This research only studied dry weather flows. Wet weather flows are essential to broaden the scope of the data to the point where risk assessment models and standards can be developed. A study of the aquatic toxicity of wet weather flows will begin later this year conducted by the Santa Monica Bay Restoration Project. Additional studies during wet weather flows must also be conducted to assess the human health risk from exposure to toxicants present in storm drain effluent. To date, data on flow rates, current dilution, and dilution speed into the Bay are lacking for both dry and wet weather flows. Such studies, when combined with the results of this study, will allow evaluation of the importance of the compounds present and their mass loading[19] to the Bay.

2. Development of a Quantitative Risk Assessment for Human Health and the Ecology of the Bay

A quantitative risk assessment methodology combining the health risks from the chlorinated pesticides, PCBs, PAHs, volatile organic compounds, phthalates, and other identified carcinogens and toxicants, should be developed to investigate the risk to swimmers, surfers, and waders, as well as to address the consequences of the bioaccumulation of toxicants in fish and other sea life. To date, there are limited models or standards by which we can assess the risk to health, through dermal absorption and bioaccumulation. More sophisticated models can and should be developed, thereby allowing us to create standards capable of assessing the risks to human health posed by chemicals entering the Bay through stormwater effluent. In addition, toxicity studies that examine the impact of the releases of toxicants on sea life and the ecology of the Bay are clearly desirable.

1942 4

3. Polychlorinated Biphenyls (PCBs)

The finding of alpha-chlordane, dieldrin, and PCBs--the latter especially in the Ashland drain--represents a major finding in this study. These substances are of particular significance because of their potential toxicity, persistence and potential for bioaccumulation in the environment. Follow-up studies to identify the sources of these compounds are clearly indicated.

4. Assess Whether PAHs Attached To Sediment Desorb Into the Ocean

PAHs, one of the most potent chemicals identified in the study, are associated with sediment in the storm drain effluent (i.e., they are attached to particulates). Whether these PAHs are desorbed from the sediment when the storm drain reaches the Bay, thereby exposing living organisms, including humans, to acute toxicity, is an essential question which must be addressed in order to properly determine risk assessment. A series of studies is therefore required to determine the desorption of contaminants from the suspended sediment.

5. Heavy Metals

The scope of this study did not provide for an analysis and identification of heavy metals entering the Bay. However, preliminary work on metals indicates that heavy metals from stormwater runoff rivals, and in some cases surpasses, sewage plant discharges as a source of Santa Monica Bay pollution.[20] This preliminary evidence, when combined with the fact that heavy metals bioaccumulate, and thereby threaten both the ecology of the Bay and humans who eat food from the Bay, makes a study identifying the kinds and quantities of metals entering the Bay essential.

6. Compilation and Analysis of All Existing Literature on Stormwater Effluent Entering Santa Monica Bay

Much of the research done on stormwater effluent entering the Bay is unpublished or unreleased by state and local agencies and therefore known as "grey" literature. If researchers are to avoid duplicating efforts already undertaken, it is essential that this "grey" literature be compiled and analyzed.

B. NEEDED GOVERNMENT ACTION

1. Keep Swimmers, Waders, Surfers and People Fishing Out of, and Away from, the Storm Drains

Based upon the significant results of this study, coupled with existing evidence of pathogens and heavy metals discharged into Santa Monica Bay through the storm drain system the California State Department of Health Services should immediately take the necessary action to post bilingual warnings telling people not to swim or wade in storm drains, or around the mouth of storm drains which enter receiving waters. Surfers, swimmers, and waders should be explicitly warned that there is a chemical contaminant risk to being in the water, or around the mouth of storm drains, especially after rainfalls. This is particularly true for the season's first rainfall, which flushes a toxic cocktail of compounds through the storm drains and into the Bay.

This warning should not be limited to Santa Monica Bay. It is reasonable to believe that similar compounds to those found in this study are entering other bays and estuaries throughout the State, thereby requiring the warning on a statewide basis.

2. The California Ocean Plan Should be Applied to Storm Drain Effluent and Discharge

Stricter standards should be adopted if the present three year review of the Plan does not protect public health and preservation of the marine ecosystem from both storm drain effluent and point source discharge into ocean waters. The Ocean Plan should be amended to clarify its applicability to stormwater discharges.

3. The State of California Must Develop a Coherent Management Strategy for Storm Drains

California urban stormwater regulations are similar to Federal EPA regulations outlined in Section 319 of the Federal Clean Water Act. Section 319 emphasizes a weak, voluntary approach to controlling stormwater runoff (non-point source pollution). Because toxicants represent a serious threat to both the vitality of coastal ecosystems and human health, the State should establish mandatory stringent controls for stormwater pollution. While several non-point source programs are seeking to assess the environmental impacts of polluted runoff contamination, including the Los Angeles County Public Works Department in its proposed NPDES monitoring program, few cities have adequately brought about the implementation of pollution control measures.

Such a management strategy must be concerned with both treatment measures as applied to storm drains and source reduction, and recycling of toxicants which enter the Bay through storm drain effluent.

The problem of chemical contamination of the Bay is, of course, ultimately a question of huge economic and social proportions which, to date, society has been

VOL 12 1 9 4 2 6

reluctant to address. While there are technical "remedial" techniques which can and should be used like filter strips and infiltration devices, as well as careful land use planning, the issue of toxic contamination can only be solved by a commitment to source reduction and recycling.

Source reduction, recycling, and the creation of non-toxic alternatives are issues which can, in the current economic climate, be used to argue against the establishment of mandatory controls for storm drain toxic pollution. Such arguments, however, must be weighed against the ultimate cost to health, the ecology, and that part of the economy (tourism, fishing, coastal real estate) dependent on a healthy coastal ecosystem. Policymakers must address the fact that the creation of non-toxic alternatives would create an entire new economic base for the State of California. In addition, fees[21] can be charged to those "impervious properties" which generate stormwater runoff, and which in turn can be used to subsidize the recycling of toxins, the reduction of toxins at the source, and the creation of non-toxic alternatives.

C. The Role of Local Governments

Local governments can use the state non-point source management plan to help identify the degraded local waters and stormwater pollution sources. Thereafter local governments can impose initial "remedial" solutions through implementing land use ordinances which may contain some of the following:

1. Catch basins--boxes placed underneath gutters which catch solids and allow liquid to flow over the edge--used at the mouth of storm drain openings can act as the first point of sediment settling, thereby reducing the flow of toxicants into the Bay.

2. The placement of vegetation on the sides of storm drain channels has been demonstrated to significantly reduce the amount of pollutants in stormwater. This is accomplished by slowing the velocity of the water, thereby allowing toxicants to attach to the vegetation.

3. Placing gravel and small stones in storm drain channels. This will attract the PAHs, chlorinated hydrocarbons, and heavy metals in the flow of effluent, thereby further reducing the entry of toxicants into the Bay.

A more sophisticated yet still palliative technology involves placing mini-chemical pre-treatment facilities in storm drains. Mini pre-treatment filtration plants, while effective at decreasing the amount of toxics which flow into the Bay, alone cannot solve the problem.

D. The Role of Individual Citizens

Individual citizens represent an army of people who can successfully wage war against toxic pollution in stormwater runoff. There are a number of actions individuals can take to help.

1. Recycle Used Motor Oil.

Yearly, the equivalent of 35 Exxon Valdez oil spills enter coastal waters through storm drain runoff, most of which comes from dumping by people who change their own motor oil. Used motor oil should be recycled, or taken to a toxic waste facility. The cessation of this kind of illegal dumping by individuals can aid immeasurably in keeping toxicants out of the storm drain system.

2. Purchase Non-toxic Household Products.

An array of non-toxic household cleaners and products are available in today's market place. Toxic household cleaners and products often find their way into storm drains. These products should be replaced with non-toxic alternatives.

3. Proper Storage and Clean-up of Household Chemicals.

Individuals can insure that substances such as pesticides, fertilizers, paints, preservatives, strippers and solvents are stored in dry places away from water sources. Once used, these substances should not be disposed of in the local storm drain. They should be either recycled or brought to local toxic or hazardous metals disposal sites.

4. Increase Vegetation Around the Home.

By increasing the amount of vegetated area around a home, a homeowner increases the porosity of the soil and reduces soil erosion, which lessens the amount of stormwater runoff. (The vegetated areas act as a natural filter, slowing the movement of stormwater runoff which allows many contaminants to settle out.)

5. Educate Politicians to Enact Laws and Policies Which Will Stop Chemical Contamination of the Bay.

Ultimately removing chemical contaminants from storm drains and the Bay is a question of political will. We have the technology and the alternatives to solve the problem. We do not at the present time have the will to do so. Politicians respond to constituent pressure. Concerned individuals should, therefore, educate their elected representatives to the importance of removing toxic chemicals from the storm drain system.

CONCLUSION

Santa Monica Bay represents a natural resource of untold beauty and benefit to the citizens of Southern California. Its economic value in terms of coastal tourism and real estate is in the 40 billion dollar range. Its sport and commercial fishing value is in the 2.2 billion dollar range. It is a focal point for the region and a recreational and esthetic treasure. For many it is also a source of food.

It is clear from this study that chemical contamination is a threat to both the vitality of the Bay and to those humans who use the Bay. Given that our life styles are dependent upon toxic chemicals, it is a certainty that toxicants will continue to enter Santa Monica Bay through the storm drain system. Each of us therefore must make a choice either to phase out toxics from our lifestyles and pressure elected officials to enact laws and policies which will remove toxins from the environment, or to pass on to our children and their children a Santa Monica Bay polluted by toxic chemicals.

[7] Studies conducted under the auspices of the City of Santa Monica have identified a number of chemical agents in the effluent from the Pico-Kenter storm drain. Chlorinated hydrocarbon solvents and suspected carcinogens were detected during 1985 and 1986. Between 1989-90 bromoform, chloroform, toluene, xylene, perchloroethylene, polycyclic aromatic hydrocarbons, nitroaromatics, bromodichloromethane and others in the Pico-Kenter storm drain. A study by Schager and Gossett (June 1988) identified DDT, PCBs, PAHs, and alkalines in Ballona Creek. In addition, Heal the Bay, in conjunction with the City of Los Angeles, the Los Angeles County Sanitation Districts, and the Santa Monica Bay Restoration Project has studied the problem of human fecal matter discharged from storm drains. Engineering Science under

contract with the City of Los Angeles, has monitored runoff from different land use types in Los Angeles. Dr. Michael K. Stenstrom (Department of Civil and Environmental Engineering, UCLA), also in conjunction with the Santa Monica Bay Restoration Project, is monitoring toxicity in marine organisms in the Bay. More recently, Fisher et. al. (1993), in a paper being prepared for publication, have reported the presence of dioxins, furans, and polychlorinated naphthalenes in storm drain effluent entering the Bay.

[8] Acenaphthene, anthracene, benz(a)anthracene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(g,h,i)perylene, benzo(a)pypene, chrysene, dibenzo(a,h)anthracene, dibenzofuran, fluoranthene, fluorene, indeno(1,2,3,4-c,d)pyrene, 2-methyl apthalene, naphthalene, phenanthrene, and pyrene.

[9] Benz(a)anthracene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(a)pyrene, chrysene, dibenzo(a,h)anthracene, and indeno(1,2,3,4-c,d)pyrene.

[10] California's Proposition 65 classifies chemicals as carcinogens when they are known to cause cancer in animals. This classification is not used by U.S. EPA.

[12] Ibid.

[13] The six phthalates that were found in the storm drain effluent are bis(2-ethylhexyl)phthalate (DEHP), butyl benzyl phthalate, dimethyl phthalate, diethyl phthalate, di-n-butyl phthalate, di-n-octyl phthalate.

[14] "Appropriate control" in this context means an extensive quality assurance/quality control program.

[15] The 33 volatile organic compounds found were dichlorodifluoromethane, chloromethane, carbon disulfide, methlyene chloride (1), trans-1,2-dichloroethene, 2-butanone, bromochloromethane, chloroform, 1,1,1-trichloroethane, benzene, trichloroethene, dibromomethane, bromodichloromethane, 4-methyl-2-pentanone, toluene, tetrachloroethene, 2-henanone, dibromochloromethane, styrene, bromoform, 1,2,4-trimethylbenzene, napthalene, 1,1-dichloropropene, p-isopropyltoluene, (m+p)-xylene, o-xylene, 1,1-dichloroethane, 1,2-dichlorobenzene. Five compounds, bromoform, chloroform, dibromochloromethane, dichloromethane(methylene chloride), and 4-methyl-2-pentanone, had over all averages in the ppb range. The largest number of compounds and the greatest concentrations of the trihalomethanes, bromoform, chloroform, and dibromochloromethane, and 9 methylene chloride, were 10.6, 4.1, 4.9, 6.3 ppb at this site.

[16] The carcinogen methylene chloride after analyzing appropriate controls was found in excess of EPA Drinking Water Standards.

[17] The actual chemicals identified can be found in the Report on Tables 14 (page 63), and 22 (page 110-11).

[18] Styrene is associated with point discharges, thereby indicating that it may have been illegally dumped.

[19] Mass loading is defined as the amount of chemicals released into the receiving water from a storm drain over a specified time period.

[20] Supra nt. 1.

[21] Innovative tools for funding storm water management exist and should be investigated by those in State and local governments who wish to free storm drains from toxic runoff. One innovative financing tool now being implemented by the City of Los Angeles, is commonly known as "storm water utility." These are local government entities that fund storm water management services through "user Charges" which pass on storm water management costs to the "generators" of the runoff.

NOTE ON CONSOLIDATION

This report contains hydrologic data for the 1987-88 water year. On January 1, 1985, the Los Angeles County Flood Control District consolidated with the Los Angeles County Road Department and portions of the Los Angeles County Engineer to become the Los Angeles County Department of Public Works. The hydrologic data processing and reporting functions formerly carried out by the Flood Control District have now been assumed by the Department of Public Works.

ABOUT THIS REPORT

The 1987-88 Hydrologic Report represents a significant departure in terms of data content and format from reports published previously by the Department of Public Works and its predecessor, the Los Angeles County Flood Control District. The changes primarily entail the reporting of less detailed hydrologic data than were previously published, such as monthly and annual summaries instead of daily data. We apologize for any inconvenience this may cause our users, but it was felt necessary to make these changes to be current in our data publishing.

With the rapid development of computing technology, there appears to be less demand for hydrologic data in written form, and it is our intention at some future time to phase out the published book reports and make the data available on computer diskettes. In the meantime, any user who desires more detailed information about any of the types of hydrologic data which we manage can write the Custodian of Hydrologic Records at:

Los Angeles County Department
of Public Works
Hydraulic/Water Conservation Division
P.O. Box 1460
Alhambra, CA 91802-1460

or telephone: (818) 458-6112

INTRODUCTION

This report contains hydrologic data within Los Angeles County for the period beginning October 1, 1987 and ending September 30, 1988. The data are presented in seven sections.

1. Precipitation - lists 385 active rainfall stations and presents corresponding seasonal rainfall amounts.

2. Evaporation - lists all locations for which evaporation data is on file and provides monthly evaporation amounts at 14 locations.

3. Runoff - presents the maximum, minimum, and mean of the daily flow rates for each month and the monthly volumes for 53 streamflow stations and three Metropolitan Water District outlets.

4. Dam Operation - presents the maximum and minimum of the daily inflow and outflow rates for each month, the instantaneous peak inflow and outflow rates and storage volumes for 14 dams and reservoirs.

5. Erosion Control - list debris basins and debris production amounts and displays maps of major watershed burns.

6. Water Quality Monitoring - presents maps of surface and groundwater sampling locations, and data at selected locations.

7. Conservation and Groundwater - presents records of water conserved at various facilities, water injected at seawater barrier projects, well hydrographs, and groundwater basins.

Where practical, data which would satisfy immediate needs and serve as useful reference are published in these reports. Several tables appear listing locations where unpublished data are available. Additional information may be obtained by writing to:

VOL 12

1943

THE LOS ANGELES COUNTY

TOPOGRAPHY

The County of Los Angeles covers an area of 4,083 square miles and measures approximately 66 miles in the east - west and 73 miles in the north - south directions.

The terrain within the County can be classified in broad terms as being 26 percent mountainous, 12 percent coastal plain; and 62 percent hills, valleys, or deserts. Relief of the terrain ranges from sea level to a maximum elevation of 10,000 feet. The coastal plain is generally of mild slope and contains relatively few depressions or natural ponding areas. The slopes of main river systems crossing the coastal plain, such as the San Gabriel River, Los Angeles River, and Ballona Creek, range from 4 to 14 feet per mile.

Topography in the mountainous area is generally rugged with deep, V-shaped canyons separated by sharp dividing ridges. Steepwalled canyons with side slopes of 70 percent or more are common. The gradient of principal canyons in the San Gabriel Mountains ranges from 150 to 850 feet per mile. Mountain ranges are aligned in a general east-west direction, the major range being the San Gabriel Mountains. The majority of mountain ridges lie below Elevation 5,000, the total area above this level being approximately 210 square miles.

GEOLOGY - SOILS

Igneous, sedimentary, and metamorphic rock groups are all represented within the County. The San Gabriel Mountains and Verdugo Hills are composed primarily of highly fractured igneous rock, with large areas of granitic rock formation being exposed above soils which are coarse and porous. Faulting and deep weathering have produced porous zones in the rock formation; however, rock masses have produced a comparatively shallow soil mantle due to the steepness of slopes which accelerates erosion of the fine material.

LAND USE

The principal vegetative cover of upper mountain areas consists of various species of brush and shrubs known as chaparral. Most trees found on mountain slopes are oak, with alder, willow, and sycamore found along streambeds at lower elevations. Pine, cedar, and juniper are found in ravines at higher elevations and along high mountain summits.

The chaparral is extremely flammable, and extensive burns of the mountain vegetation frequently occur during dry, low-humidity weather accompanied by high winds. Chaparral has the ability to sprout following fires and grows rapidly to re-establish the watershed cover within a period of 5 to 10 years.

VOL 12 1944

Grasses are the principal natural vegetation on the hills. Much of the hill land and nearly all of the valley land in the densely populated portion of the County south of the San Gabriel Mountains has been converted to urban and suburban use. Development of the Santa Clarita Valley and desert areas to the north of the San Gabriel Mountains is sparse at present but is proceeding at an accelerated rate.

Other mountains and hilly reaches within the Department are composed primarily of folded and faulted sedimentary rocks, including shale, sandstone, and conglomerate. Residual soils in these areas are shallow and are generally less pervious than those of the San Gabriel Mountain range.

Valley and desert soils are alluvial and vary from coarse sand and gravel near canyon mouths to silty clay and gravel or clay in lower valleys and the coastal plain. The alluvial fill has been built up by repeated deposition of debris to depths as great as 2,000 feet in places. This fill is quite porous in areas of relatively low clay content. Impervious layers and irregularities in the underlying bedrock divide the alluvium into several County groundwater basins. Valley soils are generally well drained and relatively few perched water or artesian areas are present.

CLIMATE

The climate within the County varies between subtropical on the Pacific Ocean side of the San Gabriel mountain range to arid in the Mojave Desert. Nearly all precipitation occurs during the months of December through March. Precipitation during summer months is infrequent, and rainless periods of several months are common. Snowfall at elevations above 5,000 feet is frequently experienced during the winter storms, but the snow melts rapidly except on higher peaks and the northern slopes. Snow is rarely experienced on the coastal plain.

January and July are the coldest and warmest months of the year, respectively. At Los Angeles, the 30-year average daily minimum temperature for January is 48 degrees above zero. The average daily maximum temperature for July is 84 degrees. At Mount Wilson (Elevation 5,850 feet), the 30-year average daily minimum temperature for January is 36 degrees above zero and the average daily maximum temperature for July is 81 degrees.

HYDROMETEOROLOGIC CHARACTERISTICS

Coastal and Mountain Areas

Precipitation in the Los Angeles area occurs primarily in the form of winter orographic rainfall associated with extratropical cyclones of North Pacific origin. Major storms consists of one or more frontal systems and occasionally last four days or longer. Air masses and frontal systems associated with major storms commonly extend for 500 to 1,000 miles in length and produce rainfall simultaneously throughout the County. Major storms approach Southern California from the west or southwest with southerly winds which continue until frontal passage. The mountain ranges lie directly across the path of the inflow of warm, moist air, and orographic effects cause precipitation to be greatly intensified.

VOL 12

1945

The effect of snowmelt upon flood runoff is of significance in the few cases when warm spring rains from southerly storms fall on a snowpack. During major storms, temperatures throughout the County may remain above freezing.

Average individual storm rainfall amounts and intensities conform to a fairly definite aerial pattern which reflects general effects of topographic differences.

Desert Areas

Summer convective rainfall is principally experienced in the upper San Gabriel Mountains and the Mojave Desert regions. In many desert areas, the most serious flooding occurs as a result of summer convective storms.

RUNOFF CHARACTERISTICS

Mountain Areas

In mountain areas, the steep canyon slopes and channel gradients are conducive to rapid concentration of storm runoff quantities. Depression storage and detention storage effects are minor in the rugged terrain. Soil moisture during a storm has a pronounced effect on runoff from the porous soils supporting a good growth of deeprooted vegetation such as chaparral. Soil moisture deficiency is greatest at the beginning of a rainy season, having been depleted by evapotranspiration process during the dry summer months. Precipitation during periods of soil moisture deficiency is nearly entirely absorbed by soils, and except for periods of extremely intense rainfall, significant runoff does not occur until soils are wetted to field moisture capacity. Due to high infiltration rates and porosity of mountain soils, runoff occurs primarily as subsurface flow or interflow rather than as direct runoff. Spring or base flow is essentially limited to portions of the San Gabriel mountain range, most streams in the Department being intermittent.

Runoff from a mountain watershed recently denuded by fire exceeds that for the unburned state due to greatly increased quantities of inorganic debris present in the flow and lowflows from a denuded watershed. Debris production from a major storm has amounted to as much as 120,000 cubic yards per square mile of watershed. Boulders up to eight feet in diameter have been deposited in a valley area a considerable distance from their source.

Debris quantities equal in volume to storm runoff, or in other words 100 percent bulking of runoff from a major storm, have been recorded. Where debris-laden flow traverses an alluvial fill unconfined by flood control works, flood discharges follow an unpredictable path across the debris cone formed at the canyon mouth.

Hill and Valley Areas

In hill areas, runoff concentrates rapidly from the generally steep slopes; however, runoff rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size. In those hill areas which have been developed for residential use, concentration times become considerably decreased due to drainage improvements, and runoff volumes and rates become increased due to increased imperviousness. On the other hand, erosion is controlled and debris content of storm flow is practically eliminated. Debris production rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size.

In highly developed valley areas, local runoff volumes have increased as the soil surface has become covered by impervious materials. Peak runoff rates for valley areas have also increased due to elimination of natural ponding areas and improved hydraulic efficiency of water carriers such as streets and storm drain systems.

VOL 12

1947

FLOOD CONTROL AND WATER CONSERVATION

VOL 12

1948

FLOODS. . .AN OLD STORY

Floods in Los Angeles County have been recorded as far back as the days of the Mission Padres. For centuries waters have swept out of the San Gabriel Mountains causing extensive property damage and taking a great toll of lives.

Such a flood occurred in 1914 causing over $10 million in property damage and taking many lives. As a result, the State legislature passed an act creating the Los Angeles County Flood Control District.

The Department was assigned two tasks. . .control the floods and conserve the water.

CONTROLLING THE WATERS

Successful early bond issues financed construction of the 14 dams which the Department built high in the San Gabriel Mountains to impound storm waters until they could be released in an orderly fashion. Debris basins were constructed to trap eroded materials which had caused terrible damage in the past. Flood channel improvements were undertaken to confine the waters.

Department engineers prepared a Comprehensive Plan in the early 1930's which provided for the control of flooding and the saving of as much of the water as practicable. With minor modifications, it is still the plan today.

Federal legislation in 1936 brought the United States Army Corps of Engineers into the local flood control picture. Since that time, the two agencies have been jointly persuing construction of the Comprehensive Plan. The Department also cooperates with the United States Soil Conservation Service and Forestry Service in erosion control and debris reduction programs.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water conservation facilities adjacent to river channels and their tributaries permits water to be percolated into ground reservoirs for later pumping by consumers. These water conservation facilities are located in areas where the underlying soils are composed of porous sands and gravel formations. Some resemble rice paddies, while others are deep basins which were once gravel pits.

The importance of this activity is apparent when it is realized that about 35 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, seriously depleted these supplies on numerous occasions down through the years.

Other major conservation efforts by the Department include combatting the serious intrusion by salt water to underground fresh well supplies along the Pacific Ocean and the utilization of reclaimed sewage waters in spreading operations.

VOL 12

ORGANIZED TO DO THE JOB

Day-to-day administration of Department affairs is vested in the Director of Public Works who is appointed by and responsible to the Los Angeles County Board of Supervisors. A part of the Department's activities involve the construction of flood control and water conservation facilities, and the operation and maintenance of dams, debris basins, spreading grounds, channels, and storm drains.

PRECIPITATION

PRECIPITATION

This section contains annual precipitation data collected by the Department for the period beginning October 1, 1987 and ending September 30, 1988. Although the Department operates and maintains 385 rainfall stations, including standard and automatic gages which record amounts for durations ranging from 15 minutes to 24 hours, only annual amounts for the report period are listed herein. Additional data can be obtained by contacting the custodian of hydrologic records at the location shown in the front of the report.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions in the County and Southern California in real time, i.e., as they occur. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels, and which forecast peak flows in the Los Angeles River and the Rio Hondo.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The cooperation of observers in furnishing rainfall data to the Department as a public service is appreciated. The effort of the many agencies and individuals who have so freely cooperated with us in the collection of this data have resulted in the large number of complete records for the period covered by this report.

EVAPORATION

VOL 12

EVAPORATION

Data for 14 active evaporation stations were reported to the Department during the 1987-88 water year. Daily records of active and inactive Department stations, as well as some stations of other agencies, are available in the Department's files. Monthly and seasonal evaporation has been published in the Department's Annual or Biennial Reports on Hydrologic Data since the 1931-32 season.

COOPERATION

The Department receives evaporation data from the Los Angeles City Department of Water and Power, The Metropolitan Water District, Southern California Edison Company, United States Forest Service, County Departments, California Department of Water Resources, and various individuals.

LENGTH OF RECORD

The first land pan installed by this Department was at Santa Anita Dam in March of 1929. There are 30 evaporation stations which have records of 15 seasons or more in the Department's files.

RUNOFF

R0052777

R U N O F F

The Department operated or received data from 88 water-stage recording stations during the 1987-88 water year. Data from 56 of those stations are summarized and published in this volume.

RECORDS OF STREAMFLOW

Records published give the following information:

1. Station description which presents location, drainage area, type of channel, control, regulations, diversions, and available records.

2. Discharge tabulation which summarizes the maximum, minimum, and mean of the daily flow rates in second-feet for each month and the total monthly volumes in acre-feet.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorlogical conditions in the County and Southern California in real time, i.e., as they occur. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels, and which forecast peak flows in the Los Angeles River and the Rio Hondo.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The Department receives streamflow data from other agencies and publishes, or has access to, the records for local stations. Department hydrographers also make periodic streamflow measurements and observations at installations belonging to these organizations. Data from 25 of the Department's stations are reviewed and published in the Geological Survey's annual water supply papers.

Agencies with which the Department exchanges data are:

United States Geological Survey, Water Resources Division

United States Corps of Engineers

State Department of Water Resources

The Metropolitan Water District

San Gabriel River Water Committee

LEGEND

Stations are designated by letters and numbers which indicate ownership, operation agency, and type of station. The letters used have the following connotations:

Prefix F - Indicates a station owned and operated by the Los Angeles County Department of Public Works.

Prefix E - Indicates a station owned and operated by the Corps of Engineers, Department of the Army but operated and maintained by the United States Geological Survey.

Prefix U - Indicates a station originally constructed and operated by the United States Geological Survey, Water Resources Division, now operated by the Department.

Prefix P - Indicates a station owned and operated by the Department formerly, operated by the Pasadena Water Department.

Prefix L - Indicates a station owned and operated by the Department formerly, operated in cooperation with the Little Rock - Palmdale Irrigation District.

Suffix R - Indicates a recorder station.

Suffix B - Indicates that the station has been moved. B represents second location, C a third location, etc.

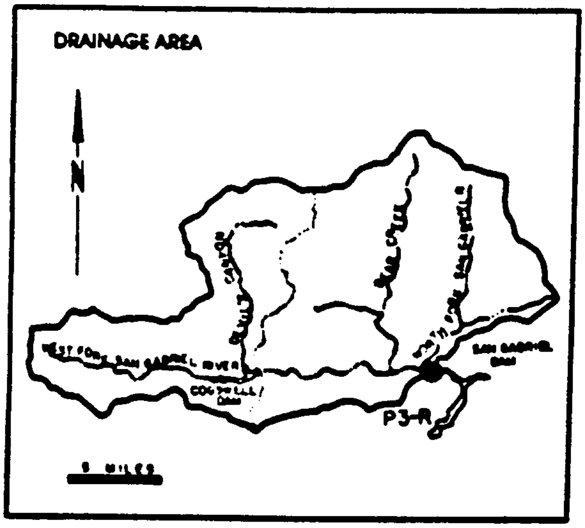
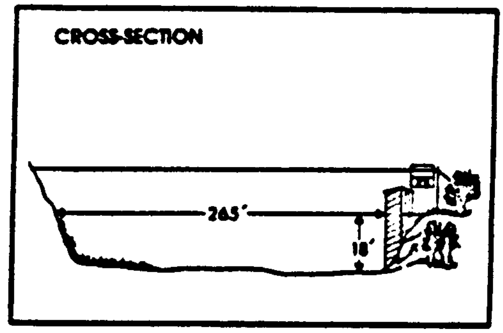
SAN GABRIEL RIVER
West Fork above Forks
STATION NO. P3-R





RECORDER- continuous water stage.

METHOD OF MEASUREMENTS- wading or from cable car.

DRAINAGE AREA- 102.0 square miles.

LOCATION- 1.5 miles above confluence with East Fork.

REGULATION- partially regulated by Cogswell Dam.

CHANNEL- natural, sand, gravel, and boulders.

CONTROL- subject to shifts in natural bottom.

LENGTH OF RECORD- at Station P3-R, December 3, 1930 to July 12, 1938 and September 27, 1938 to date. at Station P3B-R, July 12, 1938, to September 27, 1938.

REMARKS- for records prior to December 3, 1930 refer to Station P1-R.

WATER YEAR : 1987-88
(DISCHARGE IN SEC-FT)

STATION NO. : P3-R DRAINAGE AREA : 102.00 SQ. MI.

RECORDER- continuous water stage.
METHOD OF MEASUREMENTS- wading or from bridge.
DRAINAGE AREA- 51.9 square miles.
LOCATION- Bouquet Canyon Creek at Urbandale Avenue, 3.8 miles northeast of Saugus.
REGULATION- Bouquet Reservoir.
CHANNEL- concrete sides with natural bottom, trapezoidal in section.
CONTROL- concrete stabilizer.
LENGTH OF RECORD- October 11, 1967 to date.

WATER YEAR : 1987-88
(DISCHARGE IN SEC-FT)

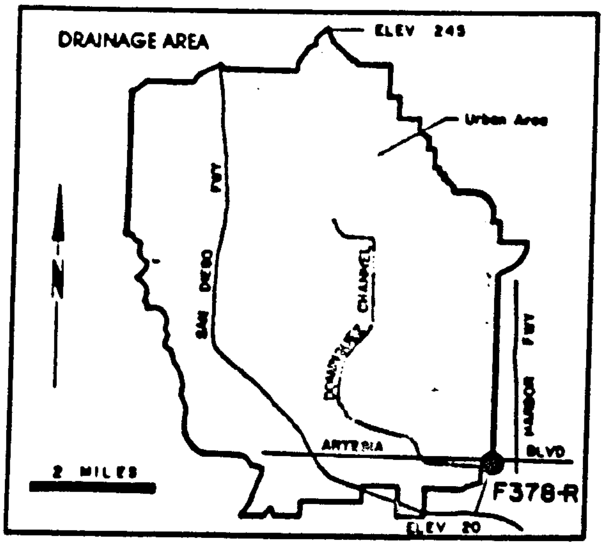
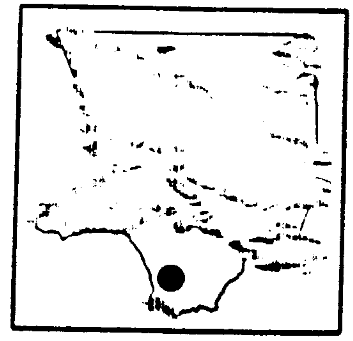
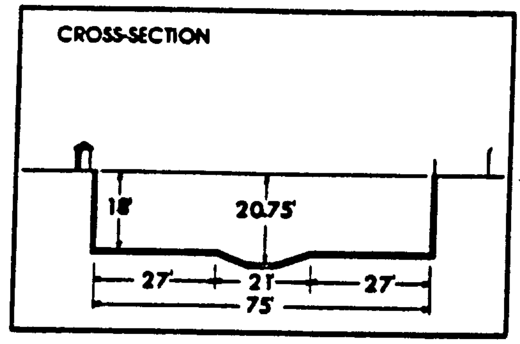
DOMINGUEZ CHANNEL
at Vermont Avenue
STATION NO. F378-R







RECORDER- continuous water stage.
METHOD OF MEASUREMENTS- low flows measured by wading. High flows measured from Vermont Avenue bridge.
DRAINAGE AREA- 37.1 square miles.
LOCATION- on the south bank, 93 feet above Vermont Avenue, about one mile south of Gardena.
REGULATION- none
CHANNEL- rectangular concrete with trapezoidal low flow channel at center.
LENGTH OF RECORD- November 23, 1966 to date.
REMARKS- gage is affected by tides greater than 4.0 feet above mean lower low water.

RESERVOIRS

VOL 12

19530

RESERVOIRS

Following the damaging flood of 1914 and creation of the Los Angeles County Flood Control District in 1915, it initiated a program of flood control and water conservation including the construction of 14 dams. These dams were operated by the Department during the period covered by this report. In addition, five Corps of Engineers' dams and Morris Dam owned by The Metropolitan Water District were utilized to achieve flood control and water conservation. The Corps of Engineers' dams are: Hansen Dam on Tujunga Wash, Sepulveda Dam on the Los Angeles River, Santa Fe Dam on the San Gabriel River, Whittier Narrows Dam serving both the Rio Hondo and San Gabriel River, and San Antonio Dam on San Antonio Creek.

OPERATION

The reservoirs are operated to control flood waters during storm periods. Post storm releases are made, when feasible, in amounts which can be conserved in downstream spreading grounds and by channel percolation.

SAN GABRIEL DAM HYDROELECTRIC PLANT

In December 1987, construction of two hydroelectric generator units at San Gabriel Dam was completed by San Gabriel Hydroelectric Partnership, a joint venture between private investors and the County of Los Angeles. The generator units are operated by Department personnel and the power generated is purchased by Southern California Edison Company. During December 1987 to July 1988, over two million kilowatt-hours of energy have been generated resulting in revenues of over $150,000.00. Recently an optimization computer was installed on Unit 1 to schedule power production during hours of peak energy demand.

RECORDS

The storage and flow records at the 14 Department reservoirs are summarized on the Dam Operation Record Sheets. The sheets show:

1. Reservoir water surface elevations based on the spillway datum. Elevations are obtained from water stage recorder graphs or interpolation from staff gage readings and recorded as of midnight of each day. Only maximum and minimum water surface elevations for each year are shown.

2. Storage in acre-feet based on the most recent topographic surveys. Annual storage volumes are shown.

3. Inflow in cubic feet per second. This is usually calculated from storage change and known outflow. When outflow is not known, the inflow may be determined from gaging station records or interpolated between measurements. Only the maximum and minimum of the daily flow rates for the year and the instantaneous peak flow rate are shown.

4. Outflow in cubic feet per second. These values are determined from gaging station records, known valve openings and rating curves, or from storage change and known inflow. Only the maximum and minimum of the daily outflow rates for the year and the instantaneous peak outflow rate are shown.

5. Discrepancies between outflow and storage losses at certain dams are attributable to percolation and/or evaporation losses. Total monthly evaporation losses are determined from the measurements made on floating or land evaporation pans. In those cases where no allowances were made for evaporation, the amounts are necessarily included in the flow values. Accuracy of the flow records computed from storage records is dependent on the frequency with which storage data are revised to keep in step with the physical change in reservoirs.

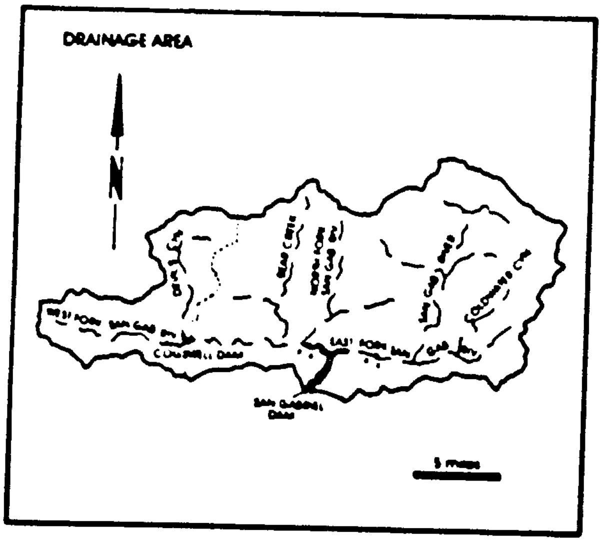
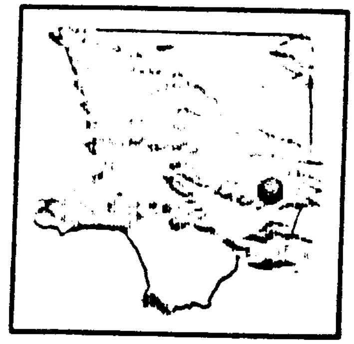
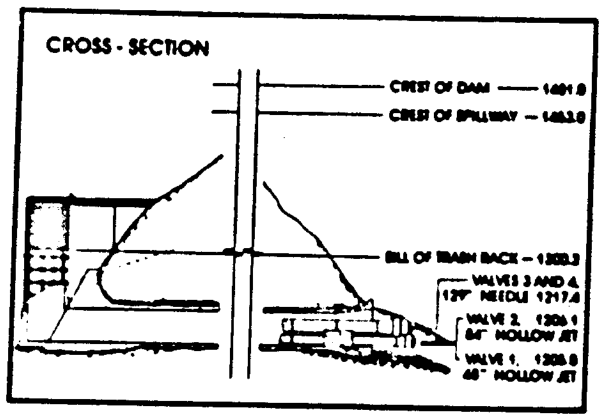
SAN GABRIEL DAM
AND RESERVOIR







PURPOSE - Flood Control and Conservation.
DATE CONSTRUCTED - Started December 1932. Completed July 1939.
LOCATION - San Gabriel Canyon, 7.5 miles north of Azusa.
DRAINAGE AREA - 163.5 square miles (uncontrolled)
39.2 square miles (controlled)
Total 202.7 square miles
(Includes Cogswell drainage)
CAPACITY - 41,549 acre - feet.
SPILLWAY ELEVATION - 1,453 feet.

EROSION CONTROL

VOL 12

1

9561

EROSION CONTROL

Each year eroded material in various forms (trees, rock, sand, etc.) flows out of the mountain watersheds of Los Angeles County. In an effort to control this potentially disruptive force, the Department maintains a series of debris basins in canyon mouths and upstream stabilization structures in selected watersheds.

PURPOSE

The purpose of a debris basin is to entrap the debris flows emanating from the canyon and let the relatively desilted water pass into flood control channels.

From 1987 to 1988, the number of debris basins increased from 129 to 131 yielding a total maximum capacity of 7,648,700 cubic yards.

Records of sediment inflow at individual debris basins and amounts excavated and removed are available in the Hydraulic/Water Conservation Division.

STABILIZATION STRUCTURES

Stabilization structures are constructed to control erosion in natural canyons. They serve to prevent downcutting by stabilizing alluvium deposits. In addition, they store debris generated by the watershed and serve to stabilize side banks, reducing side slope sloughing and bank erosion.

The Department maintains 225 stabilization structures in 47 major watersheds. No structures have been constructed since the 1973-74 water year.

EMERGENCY STRUCTURES

Emergency structures (rail and timber, and crib type) have been constructed to entrap the debris inflow from burned watersheds. They serve to protect the existing structures (road, channel, residence, etc.) located immediately downstream of the watersheds. Currently, 38 emergency structures exist with a total maximum capacity of 341,600 cubic yards.

SEDIMENT REMOVAL FROM RESERVOIRS

Sediment deposition in reservoirs reduces the storage capacities and adversely affects flood control and water conservation efforts. Sediment removal is periodically necessary and is generally an expensive effort due to large quantities, the need to deal with water inflows, and in several cases, remote locations and limited accessibility for equipment.

Where practical, the Department encourages sediment removal by permittees at no cost to the Department such as at Eaton Wash and Devil's Gate Dams.

The Department presently is studying the feasibility of various methods for the removal and long-term management of sediment in the three reservoirs in San Gabriel Canyon. These three currently contain about 36 million cubic yards - about three-quarters of the cumulative volume of sediment currently behind all dams under the Department's control.

WATER QUALITY

WATER QUALITY

Since its conception, the Flood Control District (now Department of Public Works) has actively engaged in operations which have proven indispensable in preserving the integrity of our water resources, both quantity and quality, and has aided in the establishment of regulations or controlling criteria by those agencies so empowered.

Prior to March 1986, monitoring activities in the field of water quality control were conducted by the Water Quality Section of Hydraulic/Water Conservation Division. In March 1986, the responsibilities of conducting such activities were transferred to Waste Management Division as a result of the consolidation. These activities include, among others, the collection of water quality samples, their analyses, and the interpretation and reporting of the resulting data.

Areas of involvement include the monitoring of all groundwater basins through the sampling of numerous wells, the monitoring of storm and low water flows at various strategic locations on the major streams or channels, and an assumed or obligated responsibility to monitor the quality effects and subsurface travel of recharge areas, specifically the Whittier Narrows Spreading Grounds area.

The Water Quality Section, together with personnel of other Departmental divisions, also conducts investigations into pollutional problems relative to our facilities, particularly those from industrial discharges, vehicle accidents, ruptured pipelines, or the indiscriminate dumping of various waste products.

The principal objectives of these investigations are to determine the degree and apparent source or origin of the pollution and to take the necessary action that will immediately abate the existing problem and possibly provide a means to prevent or limit recurrence.

SURFACE WATER QUALITY

The Surface Water Quality Monitoring Program involves the sampling of dry weather flows of a number of the principal water conveyance systems within the County prior to July 1984, samples were collected at 31 stations located on the Los Angeles River, San Gabriel River, Santa Clara River, Rio Hondo Channel, Coyote Creek, Dominguez Channel, Ballona Creek, Centinela Creek, San Jose Creek, Topanga Canyon Channel, Malibu Creek, and Kenter Avenue Drain. Samples were collected monthly at each station and analyzed by the Department's Water Quality Laboratory for major minerals, total dissolved solids (TDS), total hardness, specific conductance, pH, dissolved oxygen demand, coliform, fecal coliform, and enterococci. In addition to these constituents, residual chlorine, total organic carbon (TOC), and chlorinated pesticides were also determined at selective locations as well as an annual analysis for trace metals such as barium, copper, chronium, lead, mercury, nickel, selenium, silver, zinc, iron, and manganese.

In July 1984, the monitoring program was reduced in terms of sampling location and monitoring frequency as well as number of constituents analyzed. The modified program involves collection of monthly/quarterly samples from

VOL 12 19577

21 monitoring stations for ph, total dissolved solids, specific conductance, and dissolved oxygen analyses. In addition, an annual sample is collected from each of the 21 stations for more extensive analyses. Since July 1984, this Department closed its laboratory and has utilized a contract laboratory to perform all the above analyses.

A selective list of total dissolved solids is shown for some of the sampling locations on the streams and channels monitored under the Surface Water Quality Program. For a conception of the analysis performed on surface flows, a yearly compilation of constituent determination is shown for one (Los Angeles River at Wardlow) of the sampling stations in the program.

This program has been expanded, effective January 1, 1988, to approximate the pre-1984 monthly program with the addition of various organic constituents. Implementation of the modified program started May 1, 1988.

STORM WATER QUALITY

The annual Storm Water Quality Program is a comprehensive sampling of major storm flows at many locations throughout the County. The samples are analyzed for major minerals, specific conductance, suspended solids, pH, dissolved oxygen, biochemical oxygen demand, total coliform, fecal coliform, enterococci, total organic carbon, and nutrients level.

In 1984, the number of sampling stations for this program was reduced to 15 including San Gabriel River and Rio Hondo Spreading Grounds where samples were collected up to four times annually for extensive analyses including purgeable and non-purgeable organics.

In addition, storm samples are taken at various gaging stations and spreading grounds. The flow data is recorded at the time each sample is taken and these samples are analyzed for specific conductance.

GROUNDWATER QUALITY

The annual sampling of water wells, under a selected scheduling, in five major basins in Los Angeles County comprise the Groundwater Quality Program. The program, initiated in 1970, is coordinated with the State of California Department of Water Resources and the City of Los Angeles Department of Water and Power.

These agencies participate in the obtainment and analysis of samples. All the water wells samples are active production wells used either for municipal supply irrigation, or for industrial purposes and are selected to represent a general portrayal of basin water quality conditions. The samples taken under this program are analyzed for major mineral, total dissolved solids, electrical conductivity, ph and, in specific cases, phosphate, iron, manganese, fluoride, or boron.

WATER QUALITY DATA ACCESSIBILITY

Data acquired from the various programs are on file in the Water Quality Section. In addition, all data is accessible to any user through STORET, an

Environmental Protection Agency computer system that stores, retrieves, and manipulates data using agency code 21CALAFD.

WATER CONSERVATION

R0052902

VOL 12

1997

WATER CONSERVATION

Information presented in this section includes amounts of local, imported, and reclaimed water conserved in spreading areas, and information on the seawater barrier projects which prevent salt water intrusion to groundwater zones in the coastal areas. Pertinent data are presented regarding the locations and descriptions of Department conservation facilities, as well as facilities owned by others. Also included are groundwater maps delineating elevations recorded during the report period and hydrographs of selected key wells.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water spreading facilities adjacent to river channels and in soft-bottom channels permits water to percolate into underground reservoirs for later pumping. These water spreading facilities are located in areas where the underlying soils are composed of sand and gravel formations and some are deep basins which were once gravel pits.

The various types of water conserved, local, imported, and reclaimed, are construed to have the following meanings in this section: Local water is primarily runoff due to rainfall on the mountain and valley watersheds within the County. Imported water is water originating outside the County which is transported to and delivered within the County. Reclaimed water is the effluent produced by the Whittier Narrows Water Reclamation Plant, the San Jose Creek Water Renovation Plant, and the Pomona Reclamation Plant, all operated by the Los Angeles County Sanitation Districts.

The importance of this activity is apparent when it is realized that about 35 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County combined with periodic droughts seriously depleted these supplies on numerous occasions down through the years.

The Department's policy is to conserve the maximum amount of storm water possible consistent with considering runoff quantity and quality, capacities of the spreading facilities, and groundwater conditions.

SPREADING GROUNDS

The total gross area of spreading areas owned and operated by the Department during this report amounted to 2,369 acres. The Department also assisted in the operation and maintenance of 679 acres of spreading grounds owned by others. An additional 246 acres of spreading grounds are controlled, maintained, and operated by other agencies. The total gross acreage of spreading grounds in the County is 3,294 acres.

IMPORTED WATER

During this period, imported Colorado River water and State Project water for spreading was obtained from The Metropolitan Water District. Also imported State Project Water for spreading was obtained from the San Gabriel Valley Municipal Water District.

Imported water for groundwater recharge in the Coastal Plain was spread in the Department's facilities in the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds and San Gabriel River systems south of Whittier Narrows Dam on behalf of the Central and West Basin Water Replenishment District.

Imported water for groundwater recharge in the San Gabriel Valley was spread in Santa Fe Spreading Grounds, in the San Gabriel River between Morris Dam and the spreading grounds, in Irwindale Spreading Basin and in Forbes Spreading Grounds on behalf of MWD, the Main San Gabriel Basin Watermaster, and the San Gabriel Valley Municipal Water District.

RECLAIMED WATER

The County Sanitation Districts' Whittier Narrows Water Reclamation Plant effluent, purchased by the Central and West Basin Water Replenishment District, was transported to the Rio Hondo and San Gabriel Spreading Grounds and San Gabriel River System for groundwater replenishment.

The County Sanitation Districts' San Jose Creek Water Reclamation Plant, activated in May 1972, made its first delivery of effluent in November 1972. The portion of the effluent that is spread is also purchased by the Central and West Basin Water Replenishment District.

The maximum amount of reclaimed water allowed includes Pomona Plant Water for spreading annually in the Montebello Forebay was increased from 32,700 acre-feet to 37,700 acre-feet in the 1986-87 water year, and to 42,700 acre-feet effective July 1988.

SEAWATER BARRIER PROJECTS

The Department operates three barrier projects to protect the groundwater in the West Coast and Central Basins against seawater intrusion by creating freshwater pressure ridges along the coastline. The pressure ridges are created by injecting fresh water through a series of injection wells. During the report period, 24,300 acre-feet of water were injected at the West Coast Basin Barrier Project, 7,050 acre-feet at the Dominguez Gap Barrier Project, and 4,000 acre-feet at the Los Angeles part of the Alamitos Barrier Project. On behalf of the Orange County Water District, 2,170 acre-feet of water were injected at the Orange County portion of the Alamitos Barrier Project.

SEASONAL DATA AND MAPS

During this report period, monthly and semiannual measurements of groundwater levels in observation wells located throughout the groundwater basins in Los Angeles County were made and processed.

Hydrographs of selected key wells are included in this report.

VOL 12

GROUNDWATER BASINS AND GROUNDWATER RECHARGE

Groundwater in Los Angeles County is stored in basins underlying five major geographic areas. These groundwater basins are separated by geologic features which impede groundwater movement or sometimes by arbitrary political boundaries. Following is a background and summary of the Department's groundwater recharge activities within each of these areas.

The Department operates 2,369 acres of spreading grounds and basins and soft-bottom channel spreading areas for replenishment of local aquifers to increase water supplies. During the report period, the Department conserved more than 124,000 acre-feet of storm runoff.

The conservation of local runoff is supplemented by spreading imported water and reclaimed water purchased by water agencies. During the period, 72,150 acre-feet of imported water and 40,200 acre-feet of reclaimed water were spread.

SAN GABRIEL VALLEY

The Department operates 20 spreading grounds in the San Gabriel Valley to receive direct valley runoff and flows from the San Gabriel Mountains, some can also receive imported water. During the report period, the Department added approximately 47,900 acre-feet of local water and 47,200 acre-feet of imported water to the groundwater stored in the basins underlying the San Gabriel Valley.

Main San Gabriel Basin

This is the largest basin underlying the San Gabriel Valley with an estimated storage capacity of 9.5 million acre-feet. It reacts quickly to artificial spreading in Santa Fe Reservoir Spreading Grounds and to percolation in the San Gabriel River downstream of Santa Fe Dam. Citrus Spreading Grounds which was dormant for 17 years, was reactivated in early 1985. The basins were reconfigured by permittee and contract work to increase the surface storage capacity from 25 acre-feet to 85 acre-feet and a 35-50 cfs intake from Big Dalton Wash was constructed. During this period, construction of a new intake structure with a capacity of 200 cfs was started.

During the report period, the Department replenished the Main San Gabriel Basin with 18,700 acre-feet of local water and 23,400 acre-feet of imported water.

Upper San Gabriel Canyon Basin

Approximately 16,500 acre-feet of local water and approximately 22,800 acre-feet of imported water were recharged by the Department through its San Gabriel Canyon Spreading Grounds and by percolation in the adjacent San Gabriel River. Also, 6,000 acre-feet of water were routed to Fish Canyon Spreading Grounds which is operated by the Committee of Nine. A contract for an intake system with a capacity of 200 cfs for San Gabriel Canyon Spreading Grounds was under way during the report period.

1 9500

Lower Canyon Basin

The basin is located south of the Upper San Gabriel Canyon Basin and is separated from it by the underground Lohmon Dike. Groundwater cascades over the Lohmon Dike from the Upper San Gabriel Canyon Basin and recharges the Lower San Gabriel Canyon Basin. The Department spread 610 acre-feet of local water in Sawpit Spreading Grounds which is within the Lower Canyon Basin.

Wayhill Basin

A contract was awarded to improve the storage capacity and construct a new intake at Forbes Spreading Grounds.

The Department spread 370 acre-feet of local water and 1,000 acre-feet of imported water in the Wayhill basin.

Foothill Basin

The Department spread 770 acre-feet of local water at its San Dimas Canyon Spreading Grounds facility in the Foothill Basin.

Glendora Basin

The Department spread 470 acre-feet of local water in its Dalton facilities within the Glendora Basin.

Claremont Heights Basin

Ten acre-feet of local water were diverted to the Pomona Valley Protective Associaton's Thompson Creek Spreading Grounds which benefits the groundwater in the Claremont Heights Basin.

Live Oak Basin

The Department has no spreading facilities in the Live Oak basin.

Chino Basin

The basin is located in the most eastern part of the County. No Department recharge facilities are located within the Chino Basin.

San Dimas Basin

The basin is north of the San Jose Hills, east of the Main Basin, and south of the Wayhill Basin. The Department spread 70 acre-feet of local water in its Live Oak Spreading Grounds to recharge the basin.

Pomona Basin

The basin is located south of Claremont, Live Oak, and San Dimas Basins, and north of the Chino Basin and northeast of the San Jose Hills. The Department has no water spreading facilities within this basin.

Puente, Spadra, and Walnut Basins

No spreading occurs in this area.

Raymond Basin

The basin covering approximately 40 square miles is located in the northwest corner of the San Gabriel Valley and is separated from the Main San Gabriel Basin by the Raymond Fault. The Raymond Basin contains the Monk Hill Basin and the Pasadena and Santa Anita subareas. The Department recharged 2,810 acre-feet of local water by its spreading facilities in the Raymond Basin and diverted 1,590 acre-feet to the City of Sierra Madre's spreading facility during the report period.

COASTAL PLAIN

The groundwater basins underlying the Coastal Plain are divided by geological features into the Central (includes the Montebello and Los Angeles Forebays), West Coast, Santa Monica, and Hollywood Basins. During the period October 1, 1987 to September 30, 1988, the Department recharged 50,100 acre-feet of local water, 25,000 acre-feet of imported water, and 40,200 acre-feet of reclaimed water to the basins underlying the Coastal Plain. Most of the water was spread in the Montebello Forebay.

The Department is continuing with improvements in the Montebello Forebay to maximize water conserved and to simplify the spreading operations.

Central Basin

The Central Basin has the most storage capacity of the basins in the Coastal Plain. In addition to the waters recharged in the Department's spreading facilities, water injected in the Alamitos Barrier Project also contributes to the replenishment of the groundwater stored in the Central Basin. The Montebello Forebay is the groundwater recharge intake for the pressure aquifers underlying the Central Basin.

Rio Hondo Coastal Basin Spreading Grounds

On the east side of the Rio Hondo Spreading Grounds, 31 basins have been deepened and combined into 10 basins, increasing conservation storage capacity from 1,600 acre-feet to 4,500 acre-feet. Also, a 1,000 cfs gravity-flow-type intake structure has been constructed to provide a larger inflow to the new basins. A Phase I contract for construction of interbasin structures to handle higher flows for that part of the Rio Hondo Spreading Grounds east side spreading facilities below Washington Boulevard has been completed. A Phase II contract for construction of interbasin structures in the Rio Hondo Spreading Grounds east side upstream of Washington Boulevard started on June 18, 1988.

VOL 12

San Gabriel River

Air-inflatable rubber dams have been installed on stabilizers in the soft-bottom river at Washington Boulevard and upstream of Telegraph Road to provide additional surface storage for water conservation and to eliminate the need to use sand levees which wash out with high river flows.

A contract was begun on June 6, 1988 for the installation of three additional rubber dams in the San Gabriel River: upstream of Slauson Avenue, upstream of Florence Avenue, and upstream of Firestone Boulevard.

West Coast Basin

The West Coast Basin is the second largest basin underlying the Coastal Plain and is separated from the Central Basin by the Newport-Inglewood Fault zone. Groundwater is primarily recharged by Central Basin subsurface flows and by water injected by the Department in the West Coast Basin and Dominguez Gap Barrier Projects. Groundwater elevations in the West Coast Basin are below sea level except in the area of the West Coast Basin Barrier injection mound.

SAN FERNANDO VALLEY

The San Feranando Valley is also called the Upper Los Angeles River Area (ULARA). Most of the runoff from the surrounding mountains flows to the Valley.

San Fernando Main Basin

The basin is the largest basin underlying the San Fernando Valley. During the report period, 23,200 acre-feet of local water spread by the Department recharged this basin. Pacoima Spreading Grounds were improved beginning in 1985 and continuing into this period by combining and excavating 36 basins into 12 basins and replacing the flashboard structures with spillway type structures. Improvements to the intake were also made.

Sylmar Basin

A much smaller basin underlying the San Fernando Valley is the Sylmar Basin; the Department has no spreading facility within this basin.

Verdugo and Eagle Rock Basins

The small Verdugo and Eagle Rock Basins comprise the remaining basins underlying the San Fernando Valley. The Department has no spreading facilities within either basin.

SANTA CLARITA VALLEY

The Department has no spreading facilities in the area. Most of the Valley area is farmland, permitting substantial natural percolation.

The Upper Santa Clarita subunit comprises five basins. The groundwater in storage in this subunit increased considerably after the heavy rains in 1969.

1 9603

VOL 12

ANTELOPE VALLEY

There are several groundwater basins underlying the Antelope Valley, five of them are located within Los Angeles County.

During this report period, the Department recharged over 2,900 acre-feet of local water in its spreading facility in the Big Rock area to groundwater in the Pearland Basin.

The groundwater level in the Lancaster Basin, has declined steadily since 1925 and reached a new historic low during the report period.

LOS ANGELES COUNTY DEPARTMENT OF PUBLIC WORKS
WATER CONSERVATION DIVISION

SUMMARY OF DATA ON SPREADING FACILITIES
NOT OWNED BY THE DISTRICT
UPDATED THROUGH SEPTEMBER [illegible]

GROUNDS	TYPE	SEASON FIRST USED	AREA IN ACRES: GROSS	AREA IN ACRES: WETTED	CAPACITIES*: CHANNEL** (CFS)	CAPACITIES*: INTAKE (CFS)	CAPACITIES*: STORAGE (A.F.)	CAPACITIES*: PERCOLATION (CFS)	LOCATION	SOURCE OF WATER	REMARKS
GROUNDS IN WHICH DISTRICT DOES CONSTRUCTION MAINTENANCE AND DOES OPERATIONS:											
SIERRA MADRE	SHALLOW BASINS	ABOUT [illegible]	[illegible]	[illegible]	-	[illegible]	[illegible]	[illegible]	CITY OF SIERRA MADRE. NORTH SIDE OF [illegible] AVENUE, ONE HALF MILE WEST OF SANTA ANITA AVENUE.	LITTLE SANTA ANITA CREEK AND STREET RUNOFF ONLY PRIOR TO 1951-52. STARTING IN 1951-52 ALSO CONTROLLED FLOWS FROM SANTA ANITA DAM.	NO RECORDS OF WATER SPREAD PRIOR TO 1951-52. [illegible] ULTIMATE CAPACITY ESTIMATED [illegible]. THREE BASINS ADDED IN [illegible]
FISH CREEK	SHALLOW BASINS	ABOUT [illegible]	[illegible]	[illegible]	-	-	-	[illegible]	WESTERLY SIDE OF SAN GABRIEL RIVER BELOW MOUTH OF FISH CANYON AND NORTH OF THE CITY OF AZUSA.	THE "COMMITTEE OF NINE" DIVERTS WATER TO CAL AMERICAN PIPELINE [illegible] DIVERTS FLOW TO FISH CREEK [illegible]	OWNED AND OPERATED BY CAL-AMERICAN WATER COMPANY.
THOMPSON CREEK	DITCHES CHECKS AND DEEP BASINS	ABOUT [illegible]	[illegible]	[illegible]	-	[illegible]	-	[illegible]	[illegible] AND ADJACENT TO THOMPSON CREEK DAM. EAST SIDE OF CREEK.	[illegible], WILLIAMS, PALMER, AND [illegible] CREEKS. ALSO THOMPSON CREEK. [illegible] ELEVATION [illegible].	OPERATED BY POMONA VALLEY PROTECTIVE ASSOCIATION. IN ADDITION TO THE [illegible] ACRES, SOME AREA WITHIN THOMPSON CREEK RESERVOIR IS USED TO SPREAD [illegible]. WATER SPREAD IN AREA SINCE ABOUT [illegible].
SAN ANTONIO	DITCHES CHECKS AND SHALLOW BASINS	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	-	[illegible]	BOTH SIDES OF SAN ANTONIO CREEK FROM TWO AND ONE HALF MILES ABOVE BASE LINE NORTH-WESTERLY TO BASE LINE.	CONTROLLED RELEASES FROM THE SAN ANTONIO FLOOD CONTROL DAM.	OPERATED BY POMONA VALLEY PROTECTIVE ASSOCIATION. WEST SIDE OF CHANNEL [illegible] ACRES. EAST SIDE OF CHANNEL [illegible]. IN ADDITION THERE ARE [illegible] ACRES EAST OF CHANNEL IN SAN BERNARDINO COUNTY. WATER SPREAD IN VICINITY ON AND OFF AS EARLY AS ABOUT [illegible].
TOTALS:			[illegible]	-	-	-	-	[illegible]			
GROUNDS CONTROLLED BY OTHERS. THE DISTRICT COOPERATING:											
[illegible] (CITY OF LOS ANGELES)	SHALLOW BASINS	[illegible]	[illegible]	[illegible]	[illegible]	-	[illegible]	[illegible]	SAN FERNANDO VALLEY, NORTH OF LOS ANGELES RIVER, ABOVE [illegible] STREET.	LOS ANGELES RIVER. PARTIALLY CONTROLLED BY VARIOUS DAMS. RELEASE OF [illegible] VALLEY WATER FROM CHATSWORTH RESERVOIR. GROUNDWATER FROM WELLS IN THE WEST END OF SAN FERNANDO VALLEY.	
L.A.CITY DEPT. OF WATER AND POWER TUJUNGA	SHALLOW BASINS	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	-	[illegible]	SAN FERNANDO VALLEY, EAST SIDE OF TUJUNGA WASH AT [illegible] BOULEVARD.	LOS ANGELES CITY'S OWENS VALLEY AQUEDUCT AND CONTROLLED RELEASES FROM HANSEN DAM.	PRIOR TO [illegible] FLOOD, USED [illegible] ACRES [illegible]. TUJUNGA CHANNEL ON [illegible] SIDE OF GROUNDS PAVED IN [illegible].
CITY OF POMONA	DITCHES CHECKS AND SHALLOW BASINS	[illegible]	[illegible]	[illegible]	[illegible]	-	-	-	NORTH OF CLAREMONT, ONE HALF MILE NORTH OF FOOTHILL BOULEVARD AND ONE-EIGHTH MILE WEST OF MILLS AVENUE.	SAN ANTONIO CREEK WATER DELIVERED THROUGH LOOP [illegible] CANYON WATER COMPANY'S PIPE LINE. ALSO SOME LOCAL RUNOFF.	WATER SPREAD IN VICINITY ON AND OFF SINCE ABOUT [illegible]. GROUNDS ACQUIRED BY CITY OF POMONA, OCTOBER [illegible]. NO RECORDS OF WATER SPREAD PRIOR TO [illegible]. DEEP BASIN COMPLETED IN [illegible].
TOTALS:			[illegible]	[illegible]	-	-	-				

* THE CAPACITIES LISTED ARE BASED ON INFILTRATION RATES WHICH MAY BE EXPECTED TO PERSIST FOR AT LEAST FIVE DAYS BUT ARE NOT VALID FOR SUSTAINED SPREADING OPERATIONS.

** DESIGN CAPACITY OF MAIN CONCRETE CHANNEL.

ABOUT THIS REPORT

The 1988-89 Hydrologic Report represents a significant departure in terms of data content and format from reports published previously by the Department of Public Works and its predecessor, the Los Angeles County Flood Control District. The changes primarily entail the reporting of less detailed hydrologic data than were previously published, such as monthly and annual summaries instead of daily data. We apologize for any inconvenience this may cause our users.

With the rapid development of computing technology, there appears to be less demand for hydrologic data in written form, and it is our intention at some future time to phase out the published book reports and make the data available on computer diskettes. In the meantime, any user who desires more detailed information about any of the types of hydrologic data which we manage can write the Custodian of Hydrologic Records at:

Los Angeles County Department of Public Works
Hydraulic/Water Conservation Division
P.O. Box 1460
Alhambra, CA 91802-1460

or telephone: **(818) 458-6112**

VOL 12

1952

INTRODUCTION

This report contains hydrologic data within Los Angeles County for the period beginning October 1, 1988 and ending September 30, 1989. The data are presented in seven sections.

Precipitation - lists 383 active rainfall stations and presents corresponding seasonal rainfall amounts.

Evaporation - lists all locations for which evaporation data is on file and provides monthly evaporation amounts at 14 locations.

Runoff - presents the maximum, minimum, and mean of the daily flow rates for each month and the monthly volumes for 50 streamflow stations and three Metropolitan Water District outlets.

Dam Operation - presents the maximum and minimum of the daily inflow and outflow rates for each month, the instantaneous peak inflow and outflow rates and storage volumes for 14 dams and reservoirs.

Erosion Control - list debris basins and debris production amounts and displays maps of major watershed burns.

Water Quality Monitoring - presents maps of surface and groundwater sampling locations, and data at selected locations.

Conservation and Groundwater - presents records of water conserved at various facilities, water injected at seawater barrier projects, well hydrographs, and groundwater basins.

Where practical, data which would satisfy immediate needs and serve as useful reference are published in these reports. Several tables appear listing locations where unpublished data are available. Additional information may be obtained by writing to:

VOL 12

LOS ANGELES COUNTY

TOPOGRAPHY

The County of Los Angeles covers an area of 4,083 square miles and measure approximately 66 miles in the east - west and 73 miles in the north - south directions.

The terrain within the County can be classified in broad terms as being 26 percent mountainous, 12 percent coastal plain; and 62 percent hills, valleys, or deserts. Relief of the terrain ranges from sea level to a maximum elevation of 10,000 feet. The coastal plain is generally of mild slope and contains relatively few depressions or natural ponding areas. The slopes of main river systems crossing the coastal plain, such as the San Gabriel River, Los Angeles River, and Ballona Creek, range from 4 to 14 feet per mile.

Topography in the mountainous area is generally rugged with deep, V-shaped canyons separated by sharp dividing ridges. Steepwalled canyons with side slopes of 70 percent or more are common. The gradient of principal canyons in the San Gabriel Mountains ranges from 150 to 850 feet per mile. Mountain ranges are aligned in a general east-west direction, the major range being the San Gabriel Mountains. The majority of mountain ridges lie below Elevation 5,000, the total area above this level being approximately 210 square miles.

GEOLOGY - SOILS

Igneous, sedimentary, and metamorphic rock groups are all represented within the County. The San Gabriel Mountains and Verdugo Hills are composed primarily of highly fractured igneous rock, with large areas of granitic rock formation being exposed above soils which are coarse and porous. Faulting and deep weathering have produced porous zones in the rock formation; however, rock masses have produced a comparatively shallow soil mantle due to the steepness of slopes which accelerates erosion of the fine material.

LAND USE

The principal vegetative cover of upper mountain areas consists of various species of brush and shrubs known as chaparral. Most trees found on mountain slopes are oak, with alder, willow, and sycamore found along streambeds at lower elevations. Pine, cedar, and juniper are found in ravines at higher elevations and along high mountain summits.

The chaparral is extremely flammable, and extensive burns of the mountain vegetation frequently occur during dry, low-humidity weather accompanied by high winds. Chaparral has the ability to sprout following fire and grows rapidly to re-establish the watershed cover within a period of 5 to 10 years.

Grasses are the principal natural vegetation on the hills. Much of the hill land and nearly all of the valley land in the densely populated portion of the County south of the San Gabriel Mountains has been converted to urban and suburban use. Development of the Santa

1953

Clarita Valley and desert areas to the north of the San Gabriel Mountains is sparse at present but is proceeding at an accelerated rate.

Other mountains and hilly reaches within the Department are composed primarily of folded and faulted sedimentary rocks, including shale, sandstone, and conglomerate. Residual soils in these areas are shallow and are generally less pervious than those of the San Gabriel Mountain range.

Valley and desert soils are alluvial and vary from coarse sand and gravel near canyon mouths to silty clay and gravel or clay in lower valleys and the coastal plain. The alluvial fill has been built up by repeated deposition of debris to depths as great as 2,000 feet in places. This fill is quite porous in areas of relatively low clay content. Impervious layers and irregularities in the underlying bedrock divide the alluvium into several County groundwater basins. Valley soils are generally well drained and relatively few perched water or artesian areas are present.

CLIMATE

The climate within the County varies between subtropical on the Pacific Ocean side of the San Gabriel mountain range to arid in the Mojave Desert. Nearly all precipitation occurs during the months of December through March. Precipitation during summer months is infrequent, and rainless periods of several months are common. Snowfall at elevations above 5,000 feet is frequently experienced during the winter storms, but the snow melts rapidly except on higher peaks and the northern slopes. Snow is rarely experienced on the coastal plain.

January and July are the coldest and warmest months of the year, respectively. At Los Angeles, the 30-year average daily minimum temperature for January is 47 degrees above zero. The average daily maximum temperature for July is 83 degree. At Mount Wilson (Elevation 5,850 feet), the 30-year average daily minimum temperature for January is 35 degrees above zero and the average daily maximum temperature for July is 80 degrees.

HYDROMETEOROLOGIC CHARACTERISTICS

Coastal and Mountain Areas

Precipitation in the Los Angeles area occurs primarily in the form of winter orographic rainfall associated with extratropical cyclones of North Pacific origin. Major storms consists of one or more frontal systems and occasionally last four days or longer. Air masses and frontal systems associated with major storms commonly extend for 500 to 1,000 miles in length and produce rainfall simultaneously throughout the County. Major storms approach Southern California from the west or southwest with southerly winds which continue until frontal passage. The mountain ranges lie directly across the path of the inflow of warm, moist air, and orographic effects cause precipitation to be greatly intensified.

The effect of snowmelt upon flood runoff is of significance in the few cases when warm spring rains from southerly storms fall on a snowpack. During major storms, temperatures throughout the County may remain above freezing.

Average individual storm rainfall amounts and intensities conform to a fairly definite aerial pattern which reflects general effects of topographic differences.

Desert Areas

Summer convective rainfall is principally experienced in the upper San Gabriel Mountains and the Mojave Desert regions. In many desert areas, the most serious flooding occurs as a result of summer convective storms.

RUNOFF CHARACTERISTICS

Mountain Areas

In mountain areas, the steep canyon slopes and channel gradients are conducive to rapid concentration of storm runoff quantities. Depression storage and detention storage effects are minor in the rugged terrain. Soil moisture during a storm has a pronounced effect on runoff from the porous soils supporting a good growth of deeprooted vegetation such as chaparral. Soil moisture deficiency is greatest at the beginning of a rainy season, having been depleted by evapotranspiration process during the dry summer months. Precipitation during periods of soil moisture deficiency is nearly entirely absorbed by soils, and except for periods of extremely intense rainfall, significant runoff does not occur until soils are wetted to field moisture capacity. Due to high infiltration rates and porosity of mountain soils, runoff occurs primarily as subsurface flow or interflow rather than as direct runoff. Spring or base flow is essentially limited to portions of the San Gabriel mountain range, most streams in the Department being intermittent.

Runoff from a mountain watershed recently denuded by fire exceeds that for the unburned state due to greatly increased quantities of inorganic debris present in the flow and lowflows from a denuded watershed. Debris production from a major storm has amounted to as much as 223,000 cubic yards per square mile of watershed. Boulders up to eight feet in diameter have been deposited in a valley area a considerable distance from their source.

Debris quantities equal in volume to storm runoff, or in other words 100 percent bulking of runoff from a major storm, have been recorded. Where debris-laden flow traverses an alluvial fill unconfined by flood control works, flood discharges follow an unpredictable path across the debris cone formed at the canyon mouth.

Hill and Valley Areas

In hill areas, runoff concentrates rapidly from the generally steep slopes; however, runoff rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size. In those hill areas which have been developed for residential use,

VOL 12

1955

concentration times become considerably decreased due to drainage improvements, and runoff volumes and rates become increased due to increased imperviousness. On the other hand, erosion is controlled and debris content of storm flow is practically eliminated. Debris production rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size.

In highly developed valley areas, local runoff volumes have increased as the soil surface has become covered by impervious materials. Peak runoff rates for valley areas have also increased due to elimination of natural ponding areas and improved hydraulic efficiency of water carriers such as streets and storm drain systems.

VOL 12

1956

FLOOD CONTROL AND WATER CONSERVATION

FLOODS. . AN OLD STORY

Floods in Los Angeles County have been recorded as far back as the days of the Mission Padres. For centuries waters have swept out of the San Gabriel Mountains causing extensive property damage and taking a great toll of lives.

Such a flood occurred in 1914 causing over $10 million in property damage and taking many lives. As a result, the State legislature passed an act creating the Los Angeles County Flood Control District.

The Department was assigned two tasks. . .control the floods and conserve the water.

