analysis varied between 50-1000 ml based on passage through the filter, rather than the anticipated residue weight. Residue measurements were made at LBES using a 1.25 liter sample collected in a clear Wheaton media bottle. After collection, the bottle was chilled on blue ice and transported to LBES for processing. Residue samples were generally processed within 6 hours of collection, although approximately 10% of the samples required up to 12 hours for completion, due to scheduling conflicts. Samples held for more than 4 hours were refrigerated until analysis was undertaken. All samples were allowed to dry overnight in a standard laboratory oven. Poor balance performance during the first 3 weeks led to unreliable results and required that the balance be repaired. Enumerations during this period are accurate to only about 10 mg. rather than the 1 mg observed during the bulk of the study.

The analytical chemistry methodologies employed during this study were Inductively Coupled Plasma Atomic Emission Spectrometric (ICP-AES) analysis of metals (EPA method 200.7), hexavalent chromium (EPA method 218.5 modified for ICP-AES analysis), total organic carbon (EPA method 415.2), organochlorine pesticides (EPA method 608), purgeable or volatile organics (modified from EPA method 624) and extractable or semi-volatile organics (modified from EPA method 625). The first three methods are taken from Methods for Chemical Analysis of Water and Wastewater (EPA-600/4-79-020 rev. March 1983), while the latter three are from Methods for Organic Chemical Analysis of Municipal and Industrial Wastewater (EPA-600/4-82-057). As anticipated in our QA plan, several changes were undertaken to better utilize our instruments in the low analyte concentration ranges which were observed during this study. These changes were minor and primarily served to increase and evaluate our sensitivity in the observed matrix.

The analysis for metals was conducted by Mr. Leon McAnulty, a senior staff technician at the Laboratory of Biomedical and Environmental Sciences of UCLA, using a research grade simultaneous Inductively Coupled Plasma-Atomic Emission Spectrometer (ICP-AES), with a 1.5 meter focal length. Samples collected during 1989 were analyzed with a meinhard nebulizer, while samples collected after that time were analyzed using the more sensitive ultrasonic nebulizer. Since acid digestions using ultra-high purity acids, new acid washed fleakers, and milli-q water, resulted in unacceptable levels of metal contamination, digestions were undertaken only on those samples that had greater than 100 mg/L of suspended solids. The detection limits reported in appendix B (Data Summary and Comparison to Relevant Standards) were determined using the method of the International Union of Pure and Applied Chemistry.

The primary change in the hexavalent chromium method (218.5) was analysis by the ICP-AES, rather than graphite AA, in order to utilize the sensitive ultrasonic nebulizer. Sample preparation was undertaken by project staff. During early March, the author became aware that hexavalent chromium blanks were contaminated at around 7 PPB. While this was above the method detection limit of 5 PPB, it was below the Ocean Plan Water Quality Objective (with 5:1 initial dilution) of about 10 PPB and did not warrant the significant time and financial expenditures required to find and replace the contaminant source. Reported values are not adjusted.

Because of equipment scheduling conflicts the analysis for Total Organic Carbon (method 218.5) could not begin until late December. Samples collected prior to this time were acidified and refrigerated, then analyzed, out of holding time compliance. The carbon concentrations in these non-compliance samples were typical of values seen during most of the study and were included in the data base. TOC analyses were undertaken by project staff under the supervision of the QA officer. Some samples containing high dissolved solids (salt) concentrations gave erroneous results due to chloride interferences and were excluded from the data base.

The delays encountered in performing organochlorine pesticides analyses was one of the more significant frustrations of the project. Fortunately, the purchase of a service agreement ensured that it was not one of the more costly aspects. Upon initiating the laboratory phase of this project, the Varian 3500 gas chromatograph with dual electron capture detectors was found to be severely malfunctioning. After a dozen service visits, the unit was returned to Varian and completely refurbished. It was only after a second certified lab unit failure, that the detector insulation was found to degrade over time. Following the return and evaluation of the GC in mid-April, pesticide analyses were begun, using both DB-5 and DB-1701 30 meter capillary columns hooked in parallel through a chromafit zero dead volume Y splitter, and integrated on a Spectrophysics 4270. Analyses was made using 4,4'-dibromooctafluorobiphenyl (DBOFBP) as an internal standard and hexabromobenzene as a surrogate. The choice of hexabromobenzene was made due to the unavailability of dibutyl-chlorendate, but it was found to be a poor substitute. The compound precipitated out of the spiking solution during freezer storage, then was slow to re-enter solution when returned to room temperature. This information became available after many analyses were completed and the bulk of the pesticide samples had been extracted. Fortunately, the recoveries from spiked samples indicate that extraction efficiencies were generally good. Sample extraction from the complex and organically rich matrix, was accomplished through the use of centrifuging and glass wool filtering. Concentration was performed using a combination of hot water baths, tube and block heaters. After analyses had begun, it was determined that alumina (neutral super III) clean-up was routinely required. Even with this step, most samples contained a significant number of false positives that would appear on one or the other, but not both, chromatograms. As discussed in appendix A, sample spikes were prepared using surplus EPA QA samples diluted to about the CLP detection limit. The extracted samples were stored at about -20C until analysis, at which time they received alumina clean-up and were reconstituted to a volume of 1 ml. Due to the delays in starting this analysis, one fourth of the total number of pesticide samples were analyzed out of holding time compliance.

The analysis of volatile compounds was performed at the Institute of Geophysics and Planetary Physics under the direction of Mr. Edward Ruth, a senior staff technician with over 4 years experience with the GC/MS and an extensive analytical chemistry background. The analysis was conducted using a Tekmar purge and trap unit with cryofocusing interface to a Finnigan gas chromatograph with DB-624 capillary column and mass spectrometer. The analysis was a hybrid of the 624 wastewater and 524 drinking water methods, using a 25 ml water volume to increase sensitivity. Six hazardous substance list compounds were also simultaneously analyzed and the results are included in the data summary appendix. The surrogate spiking compound, 4-Bromofluoro-benzene, was utilized during the analysis and the priority pollutants quantified by addition of three internal standards to the water sample.

The extraction of semi-volatile (method 625) compounds was performed at LBES by the QA officer. The only substantial change in methodology, was the combining of acid and base neutral extracts prior to concentration and analysis as a single GC/MS extract. The results given in the QA supplement (appendix A) demonstrate the validity of this modification. Extraction was conducted in groups of eight: 3 sample pairs, a travel blank and a spiked duplicate

VOL 12

1 5735

sample. As with the pesticide extraction, centrifugation and filtering was required to separate the aqueous/organic emulsion. A third "humic" layer formed between the two normal layers and was returned to the separatory funnel between extractions. Spikes were at either 20 or 40 PPB rather than the 100 PPB used in the method description. The analysis of extractable compounds was performed at the Institute of Geophysics and Planetary Physics under the direction of Mr. Edward Ruth using a Finnigan gas chromatograph with a DB-5 capillary column and mass spectrometer detector. Each sample contained 6 extraction surrogates and 6 internal standards.

During the brief spiking study, organic test compounds of interest were prepared at various concentrations, in 50 ml of acetone, then mixed into the holding tank just prior to beginning the treatment process. Methanol was originally used as the diluting solvent, but was found to have a significant ozone demand as a free radical scavenger. After the treatment process had run for approximately 10 minutes and was nearing equilibrium, normal influent and effluent samples pairs were taken for biological and chemical analyses. The effluent water was held in holding tanks and slowly pumped through granulated activated carbon (GAC) to remove the offending spiked compounds before being release back to the storm drain. The chemical analysis was performed using liquid-liquid micro-extraction and the pesticide method analytical instrumentation. To summarize the method, 30 ml of water was combined with 2 ml of hexane and vigorously (vortex) mixed for 1 minute. The organic layer was removed using fresh disposable pasteur pipettes and added to the 1 ml mark on an autosampler vial. The internal standard (DBOFBP) and a few anhydrous sodium sulfate crystals (to prevent water from contaminating the GC) were added to the extract, which was then analyzed. Since funding for the spiking study was not provided for in the agreement, it was not included or cleared in the QA/QC plan, but was described to the project review board and SMBRP technical advisory committee. Due to the carrier solvent, TOC analyses are only available for the pre-spike influent waters.

Information regarding the methodology for the mutagenicity extraction and assay can be obtained from the project QA officer or Dr. John Froines of the UCLA School of Public Health. The basic method called for resin extraction of influent and effluent waters, followed by extraction and concentration in hexane and acetone. The extracts were serially diluted and plated, following the EPA Interim Procedures for Conducting the Ames Mutagenicity Test (EPA 1983). Extractions and mutagenicity analyses were undertaken by staff under the direction of Dr. John Froines.

The bacteriologic analyses were undertaken by project staff working at the pilot plant site and by the certified laboratory. The methodology proposed in appendix B of the pre-project Quality Assurance plan was followed with minor adjustments for correct bracketing of the bacteria numbers and collection of the effluent

VOL 12

15736

samples in recently emptied dilution bottles. All of the 438 samples collected during this study were analyzed by project staff for the most probable number (MPN) of total and fecal coliform organisms in both the influent and effluent water. The analysis was undertaken using the Minimal Media Ortho-nitrophenyl-beta-D-galactopyranoside 4-Methyl Umbelliferyl-beta-D-Glucuronide method, also referred to by the specific generic name of Minimal Media O-MUG or MMO-MUG as in the EPA final ruling on its use (EPA, 1989). The supplier was Environetics (formerly Access Analytical) which markets the product under the Colilert® brand name. Briefly, a potentially contaminated water sample, is mixed, in a test tube with a sterile powder consisting of growth media, the two sugar dye complexes listed above, and antibiotics to inhibit the growth of competing organisms. The tube is then sealed, mixed and incubated at 36°C for 24 hours. Coliform organisms produce the enzyme beta-galactosidase, which cleaves the ONPG sugar dye complex, causing the culture to become yellow. Similarly, _Escherichia coli_, the primary fecal coliform, produces the enzyme beta-glucuronidase, which cleaves MUG releasing a greenish fluorescent dye that is clearly visible under ultraviolet light.

Using the same statistical methods developed for the Multiple Tube Fermentation (MTF) method, it is them possible to take the results from the MMO-MUG analysis and estimate the number of total and fecal coliform organisms per volume of the original sample. The certified laboratory initially used the Membrane Filtration (MF) method 9222A-E (APHA 1989) for total and fecal coliform analyses, but shifted to the MMO-MUG method mid-way through the project. The enterococcus analyses were only undertaken by the certified laboratory which always used the membrane filtration standard method 9230 A,C (APHA 1989). While the results were decipherable, the project QA officer found that the bacterial analyses from the certified laboratory were frequently erroneous and that their results required some interpretation. This difficulty is further elaborated in appendix A.

The virus spiking study was conducted by Charles McGee and staff of the Sanitation Districts of Los Angeles County on June 5, 1990, using a modification of Standard Method 9510-B (APHA 1989). Attenuated, vaccine strain type 1, poliovirus was added to about 85 gallons of water pumped from the storm drain into the surface holding tank. The tank was then mixed for about 5 minutes prior to being pumped into the treatment system. Influent samples were taken at the beginning and termination of each run. Effluent samples were collected after 20, 40, and 60 gallons of seeded water had been treated. The quantity of virus in the samples was determined at the County Sanitation Districts Laboratory. Samples were assayed on Buffalo Green Monkey Kidney cells using the plaque forming unit technique (EPA 1984).

RESULTS

The database is fully summarized and tabulated in appendix B, and includes comparisons to drinking water standards and California Ocean Plan standards and objectives. The following results are taken from the database, and appendix B, and consists of that information which the author believes is most pertinent to this report and future research and policy issues. Since the intent of the study was to provide research information, the reported values are often well below normal CLP (Contract Laboratory Program) reporting levels and the concentrations and detection limits should be judiciously noted. Both the arithmetic and geometric means were calculated, and if the geometric was less than about 75% of the arithmetic mean, the data was assumed to be skewed and the log normal distribution and geometric statistics are both reported. The observation of skewed data is common in the environmental field (APHA, 1989) and the use of the log normal distribution acts to decrease the overwhelming influence that a small number of high samples can have on the overall sample group. As an extreme example, the sanitary sewage spill resulted in water with an ozone demand that exceeded the generating capacity of the pilot plant and high bacterial counts were observed in the effluent. The overall project arithmetic mean and 90th percentile for the total coliform count in the disinfected water were 7,600 and 13,200 organisms per 100 ml. respectively, while the log-normal or geometric values were only 160 and 5,600. While the geometric mean is only 2.1% of the arithmetic mean, the high values converge in each distribution. Skewed data were prevalent in the metals, biological and "significantly" detected organics, but the distribution was normal among the remaining organics where "noise" below the detection limit predominated.

The mean absorbed, or effective, ozone dose was around 12.5 mg/L (PPM), although exposures of twice that concentration were occasionally utilized. Although higher values are often used to control specific problems such as color, taste, odor or chemical contamination, the drinking water industry typically disinfects with ozone concentrations below 5 mg/L (Tate, 1991). The geometric mean of the effluent water ozone residual was 0.31 mg/L, although many samples of greater than 2 mg/L were produced. Dissolved ozone rapidly degrades and residuals will drop within a few minutes of treatment. Since ozone is not used to provide distribution system disinfection, it is not closely monitored in the water industry.

Among the physical parameters, the ozone treatment appears to have caused an increase in temperature and decrease in pH. The former result was due to the compression of air during the first part of the study, and was not observed after switching to bottled oxygen. The maximal temperature increase was about 1.5°C and should not be sufficient to constrain the release of the effluent. The mean pH was normally reduced from 8.1 to 7.8 and the value of

VOL 12 1578

well ozonated effluent water was generally a half pH unit below that of the influent. Only a few of the influent samples exceeded the Ocean Plan Water Quality Objective of 6.0-9.0 pH units and none of the effluent samples were in violation.

Ozonation had little effect on solids or conductance which are primarily inorganic characteristics. The geometric mean of both influent and effluent dissolved solids (690 mg/L) and conductance (1070 µmho/cm) were about 80% of the arithmetic mean and the data approximated a normal distribution. The geometric mean of suspended (22 mg/L) and settleable (<0.1 ml/L) solids were both significantly below the Ocean Plan Water Quality Objectives and about 20% of the arithmetic mean, indicating that the data were highly skewed. The data for suspended solids is plotted on a log scale in figure 3. The plots of both influent and effluent data are virtually identical, indicating that ozone had little influence on this parameter. The results are characterized by normally low values punctuated by brief periods of contamination, when values would rise above the 240 mg/L objective. At concentrations between 60 and 240 mg/L the Ocean Plan calls for a reduction in suspended solids to no more than 60 mg/L. At levels above 240 mg/L the source is required to remove 75% of the suspended material. The skewed distribution is primarily associated with brief upstream events (construction and sewer break) when values rose to levels 100 times greater than the Water Quality Objectives.

The influence of ozone on turbidity was difficult to assess, since freshly treated water contained light scattering micro-bubbles, while settling could be expected to occur in seasoned samples. Paired samples checked 10-20 minutes after collection, generally showed a slight (10-20%) decrease in turbidity, but it would be speculative to suggest that ozone was the causative agent. Color was not monitored during the study, but it was visually evident that ozonation decreased the orange brown color associated with the dissolved humic and fulvic acids that result when water passes through decaying organic matter. In Myrtle Beach, South Carolina highly organic influent water containing 150-450 color units, is reduced to as little as 5 units using ozone doses of up to 10 mg/L (Ferguson, Gramith and McGuire, 1991).

Bacterial and viral analyses conclusively demonstrated that ozone was an extremely effective disinfectant of storm drain dry-weather flow, reducing microbial counts by a geometric mean of 3.4 log (99.96%). The remainder of the biologic results will be elucidated in the discussion section in conjunction with a discussion of the goals and conclusions of this study.

The Total Organic Carbon (TOC) content of the influent and effluent waters ranged from 2.2 mg/L, the day after a rain storm, to 124 mg/L when the sewer break was flowing maximally. While most values were between 7 and 30 mg/L, the mean TOC level was 19 mg/L and the distribution was only slightly skewed. While ozone can

VOL 12

15739

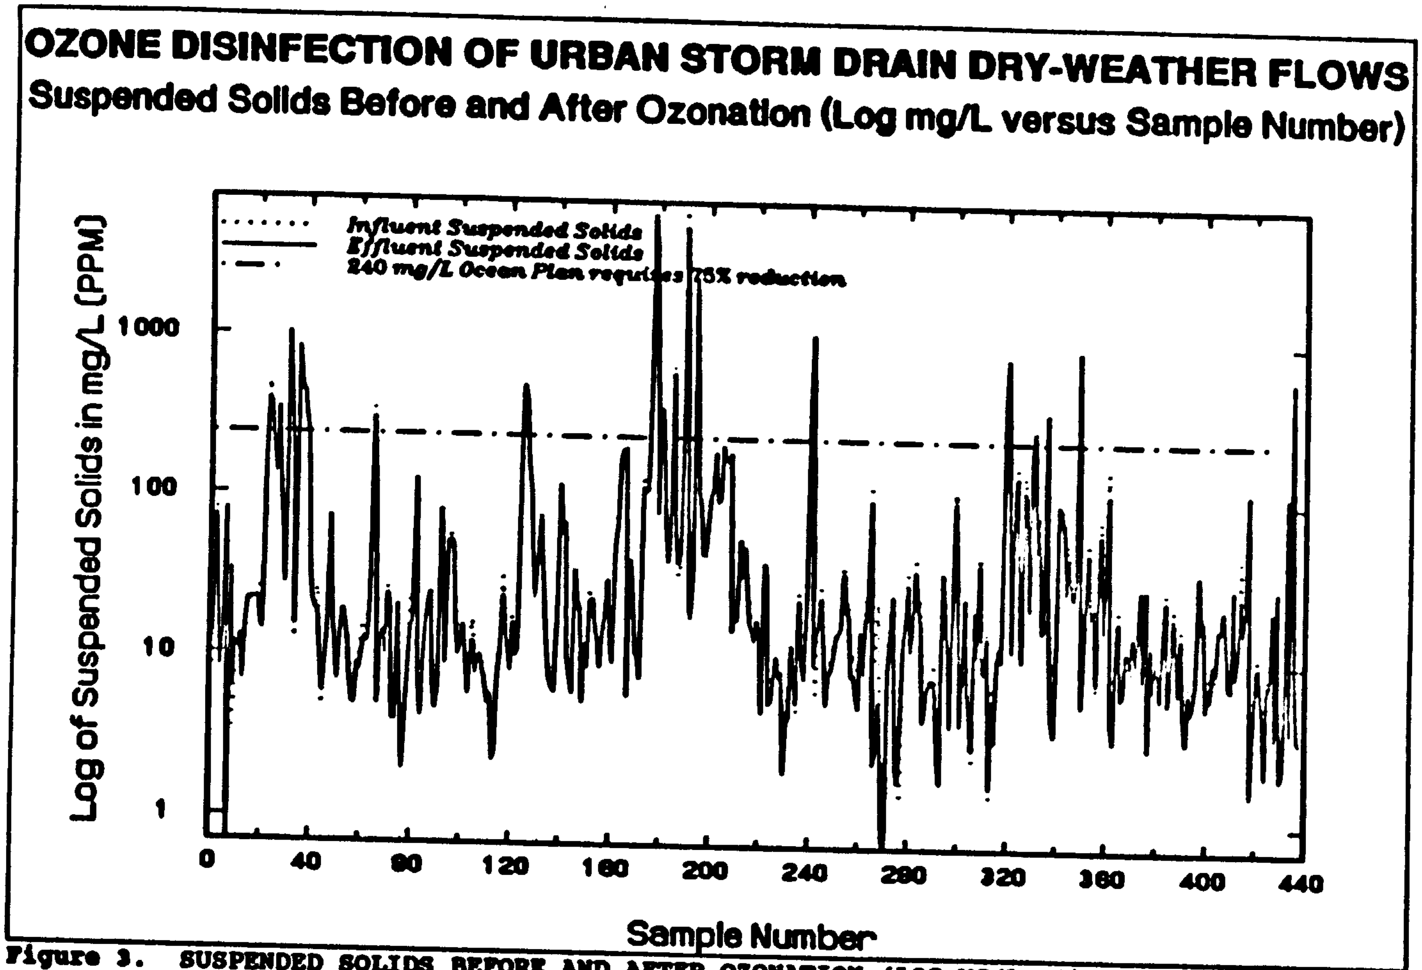

Figure 3. SUSPENDED SOLIDS BEFORE AND AFTER OZONATION (LOG MG/L VERSUS SAMPLE NUMBER).

mineralize moderate levels of some organic compounds (Glaze and Kang 1988), the high TOC levels observed in this study assure that most was consumed in breaking cellular material and humic and fulvic matter into simpler organic units. As observed in this study, this would not result in a net TOC decrease. While the source and treatment variability assure that the data is widely scattered, the regression lines in figure 4 show that ozone demand increased, and observed ozone residuals decreased, with TOC concentration as would be intuitively expected.