CONTROLLING THE WATERS

Successful early bond issues financed construction of the 14 dams which the Department built in the San Gabriel Mountains and foothills to impound storm waters until they could be released in an orderly fashion. Debris basins were constructed to trap eroded materials which had caused terrible damage in the past. Flood channel improvements were undertaken to confine the waters.

Department engineers prepared a Comprehensive Plan in the early 1930's which provided for the control of flooding and the saving of as much of the water as practicable.

Federal legislation in 1936 brought the United States Army Corps of Engineers into the local flood control picture. Since that time, the two agencies have been jointly persuing construction of the Comprehensive Plan. The Department also cooperates with the United States Soil Conservation Service and Forestry Service in erosion control.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water conservation facilities in or adjacent to river channels and their tributaries permits water to be percolated into ground reservoirs for later pumping and supply to consumers. These water conservation facilities are located in areas where the underlying soils are composed of porous sands and gravel formations. Some resemble rice paddies, while others are deep basins which were once gravel pits.

The importance of this activity is apparent when it is realized that about 35 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, seriously depleted these supplies on numerous occasions down through the years.

Other major conservation efforts by the Department include combatting the serious intrusion by salt water to underground fresh well supplies inland from the Pacific Ocean and the utilization of imported water and reclaimed sewage waters in spreading operations.

ORGANIZED TO DO THE JOB

Day-to-day administration of Department affairs is vested in the Director of Public Works who is appointed by and responsible to the Los Angeles County Board of Supervisors. A part of the Department's activities involve the construction of flood control and water conservation facilities, and the operation and maintenance of dams, debris basins, spreading grounds, channels, and storm drains.

PRECIPITATION

R0052964

PRECIPITATION

This section contains annual precipitation data collected by the Department for the period beginning October 1, 1988 and ending September 30, 1989. Although the Department operates and maintains 358 rainfall stations, including standard and automatic gages which record amounts for durations ranging from 15 minutes to 24 hours, only annual amounts for the report period are listed herein. Additional data can be obtained by contacting the custodian of hydrologic records at the location shown in the front of the report.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meterological conditions in the County and Southern California in real time, i.e., as they occur. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels. The system can forecast peak flows in the Los Angeles, Rio Hondo, and San Gabriel Rivers.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The cooperation of observers in furnishing rainfall data to the Department as a public service is appreciated. The effort of the many agencies and indi viduals who have so freely cooperated with us in the collection of this data have resulted in the large number of complete records for the period covered by this report.

EVAPORATION

VOL 12

EVAPORATION

Data for 14 active evaporation stations were reported to the Department during the 1988-89 water year. Daily records of active and inactive Department stations, as well as some stations of other agencies, are available in the Department's files. Monthly and seasonal evaporation has been published in the Department's Annual or Biennial Reports on Hydrologic Data since the 1931-32 season.

COOPERATION

The Department receives evaporation data from The Metropolitan Water District, Palmdale Water District, California Department of Water Resources, and Descanso Gardens.

LENGTH OF RECORD

The first land pan installed by this Department was at Santa Anita Dam in March of 1929. There are 30 evaporation stations which have records of 15 seasons or more in the Department's files.

RUNOFF

R0052985

RUNOFF

The Department operated or received data from 81 water-stage recording stations during the 1988-89 water year. Data from 51 of those stations are summarized and published in this volume.

RECORDS OF STREAMFLOW

Records published give the following information:

1. Station description which presents location, drainage area, type of channel, control, regulations, diversions, and available records.

2. Discharge tabulation which summarizes the maximum, minimum, and mean of the daily flow rates in second-feet for each month and the total monthly volumes in acre-feet.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions at 27 locations in the County. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels, and which forecast peak flows in the Los Angeles and San Gabriel Rivers and the Rio Hondo Channel.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The Department receives streamflow data from other agencies, or has access to the records for local stations. Department hydrographers also make periodic streamflow measurements and observations at installations belonging to these organizations. Data from 25 of the Department's stations are reviewed and published in the Geological Survey's annual water supply papers.

Agencies with which the Department exchanges data are:

United States Geological Survey, Water Resources Division
United States Corps of Engineers
State Department of Water Resources
The Metropolitan Water District
San Gabriel River Water Committee

LEGEND

Stations are designated by letters and numbers which indicate ownership, operation agency, and type of station. The letters used have the following connotations:

Prefix F - Indicates a station owned and operated by the Los Angeles County Department of Public Works.

Prefix E - Indicates a station owned and operated by the Corps of Engineers, Department of the Army but operated and maintained by the United States Geological Survey.

Prefix U - Indicates a station originally constructed and operated by the United States Geological Survey, Water Resources Division, now operated by the Department.

Prefix P - Indicates a station owned and operated by the Department formerly, operated by the Pasadena Water Department.

Prefix L - Indicates a station owned and operated by the Department formerly, operated in cooperation with the Little Rock - Palmdale Irrigation District.

Suffix R - Indicates a recorder station.

Suffix B - Indicates that the station has been moved. B represents second location, C a third location, etc.

BOUQUET CANYON CREEK
at Urbandale Avenue
STATION NO. F377-R

RECORDER- continuous water stage.
METHOD OF MEASUREMENTS- wading or from bridge.
DRAINAGE AREA- 51.9 square miles.
LOCATION- Bouquet Canyon Creek at Urbandale Avenue, 3.5 miles northeast of Saugus.
REGULATION- Bouquet Reservoir.
CHANNEL- concrete sides with natural bottom, trapezoidal in section.
CONTROL- concrete stabilizer.
LENGTH OF RECORD- October 11, 1967 to date.

DOMINGUEZ CHANNEL
at Vermont Avenue
STATION NO. F378-R

RECORDER- continuous water stage.
METHOD OF MEASUREMENTS-low flows measured by wading. High flows measured from Vermont Avenue bridge.
DRAINAGE AREA- 37.1 square miles.
LOCATION- on the south bank, 93 feet above Vermont Avenue, about one mile south of Gardena.
REGULATION- none
CHANNEL- rectangular concrete with trapezoidal low flow channel at center.
LENGTH OF RECORD- November 23, 1966 to date.
REMARKS- gage is affected by tides greater than 4.0 feet above mean lower low water.

WATER YEAR : 1988 - 89

RESERVOIRS

RESERVOIRS

Following the damaging flood of 1914 and creation of the Los Angeles County Flood Control District in 1915, it initiated a program of flood control and water conservation including the construction of 14 dams. These dams were operated by the Department during the period covered by this report. In addition, five Corps of Engineers' dams and Morris Dam owned by The Metropolitan Water District were utilized to achieve flood control and water conservation. The Corps of Engineers' dams are: Hansen Dam on Tujunga Wash, Sepulveda Dam on the Los Angeles River, Santa Fe Dam on the San Gabriel River, Whittier Narrows Dam serving both the Rio Hondo and San Gabriel River, and San Antonio Dam on San Antonio Creek.

OPERATION

The reservoirs are operated to control flood waters during storm periods. Post storm releases are made, when feasible, in amounts which can be conserved in downstream spreading grounds and by channel percolation.

SAN GABRIEL DAM HYDROELECTRIC PLANT

In December 1987, construction of two hydroelectric generator units at San Gabriel Dam was completed by San Gabriel Hydroelectric Partnership, a joint venture between private investors and the County of Los Angeles. The generator units are operated by Department personnel and the power generated is purchased by Southern California Edison Company. During the report period, over four and one-half million kilowatt-hours of energy have been generated resulting in revenues of over $330,000. Recently an optimization computer was installed on Unit 1 to schedule power production during hours of peak energy demand.

RECORDS

The storage and flow records at the 14 Department reservoirs are summarized on the Dam Operation Record Sheets. The sheets show:

1. Reservoir water surface elevations based on the spillway datum. Elevations are obtained from water stage recorder graphs or interpolation from staff gage readings and recorded as of midnight of each day. Only maximum and minimum water surface elevations for each year are shown.

2. Storage in acre-feet based on the most recent topographic surveys. Annual storage volumes are shown.

3. Inflow in cubic feet per second. This is usually calculated from storage change and known outflow. When outflow is not known, the inflow may be determined from gaging station records or interpolated between measurements. Only the maximum and minimum of the daily flow rates for the year and the instantaneous peak flow rate are shown.

VOL 12

1939

4. Outflow in cubic feet per second. These values are determined from gaging station records, known valve openings and rating curves, or from storage change and known inflow. Only the maximum and minimum of the daily outflow rates for the year and the instantaneous peak outflow rate are shown.

5. Discrepancies between outflow and storage losses at certain dams are attributable to percolation and/or evaporation losses. Total monthly evaporation losses are determined from the measurements made on floating or land evaporation pans. In those cases where no allowances were made for evaporation, the amounts are necessarily included in the flow values. Accuracy of the flow records computed from storage records is dependent on the frequency with which storage data are revised to keep in step with the physical change in reservoirs.

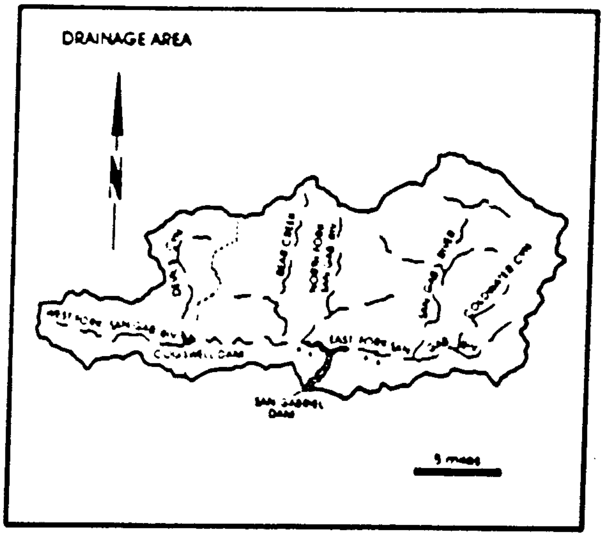
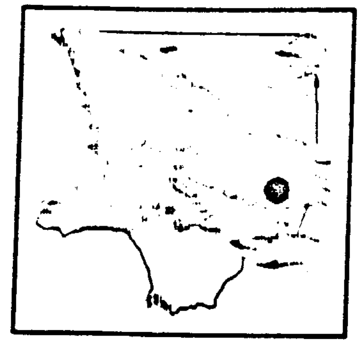
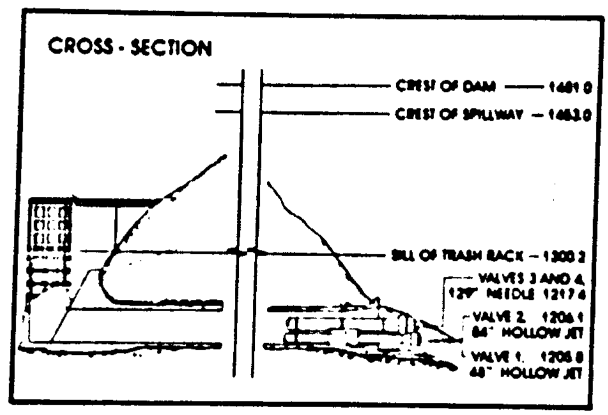
SAN GABRIEL DAM
AND RESERVOIR







PURPOSE - Flood Control and Conservation.
DATE CONSTRUCTED - Started December 1932. Completed July 1939.
LOCATION - San Gabriel Canyon, 7.5 miles north of Azusa.
DRAINAGE AREA - 163.5 square miles (uncontrolled)
39.2 square miles (controlled)
Total 202.7 square miles
(includes Cogswell drainage)
CAPACITY - 41,549 acre - feet.
SPILLWAY ELEVATION - 1,453 feet.

DAM OPERATION RECORD SUMMARY

EROSION CONTROL

EROSION CONTROL

Each year eroded material in various forms (trees, rock, sand, etc.) flows out of the mountain watersheds of Los Angeles County. In an effort to control this potentially disruptive force, the Department maintains a series of debris basins in canyon mouths and upstream stabilization structures in selected watersheds.

PURPOSE

The purpose of a debris basin is to entrap the debris flows emanating from the canyon and let the relatively desilted water pass into flood control channels.

From 1988 to 1989, the number of debris basins was changed from 131 to 114 by downgrading 20 to inlets, then adding 3 new basins. This gives a total capacity of 7,561,600 cubic yards.

Records of sediment inflow at individual debris basins and amounts excavated and removed are available in the Hydraulic/Water Conservation Division.

STABILIZATION STRUCTURES

Stabilization structures are constructed to control erosion in natural canyons. They serve to prevent downcutting by stabilizing alluvium deposits. In addition, they store debris generated by the watershed and serve to stabilize side banks, reducing side slope sloughing and bank erosion.

The Department maintains 225 stabilization structures in 47 major watersheds. No structures have been constructed since the 1973-74 water year.

EMERGENCY STRUCTURES

Emergency structures (rail and timber, and crib type) have been constructed to entrap the debris inflow from burned watersheds. They serve to protect improvements (road, channel, residence, etc.) located immediately downstream of the watersheds. Currently, 39 emergency structures exist with a total maximum capacity of 349,500 cubic yards. Five major fires, (those over 500 acres), burned 11,380 acres in this water year and are shown on page PE2. Emergency structures were built below one of these fires.

SEDIMENT REMOVAL FROM RESERVOIRS

Sediment deposition in reservoirs reduces the storage capacities and adversely affects flood control and water conservation efforts. Sediment removal is periodically necessary and is generally an expensive effort due to large quantities, the need to deal with water inflows, and in several cases, remote locations and limited accessibility for equipment.

Where practical, the Department encourages sediment removal by permittees at no cost to the Department such as at Eaton Wash and Devil's Gate Dams.

The Department presently is studying the feasibility of various methods for the removal and long-term management of sediment in the three reservoirs in San Gabriel Canyon. These three currently contain about 36 million cubic yards - about three-quarters of the cumulative volume of sediment currently behind all dams under the Department's control.

DEBRIS BASIN - DESIGN DATA

Including 1988-1989 Season

Compiled by: Hydraulic and Water Conservation Division - Sedimentation Section
Date: October 1,1989

DATA SHEET A

(1) LOWEST CLEAR WATER OUTLET, NOT SPILLWAY.
(2) ELEVATION OF SPILLWAY NOTCH.
(3) FLOW LINE OF SLUICEWAY.
(4) ELEVATION OF SPILLWAY INTO OUTLET CHANNEL. ELEVATION OF OVERFLOW SPILLWAY 1030.0 FEET.
(5) ONE 30-INCH REINFORCED CONCRETE PIPE.
(6) FOUR 36-INCH CORRUGATED METAL PIPES.
(7) ONE 36-INCH REINFORCED CONCRETE PIPE.
(8) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.
(9) PIT-TYPE BASIN.
(10) INFORMATION UNAVAILABLE.
(11) MAXIMUM CAPACITY MAY BE LESS THAN SHOWN AND IS BEING REVIEWED. FIELD INSPECTION SUGGESTS BASIN IS NEAR ITS FULLEST POSSIBLE CAPACITY.
(12) SPECIAL CLEANOUT REQUIRED DUE TO LIMITED STORAGE.
(13) TRANSFERRED FOR MAINTENANCE AFTER THE 87-88 STORM SEASON. FIRST DEBRIS SEASON WILL BE 88-89.
(14) CLEANOUT WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1128.9 AGAINST FACE OF DAM.
(15) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN.
(16) VALUES ARE BASED ON RECENTLY APPROVED CUTPLANS.

114 DEBRIS BASINS

VOL 12

DEBRIS BASIN-DEBRIS PRODUCTION HISTORY

Including 1988-1989

DATA SHEET D

Compiled by: Hydraulic and Water Conservat
Division - Sedimentation Sect
Date: October 1,1989

(1) VOLUME OF DEBRIS DEPOSITED IN BASINS DOES NOT INCLUDE DEBRIS SLUICED THROUGH OPEN PORTS OR NOTCH.
(2) VOLUME OF DEBRIS DEPOSITED DOES NOT INCLUDE DEBRIS WHICH PASSED OVER SPILLWAY DURING THE STORMS IN 1968-69 SEASON.
(3) INCLUDING DEBRIS FROM UPSTREAM BASIN OR DAM.
(4) VOLUME OF DEBRIS DEPOSITED DOES NOT INCLUDE DEBRIS WHICH PASSED OVER SPILLWAY DURING THE STORMS IN 1977-78 SEASON.
(5) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.
(6) NO SIGNIFICANT DEBRIS INFLOWS RECORDED.
(7) NO RECORDS OF DEBRIS DEPOSITION EXIST FOR THE FIRST 9 SEASONS.
(8) INFORMATION UNAVAILABLE.
(9) MAXIMUM CAPACITY MAY BE MORE THAN SHOWN AND IS BEING REVIEWED.
(10) SPECIAL CLEANOUT REQUIRED DUE TO LIMITED STORAGE.
(11) TRANSFERRED FOR MAINTENANCE AFTER 87-88 STORM SEASON. FIRST DEBRIS SEASON WILL BE 88-89.
(12) CLEANOUT WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1128.9 AGAINST FACE OF DAM.
(13) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN.
(14) TO BE CLEANED.

WATER QUALITY

VOL 12

1987

WATER QUALITY

Since its conception, the Flood Control District (now Department of Public Works) has actively engaged in operations which have proven indispensable in preserving the integrity of our water resources, both quantity and quality, and has aided in the establishment of regulations or controlling criteria by those agencies so empowered.

Prior to March 1986, monitoring activities in the field of water quality control were conducted by the Water Quality Section of Hydraulic/Water Conservation Division. In March 1986, the responsibilities of conducting such activities were transferred to Waste Management Division as a result of the consolidation. These activities include, among others, the collection of water quality samples, their analyses, and the interpretation and reporting of the resulting data.

Areas of involvement include the monitoring of all groundwater basins through the sampling of numerous wells, the monitoring of storm and low water flows at various strategic locations on the major streams or channels, and an assumed or obligated responsibility to monitor the quality effects and subsurface travel of recharge areas, specifically the Whittier Narrows Spreading Grounds area.

The Water Quality Section, together with personnel of other Departmental divisions, also conducts investigations into pollution problems relative to our facilities, particularly those from industrial discharges, vehicle accidents, ruptured pipelines, or the indiscriminate dumping of various waste products.

The principal objectives of these investigations are to determine the degree and apparent source or origin of the pollution and to take the necessary action that will immediately abate the existing problem and possibly provide a means to prevent or limit recurrence.

The above-mentioned activities of the Water Quality Section have recently been intensified, particularly in the areas of interfacing with other counties, cities, environmental organizations, as well as Federal and State agencies, in response to and in voicing the Department's concerns over the proposed require ments of the 1987 Amendments to the Federal Clean Water Act. It is anticipated that the Act will be implemented by the United States Environmental Protection Agency (EPA) with final regulations during the second half of 1990. The said Amendments require National Pollutant Discharge Elimination System (NPDES) permits on discharges of municipal storm sewers into the waters of the United States. Although the NPDES permit requirements are still being developed by the EPA, the final requirements are expected to require a more thorough water quality monitoring within the storm drain system; adoption by municipalities/cities of ordinances prohibiting illegal storm drain hook-ups; and responding to and containing spills of hazardous materials in the storm drains. These Amendments recognize that land drainage flows are the last major discharges currently unregulated.

VOL 12

SURFACE WATER QUALITY

Prior to 1984, dry weather samples were collected from 30 sampling stations on a monthly basis for analysis such as general minerals, bacteria, pesticides, and heavy metals. In addition, storm samples were also collected and analyzed at least three times annually from the same 30 stations during storm season.

From 1984 to 1987, as a result of reorganization, the number of surface water monitoring stations was reduced to 21, while the parameters analyzed were reduced to include only total dissolved solids, pH, and dissolved oxygen. Storm sampling activities were also significantly curtailed.

In 1988, recognizing the inadequacy of the then existing monitoring program to meet the Department's need in dealing with all the important issues in the areas of water quality, the Department Administration approved and implemented an expanded monitoring program effective May 1, 1988.

There are 28 monitoring stations in the Department's current Surface Water Quality Monitoring Program, from which dry weather samples are collected and analyzed on a monthly basis. These sampling stations are strategically located throughout the Department's major storm drains and water conservation facilities where the flows are representative of typical land uses as well as areas of significant water quality concerns. Of the 28 monitoring stations in the program, six are located at the outlets to Santa Monica Bay, while on is located in the mountain area where the flow is considered to be natural and uncontaminated with the various pollutants associated with urbanization and developed land uses.

Monthly dry weather samples, thus collected, are analyzed for general minerals, (pH, specific conductance, total dissolved solids, total hardness, potassium sulfate, calcium, magnesium, chloride, fluoride, nitrate-nitrogen, nitrite- nitrogen, ammonium-nitrogen, phosphate-P, boron, iron, and manganese) bacteria, pesticides, heavy metals (silver arsenic, barium, cadmium, chromium, mercury, lead, selenium, copper, nickel, zinc, and chromium [VI]), oil and grease, total organic carbon, total petroleum hydrocarbons, PCB's, biochemical oxygen demand, and volatile organic compounds (TCE, carbon tetrachloride, vinyl chloride, 1,2 dichlorethene, benzene, 1,1 dichloroethylene, 1,1,1 trichloroethane, p-dichlo robenzene). In addition, storm samples are collected for three to four storms annually from 21 stations, including San Gabriel Coastal and Rio Hondo Spreading Grounds for extensive analysis similar to those for dry weather samples, with additional testing of total suspended solids and volatile suspended solids to be included. For storm samples collected at San Gabriel Coastal and Rio Hondo Spreading Grounds, priority pollutant constituents are also analyzed under an agreement with the Central and West Basin Water Replenishment District.

1988

A selective list of total dissolved solids is shown for some of the sampling locations on the streams and channels monitored under the Surface Water Quality Program. For a conception of the analysis performed on surface flows, a yearly compilation of constituent determination is shown for one (Los Angeles River at Wardlow) of the sampling stations in the program.

GROUNDWATER QUALITY

The annual sampling of water wells, under a selected scheduling, in five major basins in Los Angeles County comprise the Groundwater Quality Program. The program, initiated in 1970, is coordinated with the State of California Department of Water Resources and the City of Los Angeles Department of Water and Power. These agencies participate in the obtainment and analysis of samples.

All the water wells samples are active production wells used either for municipal supply, irrigation, or for industrial purposes and are selected to represent a general portrayal of basin water quality conditions. The samples taken under this program are analyzed for major mineral, total dissolved solids, electrical conductivity, pH, and in specific cases, phosphate, iron, manganese, fluoride, or boron.

WATER QUALITY DATA ACCESSIBILITY

Data acquired from the various programs are on file in the Water Quality Section. In addition, all data is accessible to any user through STORET, an Environmental Protection Agency computer system that stores, retrieves, and manipulates data using agency code 21CALAFD.

WATER CONSERVATION

VOL 12

1980

WATER CONSERVATION

Information presented in this section includes amounts of local, imported, and reclaimed water conserved in spreading areas, information on the seawater barrier projects which prevent saltwater intrusion to groundwater zones in the coastal areas. Pertinent data are presented regarding the locations and descriptions of Department water conservation facilities, as well as facilities owned by others. Also included are groundwater maps delineating static groundwater elevations recorded during the report period and hydrographs of selected key wells.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water conservation facilities adjacent to river channels, and in soft-bottom channels permits water to percolate into groundwater reservoirs for later pumping. These water spreading facilities are located in areas where the underlying soils are composed of pervious formations.

The various types of water conserved, local, imported, and reclaimed, are construed to have the following meanings in this section: Local water is primarily runoff due to rainfall on the mountain and valley watersheds, dam releases, and rising water within the County. Imported water is water originating outside the County either from Northern California or from the Colorado River, commonly blended from both sources which is transported to and delivered within the County. Reclaimed water is the effluent produced by the Whittier Narrows Water Reclamation Plant, the San Jose Creek Water Reclamation Plant, and the Pomona Reclamation Plant, all operated by the Los Angeles County Sanitation Districts.

The importance of this activity is apparent when it is realized that about 35 to 45 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, seriously depleted these supplies on numerous occasions down through the years.

The Department's policy is to conserve the maximum amount of storm water possible consistent with considering runoff quantity and quality, capacities of the spreading facilities, and groundwater conditions.

SPREADING GROUNDS

The total gross area of spreading grounds owned and operated by the Department during this report period amounted to 2,369 acres. The Department also assisted in the operation and maintenance of 679 acres of spreading grounds owned by others. An additional 246 acres of spreading grounds are controlled, maintained, and operated by other agencies. The total gross acreage of spreading grounds in the County is 3,294 acres.

VOL 12

IMPORTED WATER

During this report period, imported Colorado River and State Project water for spreading was obtained from the Metropolitan Water District. Also imported State Project Water for spreading was obtained from the San Gabriel Valley Municipal Water District. Imported water for groundwater recharge in the Coastal Plain was spread in the Department's facilities in the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds and San Gabriel River systems south of Whittier Narrows Dam on behalf of the Central and West Basin Water Replenishment District. Imported water for groundwater recharge in the San Gabriel Valley was spread in Santa Fe Spreading Grounds, in the San Gabriel River between Morris Dam and the spreading grounds, in Irwindale Spreading Basin and in Forbes Spreading Grounds on behalf of MWD, the Main San Gabriel Basin Watermaster, and the San Gabriel Valley Municipal Water District.

RECLAIMED WATER

The County Sanitation Districts' Whittier Narrows Water Reclamation Plant effluent, purchased by the Central and West Basin Water Replenishment District, was transported to the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds and San Gabriel River System for groundwater replenishment.

The County Sanitation Districts' San Jose Creek Water Reclamation Plant, activated in May 1972, made its first delivery of effluent in November 1972. The portion of the effluent that is spread is also purchased by the Central and West Basin Water Replenishment District.

The maximum amount of reclaimed water allowed for spreading annually in the Montebello Forebay was increased from 32,700 acre-feet to 37,700 acre-feet in the 1986-87 water year, to 42,700 acre-feet in July 1988, and to 50,000 acre-feet effective July 1989.

1 9 8 1

SEAWATER BARRIER PROJECTS

The Department operates three barrier projects to protect the groundwater in the West Coast and Central Basins against seawater intrusion by creating freshwater pressure ridges along the coastline. The pressure ridges are created by injecting fresh water through a series of injection wells. During the report period, 22,735 acre-feet of water were injected at the West Coast Basin Barrier Project, 5,223 acre-feet at the Dominguez Gap Barrier Project, and 3,901 acre-feet at the Los Angeles part of the Alamitos Barrier Project. On behalf of the Orange County Water District, 1,675 acre-feet of water were injected at the Orange County portion of the Alamitos Barrier Project.

SEASONAL DATA AND MAPS

During this report period, monthly and semi-annual measurements of groundwater levels in observation wells located throughout the groundwater basins in Los Angeles County were made and processed.

VOL 12

Hydrographs of selected key wells are included in this report.

GROUNDWATER BASINS AND GROUNDWATER RECHARGE

Groundwater in Los Angeles County is stored in basins underlying five major geographic areas. These groundwater basins are separated by geologic features which impede groundwater movement or sometimes by arbitrary political boundaries. Following is a background and summary of the Department's groundwater recharge activities within each of these areas.

The Department operates 2,369 acres of spreading grounds and basins and soft-bottom channel spreading areas for replenishment of local aquifers to increase water supplies. During the report period, the Department conserved more than 59,900 acre-feet of storm runoff.

The conservation of local runoff is supplemented by spreading imported water and reclaimed water purchased by water agencies. During the period, 107,442 acre-feet of imported water and 52,374 acre-feet of reclaimed water were spread.

The Department is continuing its efforts to improve its water spreading facilities in order to maximize the amounts of water conserved and to simplify the spreading operations.

SAN GABRIEL VALLEY

The Department operates 20 spreading grounds in the San Gabriel Valley to receive direct valley runoff and flows from the San Gabriel Mountains, some can also receive imported water. During the report period, the Department added approximately 29,870 acre-feet of local water and 61,440 acre-feet of imported water to the groundwater stored in the basins underlying the San Gabriel Valley.

The following construction projects were performed in San Gabriel Valley during the report period:

1. Forbes Spreading Grounds:

The existing basins were deepened and the flashboard structures were replaced with concrete spillways. A new intake was constructed to deliver 100 cfs.

2. Citrus Spreading Grounds:

The existing basins were combined into two basins. A new intake system was constructed to deliver 200 cfs and the existing intake capacity was increased from 25 to 85 cfs.

A contract was awarded to construct the "Granado Drain" to direct excess Covina Irrigation Company water to Big Dalton Wash for spreading in Citrus Spreading Grounds.

1982

3. Santa Fe Spreading Grounds:

The existing 23 west basins were combined into four basins averaging 7.5 feet deep. Six flashboard structures and 14,500 linear feet of levee were eliminated resulting in the removal of 800,000 cubic yards of soil. The storage capacity was increased by 577 acre-feet.

4. San Gabriel Canyon Spreading Grounds:

The Department constructed a 250 cfs intake from the river to basin 2.

5. Irwindale Spreading Basin:

The Department acquired the adjacent Manning Pit and is evaluating its long-term filling and an overflow connection from Irwindale Basin.

6. Eaton Wash Spreading Grounds and Eaton Basin:

A contract was awarded to install motor operators on the intake gates at Eaton Wash Spreading Grounds (Raymond Basin) and to install new gates with electric motor operators at Eaton Basin (Main San Gabriel Basin).

Main San Gabriel Basin

This is the largest basin underlying the San Gabriel Valley with an estimated storage capacity of 9.5 million acre-feet. It reacts quickly to artificial spreading in Santa Fe Reservoir Spreading Grounds and to infiltration in the San Gabriel River downstream of Santa Fe Dam.

During the report period, the Department replenished the Main San Gabriel Basin with 16,610 acre-feet of local water and 38,700 acre-feet of imported water.

Upper San Gabriel Canyon Basin

Approximately 6,175 acre-feet of local water and approximately 21,440 acre-feet of imported water were recharged by the Department through its San Gabriel Canyon Spreading Grounds and by percolation in the adjacent San Gabriel River. Also, 5,375 acre-feet of water were routed to Fish Canyon Spreading Grounds which is operated by the Committee of Nine.

Lower Canyon Basin

The basin is located south of the Upper San Gabriel Canyon Basin and is separated from it by the underground Lohmon Dike. Groundwater cascades over the Lohmon Dike from the Upper San Gabriel Canyon Basin and recharges the Lower San Gabriel Canyon Basin. The Department spread 605 acre-feet of local water in Sawpit Spreading Grounds which is within the Lower Canyon Basin.

VOL 12 1984

Wayhill Basin

The Department spread 30 acre-feet of local water and 1,300 acre-feet of imported water in the wayhill basin.

Foothill Basin

The Department spread 690 acre-feet of local water at its San Dimas Canyon Spreading Grounds facility in the Foothill Basin.

Glendora Basin

The Department spread 345 acre-feet of local water in its Dalton facilities within the Glendora Basin.

Claremont Heights Basin

Approximately 10 acre-feet of local water were diverted to the Pomona Valley Protective Association's Thompson Creek Spreading Grounds which benefits the groundwater in the Claremont Heights Basin.

Live Oak Basin

The Department has no spreading facilities in the Live Oak Basin.

Chino Basin

The basin is located in the most eastern part of the County. No Department recharge facilities are located within the Chino Basin.

San Dimas Basin

The basin is north of the San Jose Hills, east of the Main Basin, and south of the Wayhill Basin. The Department spread 30 acre-feet of local water in its Live Oak Spreading Grounds to recharge the basin.

Pomona Basin

The basin is located south of claremont, Live Oak, and San Dimas Basins, and north of the Chino Basin and northeast of the San Jose Hills. The Department has no water spreading facilities within this basin.

Puente, Sapdra, and Walnut Basins

No spreading occurs in this area.

VOL 12

Raymond Basin

The basin covering approximately 40 square miles is located in the northwest corner of the San Gabriel Valley and is separated from the Main San Gabriel Basin by the Raymond Fault. The Raymond Basin contains the Monk Hill Basin and the Pasadena and Santa Anita Subareas. The Department recharged 1,060 acre-feet of local water by its spreading facilities in the Raymond Basin and diverted 1,200 acre-feet to the City of Sierra Madre's spreading facility during the report period.

COASTAL PLAIN

The groundwater basins underlying the Coastal Plain are divided by geological features into the Central (includes the Montebello and Los Angeles Forebays), West Coast, Santa Monica, and Hollywood Basins. During the period October 1, 1988 to September 30, 1989, the Department recharged 15,500 acre-feet of local water, 46,000 acre-feet of imported water, 52,375 acre-feet of reclaimed water to the groundwater basins underlying the Coastal Plain. Most of the water was spread in the Montebello Forebay.

During the report period, the first phase of the Groundwater Recharge Telemetry System (GRTS I) was being installed. GRTS I will provide computerized remote monitoring of flows in Montebello Forebay tributary to our Rio Hondo and San Gabriel Coastal Basin Spreading Grounds, and remote monitoring and control of San Gabriel Coastal Basin Spreading Grounds operations. Central computer stations will be located at the Rio Hondo Headworks and our Fremont headquarters Operation Center. The system will be used in conjunction with our ALERT (Automatic Local Evaluation in Real Time) System.

The next phase for GRTS II will provide remote control for the Rio Hondo Spreading Grounds and the five rubber dams in the San Gabriel River.

Central Basin

The Central Basin has the most storage capacity of the basins in the Coastal Plain. In addition to the water recharged in the Department's spreading facilities, water injected in the Alamitos Barrier Project also contributes to the replenishment of the pressure aquifers underlying the Central Basin.

Rio Hondo System

A. Rio Hondo Coastal Basin Spreading Grounds

1. Extensive modification of the east side grounds combined 31 basins into 10 large basins, added 2,900 acre-feet of storage capacity making the total storage 4,500 acre-feet.

2. A 1,000 cfs gravity flow type intake structure was installed.

1985

R0053120

3. Approximately 4.5 miles of levees were removed and 350,000 square feet of roadways were paved.

4. One thousand eight hundred flashboards were eliminated.

B. Whittier Narrows Dam - Rio Hondo Side

A concept plan was devised to increase the conservation pool from 2,500 acre-feet to 3,700 acre-feet. This enlargement plan is presently under negotiation with the U.S. Army Corps of Engineers.

San Gabriel System

A. San Gabriel Coastal Basin Spreading Grounds

1. The existing basins were combined into four large basins adding 300 acre-feet of storage.

2. A structure was installed in the intake canal to divert flows into basin 1, in order to increase the intake capacity.

B. San Gabriel River

1. The Department has completed the installation of five air inflated rubber dams each 200 feet long, six to seven feet high on the stabilizers in the soft bottom river from Washington Boulevard to Florence Avenue, adding 500 acre-feet of storage.

2. The Department had a contract to extend the storm drain (Choiser Drain) outlet to downstream of the rubber dam in the San Gabriel River in Washington Boulevard to prevent backflow in the drain due to the potential for water levels in back of the dam.

West Coast Basin

The West Coast Basin is the second largest basin underlying the Coastal Plain and is separated from the Central Basin by the Newport-Inglewood Fault zone. Groundwater is primarily recharged by Central Basin subsurface flows and by water injected by the Department in the West Coast Basin and Dominguez Gap Barrier Projects. Groundwater elevations in the West Coast Basin are below sea level except in the area of the West Coast Basin Barrier injection mound.

Dominguez Spreading Grounds

Approximately 25,000 cubic yard of silt were removed from the west side basin of Dominguez Spreading Grounds.

VOL 12

1987

SAN FERNANDO VALLEY

The San Fernando Valley is also called the Upper Los Angeles River Area (ULARA). Most of the runoff from the surrounding mountains flows to the Valley.

Pacoima Spreading Grounds

The 36 existing basins were combined and excavated into 12 basins and a portion of the interbasin hydraulic system was constructed. This modification added 200 acre-feet of storage capacity.

San Fernando Main Basin

The basin is the largest basin underlying the San Fernando Valley. During the report period, 11,100 acre-feet of local water spread by the Department recharged this basin.

Sylmar Basin

A much smaller basin underlying the San Fernando Valley is the Sylmar Basin; the Department has no spreading facility within this basin.

Verdugo and Eagle Rock Basins

The small Verdugo and Eagle Rock Basins comprise the remaining basins underlying the San Fernando Valley. The Department has no spreading facilities within either basin.

SANTA CLARITA VALLEY

The Department has no spreading facilities in the area. Most of the Valley are is farmland, permitting substantial natural percolation.

The Upper Santa Clarita subunit comprises five basins.

ANTELOPE VALLEY

There are several groundwater basins underlying the Antelope Valley, five of them are located within Los Angeles County.

During this report period, the Department recharged over 1,100 acre-feet of local water in its spreading facility in the Big Rock area to groundwater in the Pearland Basin.

The groundwater level in the Lancaster Basin, has declined steadily since 1925 and reached a new historic low during the report period.

INTRODUCTION

This report contains hydrologic data relative to Los Angeles County for the period beginning October 1, 1990 and ending September 30, 1991. The data are presented in seven sections.

Precipitation - lists 294 active rainfall stations and presents corresponding seasonal rainfall amounts.

Evaporation - lists all locations for which evaporation data is on file and provides monthly evaporation amounts at 14 locations.

Runoff - presents the maximum, minimum, and mean of the daily flow rates for each month and the monthly volumes for 48 streamflow stations.

Dam Operation - presents the maximum and minimum of the daily inflow and outflow rates for each month, the instantaneous peak inflow and outflow rates and storage volumes for 14 dams and reservoirs.

Erosion Control - lists debris basins and debris production amounts.

Water Quality Monitoring - presents maps of surface and groundwater sampling locations, and data at selected locations.

Conservation and Groundwater - presents records of water conserved at various facilities, water injected at seawater barrier projects, well hydrographs, and static groundwater contour maps.

Where practical, data which would satisfy immediate needs and serve as useful reference are published in these reports. Several tables appear listing locations for which unpublished data are available. Additional information may be obtained by writing to:

LOS ANGELES COUNTY

TOPOGRAPHY

The County of Los Angeles covers an area of 4,083 square miles and measures approximately 66 miles in the east - west and 73 miles in the north - south directions.

The terrain within the County can be classified in broad terms as being 25 percent mountainous; 10 percent coastal plain; and 65 percent hills, valleys, or deserts. Relief of the terrain ranges from sea level to a maximum elevation of 10,000 feet. The coastal plain is generally of mild slope and contains relatively few depressions or natural ponding areas. The slopes of main river systems crossing the coastal plain, such as the San Gabriel River, Los Angeles River, and Ballona Creek, range from 4 to 14 feet per mile.

Topography in the mountainous area is generally rugged with deep, V-shaped canyons separated by sharp dividing ridges. Steepwalled canyons with side slopes of 70 percent or more are common. The gradient of principal canyons in the San Gabriel Mountains ranges from 150 to 850 feet per mile. Mountain ranges are aligned in a general east-west direction with the major range being the San Gabriel Mountains. The majority of mountain ridges lie below Elevation 5,000 feet. The total area above this level is approximately 210 square miles.

GEOLOGY - SOILS

Igneous, sedimentary, and metamorphic rock groups are all represented within the County. The San Gabriel Mountains and Verdugo Hills are composed primarily of highly fractured igneous rock, with large areas of granitic rock formation being exposed above soils that are coarse and porous. Faulting and deep weathering have produced porous zones in the rock formation; however, rock masses have produced a comparatively shallow soil mantle due to the steepness of slopes which accelerates erosion of the fine material.

LAND USE

The principal vegetative cover of upper mountain areas consists of various species of brush and shrubs known as chaparral. Most trees found on mountain slopes are oak, with alder, willow, and sycamore found along streambeds at lower elevations. Pine, cedar, and juniper are found in ravines at higher elevations and along high mountain summits.

The chaparral is extremely flammable, and extensive burns of the mountain vegetation frequently occur during dry, low-humidity weather accompanied by high winds. Chaparral has the ability to sprout following fire and grows rapidly to re-establish the watershed cover within a period of 5 to 10 years.

Grasses are the principal natural vegetation on the hills. Much of the hill land and nearly all of the valley land in the densely populated portion of the County south of the San Gabriel Mountains has been converted to urban and suburban use. Development of the

Santa Clarita Valley and desert areas to the north of the San Gabriel Mountains is sparse at present but is proceeding rapidly.

Other mountains and hilly reaches are composed primarily of folded and faulted sedimentary rock, including shale, sandstone, and conglomerate. Residual soils in these areas are shallow and are generally less pervious than those of the San Gabriel Mountain range.

Valley and desert soils are alluvial and vary from coarse sand and gravel near canyon mouths to silty clay and gravel or clay in lower valleys and the coastal plain. The alluvial fill has been built up by repeated deposition of debris to depths as great as 2,000 feet in places. This fill is quite porous in areas of relatively low clay content. Impervious layers and irregularities in the underlying bedrock divide the alluvium into several County groundwater basins. Valley soils are generally well drained but there are a few areas having perched water.

CLIMATE

The climate within the County varies between subtropical on the Pacific Ocean side of the San Gabriel Mountain range to arid in the Mojave Desert. Nearly all precipitation occurs during the months of December through March. Precipitation during summer months is infrequent, and rainless periods of several months are common. Snowfall at elevations above 5,000 feet is frequently experienced during the winter storms, but the snow melts rapidly except on higher peaks and the northern slopes. Snow is rarely experienced on the coastal plain.

January and July are the coldest and warmest months of the year, respectively. At Los Angeles, the 30-year average daily minimum temperature for January is 48 degrees above zero. The average daily maximum temperature for July is 84 degrees. At Mount Wilson (Elevation 5,850 feet), the 30-year average daily minimum temperature for January is 35 degrees above zero and the average daily maximum temperature for July is 80 degrees.

HYDROMETEOROLOGIC CHARACTERISTICS

Coastal and Mountain Areas

Precipitation in the Los Angeles area occurs primarily in the form of winter orographic rainfall associated with extratropical cyclones of North Pacific origin. Major storms consist of one or more frontal systems and occasionally last four days or longer. Air masses and frontal systems associated with major storms commonly extend for 500 to 1,000 miles in length and produce rainfall simultaneously throughout the County. Major storms approach Southern California from the west or southwest with southerly winds which continue until frontal passage. The mountain ranges lie directly across the path of the inflow of warm, moist air, and orographic effects greatly intensify precipitation.

The effects of snowmelt upon flood runoff is of significance in the few cases when warm spring rains from southerly storms fall on a snowpack. During major storms, temperatures throughout the County may remain above freezing. Average individual storm rainfall amounts and intensities conform to a fairly definite aerial pattern which reflects general effects of topographic differences.

Desert Areas

Summer convective rainfall is principally experienced in the upper San Gabriel Mountains and the Mojave Desert regions. In many desert areas, the most serious flooding occurs as a result of summer convective storms.

RUNOFF CHARACTERISTICS

Mountain Areas

In mountain areas, the steep canyon slopes and channel gradients promote a rapid concentration of storm runoff quantities. Depression storage and detention storage effects are minor in the rugged terrain. Soil moisture during a storm has a pronounced effect on runoff from the porous soils supporting a good growth of deeprooted vegetation such as chaparral. Soil moisture deficiency is greatest at the beginning of a rainy season, having been depleted by the evapotranspiration process during the dry summer months. Precipitation during periods of soil moisture deficiency is nearly entirely absorbed by soils, and except for periods of extremely intense rainfall, significant runoff does not occur until soils are wetted to field moisture capacity. Due to high infiltration rates and porosity of mountain soils, runoff occurs primarily as subsurface flow or interflow rather than as direct runoff. Spring or base flow is essentially limited to portions of the San Gabriel Mountain range. Consequently, most streams in the County are intermittent.

Runoff from a mountain watershed recently denuded by fire exceeds that for the unburned state due to greatly increased quantities of inorganic debris present in the flow and increased direct runoff resulting from lowered infiltration rates. Debris production from a major storm has amounted to as much as 223,000 cubic yards per square mile of watershed. Boulders up to eight feet in diameter have been deposited in valley areas a considerable distance from their source.

Debris quantities equal in volume to storm runoff, or in other words 100 percent bulking of runoff from a major storm, have been recorded. Where debris-laden flow traverses an alluvial fill unconfined by flood control works, flood discharges follow an unpredictable path across the debris cone formed at the canyon mouth.

Hill and Valley Areas

In hill areas, runoff concentrates rapidly from the generally steep slopes; however, runoff rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size. In those hill areas which have been developed for residential use, concentration times become considerably decreased due to drainage improvement, and runoff volumes and rates become increased due to increased imperviousness. On the other hand, erosion is controlled and debris is practically eliminated from storm flows. Debris production rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size.

In highly developed valley areas, local runoff volumes have increased as the soil surface has become covered by impervious materials. Peak runoff rates for valley areas have also increased due to elimination of natural ponding areas and improved hydraulic efficiency of water carriers such as streets and storm drain systems.

FLOOD CONTROL AND WATER CONSERVATION

FLOODS. . AN OLD STORY

Floods in Los Angeles County have been recorded as far back as the days of the Mission Padres. For centuries waters have swept out of the San Gabriel Mountains causing extensive property damage and taking a great toll of lives.

Such a flood occurred in 1914 causing over $10 million in property damage and taking many lives. As a result, the State legislature enacted the statute creating the Los Angeles County Flood Control District. The responsibilities and authority vested in the Flood Control District are now part of the Los Angeles County Department of Public Works.

The Department has two tasks. . .control the floods and conserve the water.

CONTROLLING THE WATERS

Successful early bond issues financed construction of the 14 dams which the Department built in the San Gabriel Mountains and foothills to impound storm waters until they could be safely released. Debris basins were constructed to trap eroded materials which had caused terrible damage in the past. Flood channel improvements were undertaken to confine the waters.

Department engineers prepared a Comprehensive Plan in the early 1930's which would control flooding and save as much of the water as practicable when fully implemented.

Federal legislation in 1936 brought the United States Army Corps of Engineers into the local flood control picture. Since that time, the two agencies have been jointly pursuing implementation of the Comprehensive Plan. The Department also cooperates with the United States Soil Conservation Service and Forestry Service in erosion control.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water conservation facilities in or adjacent to river channels and their tributaries permits water to be percolated into underground reservoirs for later pumping and supply to consumers. These water conservation facilities are located in areas where the underlying soils are composed of porous sands and gravel formations. Some resemble rice paddies, while others are deep basins which were once gravel pits.

The importance of this activity is apparent when it is realized that about 35 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, seriously depleted these supplies on numerous occasions throughout the history of the County.

VOL 12

Other major conservation efforts by the Department include combatting the serious salt water intrusion into underground fresh water supplies inland from the Pacific Ocean and utilizing imported water and reclaimed sewage waters in spreading operations.

ORGANIZED TO DO THE JOB

Day-to-day administration of Department affairs is vested in the Director of Public Works who is appointed by and responsible to the Los Angeles County Board of Supervisors. A part of the Department's activities involve the planning, design and construction of flood control and water conservation facilities, and the operation and maintenance of dams, debris basins, spreading grounds, channels, and storm drains.

PRECIPITATION

PRECIPITATION

This section contains annual precipitation data collected by the Department for the period beginning October 1, 1990 and ending September 30, 1991. Although the Department operates and maintains 294 rainfall stations, including standard and automatic gages which record amounts for durations ranging from 5 minutes to 24 hours, only annual amounts for the report period are listed herein. Additional data can be obtained by contacting the custodian of hydrologic records at the location shown in the front of the report.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions in the County and Southern California in real time, i.e., as they occur. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The cooperation of observers in furnishing rainfall data to the Department as a public service is appreciated. The effort of the many agencies and individuals who have so freely cooperated with us in the collection of this data have resulted in the large number of complete records for the period covered by this report.

EVAPORATION

Data for 14 active evaporation stations were reported to the Department during the 1990-91 water year. Daily records of active and inactive Department stations, as well as some stations of other agencies, are available in the Department's files. Monthly and seasonal evaporation has been published in the Department's Annual or Biennial Reports on Hydrologic Data since the 1931-32 season.

COOPERATION

The Department receives evaporation data from The Metropolitan Water District, Palmdale Water District, California Department of Water Resources, and Descanso Gardens.

LENGTH OF RECORD

The first land pan installed by this Department was at Santa Anita Dam in March 1929. There are 30 evaporation stations which have records of 15 seasons or more in the Department's files.

EVAPORATION STATION LIST 1990 - 91

RUNOFF

The Department operated or received data from 81 water-stage recording stations during the 1990-91 water year. Data from 48 of those stations are summarized and published in this volume.

RECORDS OF STREAMFLOW

Records published give the following information:

1. Station description which presents location, drainage area, type of channel, control, regulations, diversions, and available records.

2. Discharge tabulation which summarizes the maximum, minimum, and mean of the daily flow rates in second-feet for each month and the total monthly volumes in acre-feet.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions at 27 locations in the County. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The Department receives streamflow data from other agencies, or has access to the records for local stations. Data from 7 of the Department's stations are published in the United States Geological Survey's annual water supply papers.

Agencies with which the Department exchanges data are:

United States Geological Survey, Water Resource Division
United States Corps of Engineers
State Department of Water Resources
The Metropolitan Water District
San Gabriel River Water Committee

RESERVOIRS

VOL 12

19952

RESERVOIRS

Following the damaging flood of 1914 and creation of the Los Angeles County Flood Control District in 1915, a program of flood control and water conservation was initiated. Part of this program included the construction of 14 dams. These dams were operated by the Department during the period covered by this report. In addition, two Corps of Engineers' dams, Santa Fe Dam and Whittier Narrows Dam, and Morris Dam owned by The Metropolitan Water District were operated in conjunction with the Department dams to achieve flood control and/or water conservation.

OPERATION

The reservoirs are operated to control flood waters during storm periods. Post storm releases are made, when feasible, in amounts which can be conserved in downstream spreading grounds and by channel percolation. Cleanouts are done to regain storage capacity in reservoirs (see Erosion Control for cleanout data). Cogswell Reservoir had valve cylinders replaced this water year during a dry cleanout.

RECORDS

The storage and flow records at the 14 Department reservoirs are summarized on the Dam Operation Record Sheets. The sheets show:

1. Reservoir water surface elevations. Elevations are obtained from water stage recorder graphs or interpolation from staff gage readings and recorded as of midnight of each day. Only maximum and minimum water surface elevations for each year are shown.

2. Storage in acre-feet based on the most recent topographic surveys. Annual storage volumes are shown.

3. Inflow in cubic feet per second. This is usually calculated from storage change and known outflow. Only the maximum and minimum of the daily flow rates for the year and the instantaneous peak flow rate are shown.

4. Outflow in cubic feet per second. These values are determined from gaging station records, or when these are not available, from valve and spillway rating curves. Only the maximum and minimum of the daily outflow rates for the year and the instantaneous peak outflow rate are shown.

5. Discrepancies between outflow and storage losses at certain dams are attributable to evaporation and/or percolation losses. Total monthly evaporation losses are determined from the measurements made on land evaporation pans. In those cases where no allowances were made for evaporation, the amounts are necessarily included in the flow values. Accuracy of flow records computed from storage records is dependent on the frequency with which storage data are revised to keep in step with the physical change in reservoirs.

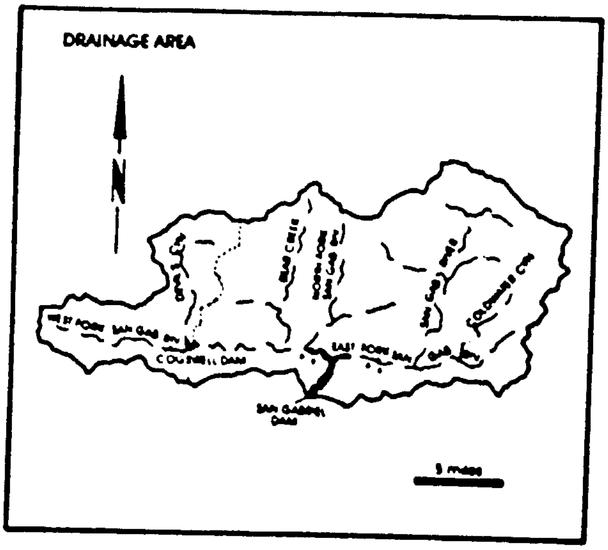
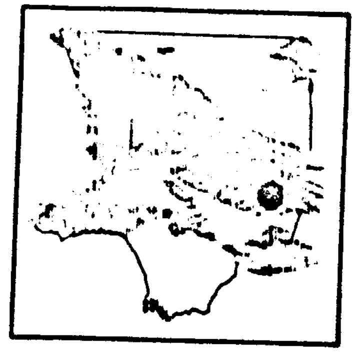
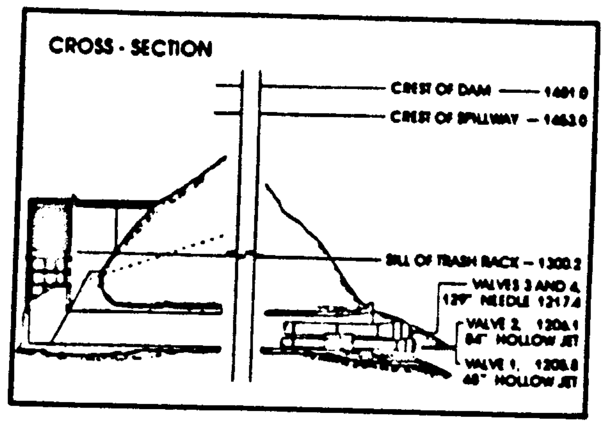
SAN GABRIEL DAM
AND RESERVOIR







PURPOSE - Flood Control and Conservation.
DATE CONSTRUCTED - Started December 1932. Completed July 1939.
LOCATION - San Gabriel Canyon, 7.5 miles north of Azusa.
DRAINAGE AREA - 163.5 square miles (uncontrolled)
39.2 square miles (controlled)
Total 202.7 square miles
(Includes Cogswell drainage)
CAPACITY - 41,549 acre - feet.
SPILLWAY ELEVATION - 1,453 feet.

EROSION CONTROL

VOL 12

1983

R0053288

VOL 12

1 1984

EROSION CONTROL

Each year eroded material in various forms (trees, rock, sand, etc.) flows out of the mountain watersheds of Los Angeles County. In an effort to control this potentially disruptive force, the Department maintains a series of debris basins in canyon mouths and upstream stabilization structures in selected watersheds.

DEBRIS BASINS

The purpose of a debris basin is to entrap the debris flows emanating from the canyon and let the relatively desilted water pass into flood control channels.

From 1990 to 1991, the number of debris basins was changed from 115 to 114 by declassifying an existing debris basin to a drain inlet. This gives a total capacity of approximately 7,603,725 cubic yards.

Records of sediment inflow at individual debris basins and amounts excavated and removed are available in the Hydraulic/Water Conservation Division.

STABILIZATION STRUCTURES

Stabilization structures are constructed to control erosion in natural canyons. They serve to prevent downcutting by stabilizing alluvial deposits. In addition, they store debris generated by the watershed and serve to stabilize side banks, reducing side slope sloughing and bank erosion.

The Department maintains 225 stabilization structures in 47 major watersheds. No structures have been constructed since the 1973-74 water year.

EMERGENCY STRUCTURES

Emergency structures (rail and timber) have been constructed to entrap the debris inflow from burned watersheds. They serve to protect improvements (road, channel, residence, etc.) located immediately downstream of the watersheds. Currently 36 emergency structures exist with a total maximum capacity of 272,215 cubic yards. No major fires (those over 500 acres) occurred in this water year.

SEDIMENT REMOVAL FROM RESERVOIRS

Sediment deposition in reservoirs reduces the storage capacities and adversely affects flood control and water conservation efforts. Sediment removal is periodically necessary and is generally an expensive effort due to large quantities, the need to deal with water inflows, and in several cases, remote locations and limited accessibility for equipment.

Where practical, the Department encourages sediment removal by permittees at no cost to the Department such as at Eaton Wash and Devil's Gate Dams.

During the 1990-91 water year the Department initiated cleanouts in Cogswell Reservoir and Morris Reservoir. These are two of three reservoirs in San Gabriel Canyon which collectively contain 36 million cubic yards (cy), about three-quarters of the cumulative volume of sediment currently behind all dams under the Department's control.

Cogswell Reservoir was cleaned out mechanically and the removed material was placed in a canyon sediment placement site (SPS) upstream of the dam. (The location of the SPS was mandated by the US Forest Service because of accessibility, aesthetics and safety reasons.) About 450,000 cy of material was removed with this year's cleanout.

Morris reservoir's cleanout consisted of a Pilot Sluicing Project. This is the first debris removed from Morris Reservoir in its 57 year history. About 435,000 cy of material was removed with this year's cleanout.

D E B R I S   B A S I N - D E S I G N   D A T A

Including 1990-1991 Season

Compiled by: Hydraulic and Water Conservation Division - Sedimentation Section
Date: October 1, 1991

DATA SHEET A

(1) LOWEST CLEAR WATER OUTLET, NOT SPILLWAY.
(2) ELEVATION OF SPILLWAY NOTCH.
(3) FLOW LINE OF SLUICEWAY.
(4) ELEVATION OF SPILLWAY INTO OUTLET CHANNEL. ELEVATION OF OVERFLOW SPILLWAY 1036.9 FEET.
(5) ONE 30-INCH REINFORCED CONCRETE PIPE.
(6) FOUR 36-INCH CORRUGATED METAL PIPES.
(7) ONE 36-INCH REINFORCED CONCRETE PIPE. (ELEVATED INLET)
(8) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.
(9) PIT-TYPE BASIN.
(10) INFORMATION UNAVAILABLE.
(11) MAXIMUM CAPACITY MAY BE LESS THAN SHOWN AND IS BEING REVIEWED. FIELD INSPECTION SUGGESTS BASIN IS NEAR ITS FULLEST POSSIBLE CAPACITY.
(12) SPECIAL CLEANOUT REQUIRED DUE TO LIMITED STORAGE.
(13) CLEANOUT WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1120.9 AGAINST FACE OF DAM.
(14) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN
(15) VALUES ARE BASED ON RECENTLY APPROVED CUTPLANS
(16) SPILLWAY IS STREET
(17) CLEANED FALL OF 1991
(18) CAPACITY REDUCED FOR 5% MAX CONE SLOPE
(19) DRAINAGE AREA CORRECTED JUNE 1991

AFTON REMOVED FROM D/B LIST JULY 1991
CEDARWOOD REMOVED FROM D.B LIST AUGUST 1991

VOL 12 1997

WATER QUALITY

Since its conception, the Flood Control District (now Department of Public Works) has actively engaged in operations which have proven indispensable in preserving the integrity of our water resources, both quantity and quality, and has aided in the establishment of regulations or controlling criteria by those agencies so empowered.

Prior to March 1986, monitoring activities in the field of water quality control were conducted by the Water Quality Section of Hydraulic/Water Conservation Division. In March 1986, the responsibilities of conducting such activities were transferred to Waste Management Division as a result of the consolidation. These activities include, among others, the collection of water quality samples, their analyses, and the interpretation and reporting of the resulting data.

Areas of involvement include the monitoring of all groundwater basins through the sampling of numerous wells, the monitoring of storm and low water flows at various strategic locations on the major streams or channels, and an assumed or obligated responsibility to monitor the quality effects and subsurface travel of recharge areas, specifically the Whittier Narrows Spreading Grounds area.

The Water Quality Section, together with personnel of other Departmental divisions, also conducts investigations into pollution problems relative to our facilities, particularly those from industrial discharges, vehicle accidents, ruptured pipelines, or the indiscriminate dumping of various waste products.

The principal objectives of these investigations are to determine the degree and apparent source or origin of the pollution and to take the necessary action that will immediately abate the existing problem and possibly provide a means to prevent or limit recurrence.

Since 1986, the Water Quality Section also has been conducting the screening of proposed connections to County storm drains, and developments over County right-of-ways, for the purpose of minimizing/eliminating potential of pollutants to the storm drain waters and, thereby, to the environment.

The above-mentioned activities of the Water Quality Section have recently been intensified, particularly in the areas of interfacing and coordinating with other municipalities/cities, environmental organizations, as well as Federal and State agencies, in an effort to comply with the regulations and requirements mandated under the 1987 Clean Water Act, whereby the Department's storm drain system is under the National Pollutant Discharge Elimination System (NPDES) permitting regulations of the California Regional Water Quality Control Board (CRWQCB).

The NPDES Permit (CA0061654) issued for the storm drain system in Los Angeles County requires the development of programs to improve the quality of stormwater/urban runoff discharges into the storm drain system. Los Angeles County, represented by the Department of Public Works, is the Principal Permittee and the cities within the County are

Co-Permittees. The drainage area covered by the Permit will become active in three phases, with Phase 1, the Santa Monica Bay Drainage Basin, having begun July 1, 1990.

The Permit requires the County, together with the cities in the County, to (a.) develop and implement a stormwater/urban runoff monitoring program to gather data on the type and source of pollutants within the drainage basin, and (b.) develop and implement Best Management Practices (BMPs) to reduce the amount of pollutants that find their way into the storm drain system.

SURFACE WATER QUALITY

Prior to 1984, dry weather samples were collected from 30 sampling stations on a monthly basis for analysis such as general minerals, bacteria, pesticides, and heavy metals. In addition, storm samples were also collected and analyzed at least three times annually from the same 30 stations during storms season.

From 1984 to 1987, as a result of reorganization, the number of surface water monitoring stations was reduced to 21, while the parameters analyzed were reduced to include only total dissolved solids, pH, and dissolved oxygen. Storm sampling activities were also significantly curtailed.

In 1988, recognizing the inadequacy of the then existing monitoring program to meet the Department's need in dealing with the important issues in the areas of water quality, the Department Administration approved and implemented an expanded monitoring program effective May 1, 1988.

There are 28 monitoring stations in the Department's current Surface Water Quality Monitoring Program, from which dry weather samples are collected and analyzed on a monthly basis. These sampling stations are strategically located throughout the Department's major storm drains and water conservation facilities where the flows are representative of typical land uses as well as areas of significant water quality concerns. Of the 28 monitoring stations in the program, six are located at the outlets to Santa Monica Bay, while one is located in the mountain area where flow is considered to be natural and uncontaminated with the various pollutants associated with urbanization and developed land uses.

Monthly dry weather samples, thus collected, are analyzed for general minerals (pH, specific conductance, total dissolved solids, total hardness, potassium sulfate, calcium, magnesium, chloride, fluoride, nitrate-nitrogen, nitrite-nitrogen, ammonium-nitrogen, phosphate-P, boron, iron, and manganese), bacteria, pesticides, heavy metals (silver arsenic, barium, cadmium, chromium, mercury, lead, selenium, copper, nickel, zinc, and chromium [VI]), oil and grease, total organic carbon, total petroleum hydrocarbons, PCB's, biochemical oxygen demand, and volatile organic compounds (TCE, carbon tetrachloride, vinyl chloride, 1,2 dichlorethene, benzene, 1,1 dichloroethylene, 1,1,1 trichloroethane, p-dichlorobenzene). In addition, storm samples are collected for three to four storms annually from 21 stations, including San Gabriel Coastal and Rio Hondo Spreading Grounds for extensive analysis similar to those for dry weather samples, with additional testing of total suspended solids and volatile suspended solids to be included. For storm samples collected at San Gabriel Coastal and Rio Hondo Spreading Grounds, priority pollutant constituents are also analyzed under an agreement with the Central and West Basin Water Replenishment District.

A selective list of total dissolved solids is shown for some of the sampling locations on the streams and channels monitored under the Surface Water Quality Program. For a conception of the analysis performed on the surface flows, a yearly compilation of constituent determination is shown for one (Los Angeles River at Wardlow) of the sampling stations in the program.

GROUNDWATER QUALITY

The annual sampling of water wells, under a selected scheduling, in five major basins in Los Angeles County comprise the Groundwater Quality Program. The program, initiated in 1970, is coordinated with the State of California Department of Water Resources and the City of Los Angeles Department of Water and Power. These agencies participate in the obtainment and analysis of samples.

All the water well samples are from active production wells used either for municipal supply, irrigation, or for industrial purposes and are selected to represent a general portrayal of basin water quality conditions. The samples taken under this program are analyzed for major minerals, total dissolved solids, electrical conductivity, pH, and in specific cases, phosphate, iron, manganese, fluoride, or boron.

WATER QUALITY DATA ACCESSIBILITY

Data acquired from the various programs are on file in the Water Quality Section. In addition, all data is accessible to any user through STORET, an Environmental Protection Agency computer system that stores, retrieves, and manipulates data using agency code 21CALAFD.

WATER CONSERVATION

VOL 12

2 00017

WATER CONSERVATION

Information presented in this section includes amounts of local, imported, and reclaimed water conserved in spreading areas and information on the seawater barrier projects which prevent saltwater intrusion to groundwater zones in the coastal areas. Pertinent data is presented regarding the locations and descriptions of Department water conservation facilities, a well as facilities owned by others. Also included are groundwater maps delineating static groundwater elevations recorded during the report period and hydrographs of selected key wells.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waters as practicable. The use of water conservation facilities adjacent to river channels, and in soft-bottom channels permits water to percolate into groundwater basins for later pumping. These water spreading facilities are located in areas where the underlying soils are composed of pervious formations.

The various types of water conserved, local, imported, and reclaimed, are construed to have the following meanings in this section: Local water is primarily runoff due to rainfall on the mountain and valley watersheds, dam releases, and rising water within the County. Imported water is water originating outside the County either from Northern California or from the Colorado River. Reclaimed water is the effluent produced by the Whittier Narrows Water Reclamation Plant, the San Jose Creek Water Reclamation Plant, and the Pomona Reclamation Plant, all operated by the Los Angeles County Sanitation District.

The importance of this activity is apparent when it is realized that about 30 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, has seriously depleted these supplies on numerous occasions.

The Department's policy is to conserve the maximum amount of storm water possible consistent with considering runoff quantity and quality, capacities of the spreading facilities, and groundwater conditions.

IMPORTED WATER

During this report period, imported Colorado River and State Project water for spreading was received from the Metropolitan Water District. Imported water for groundwater recharge in the Coastal Plain was spread at the Department's facilities in the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds on behalf of the Central and West Basin Water Replenishment District. Imported water for groundwater recharge in the San Gabriel Valley was spread in Santa Fe Spreading Grounds, in the San Gabriel River between Morris and Santa Fe Dams, in Irwindale Spreading Basin and in Citrus and Forbes Spreading Grounds on behalf of MWD, the Main San Gabriel Basin Watermaster, Three Valleys Municipal Water District, and the San Gabriel Valley Municipal Water District.

RECLAIMED WATER

The County Sanitation District's Whittier Narrows Water Reclamation Plant effluent, purchased by the Central and West Basin Water Replenishment District, was transported to the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds for groundwater replenishment.

The County Sanitation District's San Jose Creek Water Reclamation Plant, activated in May 1972, made its first delivery of effluent in November 1972. The portion of the effluent that is spread is also purchased by the Central and West Basin Water Replenishment District.

Water from the Pomona Reclamation Plant is released down the San Jose Creek - San Gabriel River System to the Department's recharge facilities in the Rio Hondo and San Gabriel Coastal Basin spreading grounds.

The maximum amount of reclaimed water allowed for spreading in the Montebello Forebay, effective July 1991, is 60,000 acre-feet per year, but not to exceed 150,000 acre-feet over a three year period.

SEAWATER BARRIER PROJECTS

The Department operates three barrier projects to protect the groundwater in the West Coast and Central Basins against seawater intrusion by creating freshwater pressure ridges along the coastline. The pressure ridges are created by injecting fresh water through a series of injection wells. During the report period, 16,037 acre-feet of water was injected at the West Coast Basin Barrier Project, 7,757 acre-feet at the Dominguez Gap Barrier Project, and 4,096 acre-feet at the Los Angeles part of the Alamitos Barrier Project. On behalf of the Orange County Water District, 1,818 acre-feet of water was injected at the Orange County portion of the Alamitos Barrier Project.

The following seawater barrier improvements were completed during the 1990-91 water year:

1. Alamitos Barrier Project:

    Four multi-zone injection wells were constructed along the southeasterly reach of the barrier. This construction project was managed by the Orange County Water District and our Department shared in the capital construction cost.

2. Dominguez Gap Barrier Project

    A geologic investigation was begun to determine the cause of surface leakage along the barrier alignment. This included the construction of 17 shallow piezometers. The data collected from this project will be used to evaluate the liquefaction potential and the integrity of the confining cap. We will also use this data to determine the maximum water surface elevations and the injection pressures for the optimum operations of the barrier.

3. West Coast Basin Barrier Project

Five single zone injection wells were constructed in the northerly portion of Lower San Pedro Aquifer in the barrier.

SEASONAL DATA AND MAPS

During this report period, weekly, monthly, and semi-annual measurements of groundwater levels in observations wells located throughout the groundwater basins in Los Angeles County were made and processed.

Hydrographs of selected key wells are included in this report.

GROUNDWATER BASINS AND GROUNDWATER RECHARGE

Groundwater in Los Angeles County is stored in basins underlying five major geographic areas. These groundwater basins are separated by geologic features which impede groundwater movement or sometimes by arbitrary political boundaries. The following is a background summary of the Department's groundwater recharge activities within each of these areas:

The Department operates 2,436 acres of spreading grounds and soft-bottom channel spreading areas for replenishment of local aquifers to increase water supplies. The Department also assisted in the operation and maintenance of 269 acres of spreading grounds owned by others. An additional 656 acres of spreading grounds are controlled, maintained, and operated by other agencies. The total gross acreage of spreading grounds in the county is 3,361 acres. During the report period, the Department conserved approximately 167,564 acre-feet of storm runoff.

The conservation of local runoff is supplemented by spreading imported water and reclaimed water purchased by water agencies. During the period, 113,301 acre-feet of imported water and 53,864 acre-feet of reclaimed water were spread.

The Department is continuing its efforts to improve its water spreading facilities in order to maximize the amounts of water conserved and to simplify the spreading operations.

<u>SAN GABRIEL VALLEY</u>

The Department operates 20 spreading grounds in the San Gabriel Valley that receive direct valley runoff and flows from the San Gabriel Mountains. Some of these spreading grounds can also receive imported water. During the report period, the Department added approximately 92,725 acre-feet of local water and 62,697 acre-feet of imported water to the groundwater stored in the basins underlying the San Gabriel Valley and diverted 4,104 acre-feet of local water to grounds owned by others.

VOL 12

The following projects were constructed in the San Gabriel Valley during the report period:

1. Irwindale Spreading Basin:

   Construction of the inlet structure to Manning Pit was completed.

2. Eaton Wash Spreading Grounds:

   Modification and earthwork in basins, construction of a drainage system and construction of intake weir structures with motorized gates were completed.

Main San Gabriel Basin

This is the largest basin underlying the San Gabriel Valley with an estimated storage capacity of 9.5 million acre-feet. It reacts quickly to artificial spreading in Santa Fe Reservoir Spreading Grounds and to infiltration in the San Gabriel River Downstream of Santa Fe Dam.

During the report period, the Department replenished the Main San Gabriel Basin with 72,780 acre-feet of local water and 34,597 acre-feet of imported water. Also, a new historic low for the groundwater elevation in the San Gabriel Main Basin was recorded. Well 3030F in Baldwin Park recorded a new historic low groundwater elevation of 196.7 ft on March 2, 1991.

Upper San Gabriel Canyon Basin

Approximately 13,667 acre-feet of local water and approximately 27,200 acre-feet of imported water were recharged by the Department through its San Gabriel Canyon Spreading Grounds and by percolation in the adjacent San Gabriel River. Also, 2,648 acre-feet of local water was routed to Fish Canyon Spreading Grounds which is operated by the Committee of Nine.

Lower San Gabriel Canyon Basin

The basin is located south of the Upper San Gabriel Canyon Basin and is separated from it by the underground Lohmon Dike. Groundwater cascades over the Lohmon Dike from the Upper San Gabriel Canyon Basin and recharges the Lower San Gabriel Canyon Basin. The Department spread 462 acre-feet of local water in Sawpit Spreading Grounds which is within the Lower Canyon Basin.

Wayhill Basin

The Department spread 281 acre-feet of local water and 900 acre-feet of imported water at Forbes spreading facility in the Wayhill Basin.

2 0021

VCL 12 2-0022

Foothill Basin

The Department spread 2,008 acre-feet of local water at its San Dimas Canyon Spreading Grounds facility in the Foothill Basin.

Glendora Basin

The Department spread 467 acre-feet of local water in its Dalton facilities within the Glendora Basin.

Claremont Heights Basin

Approximately 87 acre-feet of local water were diverted to the Pomona Valley Protective Association's Thompson Creek Spreading Grounds which benefits the groundwater in the Claremont Heights Basin.

Live Oak Basin

The Department has no spreading facilities in the Live Oak Basin.

Chino Basin

The basin is located in the most eastern part of the County. No Department recharge facilities are located within the Chino Basin.

San Dimas Basin

The basin is north of the San Jose Hills, east of the Main Basin, and south of the Wayhill Basin. The Department spread 186 acre-feet of local water in its Live Oak Spreading Grounds to recharge the basin.

Pomona Basin

The basin is located south of Claremont, Live Oak, and San Dimas Basins, and north of the Chino Basin and northeast of the San Jose Hills. The Department has no water spreading facilities within this basin.

Puente and Spadra Basins

No spreading occurs in this area.

Raymond Basin

The basin covering approximately 40 square miles is located in the northwest corner of the San Gabriel Valley and is separated from the Main San Gabriel Basin by the Raymond Fault. The Raymond Basin contains the Monk Hill Basin and the Pasadena and Santa

Anita Subareas. The Department recharged 2,874 acre-feet of local water by its spreading facilities in the Raymond Basin and diverted 1,369 acre-feet to the City of Sierra Madre's spreading facility during the report period.

COASTAL PLAIN

The groundwater basins underlying the Coastal Plain are divided by geological features into the Central (includes the Montebello and Los Angeles Forebays), West Coast, Santa Monica, and Hollywood Basins. During the period of October 1, 1990 to September 30, 1991, the Department recharged 41,998 acre-feet of local water, 52,937 acre-feet of imported water, and 50,100 acre-feet of reclaimed water to the groundwater basins underlying the Coastal Plain. Most of the water was spread in the Montebello Forebay.

The following projects were constructed in the Coastal Plain during the report period:

1. Rio Hondo Coastal Basin Spreading Ground West Side:

   Construction of about 5 miles of chain link fence with electric roller gates operated by loop sensors were completed along with construction of a bike trail under the AT and SF Rail Road.

2. West Coast Basin Saline Water Plume Mitigation Study:

   James M. Montgomery Consulting Engineers and Camp, Dresser and McKee, Inc., continue the development of the groundwater model for this study.

   These consultants have completed Task 4, which describes selected alternatives for plume mitigation. Also completed is Task 5 of the study, which evaluates and ranks the plume mitigation and basin management alternatives.

Central Basin

The Central Basin has the most storage capacity of the basins in the Coastal Plain. In addition to the water recharged in the Department's spreading facilities, water injected in the Alamitos Barrier Project also contributes to the replenishment of the pressure aquifers underlying the Central Basin.

West Coast Basin

The West Coast Basin is the second largest basin underlying the Coastal Plain and is separated from the Central Basin by the Newport-Inglewood Fault zone. Groundwater is primarily recharged by Central Basin subsurface flows and by water injected by the Department in the West Coast Basin and Dominguez Gap Barrier Projects. Groundwater elevations in the West Coast Basin are below sea level except in the area of the West Coast Basin Barrier injection mound.

The Department spread 96 acre-feet of water in the Dominguez Spreading Grounds.

Santa Monica and Hollywood Basins

The Department has no spreading facilities in either the Santa Monica or Hollywood groundwater basins.

SAN FERNANDO VALLEY

The San Fernando Valley is also called the Upper Los Angeles River Area (ULARA). Most of the runoff from the surrounding mountains flows to the Valley.

San Fernando Main Basin

The basin is the largest basin underlying the San Fernando Valley. During the report period, 18,162 acre-feet of local water and 504 acre-feet of imported water were spread by the Department. The County entered into an agreement with the City of Los Angeles to spread water at the newly renovated Tujunga Wash Spreading Grounds which is located approximately two miles downstream of Hansen Spreading Grounds. The City installed a rubber dam diversion and appurtenant facilities for County Spreading operations which started in March 1990.

Sylmar Basin

A much smaller basin underlying the San Fernando Valley is the Sylmar Basin; the Department has no spreading facility within this basin.

Verdugo and Eagle Rock Basins

The small Verdugo and Eagle Rock Basins comprise the remaining basins underlying the San Fernando Valley. The Department has no spreading facilities within either basin.

SANTA CLARITA VALLEY

The Department has no spreading facilities in the area. Most of the Valley is farmland, permitting substantial natural percolation.

The Upper Santa Clarita subunit comprises five basins.

ANTELOPE VALLEY

There are several groundwater basins underlying the Antelope Valley, five of them are located within Los Angeles County.

During this report period a private water company under contract with the Department recharged over 489 acre-feet of local water in its spreading facility in the Big Rock area to groundwater in the Pearland Basin.

The groundwater level in the Lancaster Basin has declined steadily since 1925 and reached a new historic low during the report period.

INTRODUCTION

This report contains hydrologic data relative to Los Angeles County for the period beginning October 1, 1991 and ending September 30, 1992. The data are presented in seven sections.

Precipitation - lists 294 active rainfall stations and presents corresponding seasonal rainfall amounts.

Evaporation - lists all locations for which evaporation data is on file and provides monthly evaporation amounts at 14 locations.

Runoff - presents the maximum, minimum, and mean of the daily flow rates for each month and the monthly volumes for 40 streamflow stations.

Dam Operation - presents the maximum and minimum of the daily inflow and outflow rates for each month, the instantaneous peak inflow and outflow rates and storage volumes for 14 dams and reservoirs.

Erosion Control - lists debris basins and debris production amounts.

Water Quality Monitoring - presents maps of surface and groundwater sampling locations, and data at selected locations.

Conservation and Groundwater - presents records of water conserved at various facilities, water injected at seawater barrier projects, well hydrographs, and static groundwater contour maps.

Where practical, data which would satisfy immediate needs and serve as useful reference are published in these reports. Several tables appear listing locations for which unpublished data are available. Additional information may be obtained by writing to:

LOS ANGELES COUNTY

TOPOGRAPHY

The County of Los Angeles covers an area of 4,083 square miles and measures approximately 66 miles in the east - west and 73 miles in the north - south directions.

The terrain within the County can be classified in broad terms as being 25 percent mountainous; 10 percent coastal plain; and 65 percent hills, valleys, or deserts. Relief of the terrain ranges from sea level to a maximum elevation of 10,000 feet. The coastal plain is generally of mild slope and contains relatively few depressions or natural ponding areas. The slopes of main river systems crossing the coastal plain, such as the San Gabriel River, Los Angeles River, and Ballona Creek, range from 4 to 14 feet per mile.

Topography in the mountainous area is generally rugged with deep, V-shaped canyons separated by sharp dividing ridges. Steepwalled canyons with side slopes of 70 percent or more are common. The gradient of principal canyons in the San Gabriel Mountains ranges from 150 to 850 feet per mile. Mountain ranges are aligned in a general east-west direction with the major range being the San Gabriel Mountains. The majority of mountain ridges lie below Elevation 5,000 feet. The total area above this level is approximately 210 square miles.

GEOLOGY - SOILS

Igneous, sedimentary, and metamorphic rock groups are all represented within the County. The San Gabriel Mountains and Verdugo Hills are composed primarily of highly fractured igneous rock, with large areas of granitic rock formation being exposed above soils that are coarse and porous. Faulting and deep weathering have produced porous zones in the rock formation; however, rock masses have produced a comparatively shallow soil mantle due to the steepness of slopes which accelerates erosion of the fine material.

LAND USE

The principal vegetative cover of upper mountain areas consists of various species of brush and shrubs known as chaparral. Most trees found on mountain slopes are oak, with alder, willow, and sycamore found along streambeds at lower elevations. Pine, cedar, and juniper are found in ravines at higher elevations and along high mountain summits.

The chaparral is extremely flammable, and extensive burns of the mountain vegetation frequently occur during dry, low-humidity weather accompanied by high winds. Chaparral has the ability to sprout following fire and grows rapidly to re-establish the watershed cover within a period of 5 to 10 years.

Grasses are the principal natural vegetation on the hills. Much of the hill land and nearly all of the valley land in the densely populated portion of the County south of the San Gabriel Mountains has been converted to urban and suburban use. Development of the

Santa Clarita Valley and desert areas to the north of the San Gabriel Mountains is sparse at present but is proceeding rapidly.

Other mountains and hilly reaches are composed primarily of folded and faulted sedimentary rock, including shale, sandstone, and conglomerate. Residual soils in these areas are shallow and are generally less pervious than those of the San Gabriel Mountain range.

Valley and desert soils are alluvial and vary from coarse sand and gravel near canyon mouths to silty clay and gravel or clay in lower valleys and the coastal plain. The alluvial fill has been built up by repeated deposition of debris to depths as great as 2,000 feet in places. This fill is quite porous in areas of relatively low clay content. Impervious layers and irregularities in the underlying bedrock divide the alluvium into several County groundwater basins. Valley soils are generally well drained but there are a few areas having perched water.

CLIMATE

The climate within the County varies between subtropical on the Pacific Ocean side of the San Gabriel Mountain range to arid in the Mojave Desert. Nearly all precipitation occurs during the months of December through March. Precipitation during summer months is infrequent, and rainless periods of several months are common. Snowfall at elevations above 5,000 feet is frequently experienced during the winter storms, but the snow melts rapidly except on higher peaks and the northern slopes. Snow is rarely experienced on the coastal plain.

January and July are the coldest and warmest months of the year, respectively. At Los Angeles, the 30-year average daily minimum temperature for January is 48 degrees above zero. The average daily maximum temperature for July is 84 degrees. At Mount Wilson (Elevation 5,850 feet), the 30-year average daily minimum temperature for January is 35 degrees above zero and the average daily maximum temperature for July is 80 degrees.

HYDROMETEOROLOGIC CHARACTERISTICS

Coastal and Mountain Areas

Precipitation in the Los Angeles area occurs primarily in the form of winter orographic rainfall associated with extratropical cyclones of North Pacific origin. Major storms consist of one or more frontal systems and occasionally last four days or longer. Air masses and frontal systems associated with major storms commonly extend for 500 to 1,000 miles in length and produce rainfall simultaneously throughout the County. Major storms approach Southern California from the west or southwest with southerly winds which continue until frontal passage. The mountain ranges lie directly across the path of the inflow of warm, moist air, and orographic effects greatly intensify precipitation.

The effects of snowmelt upon flood runoff is of significance in the few cases when warm spring rains from southerly storms fall on a snowpack. During major storms, temperatures throughout the County may remain above freezing. Average individual storm rainfall amounts and intensities conform to a fairly definite aerial pattern which reflects general effects of topographic differences.

Desert Areas

Summer convective rainfall is principally experienced in the upper San Gabriel Mountains and the Mojave Desert regions. In many desert areas, the most serious flooding occurs as a result of summer convective storms.

RUNOFF CHARACTERISTICS

Mountain Areas

In mountain areas, the steep canyon slopes and channel gradients promote a rapid concentration of storm runoff quantities. Depression storage and detention storage effects are minor in the rugged terrain. Soil moisture during a storm has a pronounced effect on runoff from the porous soils supporting a good growth of deeprooted vegetation such as chaparral. Soil moisture deficiency is greatest at the beginning of a rainy season, having been depleted by the evapotranspiration process during the dry summer months. Precipitation during periods of soil moisture deficiency is nearly entirely absorbed by soils, and except for periods of extremely intense rainfall, significant runoff does not occur until soils are wetted to field moisture capacity. Due to high infiltration rates and porosity of mountain soils, runoff occurs primarily as subsurface flow or interflow rather than as direct runoff. Spring or base flow is essentially limited to portions of the San Gabriel Mountain range. Consequently, most streams in the County are intermittent.

Runoff from a mountain watershed recently denuded by fire exceeds that for the unburned state due to greatly increased quantities of inorganic debris present in the flow and increased direct runoff resulting from lowered infiltration rates. Debris production from a major storm has amounted to as much as 223,000 cubic yards per square mile of watershed. Boulders up to eight feet in diameter have been deposited in valley areas a considerable distance from their source.

Debris quantities equal in volume to storm runoff, or in other words 100 percent bulking of runoff from a major storm, have been recorded. Where debris-laden flow traverses an alluvial fill unconfined by flood control works, flood discharges follow an unpredictable path across the debris cone formed at the canyon mouth.

Hill and Valley Areas

In hill areas, runoff concentrates rapidly from the generally steep slopes; however, runoff rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size. In those hill areas which have been developed for residential use, concentration times become considerably decreased due to drainage improvement, and runoff volumes and rates become increased due to increased imperviousness. On the other hand, erosion is controlled and debris is practically eliminated from storm flows. Debris production rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size.

In highly developed valley areas, local runoff volumes have increased as the soil surface has become covered by impervious materials. Peak runoff rates for valley areas have also increased due to elimination of natural ponding areas and improved hydraulic efficiency of water carriers such as streets and storm drain systems.

FLOOD CONTROL AND WATER CONSERVATION

FLOODS. . AN OLD STORY

Floods in Los Angeles County have been recorded as far back as the days of the Mission Padres. For centuries waters have swept out of the San Gabriel Mountains causing extensive property damage and taking a great toll of lives.

Such a flood occurred in 1914 causing over $10 million in property damage and taking many lives. As a result, the State legislature enacted the statute creating the Los Angeles County Flood Control District. The responsibilities and authority vested in the Flood Control District are now part of the Los Angeles County Department of Public Works.

The Department has two tasks. . .control the floods and conserve the water.

CONTROLLING THE WATERS

Successful early bond issues financed construction of the 14 dams which the Department built in the San Gabriel Mountains and foothills to impound storm waters until they could be safely released. Debris basins were constructed to trap eroded materials which had caused terrible damage in the past. Flood channel improvements were undertaken to confine the waters.

Department engineers prepared a Comprehensive Plan in the early 1930's which would control flooding and save as much of the water as practicable when fully implemented.

Federal legislation in 1936 brought the United States Army Corps of Engineers into the local flood control picture. Since that time, the two agencies have been jointly pursuing implementation of the Comprehensive Plan. The Department also cooperates with the United States Soil Conservation Service and Forestry Service in erosion control.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water conservation facilities in or adjacent to river channels and their tributaries permits water to be percolated into underground reservoirs for later pumping and supply to consumers. These water conservation facilities are located in areas where the underlying soils are composed of porous sands and gravel formations. Some resemble rice paddies, while others are deep basins which were once gravel pits.

The importance of this activity is apparent when it is realized that about 30 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, seriously depleted these supplies on numerous occasions throughout the history of the County.

Other major conservation efforts by the Department include combatting the serious salt water intrusion into underground fresh water supplies inland from the Pacific Ocean and utilizing imported water and reclaimed sewage waters in spreading operations.

ORGANIZED TO DO THE JOB

Day-to-day administration of Department affairs is vested in the Director of Public Works who is appointed by and responsible to the Los Angeles County Board of Supervisors. A part of the Department's activities involve the planning, design and construction of flood control and water conservation facilities, and the operation and maintenance of dams, debris basins, spreading grounds, channels, and storm drains.

PRECIPITATION

VOL 12

2

0087

PRECIPITATION

This section contains annual precipitation data collected by the Department for the period beginning October 1, 1991 and ending September 30, 1992. Although the Department operates and maintains 293 rainfall stations, including standard and automatic gages which record amounts for durations ranging from 5 minutes to 24 hours, only annual amounts for the report period are listed herein. Additional data can be obtained by contacting the custodian of hydrologic records at the location shown in the front of the report.

RAINFALL AMOUNTS

For the year, rainfall recorded at the downtown Los Angeles station (No. 716) reached 23.26 inches, or 150 percent of the long-term average of 15.51 inches. The Cogswell Dam station (No. 334B) recorded 52.35 inches for the year which is 159 percent of the long-term average of 32.88 inches. The County received the greatest amount of rainfall during the month of February, with the San Fernando Valley in the vicinity of the Sepulveda Basin being among the hardest-hit areas. The above two stations recorded rainfall of 9.02 inches and 23.22 inches, respectively, during that month.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions in the County and Southern California in real time, i.e., as they occur. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The cooperation of observers in furnishing rainfall data to the Department as a public service is appreciated. The effort of the many agencies and individuals who have so freely cooperated with us in the collection of this data have resulted in the large number of complete records for the period covered by this report.

EVAPORATION

Data for 14 active evaporation stations were reported to the Department during the 1991-92 water year. Daily records of active and inactive Department stations, as well as some stations of other agencies, are available in the Department's files. Monthly and seasonal evaporation has been published in the Department's Annual or Biennial Reports on Hydrologic Data since the 1931-32 season.

COOPERATION

The Department receives evaporation data from The Metropolitan Water District, Palmdale Water District, California Department of Water Resources, and Descanso Gardens.

LENGTH OF RECORD

The first land pan installed by this Department was at Santa Anita Dam in March 1929. There are 30 evaporation stations which have records of 15 seasons or more in the Department's files.

RUNOFF

R0053409

RUNOFF

The Department operated or received data from 65 water-stage recording stations during the 1991-92 water year. Data from 40 of those stations are summarized and published in this volume.

The above normal rainfall during this report period and especially the heavy storm activity during February have resulted in heavy runoff in the rivers, channels, and streams. The Los Angeles River in particular during February 10th, experienced flow rates at near-channel capacity at some locations.

RECORDS OF STREAMFLOW

Records published give the following information:

1. Station description which presents location, drainage area, type of channel, control, regulations, diversions, and available records.

2. Discharge tabulation which summarizes the maximum, minimum, and mean of the daily flow rates in second-feet for each month and the total monthly volumes in acre-feet.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions at 57 locations in the County. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The Department receives streamflow data from other agencies, or has access to the records for local stations. Data from 7 of the Department's stations are published in the United States Geological Survey's annual water supply papers.

Agencies with which the Department exchanges data are:

United States Geological Survey, Water Resource Division
United States Corps of Engineers
State Department of Water Resources
The Metropolitan Water District
San Gabriel River Water Committee

VOL 12 2 0106

LEGEND

Stations are designated by letters and numbers which indicate ownership, operation agency, and type of station. The letters used have the following connotations:

Prefix F - Indicates a station owned and operated by the Los Angeles County Department of Public Works.

Prefix E - Indicates a station owned by the Corps of Engineers, Department of the Army, but operated and maintained by the United States Geological Survey.

Prefix U - Indicates a station originally constructed and operated by the United States Geological Survey, Water Resources Division, now operated by the Department.

Prefix P - Indicates a station owned and operated by the Department, formerly operated by the Pasadena Water Department.

Prefix L - Indicates a station owned and operated by the Department, formerly owned by Little Rock Water District.

Suffix R - Indicates a recorder station.

Suffix B - Indicates that the station has been moved. B represents second location, C a third location, etc.

VOL 12 2015-1

RESERVOIRS

Following the damaging flood of 1914 and creation of the Los Angeles County Flood Control District in 1915, a program of flood control and water conservation was initiated. Part of this program included the construction of 14 dams which were completed between 1920 and 1939. These dams were operated by the Department during the period covered by this report. In addition, five Corps of Engineers' dams, Lopez, Hansen, Santa Fe, Sepulveda and Whittier Narrows Dams, and Morris Dam owned by The Metropolitan Water District were operated in conjunction with the Department dams to achieve flood control and/or water conservation.

OPERATION

The reservoirs are operated to control flood waters during storm periods. Post storm releases are made, when feasible, in amounts which can be conserved in downstream spreading grounds and by channel percolation. Cleanouts are done to regain storage capacity in reservoirs (see Erosion Control for cleanout data).

RECORDS

The storage and flow records at the 14 Department reservoirs are summarized on the Dam Operation Record Sheets. The sheets show:

1. Daily reservoir water surface elevations. Elevations are obtained from water stage recorder graphs or interpolation from staff gage readings and recorded as of midnight of each day. Only maximum and minimum water surface elevations for each year are shown.

2. Available storage in acre-feet based on the most recent topographic surveys. Annual storage volumes are shown.

3. Stream inflow rates in cubic feet per second. This is usually calculated from storage change and known outflow.

4. Outflow in cubic feet per second. These values are determined from gaging station records, or when these are not available, from valve and spillway rating curves. Only the maximum and minimum of the daily outflow rates for the year and the instantaneous peak outflow rate are shown.

5. Discrepancies between outflow and storage losses at certain dams are attributable to evaporation and/or percolation losses. Total monthly evaporation losses are determined from the measurements made on land evaporation pans. In those cases where no allowances were made for evaporation, the amounts are necessarily included in the flow values. Accuracy of flow records computed from storage records is dependent on the frequency with which storage data are revised to keep in step with the physical change in reservoirs due to sediment deposition, accumulation and removal.

EROSION CONTROL

VOL 12

2 0184

EROSION CONTROL

Each year eroded material in various forms (trees, rock, sand, etc.) flows out of the mountain watersheds of Los Angeles County. In an effort to control this potentially disruptive force, the Department maintains a series of debris basins in canyon mouths and upstream stabilization structures in selected watersheds.

DEBRIS BASINS

The purpose of a debris basin is to entrap the debris flows emanating from the canyon and let the relatively desilted water pass into the flood control channels.

In the 1991-1992 water year, there were 114 debris basins. The total maximum capacity of the basins is approximately 7,573,050 cubic yards.

The Department cleaned out fifty debris basins and removed approximately 434,200 cubic yards of sediment.

Records of sediment inflow at individual debris basins and amounts excavated and removed are available in the Hydraulic/Water Conservation Division.

STABILIZATION STRUCTURES

Stabilization structures are constructed to control erosion in natural canyons. They serve to prevent downcutting by stabilizing alluvium deposits. In addition, they store debris generated by the watershed and serve to stabilize side banks, reducing side slope sloughing and bank erosion.

The Department maintains 225 stabilization structures in 47 major watersheds. No structures have been constructed since the 1973-74 water year.

EMERGENCY STRUCTURES

Emergency structures (rail and timber, and crib type) have been constructed to entrap the debris inflow from burned watersheds. They serve to protect improvements (road, channel, residence, etc.) located immediately downstream of the watersheds. Currently, 34 emergency structures exist with a total maximum capacity of 269,600 cubic yards. One major fire (over 500 acres) burned 1323 acres in this water year and is shown on the Burned Area Location Map on page PE2.

SEDIMENT REMOVAL FROM RESERVOIRS

Sediment deposition in reservoirs reduces the storage capacities and adversely affects flood control and water conservation efforts. Sediment removal is periodically necessary and is generally an expensive effort due to large quantities, the need to deal with water inflows, and in several cases, remote locations and limited accessibility for equipment.

Where practical, the Department encourages sediment removal by permittees at no cost to the Department such as at Eaton Wash and Devil's Gate Dams.

During the 1991-92 water year the Department completed cleanouts in Cogswell Reservoir and Morris Reservoir. These are two of three reservoirs in San Gabriel Canyon which collectively contain 36 million cubic yards (cy), about three-quarters of the cumulative volume of sediment currently behind all dams under the Department's control.

Morris reservoir's cleanout consisted of a Pilot Sluicing Project. This is the first debris removed from Morris Reservoir in its 57 year history. About 435,000 cy of material was removed with this year's cleanout.

The Department has also developed a Sediment Management Plan (SMP) with the goal of maintaining current flood control and water conservation capacities at the San Gabriel Canyon Reservoirs. The SMP identifies feasible alternatives for the removal, transport, and disposal of sediment from Cogswell, San Gabriel, and Morris Reservoirs. Sediment removal alternatives identified in the SMP include sluicing, flow assisted sediment transport, dredging, trucking, use of conveyor belts, and construction of a slurry pipeline. The Department is currently preparing an environmental document to evaluate the impacts of the various sediment removal concepts.

DATA SHEET A

DEBRIS BASIN - DESIGN DATA

Including 1991-1992 Storm Season

Compiled by: Hydraulic and Water Conservation Division - Sedimentation Management
Date: December 31, 1992
FILE:DSAR92.WK4

(1) LOWEST CLEAR WATER OUTLET, NOT SPILLWAY.
(2) ELEVATION OF SPILLWAY NOTCH.
(3) FLOW LINE OF SLUICEWAY.
(4) ELEVATION OF SPILLWAY INTO OUTLET CHANNEL. ELEVATION OF OVERFLOW SPILLWAY 1036.9 FEET.
(5) ONE 30-INCH REINFORCED CONCRETE PIPE.
(6) FOUR 36-INCH CORRUGATED METAL PIPES.
(7) ONE 36-INCH REINFORCED CONCRETE PIPE. (ELEVATED INLET)
(8) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.
(9) PIT-TYPE BASIN.
(10) INFORMATION UNAVAILABLE.
(11) SPECIAL CLEANOUT REQUIRED DUE TO LIMITED STORAGE.
(12) CLEANOUT REQUIRED WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1128.9 AGAINST FACE OF DAM.
(13) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN
(14) VALUES ARE BASED ON RECENTLY APPROVED CUTPLANS OR NEW MAX. CAPACITY
(15) REDUCED CAPACITY BASED ON 5% MAX CONE SLOPE
(16) CAPACITY BASED ON "F" DRAWINGS AND IT WILL BE REVISED BASED ON A NEW TOPO MAP.
(17) BASIN BEING REPLACED WITH NEW DEBRIS BASIN DOWNSTREAM.
(18) SPILLWAY LEVEL STORAGE CAPACITY.
(19) MAXIMUM CAPACITY MAY BE MORE THAN SHOWN AND WILL BE REVIEWED.

DATA SHEET B

DEBRIS BASIN-DEBRIS PRODUCTION HISTORY

Including 1991 - 1992 Storm Season

Compiled by: Hydraulic and Water Conservation Division - Sedimentation Management
Date: December 31, 1992
FILE: DSB92.WK4.

VOL 12

(1) VOLUME OF DEBRIS DEPOSITED IN BASINS DOES NOT INCLUDE DEBRIS SLUICED THROUGH OPEN PORTS OR NOTCH.

(2) VOLUME OF DEBRIS DEPOSITED DOES NOT INCLUDE DEBRIS WHICH PASSED OVER SPILLWAY DURING THE STORMS IN 1968-69 SEASON.

(3) INCLUDING DEBRIS FROM UPSTREAM BASIN OR DAM.

(4) VOLUME OF DEBRIS DEPOSITED DOES NOT INCLUDE DEBRIS WHICH PASSED OVER SPILLWAY DURING THE STORMS IN 1977-78 SEASON.

(5) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.

(6) NO SIGNIFICANT DEBRIS INFLOWS RECORDED.

(7) NO DEBRIS RECORDS EXIST FOR THE FIRST 9 SEASONS.

(8) INFORMATION UNAVAILABLE.

(9) MAXIMUM CAPACITY MAY BE MORE THAN SHOWN AND WILL BE REVIEWED.

(10) SPECIAL CLEANOUT REQUIRED DUE TO LIMITED STORAGE

(11) SPECIAL CLEANOUT REQUIRED DUE TO BURNED WATERSHED

(12) CLEANOUT REQUIRED WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1128.9 AGAINST FACE OF DAM.

(13) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN.

(14) INCLUDING DEBRIS DATA FROM PREVIOUS BASIN.

(15) BASIN BEING REPLACED WITH NEW DEBRIS BASIN DOWNSTREAM

(16) BASIN TO BE CLEANED.

WATER QUALITY

WATER QUALITY

Since its conception, the Flood Control District (now Department of Public Works) has actively engaged in operations which have proven indispensable in preserving the integrity of our water resources, both quantity and quality, and has aided in the establishment of regulations or controlling criteria by those agencies so empowered.

Prior to March 1986, monitoring activities in the field of water quality control were conducted by the Water Quality Section of Hydraulic/Water Conservation Division. In March 1986, the responsibilities of conducting such activities were transferred to Waste Management Division as a result of the consolidation. These activities include, among others, the collection of water quality samples, their analyses, and the interpretation and reporting of the resulting data.

Areas of involvement include the monitoring of all groundwater basins through the sampling of numerous wells, the monitoring of storm and low water flows at various strategic locations on the major streams or channels, and an assumed or obligated responsibility to monitor the quality effects and subsurface travel of recharge areas, specifically the Whittier Narrows Spreading Grounds area.

The Water Quality Section, together with personnel of other Departmental divisions, also conducts investigations into pollution problems relative to our facilities, particularly those from industrial discharges, vehicle accidents, ruptured pipelines, or the indiscriminate dumping of various waste products.

The principal objectives of these investigations are to determine the degree and apparent source or origin of the pollution and to take the necessary action that will immediately abate the existing problem and possibly provide a means to prevent or limit recurrence.

Since 1986, the Water Quality Section also has been conducting the screening of proposed connections to County storm drains, and developments over County right-of-ways, for the purpose of minimizing/eliminating potential of pollutants to the storm drain waters and, thereby, to the environment.

The above-mentioned activities of the Water Quality Section have recently been intensified, particularly in the areas of interfacing and coordinating with other municipalities/cities, environmental organizations, as well as Federal and State agencies, in an effort to comply with the regulations and requirements mandated under the 1987 Clean Water Act, whereby the Department's storm drain system is under the National Pollutant Discharge Elimination System (NPDES) permitting regulations of the California Regional Water Quality Control Board (CRWQCB).

The NPDES Permit (CA0061654) issued for the storm drain system in Los Angeles County requires the development of programs to improve the quality of stormwater/urban runoff discharges into the storm drain system. Los Angeles County, represented by the Department of Public Works, is the Principal Permittee and the cities within the County are

Co-Permittees. The drainage area covered by the Permit will become active in three phases, with Phase I, the Santa Monica Bay Drainage Basin, having begun July 1, 1990.

Phase II, which involves San Fernando and San Gabriel Drainage Basins, has begun in July 1992.

The Permit requires the County, together with the cities in the County, to (a.) develop and implement a stormwater/urban runoff monitoring program to gather data on the type and source of pollutants within the drainage basin, and (b.) develop and implement Best Management Practices (BMPs) to reduce the amount of pollutants that find their way into the storm drain system.

SURFACE WATER QUALITY

Prior to 1984, dry weather samples were collected from 30 sampling stations on a monthly basis for analysis such as general minerals, bacteria, pesticides, and heavy metals. In addition, storm samples were also collected and analyzed at least three times annually from the same 30 stations during storms season.

From 1984 to 1987, as a result of reorganization, the number of surface water monitoring stations was reduced to 21, while the parameters analyzed were reduced to include only total dissolved solids, pH, and dissolved oxygen. Storm sampling activities were also significantly curtailed.

In 1988, recognizing the inadequacy of the then existing monitoring program to meet the Department's need in dealing with the important issues in the areas of water quality, the Department Administration approved and implemented an expanded monitoring program effective May 1, 1988.

There are 28 monitoring stations in the Department's current Surface Water Quality Monitoring Program, from which dry weather samples are collected and analyzed on a monthly basis. These sampling stations are strategically located throughout the Department's major storm drains and water conservation facilities where the flows are representative of typical land uses as well as areas of significant water quality concerns. Of the 28 monitoring stations in the program, six are located at the outlets to Santa Monica Bay, while one is located in the mountain area where flow is considered to be natural and uncontaminated with the various pollutants associated with urbanization and developed land uses.

Monthly dry weather samples, thus collected, are analyzed for general minerals (pH, specific conductance, total dissolved solids, total hardness, potassium sulfate, calcium, magnesium, chloride, fluoride, nitrate-nitrogen, nitrite-nitrogen, ammonium-nitrogen, phosphate-P, boron, iron, and manganese), bacteria, pesticides, heavy metals (silver arsenic, barium, cadmium, chromium, mercury, lead, selenium, copper, nickel, zinc, and chromium [VI]), oil and grease, total organic carbon, total petroleum hydrocarbons, PCB's, biochemical oxygen demand, and volatile organic compounds (TCE, carbon tetrachloride, vinyl chloride, 1,2 dichlorethene, benzene, 1,1 dichloroethylene, 1,1,1 trichloroethane, p-dichlorobenzene). In addition, storm samples are collected for three to four storms annually from 21 stations, including San Gabriel Coastal and Rio Hondo Spreading Grounds for extensive analysis similar to those for dry weather samples, with additional testing of total suspended solids and volatile suspended solids to be included. For storm samples collected at San Gabriel Coastal and Rio Hondo Spreading Grounds, priority pollutant constituents are also analyzed under an agreement with the Central and West Basin Water Replenishment District.

A selective list of total dissolved solids is shown for some of the sampling locations on the streams and channels monitored under the Surface Water Quality Program. For a conception of the analysis performed on the surface flows, a yearly compilation of constituent determination is shown for one (Los Angeles River at Wardlow) of the sampling stations in the program.

GROUNDWATER QUALITY

The annual sampling of water wells, under a selected scheduling, in five major basins in Los Angeles County comprise the Groundwater Quality Program. The program, initiated in 1970, is coordinated with the State of California Department of Water Resources and the City of Los Angeles Department of Water and Power. These agencies participate in the obtainment and analysis of samples.

All the water well samples are from active production wells used either for municipal supply, irrigation, or for industrial purposes and are selected to represent a general portrayal of basin water quality conditions. The samples taken under this program are analyzed for major minerals, total dissolved solids, electrical conductivity, pH, and in specific cases, phosphate, iron, manganese, fluoride, or boron.

WATER QUALITY DATA ACCESSIBILITY

Data acquired from the various programs are on file in the Water Quality Section. In addition, all data is accessible to any user through STORET, an Environmental Protection Agency computer system that stores, retrieves, and manipulates data using agency code 21CALAFD.

WATER CONSERVATION

R0053527

WATER CONSERVATION

Information presented in this section includes amounts of local, imported, and reclaimed water conserved in spreading areas and information on the seawater barrier projects which prevent saltwater intrusion to groundwater zones in the coastal areas. Pertinent data is presented regarding the locations and descriptions of Department water conservation facilities, a well as facilities owned by others. Also included are groundwater maps delineating static groundwater elevations recorded during the report period and hydrographs of selected key wells.

CONSERVING THE WATERS

In addition to the flood control program, the Department has the equally important task of conserving as much of the storm and other waters as practicable. The use of water conservation facilities adjacent to river channels, and in soft-bottom channels permits water to percolate into groundwater basins for later pumping. These water spreading facilities are located in areas where the underlying soils are composed of permeable formations.

The various types of water conserved, local, imported, and reclaimed, are construed to have the following meanings in this section: Local water is primarily runoff due to rainfall on the mountain and valley watersheds, dam releases, and rising water within the County. Imported water is water originating outside the County either from Northern California or from the Colorado River. Reclaimed water is the effluent produced by the Whittier Narrows Water Reclamation Plant, the San Jose Creek Water Reclamation Plant, and the Pomona Reclamation Plant, all operated by the Los Angeles County Sanitation District.

The importance of this activity is apparent when it is realized that about 30 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, has seriously depleted these supplies on numerous occasions.

The Department's policy is to conserve the maximum amount of storm water possible consistent with considering runoff quantity and quality, capacities of the spreading facilities, and groundwater conditions.

IMPORTED WATER

During this report period, imported Colorado River and State Project water for spreading was received from the Metropolitan Water District (MWD). Imported water for groundwater recharge in the Coastal Plain was spread at the Department's facilities in the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds on behalf of the Water Replenishment District of Southern California. Imported water for groundwater recharge in the San Gabriel Valley was spread in Santa Fe Spreading Grounds, in the San Gabriel River, in Irwindale Spreading Basin/Manning Pit, and in Forbes Spreading Grounds on behalf of MWD, the Main San Gabriel Basin Watermaster, Three Valleys Municipal Water District, and the San Gabriel Valley Municipal Water District.

VOL 12 2024

RECLAIMED WATER

The County Sanitation District's Whittier Narrows Water Reclamation Plant effluent, purchased by the Water Replenishment District of Southern California, was transported to the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds for groundwater replenishment.

The County Sanitation District's San Jose Creek Water Reclamation Plant, activated in May 1972, made its first delivery of effluent in November 1972. The portion of the effluent that is spread is also purchased by the Water Replenishment District of Southern California.

Water from the Pomona Reclamation Plant is released down the San Jose Creek - San Gabriel River System to the Department's recharge facilities in the Rio Hondo and San Gabriel Coastal Basin spreading grounds.

The maximum amount of reclaimed water allowed for spreading in the Montebello Forebay, effective July 1991, is 60,000 acre-feet per year, but not to exceed 150,000 acre-feet over a three year period.

SEAWATER BARRIER PROJECTS

The Department operates three barrier projects to protect the groundwater in the West Coast and Central Basins against seawater intrusion by creating freshwater pressure ridges along the coastline. The pressure ridges are created by injecting fresh water through a series of injection wells. During the report period, 22,180 acre-feet of water was injected at the West Coast Basin Barrier Project, 6,893 acre-feet at the Dominguez Gap Barrier Project, and 4,172 acre-feet at the Los Angeles part of the Alamitos Barrier Project. On behalf of the Orange County Water District, 1,553 acre-feet of water was injected at the Orange County portion of the Alamitos Barrier Project.

The following seawater barrier improvements were completed during the 1991-92 water year:

1. Alamitos Barrier Project:

   No construction activity occurred during this period.

2. Dominguez Gap Barrier Project

   Construction began on ten multizone observation wells. The geohydrologic information gathered from this drilling contract will be used for determination of the required remedial improvements for mitigating intrusion around the North-South leg of the barrier.

3. West Coast Basin Barrier Project

During this period the construction of three injection wells and two observation wells was completed. In addition, construction commenced for three injection wells and two observation wells.

These wells were constructed as part of the Department's consultant study recommendations to mitigate barrier deficiencies in the Silverado and Lower San Pedro aquifers.

SEASONAL DATA AND MAPS

During this report period, weekly, monthly, and semi-annual measurements of groundwater levels in observation wells located throughout the groundwater basins in Los Angeles County were made and processed.

Hydrographs of selected key wells are included in this report.

GROUNDWATER BASINS AND GROUNDWATER RECHARGE

Groundwater in Los Angeles County is stored in basins underlying five major geographic areas. These groundwater basins are separated by geologic features which impede groundwater movement or sometimes by arbitrary political boundaries. The following is a background summary of the Department's groundwater recharge activities within each of these areas:

The Department operates 2,436 acres of spreading grounds and soft-bottom channel spreading areas for replenishment of local groundwater supplies. The Department also assisted in the operation and maintenance of 269 acres of spreading grounds owned by others. An additional 656 acres of spreading grounds are controlled, maintained, and operated by other agencies. The total gross acreage of spreading grounds in the county is 3,361 acres. During the report period, above normal rainfall allowed the Department to conserve approximately 389,270 acre-feet of storm runoff.

The conservation of local runoff is supplemented by spreading imported water and reclaimed water purchased by water agencies. During the period, 102,505 acre-feet of imported water and 46,900 acre-feet of reclaimed water were spread.

The Department is continuing its efforts to improve its water spreading facilities in order to maximize the amounts of water conserved and to simplify the spreading operations.

SAN GABRIEL VALLEY

The Department operates 20 spreading grounds in the San Gabriel Valley that receive direct valley runoff and flows from the San Gabriel Mountains. Some of these spreading grounds can also receive imported water. During the report period, the Department added approximately 214,275 acre-feet of local water and 59,100 acre-feet of imported water to the groundwater stored in the basins underlying the San Gabriel Valley and diverted 4,933 acre-feet of local water to grounds owned by others.

Main San Gabriel Basin

This is the largest basin underlying the San Gabriel Valley with an estimated storage capacity of 9.5 million acre-feet. It reacts quickly to artificial spreading in Santa Fe Reservoir Spreading Grounds and to infiltration in the San Gabriel River Downstream of Santa Fe Dam.

During the report period, the Department replenished the Main San Gabriel Basin with 178,533 acre-feet of local water and 53,573 acre-feet of imported water. Well 3030F in Baldwin Park recorded a high groundwater elevation for the report period of 238.7 ft on July 29, 1992.

Upper San Gabriel Canyon Basin

Approximately 25,718 acre-feet of local water and approximately 4,727 acre-feet of imported water were recharged by the Department through its San Gabriel Canyon Spreading Grounds and by percolation in the adjacent San Gabriel River. Also, 2,617 acre-feet of local water was routed to Fish Canyon Spreading Grounds which is operated by the Committee of Nine.

Lower San Gabriel Canyon Basin

The basin is located south of the Upper San Gabriel Canyon Basin and is separated from it by the underground Lohmon Dike. Groundwater cascades over the Lohmon Dike from the Upper San Gabriel Canyon Basin and recharges the Lower San Gabriel Canyon Basin. The Department spread 1,217 acre-feet of local water in Sawpit Spreading Grounds which is within the Lower Canyon Basin.

Wayhill Basin

The Department spread 175 acre-feet of local water and 800 acre-feet of imported water at Forbes spreading facility in the Wayhill Basin.

Foothill Basin

The Department spread 2,375 acre-feet of local water at its San Dimas Canyon Spreading Grounds facility in the Foothill Basin.

Glendora Basin

The Department spread 977 acre-feet of local water in its Big and Little Dalton facilities within the Glendora Basin.

Claremont Heights Basin

The Department has no spreading facilities in the Claremont Heights Basin.

Live Oak Basin

The Department has no spreading facilities in the Live Oak Basin.

Chino Basin

The basin is located in the most eastern part of the County. No Department recharge facilities are located within the Chino Basin.

San Dimas Basin

The basin is north of the San Jose Hills, east of the Main Basin, and south of the Wayhill Basin. The Department spread 13 acre-feet of local water in its Live Oak Spreading Grounds to recharge the basin.

Pomona Basin

The basin is located south of Claremont, Live Oak, and San Dimas Basins, and north of the Chino Basin and northeast of the San Jose Hills. The Department has no water spreading facilities within this basin.

Puente and Spadra Basins

No spreading occurs in this area.

Raymond Basin

The basin covering approximately 40 square miles is located in the northwest corner of the San Gabriel Valley and is separated from the Main San Gabriel Basin by the Raymond Fault. The Raymond Basin contains the Monk Hill Basin and the Pasadena and Santa Anita Subareas. The Department recharged 5,266 acre-feet of local water by its spreading facilities in the Raymond Basin and diverted 2,315 acre-feet to the City of Sierra Madre's spreading facility during the report period.

COASTAL PLAIN

The groundwater basins underlying the Coastal Plain are divided by geological features into the Central (includes the Montebello and Los Angeles Forebays), West Coast, Santa Monica, and Hollywood Basins. During the period of October 1, 1991 to September 30, 1992, the Department recharged 136,608 acre-feet of local water, 42,900 acre-feet of imported water, and 46,900 acre-feet of reclaimed water to the groundwater basins underlying the Coastal Plain. Most of the water was spread in the Montebello Forebay.

Central Basin

The Central Basin has the most storage capacity of the basins in the Coastal Plain. In addition to the water recharged in the Department's spreading facilities, water injected in the Alamitos Barrier Project also contributes to the replenishment of the pressure aquifers underlying the Central Basin.

West Coast Basin

The West Coast Basin is the second largest basin underlying the Coastal Plain and is separated from the Central Basin by the Newport-Inglewood Fault zone. Groundwater is primarily recharged by Central Basin subsurface flows and by water injected by the Department in the West Coast Basin and Dominguez Gap Barrier Projects. Groundwater elevations in the West Coast Basin are below sea level except in the area of the West Coast Basin Barrier injection mound.

James M. Montgomery Consulting Engineers and Camp, Dresser and McKee, Inc., completed the West Coast Basin Saline Water Plume Mitigation Study and their final report has been accepted.

The Department spread 46 acre-feet of water in the Dominguez Spreading Grounds.

Santa Monica and Hollywood Basins

The Department has no spreading facilities in either the Santa Monica or Hollywood groundwater basins.

SAN FERNANDO VALLEY

The San Fernando Valley is also called the Upper Los Angeles River Area (ULARA). Most of the runoff from the surrounding mountains flows to the Valley.

San Fernando Main Basin

The basin is the largest basin underlying the San Fernando Valley. During the report period, 38,386 acre-feet of local water and 505 acre-feet of imported water were spread by the Department. The County entered into an agreement with the City of Los Angeles to spread water at the newly renovated Tujunga Wash Spreading Grounds which is located approximately two miles downstream of Hansen Spreading Grounds. The City installed a rubber dam diversion and appurtenant facilities for County Spreading operations which started in March 1990.

Sylmar Basin

A much smaller basin underlying the San Fernando Valley is the Sylmar Basin; the Department has no spreading facility within this basin.

Verdugo and Eagle Rock Basins

The small Verdugo and Eagle Rock Basins comprise the remaining basins underlying the San Fernando Valley. The Department has no spreading facilities within either basin.

SANTA CLARITA VALLEY

The Department has no spreading facilities in the area. Most of the Valley is farmland, permitting substantial natural percolation.

The Upper Santa Clarita subunit comprises five basins.

ANTELOPE VALLEY

There are several groundwater subbasins underlying the Antelope Valley. Five of them are located within Los Angeles County.

The Department operates no spreading facilities in the Antelope Valley.

The hydrographs for well Nos. 9974 and 8825 are shown on page G25. They are located in the Lancaster and Little Rock subbasins respectively.

COVER PHOTO: SAN GABRIEL DAM SPILLWAY

The Department of Public Works owns and maintains 14 operating dams for flood control and water conservation purposes. The largest of these is the San Gabriel Dam located in San Gabriel Canyon north of the City of Azusa. The dam was completed in 1939, drains 163.5 square miles of the San Gabriel Mountains and had an original capacity of 53,343 arce-feet. From August through December 1992, San Gabriel Reservoir, and while the dam was empty, the valve outlet tower was modified to bring up to current seismic standards. San Gabriel's sluice gate was closed on December 23, 1992 and it took about four months for the reservoir to fill and reach spillway flow in 1993. The cover photo shows the San Gabriel Dam at spillway flow of approximately 990 cfs. Snow-capped mountains in the background of the photo represent the source of the water collected by the reservoir. INTRODUCTION

This report contains hydrologic data relative to Los Angeles County for the period beginning October 1, 1993 and ending September 30, 1994. The data are presented in seven sections.

Precipitation - lists 284 active rainfall stations and presents corresponding seasonal rainfall amounts.

Evaporation - lists all locations for which evaporation data is on file and provides monthly evaporation amounts at 14 locations.

Runoff - presents the maximum, minimum, and mean of the daily flow rates for each month and the monthly volumes for 40 streamflow stations.

Dam Operation - presents the maximum and minimum of the daily inflow and outflow rates for each month, the instantaneous peak inflow and outflow rates and storage volumes for 14 dams and reservoirs.

Erosion Control - lists debris basins and debris production amounts.

Water Quality Monitoring - presents maps of surface and groundwater sampling locations, and data at selected locations.

Conservation and Groundwater - presents records of water conserved at various facilities, water injected at seawater barrier projects, well hydrographs, and Fall, 1993 static groundwater contour maps.

Where practical, data which would satisfy immediate needs and serve as useful reference are published in these reports. Several tables appear listing locations for which unpublished data are available. Additional information may be obtained by writing to:

LOS ANGELES COUNTY

TOPOGRAPHY

The County of Los Angeles covers an area of 4,083 square miles and measures approximately 66 miles in the east - west and 73 miles in the north - south directions.

The terrain within the County can be classified in broad terms as being 25 percent mountainous; 10 percent coastal plain; and 65 percent hills, valleys, or deserts. Relief of the terrain ranges from sea level to a maximum elevation of 10,000 feet. The coastal plain is generally of mild slope and contains relatively few depressions or natural ponding areas. The slopes of main river systems crossing the coastal plain, such as the San Gabriel River, Los Angeles River, and Ballona Creek, range from 4 to 14 feet per mile.

Topography in the mountainous area is generally rugged with deep, V-shaped canyons separated by sharp dividing ridges. Steepwalled canyons with side slopes of 70 percent or more are common. The gradient of principal canyons in the San Gabriel Mountains ranges from 150 to 850 feet per mile. Mountain ranges are aligned in a general east-west direction with the major range being the San Gabriel Mountains. The majority of mountain ridges lie below Elevation 5,000 feet. The total area above this level is approximately 210 square miles.

GEOLOGY - SOILS

Igneous, sedimentary, and metamorphic rock groups are all presented within the County. The San Gabriel Mountains and Verdugo Hills are composed primarily of highly fractured igneous rock, with large areas of granitic rock formation being exposed. Faulting and deep weathering have produced porous zones in the rock formation; however, rock masses have produced a comparatively shallow soil mantle due to the steepness of slopes which accelerates erosion of the fine material.

Other mountains and hilly reaches are composed primarily of folded and faulted sedimentary rocks, including shale, sandstone, and conglomerate. Residual soils in these areas are shallow and are generally less pervious than those of the San Gabriel Mountain range.

Valley and desert soils are alluvial and vary from coarse sand and gravel near canyon mouths to silty clay, clay and sand and gravel in lower valleys and the coastal plain. The alluvial fill has been built up by repeated deposition of debris to depths as great as several thousand feet. This fill is quite porous in areas of relatively low clay content. Geologic structures and irregularities in the underlying bedrock divide the alluvium into several groundwater basins. Valley soils are generally well drained but there are a few areas having perched water.

LAND USE

The principal vegetative cover of upper mountain areas consists of various species of brush and shrubs known as chaparral. Most trees found on mountain slopes are oak, with alder, willow, and sycamore found along streambeds at lower elevations. Pine, cedar, and juniper are found in ravines at higher elevations and along high mountain summits.

The alluvial fill has been built up by repeated deposition of debris to depths as great as several thousand feet. This fill is quite porous in areas of relatively low clay content. Geologic structures and irregularities in the underlying bedrock divide the alluvium into several groundwater basins. Valley soils are generally well drained but there are a few areas having perched water.

LAND USE

The principal vegetative cover of upper mountain areas consists of various species of brush and shrubs known as chaparral. Most trees found on mountain slopes are oak, with alder, willow, and sycamore found along streambeds at lower elevations. Pine, cedar, and juniper are found in ravines at higher elevations and along high mountain summits.

The chaparral is extremely flammable, and extensive burns of the mountain vegetation frequently occur during dry, low-humidity weather accompanied by high winds. Chaparral has the ability to sprout following fire and grows rapidly to re-establish the watershed cover within a period of 5 to 10 years.

Grasses are the principal natural vegetation on the hills. Much of the hill land and nearly all of the valley land in the densely populated portion of the County south of the San Gabriel Mountains has been converted to urban and suburban use. Development of the Santa Clarita Valley and desert areas to the north of the San Gabriel Mountains is sparse at present but is proceeding rapidly.

CLIMATE

The climate within the County varies between subtropical on the Pacific Ocean side of the San Gabriel Mountain range to arid in the Mojave Desert. Nearly all precipitation occurs during the months of December through March. Precipitation during summer months is infrequent, and rainless periods of several months are common. Snowfall at elevations above 5,000 feet is frequently experienced during the winter storms, but the snow melts rapidly except on higher peaks and the northern slopes. Snow is rarely experienced on the coastal plain.

January and July are the coldest and warmest months of the year, respectively. At Los Angeles, the 30-year average daily minimum temperature for January is 48 degrees above zero. The average daily maximum temperature for July is 84 degrees. At Mount Wilson (Elevation 5,850 feet), the 30-year average daily minimum temperature for January is 35 degrees above zero and the average daily maximum temperature for July is 80 degrees.

HYDROMETEOROLOGIC CHARACTERISTICS

Coastal and Mountain Areas

Precipitation in the Los Angeles area occurs primarily in the form of winter orographic rainfall associated with extratropical cyclones of North Pacific origin. Major storms consist of one or more frontal systems and occasionally last four days or longer. Air masses and frontal systems associated with major storms commonly extend for 500 to 1,000 miles in length and produce rainfall simultaneously throughout the County. Major storms approach Southern California from the west or southwest with southerly winds which continue until frontal passage. The mountain ranges lie directly across the path of the inflow of warm, moist air, and orographic effects greatly intensify precipitation.

The seasonal normal rainfall in Los Angeles County ranges from 27.50 inches in San Gabriel Mountains to 7.83 inches in the desert. The annual County average for the annual rainfall for Los Angeles County is 15.65 inches.

The effects of snowmelt upon flood runoff is of significance in the few cases when warm spring rains from southerly storms fall on a snowpack. During major storms, temperatures throughout the County may remain above freezing. Average individual storm rainfall amounts and intensities conform to a fairly definite aerial pattern which reflects general effects of topographic differences.

Desert Areas

Summer convective rainfall is principally experienced in the upper San Gabriel Mountains and the Mojave Desert regions. In many desert areas, the most serious flooding occurs as a result of summer convective storms.

RUNOFF CHARACTERISTICS

Mountain Areas

In mountain areas, the steep canyon slopes and channel gradients promote a rapid concentration of storm runoff quantities.. Depression storage and detention storage effects are minor in the rugged terrain. Soil moisture during a storm has a pronounced effect on runoff from the porous soils supporting a good growth of deeprooted vegetation such as chaparral. Soil moisture deficiency is greatest at the beginning of a rainy season, having been depleted by the evapotranspiration process during the dry summer months. Precipitation during periods of soil moisture deficiency is nearly entirely absorbed by soils, and except for periods of extremely intense rainfall, significant runoff does not occur until soils are wetted to field moisture capacity. Due to high infiltration rates and porosity of mountain soils, runoff occurs primarily as subsurface flow or interflow in addition to direct runoff. Spring or base flow is essentially limited to portions of the San Gabriel Mountain range. Consequently, most streams in the County are intermittent.

Runoff from a mountain watershed recently denuded by fire exceeds that for the unburned state due to greatly increased quantities of inorganic debris present in the flow and increased direct runoff resulting from lowered infiltration rates. Debris production from a major storm has amounted to as much as 223,000 cubic yards per square mile of watershed. Boulders up to eight feet in diameter have been deposited in valley areas a considerable distance from their source.

Debris quantities equal in volume to storm runoff, or in other words 100 percent bulking of runoff from a major storm, have been recorded. Where debris-laden flow traverses an alluvial fill unconfined by flood control works, flood discharges follow an unpredictable path across the debris cone formed at the canyon mouth.

Hill and Valley Areas

In hill areas, runoff concentrates rapidly from the generally steep slopes; however, runoff rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size. In those hill areas which have been developed for residential use, concentration times become considerably decreased due to drainage improvement, and runoff volumes and rates become increased due to increased imperviousness. On the other hand, erosion is controlled and debris is minimized from storm flows. Debris production rates from undeveloped hill areas are normally smaller than those from mountain areas of the same size.

In highly developed valley areas, local runoff volumes have increased as the soil surface has become covered by impervious materials. Peak runoff rates for valley areas have also increased due to elimination of natural ponding areas and improved hydraulic efficiency of water carriers such as streets and storm drain systems.

FLOOD CONTROL AND WATER CONSERVATION

FLOODS...AN OLD STORY

Floods in Los Angeles County have been recorded as far back as the days of the Mission Padres. For centuries waters have swept out of the San Gabriel Mountains causing extensive property damage and taking a great toll of lives.

Such a flood occurred in 1914 causing over $10 million in property damage and taking many lives. As a result, the State legislature in 1915 enacted the statute creating the Los Angeles County Flood Control District. The responsibilities and authority vested in the Flood Control District in 1985 were transferred to, and are now part of the Los Angeles County Department of Public Works.

The Department, under the Flood Control Act, has two tasks. . .control the floods and conserve the water.

CONTROLLING THE WATERS

Successful early bond issues financed construction of the 14 dams which the Department built in the San Gabriel Mountains and foothills to impound storm waters until they could be safely released. Debris basins were constructed to trap eroded materials which had caused terrible damage in the past. Flood channel improvements were undertaken to confine the waters and convey them safely through the urbanized areas to the ocean.

Department engineers prepared a Comprehensive Plan in the early 1930's which would control flooding and save as much of the water as practicable when fully implemented.

Federal legislation in 1936 brought the United States Army Corps of Engineers into the local flood control picture. Since that time, the two agencies have been jointly pursuing implementation of the Comprehensive Plan. The Department also cooperates with the United States Natural Resources Conservation Service and Forestry Service in erosion control.

CONSERVING THE WATERS

In addition to its flood control program, the Department has the equally important task of conserving as much of the storm and other waste waters as practicable. The use of water conservation facilities in or adjacent to river channels and their tributaries permits water to be percolated into groundwater reservoirs for later pumping and supply to consumers. These water conservation facilities are located in areas where the underlying soils are composed of porous sands and gravel formations. Some resemble rice paddies, while others are deep basins which were once gravel pits.

The importance of this activity is apparent when it is realized that about 30 to 40 percent of the water used in the County is pumped from ground supplies. The growth of the County, combined with periodic droughts, seriously depleted these supplies on numerous occasions throughout the history of the County.

Other major conservation efforts by the Department include combatting the serious salt water intrusion into groundwater supplies inland from the Pacific Ocean and utilizing imported water and reclaimed waters in groundwater recharge operations.

ORGANIZED TO DO THE JOB

Day-to-day administration of Department affairs is vested in the Director of Public Works who is appointed by and responsible to the Los Angeles County Board of Supervisors. A part of the Department's activities involve the planning, design and construction of flood control and water conservation facilities, and the operation and maintenance of dams, debris basins, spreading grounds, channels, and storm drains.

PRECIPITATION

VOL 12

2

0290

VOL 12 2029 1

PRECIPITATION

This section contains annual precipitation data collected by the Department for the period beginning October 1, 1993 and ending September 30, 1994 Although the Department operates and maintains 271 rainfall stations, including 199 standard and 72 automatic gages which record amounts for durations ranging from 5 minutes to 24 hours, only annual amounts for the report period are listed herein. Additional data can be obtained by contacting the custodian of hydrologic records at the location shown in the front of the report.

RAINFALL AMOUNTS

For the year, rainfall recorded at the downtown Los Angeles station (No. 716) reached 9.07 inches, or 58 percent of the long-term average of 15.51 inches. The Cogswell Dam station (No. 334B) recorded 18.92 inches for the year which is 58 percent of the long-term average of 32.88 inches.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions in the County and Southern California in real time, i.e., as they occur. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system is also now automatically receiving rainfall data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The cooperation of observers in furnishing rainfall data to the Department as a public service is appreciated. The effort of the many agencies and individuals who have so freely cooperated with us in the collection of this data have resulted in the large number of complete records for the period covered by this report.

EVAPORATION

Data for 14 active evaporation stations were reported to the Department during the 1993-94 water year. Daily records of active and inactive Department stations, as well as some stations of other agencies, are available in the Department's files. Monthly and seasonal evaporation has been published in the Department's Annual or Biennial Reports on Hydrologic Data since the 1931-32 season.

COOPERATION

The Department receives evaporation data from The Metropolitan Water District, Palmdale Water District, California Department of Water Resources, and Descanso Gardens.

LENGTH OF RECORD

The first land pan installed by this Department was at Santa Anita Dam in March 1929. There are 30 evaporation stations which have records of 15 seasons or more in the Department's files.

RUNOFF

VOL 12

2

0306

RUNOFF

The Department operated 64 water-stage recording stations and 3 witness gages during the 1993-94 water year. Data from 40 of those stations are summarized and published in this volume.

RECORDS OF STREAMFLOW

Records published give the following information:

1. Station description which presents location, drainage area, type of channel, control, regulations, diversions, and available records.

2. Discharge tabulation which summarizes the maximum, minimum, and mean of the daily flow rates in second-feet for each month and the total monthly volumes in acre-feet.

ALERT SYSTEM (AUTOMATIC LOCAL EVALUATION IN REAL TIME)

The Department of Public Works has installed a state-of-the-art ALERT computer system to monitor meteorological conditions at 59 locations in the County. The system includes a network of field sensors that monitor precipitation amounts, river stages, and reservoir levels.

During the report period, the Department has continued to install and expand its ALERT System. The Department's ALERT system also receives rainfall, streamflow, and reservoir data from the Corps of Engineers' Los Angeles Telemetry System.

COOPERATION

The Department receives or has access to streamflow data from other agencies. Data from 5 of the Department's stations are published in the United States Geological Survey's annual water supply papers.

Agencies with which the Department exchanges data are:

United States Geological Survey, Water Resource Division
United States Corps of Engineers
State Department of Water Resources
The Metropolitan Water District
San Gabriel River Water Committee

LEGEND

Stations are designated by letters and numbers which indicate ownership, operation agency, and type of station. The letters used have the following connotations:

Prefix F - Indicates a station owned and operated by the Los Angeles County Department of Public Works.

Prefix E - Indicates a station owned by the Corps of Engineers, Department of the Army, but operated and maintained by the United States Geological Survey.

Prefix U - Indicates a station originally constructed and operated by the United States Geological Survey, Water Resources Division, now operated by the Department.

Prefix P - Indicates a station owned and operated by the Department, formerly operated by the Pasadena Water Department.

Prefix L - Indicates a station owned and operated by the Department, formerly owned by Little Rock Water District.

Suffix R - Indicates a recorder station.

Suffix B - Indicates that the station has been moved. B represents second location, C a third location, etc.

RIO HONDO
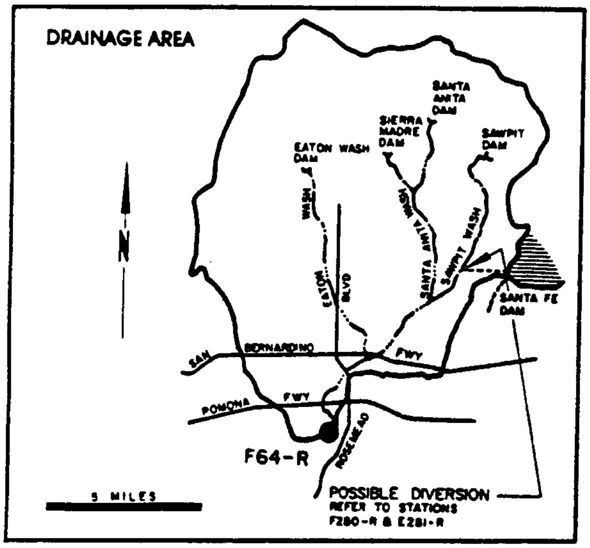
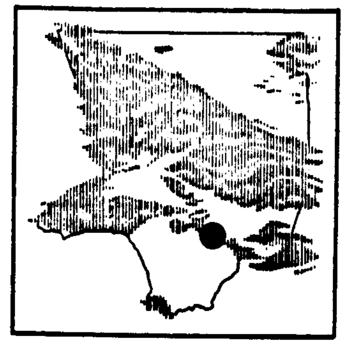
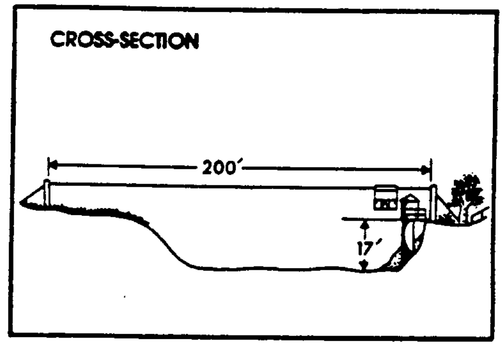
above Mission Bridge
STATION NO. F64-R







RECORDER- continuous water stage.
METHOD OF MEASUREMENTS- wading or from cable car.
DRAINAGE AREA- 115 square miles (excludes area above Santa Fe Dam).
LOCATION- 1,000 feet above San Gabriel Boulevard, west of Rosemead Boulevard, 2.0 miles northeast of Montebello.
REGULATION- partially regulated by Sierra Madre, Santa Anita, Sawpit, Eaton, and Santa Fe Dams and several debris basins.
CHANNEL- sand and silt, natural in section.
CONTROL- none.
LENGTH OF RECORD- July 1, 1928 to date.
REMARKS- subject to diversions; water purchased from the MWD passes this station for spreading in the coastal basin.

SAN GABRIEL RIVER
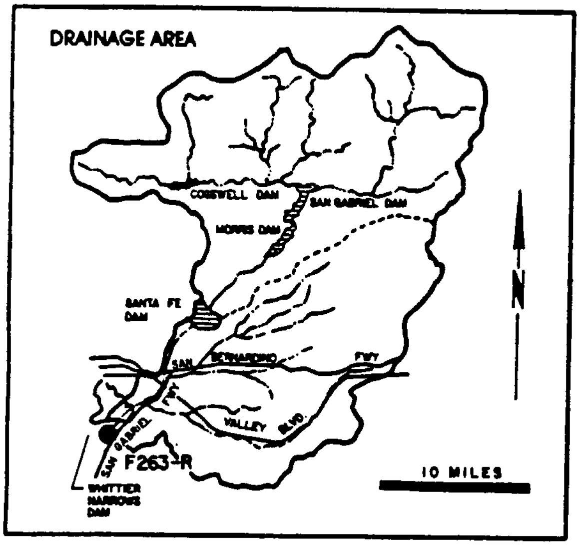
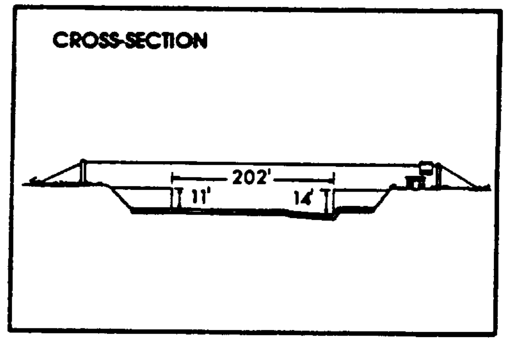
below San Gabriel River Parkway
STATION NO. F263C-R





VOL 12

2 0335

RECORDER- continuous water stage.

METHOD OF MEASUREMENTS- wading or from cable car.

DRAINAGE AREA- 206.3 square miles (excludes area above Santa Fe Dam).

LOCATION- 462.0 feet below San Gabriel River Parkway, 1.4 miles northeast of Pico Rivera.

REGULATION- partly regulated by Santa Fe, Big Dalton, Puddingstone Diversion, Puddingstone, and Thompson Creek Dams. Flows may include imported water from several Metropolitan Water District outlets. Water is at times diverted to the Zone I ditch upstream of Whittier Narrows Dam.

CHANNEL- rip-rap slopes with sand bottom trapezoidal section.

CONTROL- concrete stabilizer.

LENGTH OF RECORD - at Station F263-R February 4, 1937 to March 6, 1952. at Station F263B-R March 6, 1952 to August 9, 1968. at Station F263C-R August 9, 1968 to date.

RESERVOIRS

Following the damaging flood of 1914 and creation of the Los Angeles County Flood Control District in 1915, a program of flood control and water conservation was initiated. Part of this program included the construction of 14 dams which were completed between 1920 and 1939. These dams were operated by the Department during the period covered by this report. In addition, five Corps of Engineers' dams, Lopez, Hansen, Santa Fe, Sepulveda and Whittier Narrows Dams, and Morris Dam owned by The Metropolitan Water District were operated in conjunction with the Department dams to achieve flood control and/or water conservation.

OPERATION

The reservoirs are operated to control flood waters during storm periods. Post storm releases are made, when feasible, in amounts which can be conserved in downstream spreading grounds and by channel percolation. Cleanouts are done to regain storage capacity in reservoirs (see Erosion Control for cleanout data).

RECORDS

The storage and flow records at the 14 Department reservoirs are summarized on the Dam Operation Record Sheets. The sheets show:

1. Daily reservoir water surface elevations. Elevations are obtained from water stage recorder graphs or interpolation from staff gage readings and recorded as of midnight of each day. Only maximum and minimum water surface elevations for each year are shown.

2. Available storage in acre-feet based on the most recent topographic surveys. Annual storage volumes are shown.

3. Stream inflow rates in cubic feet per second. This is usually calculated from storage change and known outflow.

4. Outflow in cubic feet per second. These values are determined from gaging station records, or when these are not available, from valve and spillway rating curves. Only the maximum and minimum of the daily outflow rates for the year and the instantaneous peak outflow rate are shown.

5. Discrepancies between outflow and storage losses at certain dams are attributable to evaporation and/or percolation losses. Total monthly evaporation losses are determined from the measurements made on land evaporation pans. In those cases where no allowances were made for evaporation, the amounts are necessarily included in the flow values. Accuracy of flow records computed from storage records is dependent on the frequency with which storage data are revised to keep in step with the physical change in reservoirs due to sediment deposition, accumulation and removal.

VOL 12

0352

RESERVOIR CLEANOUTS

The periodical removal of Sediment is necessary in our reservoirs in order to maintain storage capacity. Sediment deposition adversely affects flood control and water conservation and storage activities in our reservoirs.

Between June 1993 and June 1994 the Department completed seven cleanouts. These cleanouts removed a total of 847,534 cyds of sediment from our reservoirs at the cost of $5.2 million. Eaton Wash Reservoir cleanout removed 314,000 CY of sediment. San Dimas Reservoir cleanout removed 87,400 CY of sediment. Santa Anita Reservoir cleanout removed 72,300 CY of sediment that was disposed of at Santa Anita SPS. Puddingstone Reservoir cleanout removed 113,600 CY of sediment. Big Dalton Sediment cleanout removed 43,000 CY of sediment that was disposed of at Dalton SPS. Live Oak removed 24,234 CY of sediment that was disposed of at Webb School. The Devil's Gate cleanout removed 193,000 CY of sediment that was disposed of at Scholl Canyon. Since the 1992 and 1993 storms were declared disaster events by the state and the federal government a portion of the total sediment inflow for these two seasons is eligible for Fema reimbursement. Currently, there are ongoing sediment removal projects at Big Tujunga, Cogswell (phase2), and Whittier Narrows. These cleanouts should restore an additional 4.9 mcy of capacity at these reservoirs at a cost of $23.2 million.

MORRIS RESERVOIR SEDIMENT TESTING

During the public review period for the San Gabriel Canyon Sediment Management Plan (SMP) Environmental Impact Statement Report/ Environmental Impact Statement a concern was raised about the possibility that the sediment within Morris Reservoir may have been contaminated by past naval activities at the facility. As a result, the Department hired a consultant to conduct a sediment testing program.

Our consultant Fugro-West, Inc. completed the Morris Reservoir sediment sampling program in October 1994. A total of 225 soil samples were collected throughout the reservoir for analytical chemistry analysis from 65 locations. Results of the analytical test data do not indicate the presence of any constituent that may be an environmental hazard. Fugro's report concludes that the sediments in the reservoir do not pose a threat to the groundwater and can be disposed of at an inert landfill.

EROSION CONTROL

EROSION CONTROL

Each year eroded material in various forms (trees, rock, sand, etc.) flows out of the mountain watersheds of Los Angeles County. In an effort to control this potentially disruptive force, the Department maintains a series of debris basins in canyon mouths and upstream stabilization structures in selected watersheds.

DEBRIS BASINS

The purpose of a debris basin is to entrap the sediment flows emanating from the canyon and let the relatively desilted water pass into the flood control channels.

In the 1993-1994 water year, the Department maintained 114 debris basins. The total maximum capacity of the basins is approximately 7,549,350 cubic yards.

The Department cleaned out 13 debris basins (Auburn, Bailey, Carriage House, Carter, Devonwood, Fair Oaks, Fern, Kinneloa West, Rubio, Sierra Madre Villa, Sunnyside, and West Ravine). The total amount of sediment removed was approximately 371,050 cubic yards.

Records of sediment inflow at individual debris basins and amounts removed from the debris basins are available in the Hydraulic/Water Conservation Division.

STABILIZATION STRUCTURES

Stabilization structures are constructed to control erosion in natural canyons. They serve to prevent downcutting by stabilizing alluvium deposits. In addition, they store debris generated by the watershed and serve to stabilize side banks, reducing side slope sloughing and bank erosion.

The Department maintains 218 stabilization structures in 47 major watersheds. No structures have been constructed since the 1973-74 water year.

EMERGENCY STRUCTURES

Emergency structures (rail and timber, crib structures are not) have been constructed to entrap the debris inflow from burned watersheds. They serve to protect improvements (road, channel, residence, etc.) located immediately downstream of the watersheds. Currently, 33 emergency structures exist with a total maximum capacity of 266,400 cubic yards. Eight major fires (over 500 acres) burned 31,331 acres in this water year and are shown on the Burned Area Location Map on page PE2.

DEBRIS BASIN - DESIGN DATA

Including 1993-1994 Storm Season

DATA SHEET A

Compiled by: Hydraulic and Water Conservation Division - Sedimentation Management
Date: November 30, 1994
FILE: DSAR94.xlw

(1) LOWEST CLEAR WATER OUTLET, NOT SPILLWAY.
(2) ELEVATION OF SPILLWAY NOTCH.
(3) FLOW LINE OF SLUICEWAY.
(4) ELEVATION OF SPILLWAY INTO OUTLET CHANNEL. ELEVATION OF OVERFLOW SPILLWAY 1036.9 FEET.
(5) ONE 30-INCH REINFORCED CONCRETE PIPE.
(6) FOUR 36-INCH CORRUGATED METAL PIPES.
(7) ONE 36-INCH REINFORCED CONCRETE PIPE. (ELEVATED INLET)
(8) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.
(9) PIT-TYPE BASIN.
(10) INFORMATION UNAVAILABLE.
(11) SPECIAL CLEANOUT REQUIRED TO LIMITED STORAGE.
(12) CLEANOUT REQUIRED WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1128.9 FEET AGAINST FACE OF DAM.
(13) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN.
(14) SPILLWAY LEVEL STORAGE CAPACITY.
(15) DATA TAKEN FROM DESIGN DRAWINGS USED FOR ENLARGING THE BASIN CAPACITY.
(16) DATA BASED ON AS-BUILT DRAWINGS.
(17) BASED ON AS-BUILT TOPOGRAPHIC MAP FOLLOWING ENLARGEMENT CONSTRUCTION.

DEBRIS BASIN-DEBRIS PRODUCTION HISTORY
Including 1993-1994 Storm Season

DATA SHEET B

Compiled by: Hydraulic and Water Conservation
Division - Sedimentatioon Management
Date: November 30, 1994
File:DSB94SHT.XLS

(1) VOLUME OF DEBRIS DEPOSITED IN BASINS DOES NOT INCLUDE DEBRIS SLUICED THROUGH OPEN PORTS OR NOTCH.
(2) VOLUME OF DEBRIS DEPOSITED IN BASINS DOES NOT INCLUDE DEBRIS WHICH PASSED OVER SPILLWAY DURING THE STORMS IN 1968-69 SEASON.
(3) INCLUDING DEBRIS FROM UPSTREAM BASIN OR DAM.
(4) VOLUME OF DEBRIS DEPOSITED IN BASINS DOES NOT INCLUDE DEBRIS WHICH PASSED OVER SPILLWAY DURING THE STORMS IN 1977-78 SEASON.
(5) DEBRIS CAPACITY AVAILABLE WITHIN RIGHT OF WAY LIMITS.
(6) NO SIGNIFICANT DEBRIS INFLOWS RECORDED.
(7) NO DEBRIS RECORDS EXIST FOR THE FIRST 9 SEASONS.
(8) INFORMATION UNAVAILABLE.
(9) MAXIMUM CAPACITY MAY BE MORE THAN SHOWN AND WILL BE REVIEWED.
(10) SPECIAL CLEANOUT REQUIRED DUE TO LIMITED STORAGE.
(11) SPECIAL CLEANOUT REQUIRED DUE TO BURNED WATERSHED.
(12) CLEANOUT REQUIRED WHEN DEBRIS REACHES OR EXCEEDS ELEV. 1128.9 FEET AGAINST FACE OF DAM.
(13) VALUES ARE COMBINED WITH COOKS DEBRIS BASIN.
(14) INCLUDING DEBRIS DATA FROM PREVIOUS BASIN.
(15) CALCULATED BASED ON THE TOTAL DEBRIS DEPOSITED IN THE BASIN DIVIDED BY THE NUMBER OF SEASONS.
(16) BASED ON DESIGN DRAWINGS USED FOR ENLARGING THE BASIN CAPACITY. THE DATA WILL BE REVISED BASED ON UPDATED TOPOGRAPHIC MAP.
(17) DEBRIS IN STORAGE DETERMINED BASED ON TOPOGRAPHIC SURVEY MAP OR FROM FIELD ESTIMATES.
(18) BASED ON AS-BUILT TOPOGRAPHIC MAP FOLLOWING ENLARGEMENT CONSTRUCTION.