There were significant differences between the arithmetic and geometric mean concentrations of most metals, especially the heavy or non "salt" metals. The "salt" metals, such as calcium, magnesium, sodium, phosphorus, silicon, and potassium, were generally in the mid to high PPM levels, normally distributed, and are not regulated. In contrast, the industrially valuable metals, such as aluminum, iron, manganese, chromium, lead, titanium and molybdenum were normally at low concentrations, which episodically rose orders of magnitude higher resulting in a skewed distribution. Many of these elements are toxic and closely regulated. The mean concentration of selenium, which is both an essential element and highly toxic, was below the drinking water standard of 10 PPB, but numerous samples above this level were observed. The highest observed value of 112 µg/L was well below the Instantaneous Maximum Ocean Plan Water Quality Objective, with 5:1 dilution, of 750. Barium, nickel, and silver were always well below standards. The mean values of arsenic and cadmium were well under the Ocean Plan and drinking water standards, but occasionally samples exceeded one or both sets of limitations. Mean chromium, copper, lead and zinc concentrations exceeded Ocean Plan Water Quality Objectives and will be subject to further discussion in later sections of the report. While the results from the hexavalent chromium analyses are complicated by contamination in the reagents, both the arithmetic and geometric mean, before (31 and 12.9 µg/L respectively) and after (29 and 11.7 µg/L) ozonation, show that no increase in concentration was observed.

Only 4 organochlorine pesticides were detected among the 86 sample pairs analyzed. The high concentrations of both lindane (γ-HCH or hexachlorocyclohexane) and endosulfan I were about 30 ng/L (PPTr) or just slightly above our detection limit and about half of the Contract Laboratory Program detection/reporting limits. Both high values were an order of magnitude below Ocean Plan Water Quality Objectives. Heptachlor is a contaminant in chlordane, that has a double bond instead of a chlorine and hydroxyl group. It was only detected in the three samples having the largest chlordane concentrations and its detection is obviously incidental. The sample containing the highest chlordane concentration also included heptachlor at 2.5 times the 30 day Ocean Plan objective of 36 PPTr.

VOL 12

1
1571

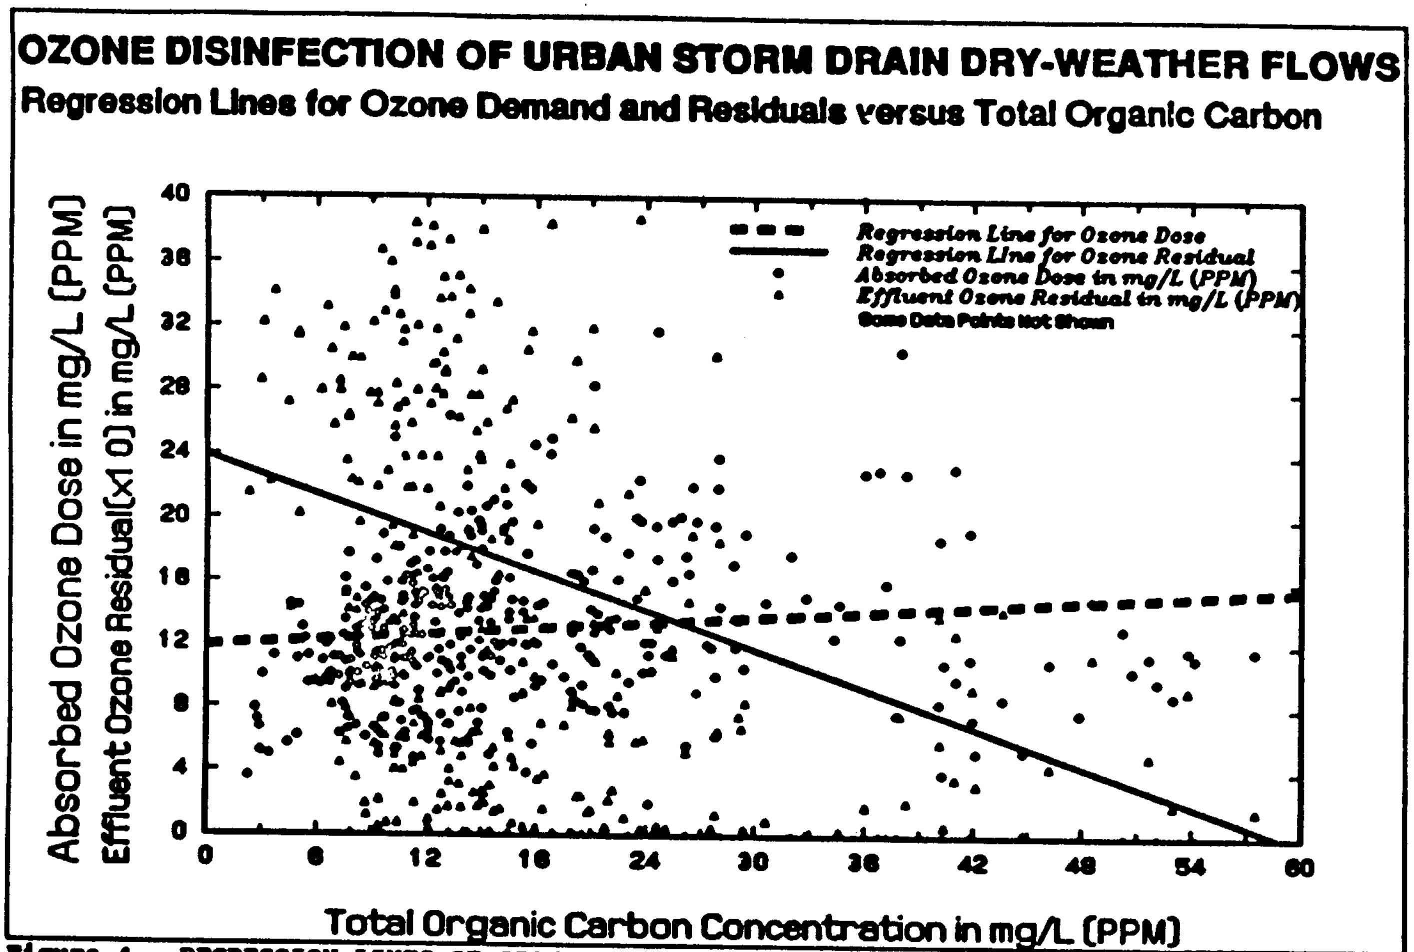

Figure 4. REGRESSION LINES OF OZONE DEMAND AND RESIDUAL WITH TOC CONCENTRATIONS.

The detection of the pesticide chlordane, was the only significant finding among the pesticide analyses. This compound was used against termites and ants and was sprayed or injected adjacent to residential foundations. While now recognizedas a probable human carcinogen, it was commercially available early in the decade and manufactured until 1988. The pesticide was first detected on 12/14/89 and concentrations diminished during the next two weeks. Following an intense rain storm, no additional detections were obsarved. The arithmetic mean concentration in the plant influent was 133 ng/L and in the effluent 59 ng/L. The influent geometric mean was 0.86 ng/L, while the effluent value was 0.78 ng/L. The 30 day Ocean Plan objective for chlordane is 1.15 ng/L (PPTr). In the most contaminated sample, an ozone dose estimated at between 15-20 mg/L, with no residual, reduced the chlordane concentration from 5700 PPTr to about 1900 PPTr. While it is impossible to accurately estimate the efficiency of removal, ozone appeared to significantly reduce the concentration of chlordane in the plant effluent. This is especially evident at the highest chlordane concentrations when it made up a significant fraction of the TOC. As pesticide concentrations decreased toward the detection limit, and chlordane became a smaller fraction of the carbon pool, the removal efficiency appeared to drop. Although speculative and based on trace concentrations (given in ng/L or PPTr) and few data points, ozone may have also reduced heptachlor (90, 30, and 24 to 55, 24, and not detected) and Endosulfan I (30 to 24) concentrations, but probably not lindane (34, 26, and 21 to 28, 27, and <20), which is an extremely stable compound.

The analysis of volatile organic compounds showed that the maximum observed values were mostly more than an order of magnitude below either drinking or Ocean Plan standards, and the means were generally less than 1 µg/L (PPB). The primary exceptions to this assertion, is that one sample contained ortho xylene at levels in the 1,000 to 100 PPB range, which was sufficiently high to saturate the detector and invalidate the accuracy of the results. By the time the instrument was returned to service, the samples were of little value due to volatilization. The second exception was that butanone, 2-hexanone, and 4-methyl-2-pentanone were all observed in the ozonated effluent at less than 4 PPB as maximum observed values. Standards do not exist for these compounds. The drinking water ozonation process is known to form aldehydes, ketones, and carboxylic acids, generally in the low PPB to PPTr range (Glaze et al., 1989), and the detection of these compounds is to be expected. Among the other observed ozonation by-products were aliphatic aldehydes such as hexanal, heptanal, octanal etc., which appeared individually in the 10-50 PPB range. There are no water standards for aldehydes, but they are found in fermented beverages (wines).

With the exception of Polynuclear Aromatic Hydrocarbons (PAHs or PNAHs) and phthalates, the results from the base-neutral-acid extractable or semi-volatile analyses were inconsequential. The maximal value of most compounds was orders of magnitude below any

VOL 12 1 5743

Ocean Plan or drinking water standards and less than 1 µg/L (PPB). Benzyl alcohol, naphthalene, 2-methylnaphthalene and nitrobenzene had maximal values in the 1-5 PPB range, but means of less than 0.5 µg/L. Benzoic acid was detected at 13, but the mean value was less than 4 PPB. Cresols (methyl phenols) were detected in the spiking run, probably as contaminants of one of the spiked compounds. Phthalates were occasionally detected at levels over 100 PPB, but the mean values were generally in the low PPB levels. These plasticizers are ubiquitous in surface waters and laboratories, and with the exception of bis 2-ethylhexyl phthalate, the values observed in this study are not untypical of the results seen in laboratory extractions. In the case of bis 2-ethylhexyl phthalate, the high value of 122 µg/L was well above the 30 day Ocean Plan dilution objective of 17.5 PPB, but the arithmetic and geometric mean were only 12 and 7.1 PPB respectively. These values are noticeably above the Phase V proposed drinking water maximum contaminant level (MCL) of 4 µg/L.

The most significant finding among the extractable analyses, was the level of Polynuclear Aromatic Hydrocarbons or PAH's. The California Ocean Plan treats PAH's as a group and the objective is based on the sum of 13 PAHs that are commonly analyzed. The Ocean Plan 30 day average, with a 5:1 dilution, requires that the sum of these 13 PAHs remain below 0.044 µg/L. The sum of the maximum observed values, for each PAH analyte, was 17 PPB and was associated with samples containing significant amounts of suspended sediment. The arithmetic and geometric means of both the influent and effluent streams ranged from 1.9 to 1.3 µg/L (PPB) indicating that a normal distribution existed and that levels were about 35 times the Ocean Plan Water Quality Objective. The sum of the mean travel blank PAH concentrations was equal to 0.22 PPB.

The results of the mutagenicity study are shown in table 1 and clearly reveal that the ozonation process did not form mutagens as measured by this extraction method and test. While ozone could conceivably be cleaving large mutagens into small volatile mutagens, that are lost during extraction, the results clearly show that mutagenicity was lower in the effluent for all Salmonella strains with, or without, S9 activation (a mammalian enzyme that makes some PAHs more mutagenic). This observation is in agreement with many of the papers cited in the review by Noot et al. (1989).

Three sets of spiking runs were conducted during the latter phases of the project. In the first chemical study, available extractable compounds were added to the influent water then pre- and post-ozonation samples were analyzed using the standard GCMS method (625). The results for 2 sample runs are given in table 2 and clearly indicate that chemical remediation did occur when the contaminants were present in significant concentrations.

In the second chemical study, 7 halogenated compounds were spiked into the treatment stream and samples taken before and after ozonation. The compounds were chosen as examples of a halogenated solvent (1,1,1-Trichloroethane), surrogate gasoline-like components (Benzyl Chloride or α-Chlorotoluene and 124-Trichlorobenzene), PAHs (9,10-Dibromoanthracene) and halogenated pesticides (Aldrin and Lindane). Calibration standards were prepared in milli-q water, then both standards and samples were extracted as described in the methods section. The calibration standards and samples were then analyzed using the pesticide analytical equipment, and the results are given in table 3. While no explanation for the anomalous increase in TCE concentrations is available, it is notable that the concentrations of most other compounds decreased. In retrospect, this was especially impressive given the relatively high concentrations of Benzyl Chloride.

The third spiking study examined the disinfection of virus (attenuated polio) by ozone and was generously undertaken by the Los Angeles County Sanitation District. This study was conducted on June 5, 1990, just prior to the time when the sanitary sewage spill overwhelmed operations. While a negligible loss of virus occurred due to toxicity (20% reduction), each of three replicates taken during three separate sample runs, showed viral reductions of 99.96% (3.8 log) or greater. Bacterial kill during these runs was unusually low and ranged between 1.7 and 3.6 log. Significant turbidity was observed during two of the three runs (8, 98, and 80 NTU). The applied ozone doses were moderately high at 15, 19 and 15 mg/L (PPM) and dissolved ozone residuals were negligible.

An analysis of the sediments contained behind the storm drain weir was undertaken and although this evaluation did not relate directly to the use of ozone, it does have implications for the disposal of sludge that might accumulate in a treatment facility. Coarse sediments were collected on 2/13/90 and both fine and coarse sediments were taken on 6/21/90. The extracts was analyzed for organochlorine pesticides and semi-volatile compounds and the estimated concentrations are given in table 4. The reporting of 4,4'-DDE should be viewed with suspicion, since the levels detected were at the limit of quantification, the extract contained numerous interfering peaks, and neither DDD nor DDT were detected. The levels of polynuclear aromatic hydrocarbons detected in the storm drain sediments is both significant and predictable given our knowledge of combustion particulates and aerial deposition.

DISCUSSION

The primary goal of this project was to demonstrate whether ozone would be an effective disinfectant for dry-weather storm drain flows, particularly those of the Kenter Canyon drain. The secondary goal was to characterize the variance, in concentration, of some low flow pollutants and determine whether the observed levels would inhibit disinfection or be beneficially reduced during ozonation. Others goals were to define the important treatment parameters, develop a prototype process train, estimate the cost of treatment, and elucidate the operational response to a sudden influx of contaminants. The answers to these questions would determine whether the project should continue beyond the pilot plant phase and what goals to set for that expanded facility.

The pilot plant study proved that ozone was extremely efficient in disinfecting the Pico Kenter Canyon storm drain dry-weather flow. As summarized in table 5, the overall reduction in bacterial numbers was over two and half log, or three and half log based on the more representative geometric mean. Furthermore, these statistics severely under-report disinfection for at least three reasons: First, the plant was not always operated optimally, many runs were performed to compare the relative importance of contact time and ozone concentration or some other parameter; Second, less than half of the samples were prepared using oxygen, rather than air, as the feed gas, so that during the first half of the study applied ozone dosages were relatively low; Third, the analytical method is insensitive to counts of less than two, so that 100% disinfection is still reported in the database as a most probable number of 2 organisms per 100 ml. As seen in figures 5, 6, and 7, disinfection was greatest during the latter phase of the project and a full scale facility should be able to maintain a 5 log (99.999%) reduction in bacterial and viral numbers, based on total coliform counts. Finally, while this study analyzed benign indicator bacteria counts, it should be noted that ozone has been used against a variety of pathogens (Ferguson, Gramith and McGuire 1991) and, while a few species are relatively resistant (Ferguson et al. 1990), the vast majority succumb to ozone more rapidly than other common disinfectants.

Table 5. REDUCTION IN MICROBIAL COUNTS FOLLOWING OZONATION.

Micro Organism Type	Arithmetic		Geometric	
Total Coliform	2.4 log	(99.6%)	3.5 log	(99.97%)
Fecal Coliform	2.5 log	(99.7%)	3.4 log	(99.96%)
Enterococcus sp.	2.9 log	(99.9%)	3.4 log	(99.96%)
Polio Virus (Vaccine Strain)	3.5 log (99.97%)

Major economies of scale exist in sizing air preparation and ozone generation equipment and a full scale facility of this type should probably be sized at 5 to 10 times the anticipated mean ozone demand. The major variable expense of treatment, is the electrical ozone generation costs, which is directly proportional to the quantity of ozone produced and consumed and few penalties exist for over designing this aspect of the treatment train. While the pilot phase demonstrated that bacterial numbers were often reduced 5-6 log, a full-scale efficiently operated facility should be able to consistently achieve a 4.5 to 5 log reduction in bacterial counts. This compares with the experience of the drinking water industry which, while using more rigorous filtration processes, is able to achieve a 7-8 log bacterial reduction (Ferguson et al. 1990) using an ozone dose of only 4 mg/L.

The highly variable concentration of contaminants in the flow have confounded the statistical analyses of the parameters that influenced the disinfection process. Intuitively ozone dose and residual would be expected to correlate with disinfection. Contact time also appeared to correlate with disinfection, however, the exposures in this project were relatively short (2-6 minutes) and other research suggests that little correlation exists for periods greater than six minutes (Ferguson et al. 1990). While pH decreased with degree of disinfection, this is probably an artifact of ozonation rather than a direct contribution to sterilization. Total organic carbon was normally inversely proportional to disinfection efficacy, especially at high TOC concentrations. Since ozone indiscriminately reacts with both organismic and inanimate carbon, as the proportion of the latter increases, the amount of ozone acting on microbial carbon must correspondingly decrease. Turbidity, settleable solids, and suspended solids were generally correlated with each other, but appeared to have risen from both inorganic and organic sources. Disinfection generally continued, albeit at lower efficiencies, in the presence of inorganic material, such as was present when extensive upstream concrete cutting flushed large quantities of loamy sediments into the storm drain. In contrast, when the sanitary sewer ruptured into the drain, turbidity, solids and TOC all increased significantly and disinfection was reduced to one or two log. Fortunately these periods were exceptional and disinfection normally proceeded efficiently.