WATER QUALITY

Since its conception, the Flood Control District (now Department of Public Works) has actively engaged in operations which have proven indispensable in preserving the integrity of our water resources, both quantity and quality, and has aided in the establishment of regulations or controlling criteria by those agencies so empowered.

Prior to March 1986, monitoring activities in the field of water quality control were conducted by the Water Quality Section of Hydraulic/Water Conservation Division. In March 1986, the responsibilities of conducting such activities were transferred to Waste Management Division as a result of the consolidation. These activities include, among others, the collection of water quality samples, their analyses, and the interpretation and reporting of the resulting data.

Areas of involvement include the monitoring of all groundwater basins through the sampling of numerous wells, the monitoring of storm and low water flows at various strategic locations on the major streams or channels, and an assumed or obligated responsibility to monitor the quality effects and subsurface travel of recharge areas, specifically the Whittier Narrows Spreading Grounds area.

The Water Quality Section, together with personnel of other Departmental divisions, also conducts investigations into pollution problems relative to our facilities, particularly those from industrial discharges, vehicle accidents, ruptured pipelines, or the indiscriminate dumping of various waste products.

The principal objectives of these investigations are to determine the degree and apparent source or origin of the pollution and to take the necessary action that will immediately abate the existing problem and possibly provide a means to prevent or limit recurrence.

Since 1986, the Water Quality Section also has been conducting the screening of proposed connections to County storm drains, and developments over County right-of-ways, for the purpose of minimizing/eliminating potential of pollutants to the storm drain waters and, thereby, to the environment.

The above-mentioned activities of the Water Quality Section have recently been expanded, particularly in the areas of interfacing and coordinating with other municipalities/cities, environmental organizations, as well as Federal and State agencies. In compliance with mandates under the 1987 Clean Water Act, the Department is implementing tasks required by the National Pollutant Discharge Elimination System (NPDES) municipal stormwater permit.

The NPDES Permit (CA0061654) issued for the storm drain system in Los Angeles County requires the development and implementation of programs to improve the quality of stormwater/urban runoff discharges into the storm drain system. Los Angeles County, represented by the Department of Public Works, is the Principal Permittee and the cities within the County are Co-Permittees. The drainage area covered by the Permit is divided into three phases; with Phase I, the Santa Monica Bay Drainage Basin, having begun July 1, 1990, Phase II, which involves the Upper L.A. River and Upper San Gabriel River Drainage Basins, having begun in July 1992, and Phase III, which includes the

Lower L.A. River, Lower San Gabriel River, and Santa Clarita River Drainage Basins, initiated in July 1993.

The Permit requires the County, together with the cities to develop and implement a stormwater/urban runoff monitoring program to gather data on the type and source of pollutants within the drainage basins. The permit also requires the development and implementation of Best Management Practices (BMPs) to reduced the amount of pollutants that find their way into the storm drain system and to implement procedures to detect and eliminate illegal discharges.

SURFACE WATER QUALITY

Prior to 1984, dry weather samples were collected from 30 sampling stations on a monthly basis for analysis such as general minerals, bacteria, pesticides, and heavy metals. In addition, storm samples were also collected and analyzed at least three times annually from the same 30 stations during storms season.

From 1984 to 1987, as a result of reorganization, the number of surface water monitoring stations was reduced to 21, while the parameters analyzed were reduced to include only total dissolved solids, pH, and dissolved oxygen. Storm sampling activities were also significantly curtailed.

In 1988, recognizing the inadequacy of the then existing monitoring program to meet the Department's need in dealing with the important issues in the areas of water quality, the Department Administration approved and implemented an expanded monitoring program effective May 1, 1988.

There are 28 monitoring stations in the Department's current Surface Water Quality Monitoring Program, from which dry weather grab samples are collected and analyzed on a monthly basis. These sampling stations are strategically located throughout the Department's major storm drains and water conservation facilities where the flows are representative of typical land uses as well as areas of significant water quality concerns. Of the 28 monitoring stations in the program, six are located at the outlets to Santa Monica Bay, while one is located in the mountain area where flow is considered to be natural and uncontaminated with the various pollutants associated with urbanization and developed land uses.

Monthly dry weather grab samples, thus collected, are analyzed for general minerals (pH, Specific Conductance, Total Dissolved Solids, total Hardness, Potassium Sulfate, Calcium, Magnesium, Chloride, Fluoride, Nitrate-Nitrogen, Nitrite-Nitrogen, Ammonium-Nitrogen, Phosphate-P, Boron, Iron, and Manganese), bacteria, pesticides, heavy metals (Silver Arsenic, Barium, Cadmium, Chromium, Mercury, Lead, Selenium, Copper, Nickel, Zinc, and Chromium [VI]), Oil and Grease, Total Organic Carbon, Total Petroleum Hydrocarbons, PCB's, Biochemical Oxygen Demand, and Volatile Organic Compounds (TCE, Carbon Tetrachloride, Vinyl Chloride, 1,2 Dichloroethene, Benzene, 1,1 Dichloroethylene, 1,1,1 Trichloroethane, p-Dichlorobenzene). In addition, storm samples (also grab) are collected for three to four storms annually from 21 stations, including San Gabriel Coastal and Rio Hondo Spreading Grounds for extensive analysis similar to those for dry weather samples, with additional testing of Total suspended Solids and Volatile Suspended Solids to be included For storm samples collected at San Gabriel Coastal and Rio Hondo Spreading Grounds, priority pollutant constituents are also analyzed under an agreement with the Central and West Basin Water Replenishment District.

A selective list of total dissolved solids is shown for some of the sampling locations on the streams and channels monitored under the Surface Water Quality Program. For a conception of the analysis performed on the surface flows, a yearly compilation of constituent determination is shown for one (Los Angeles River at Wardlow) of the sampling stations in the program.

Beginning in early 1994, a more extensive Stormwater/Urban runoff Monitoring program utilizing automated sampling was established as required by the National Pollutant Discharge Elimination System (NPDES) Municipal Stormwater Permit. This program calls for installation of automated samplers within all major drainage basins, beginning with the Santa Monica Bay Drainage Basin, to collect flow-composite samples to better characterize sampling events. Nine (9) automated monitoring stations within the Santa Monica Bay Drainage Basin have been constructed from which data collection began in the 1994-95 storm season. While this new monitoring program is developing, the existing monitoring program will be maintained.

GROUNDWATER QUALITY

The Department's Groundwater Monitoring Program, which was initiated in the 1970's underwent thorough reevaluation in September 1993, and January 1994, to eliminate duplication of analyses among participating agencies. It was determined that the majority of the 314 wells in the program were already being sampled by the various watermasters within the County. The Department has discontinued its annual sampling activities for the program. However, we maintain the existing groundwater quality records and, upon request, provide the data to the public.

WATER, QUALITY DATA ACCESSIBILITY

Data acquired from the various programs are on file in the Water Quality Section. In addition, all data is accessible to any user through STORET, an Environmental Protection Agency computer system that stores, retrieves, and manipulates data using agency code 21CALAFD.

WATER CONSERVATION

WATER CONSERVATION

Information presented in this section includes amounts of local, imported, and reclaimed water conserved in spreading areas and information on the seawater barrier projects which prevent saltwater intrusion into groundwater zones in the coastal areas. Pertinent data is presented regarding the locations and descriptions of the Department's water conservation facilities, a well as facilities owned by others. Also included are groundwater maps delineating static groundwater elevations recorded during the report period and hydrographs of selected key wells.

CONSERVING THE WATERS

In addition to the flood control program, the Department has the equally important task of conserving as much of the storm and other waters as practicable. The use of water conservation facilities adjacent to river channels, and in soft-bottom channels permits water to percolate into groundwater basins for later pumping. These water spreading facilities are located in areas where the underlying soils are composed of permeable formations.

The various types of water conserved, local, imported, and reclaimed, are construed to have the following meanings in this section: Local water is primarily runoff due to rainfall on the mountain and valley watersheds, dam releases, and rising water within the County. Imported water is water originating outside the County either from Northern California or from the Colorado River. Reclaimed water is the effluent produced by the Whittier Narrows Water Reclamation Plant, the San Jose Creek Water Reclamation Plant, and the Pomona Reclamation Plant, all operated by the Los Angeles County Sanitation District.

The importance of this activity is apparent when it is realized that about 30 to 40 percent of the water used in the County is pumped from groundwater-supplies. The growth of the County, combined with periodic droughts, has seriously depleted these supplies on numerous occasions.

The Department's policy is to conserve the maximum possible amount of storm water consistent with runoff quantity and quality, capacities of the spreading facilities, and groundwater conditions.

IMPORTED WATER

During this report period, imported Colorado River and State Project water for spreading was received from the Metropolitan Water District (MWD) for spreading-Imported water in the Coastal Plain was spread at the Department's facilities in the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds on behalf of the Water Replenishment District of Southern California. Imported water in the San Gabriel Valley was spread in Santa Fe Spreading Grounds, in the San Gabriel River, in Irwindale Spreading Basin/Manning Pit, and in Forbes Spreading Grounds on behalf of the Upper San Gabriel Valley Municipal Water District, and the San Gabriel Valley Municipal Water District.

RECLAIMED WATER

The County Sanitation District's Whittier Narrows Water Reclamation Plant effluent, purchased by the Water Replenishment District of Southern California, is transported to the Rio Hondo and San Gabriel Coastal Basin Spreading Grounds for groundwater replenishment.

The County Sanitation District's San Jose Creek Water Reclamation Plant, made its first delivery of effluent in November 1972. The portion of the effluent that is spread is also purchased by the Water Replenishment District of Southern California.

Water from the Pomona Reclamation Plant is released down the San Jose Creek - San Gabriel River System to the Department's recharge facilities in the Rio Hondo and San Gabriel Coastal Basin spreading grounds.

The maximum amount of reclaimed water allowed for spreading in the Montebello Forebay, effective July 1991, is 60,000 acre-feet per year, but not to exceed 150,000 acre-feet over a three year period.

SEAWATER BARRIER PROJECTS

The Department operates three barrier projects to protect the groundwater in the West Coast and Central Basins against seawater intrusion by creating freshwater pressure ridges along the coastline. The pressure mound are created by injecting fresh water through a series of injection wells. During the report period, 15,482 acre-feet of water was injected at the West Coast Basin Barrier Project, 5,527 acre-feet at the Dominguez Gap Barrier Project, and 3,677 acre-feet at the Los Angeles part of the Alamitos Barrier Project. On behalf of the Orange County Water District, 1,309 acre-feet of water was injected at the Orange County portion of the Alamitos Barrier Project.

The following seawater barrier improvements were completed during the 1993-94 water year:

1. Alamitos Barrier Project:

   Orange County Water District drilled 4 new injection wells.

   Two injection wells were pressure-grouted to mitigate surface leakage problems.

   41 observation well manholes were modified by retrofitting them with 9-inch watertight vaults.

2. Dominguez Gap Barrier Project

   Construction was completed on ten multizone observation wells. The geohydrologic information gathered from this drilling contract will be used for determination of the required remedial improvements for mitigating intrusion around the North-South leg of the barrier.

   A consultant study based on strontium isotopes 86/87 ratios was conducted to eliminate oil field brines and other salt sources as contaminants. The study also identified and better defined seawater intrusion paths.

3. West Coast Basin Barrier Project

   During this period the construction of three injection wells and thirteen observation wells was completed.

These wells were constructed as part of the Department's consultant study recommendations to mitigate barrier deficiencies in the Silverado and Lower San Pedro aquifers.

SEASONAL DATA AND MAPS

During this report period, weekly, monthly, and semi-annual measurements of groundwater levels in observation wells located throughout the groundwater basins in Los Angeles County were made and processed.

Hydrographs of selected key wells are included in this report.

GROUNDWATER BASINS AND GROUNDWATER RECHARGE

Groundwater in Los Angeles County is stored in basins underlying five major geographic areas. These groundwater basins are separated by geologic features which impede groundwater movement or by political boundaries. The following is a background summary of the Department's groundwater recharge activities within each of these areas:

The Department operates 2,436 acres of spreading grounds and soft-bottom channel spreading areas for replenishment of local groundwater supplies. The Department also assisted in the operation and maintenance of 269 acres of spreading grounds owned by others. An additional 656 acres of spreading grounds are controlled, maintained, and operated by other agencies. The total gross acreage of spreading grounds in the County is 3,361 acres. During the report period, below normal rainfall allowed the Department to conserve approximately 117,260 acre-feet of storm runoff.

The conservation of local runoff is supplemented by spreading imported water and reclaimed water purchased by water agencies. During the report period, 56,041 acre-feet of imported water and 53,982 acre-feet of reclaimed water were spread.

The Department is continuing its efforts to improve its water spreading facilities in order to maximize the amounts of water conserved and to simplify the spreading operations.

SAN GABRIEL VALLEY

The Department operates 20 spreading facilities in the San Gabriel Valley that receive direct valley runoff and flows from the San Gabriel Mountains. Some of these spreading facilities can also receive imported water. During the report period, the Department added approximately 51,200 acre-feet of local water and 36,541 acre-feet of imported water to the groundwater stored in the basins underlying the San Gabriel Valley and diverted 2,618 acre-feet of local water to grounds owned by others.

Main San Gabriel Basin

This is the largest basin underlying the San Gabriel Valley with an estimated storage capacity of 9.5 million acre-feet. It reacts quickly to artificial spreading in Santa Fe Reservoir Spreading Grounds and to infiltration in the San Gabriel River downstream of Santa Fe Dam.

During the report period, the Department replenished the Main San Gabriel Basin with 37,883 acre-feet of local water and 30,981 acre-feet of imported water. Well 3030F in Baldwin Park recorded a high groundwater elevation for the report period of 259.6 ft on October 20, 1993.

The following improvements were constructed in the Upper San Gabriel Canyon Basin during 1993-94 water year:

San Gabriel Canyon Spreading Grounds - Improvements completed consisted of grading and lining of portions of the inlet canal, construction of an interbasin structure, a canal diversion structure into Basin 1, and the extension of the Basin 2 intake structure. These improvements increase flow capacity, reduced weed growth and erosion, minimized maintenance reqirements, and eliminated debris plugging the trashrack and the resulting washouts that have previously occurred.

Upper San Gabriel Canyon Basin

Approximately 6,931 acre-feet of local water and approximately 4,660 acre-feet of imported water were recharged by the Department through its San Gabriel Canyon Spreading Grounds and by percolation in the adjacent San Gabriel River. Also, 1,744 acre-feet of local water was routed to Fish Canyon Spreading Grounds, which is operated by the Committee of Nine.

Lower San Gabriel Canyon Basin

The basin is located south of the Upper San Gabriel Canyon Basin and is separated from it by the underground Lohmon Dike. Groundwater cascades over the Lohmon Dike from the Upper San Gabriel Canyon Basin and recharges the Lower San Gabriel Canyon Basin. The Department spread 995 acre-feet of local water in Sawpit Spreading Grounds which is within the Lower Canyon Basin.

Wayhill Basin

The Department spread 461 acre-feet of local water and 900 acre-feet of imported water at Forbes spreading facility in the Wayhill Basin.

Foothill Basin

The Department spread 3,034 acre-feet of local water at its San Dimas Canyon Spreading Grounds facility in the Foothill Basin.

Glendora Basin

The Department spread 198 acre-feet of local water in its Big and Little Dalton facilities within the Glendora Basin.

Claremont Heights Basin

The Department has no spreading facilities in the Claremont Heights Basin.

VOL 12 2 0421

Live Oak Basin

The Department has no spreading facilities in the Live Oak Basin.

Chino Basin

The basin is located in the most eastern part of the County. No Department recharge facilities are located within the Chino Basin.

San Dimas Basin

The basin is north of the San Jose Hills, east of the Main Basin, and south of the Wayhill Basin. The Department spread 136 acre-feet of local water in its Live Oak Spreading Grounds to recharge the basin.

Pomona Basin

The basin is located south of Claremont, Live Oak, and San Dimas Basins, and north of the Chino Basin and northeast of the San Jose Hills. The Department has no water spreading facilities within this basin.

Puente and Spadra Basins

No spreading occurs in this area.

Raymond Basin

The basin covering approximately 40 square miles is located in the northwest corner of the San Gabriel Valley and is separated from the Main San Gabriel Basin by the Raymond Fault. The Raymond Basin contains the Monk Hill Basin and the Pasadena and Santa Anita Subareas. The Department recharged 2,634 acre-feet of local water by its spreading facilities in the Raymond Basin and diverted 874 acre-feet to the City of Sierra Madre's spreading facility during the report period.

COASTAL PLAIN

The groundwater basins underlying the Coastal Plain are divided by geological features into the Central (includes the Montebello and Los Angeles Forebays), West Coast, Santa Monica, and Hollywood Basins. During this report period, the Department recharged 43,463 acre-feet of local water, 19,500 acre-feet of imported water, and 53,982 acre-feet of reclaimed water to the groundwater basins underlying the Coastal Plain. Most of the water was spread in the Montebello Forebay.

Central Basin

The Central Basin has the most storage capacity of the basins in the Coastal Plain. In addition to the water recharged in the Department's spreading facilities, water injected in the Alamitos Barrier Project also contributes to the replenishment of the pressure aquifers underlying the Central Basin.

The following project was constructed in the Central Basin during 1993-94 water year:

> Rio Hondo Coastal Basin Spreading Grounds - Replaced approximately 3,600 feet of open drainage ditch, which previously experienced severe erosion and seepage problems, with a 72-inch reinforced concrete pipe.

West Coast Basin

The West Coast Basin is the second largest basin underlying the Coastal Plain and is separated from the Central Basin by the Newport-Inglewood Fault zone. Groundwater is primarily recharged by Central Basin subsurface flows and by water injected by the Department in the West Coast Basin and Dominguez Gap Barrier Projects. Groundwater elevations in the West Coast Basin are below sea level except in the area of the West Coast Basin Barrier injection mound.

Santa Monica and Hollywood Basins

The Department has no spreading facilities in either the Santa Monica or Hollywood groundwater basins.

SAN FERNANDO VALLEY

The San Fernando Valley is also called the Upper Los Angeles River Area (ULARA). Most of the runoff from the surrounding mountains flows to the Valley.

San Fernando Main Basin

The basin is the largest basin underlying the San Fernando Valley. During the report period, 19,980 acre-feet of local water and no imported water were spread by the Department. The County entered into an agreement with the City of Los Angeles to spread water at the newly renovated Tujunga Wash Spreading Grounds which is located approximately two miles downstream of Hansen Spreading Grounds. The City installed a rubber dam diversion and appurtenant facilities for County Spreading operations which started in March 1990.

Sylmar Basin

A much smaller basin underlying the San Fernando Valley is the Sylmar Basin; the Department has no spreading facility within this basin.

Verdugo and Eagle Rock Basins

The small Verdugo and Eagle Rock Basins comprise the remaining basins underlying the San Fernando Valley. The Department has no spreading facilities within either basin.

SANTA CLARITA VALLEY

The Department has no spreading facilities in the area. Most of the Valley is farmland, permitting substantial natural percolation.

The Upper Santa Clarita subunit comprises five basins.

VOL 12

2 0423

ANTELOPE VALLEY

There are several groundwater subbasins underlying the Antelope Valley. Five of them are located within Los Angeles County.

The Department operates no spreading facilities in the Antelope Valley.

The hydrographs for well Nos. 9974 and 8825 are shown on pages G41 and G43. They are located in the Lancaster and Little Rock subbasins respectively.

' DATA ON SPREADING FACILITIES
VNED BY THE DEPARTMENT
) THROUGH SEPTEMBER 1994

)N°	LOCATION	SOURCE OF WATER	REMARKS
	CITY OF SIERRA MADRE, SOUTH SIDE OF GRANDVIEW AVENUE, ONE HALF MILE WEST OF SANTA ANITA AVENUE	LITTLE SANTA ANITA CREEK AND STREET RUNOFF ALSO CONTROLLED FLOWS FROM SANTA ANITA DAM.	THE DEPARTMENT DIVERTS WATER TO THIS FACILITY.
	WESTERLY SIDE OF SAN GABRIEL RIVER BELOW MOUTH OF FISH CANYON AND NORTH OF THE CITY OF AZUSA.	THE 'COMMITTEE OF NINE'.	OWNED AND OPERATED BY CAL-AMERICAN WATER COMPANY.
	SOUTHERLY FROM, AND ADJACENT TO THOMPSON CREEK DAM, EAST SIDE OF CREEK. ELEVATION 1,625.	COBAL, WILLIAMS, PALMER, AND PADUA CREEKS, ALSO THOMPSON CREEK WHEN RESERVOIR ABOVE	OPERATED BY POMONA VALLEY PROTECTIVE ASSOCIATION. THE DEPARTMENT DIVERTS WATER TO THIS FACILITY.
	SAN FERNANDO VALLEY, EAST SIDE OF TUJUNGA WASH AT ROSCOE BOULEVARD.	LOS ANGELES CITY'S OWENS VALLEY AQUEDUCT AND CONTROLLED RELEASES FROM HANSEN DAM.	THE DEPARTMENT ENTERED INTO AN AGREEMENT WITH THE CITY OF LOS ANGELES TO OPERATE THIS FACILITY.

Illicit Discharge Investigations

Program Element

Illicit Discharge Investigations in Priority Area

Program Goal

An effective illicit discharge investigation program should detect the presence, identify the source, and plan the control of illicit discharges to co-permittee storm drain systems and/or receiving waters. Co-permittee programs that follow this Countywide approach to illicit discharge investigations should achieve the following objectives:

- Investigate locations where illicit discharges are commonly found.
- Thoroughly inspect these areas for evidence of illicit discharges.
- Accurately record observations and conduct sampling.
- Use appropriate efforts to identify sources of illicit discharges.
- Plan appropriate follow-up actions.

Background

Why Implement This Program?

Illicit discharges, as defined by the federal regulations are *any discharge to a municipal separate storm sewer that is not composed entirely of stormwater except discharges pursuant to a NPDES permit (other than the NPDES permit for discharges from the municipal separate storm sewer) and discharges relating to fire fighting activities.* Illicit discharges are caused by activities ranging from car washing and lawn watering to practices such as illicit connections of sanitary sewers to storm drains and dumping used oil into storm drains.

Illicit discharges are flows not composed entirely of storm water.

Under the Ventura County stormwater NPDES permit, certain discharges are prohibited outright, while others are prohibited if, in the judgment of the Regional Board or the municipality, they cause specific receiving water limit violations or constitute a significant pollutant discharge. The permit requires municipalities to detect, identify, and manage significant illicit discharges to their municipal storm drain systems.

The 1981 Nationwide Urban Runoff Program (NURP), an extensive survey of the nation's municipal storm drain systems, concluded that illicit discharges have the potential to adversely affect the quality of urban runoff. Since that time, further investigations into illicit discharges have shown that large amounts of wastes are improperly discarded into storm drains. Recent field inspection results verify that illicit discharges are not uncommon in Ventura County.

Table 1
Common Sources of Illicit Discharges

- Sanitary wastewater
- Septic tank effluent
- Household chemicals
- Gasoline filling stations
- Vehicle maintenance/repair
- Laundry wastewater
- Carpet cleaning wastewater
- Acid wash water
- Leaking tanks and pipes
- Miscellaneous process waters
- Loading docks
- Motor oil
- Wet sanding operation runoff
- Solvents
- Steam cleaning runoff
- Outside storage
- Landscape runoff
- Leaking air compressors

What Discharges are Illicit or Unacceptable?

The majority of observations of illicit discharges are found in older residential areas and areas used for industrial or commercial activities. Recent EPA guidance on illicit discharge investigations (1993), the California Storm Water BMP Handbook (1993) and the pilot illicit discharge control program conducted by Simi Valley have identified potential inappropriate entries into storm drainage systems from residential, commercial, and industrial areas. Table 1 summarizes common sources of illicit discharges.

What Illicit Discharges Are Conditionally Acceptable?

In general, illicit discharges are prohibited from entering storm drainage systems without an NPDES permit. This prohibition does not apply to the illicit discharges identified in the Ventura County permit (Table 2), unless the Regional Board determines that these discharges cause specific receiving water limit violations.

Table 2
Conditionally Acceptable Illicit Discharges

- water line flushing
- landscape irrigation
- diverted stream flows
- rising groundwater
- uncontaminated ground water infiltration to storm drains
- uncontaminated pumped groundwater
- discharges from potable water sources
- foundation drains
- air conditioning condensation
- irrigation water
- natural springs
- water from crawl space pumps
- footing drains
- lawn watering
- individual residential car washing
- riparian habitat/wetland flows
- dechlorinated swimming pool discharges
- discharges or flows from emergency fire fighting activities
- other types of illicit discharges identified in annual reports by the Countywide Program, as approved by the Regional Board

Table 3
Target Businesses for Illicit Discharge Investigations

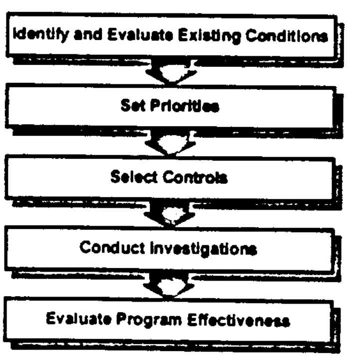
- gas stations
- automobile service facilities
- commercial laundries
- carpet cleaners
- painting contractors
- metal finishing facilities
- pool cleaning operations
- salvage yards
- recycling facilities
- restaurants
- machine shops
- facilities with outside storage

Who Is the Program Audience?

While investigations into illicit discharges must address the entire drainage system, initial investigations should target older residential areas and certain businesses where illicit discharges commonly occur. Illicit discharge investigations by Simi Valley and other communities found that the business categories listed in Table 3 are often sources of illicit discharges and should be targeted by an illicit discharge control program.

Countywide Program Approach

This section describes the suggested Countywide approach for the Illicit Discharge Investigation Program. The approach draws from USEPA's User's Guide; previous illicit discharge investigations by the Cities of Stockton, Oxnard, and Salinas; and the pilot Illicit Discharge Control Program conducted in Simi Valley. An overview of this approach appears next, followed by a detailed discussion of each step of the approach.



The figure on the left illustrates the Countywide Approach to illicit discharge investigations. This approach involves five steps:

1. *Identify and evaluate existing conditions.* Getting ready for an illicit discharge inspection program involves obtaining and reviewing available data about storm drains, land uses, and pollutant sources, and coordinating with other agencies responsible for investigating and regulating pollution.

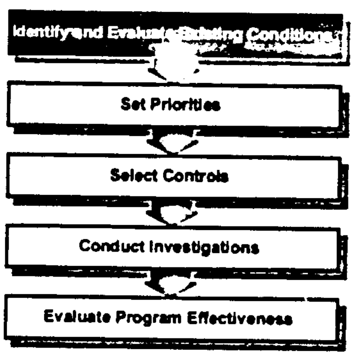
2. *Set Priorities.* Activities most likely to cause illicit discharges should be investigated first, and investigation and sampling procedures should be appropriate for these activities.

3. *Select Controls.* Illicit discharge control will begin with distribution of educational flyers to parties most likely to cause illicit discharges, with followup action based on field observations.

4. *Conduct Investigations.* Illicit discharge investigations involve field inspections, field testing, record keeping, tracking discharge sources, field data analysis, followup investigations, and control verification.

5. *Evaluate Program Effectiveness.* Evaluation and reporting of program effectiveness demonstrates permit compliance and improves future investigations.

Each co-permittee has already completed the first two steps of this approach and has selected priority targets for illicit discharge investigations during 1995. Volume 1 of the Ventura Countywide NPDES Stormwater Permit Application describes the selection process and priority targets. Findings are summarized below. Each co-permittee should follow the remaining steps to complete illicit discharge investigations within priority areas during 1995. The entire approach should then be repeated in subsequent years.



Identify and Evaluate Existing Conditions

This section describes information that should be reviewed before starting illicit discharge investigations. Much of this information is found in Volume 1 of the Countywide permit application. This volume contains information on established public agency programs, pollutant types and possible sources, business groups, land use, drainage patterns, and receiving waters. Volume 1 also identifies locations that the co-permittees will investigate for illicit discharges during FY 1994/95. The co-permittees should review and revise this information as needed to establish investigation priorities in subsequent years of the permit term.

Evaluation of Available Data

Illicit discharge investigations begin with review of available information about the drainage system and potential sources of pollution. The permit application contains maps of storm drains, land use, and significant known pollutant sources, lists of industries, and other types of information about stormwater pollution. Table 4 lists additional types of information that should be reviewed before field investigations begin. Using inadequate information may result in the inspection of areas less likely to produce illicit discharges or the omission of areas from inspection which have a high likelihood of illicit discharges. Some of the information in Table 4 may not be pertinent to a particular storm drain system or may be unavailable. Additional sources or types of information may be identified by each co-permittee.

The initial data collection effort should produce adequate information to perform an informed analysis and prioritization of areas most likely to contain illicit discharges.

VOL 12

Several public agencies have jurisdiction over the dischargers that will be of concern to the co-permittees and should be contacted during the initial data collection effort.

Coordination with Established Programs

The public agencies listed in Table 4 often have jurisdiction over possible sources of illicit discharges and should be contacted during the initial data collection effort. For example, the Environmental Health Department may have data concerning spill control plans and hazardous materials inventories for local businesses. Local Fire Departments may also be a source of information on spill management and hazardous materials storage at local businesses. Wastewater industrial pretreatment programs will have wastewater monitoring data and information on facility operations from their industrial inspection program. They may also have information on smaller commercial businesses from their pollution prevention programs or their industrial user surveys. The Air Quality Management Control District conducts inspections of businesses looking for sources of air pollution and may have information that would be useful for identifying sources of illicit

Table 4
Potential Data Requirements for Illicit Discharge Control Program

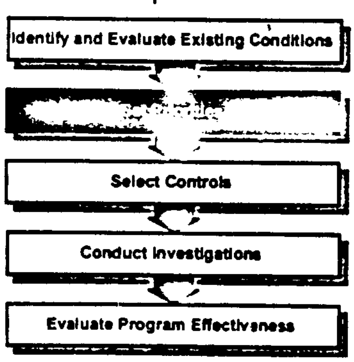
Information Source	Type of Information Available
Ventura County Environmental Health Department	List of landfills List of hazardous waste TSDR facilities Hazardous Material Inventories for local businesses
Local Fire Departments	Fire Department chemical storage inspection records Spill reports
Pretreatment/Source Control Programs	Existing receiving water quality and urban runoff data List of industries, locations, and contacts Spill reports and spill prevention plans Process and chemical storage information
Air Pollution Control District	List of industries, locations, and contacts
Water Conservation Programs	Storm drain maintenance records Water use records Existing receiving water quality and urban runoff data
Public Works Department	Storm drain maintenance records Land use maps Storm drain system maps (including detention basins, if any) Topographic maps Maps of existing septic systems Current business licenses
Regional Water Quality Control Board	List of NPDES permittees discharging to the storm drain

2 0490

R0053795

discharges. Water conservation programs may be able to provide water usage records and may be helpful in identifying and preventing discharges to the storm drains. Public Works Departments may be able to provide maintenance records that may describe evidence of illicit discharges.

There are distinct reasons to coordinate illicit discharge investigations and related activities of other agencies. Most businesses are inspected by several public agencies, each with its own set of requirements and regulations. As a result there are often contradictions between the various agencies' requirements that can make compliance difficult and confusing for a business. This issue was pointed out by several businesses that were inspected during the pilot program. There may be opportunities to work with other agencies to combine inspections or minimize any apparent inconsistencies between programs. Working with other agencies may also optimize the use of limited resources and allow a more unified message to be delivered to the community.



Set Priorities

To be most effective, initial investigations should be conducted in locations where illicit discharges are most likely to occur. This section describes how the data collected in the first step can be used to define priority locations for illicit discharge investigations. This approach was used by most co-permittees to define locations for illicit discharge investigations during 1995, as discussed in the permit application. Each year, the co-permittees should review and revise program priorities to select locations for subsequent illicit discharge investigations.

The prioritization process prescribed for Ventura County begins with organization of the data collected during the evaluation of existing conditions. The data are first organized by drainage basin (drainage basins are subunits of each city's watershed). Then basins are compared according to criteria about illicit discharges selected from available data and previous field experience. Basins are ranked from highest to lowest probability of containing illicit discharges using a matrix like the following one.

Basin	Criteria			Overall Score	Rank

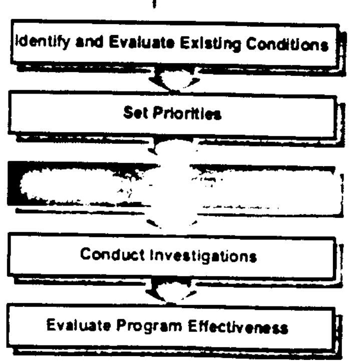
Criteria based on actual observations are given higher scores. Once scores are given, overall scores are tabulated for each basin. The basins are then ranked in order of highest overall score (sum of individual characteristics scores) to the lowest overall score. The highest ranked drainage basins are the first areas investigated for illicit discharges. This method is described in more detail in Attachment 1.

Ranking of drainage basins was conducted by the co-permittees at the end of 1993 using, for the most part, the matrix approach. The following criteria were used to rank basins:

- Industrial area fraction
- Commercial area fraction
- Density of residential areas
- Types of industry/commercial business (e.g., automotive related)
- Older areas (base date on changes to plumbing code, other factors)
- Areas with hazardous material storage
- Number of previously-observed illicit discharges
- Frequency of spill reports
- Density of septic systems

Table 5 lists locations selected by each co-permittee for illicit discharge investigations using this approach. In some cases, the co-permittees included additional criteria based on personal knowledge of activities undertaken in the watershed, or excluded some criteria, such as number of spills reported, due to lack of information. The City of Camarillo based their prioritization almost exclusively on land use and age of facilities, since no information was available on hazardous materials storage, illicit discharges, or spills. The City of Santa Paula had more information but decided to conduct illicit discharge investigations at certain high priority businesses (e.g., automotive businesses, transportation businesses, and hazardous materials handlers) regardless of location.

It is interesting to note which basin characteristics weighed prominently in determining the high priority drainage basins. Fraction of industrial area, age of facilities and infrastructure, and hazardous materials storage appear to be the common determining factors.



Select Controls

Once the high-priority basins have been identified, potential or existing sources of illicit discharges can be targeted for control. Some of the potential sources were listed earlier as the "target audience" and include automobile service facilities, painting contractors, carpet cleaners and pool cleaning operations. Appropriate best management practices (BMPs) are required to effectively control on-site pollutant generating

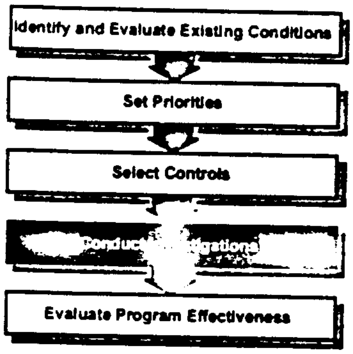
Table 5
Characteristics of the High Priority Drainage Basins

Co-permittee	Characteristics of the High Ranked Basins	Highest Priority Basin [1]
Camarillo	Older facilities and infrastructure, large number of automotive-related businesses	Basin 12
County of Ventura	Older facilities and presence of septic systems	Black Canyon
Fillmore	Older facilities and infrastructure	Between Ventura St. and Railroad
Moorpark	Large industrial area, large number of businesses of concern, known hazardous materials storage	Basin F
Ojai	Large number of businesses of concern, presence of older facilities and businesses, known hazardous materials storage	Basin I
Oxnard	Citywide illicit discharge investigations	All Basins
Port Hueneme	Larger industrial area located near waterfront	Basin 5
San Buenaventura	Larger industrial area, concentration of older facilities	Auto Center, older industrial areas
Santa Paula	Presence of older facilities and infrastructure, known hazardous materials storage	All areas
Simi Valley	Frequent spill reports, stored hazardous materials, many businesses of concern	N. Simi, Tapo
Thousand Oaks	High number of spill reports, large number of businesses of concern	Basin 10

[1] Rating matrices and maps locating priority basins can be found in Attachment 2.

activities at the targeted industries. For example, BMPs were developed for automobile service facilities for use during the pilot program.

The controls are selected with input from the business community in order to ensure compatibility with local practices and thus facilitate implementation. Developing a "Clean Business Program" may be one approach to implementing controls. Other controls are being developed as part of the countywide program and will be available to the co-permittees as they become available. In the interim, an initial set of BMPs for common activities generic to most residents and businesses may be appropriate. Handouts listing these BMPs that can be distributed during illicit discharge investigations are found in Attachment 3.



Conduct Investigations

The Countywide approach to illicit discharge investigations involves three types of investigations: field inspection and testing, illicit discharger identification, and followup planning. This section describes each type of investigations in detail.

Field Inspection and Testing

Field inspection involves visual observation of the storm drain system and visual observation of activities on the surface that may cause illicit discharges. A two to three person field inspection crew should thoroughly investigate the entire surface and subsurface drainage system for evidence of illicit discharge. On the surface, the inspection crew investigates accessible areas around residences and businesses, as well as nearby catch basins, for evidence of illegal dumping and other activities that could result in stormwater pollution. The surface inspections were shown during the pilot program to be the most successful in identifying illicit discharges. The crew should also inspect open channels near known and previously unidentified points of discharge, as well as manholes at strategic locations within the storm drain system. The crew may conduct field testing with probes, test kits, and water sample collection/analysis. Field testing helps detect illicit discharges and identify their sources, not quantify pollutants. Surface/storm drain field inspection and testing procedures follow.

Advance Planning. An effective field inspection program requires good advance planning. First, at least 4 people should be trained to conduct inspections so that qualified staff are available each day for the 2 to 3 person inspection crews. Inspections must be conducted during dry weather, usually in the summer when groundwater seepage is low. Before entering the field, the inspection crew should locate an initial set of inspection sites on a storm drain/street map:

- All known or suspected pollutant-generating activities
- Priority businesses
- Other locations representative of activities within the drainage basin.
- All locations where drains enter open channels
- Representative catch basins and storm drain manholes

In the field, other sites should also be inspected if suspicious conditions are observed. Finally when inspections are about to begin, obtain the equipment and store it in the vehicle used by the inspection crew. Table 6 lists equipment required for field inspections.

Table 6
Field Equipment for Illicit Discharge Investigations

Field Inspection Equipment
- Storm drain system map
- Field data log book
- Inspection checklists (Attachment 3)
- Tape measure
- First Aid kit
- Camera and film
- BMP Handouts

Field Testing Equipment
- Graduated container, stopwatch to measure flow
- Temperature/pH/conductivity (EC) probe
- Field test kits (e.g., Lamotte test kit)
- 12-1 liter amber glass sample bottles
- 12-1 liter HDPE sample bottles
- Cooler with ice for sample preservation
- Gloves
- Splash goggles/safety glasses

Visual Observation. Evidence of illicit discharges may only consist of visual observations because most illicit discharges are intermittent and will probably not be flowing when inspected. Table 7 lists the types of visual observations that should be recorded using the inspection checklists for drainage systems and business facilities located in Attachment 3. Also, take photos of visual observations to aid subsequent data analysis and followup planning.

Field Tests. If flow is observed at either surface or storm drain inspection sites, the field inspection crew should collect a sample, measure flow, and attempt to trace the flow to its source. This effort is coordinated between the storm drain crew and the surface crew. First, the storm drain crew uses the probe to measure the pH, temperature and conductivity (EC). If any of these parameters are abnormal or strong odors or flow discoloration are detected, the sample is analyzed with the field test kit. The test kit detects the presence of copper, phenols, detergents, and chlorine. Findings are recorded on the inspection checklist.

Table 7
Recommended Types of Visual Observations

All Inspection Locations
- General site description
- Amount, appearance, odor of debris
- Stains
- Structural cracking and corrosion
- Vegetative growth
- Poor outside housekeeping practices
- Pipes/hoses directed toward drainage system

Business Inspection Locations
- Vehicle and equipment fueling
- Vehicle and equipment washing and steam cleaning
- Outdoor loading/unloading areas
- Outdoor container storage of liquids
- Outdoor process equipment
- Outdoor storage areas
- Waste handling and disposal

Simi Valley field tested two types of field kits: DREL 2000 and Lamotte. The DREL 2000 is a portable spectrophotometer which yields very conclusive analytical results, but requires more time and auxiliary equipment to operate than the Lamotte system. The Lamotte system consists of field test kits which are simple to operate and yield quick results. However, the results are useful only for establishing an order of magnitude number.

Field Sampling. If visual observations are abnormal and/or the field tests detect high concentrations of any constituent, the field crew should collect samples for laboratory analysis. Two types of one liter containers are used: amber glass bottles to collect samples for organic, oil and grease,and TPH analysis, and plastic (HDPE) bottles to collect samples for metals analysis. If there is enough flow, the field crew should fill 2 amber glass sample bottles and 2 HDPE sample bottles to obtain enough sample volume for analysis of metals, organic and conventional pollutants. If there is a limited quantity or sampling is difficult, the field crew should collect as much sample as possible so that the laboratory can run a limited set of analyses. The samples are placed in a cooler filled with ice and transported to the lab(s) on the same day. Arrangements should be made prior to the field inspection with analytical laboratory(s) capable of performing the required analyses. Also, the laboratory can usually supply properly cleaned sample bottles.

Sample Analysis. The laboratory analyses run on each sample should be determined using the results of the field testing and visual observations. Given the potential high cost for laboratory work, it is prudent to limit the number of analytical parameters (or analytes) tested for each sample. First, general indicator analyses (e.g., total organic carbon (TOC), total organic halogens (TOX), oil and grease, biochemical oxygen demand (BOD), fecal coliform, and ammonia) should be run. Additional tests may be selected based on the findings of indicator analyses, visual observations, field tests, and information collected in Step 1 on the types of chemicals stored (and/or spilled) within each basin.

Illicit Discharger Identification

Typical illicit discharges are intermittent and may not be detected during the initial field inspection. Follow-up inspections may be warranted.

Many illicit dischargers will be identified by the field inspection procedures described above. Additional techniques may be needed to identify other sources of illicit discharges. These techniques include analysis of the field inspection data, and follow-up inspections of businesses, residences, and drainage systems.

Analysis of Field Inspection Data. When field inspections and sample analysis are complete, data analysis is performed to identify the most probable sources of illicit discharges. In some cases, field inspection crews may be able to conduct data analysis in the field, with immediate followup by the crew. In other cases, the discharge source may not be obvious and it may be more productive to analyze the data at the office. There, analytical results from field sampling can be compared with typical stormwater quality values (as defined by EPA's Nationwide Urban Runoff Program, NURP) to determine if the discharge is a concern. If the discharge poses a threat then records of chemical storage, use and spills should be reviewed for potential illicit dischargers. This data can be used to determine which businesses to investigate and to guide facility inspections. For example, if high levels of oil and grease are found (greater than 5.0 mg/L) in the discharge then restaurants or vehicle service facilities are likely candidates for followup inspections. Likewise, if the discharge has high BOD (greater than 20 mg/L) or fecal coliform counts greater than 100,000 MPN/100 mL then follow up inspections should focus on sanitary sewer cross connections.

Followup Investigations of Businesses and Residences. When evidence of illicit discharges is tracked to a source on private property, there are three approaches that can be taken depending on the experience and legal authority of the inspection team, the conclusiveness of the field inspection data, and the availability of background data on pollutant sources and drainage patterns:

Followup investigations may be referred to an agency with authority to enter the business or residence, deferred to a future date, or conducted immediately by the field inspection crew.

- The first approach is to refer the name and location of the business or resident suspected of illicit discharge to a program with the appropriate authority for follow-up. This may be the Stormwater Industrial/Commercial Business program, the Industrial Pretreatment Program, or the Environmental Health Department. The programs that should conduct this follow-up should be designated prior to conducting the illicit discharge investigations. Copies of the inspection reports should be sent to the appropriate program with a request for follow-up. Special attention should be given by those inspectors to the problems indicated by the field storm drain inspections. Examples of such special consideration include visual inspection of storm drains, roads, and ditches in each facility near or around chemical storage areas or areas in which these chemicals are used. Furthermore, these inspectors should record the results of all investigations prompted by field inspection data regardless of outcome. Businesses/residents should be notified of the impending inspection according to standard procedures of the agency conducting the followup.

- For the second approach, the illicit discharge inspection crew may have the authority to conduct the business investigation but may prefer to do this at a later date. In this case, a letter can be sent to the business describing the nature of the problem and advising them that an inspection will be conducted in the near future. The Business Inspection Checklist can be mailed along with this notification if desired.

- A third approach is to conduct the inspection at the time the illicit discharge is discovered. In this case, the storm drain crew is called to the surface for assistance in documenting the discharge and approaching the resident or owner/manager of the facility(s) under suspicion. One member of the crew meets with the resident or facility personnel and explains the potential stormwater contamination problem. Next, the inspection crew inspects the grounds for other sources of potential contamination and document the discharge by taking pictures, sampling and running the appropriate tests. These initial inspections should be viewed as opportunities to educate the public about the overall stormwater program and to provide the resident or business with information on how to eliminate illicit discharges.

Followup Storm Drain Investigations. Sources of remaining unexplained flows (after field inspection and followup investigation of residences and businesses) may be identified through the following alternative detection methods:

Followup storm drain investigations involving dye tests, smoke tests, and TV inspections are expensive and time-consuming, and thus will be used as a last resort.

- *Dye Tests.* Dye tests in areas where storm drain flows are unexplained may reveal illicit structural connections. Typical dye tests consist of the addition of fluorescent dye to a floor drain or waste line from a domestic, commercial or industrial process, followed by monitoring for the dye in downstream storm drains. Dye testing proceeds facility by facility (in each area where unexplained flow exists) until all facilities in the area are tested.

- *Smoke Tests.* Smoke testing in problem areas is another method of illicit discharge identification. Storm drains are sealed via sand bags or other sealing devices (plugs, etc.) and smoking incendiary devices are ignited upstream of the seal. Simultaneous inspections inside area facilities should reveal illicit connections even in the absence of flow. Since illicit discharges are intermittent, smoke tests offer real advantages over other types of illicit discharge source identification methods. However, since many legitimate connections to a storm drain may exist (roof drains, street drains, etc.) smoke may be observed extensively and some illicit connections may be missed.

- *T.V. Inspections.* Robotized or otherwise mobile television cameras allow visual inspection of storm drains (pipes) too small or dangerous for personnel to enter. Although an excellent method of identifying and documenting illicit connections, T.V. inspections have high costs. Some co-permittees may currently have T.V. equipment at their disposal.

VOL 12

20498

R0053803

Since these methods are expensive and time consuming, their implementation is a last resort and will probably only be used once the more easily identifiable discharges are eliminated. A detailed description of these methods can be found in the California Stormwater BMP Handbook - Municipal .

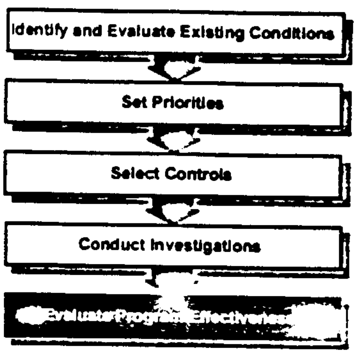
Illicit Discharge Control Planning

Once illicit dischargers are identified, actions to eliminate the discharges are initiated. The suggested strategy is to focus initial efforts on education, public outreach and technical assistance. These methods encourage voluntary compliance. Enforcement mechanisms are used only when voluntary techniques have been unsuccessful. Illicit discharge control programs are part of the Programs for Industrial and Commercial Businesses and Programs for Residents. These programs are summarized here and described in detail in separate Countywide program approaches developed for these programs.

Voluntary compliance is encouraged by focussing initial efforts on education, public outreach and technical assistance. Enforcement mechanisms are used only when voluntary techniques have been unsuccessful.

Community Education/Outreach Methods. Methods of communicating with businesses or residents with illicit discharges must be devised to ensure understanding of the program and proper implementation of the required BMPs. For retail businesses, a "Clean Business" outreach program was begun in 1995 for automobile service businesses and scheduled to be extended to restaurants and other businesses in subsequent years. The "Clean Business" concept merges facility inspections by municipalities, education of business owners and employees about appropriate controls, solicitation of their comments on the ability to implement the controls, and "awards" for implementing controls. Other types of business outreach (e.g., presentations to trade organizations, distribution of handouts/brochures with business license applications and renewals) may also be examined. For residents, the Countywide program has developed an inlet stenciling program, brochures about illicit discharges and proper refuse disposal, a display for community events, and presentation materials for speaking engagements. This material is being incorporated into residential outreach programs being implemented by each co-permittee.

Regulatory Procedures. If education and technical assistance efforts do not result in a business or resident eliminating its sources of illicit discharges, then enforcement may be necessary. During the initial implementation phase, the co-permittees will enforce illicit discharge control as allowed by existing ordinances. During the full implementation phase, additional ordinances/enforcement programs will be developed to supplement control achievable under voluntary programs and/or existing ordinances. In the event that an illicit discharger is uncooperative, legal authority must be in place and used to enforce stormwater ordinances. Recourse against uncooperative dischargers is similar to POTW pretreatment program authority with the exception of discharge permitting. Fines, compliance schedules, cease and desist orders, and legal action are all avenues available to co-permittees to require companies to comply. Ordinances should be reviewed to confirm that adequate legal authority is in place to carry out necessary enforcement actions.



Evaluate Program Effectiveness

Methods of data collection and record keeping are necessary to periodically assess program effectiveness and report results to the Ventura County Flood Control District and the Regional Board. Table 8 lists the type of information that can be tracked and how it can be used to assess program effectiveness. Included in Attachment 5 is a spreadsheet that may be used to compile the program results. By July 15, each co-permittee should complete the spreadsheet and submit it to the VCFCD for evaluation and compilation into the annual report to the Regional Board due September 1. At that time, an assessment of the Countywide program approach will be made.

Table 8
Possible Program Assessments

Type of Information	Program Results	Possible Assessments
Inspection Results	Number of facilities inspected	■ Inspector productivity ■ Number of problem facilities
	Number of illicit discharges detected	■ Stormwater quality from the applicable jurisdiction ■ Inspector effectiveness ■ Program effectiveness
	Number of illicit dischargers identified	■ Inspector effectiveness ■ Program effectiveness
	Number of illicit discharges abated	■ Success of inspection/education efforts
	Type of illicit discharges	■ Stormwater quality risks ■ Refocus of target efforts
Program Economics	Number of inspector-hrs per identified illicit discharger	■ Inspector efficiency ■ Effective staffing levels
	Number of personnel-hrs per identified illicit discharger	■ Effective staffing levels ■ Staffing projections
	Cost per identified illicit discharger	■ Cost per desired benefit ■ Budget projections
	Cost per illicit discharge abated	■ Cost per desired benefit ■ Budget projections

Periodically, it will be necessary to reassess the work effort including modifying the priority areas/analytes, determining effectiveness of outreach efforts, quantifying the removal of illicit discharges, and redirecting staff resources. The assessments listed in Table 8 are intended to define cost-effective approaches to future illicit discharge investigations. Some specific items to consider when conducting long range planning are:

- Follow-up inspections in priority drainage basins where outreach has been conducted
- Targeting new activities in the priority drainage basins
- Targeting additional drainage basins for inspections
- Modification of inspection program with regard to number of inspectors and tasks during inspections
- Frequency of inspections in one drainage basin to effectively identify illicit discharges
- Modification of existing handouts or development of new handouts

Program Administration Needs

Estimates of staff time, staffing levels, and other operating expenses were prepared as part of the pilot illicit discharge program conducted by Simi Valley. These estimates are discussed below and may be used as the basis for determining program staffing and budgets. Other factors to be considered in program development include the frequency with which field investigations are conducted and how much follow-up can be coordinated with other programs.. The pilot program concluded that field screening should be conducted more often than once per year due to the intermittent nature of many illicit discharges. As discussed earlier, there are other municipal programs that could aid in illicit discharge investigations.

The cost estimates were based on actual expenses incurred during the pilot program to conduct investigations of 33 separate occurrences of illicit discharges and contact 20 businesses regarding the source of the illicit discharges. To facilitate program preparation and budgeting by other co-permittees, the Simi Valley estimates were converted to convenient multipliers (amount per occurrence of illicit discharge and amount per business investigated) and are presented in Table 9.

Table 9
Level-of-Effort Multipliers

Budget Category	Total Amount for Drainage Basin[7]	Amount per Outfall	Amount per Investigated Business
Staff Hours:			
Inspector[1]	167	4.8 hrs	8.8 hrs
Lab Technician[2]	67	1.9 hrs	3.2 hrs
Supervisor[3]	84	2.4 hrs	4.2 hrs
Manager[4]	8	0.2 hrs	0.4 hrs
Total Hours	326	9	17
Vehicles[5]	$1,300	$37	$65
Field Analyses (by DREL 2000)[6]	$6,800	$194	$340
Field Analyses (by Lamotte)[6]	$830	$24	$42
Total Cost (DREL 2000)	$16,906	$482	$854
Total Cost (Lamotte)	$10,936	$312	$556

1 2 inspectors per investigation @ $26.79/hr
2 1 laboratory technician per investigations @ $23.59/hr
3 supervisor @ $28.98/hr
4 manager @ $39.66/hr
5 2 vehicles @ $6.50/hr, 1 vehicle @ $7.50/hr
6 analyses include temperature, dissolved oxygen, phenol, pH, chlorine, copper, detergents
7 drainage basin consists of 763 acres, 43% residential, 23% commercial, 9% industrial. There are 35 outfalls in the drainage basin. 33 sites were investigated, 4 in channel, 29 on surface.

The multipliers can be used to project staffing and equipment budgets by a particular co-permittee. However, the amounts are based on initial implementation of the program when the more obvious discharges are identified and when more time is spent with each discharger in explaining the program requirements. Amounts may decrease or increase in subsequent years as education yields widespread awareness or enforcement actions become necessary.

Estimated staff hours were based on using two inspectors and one lab technician to inspect outfalls within drainage channels and inspect facilities and residential areas, perform laboratory analyses, and document all activities. During inspections, approximately 70% of the staff time was spent investigating surface locations and 30% of the time was spent investigating the outfalls. For safety reasons, two persons were assigned to the channel investigations at all times. Although only one person was assigned to perform

VOL 12

2

0502

surface investigations, it was determined that using two persons at the surface would greatly increase investigation efficiency. When businesses were contacted regarding a potential problem, an average of 45 minutes to an hour was spent describing the program requirements, explaining identified problems, and prescribing corrective actions. Hours spent by the program manager were estimated based on any necessary enforcement actions. The two different costs for field analyses were based on the two types of analytical equipment used during the pilot program.

Implementation Schedule

The implementation schedule shown in Table 10 includes a period of initial implementation to test the program on priority businesses or areas and then a date for assessment and possible refocus of efforts. Additional dates and deliverables to be incorporated in the schedule will consist of a semiannual submittal to the county on program effectiveness.

Table 10
Proposed Implementation Schedule

Program Task	Annual Illicit Discharge Investigation Schedule
Identify and Evaluate Existing Conditions	September 1 - December 31
Set Priorities	January 1 - February 28
Select Controls	January 1 - February 28
Field Investigations	April 15 - July 15
Program Effectiveness Evaluation and Reporting	July 15 - September 1

Field Experience

In the fall of 1993, the City of Simi Valley conducted a pilot illicit discharge control program. It was designed to satisfy the requests of the Regional Board to begin early implementation of certain programs, and to evaluate the program work plan that was included in the permit application.

The North Simi Drain was chosen as the targeted high priority basin for the pilot program. The North Simi Drain is composed of 35 outfall/screening points within the drainage channel. During dry weather field screening in 1992, four of these screening points were identified with measurable flow and four additional screening points had unmeasurable flow and the remaining screening points had no flow. One discharge was clearly oil/petroleum product wastes. Surface inspection revealed 78% (15 of 19) of the pollution sources. The remaining 22% were identified from the channel, either with flow or by visual observation of stains. Only 10% (2 of 19) of all the identified pollution sources had actual flow at the time of the inspection whether found on the surface or in the channel. A total of 75% of the discharges identified during the pilot program were new since the previous year's dry weather field characterization which consisted of visual observation within the channel only.

The City of Simi Valley assigned two inspectors and one lab technician to the pilot program. The project was completed in approximately two weeks, including canvassing the North Simi Drain, inspection of facilities and residential areas, laboratory analyses and documentation.

Preparation and development of the pilot program field inspection presented many challenges and resulted in many interesting observations.

The handouts used in the pilot program were a key element in achieving the goal of voluntary compliance. The handouts were developed based on materials used in other jurisdictions and tailored to the Simi Valley project. The initial format chosen was a three-fold information sheet describing general housekeeping practices that reduce discharges. Separate, more detailed BMPs specific to the automotive industry were prepared for insertion into the three-fold depending on the specific issues identified at a facility. This proved cumbersome in the field and the BMPs were combined with the three-fold resulting in a booklet that was distributed as appropriate. If a facility had any potential to discharge or was on a common lot where discharge was an issue, the handouts were distributed. Businesses which had no evidence of discharge or potential to discharge did not receive handouts.

Organizing the inspection crew was a challenge initially. The initial format of two staff members in the channel and one staff member on the surface proved to be less efficient. The system was modified to emphasize surface inspections as discussed above in the section on inspection programs.

Personnel at the inspected facilities revealed a surprising appreciation for the advance notice of impending regulations. One service manager indicated that the handouts and BMP materials would be incorporated into safety meetings and copies would be distributed to all service personnel. The pilot program found that the solution to illicit discharges at most facilities involved improving housekeeping procedures. The most feasible BMPs included berming, covering and cleaning.

Based on the experiences during the pilot program, recommendations for future inspection programs included the following:

- Develop industry specific BMP handouts and technical assistance brochures to be used by all co-permittees.
- Provide English and Spanish translations of all handouts and brochures.
- Direct the drafting of a model ordinance to ensure consistent language and enforcement county wide.
- Define enforcement tools to be used to abate illicit discharges. Focus primarily on public education/outreach and voluntary compliance.
- Emphasize visual observation at the surface with observation in the channel as a support during the field inspection program.

sources. The remaining 22% were identified from the channel, either with flow or by visual observation of stains. Only 10% (2 of 19) of all the identified pollution sources had actual flow at the time of the inspection whether found on the surface or in the channel. A total of 75% of the discharges identified during the pilot program were new since the previous year's dry weather field characterization which consisted of visual observation within the channel only.

The City of Simi Valley assigned two inspectors and one lab technician to the pilot program. The project was completed in approximately two weeks, including canvassing the North Simi Drain, inspection of facilities and residential areas, laboratory analyses and documentation.

Preparation and development of the pilot program field inspection presented many challenges and resulted in many interesting observations.

The handouts used in the pilot program were a key element in achieving the goal of voluntary compliance. The handouts were developed based on materials used in other jurisdictions and tailored to the Simi Valley project. The initial format chosen was a three-fold information sheet describing general housekeeping practices that reduce discharges. Separate, more detailed BMPs specific to the automotive industry were prepared for insertion into the three-fold depending on the specific issues identified at a facility. This proved cumbersome in the field and the BMPs were combined with the three-fold resulting in a booklet that was distributed as appropriate. If a facility had any potential to discharge or was on a common lot where discharge was an issue, the handouts were distributed. Businesses which had no evidence of discharge or potential to discharge did not receive handouts.

Organizing the inspection crew was a challenge initially. The initial format of two staff members in the channel and one staff member on the surface proved to be less efficient. The system was modified to emphasize surface inspections as discussed above in the section on inspection programs.

Personnel at the inspected facilities revealed a surprising appreciation for the advance notice of impending regulations. One service manager indicated that the handouts and BMP materials would be incorporated into safety meetings and copies would be distributed to all service personnel. The pilot program found that the solution to illicit discharges at most facilities involved improving housekeeping procedures. The most feasible BMPs included berming, covering and cleaning.

Based on the experiences during the pilot program, recommendations for future inspection programs included the following:

- Develop industry specific BMP handouts and technical assistance brochures to be used by all co-permittees.
- Provide English and Spanish translations of all handouts and brochures.
- Direct the drafting of a model ordinance to ensure consistent language and enforcement county wide.
- Define enforcement tools to be used to abate illicit discharges. Focus primarily on public education/outreach and voluntary compliance.
- Emphasize visual observation at the surface with observation in the channel as a support during the field inspection program.

ATTACHMENT 1

PRIORITIZATION PROCESS FOR DETECTION OF ILLICIT DISCHARGES

Prioritization of potential illicit discharge[1] areas is essential to effective illicit discharge detection and control programs. Past experience has shown the majority of observations of illicit discharges to occur in areas with characteristic land uses, age, history, and demography. The relationship between basin characteristics and frequency of illicit discharge detection allows the design of a more effective inspection program by focusing inspection efforts in priority areas. Prioritization of potential illicit discharge program basins will allow more efficient detection of illicit discharges.

Workplans developed by each co-permittee for detection and control of illicit discharges should include specific methods of prioritization of areas which select subject areas on the basis of past experience. Following a uniform prioritization process will enhance documentation of the area selection process and program reporting. This memo details a decision making method for basin prioritization known as the matrix method. This method basically consists of assigning numeric values (scores) to certain basin characteristics and summing the values to arrive at a ranking or prioritization of basins for further illicit discharge inspection.

Generic basin characteristics have been identified which signify greater risk of illicit discharge. The those characteristics are listed as follows:

Industrial area fraction
Commercial area fraction
Types of industry/commercial business (automotive related?)
Density of residential areas
Older areas (base date on changes to plumbing code, other factors)
Areas with hazardous material storage
Number of observed illicit discharges (maintenance personnel knowledge)
Frequency of spill reports
Density of septic systems

It is not expected that information will be available for all of these characteristics. Also, this list is not meant to be exclusive. Other characteristics which can be shown to indicate the existence of illicit discharges may be defined locally. The matrix technique works best when a relatively large number (> 3) of characteristics are used and the effects of the characteristics are weighted in proportion to the magnitude of the effect. The list presented above is meant to be a tool for beginning the data collection and prioritization process.

Basins are ranked from highest to lowest "probability" of containing illicit connections or illegal dumping in the matrix approach. Each basin is given a score with regard to each

[1]For our purposes, illicit discharges include both illicit connections (*e.g.* cross connections) and illegal dumping (*e.g.* oil dumping).

characteristic. Overall scores are then tabulated for each basin. The basins are then ranked in order of highest overall score (sum of individual characteristics scores) to lowest overall score. If the score or group of scores for a given characteristic seems to be disproportionately high or low when compared to the remaining characteristic scores, then the scoring system for that characteristic should be adjusted. Characteristics based on actual observations of illicit discharges should be given higher scores. The following table is an example of the matrix to be used in ranking the basins:

Table 1: Example Matrix of Basin Comparison

Basin	Characteristic——————→			Overall Score	Rank
A					
B					
C					

Methods of Scoring Basins on the Basis of Watershed Characteristics

Methods of scoring must be developed for each specific characteristic. The scoring should be consistent between characteristics so as not to bias the overall score toward a single or group of characteristics. A simple "1 to 5" approach usually works well and can be modified up or down for characteristics with extreme effects. Although the approach to developing characteristic scores is subjective, the matrix approach will work well even though the scores do not exactly reflect the actual probabilities of the basin containing illicit discharges. Scoring methods for each of the generic list of characteristics presented in the table above are developed using the "1 to 5" approach with a few of the characteristics slightly higher or lower. Some characteristics identified above exist only over a fraction of a basin area. In that case the scores are multiplied by the fractional area covered by the characteristic. Characteristics identified in addition to those presented here should be scored in a manner consistent with this technique (*i.e.* 1 to 5 and based on fractional coverage (area)).

<u>Industrial Area Fraction</u>

Since the probability of containing illicit discharges is directly proportional to the fraction of industrial area fraction, the scoring of this characteristic is fairly simple. The following scoring scale may be used:

Industrial Area Fraction	Score
0-20%	1
20-40%	2
40-60%	3
60-80%	4
80-100%	5

VOL 12

2 05/1

Commercial Area Fraction

Commercial areas are nearly as likely to contain illicit discharges as industrial areas. Therefore, the scoring should be nearly the same as for industrial areas.

Commercial Area Fraction	Score
0-20%	1
20-40%	2
40-60%	3
60-80%	4
80-100%	5

Type of Business (Automotive)

Recently, observations of illicit discharges have correlated (subjectively) frequency of illicit discharge with certain types of industries, primarily automotive related. Recommended scoring for basins with automotive related industries is as follows:

Score	=	Major Automotive Related Business	-	5
		Average Automotive Related Business	-	3
		Minor Automotive Related Businesses	-	1
		No Automotive Related Businesses	-	0

Density of Residential Areas

Residential density is most often expressed in relative terms such as low, medium, and high. Some municipalities describe residential density based on the types of structures in the area, such as "multiple - single" family or the "detached - attached" designations or a combination of both. The recommended scoring methods to use are Low = 1, Medium = 2, and High = 3. In the case where information is available on the types of housing structures, the following scoring method is recommended:

Residential Density	Fraction of Area	Score
Low	p	p*1
Medium	p	p*2
High	p	p*3
Non-residential area	p	p*0
Characteristic Ranking Score = Sum of Scores	$\sum = 1$	$\sum$ Scores

Multiplying the density by the fraction of area occupied by the various residential densities allows for more than one type of housing within a given watershed area.

Older Areas

The age of an urban development within an area is probably as important as any other characteristics. When assessing the age of a development, care should be taken to determine whether or not improvements have been made to the storm drain system since the development was built since recent improvements may have disconnected many illegal connections. The recommended approach to scoring development age is as follows:

Age of Area	Fraction of Basin Area	Score
30+	p	p*4
20-30	p	p*3
10-20	p	p*2
0-10	p	p*1
Undeveloped area	p	p*0
Characteristic Ranking Score = Sum of Scores	$\sum p = 1$	$\sum$ Scores

Areas with Hazardous Material Storage

Although areas with hazardous material storage are no more likely to have illicit connections than areas without hazardous material storage, extra points should be given due to the serious nature of illicit discharge if one occurs. The recommended scoring methods for the hazardous material storage characteristic is as follows:

Score = 5 - Known Hazardous Material Storage
3 - Unknown Hazardous Material Storage
0 - No known Hazardous Material Storage

Number of Observed Illicit Discharges

Maintenance personnel may be the best source available of illicit discharge information. However, this information may be qualitative and not well documented or collected in a random manner which makes scoring areas based on this characteristics difficult. Therefore a general sense of the frequencies if illicit discharges to the storm drain system in each is probably the best type information to obtain from such observations. Observations should be given a high weighting factor values including negative observations (*i.e.* Low frequencies of illicit discharges) The recommended scoring for this type of information is as follows:

Illicit Discharge Frequency	Score
High Frequency	5
Moderately Frequent	3
Low Frequency	1

These scores may be weighted to account for the fact that this characteristic is the most important of all the basin characteristics. Such weighting may consist of multiplying the scores by two or three depending on the accuracy and comprehensive nature of the available information.

Spill Report Frequency

Similarly, the frequency of spill reporting is an observation based measure of illicit discharging and should be given high weighting factor values. The recommended scoring for spill report frequency information is as follows:

$$\text{Score} = \frac{\text{\# of Spills Reported Within Basin}}{\text{Total \#'s of Spill Reports}} * 10$$

Density of Septic Systems

Septic system density is an indicator of potential illicit connections to storm drain systems through infiltration or direct connection. Septic system density is usually expressed as a fraction of the total area served by septic systems. The recommended scoring for the septic system density characteristic is as follows:

Score = Septic System Density * 5

EXAMPLE

In the following example, two basins are compared using fictitious basin data. One basin is a residential and commercial area and one is a heavy industrial area. The resulting scores indicate that the industrial area is more likely to have evidence of illicit discharges. Therefore, the basin would be a higher priority for illicit discharge detection and control.

VOL 12

Basin	Industrial Area	Commercial Area	Business Type	Residential Density	Age	Hazardous Material	Illicit Discharges	Spill Reports	Septic Tank Density	Total Score
A	1	2	1	1.2	2.2	0	1	0	0	8.4
B	4	1	3	0	3.6	5	5	2	0	23.6

Basin A Characteristics:

* 5% Industrial Area
* 25% Commercial
* Minor Automobile related activities
* Residential Area 30% low, 30% medium, 10% high, 30% non-residential
* 20% of the area built before 1965, 30% of the area built between 1965 and 1975, 20% built between 1975 and 1985, 10% built from 1985 to date, 20% undeveloped
* No Hazardous Material storage
* Poor records show occasional reports of illicit discharges
* No spills reported
* No septic systems in operation

Basin B Characteristics:

* 80% Industrial Area
* 20% Commercial Area
* Average number of automobile related activities
* No residential area
* 60% of the area built before 1965, 40% built between 1965 and 1975
* Known hazardous materia storage area
* High frequency of observed illicit discharges
* Of the 10 recent spill reports, 2 were from this basin
* No septic systems in operation

ILLICIT DISCHARGE CONTROL FOR THE UNINCORPORATED URBAN AREAS OF VENTURA COUNTY

There are eight distinct unincorporated urban areas of Ventura County. These areas have been rated in terms of their potential for illicit discharges to the storm drain system using the methodology described in Section 2.3.3 of the NPDES storm water permit application. These areas are shown on the enclosed Potential Pollutant Source Map. The prioritization of potential illicit discharge areas is instrumental in the detection of illicit discharges and implementation of control programs.

A prioritization process assigns numeric values based on area characteristics. The total of these values by area is used in a matrix format to rank areas for future illicit discharge monitoring and inspection. The rating matrix and ranking for each area is attached. The rating factors were evaluated based on physical characteristics, observations, and events that have occurred over the past five years. The following matrix was prepared in accordance with "Guidance on Prioritization Process for Detection of Illicit Discharges," by Larry Walker Associates, dated October 20, 1993.

The scores for the eight areas ranges from 2.2 to 8.3. The higher score means there is a greater potential for illicit discharges. The area with the highest score is the Black Canyon area near Simi Valley. This area rated the highest because of the age of the area and the number of septic systems there. The next higher rated areas, Ventura Avenue and El Rio, scored high because of their age and because they contain some commercial and industrial areas.

The two major land uses in the urbanized areas of the county are residential and agricultural. Residential land use comprises about 50% of the urbanized county and agricultural 39%. Industrial land use is about 5% and commercial land use is less than 1%. The remaining areas are divided among undeveloped and public open land. A rating of 1 in the industrial or commercial area fraction means that the area is 0-20% industrial or commercial.

There are no hazardous waste storage facilities in any of these areas. Spill reports are managed by numerous fire departments and the data was not readily available. To date, no programs have been implemented to report illicit discharges, therefore this category in the matrix was given a zero score for each area and was not considered to be a grading factor.

The County of Ventura is proposing to conduct an illicit discharge detection and inspection program, as outlined by the Management Committee. Illicit discharge activities will begin in (1) Black Canyon, as identified on the enclosed map.

Training will be given to personnel who will be participating in the illicit discharge detection and product control programs, and will include detection of potential violations and the reporting process and format.

Illicit Discharge Control for Port Hueneme

Using the guidelines prepared by the Storm Water Task Force, the City of Port Hueneme has been divided into five drainage areas. Each drainage area has been rated in terms of its priority for potential illicit discharges. The prioritization of potential illicit discharge areas is instrumental in the detection of illicit discharges and implementation of control programs. A prioritization process was developed which assigns numeric value to specific basin characteristics and sums the values. The total value is used to rank basins for future illicit discharge monitoring and inspection. This is known as the matrix method. The rating matrix and ranking for each basin is attached. Prioritized drainage areas are indicated on the land use map. The rating factors were evaluated based on experience and events that have occurred over the past five years. The following matrix was prepared in accordance with "Guidance on Prioritization Process for Detection of Illicit Discharges", by Larry Walker Associates, dated October 20, 1993.

The scores for the five drainage basins that were evaluated range from 4.5 to 6.7. In reviewing the existing land use map for Port Hueneme, it was determined that the majority of the drainage areas (approximately 80 percent) are residential. The remaining drainage areas are equally divided among commercial, industrial and undeveloped land. Drainage basin Nos. 1, 2 and 3 are mainly residential, with a very low concentration of commercial establishments. Basin Nos. 4 and 5 are mixed, with higher concentrations of industrial and commercial land uses.

To date, no programs have been implemented to report illicit discharges, therefore this category in the matrix was given a zero score for each basin and was not considered to be a grading factor. The city is proposing to conduct an illicit discharge detection and inspection program, as outlined by the Ventura County Storm Water Task Force. Illicit discharge activities will begin with the known locations and highest priority businesses located in Basin No. 5, as shown in the enclosed map.

All Port Hueneme wastewater flows are treated at the Oxnard Wastewater Treatment Facility. The City of Port Hueneme contracts with the City of Oxnard for the maintenance and operation of this facility. The Oxnard facility also conducts all source control operations. The City of Port Hueneme intends to extend the source control program to include illicit discharge detection and correction.

Training will be given to engineering personnel who will be participating in the illicit discharge detection and product control programs. The field personnel will be trained in the detection of potential violations and the reporting process and format.