The treatment of storm drain water is hampered by two major constraints. First the integrity of the storm drain as a means of rainfall conveyance must not be hindered. Second, contamination is periodic, erratic and concentrations may change by orders of magnitude over a few moments. The variability was particular evident amongst the solids (Total Solids, Suspended Solids, Dissolved Solids, and Settleable Solids), bacterial, and metal contaminants, but instances also occur among the organic analytes. Chlordane (and heptachlor), lindane, endosulfan and o-xylene were each observed as single spill events and were probably released by a household or small business. While both chlordane and o-xylene were at significant concentrations during these periods, it is unlikely that these random events could have been anticipated. While a typical wastewater treatment facility would receive these individual releases diluted by volumes of wash water and organic sludge, a low- or base-flow storm drain treatment facility would be confronted by a significantly modified and contaminated flow. The proposed storm drain facility would require a smart process train capable of distinguishing between the normal water, that can be treated during the primary disinfection process, and heavily contaminated water that should be directed elsewhere. Depending on the costs, type of contamination, and societal goals, this second path could include on-site treatment, but would probably be more economically decontaminated at a wastewater facility where dilution and additional treatment processes would moderate the spill event.

The chronic Kenter Canyon low flow chemical contamination appears to be limited to some heavy metals and polynuclear aromatic hydrocarbons (PAHs). While an actual initial dilution factor (assumed to be 5:1) would need to be determined to calculate the exact limitations, table 6 indicates that the concentrations of several metals warrant concern. Fortunately, most of the high heavy metals concentrations came from only a few of the almost 200 samples analyzed, and their exclusion would have significantly reduced the mean concentrations. Excluding PAHs, these few easily detected samples, and the described hexavalent chromium contamination, only lead and copper appear to violate the Ocean Plan Objectives for ocean release of the water.

While the recent elimination of leaded gasoline may well bring emissions of this element under standards, a few years will be required to test the hypothesis. Copper represents a more difficult regulatory quagmire. While the mean concentration of copper was about 4 times the Ocean Plan Objectives, it is only one 30th of the drinking water MCL. While no one would advocate that the water is potable, we are faced with the dilemma that water fit to drink from the standpoint of copper contamination, could not be released to the ocean. Given the overall environmental benefits of disinfection, copper would be a prime candidate for regulatory relief if construction of the ozone facility is contemplated.

The major chronic organic contaminants were the polynuclear aromatic hydrocarbons (PAHs) which consist of variously linked benzene rings and include several known and probable human carcinogens. The California Ocean Plan treats PAHs as a group with the water quality objective being based on the sum of thirteen that are commonly analyzed. The Ocean Plan 30 day average for the sum of these 13 is 8.8 ng/L (PPTr) which, with a 5:1 dilution, is equal to an effluent objective of 0.044 µg/L (PPB). The arithmetic and geometric means of both the influent and effluent streams ranged from 1.9 to 1.3 µg/L (PPB) suggesting a normal distribution and indicating that levels were 35 times the Ocean Plan Water Quality

Zinc	100	82	700	80	1160	5000

Objective. The sum of the mean travel blank PAH concentrations was equal to 0.22 PPB. In the proposed phase V drinking water regulations, the EPA plans to set maximum contaminant levels (MCLs) for 7 of the PAHs specified in the Ocean Plan. For each of these 7 PAHs, the mean value observed during this study was slightly less than the proposed MCL. Furthermore, the sum of the seven proposed drinking water MCLs (1.6 µg/L) was essentially equal to sum of the observed project means (1.9 to 1.3 µg/L) for the 13 PAHs listed in the Ocean Plan Objectives. Consequently, for PAHs we again face the regulatory dilemma that water meeting proposed drinking water maximum contaminant levels would be prohibited for ocean release.

Polynuclear aromatic hydrocarbons are associated with combustion processes and are commonly found in the particulates emitted by diesel engines. These vehicular emissions are also significant sources of metals such as lead and chromium (Manahan 1984). Although the pilot plant was located in the municipal bus yard, the runoff from the yard enters a second storm drain and the chronic contaminant concentrations observed in this study are probably attributable to basin-wide aerial deposition of particulates. This soot, which settle in street side curbs throughout the drainage basin, is probably carried by urban runoff into the storm drains and is unlikely to be effectively controlled in the immediate future. Water treatment technologies for the control of these chronic contaminants, at the mean concentrations observed in this study, include reverse osmosis/ultrafiltration and granulated activated carbon and are extremely costly with other potentially hazardous waste streams. Given the concentration of pollutants in the sediment (table 4), it is likely that much of the observed contamination was due to the submersible pump transporting sediments into the system. Future undertakings should explicitly segregate the sediments and utilize an alternative decontamination strategy, which may require some degree of administrative relief.

A secondary question relates to how the facility responds to chemical contamination and whether any chemical remediation of organic compounds would be observed. Given that metals cannot be "degraded", only isolated and removed, there were few instances in which to observe the action of ozone on hazardous substances. While the o-xylene event could not be analyzed due to saturation of the GCMS detector (the effect of air stripping would also have complicated the results), the chlordane spill provided an exciting validation that remediation does occur. At the highest concentration, 70% of the influent chlordane was apparently degraded to other, probably more polar and less toxic, compounds. This percentage dropped with influent concentration and was less than 40% when a storm washed out the contaminated sediments. The apparent loss in efficacy, with lower contaminant concentration, correlates with the simplistic concept of ozone randomly attacking and cleaving carbon macromolecules into less complex compounds that may still be susceptible to ozone directed attack.

When ozone susceptible compounds are present in the PPM level, and make up a significant fraction of the TOC, ozonation would be a meaningful remediation technology, but at sub-PPB levels in a PPM carbon soup, the removal efficacy could well be inconsequential. Automation and staging of the ozone treatment process should facilitate a rapid response to the challenge of an increase in TOC or drop in ozone residuals. Based on the results of this study, it appears that the concentration of many (trimethyl benzene, aldrin, phenol) compounds can be significantly (> 95%) reduced during disinfection. Others, such as benzyl chloride, naphthalene, 9,10-dibromoanthracene, and pyrene, are less reactive, but are still degraded when present in high concentrations. Finally some recalcitrant compounds, such as lindane and 1,1,1-trichloroethane are apparently resistent to ozone directed attack.

While the disinfection results exceeded expectations and the monitoring program found the water to be only modestly contaminated by chemicals, the question of disinfection by-products remains unresolved. The monitoring program detected mid PPB levels of aliphatic aldehydes, such as hexanal, heptanal, etc., compounds which are typical of ozone disinfection and whose environmental hazard at these levels are unknown. However, it is encouraging that in the Microtox® test, toxicity (EC$_{50}$) decreased with increasing carbon chain length from 1 PPM with formaldehyde to 5

VOL 12

1 5755

mg/L for acetylaldehyde, 300 mg/L for butanal and almost 2 gr/l (PPTh) for Benzylaldehyde (Kaiser and Ribo, 1988). The smaller, more volatile, aldehydes are also likely to be stripped with the off-gas into a catalytic ozone destruction unit which is highly reactive with aldehydes and other volatile organics. As discussed in the methods section, this reaction is exothermic and a thermocouple must be included to monitor the unit for combustion. It is also clear that ozone disinfection formed few, if any, of the halogenated byproducts seen with disinfection by chlorine, chlorine dioxide and chloramines (Jacangelo et al. 1989). While all disinfection processes produce by-products, ozone and peroxzone (ozone combined with hydrogen peroxide) produce fewer mutagens then chlorine related processes (Noot et al 1989). Furthermore, as shown in table 1, ozonation clearly did not increase the mutagenicity of the dry-weather storm drain water.

The results obtained during this project, conclusively show that ozone was an effective disinfectant for the low-flow storm drain water. While ineffective in removing metals and trace organic contaminants, ozone disinfection appeared to produce few hazardous by-products, is amenable to automation, and has some chemical remediation properties. Based on the results of this study, it appears that disinfected water can be produced which meets the 23 coliform organisms per 100 ml standard and could be made available for landscape irrigation purposes as part of an integrated treatment and reclamation facility. The project-wide mean metal concentrations are within the guidelines suggested for trace elements in irrigation waters (CWQC 1968) for most metals on any soil. The only exceptions were molybdenum which, at the level found in this study could cause illness in ruminants, and boron which is well within the standard for use on fine textured soils. The other contaminants would not be expected to negatively impact the relatively hardy plants that tolerate growth along freeways.

A potential full-scale process train is diagrammed in figures 8 and 9 and could be based on construction adjacent to a section of storm drain or at a central locality with laterals carrying the flow from adjacent drains. The first station would be an automated trash rack to remove trash during low-flow, first flush, and light storm conditions. Water in excess of treatment system pumping capacity would pass through the 1/4 inch screen and be routed to the ocean through an overflow. The sluice gates (local and remote) and trash rack would be controlled by ultrasonic level detectors. Once the water had been de-trashed, redundant submersible pumps would bring the influent water to surface level and into a filtering device such as a back pressure activated auto strainer with 100 micron filter. After filtering, the water would be monitored for flow rate, pH, conductivity, turbidity, TOC, and probably selected heavy metal ions, such as chromium and iron. Based on these results, the water would be tentatively categorized for potential end uses. Water low in contaminants would go through