ILLICIT DISCHARGE CONTROL FOR THE CITY OF SAN BUENAVENTURA

Guidelines have been prepared by the Ventura County Storm Water Management Committee. The purpose of these guidelines is to assist the co-permittee is selecting an area of their jurisdiction to look for illicit discharges to the storm drain system. These areas are shown on the enclosed Potential Pollutant Source Maps.

The prioritization of potential illicit discharge areas is instrumental in the detection of illicit discharges and implementation of control programs. The rating factors were evaluated based on physical characteristics, observations, and events that have occurred over the past five years. The areas identified in San Buenaventura for the initial illicit discharge detection program are shown on the enclosed maps. These areas were selected using personal knowledge of the city. As such the rating matrix method was not used in the prioritization. Selection was based on the age of development and types of businesses. Older industrial areas and the Auto Center were selected as priority potential illicit discharge areas. These areas are currently involved in the city's pretreatment program. The illicit discharge detection program will be conducted in conjunction with the pretreatment program.

VOL 12 2 0534

Illicit Discharge Control

Using the guidelines prepared by the Storm Water Task Force, the City of Santa Paula has rated the sixteen drainage areas. The rating matrix and resulting prioritization is attached. The rating factors were developed by City staff based upon experience and events that have occurred over the past ten years.

The prioritization of the drainage areas has mixed results. Most of the results were anticipated; however, there are some factors that have clouded the results. In reviewing the existing land use map, staff has noted that most of the drainage areas have a varied mix of land uses. Commercial, industrial, and residential areas are intertwined to the extent that concentration on one top priority area will not be sufficient to achieve the level of inspection and enforcement that is needed.

The City is proposing to conduct illicit discharge activities in all areas at the same time. Illicit discharge activities will begin with the known locations and highest priority businesses. Activities will then proceed to the lower priority businesses.

Currently, the City of Santa Paula contracts with the Ventura Regional Sanitation District (VRSD) for the maintenance and operation of the Santa Paula Treatment Plant. VRSD also conducts all source control operations. The City proposes to use VRSD to extend the source control program to include illicit discharge detection and correction. The Santa Paula Fire Department will provide inspection and technical assistance at hazardous materials locations.

The illicit discharge program will implement using the business activity prioritization listed below:

1. Automotive & Transportation (experience indicates the most violations)
2. Hazardous Materials (extension of existing hazardous materials inspections)
3. General Industrial
4. Food Service
5. General Commercial

estimate 6 - 9 months per category

In addition to the VRSD, SPFD, and Public Works inspectors, all related field personnel will be trained to be aware of potential violation and the reporting format. This training will be given to building inspectors, fire personnel, public works maintenance, and refuse personnel.

ATTACHEMENT 4
HANDOUTS FOR BUSINESSES AND RESIDENTS
ON ILLICIT DISCHARGE CONTROL

IS YOUR BUSINESS POLLUTING STORMWATER?

Even though you live miles from the ocean, you may be polluting waterways and the ocean without knowing it.

Storm drains and sanitary sewers are two separate systems that discharge to creeks, rivers, waterways, and the Pacific Ocean. Sanitary sewers are designed to collect most (but not all) liquid wastes and safely remove waste materials at treatment facilities. Storm drain channels that are located in neighborhoods, commercial developments, and industrial sites also receive wastes from clean-up activities that are washed down day after day into gutters, catch basins, and channels. Materials collected by storm drains receive no treatment, however! These materials collect until rainfall flushes pollutant materials to the nearest river or creek where they may harm wildlife, the environment, and recreational areas. The pollutants originating from our homes, businesses and a variety of sources contribute to stormwater pollution, a growing problem. This brochure briefly explains how you can the amounts of oil and grease, toxic materials, vegetation, floating materials, cleaning materials, and other substances you discharge into the storm drains.

Understanding and using this brochure will help you comply with local stormwater pollution requirements and wastewater discharge restrictions.

The Ventura Countywide Stormwater Quality Management Program has developed a seven step process for the selection of Best Management Practices (BMPs) to help you determine the best way to reduce potential stormwater pollutants. Please join us in our effort to protect the local waterways.

WHAT ARE BEST MANAGEMENT PRACTICES?

"Best Management Practices" is a term that embraces a variety of techniques used to reduce or eliminate potential stormwater pollutants at the source. Many BMPs are just good housekeeping. There are basically two types of BMPs: Source Control and Treatment Control. Source Control BMPs are operational practices, that prevent pollution by reducing potential pollutants at the source. Treatment Control BMPs are methods of treatment to remove pollutants from stormwater.

IS YOUR BUSINESS POLLUTING STORMWATER?

Even though you live miles from the ocean, you may be polluting waterways and the ocean without knowing it.

Storm drains and sanitary sewers are two separate systems that discharge to creeks, rivers, waterways, and the Pacific Ocean. Sanitary sewers are designed to collect most (but not all) liquid wastes and safely remove waste materials at treatment facilities. Storm drain channels that are located in neighborhoods, commercial developments, and industrial sites also receive wastes from clean-up activities that are washed down day after day into gutters, catch basins, and channels. Materials collected by storm drains receive no treatment, however! These materials collect until rainfall flushes pollutant materials to the nearest river or creek where they may harm wildlife, the environment, and recreational areas. The pollutants originating from our homes, businesses and a variety of sources contribute to stormwater pollution, a growing problem. This brochure briefly explains how you can the amounts of oil and grease, toxic materials, vegetation, floating materials, cleaning materials, and other substances you discharge into the storm drains.

Understanding and using this brochure will help you comply with local stormwater pollution requirements and wastewater discharge restrictions.

The Ventura Countywide Stormwater Quality Management Program has developed a seven step process for the selection of Best Management Practices (BMPs) to help you determine the best way to reduce potential stormwater pollutants. Please join us in our effort to protect the local waterways.

WHAT ARE BEST MANAGEMENT PRACTICES?

"Best Management Practices" is a term that embraces a variety of techniques used to reduce or eliminate potential stormwater pollutants at the source. Many BMPs are just good housekeeping. There are basically two types of BMPs: Source Control and Treatment Control. Source Control BMPs are operational practices, that prevent pollution by reducing potential pollutants at the source. Treatment Control BMPs are methods of treatment to remove pollutants from stormwater.

Most BMPs target a specific activity that could add pollutants to stormwater. This pamphlet concentrates on a seven-step process allowing you to select BMPs based on the activities at your facility.

SEVEN STEPS FOR BMP SELECTION

1. Identify activities by type and location

Look around your facility and identify areas where waste liquids, operation rinse water and other non-domestic wastewater could reach a storm drain or floor drain. Look for activities that discharge water such as vehicle and equipment washing, repair, mopping or hosing down floors and pavement, and outdoor storage. Look for outdoor areas where rain water could wash pollutants into the storm drain.

2. Identify BMPs already in place and evaluate

It is possible that you will already have BMPs in place, but some may need "tightening up" to achieve their full effectiveness. Some examples include:

Plans to prevent or contain spills.
Separation of wastes to allow recycling.
Preventive maintenance procedures.
Vacuuming or sweeping before or instead of mopping.

3. Identify solutions to non-stormwater discharges.

Once you have identified pollutant generating activities, you can come up with ways to stop the discharge or move the activity inside or under a roof. Another possibility is to treat the wastewater and discharge it to the sanitary sewer.

4. Start with low cost, simple Source Control BMPs.

Begin by looking for ideas for reducing or eliminating discharges that are easy to implement and are inexpensive. Often improved housekeeping or a procedural change can go a long way to reducing the generation of wastes. The axiom of "80% of the problem can be solved with 20% of the effort" probably is true for most businesses.

VOL 12

5. Consider other Source Control BMPs.

You may still have areas where the amount of pollution will be significant. The solution may involve a strategy that requires more effort. This could involve a change in equipment or material, sealing floor drains, finding a vendor who recycles spent materials, or covering a large exposed activity area.

6. Consider Treatment Control BMPs.

In a situation where a discharge can not be eliminated, the discharge should be treated. Treatment controls include oil/water separators, catch basin sumps, in-line treatment systems, filtration, or installing a diversion pipe to the sanitary sewer.

7. Prepare BMP list and priorities.

Decide which BMPs to implement first. Make sure the BMP list will meet the objective to reduce or eliminate the pollutant discharge.

2

TRAINING

0551

Another critical element to having a successful BMP program is training employees who will implement the BMPs. Training should be an integral part of your effort to reduce pollutants in stormwater. The Ventura Countywide Stormwater Quality Management Program is developing materials for various types of businesses that can be used in a training program. Materials for automotive service businesses will be ready soon, followed by materials for restaurants and other types of businesses.

STATE GENERAL PERMIT FOR INDUSTRIAL ACTIVITIES

If you are involved in certain industrial activities, you may be subject to a State General NPDES permit. Your community's stormwater program coordinator, listed below, local Ventura County representative can help you determine if you are subject to this permit.

For more information on developing and implementing BMPs, please call [include a list of contacts here].

Handout for Residents on Illicit Discharge Control (Front)

Have you seen this sign painted on the curb?

This sign on the curb is a reminder not to dispose of trash, motor oil, paint, cleaners, animal wastes, or other materials and substances into catch basins.

Stormwater will carry these substances through the storm drain system directly to our waterways and the ocean.

Storm drains are intended to carry only stormwater. Substances or materials dumped into storm drains may be harmful to fish, marine animals, birds, other wildlife and US!

You're the solution.

STOP STORMWATER POLLUTION!

- Never dispose of anything into gutters or down catch basins.
- Recycle used motor oil.
- Keep your vehicle in good working condition to prevent leaking oil, antifreeze and other fluids.
- Put trash in its proper place. Don't litter.
- Dispose of paint and other household harzardous wastes at local collection events.
- Use environmentally sound gardening practices.
- Compost or recycle yard and landscape clippings.
- Irrigate your landscape efficiently to avoid runoff.

For more ways to help protect the environment, contact one of the participating agencies.

DON'T DUMP — DRAINS TO OCEAN

Este aviso en la banqueta le prohibe tirar basura, aceite de motor, pintura, detergentes, limpiadores, desechos de animales, materiales y substancias toxicas a la cuneta y a los alcantarillados.

El agua de la lluvia transporatara estas substancias por los alcantarillados directamente a nuestros rios y oceano.

La intension de los systemas de alcantarillado es especificamente para transportar agua de lluvia. Subtancias o materiales desechados en el alcantarillado pueden ser peligrosos para los seres humanos, la fuana marina, aves y toda vida salvaje.

Usted es la solución.

COOPERE Y EVITE LA CONTAMINACIÓN DE EL AGUA DE LAS LLUVIAS.

- Nunca tire basura a la cuneta o alcantarillados.
- Reciclar el aceite de motores usado en el lugar adecuado.
- Mantener el vehiculo en buen estado para prevenir fugas de aceite, anti-congelantes u otros fluidos.
- Poner las basura en el sitio apropiado.
- Deshacerse de pinturas o productos caseros toxicos en eventos de colección local.
- Usar metodos de jardineria que protejan el ambiente.
- Reciclar o deshacerse propiamente de rebabas de pasto y corte de ramas de arboles y arbustos.
- Riegue su jardin eficientemente para evitar que corra el agua.

Si necesita mas información para ayudar a proteger el medio ambiente, comuniquese con las siguientes agencias.

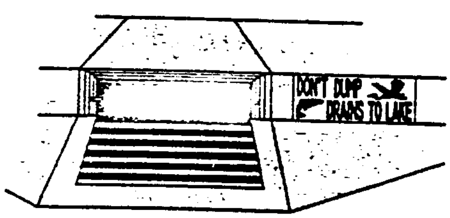
DON'T DUMP
DRAINS TO LAKE

This sign on the curb is a reminder not to dispose of trash, motor oil, paint, cleaners, animal wastes, or other materials and substances into gutters, curb inlets or catch basins.

Stormwater will carry these substances through the storm drain system directly to our waterways and the ocean.

Storm drains are intended to carry only stormwater. Substances or materials dumped into storm drains may be harmful to fish, marine animals, birds, other wildlife and US!



You're the solution.

You're the solution.
STOP STORMWATER POLLUTION!

- Never dispose of anything into the gutter or down curb inlets and catch basins.
- Recycle used motor oil.
- Keep your vehicle in good working condition to prevent leaking oil, antifreeze and other fluids.
- Put trash in its proper place. Don't litter.
- Dispose of paint and other household hazardous wastes at local collection events.
- Use environmentally sound gardening practices.
- Compost or recycle yard and landscape clippings.
- Irrigate your landscape efficiently to avoid runoff.

For more ways to help protect the environment, contact one of the participating agencies.

SANTA MONICA BAY STORMWATER POLLUTANT REDUCTION STUDY

Enclosed is Volume I and Volume II (Data Appendix) of the final report for the Santa Monica Bay Stormwater Pollutant Reduction Study. This report, and the implementation of the recommended projects herein, is a result of an agreement the City of Los Angeles has with the EPA and the State of California (Amended Consent Decree).

The study assesses the nature and extent of discharges of pollutants from stormwater runoff. A large scale map of the "Drainage Basins and Sub-Basins in the Study Area", Exhibit 1, and "Land Use Distribution Within the Study Area", Exhibit 2 are included with this report (maps are located in rear pockets of Volume I of the report). The study is structured towards development of recommended pilot-size projects for control of stormwater runoff pollutants. A primary objective of the evaluation of such projects was to recommend projects that would be compatible with the long-term stormwater management plan being developed by the City.

Potential runoff pollution control measures that could be implemented in the study area were identified. Potential pollution control measures were categorized as structural (physical facilities) and non-structural (management approaches for controlling the discharge of pollutants). The primary criteria used to evaluate alternative runoff pollution control measures were costs, efficiency, community and environmental impacts, and regulatory and institutional aspects. Costs were defined in terms of Total Suspended Solids and Oil & Grease removal per thousand dollars of investment.

The four approved projects and their current status are:

<u>Enhanced Catch Basin Cleaning</u>

Enhanced catch basin cleaning was targeted for an area of about 17,000 catch basins. The debris is being assessed as an indication of the source of pollutants, first flush versus total runoff pollution discharge characteristics, and pollutant loadings from debris "stored" in the catch basins versus those pollutants resulting from "pass through" debris during a rainfall event.

Visual inspections and data recording, and debris accumulation are now in the 23rd month. Data is continuously being entered into the information management system and adjustments to the program are continuing as the need arises.

Both dry and wet weather water quality sampling and analysis have been completed for the purposes of this study. A draft report will then be prepared describing the monitoring results, the data on debris accumulation, and the general effectiveness of the program.

Parking Lot Strip Filters

This project constructed a rapid sand stormwater filter in a typical small parking lot. All of the runoff from the lot passes through the sand filter media prior to discharge into the storm drain system. A report describing the design and construction of this project is scheduled to be completed in September, 1994.

As part of the City's long term commitment to continually evaluate the effectiveness of Best Management Practices, this rapid sand filter is being monitored and refined as needed. The City has entered into an agreement with Loyola Marymount University to assist the City in studying the long term effectiveness of the rapid sand filter. This study will include wet weather monitoring, effectiveness evaluation and improvement/refinement recommendations.

The objective of the study is to evaluate the effectiveness of the strip filter design in removing the pollutants typically associated with urban parking lot runoff. Specific recommendations are to be made for any modifications, if necessary, to the design to enhance its performance, reliability, operation and maintenance. The design may become a typical design standard to be used at other locations.

Public Education Program

The status of the various programs within the Public Education Program is as follows:

The General Outreach Program

This program included the television, billboard and media outreach campaigns. The Ocean Safe Coalition was formed to bring the media in as partners to work on stormwater pollution problems. Appointments with television stations started in June 1994 with the goal of having a Public Service Announcement (PSA) on the air. Marketing the PSA for television is underway. The City is making appointments with each local media outlet to ask them to air the PSA and join the Ocean Safe Coalition. The PSA should be on the air in October, 1994.

VOL 12 2 0561

The Grass Roots Community Outreach Program

The main component is the catch basin stencil program. Over 14,000 catch basins have been stenciled around the City by the Los Angeles Conservation Corps and the Gutter Patrol volunteer program being administered by Heal the Bay. The second major component of the Grass Roots Program is the Ocean Safe Coalition (OSC) which is a forum for clean water issues. OSC is asking business, media, government, community and environmental groups to join together around the issue of stormwater pollution abatement as it relates to federal and state regulations as well as the quality of life in the community. Over 2,000 invitations to join the OSC have been sent and the first OSC event is planned to be held before the end of 1994.

The School Education Program

A classroom curriculum pilot program ended in August, 1994. In the pilot phase, the curriculum was presented to a dozen classrooms and approximately 400 students. Revisions are underway for the final draft of the curriculum. A report describing the highlights of the Program activities will be completed in September, 1994.

Household Hazardous Waste Collection

A total of four round-up events have been completed. This completes our Consent Decree obligation for this project. Data collected from these events is being assessed. This information will be used to extrapolate the amounts of various hazardous waste materials prevented from contributing to the pollution stream affecting the Santa Monica Bay, among other things.

In conclusion, if you desire additional information about any of the four stormwater projects, please call Mr. Wing Tam, Stormwater Management Division, Bureau of Engineering, at 213-847-5225. Calls regarding the study itself should be directed to Robert LaFrance, Wastewater Program Management Division, Bureau of Engineering, at 213-847-9576.

Sincerely,

Robert S. Horii
City Engineer

EXECUTIVE SUMMARY

This Santa Monica Bay Stormwater Pollutant Reduction Study (Study) was conducted for the City of Los Angeles (City) as a requirement of the Amended Consent Decree settlement regarding protection of water quality in Santa Monica Bay. The Study describes approaches and methods for development of pilot projects for reducing pollutants transported to Santa Monica Bay in runoff flows from rainfall and in unregulated anthropogenic flows during the dry season. The Study recommends pollutant control measures to be approved by the United States Environmental Protection Agency (EPA) and implemented by the City with a cost up to $3 million. Runoff sampling techniques and analysis procedures, development of loading models for targeted runoff pollutants, identification of feasible runoff pollutant control strategies, and recommendations for pilot control projects were discussed throughout the study with City staff, interested State agencies, EPA, and concerned public environmental groups.

The evaluations of potential runoff pollutant control projects were to be used to satisfy requirements of the Consent Decree and provide guidance for development of long-term control strategies. This Study can also be used to provide performance estimates and monitoring data to a stormwater runoff management plan by the City. Additional data would be needed to develop statistical information on stormwater runoff pollutant occurrence, levels, or distributions. Conclusions regarding the assimilative capacity of the receiving waters, and the extent of impact on the receiving waters from stormwater pollutant loading, would also require additional study.

THE STUDY AREA

The area included in this study represents the region of the Los Angeles Basin that drains into Santa Monica Bay and is served by the City's Hyperion Treatment Plant (HTP). This drainage area comprises 52,600 hectares (ha) (130,000 acres) of southwestern Los Angeles County, bounded on the north by the crest of the Santa Monica Mountains, on the southwest by the Pacific Ocean, and on the east by the downtown Los Angeles area. The highly-urbanized study area includes the cities of Los Angeles, Santa Monica, Beverly Hills, Culver City, and much of El Segundo, as well as portions of unincorporated Los Angeles County. Major land uses within the study area include residential, industrial, commercial, transportation, and dedicated open space.

The study area is served by an extensive network of stormwater drains separate from the sanitary sewer system. A total of 26 major storm drainage basins, some with distinct sub-basins, enter Santa Monica Bay from the study area (Exhibit 1). Runoff pollutants enter the Bay in the storm drain system both as a result of wet weather flows following rainfall events and in dry weather flows from a variety of primarily anthropogenic sources.

2 0573

EXISTING POLLUTANT SOURCES

Existing pollutant discharges to Santa Monica Bay have a variety of both regulated point sources and unregulated nonpoint sources. Regulated discharges include municipal wastewater treatment plants, electric power generating stations, an oil refinery, and numerous other smaller permitted discharges. Nonpoint sources include drainage channels, ocean dumping, marine vessels, and other sources. Municipal wastewater treatment plants and drainage channel runoff are the most significant sources of pollutant input.

Point source discharges to Santa Monica Bay are regulated through the National Pollutant Discharge Elimination System (NPDES) permit program administered by the California Regional Water Quality Control Board, Los Angeles Region. These discharges must meet the water quality objectives established to preserve the beneficial uses of Santa Monica Bay as set forth in the Water Quality Control Plan-Los Angeles River Basin (revised 11/27/78 and as amended 1992). Pollutant loading from drainage channels is partially controlled by structural (physical facilities) and non-structural (management approaches for controlling the discharge of pollutants) runoff control measures, including debris basins, settling basins, stormdrain system maintenance, streetsweeping, catch basin cleanings, and collection of household hazardous wastes. While design and operations of the drainage system is primarily designed for flood control, some components of the system, as well as some sanitation activities, indirectly provide a degree of runoff pollution control.

DETERMINATION OF RUNOFF POLLUTANT LOADING

The methodology used to determine runoff-associated pollutant loading into Santa Monica Bay included:

1. Identification of drainage basins and major land uses
2. Selection of important runoff pollution constituents
3. Selection of detailed land-use study areas
4. Runoff sample collection and constituent analysis
5. Analysis of rainfall records
6. Typical storm study
7. Calculation of estimated pollutant loads for a typical storm and a typical rainfall year

For each major storm drain outlet, drainage areas and sub-areas were developed using topographic and stormdrain network information. Land use was mapped for five major uses that are common over the entire study area: residential, commercial, light industrial, transportation, and dedicated open space (Exhibit 2). The distribution of land uses by drainage basin was then calculated.

Pollutants were selected for detailed study based on several criteria: their potential impact on beneficial uses of Santa Monica Bay, identification with adverse effects on human health through water contact activities, identification with adverse biological effects in Santa Monica Bay, identification with adverse aesthetic effects in Santa Monica Bay and on beaches, public concern, contribution of stormwater runoff pollutant loading versus total pollutant loading in Santa Monica Bay, and implementability of pollutant controls. The most persistent, nonvolatile constituents that accumulate in the environment were selected, including metals and inorganics (arsenic, cadmium, chromium, copper, lead, mercury, nickel, silver, and zinc) and certain pesticides and herbicides.

Selection of areas for detailed study was based on the need to characterize stormwater runoff on homogeneous land-use types that could be isolated for purposes of monitoring without interference from other activities. Candidate areas were identified for light industrial, commercial, residential, and transportation land uses. In addition, a monitoring location that provided integrated information was chosen. All of the areas were located within the Ballona Creek watershed.

Stormwater runoff samples were collected at each of the five chosen locations using automatic water collection pump samplers. Each sampler was coupled with a flow-monitoring device programmed to activate the sampler based on a preprogrammed increase in flow rate within the storm drain resulting from rainfall runoff. Dry-season flow samples were collected in the same land-use areas as those for which stormwater runoff flows were collected. For dry-season samples, a 24-hour composite sample was collected at each site by combining 24 discrete hourly samples collected over a 24-hour period. The volume of samples collected was sufficient to satisfy requirements of the analyzing laboratory to complete constituent testing.

Information from flowmeter data at the sampled study sites, data from rainfall recording stations, and historical storm data was used to develop runoff hydrographs for the sampling sites and the study area. Separate hydrographs were developed for coastal and mountain regions of the study area, and for storms occurring during the dry season and the wet season.

Estimates of pollutant loading into Santa Monica Bay from the study area were developed by calculating pollutant runoff from each land use type in each drainage area, and summing the contribution of each drainage basin. Dry weather runoff pollutant input was determined by calculating the volume of dry weather runoff flows from the study area and the concentrations of target pollutants in low-flow samples collected in Ballona Creek. Pollutant concentrations in both wet-weather and dry-weather runoff frequently exceeded California Ocean Plan instantaneous maximum concentration standards. While concentrations of target pollutants were frequently higher in stormwater runoff than those in municipal wastewater treatment plant discharges, the annual mass loading of runoff pollutants was approximately 25 percent of treatment plant loadings.

The analyses indicated that the control of total suspended solids (TSS) can effectively control the discharge of most toxic metals into Santa Monica Bay. Alternative measures, primarily based on controlling the sources, would be required for reducing the load of cadmium, silver, herbicides, and pesticides. Control measures suitable for removing oil and grease (O&G) from the runoff stream would also be effective in reducing herbicides and pesticides.

EVALUATION OF RUNOFF POLLUTANT CONTROL MEASURES

Potential runoff pollution control measures that could be implemented in the study area were identified to satisfy the requirements of the Consent Decree. Potential pollution control measures were categorized as structural (physical facilities) and nonstructural (management approaches for controlling the discharge of pollutants). The primary criteria used to evaluate alternative runoff pollution control measures were costs, efficiency, community and environmental impacts, and regulatory and institutional aspects. Costs were defined in terms of TSS and O&G removal per thousand dollars of investment.

The structural runoff pollution control measures that might be implemented in the study area were divided into four major groups: detention settling, treatment, transport, and infiltration pilot programs. The non-structural runoff pollution control measures that might be implemented in the study area were divided into three major groups: improved storm drain system maintenance practices, collection of household and other waste materials, and public awareness programs.

CONCLUSIONS AND RECOMMENDATIONS

In summary, the requirements of the Consent Decree can best be met by the following control practices:

1. infiltration pilot programs
2. collect household hazardous waste materials
3. "enhanced" catch basin cleaning program
4. public education program

A detailed analysis identifies specific areas within the Santa Monica Bay drainage area where implementation of the recommended measures would be most effective. The implementation of all of the above recommended pollution control measures at all of the recommended locations within the study area are estimated to reduce the annual TSS (and associated target metals) loading by approximately 8 percent, and the annual O&G (and associated herbicides and pesticides) loading by approximately 4 percent to Santa Monica Bay.

SECTION 1

INTRODUCTION

This report is the result of the Santa Monica Bay Stormwater Pollutant Reduction Study (Study), conducted for the City of Los Angeles (City) by Engineering-Science. The Study describes approaches and methods for development of pilot projects for reducing pollutants transported to Santa Monica Bay, a semi-enclosed coastal embayment included in the United States Environmental Protection Agency's (EPA) National Estuary Program, by storm runoff from urbanized areas served by the Hyperion Treatment Plant (HTP).

PURPOSE OF THE STUDY

On February 19, 1987, the City entered into an agreement with the EPA and the State of California in settlement of a lawsuit regarding alleged violations by the City of its National Pollutant Discharge Elimination System (NPDES) permit for wastewater discharges from the HTP. This agreement, as amended, was termed the Consent Decree (USA and State of California vs. City of Los Angeles, 1987). It placed several obligations on the City regarding wastewater treatment and waste disposal. One of the terms of the Consent Decree was Item XIV, Stormwater Control Project, which required that funds be obligated for a stormwater discharge control project. Specifications and schedules were set forth in Appendix C of the Consent Decree.

The City was directed to perform a study to "assess the nature and extent of discharges of pollutants from stormwater runoff from the HTP service area into Santa Monica Bay." The results of the study were to include recommended projects "to reduce effectively the discharge of such pollutants" into the Bay. The Consent Decree mandates that the City spend $3 million to implement control measures based on Study recommendations and EPA approval.

The study was structured to lead to the recommendation of pilot-size projects for control of stormwater runoff pollutants. In-place pilot projects were also to be evaluated for their effectiveness in reducing loading of such pollutants into Santa Monica Bay. The ultimate objective of evaluating such projects was to recommend projects that would be compatible with the long-term stormwater management plan being developed by the City to deal with pollutant runoff and loading.

RELATIONSHIP TO EPA STORMWATER REGULATIONS

On November 16, 1990, the EPA issued the final rule regarding discharge permitting procedures for stormwater runoff from certain industrial sites and from large and medium municipalities. The EPA authorized the California State Water Resources Control Board (SWRCB) to issue general or individual stormwater discharge permits. The new rules target individual cities and facilities, and allow stormwater pollutants to be controlled by several municipalities acting in conjunction within a watershed. The rules are directed at improving runoff water quality in separate storm sewer systems; they ban illicit connections between sanitary sewers and storm sewers and create new requirements for collection systems receiving stormwater separate from domestic sewage. One of these requirements is an extensive monitoring program, which requires permit holders to develop discharge characterization data for five to ten "representative" storm sewer outfalls, monitor facilities which contribute "substantial" pollutant loading to the system, and detect illicit discharges. Other requirements include a stormwater management plan which utilizes best management practices to reduce pollutant loadings, a demonstration of legal authority, and a fiscal and performance evaluation of controls proposed as part of the management plan.

The EPA also issued new rules for certain industrial facilities and for construction sites. As interpreted by the California State Water Resources Control Board, these rules require each facility or site to conduct a monitoring program to identify and monitor activities which contribute to pollutant loading to the stormwater system (especially illicit connections or disposals) and to determine the effectiveness of pollutant loading reduction efforts. A Stormwater Pollution Prevention Plan must also be prepared. This plan must include best management practices to reduce pollutant loading. In addition, worker training programs and spill prevention and response programs are required for industrial facilities. (As of this writing, the general construction activity stormwater permit applies only to sites larger than five acres, but this permit may be reopened as a result of a court case).

The City and County of Los Angeles both maintain separate stormwater control systems and are both significantly affected by the implications of the rule. This study addresses stormwater pollutant runoff control on a land-use and watershed basis, without regard to municipal boundary. Many of the recommendations contained in this report, although designed to reduce stormwater pollutant loading from targeted land-use areas and locations, would be applicable on a large scale to reduce stormwater pollutant loading from entire cities. In evaluating projects to reduce runoff pollutant loading, this study addresses one area considered by EPA to be a significant problem in attaining improved water quality in receiving water bodies: improper disposal of wastes. Information gathered from implementation of recommended runoff pollution control technologies in Section 5 of this study will help guide compliance by the City with the EPA regulations.

The new rules are of great concern to cities because of the increased responsibility for controlling stormwater pollutants, the complexity of the sampling and application requirements, and the potential financial burden imposed on affected cities. Many affected cities lack the authority to control discharges or raise revenue to conduct required programs. In addition, for most pollutants, the new regulations do not set numerical limits, but rather mandate (but do not define) best management practices.

PUBLIC PARTICIPATION PROGRAM

The results of this study, and subsequent cleanup and restoration activities in and around Santa Monica Bay, affect a large cross-section of interested public organizations. Consequently, a public participation program was developed to include public input and dissemination of information during each phase of the study.

The primary focus of the public participation program was to provide the interested agencies, environmental groups, and general public with information on the Study. The program provided information about the approaches, conduct, results, and recommendations of the Study to the Inter-Agency Storm Drain Task Force (IASDTF). Formerly known as the Pico-Kenter Task Force, this latter group was originally formed to deal with aesthetic and potential public health problems associated with dry weather runoff from the Pico-Kenter storm drain system, which discharges across a heavily-used public beach in Santa Monica.

Active participants in the IASDTF included the City of Santa Monica, the City of Los Angeles, the County of Los Angeles, the California Department of Fish and Game, the Los Angeles Regional Water Quality Control Board, the Sierra Club, Heal the Bay, UCLA, and representatives from several state and federal legislators' offices.

Primarily because of its experience and familiarity with stormwater technical and environmental issues, the IASDTF was chosen to act in an advisory role for the conduct of the Study. Monthly meetings (between 1988 and 1989) with the IASDTF were used to disseminate the information and recommendations resulting from the monitoring and evaluation phases of the Study. These meetings were open to any interested parties, and were used as a public forum to solicit and receive input from individuals and groups not directly affiliated with the IASDTF. The IASDTF was fully informed as to the scope and purpose of the study, the proposed sampling regime for the study, the proposed analytical procedures to be used, and the manner in which runoff loading and control projects would be evaluated. Additional public contacts and meetings were used to convey information regarding the study to interested City groups, environmental groups, and other interested parties. A presentation on the Preliminary Draft Report was made at the special AMICI briefing held on 11 May 1989. Additional meetings were held for the City Council staff, former Board of Public Works Commissioner Ed Avila, Heal the Bay, the Regional Water Quality Control Board, and the Santa Monica Bay Restoration Project.

CONTENT OF THIS DOCUMENT

Section 2 of this study reviews the current conditions in the study area and adjacent coastal waters relating to pollutant runoff and loading. Characteristics of the drainage area from which runoff enters Santa Monica Bay are discussed. Existing pollutant inputs into the Bay are identified and quantified in terms of annual loading. Stormwater and dry-weather runoff control practices in the study area are discussed with regard to their effectiveness on controlling pollutant loading to Santa Monica Bay.

Section 3 details the approach and methodology used in determining concentrations and total loading of runoff pollutants from the study area into Santa Monica Bay. Determination of drainage basin boundaries, land use distribution, and rainfall event characteristics in the study area are discussed. Descriptions of wet and dry weather runoff sample collections at selected land use sites are presented. A calculation of runoff loading is presented based on land use distribution and rainfall characteristics for each individual drainage basin.

Section 4 presents evaluations of the suitability of several structural and nonstructural runoff pollutant control measures in reducing pollutant loading to Santa Monica Bay. The evaluation of each measure includes consideration of cost, efficiency, environmental impact, and regulatory aspects in determining its suitability in relation to runoff characteristics described in Section 3. A final listing of implementable technologies that satisfy study requirements are developed.

Section 5 includes recommendations for runoff pollution control measures to reduce pollutant loading into Santa Monica Bay, and specifies areas in the drainage basin where the recommended measures would be most effective.

Section 6 provides references and personal communications used in the preparation of this Study.

Use of measurement units in this document will be mixed. In referring to locations of discharges and distances between points of interest, English units have been used to allow the public and other interested parties to easily refer to known locations (e.g., the 5-mile outfall of the Hyperion Treatment Plant). For consistency with scientific literature and comparison with other runoff pollutant studies, metric units have been used for measurements of area (hectare [ha]), flow (liter per second [L/s]), constituent concentrations (milligrams per liter [mg/L]), pollutant loading (kilograms [kg]), and associated quantities.

A data appendix, provided under separate cover (Volume II), includes complete descriptions and analytical results for studies conducted for this project, including analyses of areal rainfall variation during sampled storms in 1988, analysis of typical storms for use in calculation of runoff pollutant loading, and analytical results of runoff sample collections by land use.

SECTION 2

STUDY APPROACH AND PRESENT CONDITIONS

CHARACTERISTICS OF THE SANTA MONICA BAY DRAINAGE AREA

The area included in this study comprises 52,600 ha (130,000 acres) of southwestern Los Angeles County. The curve of the southern California coast results in a roughly triangular-shaped region with fairly well-defined physical boundaries. The study area is bounded on the north by the crest of the Santa Monica Mountains, on the southwest by the Pacific Ocean, and on the east by the downtown area, the majority of which is not part of the drainage basin. This area represents the region of the Los Angeles Basin that drains into Santa Monica Bay and is served by the HTP (Exhibit 1).

The majority of the study area is highly urbanized. Most of the area lies in the City of Los Angeles; however, the area also includes the Cities of Santa Monica, Beverly Hills, Culver City, and much of El Segundo. These cities contract with the City of Los Angeles to provide sewage treatment services. They are, therefore, appropriate for inclusion in this investigation. Major land uses within the study area include residential, industrial, commercial, transportation, and dedicated open space. A more complete discussion of land-use distribution within the study area is included in Section 3.

The highly urbanized portions of the study area contain a high percentage of impervious surface: most of the rain falling on these surfaces quickly runs off to the storm-drain system. The northwestern portion of the study area includes the southern slopes of the Santa Monica Mountains. These slopes are primarily dedicated open space; existing residential sites generally include large lots. Some parts of this mountain area are classified residential-agricultural, and include lots zoned for equestrian use. These uses include locations with one or more animals. Areas zoned for dedicated open space generally have a very small percentage of impervious area; only a small fraction of rain falling on these surfaces escapes as runoff.

The study area is served by an extensive network of stormwater drains, separate from the sanitary sewer system. A total of 26 major storm drainage basins, some with distinct sub-basins, enter Santa Monica Bay from the study area (Exhibit 1; Table 2-1). Methodology for determining the extent of each drainage basin and sub-basins is described in Section 3. The storm-drain system was designed and constructed as a flood-control system, and acts to convey storm runoff to the ocean as quickly as possible. During the dry weather season, a significant percentage of the observed flows consist of regulated discharges, including cooling system blowdown waters, dewatering effluent, decorative fountain and pool backwash, water softener waste, commercial and industrial process water, and other effluents.

Source: Engineering-Science
[a] Numbering corresponds to basins in Exhibit 1

Various parts of the storm system draining to Santa Monica Bay are owned and managed by a number of local government agencies, including the City of Los Angeles, the County of Los Angeles, and other cities. Each of these agencies has programs for safety and maintenance of the drain system, and most are also concerned with the quality of water within and passing through their jurisdictions. It is a peculiarity of the system that agencies frequently have no control over water quality entering their jurisdictions, but may be responsible for achieving certain water quality objectives as flows exit their jurisdictions. These agencies, although responsible for maintenance within the system, often have no authority to regulate discharges to the system, nor to raise funds to conduct enforcement, monitoring, and cleanup actions.

EXISTING POLLUTANT INPUTS INTO SANTA MONICA BAY

To provide perspective, an area much larger than the area addressed in this runoff study is included in the following description of pollutant inputs into Santa Monica Bay. Santa Monica Bay is defined for this study as extending from Point Dume to Point Fermin, rather than from Point Dume to Palos Verdes Point (the usual definition), because discharges on the Palos Verdes Shelf between Palos Verdes Point and Point Fermin affect the Bay (MBC, 1988). This wider definition reflects the impossibility of attempting to separate the Bay into distinct areas affected by pollutant inputs from adjacent land areas, as might be possible for land-based drainage systems. Data are provided for 1987, the baseline analysis year for this study.

Pollutants enter Santa Monica Bay through regulated discharge points and through unregulated nonpoint sources.

Regulated Discharges

Six facilities have NPDES permits to discharge directly into the Santa Monica Bay: two wastewater treatment plants, three power generating stations, and one oil refinery.

Wastewater Treatment Plants

Two municipal wastewater treatment plants discharge directly into Santa Monica Bay. These are the HTP of the City of Los Angeles and the Joint Water Pollution Control Plant (JWPCP) of the County Sanitation Districts of Los Angeles County. The two treatment plants treat most of the municipal sewage from the Los Angeles Basin portion of Los Angeles County.

Location. HTP is located on the coast of Santa Monica Bay at Playa del Rey. It routinely discharges wastewater undergoing primary treatment and partially secondary treatment (70 percent and 30 percent, respectively, in 1987) through an 8-kilometer (km) (5-mile) outfall, which discharges west of Playa del Rey at a depth of 60 meters (m) (Figure 2-1). A 1.6-km (1-mile) outfall, discharging at a depth of 15 m, is used during emergencies; the wastewater is required to receive secondary treatment and disinfection. HTP expects to provide a level of treatment so that the total plant's discharge meets secondary standards by 1998. From 1957 to 1987, sludge was discharged from an 11-km (7-mile) outfall (which terminated at the head of Santa Monica Canyon) at a depth of 100 m (MBC, 1988). This outfall was abandoned 1 December 1987

JWPCP, located in Carson, discharges wastewater undergoing advanced primary and partial secondary treatment through either of two outfalls that terminate about 3 km offshore at depths of 60 m (Figure 2-1). Two shorter outfalls, terminating at depths of 35 and 50 m, respectively, are sometimes used in addition to the two main outfalls (MBC, 1988).

Mean Annual Discharge Volume. The annual discharge volume of HTP and JWPCP was similar from 1974 to 1987. The mean annual discharge volume of the

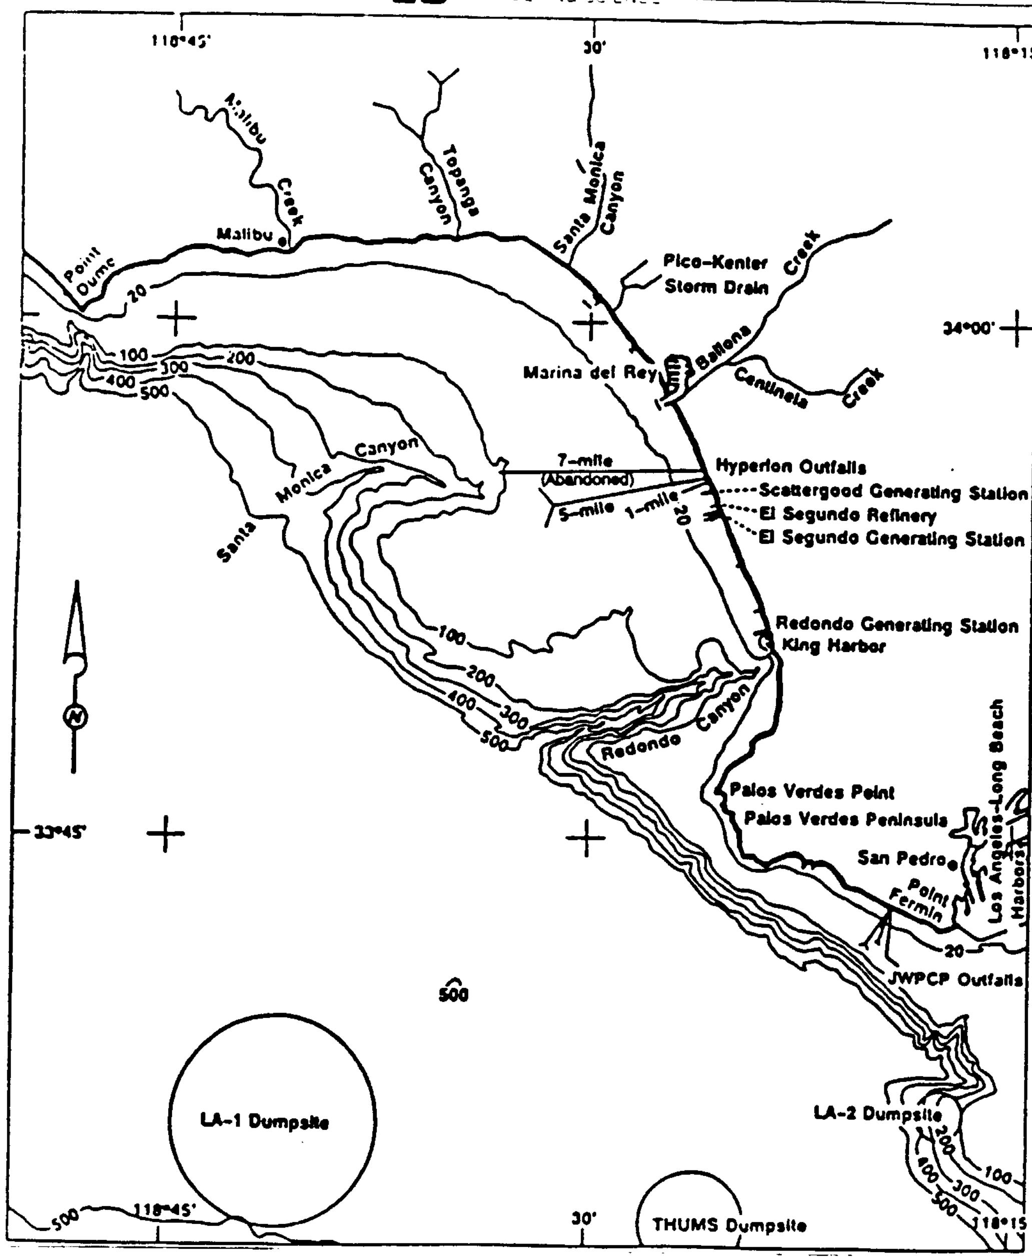

Figure 2-1 Major Discharges into Santa Monica Bay

R0053889

5-mile outfall of HTP was 507 x 10^9 liters. During the same period, the mean annual discharge volume of the 7-mile sludge outfall was 6 x 10^9 liters. Discharge from the 7-mile outfall was terminated late in 1987. The 1-mile outfall is used only in emergencies, with only a few periods of discharge per year. Hence, HTP had a mean annual discharge volume of about 513 x 10^9 liters. The discharge volume of the 5-mile pipe in 1987 was 518 x 10^9 liters. The mean annual discharge volume of the JWPCP outfalls from 1974 to 1987 was 492 x 10^9 liters. The discharge volume in 1987 was 507 x 10^9 liters (MBC, 1988).

Levels of Constituents of Concern. Levels of most constituents of concern have decreased in the effluent of HTP and JWPCP since 1974 because of improved treatment and source control; hence, recent levels are more representative than are mean levels (Table 2-2).

Several trends occurred at HTP during this period. HTP effluent concentrations and mass emissions of total suspended solids increased from 1974 to 1985 before decreasing to lower levels in 1987; a peak in 1985 resulted from construction at HTP, which temporarily reduced the number of holding tanks. Oil and grease levels remained relatively constant during this period. The levels of most metals was lower in 1987 than in 1974, but lead was higher; although most metals showed a relatively smooth decrease, levels of zinc and lead fluctuated greatly. In 1987, effluent from the 5-mile outfall had the highest concentrations of oil and grease and silver of the major regulated discharges to the Bay (Table 2-2). It had the lowest concentration of chromium. Because of the large flow volume, however, HTP was not only the major contributor (in terms of mass emissions) of oil and grease to the Bay but also of arsenic (along with JWPCP), cadmium, copper, nickel, and zinc. Total DDT was not detectable (MBC, 1988).

Most constituents at JWPCP showed a strong decreasing trend since 1974; however, silver and mercury were relatively constant. In 1987, the JWPCP effluent had the highest concentration of total suspended solids of the major discharges to the Bay (Table 2-2); however, suspended solids levels was not directly measured in storm water. The JWPCP effluent was the major contributor (excluding storm runoff) of total suspended solids to the Bay and also of arsenic (along with HTP), chromium, lead, silver, and mercury (MBC, 1988).

Regions Affected. The region most affected by the HTP and JWPCP outfalls lies offshore. In Santa Monica Bay proper, effects of the HTP outfalls occur near the ends of the outfalls, about 5 miles and 7 miles offshore and at depths of about 60 and 90 m, respectively. The disturbed area near the HTP 7-mile outfall has decreased in size since the termination of sludge discharge. The region most affected by the JWPCP outfall lies along the Palos Verdes Shelf at 60 m. Contaminants from this discharge are carried into Santa Monica Bay proper with greatest concentrations in the southern part of the Bay. The distribution of contaminated sediments and the effects on the benthic invertebrate and fish assemblages were extensive near the JWPCP outfall and somewhat less so near the HTP outfalls in the early 1970s. The affected area has decreased in both areas since then, however, apparently because of improved effluent quality (MBC, 1988).

Industrial Discharges

The El Segundo Refinery of Chevron USA is the only industrial discharger with an outfall in the Bay. It manufactures various petroleum products from crude and refined oil.

Location. The El Segundo Refinery discharges wastewater undergoing primary and secondary treatment from a 0.2-km-long outfall at a depth of 6 m; all process water (about a third of the total volume) receives secondary treatment (Judson, 1989, personal communication). Surface runoff is also discharged through the outfall. The outfall lies between the intake and discharge conduits of the Scattergood and El Segundo Generating Stations at El Segundo (Figure 2-1).

Mean Annual Discharge Volume. The refinery generally discharges about 8.9×10^9 liters/year. In 1987, the discharge volume was 8.4×10^9 liters (MBC, 1988).

Levels of Constituents of Concern. Levels of most constituents in the effluent of the El Segundo Refinery have decreased since 1983 because of improved treatment; hence, recent levels are more representative than are mean levels. In 1987, the average concentration of copper was the lowest of any of the major discharges to the Bay and mercury was the highest (Table 2-2). Because of the relatively low discharge volume of the effluent, however, the refinery was not a major contributor of mercury to the Bay. Cadmium, lead, and DDT were not detected in the effluent (MBC, 1988).

Region Affected. The region affected by the El Segundo Refinery discharge is small, lying close to shore at El Segundo. Higher phytoplankton abundance associated with a plume of ammonia (possibly from the outfall) near the sea surface in the area before 1977 is the only known effect (Eppley, 1986; MBC, 1988).

Generating Stations

Three electrical power-generating stations circulate seawater from the Bay through their systems to cool condensers. These stations are the Scattergood Generating Station of the Department of Water and Power, City of Los Angeles, and the El Segundo and Redondo Generating Stations of the Southern California Edison Company.

Location. The Scattergood and El Segundo stations are near the City of El Segundo and the Redondo station is in the City of Redondo Beach (Figure 2-1). Intake and discharge conduits generally extend about 0.3 to 0.8 km offshore and have openings at depths of 5 to 6 m (MBC, 1988).

Mean Annual Discharge Volume. The volume of water circulated through the cooling system of the power-generating stations annually is very large (i.e., 444×10^9, 511×10^9, and $1{,}046 \times 10^9$ liters for Scattergood, El Segundo, and Redondo Generating Stations, respectively). In 1987, these volumes were 419×10^9, 437×10^9, and 898×10^9 liters. Because this cooling water is unfiltered seawater (with the contaminant levels of the sea offshore), it is unreasonable to use these flows in calculations of annual loadings. Wastes produced within the stations and surface runoff are held in settling basins before being discharged through the circulating seawater to the ocean. The mean volume of water discharged from the retention basins in 1987 was 166 x 10^6, 221 x 10^6, and 1,658 x 10^6 liters, or about 1,000 times less than cooling system flow volumes; these discharges contain most of the plant-generated contaminants (MBC, 1988).

Levels of Constituents of Concern. Levels of constituents for 1987 at the three generating stations were generally comparable to other discharges to the Bay in concentration, but were lower (because of lower flow volumes) in mass emissions (Table 2-2). The lowest concentrations of total suspended solids and oil and grease were found in the effluents of the Redondo and Scattergood Generating Stations, respectively. Copper concentrations were generally higher in these effluents than in other discharges to the Bay, with the highest concentration in the El Segundo Generating Station effluent. The highest concentration of nickel was found at Scattergood and the highest zinc concentration was found at Redondo.

Because of the low retention basin flow, mass emissions of all constituents were low (Table 2-2). The lowest emissions of oil and grease, chromium, copper, and zinc were those of Scattergood; the lowest emission of suspended solids occurred at El Segundo; and the lowest emission of nickel occurred at both Scattergood and El Segundo.

Silver was not detected at Scattergood and El Segundo; arsenic was not detected at El Segundo; and mercury and DDT were not detected at Scattergood.

Region Affected. The region affected by discharge from the three power-generating stations lies close to shore approximately from Playa del Rey to King Harbor. Effects have been studied in connection with NPDES permits, and appear to be minimal (EQA/MBC, 1973; IRC, 1979, 1981; MBC, 1982, 1986, 1988).

Nonpoint Sources

Nonpoint sources of contamination to Santa Monica Bay consist of unregulated and largely uncontrolled sources that are distributed broadly in the area. These include drainage channels, ocean dumping, marine vessels, aerial fallout, sediment reservoirs, seeps, and advection.

Drainage Channels

Drainage channels include the streams and stormdrains that discharge into the Bay. These have a low-volume flow throughout most of the year, but discharge high volumes during and following storms.

Location. At least 68 major storm drains are along the coast between Malibu and Point Fermin, with many additional smaller drains along the Malibu and Palos Verdes Coasts; four major channels (Santa Monica Canyon, Pico-Kenter Stormdrain, Ballona Creek, and Centinela Creek) are in the study area (Figure 2-1). The major streams in the area are Malibu Creek and Ballona Creek, with smaller streams reaching the ocean along the Malibu coast. Ballona Creek and Malibu Creek drain the largest areas (more than 250 km^2 each). The drainage of Malibu Creek includes a large segment of the Santa Monica Mountains, whereas the

Ballona Creek drainage includes much of Los Angeles and communities to the west; the natural drainage to Santa Monica Bay that lies south of Ballona Creek usually extends less than 2 km inland from the shore (MBC, 1988).

Mean Annual Discharge Volume. The mean annual discharge volume of surface runoff from the 68 drainage channels reaching Santa Monica Bay is about 213×10^9 liters (NRC/COWT, 1984; MBC, 1988); however, the daily average varies greatly with season and year. The annual flow of Ballona Creek ranges from about 27×10^9 liters in a dry year (1984) to 112×10^9 liters in a wet year (1983). In general, the flow from Ballona Creek is 2 to 10 times greater than that from Malibu Creek, but in 1969 (a wet year) the flow from Malibu Creek was 1.5 times greater than the Ballona flow (MBC, 1988). During a storm in 1986, the peak flow in Ballona Creek was 275 times the dry weather flow (Schafer and Gossett, 1988). Part of the flow in Ballona Creek is from regulated discharges; during dry-weather flow, this discharge may make up a significant percentage of the total flow (Mitchell, 1988, personal communication).

Levels of Constituents of Concern. The mean concentrations of constituents of concern for the calendar years 1983-1984 (the last years of frequent periodic sampling) were generally within the range of those of the point-source discharges to the Bay in 1987 (Table 2-2). Lead and total DDT concentrations, however, were higher in surface runoff than in the point-source discharges. Total suspended solids and arsenic were not reported for drainage channels; however, suspended solids are high during storms (MBC, 1988). Compared to other drainage channels in Southern California, Ballona Creek storm water had the highest levels of oil and grease, DDT, and trace metals in 1986 (Schafer and Gossett, 1988).

The mean annual loading (mass emissions) of the constituents of concern for the years 1983-1984 was generally within the range of the point-source discharges in 1987 (Table 2-2). Drainage channels, however, contributed more mercury and total DDT to the Bay than did the point sources (MBC, 1988). Annual loading of total pesticides in surface runoff was about 117 kg during this period.

Surface runoff from drainage channels is greatest during and following storms; hence, it is generally greater in the winter. Because of the large area drained, there is a lag time between the start of the storm and the discharge of runoff to the sea. During a storm in 1986, peak flows in Ballona Creek occurred 24 hours after the rainfall began, but concentrations of most constituents were greatest at 13 hours after the beginning of the storm (when flow was 40 percent of the peak flow). Maximum concentrations of the constituents (at 13 hours) were greater than the minimum levels (generally occurring at 24 to 42 hours after the storm began) by the following multipliers: DDT, 1360; lead, 261; total suspended solids, 192; total pesticides, 162; chromium, 110; copper, 31; cadmium, 29; zinc, 26; nickel, 19; and oil and grease, 17 (Schafer and Gossett, 1988).

Region Affected. The effects of surface runoff occur along the beach and inshore waters, throughout the Bay, but primarily off Malibu and from Pacific Palisades to Playa del Rey. The effects have not been well described.

VOL 12 2 0590

Ocean Dumping

Refuse, garbage, dredge spoils, drilling muds and cuttings, military explosives, and radioactive wastes have been dumped off Southern California in the past. At present, several EPA-regulated dumpsites are active in the area, and all limit dumping to certain materials within a prescribed region. Illegal dumping occurs, but is not well documented.

Location. All ocean dumpsites are outside Santa Monica Bay. The two nearest dumpsites with continuing or recent use include the LA-2 site and the THUMS dumpsite (Figure 2-1). Another (the LA-1) site was also used before 1973. Pollution from these sources enters the Bay by prevailing water currents. The LA-2 site is located about 10 km south of Point Fermin at 180 m depth, the THUMS site at 20 km southwest of Point Fermin at 900 m, and the LA-1 site at 30 km southwest of Long Point at 760 m (MBC, 1988).

Mean Annual Discharge Volume. A mean of 138,000 m^3 of dredged sediments from the Los Angeles-Long Beach Harbors is dumped at the LA-2 site each year (MBC, 1988; USEPA, 1988). The THUMS dumpsite was used during 1986-1987 to dump 10,378 m^3 of drilling muds and cuttings, but dumping there has been discontinued (MBC, 1988).

Levels of Constituents of Concern. Sediments dumped at the LA-2 site are required to be nontoxic (as determined by bioassay tests) (MBC, 1988). Drilling muds dumped at the THUMS site are required to be water-based and chromium-free; soybean oil must be used as a lubricant. Between 1947 and 1972, a mean of 19.4 x 10^6 liters/year of caustic and acid wastes from oil refineries and 3.45 x 10^6 liters/year of acid sludge from the Montrose Chemical Company were dumped at the LA-1 site. Between 348 and 696 metric tons of DDT were dumped at the site during these years (Chartrand, et al., 1985; MBC, 1988).

Region Affected. Advection of dumpsite materials to Santa Monica Bay may occur, but this has not been studied (MBC, 1988). Effects would most likely occur at the southwest corner of the Bay and off Palos Verdes Peninsula.

Marine Vessels

Recreational, commercial, and naval vessels using the Bay represent a nonpoint source of pollution. Contaminants enter the Bay as wastewater from toilets, wash water, and accidental (or unregulated) spills and leakages. Because recreational vessels concentrate in marinas, marine vessel contaminants also concentrate there.

Location. The two marinas in the Bay are Marina del Rey and King Harbor. Commercial and naval shipping lanes lie about 5.5 km offshore of the seaward boundary of Santa Monica Bay. Oil tankers enroute to moorings offshore of the El Segundo Refinery cross the Bay periodically each year (MBC, 1988).

Mean Annual Discharge Volume. Most discharges by marine vessels are undocumented, but some are documented. Of these, a mean of 505 liters/year of petroleum products were spilled into the Bay from 1973 to 1987. These spills consisted largely of fuel oil and crude oil (MBC, 1988).

Levels of Constituents of Concern. Levels of most constituents of concern to this study resulting from marine vessel contamination are not well described. High levels of tributyl tin (TBT), used as an antifouling agent in boat paints, occur in Marina del Rey (MBC, 1988). Sacrificial zinc anodes discarded by sail and power craft contribute about 30 to 38 metric tons of zinc to the Bay each year. The use of leaded fuel by recreational vessels contributes about 0.55 metric ton/year of lead. The amount of mercury contributed to the Southern California Bight in 1971 by marine vessels (primarily bottom paint) was greater than that from municipal wastewater discharge and surface runoff combined. Similarly, the amount of PCBs and copper emissions was about half the combined input of those sources (SCCWRP, 1973; MBC, 1988); however, the input of mercury and copper from marine vessels to Santa Monica Bay is unknown.

Region Affected. Most of the spills occurred in Marina del Rey, off El Segundo, or along the shipping lanes. TBT and zinc contamination occur primarily in Marina del Rey, although also to some extent in King Harbor (MBC, 1988). The effects of contaminants from these sources have not been described for the Bay.

Other Sources

Other sources of contamination to Santa Monica Bay include aerial fallout, sediment reservoirs, seeps, and advection. These sources introduce contaminants to the Bay through the air, sediments, and water currents, respectively.

Location. Aerial fallout occurs throughout the Bay; the distribution of fallout is poorly described, particularly over the open waters of the Bay. The accumulation of contaminants in sediments from past discharges provides a continuing source of contaminants through both natural and biological processes. Major sediment reservoirs of contaminants occur on the Palos Verdes Shelf near the JWPCP outfalls (DDT, PCBs, metals), in Santa Monica Canyon near the HTP sludge outfall (metals, chlorinated hydrocarbons), and in Marina del Rey (TBT). Natural oil seeps occur at the heads of Redondo Canyon offshore of Hermosa Beach. Advection of contaminants into the area through water currents occurs throughout the outer boundary of Santa Monica Bay (as defined). Currents transport contaminants into the area from the Los Angeles-Long Beach Harbors, the Santa Barbara Channel, and possibly from offshore dumpsites (MBC, 1988).

Tar from the natural oil seeps may drift to shore between Malibu and Redondo Beach (Marconsult, 1971; MBC, 1988); however, much of the tar reaching the beach may be advected in from the Santa Barbara Channel (Hartman and Hammond, 1981; MBC, 1988). Tar from Coal Oil Point (near Santa Barbara) probably travels west, south, and east from the Santa Barbara Channel in surface currents during the spring and summer. Drift tar takes about 10 to 14 days to reach Santa Monica Bay, but is retained in the Bay circulation for 1 to 3 weeks (Hartman and Hammond, 1981).

Mean Annual Discharge Volume. Gross discharge volumes for aerial fallout and sediment reservoirs are undescribed. The volume of water advected through the Bay is very large, but otherwise undescribed. The circulation patterns of the currents are variable and have yet to be adequately described. The residency time of the water mass in Santa Monica Bay is estimated to be about 3 to 4 days (Hickey, 1988, personal communication). The mean annual discharge from the natural oil seeps is about 670,000 liters/year (MBC, 1988).

Levels of Constituents of Concern. The importance of aerial fallout as a source of contaminants to Santa Monica Bay is not known; however, for the Southern California Bight as a whole, the amount of lead and mercury entering the sea from aerial fallout was greater than from discrete sources during the early 1970s. Copper, zinc, and nickel are also important in fallout (SCCWRP, 1973; MBC, 1988). During 1973-1974, about 113 kg/year of DDT entered Santa Monica Bay through aerial fallout (MBC, 1988).

Sediments in the vicinity of the HTP and JWPCP outfalls have accumulated contaminants for years. These sediments are reservoirs for many metals and chlorinated hydrocarbons, which are released into the Bay as the sediments are re-exposed by biological activities (e.g., burrowing and erosion). Near the JWPCP outfalls, levels of DDT in sediments 0.3 m below the surface reach 375 mg/kg (MBC, 1988; SDWG, 1988). Surface sediments with levels of 1 mg/kg occur over about 100 km^2 of bottom on the Palos Verdes Shelf (Word and Mearns, 1979; MBC, 1988). Sediments in this area and near the HTP outfalls (particularly the 11-km sludge outfall) also have high levels of all trace metals. Surface levels have generally decreased since the early 1970s because of the improved quality of the effluent (MBC, 1988).

Sediments near the JWPCP outfall had oil and grease levels up to 6,900 mg/kg in 1983 (Swartz, et al., 1986; MBC, 1988). Sediments in Marina del Rey have high levels of TBT, mercury, and oil and grease, presumably from marine vessel activity (MBC, 1988).

Region Affected. The effects of sediment reservoirs occur primarily in Marina del Rey and at the discharge depths of the HTP and JWPCP outfalls. The effects of aerial fallout occur at the sea surface and along the intertidal zone where the sea surface microlayer intersects with the land. Advection effects would occur throughout the Bay, but drifting tar accumulates along the beaches. Only the effects of the offshore sediment reservoirs have been well studied.

EXISTING STORMWATER RUNOFF CONTROL PRACTICES IN THE LOS ANGELES AREA

Until recently, stormwater runoff control was viewed strictly from the standpoint of flood control. During the past few years, however, national policies have been shifting away from the traditional approaches, and nonpoint-source (NPS) pollution control is becoming a major concern. The Clean Water Act Reauthorization of 1987 for the first time specifically addressed NPS pollution.

Historically, municipalities have not developed and implemented comprehensive stormwater management programs that included pollution control. Some structural components of the City's stormwater system, as well as some sanitation activities, indirectly provide a certain degree of runoff pollution control. Several stormwater control structures are being planned or constructed that will include some measures of stormwater runoff pollution control. In the study area, several nonstructural projects have been developed, or are under development, with the specific goal of controlling the discharge of pollutants into the stormwater system. Another important component of the existing stormwater runoff control program is the County's water quality monitoring system.

Structural Facilities

The structural facilities providing stormwater runoff pollution control in the study area are existing debris basins, several settling basins under construction, and the Pico-Kenter low flow diversion.

Existing Debris Basins

The existing debris basins are the most common structures in the stormwater system that have indirectly contributed to runoff pollution control. The main purpose of these structures is to control the entry of debris materials from undeveloped land into the stormwater system. Debris basins are generally built at the uppermost section of the system, thereby providing basically no control of materials originating in urbanized areas.

The City of Los Angeles operates and maintains about 70 debris basins. About 30 out of the 70 basins are in the foothills on the northern side of the study area. They are categorized as improved or unimproved, depending on whether they are built of concrete or earth surfaces.

The capacity of the debris basins varies widely, depending on the size of the catchment area. In general, debris basins are designed to catch runoff from the 50-year-magnitude storm. The design of the outlet works is such that, while debris is retained in the basin, water is discharged into the system as efficiently as possible.

Los Angeles County also operates a number of these debris structures; however, none of these are located in the study area.

Settling Basins Under Construction

Several settling basins are currently being developed in the study area. The proposed Stone Canyon project consists of converting an existing reservoir site to a runoff detention basin. In addition to providing pollution control for the area adjacent to Stone Canyon Road north of Sunset Boulevard, this project will also relieve the existing storm drain going into UCLA.

A 1.8-million-gallon settling facility was constructed at the Los Angeles International Airport in 1989. This basin collects stormwater flows from the central terminal area. The impounded stormwater is then discharged through a three-stage clarifier for additional solids removal, and oil and grease removal before it is sent for treatment at HTP (Wilson, 1991, personal communication).

The Potrero Canyon basin, under construction along the Pacific Palisades, is a small project operated by the Los Angeles Parks and Recreation Department. Although not specifically designed as a settling facility, it will provide some stormwater pollution control benefits in the adjacent area.

Nonstructural Measures

The nonstructural practices in the area that can have an effect on stormwater runoff pollution control are stormwater system maintenance practices, streetsweeping, and household hazardous waste collection programs.

Stormwater System Maintenance Practices

In general, the maintenance of the stormwater system in the study area is the responsibility of the various cities and Los Angeles County. The City of Los Angeles provides for the maintenance of the majority of the system in the study area. Maintenance practices are generally performed on an as-needed basis. The installation of a computerized system to help coordinate these activities is considered of primary importance by Bureau of Sanitation personnel.

In addition to the as-needed approach, the portion of the stormwater system maintained by the Los Angeles County Department of Public Works receives regular annual catch-basin cleaning. Pipe inspection routines are conducted once every 3 years to determine whether cleanups are necessary.

Streetsweeping Programs

Streetsweeping is one of the maintenance activities that has an indirect effect on the removal of stormwater runoff pollutants. The City of Los Angeles schedules street cleanings once every 3 to 4 weeks. In general, the impact of street sweeping on pollution removal is proportional to the accumulation period and the sweeping technique. According to Sartor and Boyd (1972), the rate of pollutant accumulation is most rapid during the first 2 or 3 days after a significant storm, and decreases after that period.

Solids loading curves from urban streets indicate that accumulated loadings in commercial and industrial areas peak after about 10 or 12 days. As explained in Section 3 of this report, the inter-event time of typical storms in the study area is about 10 days. Streetsweeping activities are, therefore, likely to have a minor impact on the removal of pollutants in the area, since accumulated materials are more likely to be removed by rainfall than by streetsweeping.

Household Hazardous Waste Collection Programs

The City of Los Angeles and Los Angeles County are currently engaged in the collection of household hazardous wastes. The main purpose of these programs is to prevent dumping of those materials into the stormwater system.

The previous program carried out by the City consisted of eight collection sites, distributed throughout the study area and beyond. During every roundup, only one site was operated. All kinds of substances considered to be hazardous wastes were received at each site, except ammunition and explosives. Up to 600 drums of a variety of wastes were collected per roundup and about 6,100 gallons of recyclable material (paint and oil) was collected and sent to recycling facilities. Other materials were disposed of at a Class 1 landfill.

The number of different types of wastes as well as the significant amounts collected during each roundup make hazardous waste collection programs quite expensive. The average cost of each roundup was about $250,000. Nevertheless, it was estimated that only a small portion of the actual volume of waste generated per household was collected through this program.

In addition to the hazardous waste roundups, the City conducted a pilot program by which hazardous materials were collected directly from households on a by-request basis from October 1988 to April 1989. The results of this program was that the cost per household was too high. A total of 313 drums of hazardous materials, and 9,100 gallons of recyclable material was collected at a cost of $485,000. The main problem with this program was the lack of public relations and public awareness associated with it. Only 1,435 households participated in this program. Future hazardous materials collection programs will include both mobile and permanent sites (Mofidi, 1991, personal communication).

Staring February, 1994, the City initiated a new mobile household hazardous waste collection program called HAZMOBILE, which replaces the single site Hazardous Waste Roundup program (David, 1994, personal communication). The HAZMOBILE program is a miniature hazardous waste roundup on wheels. It consists of several trailers and trucks that will move around to a total of 24 different geographic areas throughout the City each year. The trailers remain on-site for a period of two weeks and receive hazardous waste during the latter part of each week, usually Thursday, Friday, and Saturday. Hazardous waste is accepted on an appointment only basis. The HAZMOBILE program is advertised in local newspapers along with the appointment telephone number 1-800-98TOXIC. Operating costs for this program are not available at this time.

Water Quality Monitoring Programs

An important aspect of the control of stormwater runoff pollution is the water quality monitoring program carried out by the Water Quality Division of the Los Angeles County Department of Public Works. The program has been in operation for several years, but it was considerably expanded in 1988. Monthly samples from 28 sampling stations throughout the County's jurisdiction are analyzed for several constituents. Most stations collect both dry- and wet-weather samples; however, only one sample per storm event is collected. Seven stations are located within the area of interest of this study. Both dry- and wet-weather samples are collected in five of these seven stations. Results of this program was published by the County's staff, and were used on a comparative basis in evaluating the water quality results of this study.

SECTION 3

DETERMINATION OF RUNOFF POLLUTANT LOADS

In order to determine runoff-associated pollutant loading into Santa Monica Bay, and to identify and prioritize pollutant sources, a methodology was developed to determine the magnitude of pollutant discharges by land-use category.

The methodology consisted of the following steps:

1. Identification of drainage basins and major land uses in the study area
2. Selection of important runoff pollution constituents
3. Selection of detailed land-use study areas for runoff sample collections
4. Collection of runoff samples and analysis of constituents
5. Analysis of rainfall records for the study area
6. Study of typical storm
7. Calculation of estimated pollutant loads for a typical storm and a typical rainfall year in the study area

The first three steps provided the framework for identifying the constituents of concern in the pollutant runoff study and the corresponding land uses where those substances originate. The concentrations of each pollutant by land-use category were determined by sampling identified areas with known land-use characteristics. The analysis of rainfall records was necessary to supplement the information provided by the sampling program.

The calculations leading to estimated pollutant loads were then based on the sampling results, estimates of runoff provided by the typical storm study, and flow information obtained from historical records. The step-wise process used for calculation of pollutant loading is illustrated in Figure 3-1. The following sections describe the methodology used to develop the data required for the calculation.

DRAINAGE BASINS AND MAJOR LAND USES IN THE STUDY AREA

Formulation of recommendations of selected control projects to achieve the objectives of this study were based on the approach of determining stormwater runoff pollutant loadings on a land-use basis. An initial step in this approach was to investigate drainage patterns within the study area in order to subdivide the area draining into Santa Monica Bay into smaller subareas. Individual control projects could then be more easily applied to these smaller areas. By determining the mix of land uses within these subareas, and relating loading ratios for each land-use type to the mix, pollutant loading for each subarea was estimated.

Twenty-six major storm-drain outlets were identified in the study area (Exhibit 1, Table 2-1). For each outlet, a drainage area was developed using topographic and

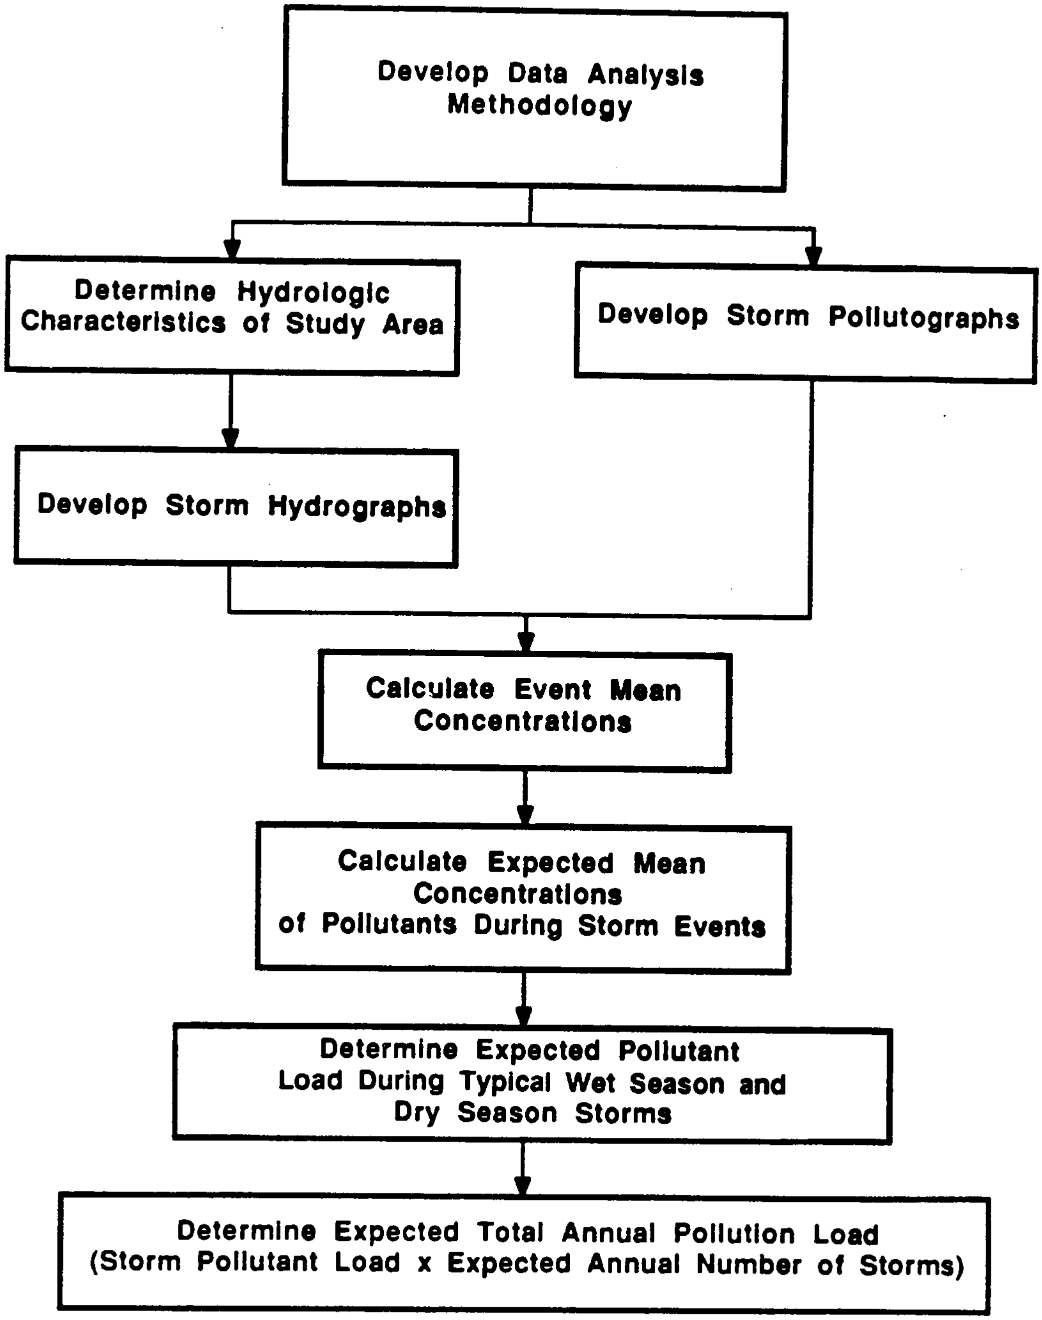

Figure 3-1 Data Analysis and Loading Calculation Methodology

SOURCE: Engineering-Science

storm-drain network information from the City of Los Angeles and the Los Angeles County Department of Public Works, along with other information on local runoff conditions. In drainage areas of substantial size, or where appropriate information was available, the drainage area for one outlet was subdivided into smaller units in order to permit the potential implementation of control projects at or within one or more of the smaller areas. As an example, the drainage area for Ballona Creek (Area 5) comprises more than 62 percent of the study area; drainage Area 5 was subdivided into 26 smaller areas that had the potential for applying individual control projects to each. This information on drainage areas and subareas was developed using a computerized geographic information system (GIS) to evaluate the spatial relationships between the storm drain system and area topography.

Land use was mapped for five major uses that are common over the entire study area: residential, commercial, light industrial, transportation, and dedicated open space (Exhibit 2). A description of these five major land uses are summarized in Appendix A. Information sources used for the development of the land-use map included:

- Los Angeles District Plan maps
- Los Angeles City zoning maps
- Los Angeles zoning consistency maps
- Culver City zoning and land-use maps
- Santa Monica zoning maps
- Beverly Hills zoning and land-use maps
- Thomas Guide Aerial Atlas

This land-use mapping information was also stored in the computerized GIS. When the two sets of mapped information (drainage area boundaries and land-use distribution) were combined, the resulting database provided an estimate of the percent occurrence of each land-use type within each drainage area and subarea. Table 3-1 shows the distributions of land uses by drainage basin. This information was used to develop information on potential target areas for applying stormwater runoff pollutant control projects, based on the results of the constituent sampling at each land-use collection site and models of runoff pollutant loading developed for the study area.

IDENTIFICATION OF IMPORTANT RUNOFF CONSTITUENTS

Selection Criteria

Development of criteria for the selection of pollutants for detailed study were based on a range of issues and concerns. The primary concern, resulting in the litigation between the City and the EPA, with active participation by a variety of citizen and environmental organizations, was that beneficial uses of Santa Monica Bay were threatened by pollutant input from stormwater and dry-season runoff flows. These uses included water-contact recreation (swimming, surfing, diving),

PSR159

fishing, boating, and consumption of fish and shellfish. Concern for the future of the Bay as a viable habitat for marine flora and fauna was also a factor.

Criteria used for the final selection of pollutants to be addressed by the Study included:

- Identification with adverse effects on human health through water contact activities
- Identification with adverse biological effects in Santa Monica Bay
- Identification with adverse aesthetic effects in Santa Monica Bay and on beaches
- Public concern
- Contribution of stormwater runoff pollutant loading versus total pollutant loading in Santa Monica Bay
- Implementability of pollutant controls

Recommendations were taken from evaluation of the historical literature, input from meetings with the City staff and other interested groups, and discussions with the project's toxicologist, Dr. James Dahlgren, regarding exposure to potentially toxic materials through direct water contact.

Potential Pollutants of Concern

In previous studies in the Los Angeles area and elsewhere (Rimer, et al., 1978; Shelley and Gaboury, 1986; LACDPW, unpublished data), stormwater runoff samples have been analyzed for many conventional water quality parameters, as well as those known to be important in municipal wastewater treatment. In addition, other constituents have been suggested as being important; ultimately, a complete list of EPA priority pollutants could be examined. These include such major classes of pollutants as metals and inorganics, pesticides, PCBs and related compounds, halogenated aliphatics, ethers, monocyclic aromatics, phenols and cresols, phthalate esters, polycyclic (polynuclear) aromatic hydrocarbons (PAH-derived from petroleum and other chemical processes), nitrosamines, and other miscellaneous compounds.

All of these compounds are potentially present in runoff waters from heavily urbanized areas with diverse land uses and a wide variety of commercial and industrial practices and processes. These pollutants are highly compartmentalized between the water (suspended solids or dissolved), sediments (organic or inorganic fractions), and biota (phytoplankton, zooplankton, macrophytes, benthos, fish, birds, and mammals [Chapman, et al., 1982]). Some heavy metals and PAHs accumulate in the sea surface microlayer (i.e., upper 0.05 to 0.10 millimeter (mm) [Cross, et al., 1988]). PAHs are readily absorbed by particles and can be transported by stormwater runoff to receiving waters. PAHs can also accumulate in bottom sediments and they have the ability to bioaccumulate in marine organisms. Many PAHs are classified as carcinogens. Hence, different fractions of the stormwater runoff may need to be examined to obtain the greatest concentrations of these constituents. In addition, many of these pollutants vary in their volatility, ability to accumulate in the environment, and persistence (Chapman, et al., 1982).

Based on chemical properties and behavior, the most persistent, nonvolatile constituents that accumulate in the environment would be of most concern, and hence should be targeted in monitoring studies. These include many of the metals and inorganics (arsenic, cadmium, chromium, copper, lead, mercury, nickel, silver, and zinc). Certain pesticides and PCB arochlors and PAHs also fall into this category. From the marine-life standpoint, those constituents that occur at acutely toxic concentrations would be of greater concern than those that cause sublethal effects, although these could also affect future generations of a species. From the human-health standpoint, human disease organisms and disease indicators, along with potential carcinogens, are important.

Human Disease Indicators

Human disease indicators - such as total coliform, fecal coliform, and enterococcus - are frequently examined in water quality samples. Coliform and fecal streptococcus (i.e., enterococcus) are common in fecal material and sewage, and are generally not pathogenic. These organisms are also frequently found at low levels in nonpoint-source runoff. Most bacteria causing infectious and enteric human diseases would be expected to enter the sea in municipal wastewater. Disease-causing enteric viruses (e.g., poliovirus, coxsackie virus, echovirus, and the virus that causes infectious hepatitis) have been found in sewage effluent, and these have been discovered in mussels in Marina del Rey and Ballona Creek. Recently, (1990) enteric viruses were demonstrated to exist in low-flow runoff entering Santa Monica Bay.

The nature of these indicators makes collections of samples difficult and rigorous. For example, such samples are not suitable for collection by automatic sampling devices left unattended for long periods. Also, collections need to be followed by almost immediate processing and analysis.

Carcinogens

Compounds considered carcinogens included dioxins, furans, and chlorophenols (Dahlgren, 1987, personal communication). Dioxins are produced as a byproduct of defoliants, by incineration of PCBs, and may occur in some waste oil (Dahlgren, 1987, personal communication; Sims, 1987, personal communication). Dioxins occur at parts per trillion levels in human fatty tissue. Other important contaminants are the organic compounds of mercury and other metals, as well as organophosphate, pyrethrate, and carbamate pesticides, phthalate esters (associated with plastics), and tetrachlorethane (a dry-cleaning solvent). Some of these compounds are highly volatile; the mechanical processes associated with stormwater runoff transport to locations where humans can be exposed are sufficiently severe to cause rapid volatilization in a very short time. The sampling method chosen for this study, although appropriate for addressing the requirements of the Consent Decree, was not suitable for collecting volatile organic materials; the unsealed head space in the collection device used would allow volatilization of these materials before the sample could be analyzed.

Selection of Target Pollutants for This Study

Target pollutants chosen for closer examination in storm-runoff and dry-season flows were selected by applying the criteria listed above to the range of potential pollutants. As discussed previously, effects on human health, whether through direct exposure or exposure to contaminated seafood, were the primary criteria. Pollutants chosen for more extensive analysis are presented on Table 3-2.

Several candidate constituents, examined in other stormwater studies, were not included in the analysis for this study. Biochemical oxygen demand (BOD) and chemical oxygen demand (COD) were not considered health hazards in open Bay waters. The exposure paths of humans to phthalate esters and purgable organics are not through contact with marine waters. Chlorinated hydrocarbons are commonly found in soot, which is prevalent over wide areas, not lending toward straightforward determination of source. Also, total coliform and fecal coliform bacteria are common in runoff from a variety of sources, which does not lend toward straightforward determination of source.

Runoff pollutant reduction recommendations developed in this report may contain measures that will be effective in reducing the loading of chosen pollutants and cover additional pollutants not specifically sampled for this study. Limitations in the scope and purpose of this study, as defined previously, preclude a complete analytical treatment of runoff constituents. Additionally, control measures recommended for those constituents that were included on the analysis list will also be effective in controlling many of the substances not tested for, as many of the latter are contained in the same water-column pollutant fractions (particulate or lipid-soluble) that the control technologies recommended in this study are designed to reduce.

SELECTION OF DETAILED STUDY AREAS

Selection of areas for detailed study was based on the need to characterize stormwater runoff traits and identify candidate areas for control of key pollutants. The methodology developed anticipated the need to identify runoff pollutant loads by land-use types occurring within the study region, and to prescribe pollutant-reduction techniques that were specific to different land-use types.

The methodology for selection of areas for detailed study included development of information on land use, drainage patterns, and availability of access to drains to collect stormwater data. Selection of candidate areas for detailed study was based on the need to collect information on homogeneous land-use types that could be isolated for purposes of monitoring without interference from other activities. Characteristics included the need to identify a single location draining an area representative of the single land-use type to monitor runoff volumes and stormwater pollutant values. Land-use and drainage maps and aerial photographs of areas were analyzed for candidate sites satisfying the above criteria.

Criteria used in choosing specific areas for study included:

- Land uses composing a significant percentage of the study area
- Land uses deemed to contribute significant pollutant loading based on historical information

Candidate areas were identified for each of the four land-use types to be evaluated by runoff sample collections (light industrial, commercial, residential, and transportation). In addition, a monitoring location that provided integrated information on the above land-use types was chosen. All of the areas were located within the Ballona Creek watershed. Each area was inspected to verify the land-use types within the area drained, to identify monitoring locations, and to isolate any potential problems in data collection not apparent from the evaluation of land-use and drainage maps and aerial photographs. The location of the monitoring station was verified in the field for each candidate area.

- Location of a land-use area of sufficient size to extrapolate to the overall study area
- Area "representative" of citywide land use
- Ability to sample a single land use from a single drain
- Location within the Santa Monica Bay drainage area
- Location within the City of Los Angeles, if possible

The candidate areas were screened against the selection criteria. Several of the candidate sites were deleted because of land-use types that were not representative of the mapped classification, drainage patterns that did not correspond with mapped information, and problems in gaining access for field monitoring. The field inspection also identified potential problems in collecting representative samples of areas upstream because of incomplete mixing or in monitoring flow volumes at the confluence of several flow streams where backwater conditions may interfere with the accuracy of flow readings.

To increase the effectiveness of any proposed pollutant-reduction measures or projects, the monitoring program focused on data collection, analysis, and control strategies that correlated these factors to specific land-use types that produce the highest loadings, and concentrations of key pollutants. For instance, studies have demonstrated that transportation facilities (e.g., highways) contribute high concentrations and a significant percentage of the loading of PAHs (Hoffman, et al., 1984). By evaluating areas used for transportation for both the percent contribution to this loading and for potential control strategies, the most effective control projects for this pollutant are likely to be identified.

The locations of study sampling locations are listed on Table 3-3. Detailed hydrographs of the areas are included as Appendix A-1.

RUNOFF SAMPLE COLLECTION AND CONSTITUENT ANALYSIS

Both stormwater runoff and dry weather runoff were sampled to develop estimates of pollutant concentrations during both wet and dry season runoff flows.

Stormwater Samples

Stormwater runoff samples were collected at each of the five chosen locations (Table 3-3) using automatic water collection pump samplers (ISCO Model 2700) to collect discrete samples at specified intervals. In examining stormwater runoff studies in the literature, the curve of runoff pollutant concentration versus time indicated that many of the major pollutants are mobilized early in the storm event (e.g. Hoffman, et al., 1984). Because a rainfall event could occur in the middle of the night or on very short notice, automated samplers left in place for extended

periods were the only feasible means of capturing the leading edge of the runoff event. As discussed previously, this collection scheme restricted the number and type of runoff constituents that could be successfully sampled.

Each sampler was coupled with a flow-monitoring device programmed to activate the sampler based on a preprogrammed increase in flow rate within the storm drain resulting from rainfall runoff. The samplers themselves were time-programmable, allowing a fixed or variable time interval between sample collections. The sampling interval was determined by examining historical duration and intensity data for rainfall events in the study area. A 15- to 30-minute interval was used for collections during the first events sampled. A 1-hour interval was used during later events to provide a picture of runoff loading over more extended periods.

Collection of water samples from storm drains was initiated soon after the beginning of the rainfall event, as the flow meters monitoring runoff levels were triggered by the increase in flow and activated the samplers. Sample collection continued until runoff flows dropped to their pre-event levels, or until all sample bottles were filled. Bottles were replaced as necessary to collect samples over the duration of elevated flows.

The volume of samples collected was sufficient to satisfy requirements of the analyzing laboratory to complete testing, using EPA or APHA methodology (Table 3-2). Filling of multiple bottles was frequently necessary for each sample to satisfy analysis requirements. Strict adherence to preservation techniques, handling, holding times, and other analysis protocols was observed.

Collection and analysis of water samples for enterococcus group bacteria was complicated by the need for sterile equipment and methods during sampling. It was, therefore, impractical to collect enterococcus samples using the automatic samplers deployed in the study area. Bacterial samples were collected by hand, using appropriate sterile techniques, by technicians while servicing the samplers during the rainfall event. This restricted the number of samples at each location, and did not allow for time-synchronous collections. As a result of these factors, bacterial samples were considered less important than other constituents because of their frequent occurrence in runoff samples and their lower potential for effective control, and were not a significant factor in the eventual evaluation and development of runoff pollutant control measures.

Dry-Weather Flows

For the collection of dry-season flow samples, automated samplers equipped with recording flowmeters were deployed in the same land-use areas as those for which stormwater runoff flows were collected. A 24-hour composite sample was collected at each site by combining 24 discrete hourly samples collected over a 24-hour period. Analytical methods for constituent analyses were identical to those used for storm runoff samples.

Water Sample Analysis Methodology

Standard analytical methods from EPA and APHA Methods (Table 3-2) were used for constituent analysis. These methods were used to allow comparability with previous and future stormwater runoff constituent studies. All chemical analyses, except dioxin and enterococcus group bacteria, were performed by Global Geochemistry Consultants in Canoga Park. Dioxin analyses were performed by California Analytical Laboratories in Sacramento. Bacteria analyses were performed by Brown & Caldwell Laboratories in Pasadena.

ANALYSIS OF RAINFALL RECORDS

Determining the runoff flows associated with storm events is of particular importance in estimating total pollutant loads. The sampling program in this study included runoff flow measurements in the field in conjunction with water sampling for runoff pollutants (using ISCO Model 2870 flowmeters). The intermittent nature and wide variability of volume of runoff flows adversely affects flowmeter performance. The range of flows to be monitored requires the flowmeter record to be fairly coarse. To supplement the field information, an analysis of the areal and temporal distribution of the storm events sampled as part of this study was also performed. The objective of this analysis was to estimate more completely the actual rainfall causing the runoff from which water samples were taken for laboratory analysis. Four storm events occurring in 1988 were analyzed. Continuous rainfall data were obtained from recording stations within the drainage area. Rainfall records were provided by the City of Los Angeles and the Los Angeles County Department of Public Works. These agencies manage separate rainfall-monitoring networks that span the entire Los Angeles Basin. The recording stations used in the analysis are indicated on Table 3-4. Only automatic recording stations were selected, as continuous records of rainfall are required for temporal analysis. The Kriging interpolation technique (Tabios and Salas, 1985) was used to define regression equations representing rainfall estimates at each site based on the recording stations' data (Appendix B-1-1).

The total rainfall estimates for the detailed study areas during each of the storm events analyzed are indicated on Table 3-5. Except for the unusually heavy storm of 27 February through 2 March, rainfall was quite constant for all storms at all locations. An example of one of the rainfall hyetographs is shown in Figure 3-2. A complete description of the data and methodology used to develop these rainfall estimates is included in Appendix B-1-1.

TYPICAL STORM STUDY

Determination of the total wet-weather pollutant load into Santa Monica Bay was based on storm runoff flows and pollutant concentrations estimated from sample flowmeter records, analysis of areal rainfall data, and constituent analysis of collected samples. Pollutant concentrations were obtained from the sampling program results. Runoff flows, on the other hand, involved conducting an analysis of rainfall records.

Conventional hydrologic methods have been established to estimate intensity-duration-frequency relationships for infrequent events because of the emphasis placed in the past on rainfall studies aimed at flood-control practices. From the standpoint of pollution control, however, low-return-period storms are significantly more important because of their considerably higher pollution load per unit volume and the economic considerations regarding the design of structural pollution control facilities.

The concept of the "typical" storm was used to develop rainfall runoff and subsequent runoff pollutant loading estimates. Unlike the long-return-period case, for which data are selected to form a partial duration series for the analysis, the typical storm study required analyzing an entire period of record. Hourly rainfall records at the Los Angeles Airport National Weather Service station (No. 045114) for the years 1949 through 1987 were used in the analysis. The statistical analysis was carried out by using the Synoptic Rainfall Data Analysis Program (SYNOP)(EPA, n.d.). Table 3-6 is a summary of SYNOP statistics for the Los Angeles Airport data. Modifications of these results were made to represent the characteristics of the whole study area, based on annual average rainfall and 1-hour

peak-intensity contours at two identified geographical regions in the study area; the coastal plain and the mountain area. Figure 3-3 shows the geographical regions in the study area. The coastal plain comprises about two-thirds of the whole area. The peak intensity of the 50-year storm is relatively constant throughout this area and averages 34 mm/hour. The average annual rainfall varies between 305 and 460 mm. Events in the mountain area have widely varying peak intensities that range between 34 and 50 mm/hour. The annual rainfall varies between 430 and 610 mm.

Separate rainfall hyetograph patterns were developed for the wet (November through April) and dry seasons (May through October) for the two geographical regions. Figure 3-4, shows typical distributions of rainfall in the coastal plain of

the study area during a 24-hour period for a wet season and a dry season storm, respectively. From examination of the two hyetographs, it is reasonable to assume that the storm pattern is the same during both the wet-weather and the dry-weather storms.

POLLUTANT LOADING ANALYSIS

This section of the report includes an estimation of the magnitude of wet- and dry-weather runoff pollutant discharges from the study area into Santa Monica Bay. The large runoff volumes resulting from periodic rainfall events in the area are associated with large pollutant loads entering the Bay over a short time period. Lower-volume dry-weather runoff produces relatively small pollutant loads over equivalent time scales, but these discharges extend throughout the year. Because of the obvious hydrologic differences, wet- and dry-weather loading estimates are calculated separately.

For this study, wet weather is defined as any storm event occurring during the year. The commonly-accepted terms of wet season (November through April) and dry season (May through October) are used here in the same context. As displayed on Table 3-6, most storms occur during the wet season (an average of 12.2 per year), but some occur during the dry season (average of 1.3 per year). Wet weather loading is the result of these storm events during both wet and dry seasons. Dry weather loading occurs year-round (during both seasons) on days when storm events do not occur.

Discussions of the assimilative capacity of the receiving waters, and the extent of impact on the receiving environment by this loading, are beyond the scope of this study. The comparative loading rates for wet- and dry-weather runoffs developed in this study, however, will be an integral part of any such environmental or biological evaluation of pollutant inputs to Santa Monica Bay.

Wet-Weather Pollutant Loading Analysis

The expected stormwater-related annual pollutant load for the entire study area was developed by summing the contributions of runoff pollutants from each land-use category and drainage basin.

Data Analysis Methodology

The methodology for determining expected mean stormwater runoff pollutant concentrations was based primarily on the findings and recommendations indicated in the Final Report of the Nationwide Urban Runoff Program (NURP) conducted by EPA between 1977 and 1982 (EPA, 1983). The process takes into account the relationship between pollutant concentrations and the corresponding runoff volumes at several points in time during a given rainfall event. It permits the assessment of pollutant load from spatial and temporal points of view. In this study, the spatial analysis was used to determine the runoff quality from different land-use types and drainage basins within the study area. The objective of the temporal analysis was to determine the significance of the time response of pollutant washoff as compared to runoff occurrence.

A basic assumption incorporated into the NURP methodology is that urban runoff flow and urban runoff pollutant concentration can be treated as independent random variables. Pollutant concentrations are characterized by a parameter known as the event mean concentration (EMC). EPA defines EMC as the total mass of pollutant discharged during a storm event divided by the corresponding runoff volume. The calculation of the EMC value for a particular storm at a given site, therefore, requires correlating a storm's hydrograph and the corresponding pollutograph.

Storm Hydrographs. In the present study, runoff hydrographs were determined primarily by flow measurements in the field. When that information was not available, rainfall data were used to develop synthetic hydrographs for the particular sites and storms by using the SCS unit hydrograph method (McCuen, 1984). The 1988 rainfall events for which hydrographs were available for analysis occurred on 14 and 15 April, 13 November, and 25 November. As an example, Figure 3-5 shows plots of the hydrographs obtained at the commercial land-use study area. Plots of all other hydrographs developed from flow measurements in the field are included in Appendix A-1.

Synthetic storm hydrographs (a hydrograph for an entire storm) were obtained by aggregating unit hydrographs (a hydrograph for a specific area over a short period of time) over the storm duration. The values of the calculation variables were calibrated by using flow data from the study area collections. The SCS unit hydrograph method is particularly suited for local conditions because, as indicated above, the duration of a typical precipitation event in the study area is 24 hours. This method is based on the following main relationships:

$$Q_p = \frac{KAR}{T_c}; \qquad R = \frac{(P - 0.2\,S)}{(P + 0.8\,S)}; \qquad S = \frac{1{,}000}{CN} - 10$$

where:

Q_p	=	Peak unit hydrograph discharge
K	=	Constant
A	=	Drainage area
R	=	Depth of excess precipitation (runoff)
T_c	=	Time of concentration
P	=	Depth of precipitation
S	=	Potential maximum retention
CN	=	SCS curve number

The calibration procedure was also used for defining runoff:rainfall relationships for the typical storms for each land-use category, as shown on Table 3-7. Because no data were available for the agricultural land use, a CN value of 80 was assumed, based on literature information (Colston, 1974).

Pollutant Concentrations. Data on runoff pollutant concentrations at each detailed study area site were obtained from analyses of samples collected during rainfall events. As an example, total suspended solids pollutographs for the commercial area are also shown in Figure 3-5 for two sampled storms. Concentrations at the beginning and end of each event were assumed to be zero. TSS pollutographs at the other sites sampled are included in Appendix A-1.

In some cases, pollutant concentrations in collected samples (if present at all) fell below laboratory detection limits for the analysis method used (i.e. they were reported as "not detected"). The detection limit is the minimum concentration of a substance that can be measured by the laboratory procedure used in the analysis of the samples. Consistent with EPA criteria, the pollution discharge analysis was carried out by assuming that the "notdetected" concentration values were equal to one-half the detection limits. The mass load of a given pollutant (mass load = flow x concentration) discharged in the period between two successive samples during a storm was assumed to be equal to the product of the samples' average pollutant concentration times the corresponding runoff volume passing the sampling station during that particular sampling period. The storm's total pollutant mass load was then calculated as the sum of the partial mass loads over the storm duration. The storm's EMC is equal to the storm's total pollutant load divided by the total runoff volume. An EMC was developed for each land use designation for each pollutant constituent.

In cases when only one pollutant concentration datum was obtained during the storm, it was assumed that this value represented the storm's mean concentration. This procedure was used in a total of five cases at three different land uses. Lack of pollutant concentration data are due to insufficient runoff flows during the time of sampling and sampler malfunctions.

cm = centimeters

In previous studies, including NURP, the log-normal distribution has been found to adequately represent the underlying probability density function of EMC values of all sampled storms for a given area, both from physical considerations (e.g., pollutant concentrations can never be negative) and through the multiplicative effects involved in stormwater runoff pollution processes. The small number of data points obtained in this study does not allow for the computation of all the statistical parameters of the underlying EMC probability density function. The most likely estimator of the concentration of a given pollutant per event can, however, be assumed equal to the geometric mean of the EMCs (EPA, 1983). The EMCs for measured constituents for each storm sampled during the study are shown on Tables 3-8 through 3-11. The geometric mean of the EMCs is expressed as the estimated mean concentration.

Table 3-11 shows two values of EMC geometric means for the transportation area. This resulted from the use of stormwater runoff pollution data collected by the Federal Highway Administration (FHwA). In 1981, the FHwA conducted several research programs throughout the United States to characterize stormwater runoff from highways. One of the sites analyzed was a 950-ft stretch of road surface on the San Diego Freeway, two miles from the Los Angeles Airport (Driscoll, et al., 1988). Table 3-12 shows the results from the FHwA study in terms of EMC values for several pollutants. The results from the FHwA research program have been included in the data analysis for this study because they represent information based on very similar land use designation and sampling methods. Inclusion of the FHwA information made the analysis more consistent with values reported in the literature, especially those resulting from the nationwide FHwA program. Table 3-11 shows the values obtained with the current data as well as those resulting from combining the FHwA and the current data. While the impact of the inclusion of this "outside" information on study results is significant, inclusion is reasonable since the sampling site and techniques meet all criteria set out for this study.

Significance of Pollutant Estimated Mean Concentrations. To identify stormwater pollutants exceeding water quality criteria established for California coastal waters, the estimated mean concentrations of pollutants shown on Tables 3-8 through 3-11 were compared with the instantaneous maximum concentration standards established in the California Ocean Plan (SWRCB, 1990). The results indicate that standards for many of the pollutants are often exceeded. TSS standards are exceeded at an average of approximately 3:1 for all land uses, with highest exceedance ratios in the commercial and transportation land uses. Lead is the heavy metal with highest ratios (average 12:1) in the residential, transportation, and commercial land uses. Its exceedance ratio in the light industrial land use is about 3:1. Concentrations of pesticides also exceeded standards in the residential and light industrial areas. The transportation area also shows high ratios for pesticides, possibly resulting from contamination from nearby residential areas. On an areawide basis, oil and grease in storm runoff appear not to pose significant pollution problems in the study area when compared to Ocean Plan standards.

Importance of Total Suspended Solids in Runoff. The objective of this study was to identify approaches for control of pollutants in stormwater runoff. Because many control measures concentrate on the removal of TSS, two relationships were investigated using information gathered during this study: the ratio of dissolved to total metals in the sampled runoff, and the correlation between TSS and the other target pollutants.

Table 3-13 shows the ratios of dissolved to total metals by land-use category. These ratios were obtained exclusively for those storms showing actual measured dissolved metal concentrations; that is, the two storms at the residential land-use site and one storm at each of the other three sites. The overall average ratio equals 38 percent. Because of the numerous nondetected values in the samples, the real value of the overall average ratio is probably lower than 38 percent.

The correlation between TSS and the other pollutants included in this study was tested by application of Spearman's rank correlation test. Table 3-14 shows the values of the Spearman r_s coefficients as well as the Z scores and the corresponding level of significance. The Z values were calculated as suggested by Champion (1980). The results indicate that significant correlations exist between TSS and all metals except cadmium and silver. Poor correlations are shown between TSS and herbicides and pesticides, which are lipid-soluble and associated with the oil and grease (O&G) fraction of runoff. The analysis results indicate that the control of TSS can effectively control the discharge of most toxic metals into Santa Monica Bay. Alternative measures, primarily based on controlling the sources, would be required for reducing the load of cadmium, silver, herbicides and pesticides. For the latter, control measures suitable for removing O&G from the runoff stream would also be effective in reducing herbicides and pesticides. Control measures for runoff pollutants, directed toward control of TSS and O&G, are evaluated in Section 4.

For purposes of comparison, Tables 3-8 through 3-11 also show the mean concentration of several stormwater EMCs as found in the literature. Some differences were found between the reported values for most pollutants and those reported herein. Specific conclusions cannot be derived because of the size of the data set; however, TSS, zinc, and lead concentrations in the commercial land use for this study appear to be consistently higher than the values reported in the literature.

The concentrations of copper, lead, and zinc in runoff from the residential and commercial sites in the study area appear to be higher than the reported values in the cited literature. Additionally, the average concentration of mercury from the residential area is higher than that found in the literature. The values of the estimated mean concentrations of pollutants for the residential site were strongly influenced by the result of the samples obtained during the 14 November 1988 storm. As indicated later in this section, these values appear to be a result of first-flush seasonal effects.

Pollutant Loading Estimates

The wet weather runoff pollution load from the study area was calculated by assuming that the estimated mean concentrations of pollutants obtained from the analysis described above are associated with the occurrence of typical storms. The spatial distribution of pollutant loads was developed by applying calculated runoff volumes and the pollutant loads associated with individual land uses to each drainage basin and sub-basin.

The pollutant loading calculation emphasized TSS and O&G control. O&G were included as runoff pollutants to be controlled in spite of the fact that they appear not to be present in significant concentrations on an areawide basis (comparison of estimated mean concentrations and Ocean Plan Standards; see Tables 3-8 through 3-11). O&G is likely to be important on a site-specific basis, such as runoff from parking lots. Also, control of the O&G fraction of runoff is the most direct technique of removing lipid-soluble pollutants from the runoff stream. Appendixes A-2 through A-5 show calculations of the TSS and O&G runoff load from a single wet season or dry season storm. These appendixes indicate land use area, estimated typical stormwater runoff volume, pollutant concentration, and total expected loads for each drainage area in both the coastal plain and mountain regions for the dry and wet seasons. TSS concentration values for open space and residential/agricultural land uses were obtained from the literature (EPA, 1974).

Research has shown that the pollution load from open space areas is negligible when compared to the load from other land uses, especially urban areas (Pitt, 1986). Furthermore, as suggested by Stenstrom, et al. (1985), the source and characteristics of any given hydrocarbon substance needs to be analyzed before it can be cataloged as a contaminant. For example, O&G from nonurbanized areas are likely to be the result of plant leaf degradation and microbial secretions. These products should not be subject to the same control approaches as O&G resulting from materials such as motor oil and diesel fuel discharges. Based on these considerations, it was determined appropriate not to include runoff from open space as a source of stormwater pollution.

Agricultural land uses, on the other hand, are often important sources of runoff pollution in terms of organic materials and nutrients. In the study area, however, agricultural land uses represent only 1.6 percent of the total area and are concentrated exclusively in the Topanga Canyon drainage basin (Basin 26, Exhibit 2). In addition, solids carried from undeveloped terrain present different characteristics from those carried from urbanized areas in terms of adsorbed materials. These solids are also an important source of replenishment material for area beaches. In this study it was determined that pollution load estimates from the agricultural land use could be excluded from the analysis, and that pollution control recommendations should be targeted to TSS and O&G from the residential, commercial, industrial, and transportation land uses in urbanized drainage basins (Basins 1 through 16, Exhibit 2).

Table 3-13

Ratio of Dissolved to Total Metals in Runoff Pollutant Sample Collections (%)

Pollutant Loading Estimates by Drainage Basin. Tables 3-15 and 3-16 present summaries of wet-weather TSS and O&G annual pollution loads by drainage basin for the study area. Only estimated loads from the residential, commercial, light industrial, and transportation land-use areas are included; loading from open space areas is not included, as discussed previously. Annual loads were calculated by multiplying the wet- and dry-season storm loads by the number of expected rainfall events during each period, as obtained from the typical rainfall analysis: 12.21 events during the wet season and 1.33 events during the dry season, each event lasting an average of 24 hours. The loading ratios for each area are equal to the ratio of two partial ratios: basin load to total watershed load and basin area to total watershed area. Loading ratios, particularly the annual loading ratio, provide guidance for recommendation of pollutant removal strategies for each drainage and subdrainage basin; for example, O&G control would be more effective in reducing total load in drainage basin 1 (loading ratio = 1.42) than in drainage basin 4 (loading ratio = 0.87).

On Tables 3-17 and 3-18, the drainage basins in the study area are ranked based on the TSS and O&G loading ratios, respectively. All drainage basins were then ranked for total pollutant loading by summing the ranking numbers for TSS and O&G, with results as indicated on Table 3-19. In this case, equal weight was given to TSS and O&G. When considering the implementation of pollution

P = Probability of significance

control measures, the relative significance of the TSS and O&G weighting for a drainage basin would depend on the characteristics of the proposed control measure to be applied: TSS removal would be the predominant factor in the design of settling facilities, whereas O&G removal would be important if oil-recycling programs are implemented. Appropriate basins would be selected based on their ranking for loading of each pollutant. Tables 3-17 and 3-18 also show the relationship between the accumulated percent area and the accumulated percent TSS and O&G loads. As an example, the Ballona Creek drainage basin (Basin 5) accounts for 63 percent of the total study area and 74 percent of the total wet-weather pollution load entering Santa Monica Bay from the study areas.

Table 3-20 shows the expected annual pollutant load of heavy metals, herbicides, and pesticides. The wet-weather estimates were calculated by averaging the weighted estimated mean concentration values from Tables 3-8 through 3-11, and multiplying by the expected annual runoff flow from the typical storms in the area.

Pollutant Loading Estimates by Land-use Category. Table 3-21 shows the ratios of total TSS and O&G loads to total area for all land-use categories. This table indicates that control measures should be directed primarily to the commercial

ha = hectare

kg = kilogram

and transportation land uses for most effective application of pollutant control measures. Again, TSS and O&G from the open space and residential/agricultural land uses have not been considered in the analysis.

Dry-Weather Pollution Analysis

Dry-weather contributions to total pollution loads into Santa Monica Bay may result primarily from effluents from permitted discharges within the drainage area (J. Mitchell, LACDPW, personal communication). Pollutant concentrations for dry-weather flow for this study were obtained by analyzing samples taken at a location on Ballona Creek near the discharge into the Bay. The sampling results are tabulated on Table 3-22. Additionally, this table shows a 6-month mean concentration of several target pollutants, as reported by the Waste Management Division of the Los Angeles County Department of Public Works. Those results were obtained from May through October 1988 as part of the County's ongoing sampling program.

As was displayed on Tables 3-8 through 3-11 for the wet-weather flow analysis, the dry-weather flow concentrations of target constituents were compared to effluent limitation values set by the California Ocean Plan standards (SWRCB, 1990). It was considered that the 6-month median value detailed in the Plan reflected adequately the relatively constant value of the discharged flows. For herbicides and pesticides, the 30-day average standard was used. Results indicate that, although the TSS and O&G concentration values are below those recommended by the standards, the 6-month median standards are exceeded by the concentration of several heavy metals, particularly lead, as well as pesticides. Table 3-22 indicates that the mean values obtained in this study are higher than those obtained by the County during the same period.

The calculation of expected dry-weather pollutant loads required estimating the corresponding flows. These were obtained from the analysis of 3 years of low-flow data at Ballona, Topanga, and Sawtelle-Westwood Creeks gauging stations (Los Angeles County, Department of Public works; unpublished data). A proportional relationship was found between drainage area and flow. Because the main interest of this study resides in the 16 drainage basin discharges from the urbanized portion of the study area, dry-weather flows for only those drainage basin discharges were estimated. The calculations were based on the assumption of a constant value throughout the study area of the flow-to-area ratio found for Ballona Creek.

Table 3-23 shows estimated flows and expected annual TSS and O&G loads from each drainage basin, based on a 365-day discharge. The dry-weather discharge at Ballona Creek represents more than 80 percent of the total estimated dry-weather flow in the 16-drainage-basin area. The expected dry-weather load of heavy metals, herbicides, and pesticides, as well as their total expected annual loads are indicated on Table 3-20.

Temporal Analysis of Runoff Pollutant Discharges

As indicated previously, the temporal analysis of the data refers to determining the significance of pollutant washoff as compared to runoff occurrence. In stormwater runoff pollution studies, the main temporal processes are the so-called "first-flush" effects. For a given storm event, the first-flush effect is described by Colston (1974) as "an initially high pollutant concentration followed by decreasing concentrations as the storm proceeds." A similar effect is possible on a season-wide basis. The first storm occurring after a relatively long dry period could carry a larger pollutant concentration than a storm occurring after a short inter-event time. This condition is referred to as seasonal first-flush.

First-flush storm-related effects are usually important in stormwater pollution studies when considering small areas of study, on the order of a few acres. In the present study, this type of condition was difficult to identify because of the size of the areas where water samples were collected. In general, for regions such as the study area, routing processes are expected to take precedence over first-flush conditions; that is, the extensive storm drain system combines flows from many areas located far apart. The resulting mixture of runoff pollutants and volumes have varying concentrations and travel times, making identification of first-flush flows difficult on any basin larger than a few acres.

Seasonal first-flush effects, on the other hand, are likely to be important in the study area because of the frequent long periods with no rainfall that permit pollutant accumulation in the streets and structures such as catchment facilities. The wet season normally lasts from November through April, and the dry season lasts from May through October. During this study's sampling program, samples were taken at the residential site during the storm of November 13, 1988. This was the first storm after a 7-month dry period that affected Southern California in 1988. As shown on Table 3-8, the data show significantly larger concentrations of all pollutants during this storm than during the other two storms sampled at that site. This could be interpreted as a result of the presence of a seasonal first-flush. Additional sampling is necessary to conclusively demonstrate this phenomenon.

Another aspect usually considered in the estimation of stormwater pollution loads is that of upper threshold values. This threshold value is defined as a volume above which complete pollutant washoff occurs and contaminant loads experience dilution effects (Louks, et al., 1984). The direct relationship between runoff volume and contaminant load is lost. Dilution effects appear during high-intensity storms, with average intensities higher than 1.25 cm/hour (0.5 in/hour). From the 38 years of rainfall records at Los Angeles Airport, it can be seen that only about 8 percent of the recorded storms have intensities higher than 1.25 cm/hour (0.5 in/hour). Based on these data, upper threshold runoff effects are unlikely to have a significance in determining average pollution loads for the study area.

TOTAL ESTIMATED ANNUAL RUNOFF POLLUTANT LOAD

Table 3-24 is a summary of total annual wet- and dry-weather TSS and O&G loads into Santa Monica Bay. The results indicate that dry-weather contributions of TSS and O&G represent only about 4 and 8 percent, respectively, of the estimated total annual runoff pollution load being discharged into the Bay. Table 3-20 displayed the total estimated annual load of heavy metals, herbicides, and pesticides into Santa Monica Bay. More than 96 percent of the total load of these substances are caused by wet-weather discharges. Table 3-25 shows comparative percent ratios of the concentrations and total annual loads of several constituents as estimated in this study versus the 1988 discharge from the HTP. For most substances - particularly lead, zinc, and mercury - wet-weather pollutant concentrations exceed the HTP discharge concentrations. Concentrations of chromium and zinc from dry-weather flows also exceed those from the HTP discharge. In terms of total annual load, however, the HTP discharges exceed the runoff pollution load for all constituents.

SECTION 4

EVALUATION OF RUNOFF POLLUTANT CONTROL MEASURES

The purpose of the analysis in this section is to identify the potential runoff pollution control measures that could be implemented in the study area. Measures selected as a result of this evaluation will be used to satisfy the requirements of the Consent Decree. Potential pollution control measures are categorized as structural and nonstructural. Structural controls are associated with the construction of physical facilities; e.g., the construction of settling basins. Nonstructural measures are primarily based on management approaches for controlling the discharge of pollutants, and include maintenance practices, such as streetsweeping (Table 4-1).

CRITERIA FOR SELECTION OF CANDIDATE MEASURES

The alternative measures are described and analyzed in terms of their design characteristics as well as their efficiencies and effectiveness. Efficiency is defined as the ability of a given control measure to remove pollutants from the site (or flows) being treated. Effectiveness is the overall pollutant removal expected from the implementation of any given measure in the entire study area. For example, pollution-removal efficiencies of treatment of dry-weather flows are close to 100 percent, but because dry-weather flows represent only about 4 percent of the total expected load from the study area into Santa Monica Bay, the effectiveness of treating 50 percent of the dry-weather flows would be only about 2 percent.

The primary criteria included in this analysis to evaluate alternative runoff pollution control measures are costs, efficiency, effectiveness, community and environmental impacts, and regulatory and institutional aspects. Technical feasibility and time required for implementation are also addressed as evaluation criteria. Costs are defined in terms of TSS and O&G removal per thousand dollars of investment.

As was discussed in Section 3, control measures were evaluated based on removal of TSS and O&G from runoff loads. The percent removal of TSS and O&G is directly proportional to percent removal of metals, herbicides, and pesticides. Annual loading for these constituents was discussed on Table 3-20.

STRUCTURAL POLLUTION CONTROL MEASURES

The structural runoff pollution control measures that might be implemented in the study area were divided into four major groups: detention settling, treatment, transport, and infiltration pilot programs. Table 4-1 lists potential structural controls. Analytical and cost estimating procedures for structural measures were developed according to EPA recommendations (EPA, 1986; Weigand, et at., 1986).

VOL 12

2051

Table 4-1

Potential Runoff Pollution Control Options

Control Strategy	Control Measure
Structural Controls	
Detention	Use North Outfall Sewer structure Construct surface detention basins Construct underground detention
Treatment	Treat dry-weather flows at drainage discharges Divert dry-weather drainage into HTP interceptor Treat wet-weather flows Develop wetlands for runoff treatment
Transport	Construct dry-weather outfall Construct wet-weather outfalls
Infiltration Pilot programs	Build porous pavements Build green strip filters Build permeable inlet basins
Nonstructural Controls	
Waste collection and Recycling	Collect household hazardous waste materials Recycle waste oil
Maintenance Practices	Increase streetsweeping frequency Upgrade streetsweeping methods Increase catch basin cleaning
Public Education	Inform public of runoff pollutant problem Introduce concepts of pollutant runoff and control Emphasize need to implement solutions

Source: Engineering-Science

Detention Settling Facilities

Detention facilities analyzed in this study are the use of the North outfall sewer structure, the construction of surface detention basins in public lands (such as parks and highway medians), and the construction of underground detention systems.

North Outfall Sewer Structure Line Storage and Settling

Project Description. The North Outfall Sewer (NOS) was used by the City of Los Angeles to collect sewer flows from the northern part of the study area and carry them to HTP. The North Outfall Replacement Sewer has allowed the NOS to be taken out of service and rehabilitated. Dry-weather flows from an area of approximately 13,000 ha could be diverted to the NOS for temporary storage. The settling process associated with this storage would remove TSS from incoming flows. Subsequently, those flows would be pumped through the HTP ocean outfall.

Costs. The costs of implementing this alternative were not specifically determined because they are far greater than the requirements stated in the Consent Decree. There would be advantages in project implementation, however, because of the use of an existing structure for runoff pollution control.

Efficiency. The pollution-removal efficiency of this project would be on the order of 90 percent (for TSS). The effectiveness in total nonpoint-source pollution removal would be about 3 percent because of the low pollution load carried by the dry-weather flows, as compared to that resulting from wet-weather conditions.

Community and Environmental Impacts. The implementation of this alternative would have a very high community acceptance and a low environmental impact.

Regulatory Institutional Aspects. Regulatory institutional aspects are not expected to preclude project implementability. The NOS is not expected to be refurbished and available for this type of project until 1996.

Construction of Surface Detention Settling Basins

Project Description. Surface settling basins are common runoff pollution control facilities. Their main purpose is the removal of suspended solids. Their efficiency varies directly with the time that flows are detained within the basin. Detention time is a function of total volume; therefore, a direct relationship exists between removal efficiency and a basin's total area. The area of the basin, of course, translates into costs.

In general, detention times in basins designed for stormwater pollution control are relatively long because many of the pollutants are associated with very small particle sizes. For instance, Cobb (1982) reports that USGS studies have found that about half of the total recoverable lead is associated with particle sizes finer than 0.0039 mm. A detention time of more than 6 hours, however, would be required to remove particles of this size. Designing a detention-settling facility with a detention time of 6 hours would allow for collection of about 70 percent of the runoff resulting from a typical storm during peak-intensity periods.

In this study, estimated size of the settling facilities was based on the design procedure proposed by EPA (1986), assuming an 80 percent reduction in TSS concentration. Some reduction of oil and grease and pesticides would also be expected in these facilities. Other assumed design parameters were an average rainfall intensity of 1.27 mm/hour (0.05 in/hour) in the study area, an expected typical total rainfall of 28.70 mm (1.13 in) during a 24-hour rainfall, and an average runoff/rainfall ratio equal to 0.35 (see Table 3-7). The 1.27-mm/hour intensity is the average wet-season rainfall intensity, estimated from 38 years of rainfall analysis (EPA, n.d., and SYNOP historical data, Table 3-6). The 28.70-mm figure is the rainfall volume expected during a typical storm.

Settling basins would be on-line facilities. They would operate as dry ponds and the retention volume would be drawn down within 72 hours of the storm occurrence to reduce odor and insect problems. Although the basins could be designed to include percolation into the ground, this analysis considered that all flows would be returned to the stormwater system.

Costs. Although the characteristics of detention facilities are site-specific, Table 4-2 shows general basin characteristics associated with the 55 drainage basins in the study area. The drainage basins are ranked by TSS loading ratio as indicated on Table 3-17. Construction and O&M cost estimates were obtained from Weigand, et al. (1986). These costs were doubled in the calculations to account for 1989 costs, local cost conditions, and engineering plus contingencies. Capital costs include an estimated $750,000 per hectare of land.

Land availability is probably the main problem facing the development of settling basins in the study area. The O&M costs could increase significantly if the concentration of pesticides in the sediment makes frequent removal of accumulated sediments necessary. Estimation of total annual costs was based on a 20-year life and a 10 percent discount rate.

Efficiency. As indicated previously, these facilities were designed for a removal efficiency of about 80 percent TSS. The TSS removal-to-investment ratio varies from 488 kg/$1,000 at drainage basin 2 to 29 kg/$1,000 at drainage basin 26.

Community and Environmental Impacts. The construction of settling basins would have implications regarding public safety. Additionally, this type of project would not be acceptable if the facilities are built in public parks and recreation activities are disrupted. Environmental impacts caused by the presence and disposal of sediments would be moderate.

Regulatory Institutional Aspects. Some regulatory institutional issues are expected to arise if this alternative is implemented because of the required approvals by the City departments, the Regional Water Quality Control Board, Los Angeles Region (RWQCB), and EPA.

During this study, it was not possible to identify an appropriate site for the construction of a detention basin within the study area because of the numerous factors associated with land acquisition that would have to be resolved. Provided that a construction site is determined, the expected implementation time is estimated to be between 1 and 2 years.

Construction of Underground Detention Settling Facilities

Project Description. Underground settling facilities operate in a fashion similar to surface settling basins. Runoff flows are detained over a certain time period to accomplish pollutant removal by allowing suspended solids to settle under quiescent

conditions. The design characteristics of these structures are indicated on Table 4-3. Design parameters used for sizing these structures were equal to those used for sizing surface settling basins. Removal efficiencies are expected to be about 80 percent.

Costs. The main advantage of underground detention facilities over settling basins is the availability of construction sites, which makes this alternative less site-specific. Underground settling facilities are generally more expensive than surface settling facilities in terms of capital and O&M costs. In this study, construction cost estimates were obtained from Weigand, et al. (1986). These costs were doubled in the calculations to account for 1989 costs, local cost conditions, and engineering and contingencies.

Efficiency. The main disadvantage of this alternative is the lower pollution removal-to-investment ratio as compared to surface settling basins. As shown on Table 4-3, the annual kilograms of TSS removal per $1,000 investment range from 361 at drainage basin 2 to 25 at drainage basin 26.

Community and Environmental Impacts. This type of facility would be more easily accepted by the community than surface settling basins. The environmental impact would probably be moderate because of the presence of sediments requiring removal and the perceived risk of groundwater contamination. Construction would result in extensive disruption of existing activities.

Regulatory Institutional Aspects. Some institutional regulatory issues are expected to arise because of O&M considerations. The estimated implementation time is between 3 and 5 years.

Treatment Facilities

Two main runoff pollution-control treatment alternatives were considered for analysis: treatment of dry-weather flows at drainage discharges and collection of dry-weather flows at drainage discharges for subsequent treatment at HTP. Additionally, facility site considerations are given for providing storage of wet-weather flows at the discharge sites for subsequent treatment in a Wastewater Treatment Plant, and development of wetland areas for runoff treatment is discussed.

Treatment of Dry-Weather Flows at Drainage Discharges

Project Description. Treatment of dry-weather flows consisting of primary sedimentation would be conducted at the discharge point of the receiving storm drain into the Bay. The addition of chemicals to the primary settling facilities may be necessary to remove heavy metals. The implementation of this alternative would require pumping the flows from the discharge site to the primary sedimentation units, which should be located in a site with adequate flood protection and as close to the discharge of the storm drain as possible.

Assuming that most dry-weather flows result from regulated discharges, removal of contaminants would be most effective if treatment takes place at the point of discharge. To be implemented, this measure would have to be added to existing NPDES permits by the RWQCB.

[c] Cost estimates include land acquisition at $750,000 per hectare
m^3/hr = cubic meter per hour
kg = kilogram

Costs. The removal costs associated with this alternative are indicated on Table 4-4. Costs were estimated by using factors developed by the U.S. Army, Corps of Engineers (1978), corrected for time, local conditions, and engineering and contingencies. The estimate of annual costs is based on a 20-year life and a 10 percent discount rate. A disadvantage of this alternative is the land requirements for construction of the facilities. This factor was not included in the cost estimates.

Efficiency. Treatment facilities are very efficient for removing a number of contaminants, including TSS and O&G. The annual TSS removal in kilograms per $1,000 invested is expected to vary from 226 at Ballona Creek and to 2 at drainage basin 14. The kilograms of O&G removed per $1,000 investment would vary from 18.8 to 1.3 in those same drainage basins. Removal effectiveness for low-flow treatment facilities would be quite low because of the very small dry-weather to wet-weather pollution ratio.

Community and Environmental Impacts. The environmental impact of developing this alternative would be high because of the presence of the treatment facilities in environmentally-sensitive areas. The community acceptance factor would be low because of the negative aesthetic impacts of the treatment plants and the perceived environmental risk.

Regulatory Institutional Aspects. Regulatory institutional issues are likely to be important because the treatment facilities would have to be operated under federal and state regulations. The period required for project implementation would be between 3 and 5 years.

Divert Dry-Weather Drainage into HTP Interceptor

Project Description. This alternative consists of constructing low-flow diversions from the drainage channels to the coastal sewer interceptor so that dry-weather flows could be treated at the HTP. Flow diversions would take place only during the dry season, which represents low-flow conditions at the treatment plant, and during periods between rainfall events when daily flows were at levels common during the dry season, and thus represents only "treatment by opportunity". The HTP has a treatment capacity of about 5.5×10^{11} liters per year (400 mgd). The average dry-weather flow for the urbanized basins (Basins 1-16) in the study area is about 349 L/s (8 mgd), which represents only about 2 percent of HTP capacity. From the standpoint of efficiency, diversion of Ballona Creek low flows alone would capture approximately 80 percent of the runoff from urbanized basins with the construction of a single diversion structure. Because of the small flows diverted, no major effects on the plant's capacity or performance would be expected.

The project would require constructing a diversion structure in the low-flow section of the Ballona Creek drainage channel. Automatic electrical operators would regulate flow diversion through a sluice gate valve so that no flow would be diverted during rainfall conditions or peak inflows at the treatment plant. The pipe carrying flows to the coastal interceptor is expected to operate entirely by gravity. The automatic operators could also be controlled by a flow-monitoring system installed at HTP.

Costs. The cost factors associated with this alternative are indicated on Table 4-5. They include an estimated $100 per year per liter/second of flow volume. This value was obtained from Engineering-Science data for operation of wastewater treatment facilities. These estimates indicate a present-worth cost for diversion and treatment of Ballona Creek low flows to HTP of $536,000. The City Bureau of Sanitation has indicated that these costs may be substantially higher.

Efficiency. Comparison of effluent water quality at HTP (Table 2-2) and Ballona Creek low-flow runoff (Table 3-22) indicate that TSS and O&G concentrations in Ballona Creek runoff average 2 and 5 times lower, respectively, than in HTP effluent. Concentrations of metals in both systems are approximately equal. In terms of TSS and O&G removal, treatment would probably have no effects on the water quality of the incoming runoff flows to HTP. TSS and O&G would simply be discharged through HTP's outfall instead of draining directly onto the nearshore zone. On the other hand, some heavy metals would be removed from the discharged flows and incorporated into the excess sludge. Because of their relatively low loads and concentrations, no effects are expected on the plant's performance, specifically in the sludge treatment and disposal processes. A best-case estimate of the average annual kilograms of TSS removed from the drainage discharge per $1,000 investment would vary between 4285 and 31 (Table 4-5) at Ballona Creek and Santa Monica Pier drainage basins, respectively. Since the Ballona Creek flow represents 80 percent of the low-flow TSS and O&G entering the bay, removal effectiveness of treating this single outflow is much higher than treating any other drainage area.

Community and Environmental Impacts. The main advantage of this alternative is the increased public perception that the responsible agencies are taking steps toward solving the perceived pollution problem in the area. The negative environmental impacts of project implementation would be minimal, since Ballona Creek does not drain into the wetlands. Fresh water flows through the wetland area via Jefferson drain and the Centinela drain and into Ballona Creek.

Regulatory Institutional Aspects. Concern exists regarding the impact of implementing this alternative on the regulatory and financial requirements of the HTP. These will need to be resolved, including EPA approval to accept runoff flows other than domestic sewage. The Sewer Limitation Ordinance adopted by the City in 1988 regulates new sewer connections by both the City and contract agencies. Any diversion of low flows would need to be evaluated against criteria used for other connections.

Storage and Treatment of Wet-Weather Flows

This alternative would consist of collecting and storing stormwater runoff flows for treatment at a treatment facility. In terms of plant capacity, this alternative cannot be implemented because the expected volume resulting from a typical storm during the wet season would be about three times the existing treatment capacity at HTP. The size of storage requirements, flow conveyance facilities, and treatment units makes this alternative nonimplementable at this time or in the near future.

A pollutant control technology that has been used widely in the Southeast is the detention of some first-flush volume of stormwater. After settling to remove pollutants, this volume is slowly released to the receiving body. In this way it operates in a similar manner to the settling basins discussed previously. This control technique may have applications in the Santa Monica Bay drainage areas in the City's long-term runoff management plan. ES estimates that capital costs required to implement this technology would be similar to those for detention basins.

Development of Wetlands for Runoff Treatment

Project Description. Treatment of stormwater runoff by routing the flows through wetland areas has proven effective in removing pollutant loads. Most studies reporting the results of the use of wetlands as a control measure indicate that they are most appropriate for removing nutrients and low levels of dissolved toxics (metals, etc.). They thereby function best as a "polishing" step at the end of a treatment series that uses other technologies to remove solids and some pollutants prior to reaching the wetlands. Because wetlands provide mostly nutrient and metals removal through biological uptake, careful studies are necessary to determine the effects of stormwaters in ecologically sensitive areas.

This study made an evaluation of the impact of using the Ballona Creek wetlands for treating stormwater runoff. A water quality objective for the Ballona Wetlands is to provide both storage and outflow for stormwater flow capacity for the 50-year storm event (Friends of Ballona Wetlands, 1990). By using wetlands only as a "polishing" step, pollutant removal efficiencies for this measure would be very low compared to other technologies. By treating the runoff flows before discharge, adequate uses of the water would be made; however, the purpose of using the wetlands as treatment units would be lost. Additionally, the treatment and flow conveyance costs would make this alternative not implementable at this time. Because of the high cost of land, the development of new wetlands in the area has also been considered infeasible.

Transport Facilities

The main alternative included under this category is the construction of dry weather outfalls. Additionally, some information is given regarding the construction of wet-weather outfalls. The outfalls would discharge into Santa Monica Bay at an undetermined distance from the beach, where dilution would decrease pollutant concentration below Ocean Plan Standards (SWRCB, 1990).

Construction of Dry-Weather Outfalls

Project Description. This alternative would consist of constructing outfalls similar to the proposed Pico-Kenter outfall system that would carry dry-weather flows for discharge at a certain distance from the beach. One problem with project implementation is the absence of pollutant-removal capabilities, which may not conform to the requirements of the Consent Decree.

Costs. The cost figures shown on Table 4-6 were developed at each discharge site using the estimated cost of the Pico-Kenter outfall as a basis point and sizing up or down as applicable. The cost estimate of the Pico-Kenter project was provided by the engineering staff of the Department of Public Works of Los Angeles County.

Efficiency. An important characteristic of this alternative is that pollutants are not actually removed from the Bay, but it is assumed that dilution effects would reduce pollutant concentrations to more acceptable levels.

Community and Environmental Impacts. The community acceptance factor of implementing this alternative is likely to be mixed. Some strong opposition would be expected from environmental groups. The actual environmental impacts are likely to be moderate. There may be a need to model the behavior and characteristics of the receiving water under the new discharge conditions.

Regulatory Institutional Aspects. Several regulatory institutional issues are expected from the development of this project because of the number of agencies and community groups involved in the decision-making process. The time period required for constructing an outfall similar to the Pico-Kenter system is estimated at about 5 years.

Construction of Wet-Weather Outfalls

As indicated previously, the expected volume resulting from a typical storm during the wet season is about three times the treatment capacity at HTP. The required size of the outfalls would, therefore, be substantially larger than the existing domestic sewage ocean outfall. Because of its high costs, it has been considered that this alternative cannot be implemented at this time.

Infiltration Pilot Programs

Project Description. Small pilot programs are recommended to assess the effectiveness of implementing site-specific runoff pollution-control measures in areas such as parking lots. Three examples of such programs are evaluated here: installation of small stormwater filters in parking lot green strips, use of porous pavements in low-traffic areas, and installation of permeable catch basins.

The proposed **stormwater filters** would be designed as slow sand filtration units with a filtration rate of about 4,000 $L/m^2 \cdot d$ (100 $gal/ft^2 \cdot d$). Figures 4-1 and 4-2 are schematic representations of one of these units, which would be installed as part of an existing green strip divider in a parking lot. During storms, runoff would be carried to these units by sloping the catchment surface toward the filter inlet. The filtered effluent would discharge into the stormwater system. Sampling and monitoring capabilities should be provided to test actual pollutant removal efficiencies. The only normal O&M procedure applied to this unit would be to replace the upper 1-inch layer of sand when water-head losses become excessive.

Porous pavement areas would consist of a coarse graded surface layer, containing at least 25 percent voids, laid on an impermeable underlayer. Colyer (1982) indicates that about 4 mm of rainfall could be retained in the voids. The retention time and the contacting surface would result in pollution reduction. The effluent from the porous pavement areas would be discharged into the stormwater system.

Problems encountered with these systems, as compared to regular asphalt pavement, are a faster wearing of the pavement surface and the need to apply special construction techniques. Control of construction would need to be more stringent than for normal road surfacings, and the costs are usually higher.

Permeable catch basins would be designed in a similar fashion to regular catch basins, except that the bottom would allow for the infiltration of runoff into the natural soil. These units could retain volumes of runoff from about 35 liters in a 300-mm chamber to 125 liters in a deep 450-mm chamber. Additional flows would be bypassed to the storm drain system. Installation of this type of catch basin should be considered as existing basins are repaired or replaced.

Pilot programs would require constant monitoring during an estimated three-year research period for determining actual pollutant-removal efficiencies. Porous pavements and green-strip filters allow easier access for these monitoring requirements than do permeable catch basins.

Costs. The construction cost of a green-strip filter collecting stormwater flows from an area of about 0.15 ha is approximately $14,000. The corresponding cost for a porous pavement area is approximately $24,000. The cost of a permeable catch basin is approximately $10,000.

Efficiency. The pollutant-removal efficiency of the filters and the porous pavement units would be about 80 percent for TSS and O&G removal. Because most of the soil in the study area is formed of clays or sandy loams with relatively low infiltration rates, the efficiency of permeable catch basins would be only about 10 percent during a typical storm event. Effectiveness of widespread implementation of these techniques has not been included in final project evaluations.

Community and Environmental Impacts. The implementation of the infiltration pilot program would result in positive community acceptance. No negative environmental impacts are expected from a pilot program or on areawide implementation of these control measures.

Regulatory Institutional Aspects. No regulatory institutional issues are expected from the implementation of a pilot program. Regulations would be necessary for implementing these measures on an areawide basis.

NONSTRUCTURAL POLLUTION CONTROL MEASURES

Modification to Existing Control Practices

Modifications to existing nonstructural control practices may be employed to reduce pollutant loadings. This can occur through changes in stormwater management techniques. As with structural controls, any changes in existing management practices must be carefully considered to ensure that meaningful pollutant-loading reductions are achieved within a reasonable cost when compared to other available control strategies.

Nonstructural controls may be either generally applicable throughout the study area or may be focused to a particular land-use or drainage area that has been identified as a source of high levels of pollutant loading. Four existing practices have been identified as feasible stormwater runoff pollution-control methods: household hazardous waste collection programs, improved street sweeping, sweeping of target areas, and increased frequency of catch basin cleaning.

Collect Household Hazardous Waste Materials

Project Description. Improper handling and disposal of hazardous waste materials can result in those materials reaching storm drains and being discharged to Santa Monica Bay and beach areas. Metals, pesticides, and oil and grease may be discharged through a variety of paths. Support of community efforts to periodically pick up household hazardous materials for proper disposal at approved sites is one way to reduce this potential contamination.

The most common method used by municipalities is to financially support a community-based pickup program of household hazardous waste materials and to publicize the availability and locations of these services. Continuing public education is required to ensure that the benefits of the program are continuous and not one-time. As indicated in Section 2, the City of Los Angeles and Los Angeles County are currently engaged in implementing this type of program in the study area.

Costs. The costs associated with the implementation of household hazardous waste collection programs vary widely, depending mainly on the amount and variety of wastes collected and the cost of waste disposal. According to City of Los Angeles estimates the cost per roundup event per year is about $250,000 (Table 4-7).

Efficiency. Experience from past roundups carried out by the City of Los Angeles indicate that the public response to this program varies widely from area to area. Similar programs in other parts of the nation have shown that the amount of hazardous waste collected is quite small as compared to the estimated availability. In terms of oil and grease removed, this program's efficiency has been estimated at 5 kilograms per $1,000 spent. Major assumptions are indicated on Table 4-7.

A recent program titled "Mobile Household Hazardous Waste Collection Program (HAZMOBILE)" was begun in February 1994. Operation details and costs have not been noted as yet. A brief description of this program is included in Section 2.

Community and Environmental Impacts. Hazardous waste pickup programs require safeguards for handling, transportation, and disposal of the material. The availability of hazardous material disposal areas must be assessed.

Regulatory Institutional Aspects. Coordination is necessary among the solid-waste handling agencies at the City and County level to gain an increased level of effectiveness of the program within the Santa Monica Bay drainage area.

Improved Streetsweeping

Project Description. This control strategy falls within the area of improved maintenance practices designed to reduce the level of TSS available to storm runoff.

Table 4-7

Household Hazardous Waste Collection Programs

Main assumptions:	
Radius of influence of collection site (km)	5
Area covered with one site (ha)	2,000
Number of additional collections per year	1
Program effectiveness	0.05
Collection cost per site (City information)	$250,000
Annual amount of O&G removed: (kg)/$1,000 investment	5

Source: Engineering-Science
O&G = oil and grease
km = kilometer
ha = hectare
kg = kilogram

Improved streetsweeping practices include acquisition of more efficient streetsweeping equipment and scheduling operations to coincide with the end of the dry season. Equipment includes vacuum streetsweepers capable of removing fine particulates from areas difficult to reach with conventional equipment.

Normal streetsweeping practices are designed to collect larger particulate matter that is generally less of a pollution problem than fine particles. Metals and other compounds resulting from tire and brake wear deposited on streets and highways, as well as pollutants from other sources, tend to be strongly associated with fine particulates.

A pilot program to demonstrate the efficiency of the equipment and frequency intervals necessary to achieve optimum system performance is recommended before proceeding with any large-scale implementation of this strategy. This could be implemented within a two-year period, including an assessment of the effectiveness of the program and assessment of the benefits of a wider-scale application. The pilot program should evaluate the quantity and type of material removed as well as the particle size distribution of the material to determine whether the goal of increasing the collection of fine particles and associated metals is satisfied.

Costs. To be an effective pollution control measure, streetcleaning frequency has to be related to pollutant accumulation and interstorm event times. Sartor and Boyd (1972) estimate that the solids loading accumulation curve in a commercial area tapers off after about 7 days after the previous cleaning. The inter-event time estimated from the typical storm study described in Section 3 of this report is about 10 days (1.3 weeks). Ten days, therefore, should be the optimum streetsweeping frequency for the area.

The City of Los Angeles operates 164 sweepers to cover a total of about 7,650 street miles. The cleaning frequency averages about once every 3.5 weeks; at that frequency, a sweeper would cover 18 miles of streets every 1.3 weeks (10 days). A total of 430 sweepers would be required to sweep 7,650 street miles every 10 days.

Assuming a similar efficiency for vacuum sweepers, a pilot program covering an impervious area of approximately 2,200 hectares could be accomplished in a high-density transportation area with eight streetsweepers. The annual cost of the pilot program would be approximately $900,000, including amortization of capital, labor, and operation and maintenance costs (Table 4-8).

Efficiency. One of the objectives of the NURP program was to establish the effects of streetsweeping on the loadings and concentrations of pollutants. The results indicated that pollutant-reduction efficiencies with conventional roller sweepers are very low - on the order of 10 percent. Occasionally, the street load after sweeping was greater than before. Novotny, et al. (1986) indicate that pollutant removal using high-efficiency equipment could be at most 25 percent. As shown on Table 4-8, in this study the efficiency of improved streetsweeping programs has been estimated at 20 percent with improved equipment such as vacuum streetsweepers. A removal rate of 70 kilograms total suspended solids per $1,000 invested has been estimated.

Community and Environmental Impacts. The increased frequency and intensity of improved streetsweeping may increase air emissions of fine particulate matter and would have associated noise impacts. The use of more efficient vacuum streetsweepers over conventional units, however, may compensate for the effect on air quality. If the operation is focused in a high-intensity transportation land use, the noise effects would be lessened. The material collected would require handling, transportation, and disposal in an appropriate landfill. Appropriate tests would have to be performed to determine the suitability of the material for disposal.

Regulatory Institutional Aspects. Coordination within City departments is desirable if the program is expanded beyond the pilot-scale demonstration. The effectiveness of improved streetsweeping may be increased if targeted areas are coordinated with cleaning of catch basins.

Sweep Target Areas

Project Description. Sweeping target areas with existing equipment to reduce particulate accumulation is another potential measure to reduce TSS loadings on storm-drainage systems. This measure is distinguished from improved streetsweeping because it does not supplement existing equipment.

Sweeping target areas entails improved scheduling designed according to criteria that consider the accumulation of material during the dry season (before the first seasonal storm) and between storm events. Target areas can be identified by identifying areas with higher pollutant loading ratios.

Costs. Assuming that a pilot program uses already programmed expenditures and existing equipment, there would be no increase in expenditures to focus streetsweeping activities in a target area, with the exception of monitoring the success of the project.

VOL 12

20671

R0053976

Table 4-8

Improved Street Cleaning

Main assumptions:	The City of Los Angeles operates 164 sweepers to cover a total of about 7,650 street miles. The cleaning frequency is about once every 3.5 weeks. A vacuum truck having a similar efficiency would cover about 18 miles of streets if the frequency is reduced to 1.3 weeks (recurrence interval of a typical storm). In terms of area, 18 street miles is about 270 ha. The average load of TSS/ha is 145 kg. A total of 7,900 kg of TSS could be removed with a sweeper if the efficiency is assumed equal to 20 percent.
Cost of a vacuum sweeper ($)	120,000
Annual O&M ($)	84,000
Annual cost (10%, 6 year)	111,600
TSS removed: (kg)/$000	70

Source: Engineering-Science
TSS = total suspended solids
O&M = operations and maintenance

Efficiency. Any improvement in removal efficiency under this strategy is principally associated with choosing areas that have higher pollutant loading ratios. Assuming that the areas now swept have an average TSS annual loading of 145 kg/ha, sweeping target areas would reduce the pollutant load to about 130 kg/ha in those areas. Considering the annual cost of operating a streetsweeper equal to $100,000, and the same assumptions indicated on Table 4-8 (except for the lower efficiency), this would imply the additional removal of approximately 40 kilograms TSS/$1,000 invested. By reprogramming 40 (equivalent to 25 percent) of the existing streetsweepers to high pollutant-loading areas, the overall removal effectiveness would be less than 1 percent.

The actual effectiveness of this program could be determined by a pilot program that would compare conditions with and without the scheduling program in a target area. Because of the practical difficulties of isolating truly high-pollutant-loading areas, scheduling operations between storms, the high cost of operating and maintaining equipment, and the low marginal removal efficiency of improved scheduling using conventional streetsweeping equipment, the project would probably have an actual cost efficiency lower than that stated. Also, because existing equipment does little to remove the small particle fraction associated with high pollutant loads, the actual pollutant load reduction for metals and oil and grease may be much less than is implied by the TSS load reductions.

Community and Environmental Impacts. Sweeping target areas would have few if any environmental effects, except for changing the areas and frequency of streetsweeping activities.

Regulatory Institutional Aspects. There are no known regulatory or institutional problems in implementing this approach. The effectiveness of sweeping target areas may be severely limited because of practical considerations, such as the ability to operate between storm events during the rainy season. The intervals between storms are too short to allow a complete pattern of sweeping between runoff events. Furthermore, the use of existing equipment in target areas would require extending the cleaning frequency in other areas beyond the average 3.5 weeks. This might result in creating nuisance problems in some parts of the study area.

Catch Basin Cleaning

Project Description. Stormwater catch basins and debris basins provide the most practical opportunity for removal of accumulated particulates and debris from the storm drainage system as now configured. Increased frequency of maintenance of existing catch basins can remove accumulated material that would otherwise be uncontrolled without additional structures or treatment. Other existing storm-drainage components, such as storm drains and channels, provide sufficient velocities to keep particles suspended during all but the lowest flow conditions and do not provide for a convenient location for collection.

Periodic catch basin cleaning is currently being performed by the City. The present catch basin cleaning effort could be improved by:

- increasing the frequency of cleaning
- review of cleaning techniques and equipment efficiency
- modification of the present monitoring and tracking system to better direct cleaning routes and timing of cleaning

The scheduling of catch basin cleaning should consider the seasonality of hydrologic events in order to attempt a reduction in loading from the first seasonal flush. A pilot program should be initiated to determine the optimum scheduling and frequency of cleaning to gain the maximum advantage from these existing structures.

Costs. Assuming a schedule that permits a field crew to clean 10 catch basins per day at a daily cost of $500 provides an estimated unit cost of approximately $50 per catch basin cleaned (Table 4-9). Cost savings per unit may be able to be realized using modified or specialized equipment, and through scheduling practices that minimize on-site time by optimizing the servicing interval.

Efficiency. As indicated on Table 4-9, a removal ratio of about 600 kg TSS per $1,000 invested has been estimated for comparing the efficiency of this alternative with other pollution-removal methods. This assumes a 20 percent removal efficiency of TSS for an average of 1 ha drainage area per catch basin, using a cleaning interval sufficient to catch the first storm of the rainy season.

Community and Environmental Impacts. Increased cleaning of catch basins would generate additional solid waste, which would have to be transported for disposal or land reclamation. The effort would have a very positive aesthetic impact on areas where catch basins experience heavy debris and trash loading.

Table 4-9

Catch Basin Maintenance and Cleaning

Main Assumption:	Catch basins in identified drainage basins with annual loading ratios > 1 would be cleaned before the start of the rainy season. This is in addition to regular maintenance activities.
Estimated number of catch basins in the study area	50,000
Estimated number of catch basins per hectare	1
Estimated annual cost of maintenance per basin ($) (City and County information)	50
Total annual cost of maintenance ($000) assuming all catch basins are cleaned annually	2,500
Assumed pollutant-removal efficiency	0.2
Annual amount of TSS removed (kg)/$1,000	615
Annual amount of O&G removed (kg)/$1,000	27

Source: Engineering-Science
TSS = total suspended solids
O&G = oil and grease
kg = kilogram

Regulatory Institutional Aspects. Several entities have responsibility for maintaining existing catch basins. Coordination of the cleaning schedules for the various maintenance personnel and equipment may be necessary to implement this program on a pilot- or full-scale basis.

A disadvantage of this program is that, without design consideration for TSS removal in existing inlet structures, high stormwater velocities that occur during storm flows may allow only the larger particles to settle out. This means that smaller particles, which are more closely associated with the pollutants of concern in this study, may be readily transmitted through existing structures. If this occurs, the effectiveness of cleaning existing structures, in terms of pollutant removal, would be greatly reduced. The pilot program recommended with this type of project should include an assessment of the particle size distribution and association with other pollutant categories for the material removed from existing inlet structures. This would be conducted through measurement of the mass, particle size distribution, and distribution of types of material collected in catch basins.