VOL 12

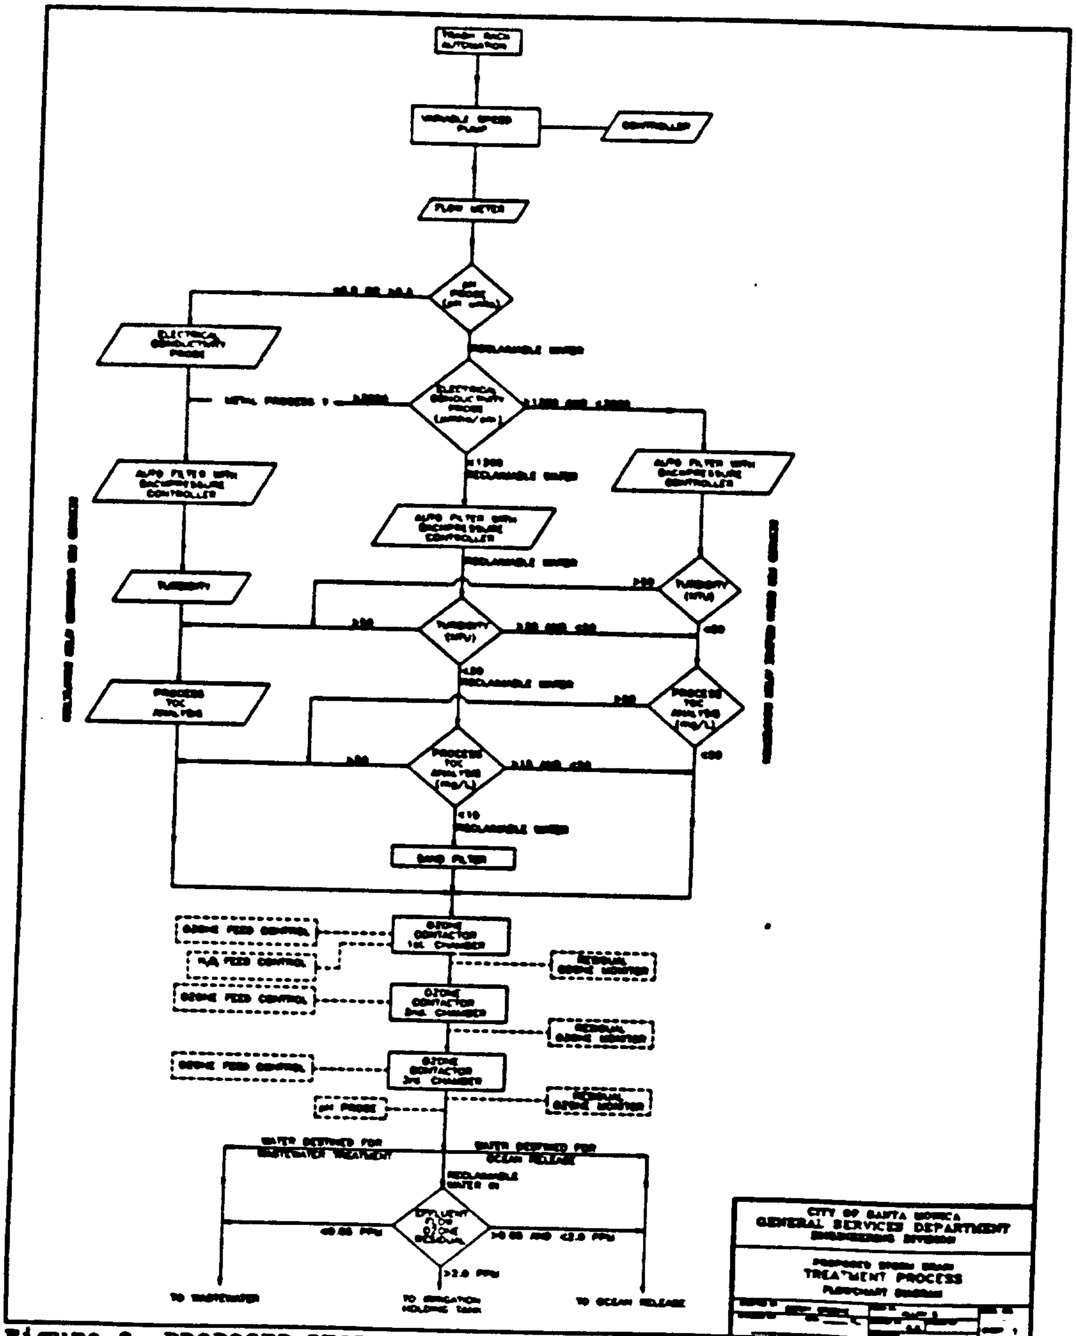

Figure 8. PROPOSED STORM DRAIN TREATMENT PLANT PROCESS FLOWCHART.

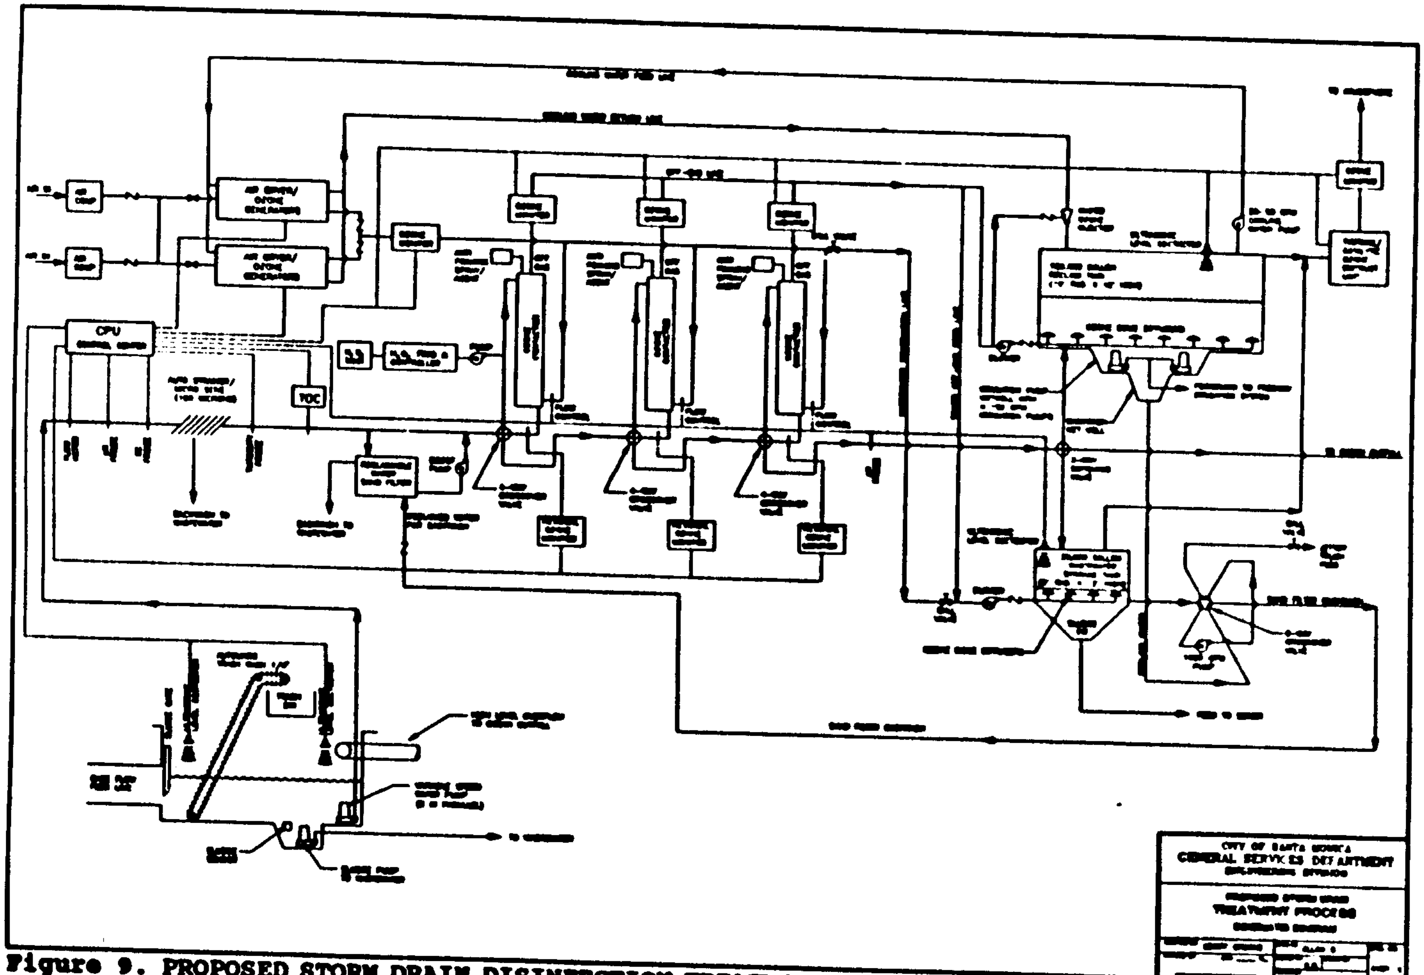

Figure 9. PROPOSED STORM DRAIN DISINFECTION TREATMENT PLANT SCHEMATIC PROCESS FLOW DIAGRAM.

a sand filter with the intention of using the water for irrigation. Water that was moderate in contamination, or in excess of landscape needs, would be slated for ocean release. The most contaminated water could be directed to the sewer or used for sewer flushing.

Following sand filtration of the reclaimable water and characterization of the lower quality waters, the next step would be ozonation in a multichamber system. The separate towers permit maintenance and monitoring of the dissolved ozone residuals and off-gas concentrations. The addition of ozone would be correlated with tower effluent ozone concentrations and influent TOC. Assuming a design consisting of three sequential towers, the residuals would be monitored after each chamber. In response to low residuals, ozone gas flow or generation would increase to some optimum higher production point and be directed to the depressed chamber and its upstream companion. Finally, based on the cumulative sensor parameters, water would be directed one of three effluent streams: the storm drain and ocean; an irrigation reclamation holding tank; or a wastewater holding tank for sewer flushing. The reclamation holding tank would also be the source of backwash water for the sand filters and cooling water for the ozone generators and compressors. The contactor tower off-gas would be passed through both reclamation and wastewater holding tanks to maintain a disinfectant residual, with the off-gas from the tanks passing through the catalytic ozone destruction unit. An auxiliary line would be available to directly feed ozone into the wastewater holding tank if chemical remediation appeared to be warranted.

Initially, the bulk of the treated water would be directed back to the storm drain for ocean release. Later, as reclamation became more significant, only water that was in excess of reuse demand or highly conductive (salty) would be directed back to the drain. Water that was low in conductivity, turbidity, TOC and moderate in pH would be directed for landscape irrigation purposes if, it also contained a significant ozone residual. Water that failed the irrigation and ocean release criteria, such as water that was high in metals, organic matter, or turbidity, would be directed to the holding tank for contaminated or wastewater. The tank overflow and any water used in flushing sewers would then be directed to a typical wastewater treatment facility, but would arrive substantially diluted. Only the dry-weather flow that is within the wastewater treatment facility's capacity and requiring full treatment would receive it. The bulk of the dry-weather flow would receive only the warranted disinfection treatment before being reclaimed or released to the ocean. Finally, water that is highly contaminated and unacceptably for disposal to the sewer system because of metal content, gasoline, or oil and grease, could be held and treated by specific measures such as oil skimming, ozonation, or ion exchange, to reduce the contamination to acceptable levels. Thus the water would be treated in a manner appropriate to the degree of contamination observed.

VOL 12

15759

The proposed treatment plant off-gas effluent stream is a potential source of cross-media contamination and it was therefore desirable to estimate the level of some contaminants that are likely to be released from the process train. In a study of automotive exhaust from traditional and oxygenated fuels, Hoekman (1992) calculated emissions in terms of milligrams of combustion by-products per mile driven, providing an easily understood standard for comparison. Estimates of treatment plant off-gas emissions of ozone, volatile organic carbon (VOC's), carbon dioxide, and carbonyl (aldehyde-like) compounds were prepared using best (manufacturer's claims), reasonable (generally observed), and worst (poor emission control performance) case scenarios. Based on the data from 6 late model California cars (1986 to 1990), the reasonable case scenarios resulted in 24 hour estimated emissions equivalent to between 10 and 20 miles of driving. With the exception of carbon dioxide, which is fixed at around 14 miles, the best case emissions estimates were less than 1 mile and worst case estimates were less than 160 miles. Therefore, the most likely estimate of treatment plant air emissions are about equivalent to one local commuter trip and represent an insignificant contribution to the local air quality problems.

While bacterial regrowth of the ozonated water in the irrigation pipeline is likely to occur, the bacteria are unlikely to include human pathogens and should not support replication of human enteric virus. The landscape irrigation system will initially require regrowth monitoring and it may become necessary to consider periodic flushing with heavily ozonated (or passed through a solid chlorinator) water with disposal to a modest injection well near the upstream terminus of the irrigation system.

SUMMARY AND CONCLUSIONS

The results proved that ozone was an extremely effective disinfectant and at doses in the range of 10-20 mg/liter was capable of reducing bacterial and viral populations by 3-5 log (99.9 to 99.999% of the microbes killed or inactivated) with contact times of less than 6 minutes. While high organic carbon (TOC) or suspended solids (turbidity) reduced the efficacy of ozonation, the process was not neutralized and samples high in inorganic solids were readily disinfected. In many effluent samples, coliform concentrations were sufficiently reduced to qualify the water for use in reclamation projects such as landscape irrigation along the Santa Monica Freeway, suggesting a possible useful purpose for the treated effluent. While ozonation by products, such as aldehydes, were detected in the plant effluent, their concentration was low (mid PPB range) and many would also be present in a chlorinated effluent. No significant increase in halogenated by-products or mutagenicity was observed following ozone disinfection. As a test of the ozonation process, a dozen hazardous organic chemicals were added to the influent water and the effluent monitored. While the four most refractory compounds passed through the facility unchanged, the concentrations of the other eight were greatly reduced during the disinfection process.

The primary hazardous chemical constituent in the influent water were metals, primarily copper, lead, zinc and chromium which are not removed by ozonation and polynuclear aromatic hydrocarbons which are at extremely low concentrations. Isolated samples did contain organic contaminants, such as ortho-xylene and the pesticide chlordane, but this did not appear to be a pervasive problem and can be attributed to isolated events that cannot be anticipated and will only be prevented through an informed and concerned public. Data on the degradation of PAH's by ozone was mixed. The mean effluent sum of PAHs was 80% of the mean influent sum value, but during the first spiking study, when concentrations of Naphthalene and Pyrene were hundreds of time higher than normal, concentrations were reduced by <95%. This suggests that PAHs, and probably many other organics, are only degraded when their proportion of the total organic carbon becomes substantial in relationship to the large bacterial and biological carbon content. With the exception of some metals, the mean concentration of most of the chemical contaminants were below the levels allowed in drinking water, and only a few contaminants were above California Ocean Plan Water Quality Objectives.

In contrast to bacterial counts which were generally high and consistently present, sediments and suspended solids were generally low, then would suddenly, and unpredictably, rise to levels hundred of times greater than the mean value. This often appeared to coincide with increased dry-weather flows, which would resuspend deposited material, so that increased per gallon treatment demand coincided with higher flow rates through the treatment system.

1576

RECOMMENDATIONS

The positive results from this study have lead the City of Santa Monica to consider construction of a full scale ozone based treatment facility, presently planned for construction near the Santa Monica Pier. While numerous institutional barriers will need to be surmounted, before a commitment to begin construction can be made, City staff is confident that any negative attributes will be greatly offset by the positive environmental outcome. The proposed facility is expected to be automated and intelligent with the capability to remove trash from all of the dry-weather flows and a least part of the first flush of wet-weather storm runoff.

In the proposed treatment train, after filtration, the influent dry-weather flows would be process monitored for parameters such as conductivity, turbidity, pH, and total organic carbon, the water would then ozonated, and the effluent retested for pH and ozone residual. Based on these parameters the effluent would be directed to the most appropriate disposition. Water that is low in conductivity (salts and metals), filtered and well disinfected (high ozone residual) would be slated for reclamation purposes. Initially, this could consist of a test section of the Santa Monica Freeway and other public works projects. If successful and warranted by the quantity and quality of the effluent, this project could then be expanded to other sections of the freeway. The bulk of the water, which is not initially needed for reclamation, would be screened, disinfected and released to the ocean. Filter backwash water and plant effluent water that is high in organic content (nominally 50 PPM as TOC) would be routed to a holding tank where oil water separators would remove floating contaminants. The contents of this tank could be utilized in municipal jetter trucks which use a high pressure stream to flush out sanitary sewers, thus routing the contaminated water to the facility traditionally designated to deal with water containing a high organic content. Water that is sufficiently high in organic content (perhaps 200 PPM) or heavy metals (based on detection with ion specific electrodes) would be investigated to determine if the contaminants would endanger downstream facilities and then either treated on-site or appropriately disposed of.

If the proposed Santa Monica facility is successful, the potential exists that the dry-weather flows from several of the adjacent storm drains could be transferred, through a new coastal interceptor, to a single treatment plant near the Santa Monica pier. The effluent from this hypothetical facility could then be distributed for use in public works projects, irrigation of neighboring freeways, released under the pier and into the ocean, or pumped into the adjacent Moss Avenue sewage pumping station for eventual treatment at the Los Angeles City Hyperion Facility.

The primary constraint on development of this facility is for the various agencies to determine the level of treatment which is compatible with the various effluent goals. As an example, the content of heavy metals and PAHs could occasionally exceed Ocean Plan Objectives for ocean release of the effluent. However, the reduction in uncontrolled and microbial emissions would be greatly reduced by construction of the facility. The reclaimed water will contain contaminants, but freeways are already the primary source of these pollutants and the landscaping flora has apparently adapted to a soil containing high concentrations of heavy metals and particulates. The treatment facility solids and sludge stream will need to be disposed of. While Santa Monica will be able to deal with "trash" from the screening process, the filter backwash, sediments, and sludge would require further processing. Assuming that ocean release is unacceptable, Santa Monica is faced with the costly choice of de-watering and disposing of the material or directing it to the sanitary sewer and perhaps being considered as an industrial point source. The cost of becoming a point source, that is treating nonpoint contaminants, may be prohibitively expensive, especially if aerial deposition is the primary source of contamination and two thirds of the drainage basin is in another jurisdiction. Unfortunately, it is possible that concerns regarding the unknown disposal costs of the these waste streams may prevent treatment of a known and potentially significant biohazard. While testing, evaluating, and operating this prototype facility, it is important that all parties be prepared to deal with some unanticipated excursions. It is vital that the known public health "big" picture remain consistently clear and not become distorted over contaminant variability and episodic spill events.

The various arms of the Santa Monica Bay Restoration Project can expedite the development of the proposed facility by continuing to contribute its group expertise on the individual policy issues. The advice of the technical advisory committee, has already been invaluable in directing the progression of this study and will hopefully continue to participate in designating the major contaminants and waste streams of concern. The public advisory committee has volunteered to translate this report into a format that can be understood and supported by the general public and will continue to reduce the level of storm drain pollution by educating the populace. Finally, the management committee and foundation wield significant authority and prestige among responsible agencies and regulators. As a consensus forming group, its support represents an essentially neutral opinion regarding the broad environmental good of the Santa Monica Bay Region. While Santa Monica gratefully acknowledges the support of the SMBRP in funding the demonstration project, the City requires the continued support and influence of the Santa Monica Bay Restoration Project to successfully commission and evaluate the proposed facility.

ACKNOWLEDGEMENTS

The project staff would like to thank the City of Santa Monica, the Santa Monica Bay Restoration Project, the California State and Regional Water Resources Control Board and the United States Environmental Protection Agency for supporting this study. In particular, we would like to thank the many members of the SMBRP Technical Advisor Committee who improved the scope and quality of the study by offering their comments and suggestions. The staff and project supporters would also like to explicitly acknowledge the voluntary contributions of the project review board: Jim Foxworthy, Engineering Department, Loyola Marymount University; Mark Gold, Heal the Bay; Rainer Hoenicke, SMBRP; John Mitchell, Los Angeles County Department of Public Works; Jack Petralia, Los Angeles County Department of Environmental Health; and Mike Stenstrom, Civil Engineering Department, UCLA. The viral disinfection study could not have been undertaken without Charles McGee and the County Sanitation District of Los Angeles County. The Hankin Ozone Systems Corporation also should be recognized and gratefully acknowledged for their loan of the ozonation equipment and expertise during most of the early phases of the project. The members of the Santa Monica Transportation Facility were also generous in assisting us in operating and protecting the pilot plant facility. Finally, the staff would like to thank the City of Santa Monica Engineering Division and General Services Department, and the UCLA Laboratory of Biomedical and Environmental Sciences, for welcoming all of us as staff members and friends.