This pilot program could also be combined with the construction of other types of inlet structures, such as permeable catch basins, as indicated previously in the description of structural pilot programs. Modifications to existing inlet structures would reduce velocities and would increase the removal effectiveness for smaller particles. This would have the same effect as constructing small area settling basins.

proposal could be implemented on a pilot scale with a voluntary recycling effort to demonstrate the recycling center concept, and document that proper controls for transport, handling, and disposal of waste oil are feasible. Currently, the hazardous waste collection programs in the area include oil collection and recycling.

Costs. Estimated costs for a pilot program, including a public education element, are in the range of $200,000 to $400,000 and could be implemented within a one-year period. If the pilot program proves successful, it would be possible to expand the program to include regulatory elements or as an expanded voluntary program within a three-year period.

Efficiency. The expected efficiency of this program is 65 kg O&G removed per $1,000 invested. This is based on an annual program cost of $400,000 and a 10 percent reduction in the amount of waste oil that enters the storm drainage system. This would result in the removal of approximately 26,000 kg of oil and grease per year.

Community and Environmental Impacts. Environmental constraints associated with air emissions and concerns over disposal of hazardous materials in waste oil products have limited existing recycling efforts.

Regulatory Institutional Aspects. If a regulatory approach were adopted, one possible method is to regulate the sale of motor-oil products to facilities that participate in a waste oil recycling program. This would require verification that a minimum percentage (for instance, 50 percent) of the oil product volume sold at the installation is accounted for through a recycling effort.

To be successful, a regulatory effort would need to be applicable to an area at least the scale of the study area and possibly to an even larger area. A voluntary program of waste-oil recovery could be conducted over a smaller geographic area, and would require a substantial public education effort as well as the potential need to financially support collection stations and waste-oil recycling centers.

Institutional considerations associated with this alternative are significant. The problems confronting the oil-recycling industry are both economic and regulatory. As additional regulations are imposed on these facilities because of air quality concerns and limitations on the transport and disposal of hazardous materials sometimes present in waste oil, many facilities have chosen to shut down.

To be successful, the program must have the support of regulatory agencies that have authority over these facilities with assurances that adequate environmental safeguards will be included at the recycling facilities in order to ensure that the recycled oil does not become an air quality or toxic waste disposal problem. The regulatory program envisioned by this alternative would require the adoption of similar local ordinances and the establishment of recycling centers involving cooperation with a number of local jurisdictions.

Public Education and Awareness

Project Description. Visible beach and ocean pollution discharged from storm drain outfalls is primarily due to the waste disposal practices of the average person. Most of the public are not aware that materials casually disposed of on the street (used motor oil, trash, animal waste, etc.) go directly into the ocean without treatment. An effective public education program must address this lack of awareness.

While some public education programs in other areas of the country with runoff pollutant problems have achieved highly productive, efficient, and positive results, any proposed public education program for the Santa Monica Bay Stormwater Pollutant Reduction Study must compete with other recommendations for the limited funding set aside for the implementation of control measures. A public education program should therefore complement other proposed control measures, and be structured in a manner that will promote the reduction of runoff pollutants while providing quantitative estimates of the effectiveness of both the control measures and the education program itself.

In the specific areas targeted for implementation of other runoff pollutant control measure pilot projects, a public education program should:

- heighten public awareness of the runoff pollutant problem
- introduce easily-understood technical concepts of pollutant runoff and control
- emphasize the need to expeditiously implement solutions

Constituent monitoring of runoff pollutant concentrations in an area where public education programs are conducted, and comparison to pollutant concentrations in an area where control measures were implemented without the benefit of a public education program, will provide a quantitative measure of the effectiveness of the education program in reducing runoff pollutants.

In the long term, this type of public education program will:

- encourage public participation in the evaluation and decision-making process
- solidify public support of solutions selected by public officials

Costs. The cost of this program can be flexible based on the Consent Decree funds available after the remaining pollutant control pilot projects are finalized. However, sufficient funding must be available to allow the program to be effective.

Efficiency. The efficiency of this type of pollutant control measure is uncertain; while there is general agreement that public education measures increase awareness of pollution control alternatives, quantification of this effectiveness is not always pursued. This type of control measure is difficult to evaluate against more traditional methods on a cost-benefit basis. A measure of the efficiency of this type of program is envisioned as part of the implementation of this measure.

Community and Environmental Impacts. This program should have only positive impacts on community awareness of the runoff pollutant problem.

Regulatory Institutional Aspects. This program will be closely coordinated with other runoff pollutant reduction techniques to maximize both the effectiveness of the entire reduction program and the awareness of the public of what is being accomplished. Similar to the efforts of the City's public awareness program regarding wastewater treatment, the stormwater runoff public awareness program

The success of design standards for stormwater pollutant load reduction is dependent on the rate of retrofitting and replacement of existing structures. Capital programming must consider whether the objective is to incorporate these measures only when upgrading storm-drainage facilities or to accelerate replacement.

Construction Standards. Improperly managed construction sites are known contributors to stormwater pollutant loading, especially TSS. Requiring temporary drainage and erosion control plans for construction activities, along with adequate enforcement of these measures, is a demonstrated control technique.

The primary elements of a control plan for runoff from construction sites include provisions for routing drainage away from graded and disturbed areas, providing measures to control soil loss on slopes, and eliminating soil tracking onto paved surfaces by construction vehicles. Long-term erosion controls include adequate soil cover materials and may require structural stabilization of erodible slopes with structural measures. Implementation of this measure requires inspection staff who have expertise in runoff control techniques and monitoring of construction sites for compliance. It could best be implemented along with the land-use controls discussed above.

Pesticides Use Control. The use of pesticides is subject to numerous federal and state regulations. From the standpoint of stormwater pollutant reduction in an urbanized area, however, the main concern is the regulation of pesticides used for lawn maintenance, primarily in residential neighborhoods. The extent of control regulations may range from prohibiting the use of certain types of pesticides to a total ban on the use of these substances.

The most common pesticides observed in sample collections during this study included DDT and benzene hexochlorides (BHCs), including lindane. DDT is illegal for use in any application (already prohibited) and BHCs cannot be sold for domestic use. DDT frequently appears in water samples due to extensive historical use and its persistence in the environment. The problem in controlling runoff of BHC materials is in controlling use. Given that the concentrations of pesticides in stormwater runoff from the local area appear to be on the average about 16 times higher than the recommended Ocean Plan standards, stringent pesticide control regulations are recommended in the study area, especially during the dry season when beach recreation use is high.

Product Restrictions. Among the materials runoff carries into the stormwater system are certain products that do not constitute sources of pollution, but rather create nuisance conditions at the points of discharge of the drainage channels. Most of these products are made of nonbiodegradable materials, such as Styrofoam containers.

Regulating the use of these products in the study area would result in significant economic as well as aesthetic benefits to the local area. Benefits would include reduced trash collection and disposal costs and more attractive beaches.

Solid-Waste Recycling. Economic incentives have resulted in extensive collection and recycling of aluminum cans, beverage bottles, and some plastics. Some of the components of household and everyday trash that find their way into stormwater drainage systems may be reusable, and are candidates for targeted recycling programs that could reduce the amount of improperly disposed solid waste in the

Table 4-10

Summary of Preliminary Evaluation of Alternatives

Alternative	Evaluation Results
Structural Measures	
Use North Outfall Sewer structure	Eliminated based on cost and long-term implementation period
Construct surface settling basins	Eliminated based on cost and difficulty of implementation
Construct underground settling facilities	Eliminated based on cost and difficulty of implementation
Treat dry-weather flows at discharges	Eliminated based on cost and possible environmental impacts
Treat dry-weather flows at HTP	Eliminated based on institutional uncertainties
Treat wet-weather flows	Eliminated based on costs
Develop wetlands for stormwater treatment	Eliminated based on costs
Construct dry-weather outfalls	Eliminated based on nonreduction of runoff pollutant loading
Construct wet-weather outfalls	Eliminated based on costs
Infiltration pilot programs	Recommended
NONSTRUCTURAL MEASURES	
Collect household hazardous waste materials	Recommended
Sweep target areas	Eliminated because the project would negatively affect current streetcleaning practices
Improve streetsweeping	Eliminated due to high initial capital costs and uncertainty regarding debris removal
Improve catch basin cleaning efficiency	Recommended
Recycle waste oil	Eliminated because of regulatory complexities
Public education program	Recommended

Source: Engineering-Science

determine if water should be allowed to infiltrate beneath the filter, rather than being diverted to the storm drain. The buildup of filtered constituents at the surface of the filter and requirements for maintenance will also be monitored.

Collect Household Hazardous Waste Materials

The City and the County of Los Angeles have previously conducted household hazardous waste materials collection programs. The City completed eight "roundups" in 1989 at eight different locations. The funding set aside for collection activities for this program is $550,000, which is estimated to fund four roundups encompassing slightly smaller areas than those conducted previously.

Information from similar programs carried out in other areas of the country (e.g. cities in Florida and Texas) indicate that there is enthusiastic public response for programs such as this. With well-designed and implemented programs, there is the possibility of even greater participation and effectiveness in these kinds of programs in the future.

Specifically, there is a need to better determine the variables that trigger public participation in these collection programs. Additionally, as part of the public education and awareness program described below, it is important to assess changes in public awareness resulting from these collection activities.

The City has a unique opportunity to help determine the triggering mechanisms and effectiveness of the collection programs simply because there are identifiable areas where collection activities have been performed and other areas where they have not. The recommended project will be designed to help assess the impact of three major variables on public response:

- location of the collection site (proximity to users, travel time, etc.)
- frequency of publicity needed to stimulate participation
- effectiveness of specific roundups versus permanent collection sites

There are several ways to test the importance of these variables, and the program will be designed to complement past and current collection activities. The before, during, and after surveys will provide pertinent information regarding changes in public awareness and attitudes toward participation in these types of programs. The present value of a two-year targeted collection program has been estimated at $550,000. The amount of oil and grease removed per $1,000 invested has been estimated at about 80 kg.

Enhanced Catch Basin Cleaning

The recommended catch basin cleaning program is designed to begin with the existing program and significantly enhance its effectiveness, while simultaneously gathering data to be used in establishing modified ongoing programs in the future. The objective of the pilot study will be to evaluate and recommend changes to the existing program that can be expanded to the remainder of the City if successful.

Table 5-1

Areas Included in Recommended Catch Basin Cleaning Program

Basin Number	Watershed

City, and be comparable to other city tracking and routing programs, such as the City's sewer maintenance management program. This activity will result in immediate, measurable benefits for the City's targeted catch basin cleaning areas and will also provide a comparison of the "enhanced" versus existing cleaning efforts.

Furthermore, the computerized scheduling and routing program will increase the City's responsiveness and effectiveness in the overall stormwater management program. This computerized program will also enable inclusion of several technical factors such as pollutant loadings and water quality data into the management and scheduling activities.

Public Education Program

Based on the success of public information programs conducted in conjunction with the City's upgrading of wastewater treatment facilities, public education and awareness activities are necessary and vital components to the City of Los Angeles' Stormwater Management program. Specific public education and awareness activities will not be determined until the other pollutant reduction actions are officially decided upon. If the mix of projects detailed above are selected, a total of $500,000 is available for public education projects. This will allow the public education and awareness activities to be specifically tailored to support and enhance the other pilot project activities. For example, there will be "before" and "after" surveys conducted in association with the placement of strip filters, catch basin cleaning, and household hazardous waste collection activities. Once these activities

VOL 12

2 0685

are determined acceptable, the public education and awareness program will be finalized.

It is anticipated that the public education activities may include the actions listed below. These activities will be conducted in the same areas where the other runoff pollutant reduction activities are planned. They will complement the construction, clean up, and collection activities, including:

- before and after survey for awareness of runoff pollutant control measures
- public school campaign within the targeted implementation areas for runoff pollutant control measures
- business, civic, environmental, and industry campaign for the targeted implementation areas
- specific neighborhood or community event(s) to accompany the collection programs

RECOMMENDED RUNOFF POLLUTANT CONTROL PROJECTS

Table 5-2 provides a summary description of the pollution-control measures described above. This group of pollution-control measures was structured so that the total cost of the package amounts to approximately $3 million. Costs were calculated in terms of present worth of the equivalent annual cost of each pollutant-control measure. In general, the proposed programs would be implemented by departments within the Bureau of Sanitation and the Bureau of Engineering of the City of Los Angeles. The City, through its Stormwater Management Program, is also planning additional stormwater related projects.

Calculation of the removal effectiveness of each proposed measure was based on the actual amount of TSS and oil and grease loading in the drainage basins recommended for treatment and the total estimated amount of these pollutants in the study area. Efficiencies were assumed to be equal to those indicated in Section 4. For example, the annual amount of TSS load in the drainage basins recommended for catch basin cleaning can be calculated from the data on Table 3-17, and is equal to 3.3 million kg. The efficiency of implementing this measure has been assumed to be equal to 20 percent. The total annual estimated load of TSS discharged from the study area is about 8 million kg.

The estimated effectiveness in TSS removal for catch basin cleaning in the specified basins would be equal to:

$$\frac{3.3 \text{ million}}{8.0 \text{ million}} \times (0.2 \text{ TSS removal efficiency}) \times 100 = 8 \text{ percent}$$

A very valuable benefit that should be derived from the implementation of the proposed programs will be the collection of information that can be used for later development of permanent runoff pollution-control measures. The recommended packages, therefore, contain several individual measures that will be implemented on a pilot basis, instead of single-measure approaches that would be more effective for controlling pollution loads in the short term. An example of an effective single-

PSR159

measure approach is the cleaning of catch basins. This measure alone could cost more than $3 million per year if implemented on an areawide basis; however, the information obtained after the program is finished would be minimal. This approach, therefore, has not been included as one of the actions recommended for implementation.

Table 5-3 displays the effectiveness of the recommended control projects in removing pollutants from runoff into Santa Monica Bay. The total removal effectiveness for TSS of the group of measures recommended is 8 percent. Based on annual loading estimates of 8 million kg/year of TSS loading to Santa Monica Bay (see Section 3), the group of measures is estimated to remove 656,000 kg of TSS from runoff flows. This calculation presumes no benefit from strip filter pilot projects, which affect very small areas on an individual basis.

The estimate of oil and grease removal effectiveness of 4.5 percent results in a calculation of more than 16,000 kg O&G removed from runoff flows on an annual basis. Estimates of reduction in runoff pollutant loading of target constituents are also included on Table 5-3. For particulate-associated pollutants, removal estimates are based on TSS removal effectiveness of the recommended control projects and annual particulate loading of target constituents. For lipid soluble-associated pollutants, removal estimates are based on O&G removal effectiveness of the recommended control projects and annual total loading of target constituents.

Pollutant removal effectiveness of strip filters and public awareness programs will be determined as part of the conduct of the pilot projects themselves.

Table 5-3

Reductions in Annual Pollutant Loading to Santa Monica Bay from Recommended Control Projects

Proposed Control Measures	Cost ($)	Removal Effectiveness[a] TSS (%)	O&G (%)
Catch basin cleaning	1,830,000	8.2	3.9
Collect household hazardous waste materials	550,000	---	0.6
Public education program	500,000	---	---
Construction of stormwater filters	120,000	---	---
TOTAL	3,000,000	8.2	4.5

Constituents	Reduction In Annual Loading (Kg)
Total Suspended Solids	656,000
Oil and Grease	16,000
Particulate-associated Pollutants[b]	
Arsenic	35
Chromium	100
Copper	434
Lead	1,257
Nickel	19
Zinc	5,247
Mercury	2
Lipid Soluble-associated Pollutants[b]	
Herbicides	12
Pesticides	0.5
Pollutants Requiring Source Controls	
Cadmium	c
Silver	c

Source: Engineering-Science

[a] 1% TSS Removal = 80,000 kg; 8.2% Removal = 656,000 kg;
1% O&G Removal = 3,700 kg; 4.5% Removal = 16,000 kg

[b] see Section 3

[c] see Section 3; loading reductions for these constituents were not estimated

TSS = total suspended solids
O&G = oil and grease

ADDITIONAL ACTIVITIES

Director's Perspective

The past two years at SCCWRP have been eventful. Our Commission has expanded to nine members. It now includes, in addition to representatives from the City of Los Angeles, County Sanitation Districts of Los Angeles County, County Sanitation Districts of Orange County, and the City of San Diego, representatives from the U.S. Environmental Protection Agency Region IX, California State Water Resources Control Board, and the Los Angeles, Santa Ana, and San Diego Regional Water Quality Control Boards. This unique forum is bound by a common purpose — to better understand man's effects on the coastal marine environment.

We also have a new director. After 10 years on staff and one year as Assistant Director, I was given the opportunity to become Director. My goal is to continue the successful tradition that has made SCCWRP a leader in coastal marine environmental research since 1969. To do this, we will emphasize the elements that have made SCCWRP successful throughout its history: quality interdisciplinary research, regional scientific expertise, large-scale perspective, technical innovation, and effective communication.

There have been other changes in staffing as well. Old and new staff alike are rising to the challenge to make SCCWRP the premier problem-solving agency working on the fate and effects of anthropogenic wastes in the coastal marine environment off Southern California.

This report features the results of projects conducted over the past two years. These projects increase our understanding of the sources, fates, and effects of anthropogenic contaminants that find their way intentionally or unintentionally into the coastal marine environment. We continue to report on the biological changes in Santa Monica Bay following termination of sludge discharge. And we continue with our survey of contaminant inputs to the coastal ocean. One salient aspect of several reports is the attempt to distinguish between natural and anthropogenic perturbations.

This is an important time for SCCWRP. Approximately 15 million people live in Southern California and their impact on the shoreline and coastal marine environment has been profound. With each passing year, our research becomes more important to the well being of the coastal marine environment. As we head into our third decade, our mission, — to understand the effects of urban wastes on the marine environment — gives us purpose and direction.

Executive Summary

SOURCES

Characteristics of effluents from large municipal wastewater treatment facilities in 1990 and 1991.

We summarize the concentrations of effluent constituents and estimates of effluent mass emissions for Hyperion Wastewater Treatment Plant, Joint Water Pollution Control Plant (JWPCP, County Sanitation Districts of Los Angeles County), County Sanitation Districts of Orange County (CSDOC) Wastewater Treatment Plants 1 and 2, and Point Loma Sewage Treatment Plant for 1990 and 1991. The trends in the mass emission of contaminants to the Southern California Bight over the past two decades are also examined.

The volume of effluent discharged from the four municipal wastewater treatment facilities declined by 12% from 1989 to 1991, perhaps as a result of water conservation efforts during the recent drought. The amount of effluent receiving secondary treatment increased from 43% of combined emissions in 1989 to 47% in 1991, while the concentrations of most effluent constituents declined. The combined emissions of suspended solids declined 5%, BOD declined 14%, and oil and grease declined 15%. The combined emissions of lead, cadmium, chromium, and mercury declined by more than 50%. Effluent concentrations of DDT and PCB were below method detection limits in 1991. Declines in constituent concentrations and mass emissions were the result of improved source control, improved primary treatment, and increased secondary treatment.

The combined flow from the four largest facilities increased 27% from 1971 to 1990 as a result of population increases. During that time, the volume of wastewater discharged by CSDOC and Point Loma doubled while the volume discharged by JWPCP and Hyperion increased only slightly. Population growth patterns, water reclamation, and inland discharge accounted for differences among the districts. Despite increases in the volume of wastewater discharged, the mass emissions of most effluent constituents have declined. The combined annual mass emission of suspended solids decreased 73%, BOD decreased 51%, and oil and grease decreased 69%. The combined mass emission of trace metals declined 94% and the combined emissions of chlorinated hydrocarbons declined more than 99% from 1971 to 1991.

Surface Runoff to the Southern California Bight

The concentrations of selected constituents were measured in dry and wet weather samples collected from the eight largest channels in Southern California between 1986 and 1988. We present estimates of the annual load of contaminants delivered to the ocean for the Santa Clara, Los Angeles, San Gabriel, Santa Ana, San Diego, and Tijuana rivers, and Calleguas and Ballona creeks. Most of the flows resulted from winter rains and discharge varied from year to year. The Santa Clara and Santa Ana rivers had no measurable flow during most of the study.

The eight channels sampled contributed about 80% of the total gauged runoff to the Southern California Bight. Annual discharges were, on average, 61% below their long-term means during 1986-87 and 31% below their long-term means in 1987-88. River discharge was a combination of surface and groundwater runoff, releases from control facilities, and inputs of domestic and industrial wastes.

The concentrations of trace metals and chlorinated hydrocarbons were generally correlated with suspended sediment and, to a lesser extent, with river discharge. The Tijuana River had the highest concentrations for most of the constituents measured. The Santa Clara River, a predominantly agricultural watershed, had the highest concentration of total DDT. The San Diego River, which drains a less developed basin, had the lowest concentrations for most of the constituents measured.

The Los Angeles, San Gabriel, and Tijuana rivers had the highest mass emissions, and the Santa Clara and San Diego rivers had the lowest. The mass emission of suspended sediment, trace metals, and chlorinated hydrocarbons increased from 1986-87 to 1987-88 in proportion to the increase in volume discharged. Most river discharge and contaminant transport in Southern California took place during winter storms that occur intermittently and unpredictably.

Hazardous Spills in the Southern California Bight

The existing data on hazardous material spills in the Southern California Bight were collected and are summarized in this report. The data were obtained from the U.S. Coast Guard's Pollution Response Branch in Washington, D.C. From 1985 through 1989, 327,115 L of hazardous materials were spilled in 1,102 separate incidents. The amount of hazardous material spilled varied by about an order of magnitude from year to year.

The majority of spills involved petroleum products, primarily diesel, fuel oil, jet fuel, and kerosene. The volume of individual spills was generally small; the median spill was 15 L for facilities and 19 L for vessels.

Spills from facilities accounted for 40% of the total number of spills and 60% of the total volume of material spilled. Most of the facility spills originated on land; a smaller proportion originated at offshore oil platforms and pipelines.

Spills from vessels accounted for 60% of the total number of spills and 40% of the total volume of material spilled. Most of the vessel spills originated with recreational boats, freighters, and tankers, although the largest volume of spills came from the U.S. Navy and towboats.

About 80% of the vessel spills and 50% of the facility spills occurred in harbors and bays. Los Angeles and Long Beach harbors were the site of more facility and vessel spills than any other waterbody.

Estimates of Ocean Disposal Inputs to the Southern California Bight

Currently, only approved dredged materials can be dumped at ocean disposal sites off Los Angeles (LA-2), Newport Beach (LA-3), and San Diego (LA-5). We estimated the total mass of dredge material and contaminants dumped at these sites between 1984 and 1991. The data were obtained from dredge permit files of the U.S. Army Corps of Engineers, U.S. Environmental Protection Agency Region IX, and local port authorities.

Fifty-three projects disposed nearly 6,000,000 yd^3 of dredge materials in the bight between 1984 and 1991. The total annual volume of dredge materials dumped ranged from 72,000 to 2,354,000 yd^3; more than 80% of the material was dumped at LA-5 and LA-3. Most of the projects dumped small quantities of materials. The smallest projects dredged sand from private docks and marinas. Six projects accounted for 58% of all dredge materials dumped. The largest project was the deepening of Newport Harbor Back Bay completed in 1987. It contributed 70% of the material dumped at LA-3 and 22% of the volume dumped at all sites during the study.

Chemistry data were reported for 37 dredge projects that represented about 90% of the total volume dumped in the bight during the study. Dredge materials from the large industrialized harbors had the highest concentrations and largest concentration ranges. The annual mass input of most constituents to the bight was correlated with the annual mass input of solids.

Total Organic Carbon and Total Nitrogen in Marine Sediments, Sediment Trap Particles, Municipal Effluents, and Surface Runoff

We report on a method adopted in our laboratory for the analysis of total organic carbon (TOC) and total nitrogen (TN) in marine sediments, effluent particles, and similar matrices. Effluents were collected from the Joint Water Pollution Control Plant (JWPCP, County Sanitation Districts of Los Angeles County), the County Sanitation Districts of Orange County Wastewater Treatment Plant (CSDOC), and the City of San Diego Point Loma

VOL 12

2 0705

Treatment Plant (PLTP). Sediment trap particles were collected near each of their ocean outfalls. Surface sediments were collected near the CSDOC and PLTP outfalls.

There were no significant differences in concentrations of TOC (25-40%) and TN (2.5-6.0%) among effluent samples from the wastewater treatment plants. The C/N ratios of effluent particles (7.1-8.4) were comparable to C/N ratios of effluents from other treatment plants. The concentrations of organic carbon and nitrogen on effluent particles have not changed in nearly two decades, while the concentrations of suspended solids have declined 60-70% since 1978.

The organic content of sediment trap particles was about 5-10% of the organic content of effluent particles from the corresponding sites. The C/N ratios of sediment trap particles (9.1-10.3) were higher than the C/N ratios of effluent particles. The lower TOC and TN concentrations, and higher C/N ratios, of sediment trap material suggest that effluent particles undergo rapid biodegradation, and perhaps dilution with plankton and terrestrial particles, upon discharge to the marine environment.

The organic content of surface sediments off Orange County and Point Loma was 1-2% of the organic content of effluent particles from the same site. The organic content of sediments at both sites was at or below levels of TOC and TN in surface sediments at the 60-m Reference Survey stations. However, the TOC and TN concentrations in surficial sediments were generally higher at stations close to the outfall and lower at stations farther away.

Sediment Model Verification

We examined the ability of two models (DECAL and SED2D) to simulate the characteristics of sediments around ocean outfalls off Point Loma (City of San Diego), Huntington Beach (County Santitation Districts of Orange County), and the Palos Verdes Peninsula (County Santitation Districts of Los Angeles County). The study investigated the sensitivity of model predictions to the input data and the consistency of the predictions. It also provided site specific predictions based on the consequences of particle aggregation.

Both models predicted areas of high sedimentation rates near the ocean outfalls; these zones were surrounded by areas of lower rates of sedimentation. There were, however, substantial uncertainties in the predictions of the fates of wastewater particles. Interestingly, the models also predicted an increase in the sedimentation of natural particles as a result of particulate-free discharges.

Uncertainties in the predictions came from questions about the aggregation of particles in the water column, the lack of data on vertical mixing within the wastefield, a poor understanding of sediment resuspension processes, and the lack of estimates of the decay rate of organic material in the water column and sediments. Until these uncertainties are addressed, it will be difficult to assess the validity of the predictions of the two models and the process representations contained within them. However, the models provide qualitative insight into the dynamics of the interaction of a wastefield and natural waters, and the localized effects on sedimentation from the discharge of wastewater effluents.

Potential Extension of the Point Loma Outfall

The application of body contact standards for bacterial concentrations to kelp beds in 1983 doubled the depth of the protected waters off Point Loma, and decreased the distance between the outer boundary of the protected area and the outfall diffuser. These changes substantially reduced the isolation of the wastefield from areas where body contact standards must be met and resulted in violations of the standard. An extension of the existing outfall into deeper water offshore is one way to meet bacterial standards in the kelp bed.

We examined the characteristics of water column density stratification and the properties of currents with current meter and thermistor data collected by Engineering Science, Inc. between March and September 1990 near the Point Loma outfall. The results were incorporated into time-dependent models of initial dilution and transport of wastewater by ocean currents.

In simulations based only on density stratification of the water column, potential intrusions of the wastefield into the kelp beds were predicted for 18-38% of the time for an outfall in 83 m, and for 4-12% of the time for an outfall in 95 m. When ocean currents were added to the model, wastewater intrusions into the kelp bed peaked at 15% of the time 1-2 km upcoast from an outfall in 83 m of

VOL 12

2 0 7 0 5

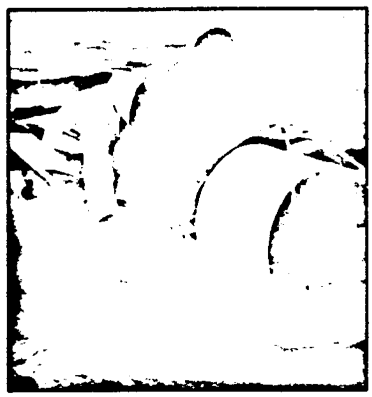
water; actual intrusions were predicted for about 40% of potential intrusions. Wastewater intrusions peaked at 7.5% of the time 4 km upcoast from an outfall in 95 m of water; actual intrusions were predicted for about 60% of potential intrusions. The increased upcoast displacement for the deeper discharge is the result of increased wastefield transport time from the diffuser to the kelp bed.

Response of Dover Sole to Termination of Sludge Discharge in Santa Monica Bay

We examined the response of Dover sole, a common deepwater flatfish, to the termination of sludge discharge by the Hyperion municipal wastewater treatment plant. The discharge of solid waste into the outer part of Santa Monica Bay ceased in November 1987 and resulted in changes in the biology of the macrofauna near the 7-mile sludge outfall.

Dover sole were most abundant in the contaminated zone near the outfall, and declined in abundance with increasing distance from the sludge outfall. The incidence of epidermal tumors and fin erosion decreased with distance from the outfall. There was little or no disease among fish collected in the reference area. The abundance of Dover sole and the incidence of disease in the contaminated zone declined after the termination of sludge discharge.

The decrease in Dover sole abundance and disease incidence after termination of solid waste discharge indicates that benthic conditions were improving near the outfall. The decline in abundance is probably related to the decreased organic content and prey abundance in the sediments. The organic content of surface sediment was significantly higher near the outfall and declined after termination of waste discharge. Sediments with high organic content support large populations of deposit feeders such as polychaetes, which are the primary prey items of Dover sole.



Temporal and Spatial Changes in Sediment Toxicity in Santa Monica Bay

We describe the temporal changes in sediment toxicity in the outer part of Santa Monica Bay following termination of sludge discharge by Hyperion wastewater treatment plant in 1987. The toxicity of sediments was tested in the laboratory with the amphipod, *Grandidierella japonica*.

The laboratory tests indicated that the toxicity of sediments in the sludge field decreased during a period of marked changes in animal species composition and abundance in the field. This suggests that the laboratory toxicity tests included the relevant sediment qualities that were important to organisms living in Santa Monica Bay.

Changes in the concentration of hydrogen sulfide, total organic carbon, and total nitrogen were related to the changes in toxicity. Low molecular weight petroleum aromatic hydrocarbons may have also played a role in the reductions in toxicity of sediments collected close to the 7-mile outfall.

By 1989, sediment quality at 100 m in the contaminated zones was similar to sediment quality in the reference zone. However, assemblages of benthic macrofauna in the contaminated zones were still adversely affected in 1990. Sediment toxicity tests with *G. japonica* were a less sensitive indicator of sediment quality in Santa Monica Bay than the composition of the benthic macrofauna in the field.

Long-Term Trends in Trawl-Caught Fishes Off Point Loma, San Diego

Information on long-term trends in demersal fish populations on the mainland shelf off Southern California is uncommon. This study examined temporal and spatial changes in trawl-caught fishes at six stations along the 60 m isobath off Point Loma from 1982 to 1991. Nearly 27,000 individuals from 57 species (28 families) were collected during a decade of semi-annual trawling.

The composition and abundance of trawl-caught fishes were similar among the six stations, although catches were lowest at the control station. Plainfin midshipman, longspine combfish, yellowchin sculpin, California tonguefish, and longfin sanddab occurred in over 90% of the trawls and accounted for 55% of the individuals collected. The 10 most abundant species accounted for 83% of the fish captured.

There were seasonal and long-term differences in trawl catches that were correlated with water temperature. Longfin sanddab, California lizardfish, and hornyhead turbot were more abundant in the winter, while Dover sole, Pacific sanddab, and rockfish were more abundant in the summer. The number of species, individuals, and biomass declined following the 1982-83 El Niño. In general, more species of fish were collected when bottom water temperatures were lower.

The similarity of trawl fish abundance and composition among the six stations, and the similarity in abundance and composition between this study and the 1990 Reference Survey, suggest that the effects of wastewater discharge on the structure of the fish assemblage off Point Loma are minimal.

1990 Reference Survey

We recently completed the third survey of chemical and biological conditions in reference areas on the mainland shelf off Southern California in the last 15 years. Seven stations along the 30, 60, and 150 m isobaths were sampled in summer 1990. We report estimates of sediment characteristics, contaminant concentrations, and biological conditions from the least impacted areas on the mainland shelf.

Shelf sediments were predominantly sandy silt. The sand content decreased, and the clay and organic content increased, with increasing water depth. Trace metal concentrations were low at all stations and were similar among depths. Sediment concentrations of DDT, PCB, and polynuclear aromatic hydrocarbons were higher at the northern stations.

The macrobenthic (>1 mm) organisms collected in grab samples were variations of the *Amphiodia urtica-Spiophanes missionensis* assemblage that inhabits the Southern California mainland shelf. Amphipods (*Amphideutopus oculatus* and *Ampelisca brevisimulata*) dominated the samples from 30 m. The brittlestar, *Amphiodia urtica*, and the polychaete, *Myriochele* sp. M., dominated samples collected at 60 m. The 150 m stations were dominated by polychaetes (*Spiophanes fimbriata* and *Myriochele* sp. M) and *Amphiodia urtica*.

Trawl catches of large, motile invertebrates (megabenthos) and fish increased with increasing depth. The asteroid, *Astropecten verrilli*, dominated collections at 30 m. The sea urchin, *Lytechinus pictus*, and the prawn, *Sicyonia ingentis* dominated collections at 60 m. The sea urchins, *Allocentrotus fragilis* and *Lytechinus pictus*, dominated the 150 m stations. Fish catches at 30 m were dominated by speckled sanddab and longfin sanddab. Pacific sanddab and longfin sanddab dominated trawl catches at the 60 m stations. Slender sole and plainfin midshipman dominated trawl catches at the 150 m stations.

The assemblages of macrobenthos, megabenthos, and demersal fishes collected in 1990 were similar to the assemblages collected in the 1977 and 1985 reference surveys.

Toxicity of Dry Weather Flow in Ballona Creek

Ballona Creek is one of the few flood control channels that flows throughout the year into Santa Monica Bay. During dry weather, it receives discharges from a variety of sources including groundwater pumping and decontamination, swimming pool drainage, and dehumidifier condensate. We determined the toxicity of dry weather flow in Ballona Creek to purple sea urchin gametes (fertilization) and embryos (development) and examined the variability in toxicity over different time scales.

Dilutions of Ballona Creek samples collected in winter 1990 and winter 1991 were toxic to sea urchin sperm and embryos, although the fertilization test was more strongly affected than the development test. There was little variability in toxicity among samples collected on the same day, but the 1991 samples were slightly more toxic than the 1990 samples. Most of the receiving water samples collected at the mouth of Ballona Creek were also toxic to sea urchin sperm.

Elevated pH was responsible for much of the toxicity, although other constituents could not be ruled out. The spatial pattern of toxicity suggested that there were upstream (dry weather flow) and downstream (Santa Monica Bay) sources. Sources contributing to the toxicity of the receiving water may be contamination from Marina del Rey or the release of toxicants from Ballona Creek sediments. ■

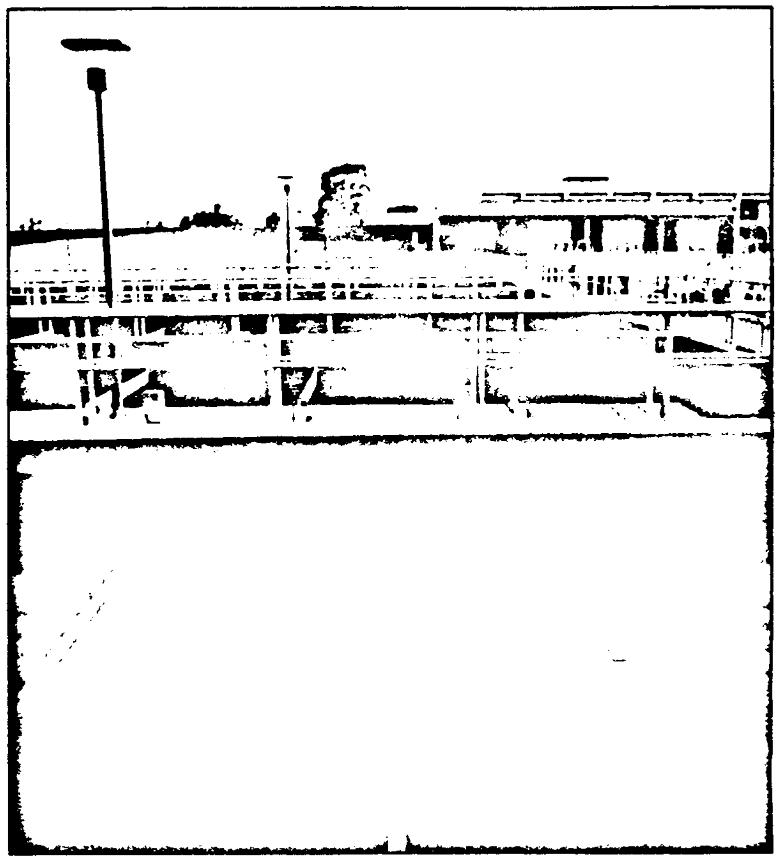
Characteristics of Effluents from Large Municipal Wastewater Treatment Facilities in 1990 and 1991

In this report, we summarize concentrations of effluent constituents and estimates of effluent mass emissions for Hyperion Wastewater Treatment Plant (City of Los Angeles), Joint Water Pollution Control Plant (JWPCP, County Sanitation Districts of Los Angeles County), County Sanitation Districts of Orange County Wastewater (CSDOC) Treatment Plants 1 and 2, and Point Loma Sewage Treatment Plant (City of San Diego) for 1990 and 1991 (Figure 1). Effluents from these facilities composed 90% of municipal effluents discharged directly to the Southern California Bight.

The discharge agencies have measured the constituents featured in this report for at least two decades. Long-term trends in the mass emission of contaminants to the Southern California Bight (SCB) are also discussed.



County Sanitation Districts of Orange County Plant No.1

Materials and Methods

We obtained the effluent data that are reported monthly and annually by each discharge agency under National Pollution Discharge Elimination System permits from the Los Angeles, Santa Ana, and San Diego Regional Water Quality Control Boards.

Annual contaminant mass emissions were estimated from the product of mean daily flow in month *i*, constituent concentration in month *i*, and the number of days in the month; these were summed over all months to obtain the annual estimate (Appendix 1). This method differs from that used in previous SCCWRP reports where we estimated mass emissions by the product of total annual flow and mean annual constituent concentration (e.g., SCCWRP 1990). Estimates by the two methods differed by <1% (Appendix 1), so the historic mass emission data have not been recalculated. Constituent concentrations below detection limits were treated as zeros in both estimation methods.

VOL 12

2070

Results

The combined daily volume of effluent discharged from the four largest municipal wastewater treatment facilities in Southern California declined by 12% from 1989 to 1991 (Table 1; Figure 2); declines at individual treatment facilities ranged from 10-14%. Most of the declines occurred from 1990 to 1991. The amount of effluent receiving secondary treatment increased from 43% of the combined emissions in 1989 to 47% in 1991 (Table 1). The greatest increase occurred at Hyperion where 48% of the flow received secondary treatment in 1989 and 58% received secondary treatment in 1991.

The concentrations of effluent constituents generally varied by about a factor of two among the four municipal wastewater treatment plants; a few constituents, such as selenium, varied by an order of magnitude (Tables 2a,b).

The differences among the effluents are due to the type of wastes (domestic and industrial), source control, volume of water removed for reclamation and inland discharge, and efficiency and degree of treatment (advanced primary or secondary).

The concentrations of some constituents varied substantially among months at individual treatment plants (Tables 2a,b). Nearly one-quarter of the mean monthly constituent concentrations had coefficients of variation greater than 50%. Coefficients of variation higher than 100% generally were due to a high

proportion of monthly contaminant concentrations below detection limits.

Effluent mass emissions from the four dischargers were generally related to flow (Tables 3a,b); the average rank correlation (r_s) among constituent mass emissions for the four treatment plants was 0.62 in 1990 and 0.44 in 1991. The JWPCP had the highest flow and generally the highest constituent mass emissions. It was followed by Hyperion, County Sanitation Districts of Orange County, and Point Loma.

From 1989 to 1991, the combined emissions of suspended

solids declined 5%, BOD declined 14%, and oil and grease declined 15% (Table 4). The discharge of suspended solids decreased 15% at Hyperion and CSDOC, and 8% at JWPCP, but it increased 22% at Point Loma. The discharge of BOD decreased 21% at Hyperion, 19% at JWPCP, and 14% at CSDOC, but it increased 7% at Point Loma. The discharge of oil and grease decreased by 33% at Hyperion, 10% at Point Loma, 6% at CSDOC, and 5% at JWPCP. [Data for 1989 are from SCCWRP (1990).]

From 1989 to 1991, their were substantial declines in the combined emissions of several trace metals (Table 4). The combined emissions of lead declined 95%, cadmium declined 79%, chromium declined 55%, and mercury declined 50%. The combined emissions of nickel declined 39%, copper declined 31%, and silver and arsenic declined 27%. The combined emissions of zinc declined 14% and selenium declined 11%. [Data for 1989 are from SCCWRP (1990).]

Effluent concentrations of DDT and PCB were below

method detection limits in 1991. Based on detectable concentrations, the estimated mass emission of DDT declined 40% from 1989 to 1990.

Discussion

The annual combined volume of effluent discharged has declined only five times since 1971 (Table 4). The lower volumes discharged in 1990 and 1991 may be the result of water conservation efforts during the drought. The concentrations of most effluent constituents declined from 1989 to 1991. The greatest change was in lead — effluent concentrations declined 92% at Hyperion and 86% at CSDOC.

Declines in constituent concentrations and mass emissions are the result of improved primary treatment, increased secondary treatment, and improved source control (the most important factor). As a consequence, the number of reported analyses with masses below detection limits (BDL) continues to increase. Some contaminant measurements are consistently below detection limits. If detection limits of the recommended techniques are

below discharge permit requirements, then BDL results are in compliance. However, BDL results complicate mass emissions estimates. We reported detection limits in the table of concentrations (Tables 2a,b) and treated BDL results as zeros for the estimates of mass emissions (Tables 3a,b).

The combined flow from the four largest facilities increased 27% between 1971 and 1990 as a result of population increases (Figure 2). This is a mean annual increase of 1.3% (sd=2.5, n=19). During this time, the volume of wastewater discharged by CSDOC and Point Loma doubled while the volume discharged by

[a]mgd=million gallons per day; 1 mgd=3,785,000 L/day
[b]solids for Hyperion 7-mile outfall are total solids
[c]mt=metric tons
[d]City of San Diego measures only soluble PO_4P

JWPCP and Hyperion increased only slightly (Figure 2). Population growth patterns, water reclamation, and inland discharge account for differences among the districts. Orange and San Diego counties have grown faster than Los Angeles County. Los Angeles County and the City of Los Angeles expanded their upstream treatment and reclamation facilities. The County reclaimed 155 mgd of water in 1990 — double the amount reclaimed 10 years ago. The volume of effluent discharged to the Los Angeles River by the Los Angeles-Glendale and Donald C. Tillman water reclamation plants

increased from 25 mgd in 1985 to 55 mgd in 1990.

Despite increases in population and the volume of wastewater discharged over the past two decades, the mass emissions of most effluent constituents have declined (Table 4). The combined annual mass emission of suspended solids has decreased 73%, BOD has decreased 51%, and oil and grease has decreased 69% (Figures 3, 4, and 5). The decline in JWPCP solids emissions between 1971 and 1989 accounts for 65% of the reduction. Termination of sludge discharge from the Hyperion 7-mile outfall (October 1987) accounts for a 40% reduction in combined emissions from 1987 to 1988. Most of the decline in BOD occurred after 1985. Reductions by JWPCP account for about 75% of the decline in oil and grease.

The combined mass emission of trace metals declined 94% from 1971 to 1991 (Table 4; Figure 6). Declines of individual metals averaged 84% (sd=19%, n=10). The greatest reductions were for chromium (99%), cadmium (99%), lead (99%), zinc (93%), mercury (93%), copper (91%), nickel (90%), and selenium (43%). From 1972 to 1990, arsenic declined 70% and silver declined 64%. The combined mass emissions of trace metals declined 36% from 1987 to 1988; termination of sludge discharge from the Hyperion 7-mile outfall accounted for about 60% of this decline.

The combined emissions of chlorinated hydrocarbons declined more than 99% from 1971 to 1990 (Table 4; Figure 7). Montrose Chemical Corporation, the largest manufacturer of DDT in the world and the only manufacturer in California, discharged DDT wastes into the Los Angeles County sewer system from 1947 to 1971. Residual waste in the sanitation system was the principal source of DDT in JWPCP effluent after that time. Concentrations of DDT in JWPCP effluent are now below detection limits (tens of pg/l).

The interpretation of long-term trends is hindered somewhat by the reliability of trace contaminant analyses, especially trace organic analyses, in early monitoring programs. Analytical methods for quantifying chlorinated hydrocarbons evolved during the 1970s and techniques were not standardized among laboratories. The older data reported herein are the best available for past discharges, but the old methods are unacceptable today. The accuracy and precision of contaminant analyses have improved over the years because of advancements in methods and instruments, and because of intercalibration among laboratories.

Conclusions

The quality of municipal wastewaters discharged to the Southern California Bight today is significantly better than the quality of wastewaters discharged in 1971. Decreases in contaminant mass emissions are due to increased source control and land disposal of sludge, improved sludge and primary treatment, and increased secondary treatment. Further reductions in mass emissions on a comparable scale are not possible. Nominal reductions

will occur due to planned increases in the volume of wastewater receiving secondary treatment, increased inland reclamation of water, and more effective source control ■

Literature Cited

Appendix 1.

Annual mass emissions (ME) of contaminants were estimated from:

$$ME=\sum_{i=1}^{12}(F_i C_i D_i) \qquad (1)$$

where:
F_i = mean daily flow in month *i*;
C_i = constituent concentration in month *i*; and
D_i = number of days in month *i*.

Historically, mass emissions were estimated from:

$$ME=\sum F_i C_m \qquad (2)$$

where:
$\sum F_i$ = total annual flow, and
C_m = mean monthly constituent concentration.

We estimated mass emissions for 1990 and 1991 by both methods. Estimates by (2) were similar to estimates by (1); the mean difference in 1990 was -0.09% (sd=1.55, n=71, min=0%, max=-10.5%) and the median difference was 0.08%. The maximum difference occurred for estimates of nickel emissions from Point Loma. Without this datum, the mean difference was 0.06% (sd=0.61, n=70, min=0%, max=-3.0%) and the median difference was 0.10%.

Method (2) was slightly, but significantly, positively biased. Nearly 70% of the 1990 estimates were higher by (2) than by (1), more than would be expected by chance alone (normal approximation to binomial test, Z=3.04, 0.002<p<0.005). Estimates by (1) were more accurate, and therefore less biased, than (2). Method (1) also allowed us to examine monthly variability in constituent concentrations (Tables 2a,b).

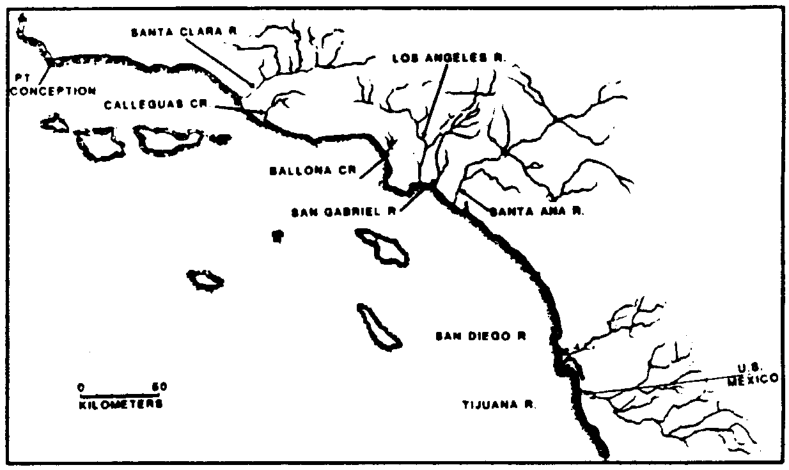
Surface Runoff to the Southern California Bight

Twenty creeks and rivers drain the coastal mountains, valleys and plains between Point Conception and the U.S./Mexican border and discharge into the Southern California Bight (SCB). A large portion of this discharge is urban runoff. Although a significant amount of data have been collected on contaminant concentrations in surface runoff, there are few published estimates of the mass of contaminants delivered to the ocean (e.g., SCCWRP 1973, Eganhouse and Kaplan 1982, SCAG 1988).

The objective of this study was to measure the concentration of selected constituents in runoff samples from the largest channels in Southern California and to estimate the mass carried to the ocean. We collected samples from eight channels during storms and low flows, and estimated the annual load of contaminants delivered to the ocean.

Figure 1.
Runoff samples were collected from the eight largest rivers and creeks that discharge to the ocean off Southern California.



Materials and Methods

Sampling Method and Locations.
Samples were collected between September 1986 and April 1988 with a sampling device patterned after the U.S. Geological Survey suspended sediment pint sampler that has been in use in Southern California for two decades (Young and Bodeen 1991). About 10 samples were collected during each storm and were distributed over rising and declining flows. Samples were collected in the middle of each channel at the same location throughout the study. The sampling device and sampling method are described in SCCWRP (1990). The sampling locations were (Figure 1):

- *Santa Clara River:* Highway 101 8 km from the ocean.
- *Calleguas Creek:* above the tidal prism at Highway 1.
- *Ballona Creek:* Inglewood Boulevard 4 km from the ocean.
- *Los Angeles River:* above the tidal prism at the Willow Street bridge in Long Beach.
- *San Gabriel River:* College Park Drive bridge 4 km above the tidal prism and below confluence of the San Gabriel River and Coyote Creek.
- *Santa Ana River:* Hamilton Street on the border between Huntington Beach and Costa Mesa.
- *San Diego River:* 4 km above the tidal prism east of Fashion Valley Road in San Diego.
- *Tijuana River:* 6 km above the ocean at Dairy Mart Road.

Analytical Methods.
The samples were analyzed for suspended solids, selected trace metals, and selected trace organics. Sampling handling and analytical methods are described in SCCWRP (1990).

Load estimates.
The load of a particular constituent in a river is the total mass of the constituent passing the point of measurement over some period of time. We estimated the load of selected constituents transported by the eight rivers with a flow-weighted ratio estimator. Where sufficient contaminant data existed, we stratified the estimates into low and high flows. The inflexion point on the flow duration curve was the cutoff between low and high flow days (SCCWRP, unpublished data). Contaminant data from the two

years were pooled to increase sample sizes.

The flow-weighted ratio estimator is based on the relation between flows and loads:

$$L = QT\frac{\sum_{i=1}^{n} c_i q_i}{\sum_{i=1}^{n} q_i}$$

where L is the load of the constituent, Q is the mean period flow, T is the total time in the period, c_i is the ith concentration, and q_i is the corresponding flow rate. The method assumes that flows are continuously monitored, mean flow can be determined accurately, concentrations are related to flows, and the underlying distributions are approximately normal. The estimation method and its assumptions and shortcomings are described in more detail in SCCWRP (1990).

River flow data were obtained from the U.S. Geological Survey, the Ventura and Los Angeles County Departments of Public Works, and the International Boundary Water Commission. Flow data are reported by water year (October 1 to the following September 30). We modified the

water year to run from September 1 to August 31 because the first storm of the study occurred in September 1986 after five months of no precipitation.

Results

Santa Clara River

The Santa Clara River is 155 km long, drains an area of 4,219 km^2, and empties into the ocean south of Ventura. The drainage basin is moderately developed with large reservoirs, extensive levees, and agricultural diversions along the coastal plain. In the last 50 km, the river flows over a permeable, sandy, alluvial plain and flow rarely reaches the ocean except during storms. Annual rainfall ranges from 35 cm at the mouth of the river to 90 cm in the mountains (Brownlie and Taylor 1981).

Discharge from the Santa Clara River during the 1987 water year (0.9×10^6 m^3) was 0.2% of the total gauged runoff to the SCB; discharge during the 1988 water year (28.4×10^6 m^3) was 4.2% of the total discharge to the SCB. Discharge during the 2-year study was <1% and 19% of the long-term annual mean (1950-88: 146.2×10^6 m^3). The flow gauge on the lower river registered flow on only 18 days in 1987 and 22 days in 1988. Runoff from one storm in February 1988 was 72% of the gauged flow for that year. Most of the discharge from the river occurred from January through March.

Eleven runoff samples were collected from storms that occurred in September 1986 and January 1987. The flow increase during the September 1986 storm was small and not recorded by the flow gauge. Discharge during the January 1987 storm (3.6×10^6 m^3) was 13% of the annual discharge. One non-storm sample was collected in October 1986. Eleven samples were analyzed for suspended solids and chlorinated hydrocarbons and 10 samples were analyzed for trace metals (Table 1). Most constituents were correlated with flow and suspended solids (Table 2). The volume of discharge from the Santa Clara River increased by nearly 3200% from the first study year to the second. Estimates of constituent mass emissions increased by a similar amount (Tables 3a,b).

Calleguas Creek.

Calleguas Creek drains 837 km^2, including the rapidly growing Simi Valley, Thousand Oaks, and Camarillo, and empties into the ocean through Mugu Lagoon. The channel is moderately developed due to levees, agriculture, and urban and suburban development. Five municipal wastewater treatment plants discharged 87,000 m^3/day (23 mgd) into the creek during the study.

Discharge from Calleguas Creek during the 1987 water year (21.7×10^6 m^3) and the 1988 water year (31.3×10^6 m^3) was 5% of the total gauged runoff to the SCB. Discharge during the 2-year study was 59% and 93% of the long-term annual mean (1969-89: 35.2×10^6 m^3). High flows (>0.8 m^3/s) occurred 12% of the days during 1987 and 17% of the days during 1988, and accounted for 29% and 51% of the the annual discharge. Most of the discharge from Calleguas Creek occurred from December through March.

Nine runoff samples were collected from Calleguas Creek

.492**	.408**							.611**	.407*

during storms in September 1986 and January 1987. These storms accounted for 1.4% of the discharge volume in 1986-87 and 1.8% of the discharge volume in 1987-88. One non-storm sample was taken in October 1986. Ten runoff samples were analyzed for suspended solids and chlorinated hydrocarbons, and nine samples were analyzed for trace metals (Table 1). The concentrations of most constituents were correlated with suspended solids, but not with flow (Table 2). The total volume discharged from Calleguas Creek increased 44% from 1987 to 1988 and so did the mass emission estimates (Tables 3a,b).

Ballona Creek.
Ballona Creek drains 232 km^2 of urbanized, predominantly residential, Los Angeles. The creek originates northeast of Baldwin Hills and empties into the ocean through Ballona Wetlands. The creek was once the outlet of the Los Angeles River. The channel is extensively developed as a result of urbanization and concrete channelization.

Discharge from Ballona Creek during the 1987 water year (21.8 x 10^6 m^3) was 4% of the total guaged runoff to the SCB; discharge during the 1988 water year (51.5 x 10^6 m^3) was 8% of the total guaged runoff to the SCB. Ballona Creek contributed 58% of the total runoff to Santa Monica Bay in 1987 and 71% in 1988. Discharge during the 2-year study was 48% and 133% of the long-term annual mean (1928-89: 38.7 x 10^6 m^3). High flows (>0.06 m^3/s) occurred 5% of the days during 1987 and 11% of the days during 1988, and accounted for 54% and 82% of the annual discharge. Most of the discharge from the creek occurred from November through March.

Fifteen runoff samples were collected from Ballona Creek during storms in September 1986, January 1987, and March 1987. Discharge during the storms averaged 2.4 x 10^6 m^3 (range: 0.7-4.5 x 10^6 m^3). The three storms accounted for 3.4%, 9.1%, and 20.5% of the total annual discharge volume. Two non-storm samples were collected in October 1986 and September 1987. Seventeen samples were analyzed for suspended solids, 16 samples were analyzed for trace metals, and 15 samples were analyzed for chlorinated hydrocarbons (Table 1). The concentrations of most constituents were correlated with suspended solids, but not with flow (Table 2). Flow-weighted mean concentrations at high flow were two to seven times greater than flow-weighted mean concentrations at low flow (Table 1).

High flow discharge accounted

for 70-97% of the estimated annual constituent loads (Tables 3a,b). Total runoff volume increased 137% from 1987 to 1988 and high flow runoff volume increased 259%. Mass emissions estimates increased 100% to 300%. Low flow volume and estimates of the constituent mass emissions were similar in both years.

Los Angeles River.
The Los Angeles River is the largest single source of gauged runoff to the SCB. It originates in the Santa Susana and Santa Monica mountains in the western part of the San Fernando Valley and also receives runoff from the western San Gabriel Mountains and the Santa Monica Mountains. The river enters the ocean in San Pedro Bay, but historically it has changed course several times and entered the ocean as far north as Ballona Creek and as far south as the San Gabriel River (Brownlie and Taylor 1981).

The Los Angeles River drains 2,155 km^2 and, for its size, is one of the most extensively controlled rivers in the world. All of the river has been channelized below the upland catchments (Brownlie and Taylor 1981). In 1982, nearly 60% of the river basin was urban and suburban, 40% was native vegetation, and 1% was agriculture (Department of Water Resources 1982).

Discharge from the Los Angeles River during the 1987 (156.4 x 10^6 m^3) and 1988 (217.3 x 10^6 m^3) water years was 33% of the total gauged runoff to the SCB. Discharge during the 2-year study was 83% and 115% of the long-term annual mean (1929-88: 189 x 10^6 m^3). High flows (>5 m^3/s) occurred 8% of the days during 1987 and 9% of the days during 1988, and accounted for 39% and 57% of the annual discharge.Most of the discharge occurred from November through March.

Fifty-three runoff samples were collected from the Los Angeles River during six storms that occurred in September 1986, January 1987, March 1987, October 1987, December 1987, and January 1988. Mean discharge during the storms was 12.9 x 10^6 m^3 (range: 2.9-21.3 x 10^6 m^3) was 6-8% of the annual discharge. One non-storm sample was collected in October 1986. Fifty-four samples were analyzed for suspended solids, trace metals, and chlorinated hydrocarbons (Table 1). The concentrations of all constituents except cadmium were correlated with flow and suspended solids (Table 2). Concentrations at high flow were three to 17 times greater than concentrations at low flow for all constituents except cadmium (Table 1).

Table 3b.

Mouth of the Los Angeles River in Queensway Bay, Long Beach

Except for cadmium, 66-95% of the estimated annual constituent loads was discharged during high flow days (Tables 3a,b). One third to one half of the estimated annual load of cadmium went out during high flow days. Total high flow volume increased 104% from 1987 to 1988. Consequently, the mass of solids and contaminants discharged during high flow days more than doubled (Tables 3a,b). Low flow volume and constituent mass emission estimates were similar in both years.

The Los Angeles-Glendale, Tillman, and Burbank water reclamation plants discharge tertiary effluent (disinfected) into the Los Angeles River. Their effluents constituted 69% of low flow, 9% of high flow, and 45% of total river discharge in the 1987 water year and 85% of low flow, 6% of high flow, and 39% of total river discharge in 1988 (SCCWRP 1990). Except for cadmium and nickel, the combined mass emissions from the three water reclamation plants accounted for less than 30% of the estimated loads delivered to the SCB by the Los Angeles River.

San Gabriel River.

The San Gabriel River drains 1,663 km^2 between the San Gabriel Mountains and the ocean and is the second largest single source of gauged runoff to the SCB. The river travels nearly 90 km from the junction of the East and West forks in the San Gabriel Valley to its mouth east of Long Beach. Annual rainfall ranges from 35 to 50 cm in the valleys and coastal plain, to 50 to 120 cm in the mountains (Brownlie and Taylor 1981). The San Gabriel River basin is extensively developed and the river is the second most controlled river in Southern California. Most of the river below the upland catchments has been channelized (Brownlie and Taylor 1981). The river receives tertiary treated wastewater from four water reclamation plants.

Discharge from the San Gabriel River was 30% of the total gauged runoff to the SCB during the 1987 water year (139.2 x 10^6 m^3) and 21% of the total gauged runoff to the SCB in 1988 (138.6 x 10^6 m^3). In both years, discharge was 115% of the long-term mean annual (1964-88: 120.9 x 10^6 m^3). Most of the discharge occurred from November through March. High flows (>5 m^3/s) occurred 10% of the days during 1987 and 11% of the days during 1988, and accounted for 31% and 39% of the annual discharge.

Sixteen runoff samples were collected from the San Gabriel river during storms in September 1986 and January 1987. These storms accounted for 5% and 9% of the flow for the year. Two non-storm samples were collected in October and November 1986. Sixteen samples were analyzed for suspended solids and chlorinated hydrocarbons, and 13 samples were analyzed for trace metals (Table 1). The concentrations of few constituents were correlated with flow or suspended solids (Table 2).

The San Gabriel River was the only channel where discharge did not increase from 1987 to 1988. Mass emission estimates for all nine constituents in 1988 declined by an amount proportional to the decline in discharge (Tables 3a,b).

Santa Ana River.

The Santa Ana River drains 4,406 km^2 and receives runoff from the San Bernardino, San Jacinto, and San Gabriel mountains. The river travels over 250 km before it empties into the ocean north of Newport Bay. Annual rainfall ranges from 30 to 45 cm in the plains and valleys to 50 to 120 cm in the mountains (Brownlie and

Taylor 1981). The Santa Ana River basin is extensively developed with water diversions for municipal and agricultural uses, flood control, and hydroelectric plants. Inputs from four municipal wastewater treatment plants (5.7 x 10^5 m^3/day, 150 mgd) augment the flow. Approximately 33% of the basin is urban and suburban, 10% is agriculture, and 57% is native vegetation (Department of Water Resources 1982, 1985).

Discharge from the Santa Ana River was 3% of the total gauged runoff to the SCB during the 1987 water year (17.6 x 10^6 m^3) and 4% of the total gauged runoff in 1988 (25.8 x 10^6 m^3). Discharge during the 2-year study was 36% and 63% of the long-term annual mean (1924-88: 40.7 x 10^6 m^3). Control facilities, spreading grounds, and the sandy river channel prevent everything but storm flow from reaching the ocean. There were no low flow days during the 2-year study; all of the flow went out in about 30% of the year. Most of the discharge from the river occurred from January through April.

Nineteen runoff samples were collected from two storms in January and April 1988. The January storm was 17%, and the April storm was 2%, of the annual flow. One non-storm sample was collected in December 1987. Twenty samples were analyzed for suspended solids and trace metals, and 19 samples were analyzed for total DDT and total PCB (Table 1). The concentrations of all constituents except total PCB were correlated with flow and suspended solids (Table 2). Total runoff volume increased nearly 50% from 1987 to 1988; annual mass emission estimates increased by a proportional amount (Tables 3a,b).

San Diego River

The San Diego River drains 1,119 km^2 extending from the Laguna Mountains in east San Diego County to the ocean near Mission Bay. The San Diego River is moderately developed. Only the last few kilometers of the channel are lined with concrete. Annual rainfall varies from 23 cm on the coastal plain to 81 cm in the mountains (Brownlie and Taylor 1981). Approximately 21% of the basin is urban and suburban, 2% is agriculture, and the remaining 77% is native vegetation (Department of Water Resources 1987).

Discharge from the San Diego River during the 1987 water year (20.0 x 10^6 m^3) and the 1988 water year (30.5 x 10^6 m^3) was 4% of total gauged runoff to the SCB. Discharge during the 2-year study was 48% and 23% of the annual mean (1982-86: 36.5 x 10^6 m^3). Most of the discharge from the river occurred from November through April. Unlike the other seven channels, the flow duration curve had no inflexion point so flows were not stratified.

Twenty-nine runoff samples were collected from storms that occurred in October 1987, January 1988, and April 1988. Discharge during the storms averaged 1.1 x 10^6 m^3 (range: 0.04-2.4

Table 4a

[2]Aroclor 1242 + Aroclor 1254

x 10^6 m^3). The three storms accounted for 0.1%, 2.6%, and 7.9% of the total annual discharge. Two low-flow samples were collected in September and December 1987. Thirty-one samples were analyzed for suspended solids, 30 samples for trace metals, and 29 samples for chlorinated hydrocarbons (Table 1). The concentrations of most constituents were correlated with suspended solids, but not with flow (Table 2). Concentrations of cadmium, nickel, and total PCB were especially low because of the high proportion of non-detectable measurements. Runoff volume increased by 53% in 1988 and mass emission estimates increased by a proportional amount (Tables 3a;b).

Tijuana River.
The Tijuana River straddles the border between the United States and Mexico. Twenty-seven percent of the drainage basin (4,483 km^2) lies in Mexico and 73% lies in the United States. The channel is moderately developed and water is diverted to San Diego and Tijuana on its way to the ocean through Tijuana Slough. On the U.S. side, 3% of the land is urban and suburban, 2% is agriculture, and 95% is native vegetation (Brownlie and Taylor 1981).

Approximately 16.6 x 10^6 m^3/yr (12 mgd) of raw sewage and industrial and agricultural wastes are discharged into the Tijuana River south of the International Border (International Boundary and Water Commission, personal communication, October 16, 1990). This was 163% of the total discharge from the river in 1987 and 41% of the total discharge in 1988.

Discharge from the Tijuana River was 2% of total gauged runoff to the SCB during the 1987 water year (10.2 x 10^6 m^3) and 6% of total gauged runoff during the 1988 water year (40.2 x 10^6 m^3). Discharge during the 2-year study was 24% and 94% of long-term annual mean (1950-88: 42.9 x 10^6 m^3). Discharge during high flows (>0.5 m^3/s) occurred 7% of the days in 1987 and 24% of the days in 1988, and accounted for 48% and 82% of the annual river discharge. Most of the discharge from the river occurred from January through April.

Twenty-seven runoff samples were collected from storms in October 1987, January 1988, and April 1988. Discharge during these storms was 1-15% (0.4-6.0 x 10^6 m^3) of the annual discharge volume. Two non-storm samples were collected in September and December 1987. Twenty-nine samples were analyzed for suspended solids, 28 samples for trace metals, and 27 samples for chlorinated hydrocarbons (Table 1). The concentrations of all constituents were positively correlated with flow and suspended solids (Table 2). The volume of discharge from the Tijuana River increased by 300% from 1987 to 1988; mass emission estimates increased by the same amount (Tables 3a,b).

Table 4b

Discussion

Hydrography.

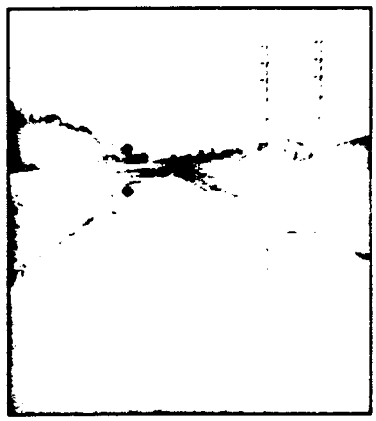
The rivers in this study occupy basins that are either moderately developed (Santa Clara, San Diego, and Tijuana rivers and Calleguas Creek) or extensively developed (Los Angeles, San Gabriel, and Santa Ana rivers and Ballona Creek) (Brownlie and Taylor 1981). In the most developed and manipulated basins, river discharge was extremely variable. The Santa Clara and Santa Ana rivers had no measurable flow for most of the year. River discharge was a combination of surface and groundwater runoff, releases from control facilities, and inputs of domestic and industrial wastes. Most of the flows resulted from winter rains; storms are short and intense, and discharge is variable from year to year.

The eight channels sampled during this 2-year study contributed about 80% of the total gauged runoff to the SCB. Annual river discharge during the study ranged from 0.9×10^6 m^3 for the Santa Clara River to 217×10^6 m^3 for the Los Angeles River. Annual discharges were, on average, 61% below their long-term means during the 1987 water year (range: 17-99% below), and 31% below their long-term means in 1988 (range: 75% below to 33% above). Rainfall in Los Angeles was 48% below its long-term average (1877-1988: 37.5 cm) during 1987 and 15% below average during 1988.

Constituent Concentrations.

Between September 1986 and April 1988, 191 runoff samples were collected from eight channels and analyzed for nine constituents; 179 samples were collected during storms and 12 samples were collected during non-storm periods. Constituent concentrations varied from one to two orders of magnitude among the channels (Table 1).

The Tijuana River, which is dominated by raw sewage, had the highest concentrations for eight of the nine constituents, and the second highest concentration for the remaining constituent. The



Storm channel in Orange County

Santa Clara River, a predominantly agricultural watershed, had the highest concentration of total DDT. The San Diego River, which drains a less developed basin, had the lowest concentrations for four of the nine constituents, and the second lowest concentrations for three of the remaining constituents. Low flow in the Los Angeles River had the lowest concentrations for five constituents and the second lowest concentrations for three of the remaining constituents. Interestingly, most of the water in the Los Angeles River at low flow is tertiary effluent from water reclamation plants.

The concentrations of most constituents were correlated with suspended sediment, and to a lesser extent with river discharge (Table 2). The average rank correlation among constituent concentrations was 0.53. The average rank correlation among constituent mass emissions was 0.86 in 1987 and 0.80 in 1988 indicating that within a channel, conditions that result in high concentrations and mass emissions for one constituent hold for the other constituents. As river discharge rises, sediment mobilization increases. Suspended sediment, usually the constituent present in the greatest amount, comes from soil erosion and, in urban areas, particles produced by automobiles, industry, and commercial activities. Contaminant concentrations and mass emissions increase with increasing sediment loads because the surface area available for adsorption increases (Williams *et al.* 1966, Bradley and Lewin 1982).

Constituent Mass Emissions.

Mass emissions varied from one to three orders of magnitude among the channels (Tables 4a,b). The Los Angeles, San Gabriel, and Tijuana rivers had the highest mass emissions, and the Santa Clara and San Diego rivers had the lowest. Mass emission estimates generally increased from 1987 to 1988 in proportion to the increase in volume discharged. For Ballona Creek and the Los Angeles River, most of the increase was associated with the increased frequency of high flows; low flow volumes and constituent mass emissions estimates were similar between years.

Not all of the channels sampled discharge directly into the ocean. Several channels discharge into harbors and lagoons; it is possible to calculate the load delivered by the river to the harbor or lagoon, but because of modifications due to processes in the receiving body of water, this is not necessarily the load delivered to the ocean. Harbors and lagoons can be a partial trap for many substances, especially sediment.

Conclusions

Urbanization has had a dramatic impact on the landscape of southern California during the past century. Rivers and streams have been extensively modified to conserve water for a growing population and to control floods (Brownlie and Taylor 1981). Urbanization increases the quantities of pollutants that reach rivers and streams. The type and concentrations of pollutants in runoff are determined by the degree of urbanization, types of land use, densities and types of vehicle traffic and animal populations, atmospheric quality, municipal cleaning practices, and specific storm characteristics (Randall and Grizzard 1983, Ellis 1986). Most river discharge and contaminant transport in southern California happens during winter storms that occur intermittently and unpredictably. ■

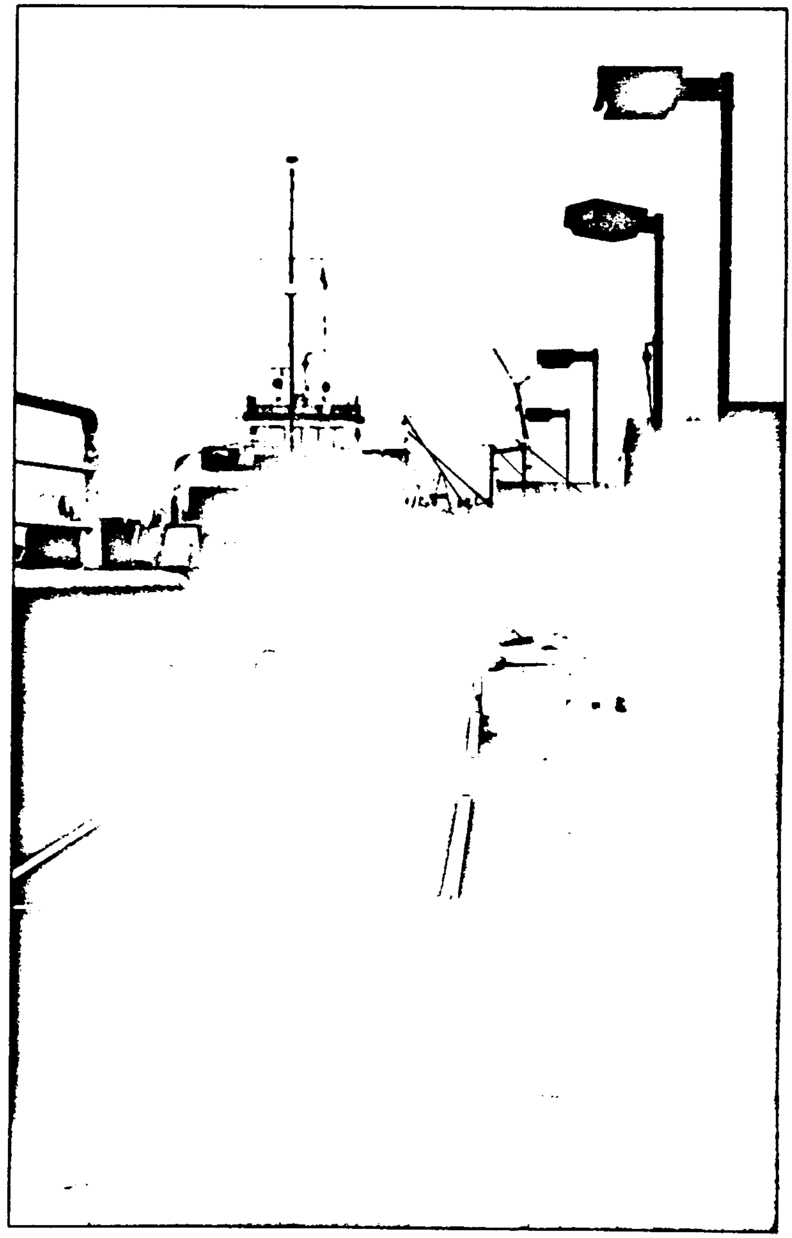
Hazardous Spills in the Southern California Bight

Pollution of the marine environment occurs through inadvertent losses of hazardous materials during production, transportation, refining, and utilization. In the past 25 years, there have been several significant hazardous material spills in the Southern California Bight (SCB). The blowout of Platform A in the Santa Barbara Channel in January 1969 released an estimated 12.3 x 10^6 L (3.25 x 10^6 gal) of oil in the first 100 days. The 70,000 t tanker *Sansinena* exploded and burned in December 1976 while it was docked in Los Angeles Harbor releasing about 5.1 x 10^6 L (32,000 bbl) of Bunker C fuel oil. In January 1990, the tanker *American Trader* ran aground and was punctured by its anchor spilling about 1.5 x 10^6 L (400,000 gal) of crude oil off Huntington Beach.