In addition to the staff acknowledgements, the author would like to individually thank Desi Alvarez for initiating the study and believing in my ability to complete it; Dr. O. R. Lunt and Dr. John Froines for sharing their UCLA Laboratory facilities; Stan Scholl, Tony Antich and especially Dave Britton for supporting the recommendations of the study and facilitating its completion. The collective guilt loading by Rainer Hoenicke, Paul Jones, Guang-Yu Wang, Craig Wilson, and Catherine Tyrrell must also be gratefully acknowledged, otherwise this report would exist only as scattered progress reports. The study could not have been completed without the tireless assistance of staff members Andy Lim, Alan Sheth, Eric Smith, and Cici Tran. Finally, I would like to thank my wife Mona, and children Nicole and Gregory, for forgiving me any spousal or parental neglect and encouraging me to complete this undertaking.

APPENDIX A

QUALITY CONTROL AND ASSURANCE REPORT

VOL 12 1569

SUMMARY

Given the scope and resources of this project, the quality assurance and control were generally excellent. The primary QA/QC failure was associated with analyses conducted out of holding time compliance primarily for pesticide and TOC analyses. Lesser problems also developed in interpreting the results from the outside (state certified) laboratory, poor choice of pesticide internal standard, and contamination in the hexavalent chromium reagents. None of these difficulties compromised the analytical value of the data. To the contrary, the analytical accuracy of the analyses exceeded that anticipated in the project Quality Assurance Plan and, with only two exceptions, significantly more analyses were undertaken, then were originally planned.

A summary of the compliance and analytical information is given in Table A1. The only reductions, from the proposed number of analyses, were among the purgeable and mutagenicity assays. This was necessitated by a doubling in anticipated analytical cost of the mutagenicity work and was approved by the project review board. The other additional analyses were financed by a combination of unmatched municipal funds, lower personnel costs, and reduced costs of the bacterial analyses. The number of analyses performed by the certified laboratory remained unchanged. Differences between the sample number collected and number included in the database were generally due to analytic problems such as salt in TOC analyses, and detector saturating concentrations of ortho-xylene in the purgeable analyses. The ozone pilot plant spiking studies and sediment sample results are contained in the text and were incompatible with inclusion in the database. The complete database, draft report, and alternative database formats have been submitted to, and should be available through, the EPA Oceanographic Data Evaluation System (ODES) network. The Data is available from the author in ODES, ASCII, and Dbase III+ formats.

ANALYTICAL QUALITY CONTROL PROCEDURES

Methodological problems that occurred during the project are included in the main report, this appendix is primarily devoted to describing the efforts undertaken to insure and demonstrate the accuracy and quality of the data obtained during the study.

The electrical conductivity meter was calibrated prior to each analysis using a 1,000 µmho/cm standard prepared using a calcium chloride solution as specified by the manufacturer. Samples were collected in polycarbonate Immhoff cones and any that measured above 3,000 µmho/cm were compared to a 10,000 µmho/cm standard. Fresh standards were prepared monthly and compared to the "expired" standards to insure that they agreed to within 5%. The meter was temperature corrected and the readout was directly recorded.

The pH meter was calibrated daily using pH 7 and 10 buffers corrected for the anticipated water temperature. The buffers were obtained from Fisher Scientific and were within expiration date. The calibration was checked just prior to use, or when the water temperature differed from the expected by more than 2°C.

Temperature was measured using a standard glass laboratory thermometer, that was checked weekly against a precision thermometer.

The nephelometer (turbidimeter) was calibrated between samples using a 40 or 5.0 NTU Amco® AEPA-1 standard. As discussed in the methods section, the 0-1, 1-10 and 10-100 scales did not completely overlap. Sample pairs that fell between the scales were compared on the same scale and could be accurately estimated up or down 1 NTU. The accuracy of the instrument and analyst was also checked using an EPA Turbidity Quality Control Sample (Lot WS 289). The 1.00 NTU sample read 1.02 on the 0-1.0 scale and 0.95 on the 1-10 scale, as compared to performance evaluation mean of 1.05 with 95% confidence interval ranging from 0.81 to 1.29. The 5.0 NTU sample was read as 5.5 NTU while the performance mean was 4.94 with a 95% confidence interval of 4.26 to 5.62 NTU. Since the samples were always measured as influent/effluent pairs, any error introduced by the scale misalignment would affect both samples and introduce a relatively neutral bias.

Immhoff cones are standardized at the factory and no calibration of the settleable solids analysis is possible.

The accuracy of the analyses for total solids (total residue, Method 160.3), dissolved solids (filterable residue, method 160.1) and suspended solids (non-filterable residue, method 160.2) were confirmed using EPA Residue Quality Control Samples (Lot RES 489). The results are given in Table A2.

Table A1. SAMPLING AND COMPLIANCE NUMERICAL ASSESSMENT BY METHOD.

Analysis Name	# of Samples		# in Extraction Compliance	Number in Analytical Compliance	Samples Added to Database

Total Solids #2	565	557	37.4	551	526	490-632

The use of the sensitive ultrasonic nebulizer, presented a metals analysis quality assurance problem, since the standard inductively coupled plasma QC samples (ICP-19 and ICP-7) were far too concentrated. Secondly, the report included with these QC samples (Lot WP988) did not include interlaboratory mean, standard deviation and 95% confidence interval for each metal. The analyst responded by diluting the ICP standards 1:50 and 1:500 respectively. The QA officer has taken interlaboratory data from trace metal analysis by atomic absorption (Water Pollution Control Sample Trace Metal I Lot WP287) and prepared table A3. The concentration of metals in the diluted ICP standards were mostly at 200 μg/L, while the interlaboratory comparison was for samples containing 100 μg/L for most metals (Al was at 500, V was at 250, Cd and Se were at 25). The 95% confidence interval in table A3 have therefore been normalized to 200 PPB. With the exception of those metals not analyzed in the interlaboratory study, it appears that the results obtained in this study are comparable to those expected using graphite furnace atomic absorption analysis.

Two samples were collected in duplicate, one being handled by project staff, while the second was sent to a certified laboratory (International Technology) for analysis. As shown in table A4, the results for sample 200B are in reasonable agreement, with the exception of magnesium, which is at concentrations only four times their detection limit. Less correlation is observed in sample 331A, especially for arsenic, chromium, lead, and selenium, which were in significantly lower concentrations in the commercial lab results.

VOL 12

15772

While it is impossible to determine the source of disagreement at this time, this sample was noted by project staff to have required the most acid, during digestion, of any sample prepared, and included matter that was not digestible. A lab that prepared water samples in bulk, could easily have under-prepared this sample resulting in undissolved particulate matter, that would have escaped analysis.

Because hexavalent chromium is subject to valence changes during transport and handling, quality control is generally performed using samples prepared at the user laboratory. Both staff and the commercial laboratory experienced methods development problems due to contamination in the reagents. Staff, with review board approval, choose to tolerate the 7 ppb level of contamination rather than suffer the expense of locating the source. The commercial lab eventually located and replaced their contaminated reagents. Based on the method of standard additions, staff found that recovery of Cr_{+6} averaged 70%. Five of the six samples analyzed by both laboratories were in basic agreement, while the sixth was reported at 45 PPB by staff while the certified lab reported 6 μg/L. A sample collected 90 minutes earlier, contained a moderate (32 PPB) concentration of total chromium. The project arithmetic and geometric mean trivalent chromium concentrations were 14.4 and 3.5 μg/L respectively.

Quality control was integral to the project Total Organic Carbon (TOC) analysis. Following instrument warm up, staff injected both 100 and 10 PPM standards and would proceed to the laboratory blank only if agreement was within 2%. If the blank was at less than 0.5 mg/L, the analysis would proceed, otherwise, the unit was recalibrated using a 5 to 7 injection standardization, then rechecked as above. If sample pairs differed by more than 10%, they were re-injected to verify variation or until a majority showed that an error had occurred during the initial injections. With the exception of samples collected during the long resin runs, sample pairs were normally in agreement. As shown in Table A5, little agreement was observed in the split samples sent for commercial analysis. Initially this was traced to the samples not being acidified and purged of carbon dioxide by the certified labs. Following this discovery, the samples were reanalyzed and the results are reported here. Samples 200 and 332 were collected during resin accumulation runs, when each type of analysis was undertaken and sampling could require 30 or more minutes. In both cases the effluent TOC sample agreed with the commercially tested sample and neither of those agreed with the influent sample. This disagreement is undoubtedly a sampling artifact associated more with coordinating sampling during the resin runs and demonstrates the variability of the flow. Although both laboratories were using the same model of instrument, efforts to improve the analytical correlation were unsuccessful during the latter part of the study. In an effort to verify internal quality assurance, the author did find that if the instrument ran too long between samples, or dilute samples followed more concentrated ones, high results were observed.

Table A3. EVALUATION OF METAL ANALYTES QUALITY CONTROL STANDARDS. All analyte concentrations are given in µg/L (PPB), n=15.

VOL 12

Although pesticide analyses were delayed due to instrumental failure, few quality control problems were encountered. During the initial phase of the study, samples were spiked using EPA Water Pollution Quality Control Sample, Chlorinated Hydrocarbon Pesticide III (Lot WP185) at the designated concentration. As presented in table A6, the results were well within the interlaboratory acceptance criteria, even though the samples were all analyzed out of holding time compliance. During the second half of the pesticide analyses, samples were spiked with EPA WQPQCS CHP I (Lot WP385), but at 1/20th the concentration used for the acceptance criteria. In both cases, quality control protocols call for spikes to be added to laboratory water rather than the more challenging field samples utilized here. The results from 13 (=n) spiked samples is presented in table A7. The acceptance criteria was taken from the report issued with the sample, but divided by 20 to normalize for the concentrations used in this series. While some of the mean recoveries were low, this is to be expected given the dilute concentrations spiked and utilization of the difficult storm drain matrix.