In this report, we summarize the existing data on hazardous material spills in the Southern California Bight between 1985 and 1990. The objective of this effort was to develop baseline information to provide insight into inadvertent spills in the SCB.



Fuel dock in Los Angeles Harbor

Methods

Data on hazardous material spills were obtained from the U.S. Coast Guard (Pollution Response Branch, Washington, D.C.) for 1985 through 1989. The Coast Guard categorizes the data by source (facility or vessel), type of material, and waterbody. They report the net amount spilled

VOL 12 2 07 3 1

(amount spilled minus amount recovered). The number of material and source categories were reduced for the tables and figures in this report. A complete list is provided in Appendix A and category definitions are provided in Appendix B.

We made several modifications to the classifications presented in the original data. We reclassified small harbors to "Pacific coastal harbors" and removed them from coastal and unclassified categories. Bays were reclassified with harbors. Turning basins in Los Angeles and Long Beach harbors were reclassified as Los Angeles/Long Beach Harbor. From 1986 on, inland spills were removed from the unclassified category and placed in an inland category. All U.S. ship spills were reclassified as "Navy vessels."

Results and Discussion

From 1985 through 1989, 327,115 L (86,424 gal or 2,058 bbl) of hazardous materials were spilled in 1,102 separate incidents in the SCB. The majority of spills (99% by volume and 96% by number) involved petroleum products (Table 1; Figure 1). Middle distillate fuels (diesel, fuel oil, jet fuel, and kerosene) were the largest class of materials spilled (50% by volume). The volume of individual spills was generally small; the median spill for all facilities was 15 L and the median spill for all vessels was 19 L (Table 1).

Spills from facilities accounted for 40% of the total number of spills and 60% of the total volume of material spilled. The greatest number and volume of facility spills involved crude oil (Table 1; Figure 1). About 60% by number and 80% by volume of the classified facility spills originated on land (Table 2; Figure 2). About 40% of the classified facility spills by number and 20% by volume originated with offshore oil pipelines and platforms.

Spills from vessels accounted for 60% of the total number of spills and 40% of the total volume of material spilled. The greatest number and volume of vessel spills involved fuel oil (Table 1; Figure 1). About 60% of the classified vessel spills by number were evenly divided among recreational boats, freighters, and

tankers (Table 2). Most of the classified vessel spills by volume originated with the U.S. Navy and towboats (Table 2; Figure 2).

About 80% of the classified spills from vessels and 50% of the classified spills from facilities occurred in harbors and bays in the SCB (Figure 3; Table 3). Los Angeles and Long Beach harbors received more facility spills (45% by volume) and vessel spills (29% by volume) than any other classified waterbody (Table 3). Within Los Angeles and Long Beach harbors, facilities spilled primarily crude oil from land facilities and vessels spilled mainly middle distillate fuels from Navy and freight vessels (Figure 4).

The amount of hazardous material spilled varied from year to year (Figures 5, 6, and 7). Annual volumes spilled by facilities varied by a factor of 21 and annual volumes spilled by vessels varied by a factor of nine. Spills from land facilities varied by a factor of 33 and spills from vessels varied by a factor of 16. Annual volumes spilled in Los Angeles and Long Beach harbors varied by a a factor of 43 for facility spills and 9 for vessel spills (Figure 8).

Conclusions

Petroleum products accounted for the majority of unintentional releases of pollutants to the Southern California Bight. Petroleum products also accounted for the majority of the volume of pollutants spilled, even in years without major accidents.

The volume of most spills was relatively small; a few spills, even in a period lacking a major spill, accounted for most of the inadvertent discharge. Since a few locations and facility types accounted for the majority of reported spills, the data assembled in this report may provide the basis for prioritizing and targeting improvements in oil spill prevention.■

Appendix A—

Category Constituents

- *MATERIAL* (classifications refer to figures)
  Middle distillate fuel: Diesel oil, fuel oil, jet fuel, kerosene.
  Gasoline: Alkylates, automobile, aviation, casinghead, polymer, reformates, straight run.
  Non Petroleum: see Table 1.
  Other oil: Absorption oil, clarified oil, cracked gas oil, lubricating oil, mineral oil, motor oil, naptha, penetration oil, range oil, spindle oil, spray oil, turbine oil, waste oil.
- *SOURCE—Facility* (classifications refer to figures)
  Miscellaneous and unclassified: Aircraft, railroad tank car, unclassified spills.
- *SOURCE—Vessel* (classifications refer to figures)
  Miscellaneous and unclassified: Commercial, government owned, industrial, mobile offshore drilling unit, offshore supply vessel, passenger, recreation, research, unclassified spills.
- *WATERBODY* (classifications refer to figures)
  Harbors: Alamitos Bay, Channel Islands Harbor, Huntington Harbor, Los Angeles/Long Beach harbors, Marina Del Rey, Newport Bay, Port Hueneme, San Diego Harbor/ Mission Bay, Santa Barbara Harbor Ventura Marina.
  Inland: Inland spills, rivers (facility spills).
  Miscellaneous and unclassified: Rivers (vessel spills), unclassified spills.
- *MATERIAL* (classifications refer to tables)
  Gasoline: Alkylates, casinghead, polymer, reformates, straight run.
  Jet fuel: JP-1, JP-4, JP-5.
  Naptha: Mineral spirits, naptha.
  Fuel oil: No. 1, 1-D, 2, 2-D, 4, 5, 6.
  Miscellaneous oil: Absorption oil, clarified oil, penetration oil, range oil, spindle oil, turbine oil.
- *SOURCES* (classifications refer to tables)
  Unclassified spills: Known source, not elsewhere classified, unknown source.

Appendix B—
Definitions

- *PETROLEUM REFINING*
  Catalytic cracking: Cracking process in the presence of a catalyst.
  Cracking: Process by which large molecules are broken into smaller molecules with lower boiling points.
  Straight run: Products from distillation rather than the cracking process.
- *PETROLEUM MATERIALS*
  Gas oil: Liquid petroleum distillate with viscosity and boiling range between kerosene and lubricating oil. A mixture of straight chain, cyclic and aromatic compounds C15 to C25 hydrocarbons. Used to make distillate-type fuel oils and diesel fuels.
  Gas oil, cracked: Gas oil in which the large molecules have been broken into smaller, lower-boiling hydrocarbon molecules.

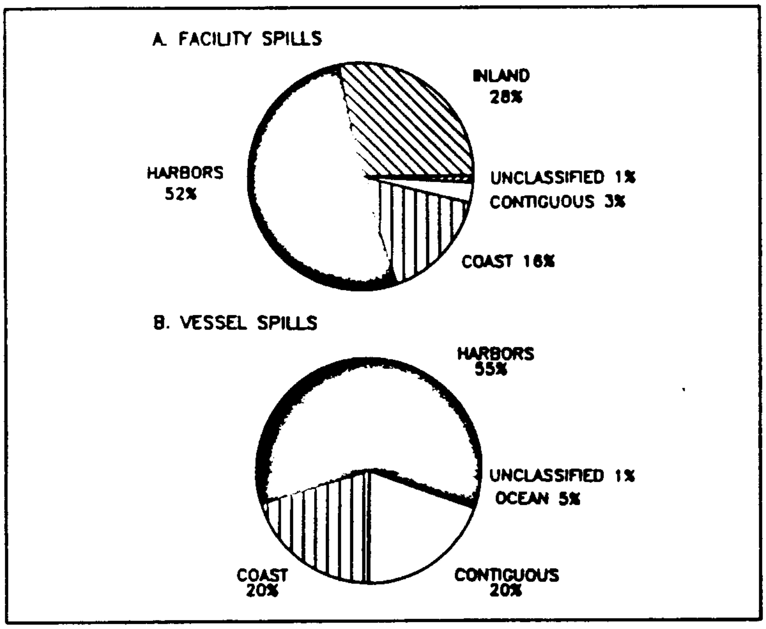
Figure 3

Location of waterbody receiving hazardous material spilled in the Southern California Bight from A) facilities and B) vessels from 1985 through 1989. Proportion is by volume.



Gasoline: C7 to C11 hydrocarbons; 10-60% straight chain paraffin content. Aromatics vary from 5-30% by weight of gasoline fraction; branched paraffins are 13-32% and cycloparaffins are 8-14%. Suitable for fuel in internal-combustion engines.
Gasoline, Automotive (4.23 g Pb/gal): Gasoline with a research octane number approximately 90 used in automobiles.
Gasoline, Aviation (4.86 g Pb/gal): Gasoline with a research octane number of 100 or more used in piston - engined aircraft.
Gasoline, Casinghead: Gasoline obtained by recovering butane, pentane, and hexane hydrocarbons present in small amounts in certain natural gases. Used in blending to produce a finished gasoline with adjusted volatility but low octane number.
Gasoline, Polymer: Gasoline produced by polymerization of low molecular weight hydrocarbons

2 0736

such as ethylene, propene, and butenes. Used in small amounts for blending with other gasolines to improve octane number.
Gasoline, Straight run: Gasoline produced by distillation without cracking or other chemical conversion processes; contains high percentage of straight chain paraffins. Octane number is low.
Gasoline blending stocks, Alkylates: High-octane product produced by petroleum refining and blended into premium motor gasoline and aviation gasoline.
Gasoline blending stocks, Reformates: High octane product obtained from low octane gasoline by heating vapors to high temperature or by passing vapors through catalyst. Blended into regular and premium gasoline.
Jet fuel: Material in kerosene boiling range used in gas-turbine jet engines.
Kerosene: Straight run fraction from crude oil; boiling range 150 to 250°C; aromatics range from 10-40%. More condensed naphtheno-aromatics and multi-ring cycloparaffins than in gasoline.
Mineral spirits: A grade of naptha.
Naphtha solvent: General term applied to refined, partly refined, or unrefined petroleum products and liquid products of natural gas. Used as solvents, dry-cleaning agents, and charge stocks to reforming (mild thermal cracking or catalytic conversion) units to make high octane gasoline.
Oil, Clarified: Heavy oil product from catalytic cracking process from which catalyst has been removed.
Oil, Crude: Liquid hydrocarbon

mixture occurring naturally in the earth; may be treated to render it suitable for transportation. Includes crude oil from which certain distillate fractions have been removed and crude oil to which certain distillate fractions may have been added.

Oil, Diesel: Composed chiefly of unbranched paraffins; volatility is similar to that of gas oil. No. 2 fuel oil with additives.

Oil, Fuel No. 1: Straight run distillate, heavier than kerosene, used almost exclusively for domestic heating

Oil, Fuel No. 1-D: Type of diesel fuel oil. Used in engines with low fuel temperatures and in high-speed engines that have frequent and wide variations in loads and speeds.

Oil, Fuel No. 2: Straight-run or cracked distillates used as general purpose domestic or commercial fuel in atomizing-type burners.

Oil, Fuel No. 2-D: Type of diesel fuel oil. Used in high-speed engines with relatively high loads and uniform speeds.

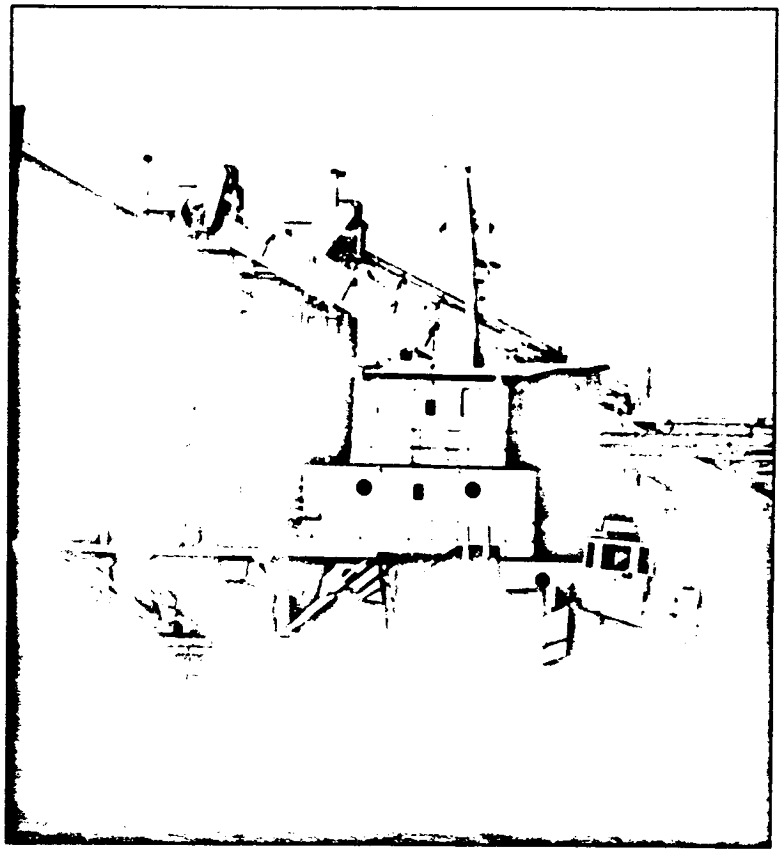
Oil, Fuel No. 4: Heavier straight run or cracked distillates used in commercial or industrial burner installations not equipped with preheating facilities.

Oil, Fuel No. 5: Bunker fuel used in furnaces and boilers of utility power plants, ships, locomotives, metallurgical operations, and industrial power plants.

Oil, Fuel No. 6: Bunker fuel (see Fuel Oil No. 5.).

Oil, Miscellaneous absorption: Miscellaneous hydrocarbon mixture; oil that extracts heavier components from a vapor mixture.

Oil, Miscellaneous lubricating: C20 to C50 compounds that include straight chain, branched, cycloparaffins, and aromatics similar to those in gas oil, but with a higher molecular weight. Usually have small amounts of additives to impart special properties such as viscosity index and detergency.



Boats unloading in Los Angeles Harbor

Oil, Miscellaneous mineral: Oil derived from mineral substances.

Oil, Miscellaneous motor: Oils used to lubricate automotive, aircraft, and diesel engines.

Oil, Miscellaneous penetrating: Used to aid a bath or liquid penetrate a material.

Oil, Miscellaneous range: Type of kerosene used for space heating.

Oil, Miscellaneous spindle: Low viscosity lubricating oil for textile and other high speed machinery.

Oil, Miscellaneous spray: Low viscosity oil used as a pesticide for trees and shrubbery.

Oil, Miscellaneous turbine: Oil used to lubricate, cool, and inhibit rusting of turbines.

- *WATERBODYS*

  Inland: Spills washed into street gutters that lead into storm drains and channels.

  Coastal: 0-3 mi from shore.

  Contiguous: 3-12 mi from shore.

  Ocean: 12-200 mi from shore.

- *SOURCES—Facility Spills*

  Designated water facility: Land facility that meets federal requirements to handle dangerous cargo.

  Land facility: Land facility other than a designated water facility or onshore marine facility.

  Onshore marine facility: Any facility that deals with marine related transportation.

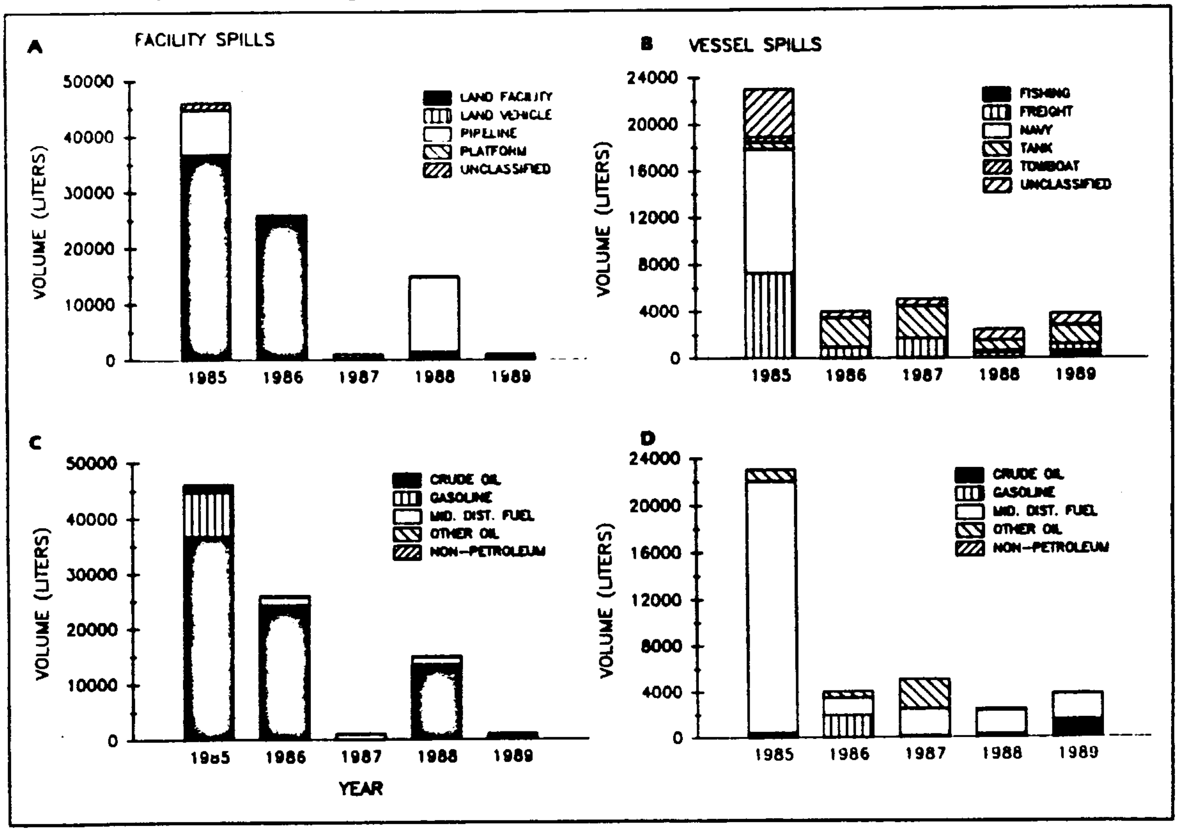
Figure 8

Source of hazardous material spilled from A) facilities and B) vessels and type of hazardous material spilled from C) facilities and D) vessels in Los Angeles and Long Beach harbors from 1985 through 1989.



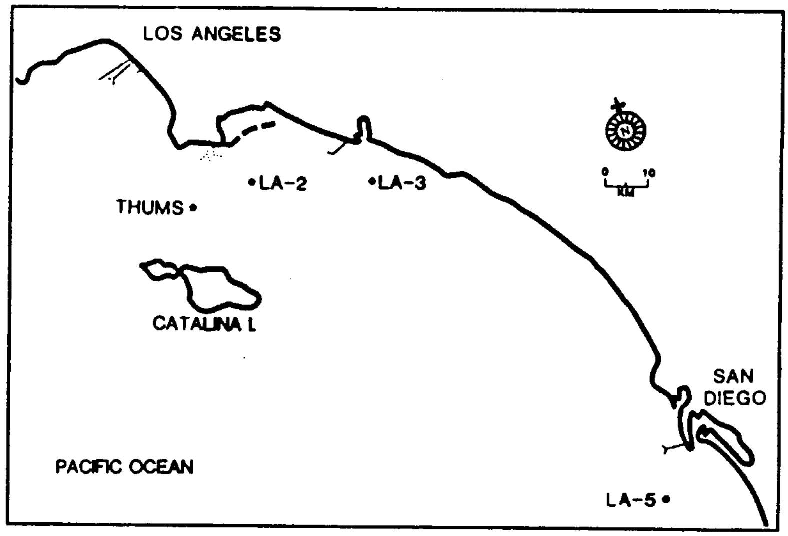
- *SOURCES—Vessel Spills*
  Combatant: U.S. Navy.
  Commercial: Any trade or business involving transportation of goods or individuals, except service performed by a combatant vessel.
  Fishing: Vessel that commercially engages in catching, taking, or harvesting fish or activity expected to result in catching, taking, or harvesting fish.
  Freight: Barge or motor vessel of more than 15 gross tons that carries freight for hire, except an oceanographic research vessel or an offshore supply vessel.
  Government owned: Vessel owned or demise chartered and operated by U.S. Government or government of a foreign country and not engaged in commercial service.
- *SOURCES—Industrial*
  Mobile offshore drilling unit: Vessel capable of drilling for the exploration or exploitation of subsea resources.
  Offshore supply: Motor vessel of more than 15 gross tons, but less than 500 gross tons, that regularly carries goods, supplies, or equipment in support of exploration, exploitation, or production of offshore mineral or energy resources and is not a small passenger vessel.
  Passenger: Vessel of at least 100 gross tons carrying at least one passenger for hire.
  Recreation: Vessel manufactured or operated primarily for pleasure or leased, rented, or chartered to another for pleasure.
  Research: Vessel that is employed in instruction of or research in oceanography or limnology.
  Tank: Vessel of the barge or motor vessel that carries oil or hazardous material in bulk as cargo or cargo residue.
  Towboat/tugboat: Commercial vessel engaged in, or intending to engage in, service of pulling along side, or any combination of pulling, pushing, pushing, or hauling along side.

Estimates of Ocean Disposal Inputs to the Southern California Bight

Fourteen designated ocean disposal sites have been used in the Southern California Bight (SCB) since 1931 for disposal of refinery wastes, chemical wastes, filter cake, oil drilling wastes, refuse and garbage, radioactive wastes, military explosives, and miscellaneous wastes (SCCWRP 1973, Chartrand *et al.* 1985). Currently, only approved dredged materials can be released at two designated ocean disposal sites off Los Angeles (LA-2) and San Diego (LA-5), and one interim ocean disposal site off Newport Beach (LA-3) (Figure 1).

Millions of cubic yards of sediments have been removed from harbors and bays to expand coastal areas and improve navigable waters in the last decade. These harbors and bays receive inputs of stormwater runoff, and support industrial and military activities. Because they are generally poorly flushed, the sediments often have high concentrations of contaminants (Anderson *et al.* 1988, National Oceanic and Atmospheric Administration 1991). Much of the material dredged from harbors and bays is dumped at offshore sites in the SCB, yet little has been published on the magnitude of dredge inputs for the region. The objective of this study was to estimate the total mass of dredge material and associated contaminants dumped in the SCB between 1984 and 1991.

Figure 1.
Location of the dredge material disposal sites in the Southern California Bight.



Materials and Methods

Permit Data

All permit applications for projects that disposed any material at sea in the SCB from January 1984 to June 1991 were examined. We obtained data from the dredge permit files of the U.S. Army Corps of Engineers (ACOE) Los Angeles District Office, the Dredge Material Tracking System (DMATS) of the U.S. Environmental Protection Agency Region IX, dredge permittees and local port authorities.

We collected data on dredging location, disposal site, completion date, volume of material disposed, and contaminant concentrations. Sediment chemistry data were obtained from technical reports, environmental impact statements, and reports for each permitted project. The trace metals included Ag, As, Cd, Cr, Cu, Hg, Ni, Pb, and Zn. The pesticides included DDT, DDE, total DDT, total identifiable chlorinated hydrocarbons (TICH), chlorinated hydrocarbons (CHC), and total organic halogens (TOH). The PCBs included individual Aroclors and total PCBs (sum of

Aroclor mixtures). There were too few measurements of organotins, oil and grease, and polycyclic aromatic hydrocarbons to estimate mass inputs.

The start and completion dates, and the actual volume of material dredged, were not available for all projects. When completion dates were not reported, the year the permit was issued was assumed to be the year of completion. When actual dredge volumes were not reported, the maximum volume estimated for the permit application was assumed to be the actual volume dredged, unless other documentation (individual dredging reports or communication with port authorities, permittees, and dredging engineers) was available.

Mass Emission Estimates

Constituent mass emissions were estimated from:

$$M = \sum_{i=1}^{n} (C_i V_i D)$$

where:
M = mass of constituent,
C_i = mean constituent concentration for i[th] permit,
V_i = volume of material dredged for i[th] permit,
D = density conversion factor from cubic yards to metric tons (mt), and
n = number of permits

The density conversion factor varied with the type of material dredged (i.e., sand, silt, clay). Density measurements for dredged materials were obtained for 17 projects in Southern California bays and harbors from 1976 to 1978 (U.S. Army Corps of Engineers 1977, 1978, 1979). Densities ranged from 0.969 to 1.361 mt/yd^3; the mean density (1.087 mt/yd^3; sd = 0.140) was used as the conversion factor.

Not all constituents were measured for each project. Chemical analyses and biological testing were not required for dredge material that was predominantly sand. When concentration data were missing for a constituent for a particular project, the mean concentration of that constituent for all projects in the same harbor was used to estimate mass emissions. Constituent concentrations for sand and concentrations below detection limits were set to zero to estimate mass emissions.

Statistical Analyses

Dredge material constituent concentrations were tested for differences among harbors by nonparametric analysis of variance (Kruskal-Wallis test; Zar 1984). Data from Los Angeles and Long Beach harbors, Huntington Harbor and Anaheim Bay, and northern and southern San Diego Bay were pooled to increase sample size. The relation between dredge mass and contaminant mass was determined by Spearman rank correlation (Zar 1984).

Results

Fifty-three projects disposed 5,971,197 yd^3 (4,565,577 m^3) of

Table 1.
Constituent concentrations (dry weight) from sediment chemistry analyses from 37 dredging permits in Southern California bays and harbors from 1984 through 1991. ΣPCB=total PCB, ΣPest=total pesticides, N=number samples, SD=one standard deviation.

dredged materials in the Southern California Bight between January 1984 and June 1991. Thirty-seven permits reported constituent concentrations for 120 dredge material samples.

Dredging Volumes

The total annual volume of materials dumped at the disposal sites ranged from 72,000 to 2,353,800 yd³ (55,000-1,800,000 m³) (Figure 2); the average annual volume was 746,400 yd³ (570,700 m³). Most of the material was dumped at LA-5 (51%) and LA-3 (32%); lesser amounts were dumped at LA-2 (16%) and THUMS (<1%). The number of permitted projects varied from year to year and dumpsite to dumpsite (Figure 2); 21 projects dumped at LA-5, 18 projects dumped at LA-3, 13 projects dumped at LA-2, and one project dumped at THUMS. The total number of projects per year ranged from two to 11 (mean = 6.6; sd = 2.8).

Disposal sites LA-2 and LA-5 were closed from 1/89 to 2/91,

although projects with sand waivers continued to dump. LA-5 received material from the largest number of projects in one year (six in 1985). The THUMS Company of Long Beach was the only company permitted to dump at the THUMS disposal site northwest of Catalina Island. They dumped a relatively small amount of drilling muds and cuttings from oil and gas exploration at the site in 1985, which is no longer in use.

Most of the dredging projects dumped small quantities of dredge materials (Figure 3). The smallest projects were predominantly sand removed from private docks and marinas in Newport Harbor. These projects ranged from 195 to 1,200 yd^3 (149-918 m^3) and disposed of their materials at LA-3 in 1989 and 1990. Six projects dumped volumes greater than 200,000 yd^3 (153,000 m^3) and composed 58% of all dredge materials dumped (four at LA-5 and two at LA-3). The largest project was the deepening of Newport Harbor Back Bay that was completed in 1987. More than 1,313,000 yd^3 (1,004,000 m^3) were dumped at LA-3, which represented 70% of the total volume dumped at that site and 22% of the total volume dumped at all sites.

Contaminant Concentrations

Chemistry data were reported for 70% of the dredge projects representing about 90% of the total volume dumped in the SCB during the study. Seventeen percent of the projects dredged sand for which chemical analyses were not required; these projects accounted for less than 0.1% of

VOL 12 2 0744

the total volume disposed. Thirteen percent of the projects did not report chemistry data, although the dredge material was submitted for biological testing; these projects represented 11% of the total volume disposed.

The number of chemical analyses ranged from 41 for nickel to 120 for cadmium and mercury (Table 1). Dredge materials from the larger, more industrialized harbors had the highest concentrations and largest concentration range (Figure 4). There were no significant differences among the harbors in the concentrations of Ag, As, Cd, Cr, Cu, Hg, Ni, Pb, Zn, or total PCB (Kruskal-Wallis test, $p>0.05$). The concentrations of pesticides were significantly higher (Kruskal-Wallis test, $H=23.35$, $p=0.001$).

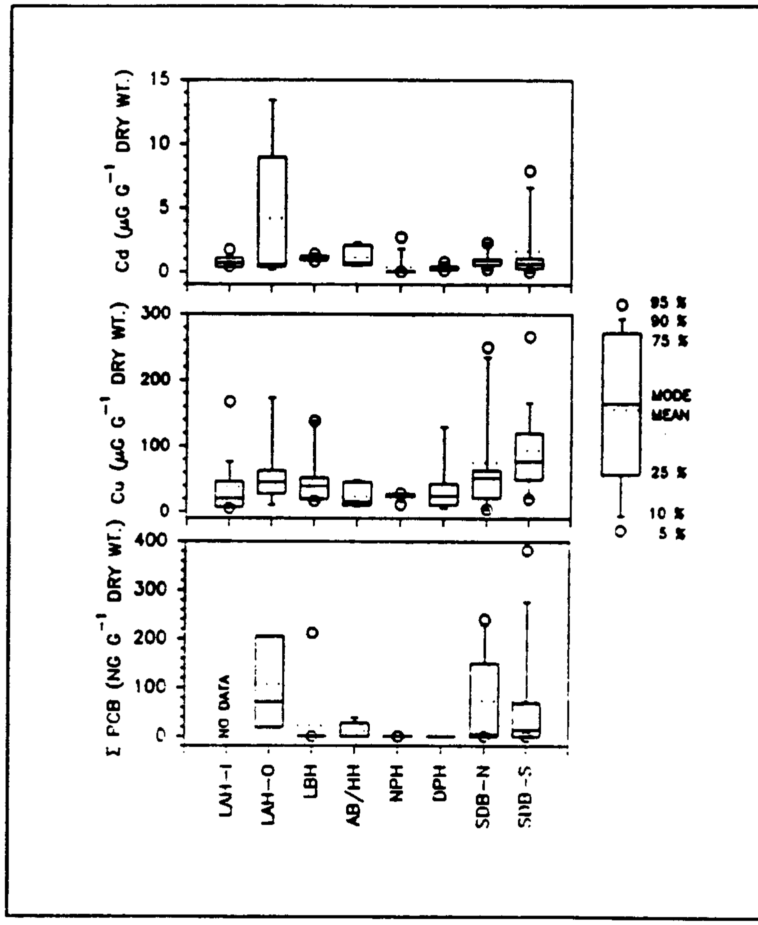
Mass Emissions Estimates

Nearly 6.5 x 10^6 mt of solids were dumped in the SCB during the study (Table 2). Most of this material was dumped at LA-5 and LA-3; lesser amounts were dumped at LA-2 and THUMS (Table 2). The LA-5 site received 86% of the arsenic, 77% of the silver, and 74% of the copper. The LA-3 site received 55% of the mercury. The LA-2 site received 89% of the pesticides, 45% of the total PCB, and 40% of the cadmium.

The annual mass input of dredge materials varied two orders of magnitude and the annual mass input of contaminants varied from one to three orders of magnitude (Table 3). The mass input of solids and seven of the 11 constituents was highest in 1987. The annual mass inputs of all constituents except Ag and total PCBs were positively correlated with the annual mass inputs of solids (Spearman r_s, $p<0.05$).

Figure 4.

LAH-I = Inner Los Angeles Harbor; LAH-O = Outer Los Angeles Harbor; LBH = Long Beach Harbor; AB/HH = Anaheim Bay and Huntington Harbor; NPH = Newport Harbor; DPH = Dana Point Harbor; SDB-N = North San Diego Bay; SDB-S = South San Diego Bay.



Discussion

On average, 746,400 yd^3 (811,300 mt) of sediments were removed from harbors and bays and dumped at offshore sites in the Southern California Bight from 1984 to 1991. Over 70% of the dredge projects were small and disposed less than 100,000 yd^3 (109,000 mt) of material. The disposal sites off San Diego (LA-5) and Newport Beach (LA-3) received more than 80% of the material.

Constituent inputs to each disposal site were not always proportional to the mass of solids received. Proportionally more arsenic, silver and copper was dumped at LA-5, proportionally more mercury was dumped at LA-3, and proportionally more cadmium, total PCB, and pesticides were dumped at LA-2. The disproportionate share of contaminant mass dumped at these sites is due to sources of contaminants peculiar to the harbors and bays from which the sediment was removed.

For example, copper has been used as an antifouling agent in bottom paints of Navy ships. Dredge materials from Navy berths in San Diego Bay composed 73% of the material disposed at LA-5 and accounted for 74% of the copper dumped in the SCB. In the past, mercury mines were located along San Diego Creek just above Newport Back Bay (Orange County Environmental Management Agency, personal communication). Dredge material from Newport Harbor and Newport Back Bay composed 77% of the material dumped at LA-3 and accounted for 54% of the mercury dumped in the SCB. The disproportionate share of pesticides dumped at LA-2 can be traced to Dominguez channel, which empties into Consolidated Slip in Los Angeles Harbor. Dominguez Channel received runoff from the Montrose Chemical Corporation, the largest manufacturer of DDT in the world and the only manufacturer in California (Chartrand *et al.* 1985). Dredge material from Los Angeles and Long Beach harbors composed all of the material dumped at LA-2 and accounted for 89% of the pesticides dumped in the SCB.

The concentrations of Cu and total PCB in dredge materials removed from Los Angeles and Long Beach harbors and San Diego Bay were compared to sediment concentrations measured by National Oceanic and Atmospheric Administration (NOAA) Mussel Watch and Benthic Surveillance Program (National Oceanic and Atmospheric Administration 1991) and by SCCWRP (Anderson *et al.* 1988). Mean Cu concentrations varied by about a factor of three in both harbors (Figure 5). The differences were not significant in San Diego Bay (Kruskal-Wallis test, H=8.83, p=0.066), but they were significant in Los Angeles and Long Beach harbors (H=17.67, p=0.001).

Mean total PCB concentrations varied by about a factor of five in both harbors (Figure 6). The differences were significant in San Diego Bay (H=26.25, p<0.001) and in Los Angeles and Long Beach harbors (H=22.76, p<0.001). In Los Angeles and Long Beach harbors, NOAA Mussel Watch, NOAA Benthic Surveillance, and SCCWRP data were not significantly different. In

San Diego Harbor, NOAA Benthic Surveillance and SCCWRP data were not significantly different. Differences in Cu and PCB concentrations could be due to differences in sampling methods, analytical techniques, or methods of quantification. For example, each group differs in the number and type of Aroclors quantified. There is also substantial heterogeneity in the distribution of PCBs within harbor sediments (SCCWRP 1990).

The estimates of mass inputs from dredge material disposal presented in this study suffer from missing data, lack of standardized chemical characterization, and inconsistent reporting. Mass inputs were calculated for each permit, although some permits lacked chemical data. Chemical characterization was not consistent among permits and detection limits varied widely. Information on project start and completion dates, dredge material density, and the total volume dumped was often missing from Army Corps of Engineers permit files and was not included in the Dredged Material Tracking System.

Inconsistent analytical techniques and reporting are illustrated by the trace organic hydrocarbon data. Various projects reported pesticides as DDT, DDE, total DDT, chlorinated hydrocarbons, total identifiable chlorinated hydrocarbons, and total organic halogens. Different projects quantified different PCB Aroclor mixtures, and some projects summed the different Aroclor mixtures and reported only total PCBs. There were too few measurements of polycyclic aromatic hydrocarbons to estimate mass inputs, although harbor and bay sediments are often significantly

Figure 5.

contaminated (Anderson and Gossett 1987). Improved characterization of dredge materials is needed before we will be able to accurately estimate the mass emissions from dredge material disposal.

Appendices

Appendix 1: Permit Process

The Marine Protection, Research, and Sanctuaries Act (MPRSA) of 1972, also known as the Ocean Dumping Act, regulates ocean dumping and phased out the disposal of certain types of wastes at sea (e.g., industrial wastes, sludges, etc.). This act established a permit process for ocean disposal that evaluates the environmental impacts of materials dumped at sea, allows enforcement of permit conditions, and establishes a process to designate and manage ocean disposal sites. Dredge material disposal in the SCB requires a federal permit from the Army Corps of Engineers (ACOE).

Ocean dumping permits are evaluated on a project-by-project basis. The Army Corps of Engineers administers all permits under the Dredged Material Disposal permit process of the MPRSA, Section 103. Permit approval is contingent upon guidelines established by the U.S. Environmental Protection Agency (EPA) Ocean Dumping Regulations (40 CFR 220-229). In the SCB, all permit applications are submitted to the ACOE Los Angeles District Office and reviewed by EPA Region IX, San Francisco. The ACOE releases

VOL 12

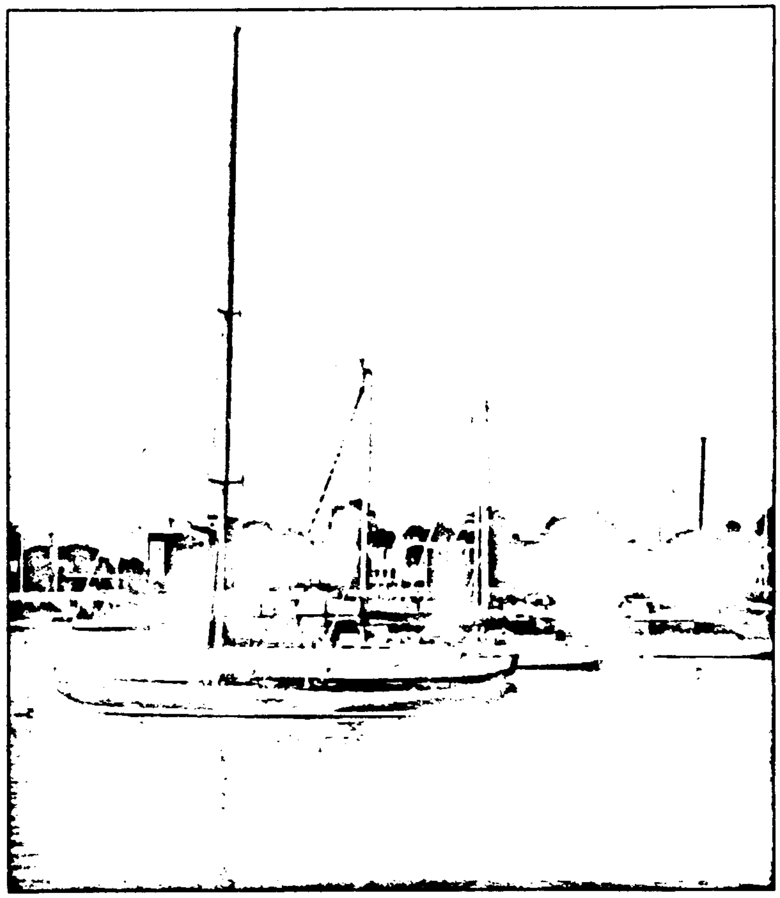
2 0748

each application for public comment and solicits opinions from federal, state, and local government agencies. The California Coastal Commission must also approve the dredging permit under a Coastal Consistency Determination.

The EPA criteria for disposal of dredged materials are based on environmental acceptability, chemical analyses, and biological tests. Permits to dredge rock, gravel, shell fragments, or sand are generally approved without extensive chemical or biological testing. Coarse grained materials, characteristic of high energy environments, generally have low organic content and low contaminant concentrations. They are used for beach replenishment if grain size is compatible with the receiving environment.

If the dredge material does not meet the exclusion criterion [40 CFR 227.13 (b)], it is submitted for chemical analyses, liquid/suspended particulate and solid phase bioassays, and bioaccumulation tests with approved species (U.S. EPA/U.S. Army Corps of Engineers 1991). Testing determines the potential for adverse biological effects resulting from disposal. If contaminant concentrations are low and bioassay and bioaccumulation results are not significant, then a permit for ocean disposal may be issued.

Dredge material that does not meet the chemical, toxicity, or bioaccumulation standards may still be dredged. Alternative disposal sites, such as sanitary landfills or diked disposal areas, must be found. Diked disposal areas, where dredge material is used for fill, are planned for the 2020 Los Angeles/Long Beach Harbor Expansion Project.



Early morning in Newport Bay

Appendix 2: Designated Dumpsites

The LA-2 disposal site is located 6.7 nm south of the breakwater at San Pedro; it has a radius of 915 m and ranges from 118 to 320 m in depth (U.S. Environmental Protection Agency 1988). The LA-5 disposal site is located 10 nm southwest of San Diego; it has a radius of 915 m and ranges from 145 to 200 m in depth (U.S. Environmental Protection Agency 1987). The LA-3 disposal site is located 9 nm south of Newport Harbor; it has a radius of 915 m and averages 457 m deep (U.S. Army Corps of Engineers, Los Angeles District, personal communication). The THUMS site, which is not currently in use, was designated in 1985 for the disposal of drilling muds and cuttings from oil and gas development in Long Beach Harbor. It is located 16 nm southwest of the Long Beach Harbor breakwater; it has a radius of 2.8 km and is approximately 890 m deep (U.S. Environmental Protection Agency 1985).

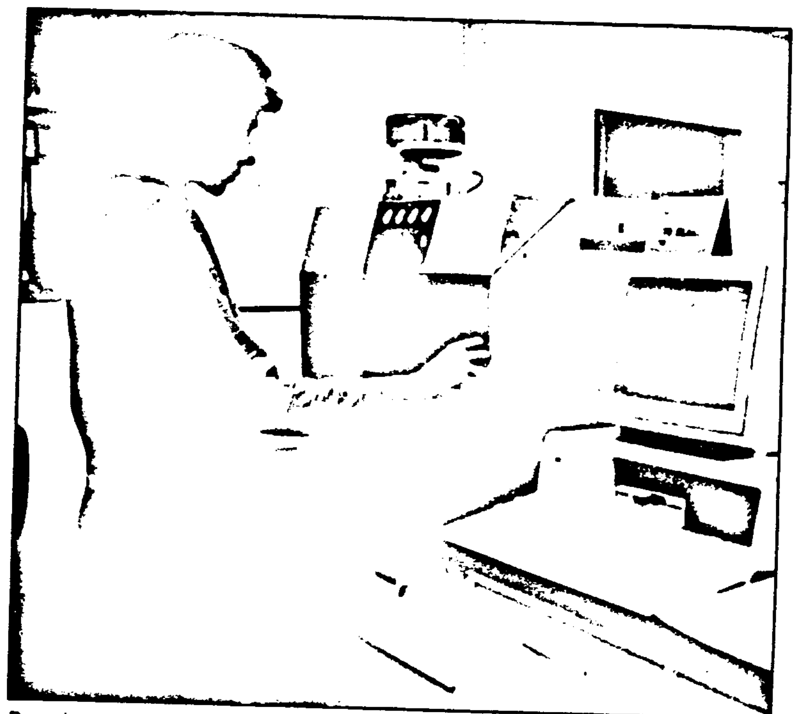
Total Organic Carbon and Total Nitrogen in Marine Sediments, Sediment Trap Particles, Municipal Effluents, and Surface Runoff

Elemental carbon and nitrogen are the basic components of organic matter entering the marine environment. Their measurement may provide a gross assessment of the origin and accumulation of organic material in marine sediments, and possibly the transport and fate of contaminants. The ratio of carbon to nitrogen (C/N) is used to identify the source of organic material. Humic substances originating from marine organisms are rich in nitrogen, hence their C/N ratios are lower than those derived from terrestrial vegetation. Typical C/N ratio of marine humic material ranges from 10 to 15, although ratios of 5 to 10 are not unusual, especially for compounds originating from algal sources. Coastal environments also have high C/N ratios as a result of microbial mineralization of organic nitrogen. Terrestrial materials generally have C/N ratios between 10 and 35 (Rashid 1985).



Running samples on the CHN analyzer

Organic carbon and nitrogen can be measured in sediments by wet chemistry or instrumental methods. The latter is the more prevalent technique because of better accuracy and precision, and shorter analysis time. The objectives of this study were: 1) to develop instrumental methods to measure organic carbon and nitrogen in wastewater effluent, marine sediment, sediment trap particles, and surface runoff, and 2) to examine the usefulness of the C/N ratio for distinguishing among sources of organic material in the marine environment.

Materials and Methods

Effluents were collected from the County Sanitation Districts of Los Angeles County Joint Water Pollution Control Plant (JWPCP), the County Sanitation Districts of Orange County Wastewater Treatment Plant (CSDOC), and the City of San Diego Point Loma Treatment Plant (PLTP). Sediment trap particles were collected near each of the three ocean outfalls. Surface sediments were collected near the CSDOC and PLTP ocean outfalls. Sample collection and analysis was conducted over a 12-month period. Water samples were collected from the Los Angeles River in Long Beach during a winter storm.

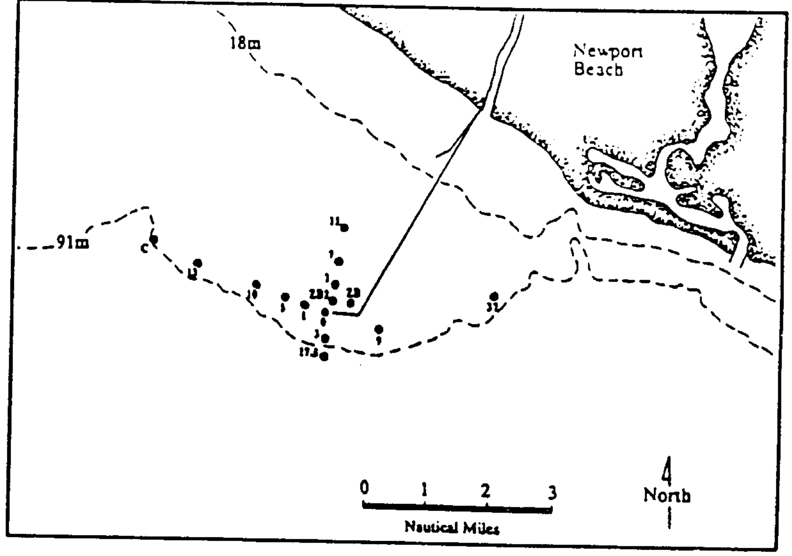
Effluents

Final effluents were collected from JWPCP, CSDOC, and PLTP every other month from January to November 1990. Twenty-four- hour composite samples were collected by treatment plant personnel in two bottles: 1) an amber glass bottle (for determination of total suspended solids), and 2) an acid-rinsed 2 L polyethylene bottle sealed with Teflon-lined cap (for determination of TOC and TN). The samples were placed on ice, returned to the laboratory within 12 hr of collection, and analyzed immediately.

About 100 ml of the effluent from the glass bottle was measured using a graduated cylinder, and filtered in an all-glass filtration assembly using pre-combusted, pre-weighed 25 mm or 47 mm Whatman GF/C glass fiber filter. The filter was washed with distilled water and transferred to a previously kilned Petri dish and dried in a vacuum desiccator for two days. Total suspended solids were determined by reweighing the dry filter on a Cahn 31 microbalance.

About 100 ml of the effluent were removed from the polyethylene bottle, filtered, dried as described above, and exposed to hydrochloric acid vapor for 18 hr to remove inorganic carbon. This is a modification of the acid vaporization technique described by Hedges and Stern (1984). The filter was then dried in an oven at 60°C for 4-6 hr to remove excess acid and water, crimped in a tin combustion boat (Carlo Erba), and analyzed for TOC and TN. We calculated particulate organic carbon (POC) and particulate nitrogen (PN) based on the amount of total suspended solids measured in the effluent.

Figure 1.
Surface sediment sampling sites near the County Sanitation Districts of Orange County municipal wastewater outfall.



Sediment Trap Particles

Sediment traps were deployed off the Palos Verdes Peninsula, Orange County (Huntington Beach), and Point Loma from October 1989 to November 1990 at elevations of 0.5, 2.0, and 5.0 m above the sea floor in 60 m of water and 1 km downcurrent from each of the outfalls (JWPCP, CSDOC, PLTP). The traps were retrieved monthly, although some moorings were lost. Particles were collected in glass centrifuge bottles in the trap. The bottles were transported to the laboratory and stored at -20°C until the particles were analyzed.

The frozen sediment trap particles were thawed at room temperature and homogenized with a glass rod. The wet sample was transferred in an acid-rinsed glass jar and dried at 60°C overnight. A 20-30 mg aliquot of the dry sample was weighed into a silver boat (Carlo Erba) using a Cahn 31 microbalance, placed in a Teflon plate, exposed to acid for 18 hr, and dried as described above. The silver boat was crimped and loaded in a tin combustion boat for analysis.

Sediments

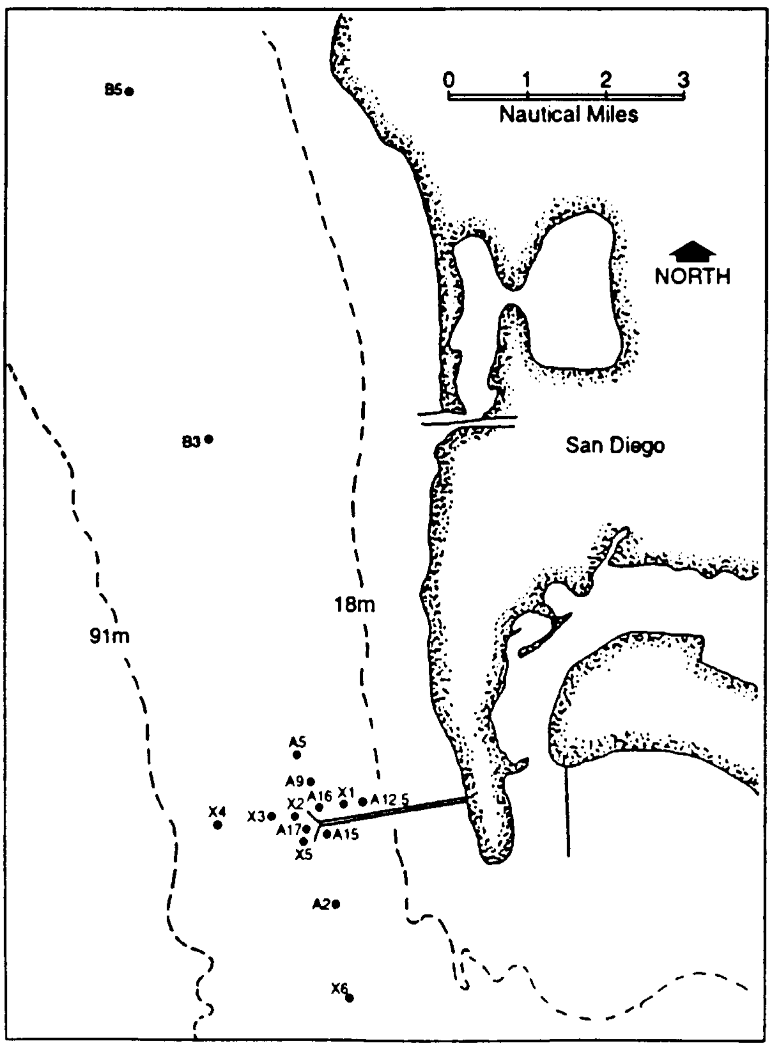
Surficial sediments were collected near the CSDOC outfall in May 1989 (Figure 1) and near the Point Loma outfall (Figure 2) in April 1989 by Van Veen grab (Stubbs *et al.* 1987). Subsamples of the upper 2 cm of the sediments were collected in precombusted glass jars covered with Teflon-lined caps, transported on ice to the laboratory, and stored at -20°C until analyzed.

The frozen sediments were thawed at room temperature and homogenized with a glass rod. The wet sediment sample was dried in an aluminum pan at 60°C overnight and stored in a glass vial. An aliquot of the dry sample was weighed and the carbonate removed as described for the sediment trap samples.

River Runoff

Water samples were collected from the Los Angeles River at Willow Street in Long Beach during a storm in January 1990. Samples were collected at 15-30 min intervals for 6 hr. Flow measurements at the time of sampling were obtained from the Los Angeles Department of Public Works. The sampler and sampling method are described in SCCWRP (1990a). Water samples were stored in polyethylene bottles and refrigerated at 5°C until analyzed. Subsamples of 15-25 ml were filtered in the same way as effluent samples and the carbonate was removed as described for sediment trap samples.

Figure 2.
Surface sediment sampling sites near the Point Loma Treatment Plant municipal wastewater outfall.



Instrumental Analysis

Carbon, hydrogen and nitrogen (CHN) were determined by flash combustion on a Carlo Erba EA 1108 CHN Elemental Analyzer equipped with an AS/23 autosampler, Porapak QS column, and a thermal conductivity detector. The sample was crimped in a tin combustion boat, placed in a quartz combustion tube packed with chromium oxide and silvered cobaltous-cobaltic oxide catalyst, and combusted at 1050°C with oxygen as the oxidizing agent. The oxides pass through a reduction tube filled with copper to convert nitrogen oxides to elemental nitrogen. The resulting compounds are separated and eluted as CO_2, N_2, and H_2O by gas chromatography. Helium was used as a carrier gas at a flow rate of 100 ml/min. Total analysis time was 10 min per sample.

The instrument was calibrated daily with standard acetanilide using a three-point calibration curve. The same standard was also processed daily as a sample to determine TOC and TN recovery. Data were acquired and processed with a DP 110 integrator and later with a Carlo Erba 100 data system that uses an IBM-compatible computer. Quality control and quality assurance data are presented in the Appendix.

Results

Effluent Particles

There were no significant differences in TOC concentrations (ANOVA, $F_{2,16}=0.346$, $p=0.71$) and TN concentrations

[a] TSS measured on 47 mm Whatman GF/C glass fiber filter
[b] TSS measured on 25 mm Whatman GF/C glass fiber filter

(ANOVA, $F_{2,16}=1.540$, $p=0.25$) among effluent samples from the three municipal wastewater treatment plants (Table 1). The variability of TOC and TN measurements was moderate; coefficients of variation (CV) ranged from 15 to 30%.

Total suspended solids were significantly different among the three effluents (ANOVA on log-transformed data, $F_{2,16}=15.94$, $p<0.001$). The CSDOC effluent had the lowest concentration; PLTP effluent had the highest concentration, and hence the highest concentrations of POC and PN. The average POC concentration in the PLTP effluent was about 40% greater than the JWPCP effluent and 70% higher than the CSDOC effluent.

Sediment Trap Particles

The concentrations of TOC and TN in sediment trap particles generally increased with trap elevation above the sea floor (Figure 3). Particles collected 5 m above the bottom had 5-20% higher average TOC concentrations, and 4-30% higher average TN concentrations, than particles collected 0.5 m above the bottom. Particles collected 2 m above the bottom had 1-12% higher average TOC concentrations, and 0-10% higher average TN concentrations, than particles collected 0.5 m off the bottom.

Sediment trap particles collected 5 m above the bottom off Palos Verdes had a 70% higher average TOC concentration, and a 60% higher average TN concentration, than particles collected 5 m above the bottom off Orange County and Point Loma.

The variability of TOC and TN concentrations was greater for particles collected off Orange County and Point Loma (CV_{TOC}=9-34%, CV_{TN}=10-53%) than particles collected off Palos Verdes (CV_{TOC}=5-8%, CV_{TN}=8-9%) (Figure 3). The coefficients of variation were about twice as large for the 5 m traps compared to the 0.5 m traps at Orange County and Point Loma.

The C/N ratios were consistent (CV range 1-3%) across all trap elevations at the three sites (Figure 3).

Sediments

0756

sediments were highest at the station closest to the end of the outfall and lowest at the station farthest downcoast (Table 2, Figure 1). The C/N ratio had a substantial range (4.7), but the variability was low (CV=11%).

The TOC and TN concentrations in surficial sediments off Point Loma were about twice those off Orange County (Table 2). The concentrations were highest at several stations upcoast and downcoast from the outfall, and lowest at two stations farthest upcoast (Figure 2). The C/N ratio had a narrow range (1.9) and low variability (CV=6%).

River Runoff

The organic content of suspended particles collected in the Los Angeles River declined as the storm progressed (Figure 4). River flow was inversely correlated with the concentrations of TOC (Spearman r_s= -0.83, p<0.002) and TN (r_s= -0.85, p<0.001), but was not correlated with the C/N ratio. During the early part of the storm when flows were less than 10 m^3/s, the TOC concentration averaged 12%, the TN concentration averaged 1.2%, and the C/N ratio was 10.8. During the storm when flows were greater than 20 m^3/s, the TOC concentration averaged 6%, the TN concentration averaged 0.5%, and the C/N ratio was 12.1.

Discussion

Effluents

Effluent particles from the three municipal wastewater treatment plants had similar TOC and TN concentrations, but because of differences in level of treatment, TSS (and POC and PN) concentrations were significantly different. Effluent at PLTP received advanced primary treatment and had the highest TSS concentration. More than 50% of the effluents from JWPCP and CSDOC receive secondary treatment (SCCWRP 1990b).

Our measurements of effluent TSS were significantly higher than effluent TSS measurements reported by CSDOC (Mann-Whitney U test, p<0.02) and PLTP (U test, p<0.001), but not by JWPCP (U test, p>0.10) (see *Characteristics of Effluents from Large Municipal Wastewater Treatment Plants in 1990* in this report). This may be a function of differences in filter pore sizes used by the laboratories. SCCWRP and JWPCP use Whatman GF/C filters with a particle retention size of 1.2 µm; CSDOC and PLTP use Whatman 934-AH filters with a particle retention size of 1.5 µm. Filters with smaller pore diameter may retain more of the suspended particles and have higher TSS concentrations[1].

Because of improved wastewater treatment practices and increased source control, effluent concentrations of suspended solids are 60-70% lower today than in 1978 (Schafer 1980, SCCWRP 1990b). Effluent particle concentrations of organic carbon and nitrogen, however, have not changed in nearly two decades. The concentration of TOC in present-day JWPCP effluent particles (25-39%) is similar to concentrations measured by Myers (1974; 28-42%), Sweeney and Kaplan (1980; 31-32%), and Venkatesan and Kaplan (1990; 25%). The range of TN concentrations measured in the present study (2.5-5.8%) was higher than concentrations measured by Sweeney and Kaplan (1980; 2.4%).

The C/N ratios of effluent particles (7.1-8.4) from the three municipal wastewater treatment plants are comparable to the C/N ratios of effluent (8.3) from South Essex District in Massachusetts (Eganhouse 1986) and the combined sewer overflow effluent (6.5-8.9) discharged to Boston Harbor (Eganhouse and Sherblom 1991).

Sediment Traps

The organic content of sediment trap particles collected off Palos Verdes, Orange County, and Point Loma was substantially less than the organic content of effluent particles from the corresponding sites. Sediment trap particles had 6-11% of the TOC concentration, and 4-9% of the TN concentration, of effluent particles. The C/N ratios of sediment trap particles (9.1-10.3) were 13-34% higher than the C/N ratios of effluent particles (7.1-8.4) from the corresponding sites.

The lower TOC and TN concentrations, and higher C/N ratios, of sediment trap material suggest that effluent particles undergo rapid biodegradation upon discharge to the marine environment (Myers 1974, Eganhouse and Kaplan 1988), and perhaps dilution with plankton and terrestrial lithogenic particles transported into the area. The higher TOC and TN concentrations of particles at the higher trap elevations suggest accumulation of sinking sewage material.

The TOC concentrations of sediment trap particles collected off the Palos Verdes Peninsula during the present study (3.0-4.1%) are comparable to TOC concentrations of flocculent material collected in shallow water off Palos Verdes by Myers (1974; 1.8-3.2%) and Sweeney and Kaplan (1980; 0.8-5.2%). The C/N ratios of their samples (8-12) are comparable with present data.

Sediments

The concentrations of TOC and TN in surface sediments off Orange County and Point Loma were at or below levels of TOC (mean=0.72% dry weight, sd=0.22, n=11) and TN (mean=0.04% dry weight, sd=0.02, n=11) in surface sediments at the 60 m Reference Survey stations (SCCWRP 1992). There was some evidence, however, for the effect of effluent discharge on sediments near the outfalls. Sediment concentrations of TOC and TN near the CSDOC outfall were 200-300% higher than concentrations at the most distant stations. Sediment concentrations of TOC and TN near the PLTP outfall were about 50% higher than concentrations at the most distant stations.

The organic content of sediments collected off Orange

[d]from sediment samples collected near CSDOC and PLTP outfalls

[1] County Sanitation Districts of Los Angeles County compared the GF/C and 934AH filters in 1992 and found no significant difference in estimates of TSS concentrations (J. Stull, County Sanitation Districts of Los Angeles County, personal communication, September 1992).

County and Point Loma was substantially less than the organic content of effluent particles from the corresponding sites. Sediments off Orange County had 10-30% of the TOC and TN concentration of sediment trap particles and <1-2% of the TOC and TN concentration of effluent particles from the same site. Sediments off Point Loma had 20-30% of the TOC and TN concentration of sediment trap particles and 1-2% of the TOC and TN concentration of effluent particles from the same site.

The patterns of C/N ratios of sediments around the outfalls were not consistent between the two sites. The high C/N ratio at station OC-37, which is located near Newport Canyon, is probably due to dilution of the sediment with terrigenous debris low in nitrogen.

No current TOC data by this method are available for sediments off Palos Verdes. A decade ago, the TOC concentration in the upper 1 cm of sediment was 6.8-8.7% (Kettenring 1981). Background levels for sediments near the JWPCP outfalls are about 1% TOC and 0.1% TN (Eganhouse and Kaplan 1988).

River Runoff

The concentrations of TOC and TN in particles collected from the Los Angeles River during a storm declined as flow increased. The C/N ratio was variable and did not correlate with flow. This was not unexpected since the source of organic material, and its removal by scouring, is probably not consistent throughout a storm. At low flow, sand-filtered, secondary effluents from three water reclamation plants make up 80-90% of stream flow (SCCWRP 1990a). The decline in the organic content and the increase in C/N ratio as river discharge increased suggests that the municipal effluents were being diluted by surface runoff.

Particles collected in the Los Angeles River during low flow had, on average, about 40% of the TOC concentration and 30% of the TN concentration of effluent particles. Particles collected in the river during high flow had, on average, about 20% of the TOC and 10% of the TN concentration of effluent

particles. The average C/N ratio of particles in runoff was about 30% higher than effluent at low flow and 40% higher than effluent at high flow.

Conclusions

We compared the organic material associated with effluent, sediment, sediment trap, and surface runoff particles by elemental analysis of organic carbon and nitrogen. Effluents had the highest organic carbon and nitrogen content and sediments had the lowest (Table 3). The results for sediment trap material and sediments suggest that effluent particles undergo rapid biodegradation, and perhaps dilution with plankton and terrestrial particles, in the marine environment.

The C/N ratio data collected in this study were not very helpful for differentiating sources of the particles, but offered some insight into areas enriched by municipal wastewater discharge. Marine organic matter is rich in N and has a C/N ratio of 5-9; terrestrial organic matter is poor in N and has a C/N ratio of at least five or six times that of terrestrial organic matter (e.g., Macdonald *et al.* 1991). Other indicators such as stable isotopes or molecular markers need to be examined to draw more definitive conclusions.■

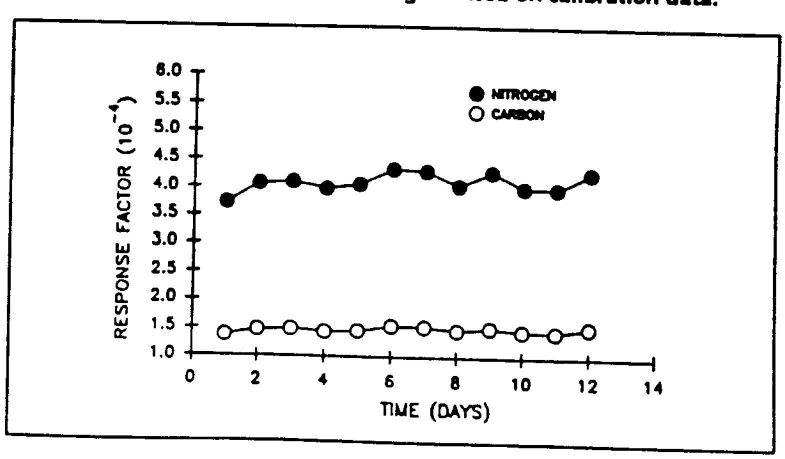
Appendix:

Quality Control/Quality Assurance

Samples of final effluent particles, sediments, and raw sludge were used to bring the method online. Analytical standards used were acetanilide, cyclohexanone, phenanthrene, and a sediment reference material (PACS-1) obtained from the Canadian Research Council.

The final effluent sample was a 24-hr composite obtained from JWPCP. A 100 ml subsample was homogenized and filtered on a 25

Figure 5.
Response factors for carbon and nitrogen based on calibration data.



mm Whatman GF/C glass fiber filter; suspended particles on the filter were transferred to a glass Petri dish and dried under vacuum for two days. The filter was then exposed to hydrochloric acid vapor for 18 hr in a desiccator to remove inorganic carbon, dried, crimped in a tin boat, and loaded in the CHN analyzer. Five replicate subsamples were analyzed to determine the variability of TOC and TN measurements.

Primary sludge was also obtained from JWPCP. The sample was thoroughly mixed in a polytron homogenizer. A 75 µl subsample was pipetted directly into a silver boat, dried at 60°C, and weighed to obtain 2-3 mg of sample. The boat was placed in a Teflon plate and acid-exposed in a desiccator for 24-48 hr, dried at 60°C, and crimped into a tin boat. Five replicate samples were prepared.

Surface sediment samples were collected from Station HR 51-1 and HR 6-1 in Santa Monica Bay. A 50 g wet subsample was dried and pulverized, and an aliquot was ground in an agate mortar and pestle, and stored in glass vials. The optimum sample size required for TOC and TN analysis was determined from 10 replicate analyses of sediments (1-50 mg) from each station.

The glass fiber filters used to filter effluents and surface runoff samples were kilned at 425°C for 4 hr and stored in glass jars sealed with Teflon-lined caps. For effluent particle analysis, blanks of kilned filter paper were processed as samples at a rate of two per eight samples. Empty silver boats were processed as blanks for the sediments and sediment trap particles. Duplicate analyses were run every 10 samples.

The precision of TOC and TN measurements was high for all sample types (Table 4). Carbon and nitrogen recoveries were consistently high for standards and sediment reference material (Table 5) The response factors, calculated daily from the standard data, was constant over time for carbon and nitrogen (Figure 5) The minimum sample size required to quantitate total nitrogen and carbon simultaneously in sediments varied with TOC content. For sediment from HR 51-1 with TOC of 11%, optimum sample size was 10-15 mg; for sediment from HR 6-1 with a TOC of 1%, optimum sample size was 35-40 mg (Figure 6).

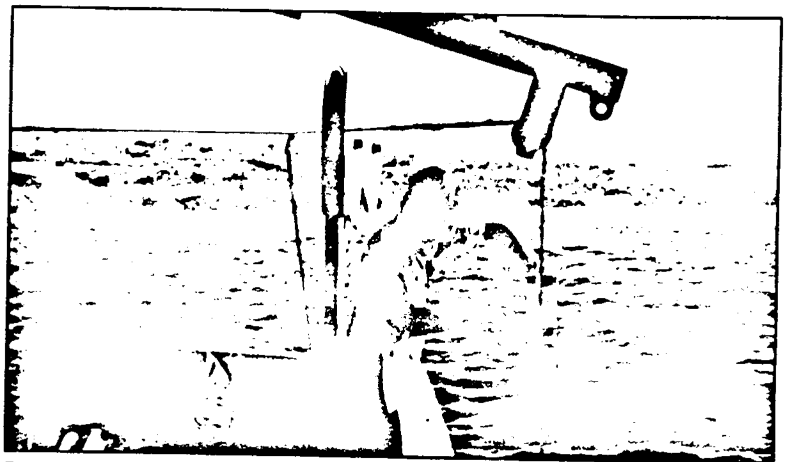
Sediment Model Verification

The characteristics of sediments surrounding an ocean outfall can be altered by the accumulation of organically enriched particles from municipal wastewater discharge. The composition and abundance of animals that live in and on the sediments can also be affected. Several numerical models have been developed to relate changes in sediments and bottom-dwelling organisms to the characteristics of wastewater discharge and the receiving environment.

Prior efforts by SCCWRP to model the fates of particles discharged from ocean outfalls focused on transport and sedimentation of discrete effluent particles, and their subsequent resuspension, transport, redeposition, and accumulation in the sediments. Sedimentation patterns predicted by these models correspond reasonably well with observed patterns (e.g., Hendricks 1984, 1987). However, predicted rates of sediment accumulation are less than observed rates.

Settling column measurements on County Sanitation Districts of Los Angeles and County Sanitation Districts of Orange County final effluents in the early 1970s suggested that most of the particle mass was associated with very small, slow-settling particles. Only about 10% of the mass of suspended solids was associated with particles with settling speeds >13 m/day; approximately one-half of the particle mass was associated with settling speeds <0.25 m/day (Myers 1974, Herring and Abati 1978, Hendricks 1983). The slow-settling particles would require two months or more to settle 15 m from a wastefield to the bottom. Fast-settling particles contribute the most to sedimentation predicted by early SCCWRP deposition simulation models—about 90% of the particle mass is predicted to be carried beyond the outfall area before reaching the bottom.



Recovering sediment traps

Particles entering the ocean may not remain as individual particles, but may coalesce among themselves or with natural particles to form larger "aggregate" particles with higher settling speeds. If the smaller particles aggregate after discharge, the sedimentation rate in the ocean will be greater than the sedimentation rate predicted from settling column measurements. The aggregation of natural particles has been observed in the ocean and the aggregation of effluent particles is suggested by laboratory and theoretical studies.

As part of a contract from the California State Water Resources Control Board, we examined the ability of two models (DECAL and SED2D) to simulate the characteristics of sediments around ocean outfalls off Point Loma (San Diego), Huntington Beach (Orange County), and the Palos Verdes Peninsula (Los Angeles County) (Hendricks and Eganhouse 1992). The model DECAL was developed by Dr. Kevin Farley of Clemson University and the set of submodels SED2D were developed by Dr. Tareah Hendricks of SCCWRP.

Methods

The modeling study: 1) examined the sensitivity of model predictions to input data and the self-consistency of the predictions, and 2) provided site specific predictions based on the consequences of particle aggregation at the three outfall sites. The DECAL and SED2D models had to be modified and expanded to accomplish this. The modeling study was supported by field and laboratory studies that provided input data for the simulations and characterized the sediments for comparison with model predictions.

The simulation of the wastefield in the water column in DECAL (ODES Tool #61; Tetra Tech 1987) was not representative of the discharge and receiving waters in Southern California (i.e., distinct subsurface wastefield isolated from the bottom by an underlying layer of receiving water). We subcontracted with Dr. Farley to conduct new studies of the aggregation process under receiving water conditions present in Southern California. A generalization of the results for a wastefield of arbitrary thickness is found in Hendricks and Eganhouse (1990).

The most important conclusions of the aggregation process studies by Castro (1990, Farley and Castro 1990) are:

1) differential particle settling was the dominant aggregation mechanism for typical ocean and discharge conditions (i.e., larger, faster settling particles falling through smaller, slower settling particles resulted in collisions and aggregation);
2) the rate of production of aggregate particles was approximately proportional to the square of the concentration of suspended solids (2.3-power) and to the thickness of the wastefield (1.2-power);
3) the settling speed of aggregate particles was approximately proportional to the squares of the suspended solids concentration (1.8-power) and wastefield thickness (1.7-power); and
4) the production of aggregate particles in the layer of receiving water beneath the wastefield could be neglected.

These results were incorporated into a new version of the DECAL model by Dr. Farley and into a new set of SED2D submodels by Dr. Hendricks. The revised models were used for sensitivity and self-consistency studies, and for site-specific simulations.

A large number of complex processes determine the fate of natural and effluent particles in the ocean (Figure 1). The following processes, which are only a subset of all the processes involved, were represented in the two simulation models:

1) initial dilution (initial concentration of effluent particles in the wastefield),
2) concentration, flux, and production rate of natural particles in the water column,
3) aggregation of particles into larger particles with faster settling speeds,
4) settling of aggregate particles as they are transported by ocean currents,
5) decay of organic material in the water column and in the sediments,
6) mobilization and demobilization of trace constituents on the particles (DECAL),
7) resuspension (DECAL and SED2D), transport, and redeposition (SED2D) of sediment particles, and
8) accumulation rate and concentration of organic material (DECAL and SED2D) and trace constituents (DECAL) in the sediments.

Although the two models had similar goals and generally incorporated representations of the same processes, the assumptions, representations, and approaches for some of the processes were substantially different (e.g., Hendricks and Eganhouse 1992).

Results and Discussion

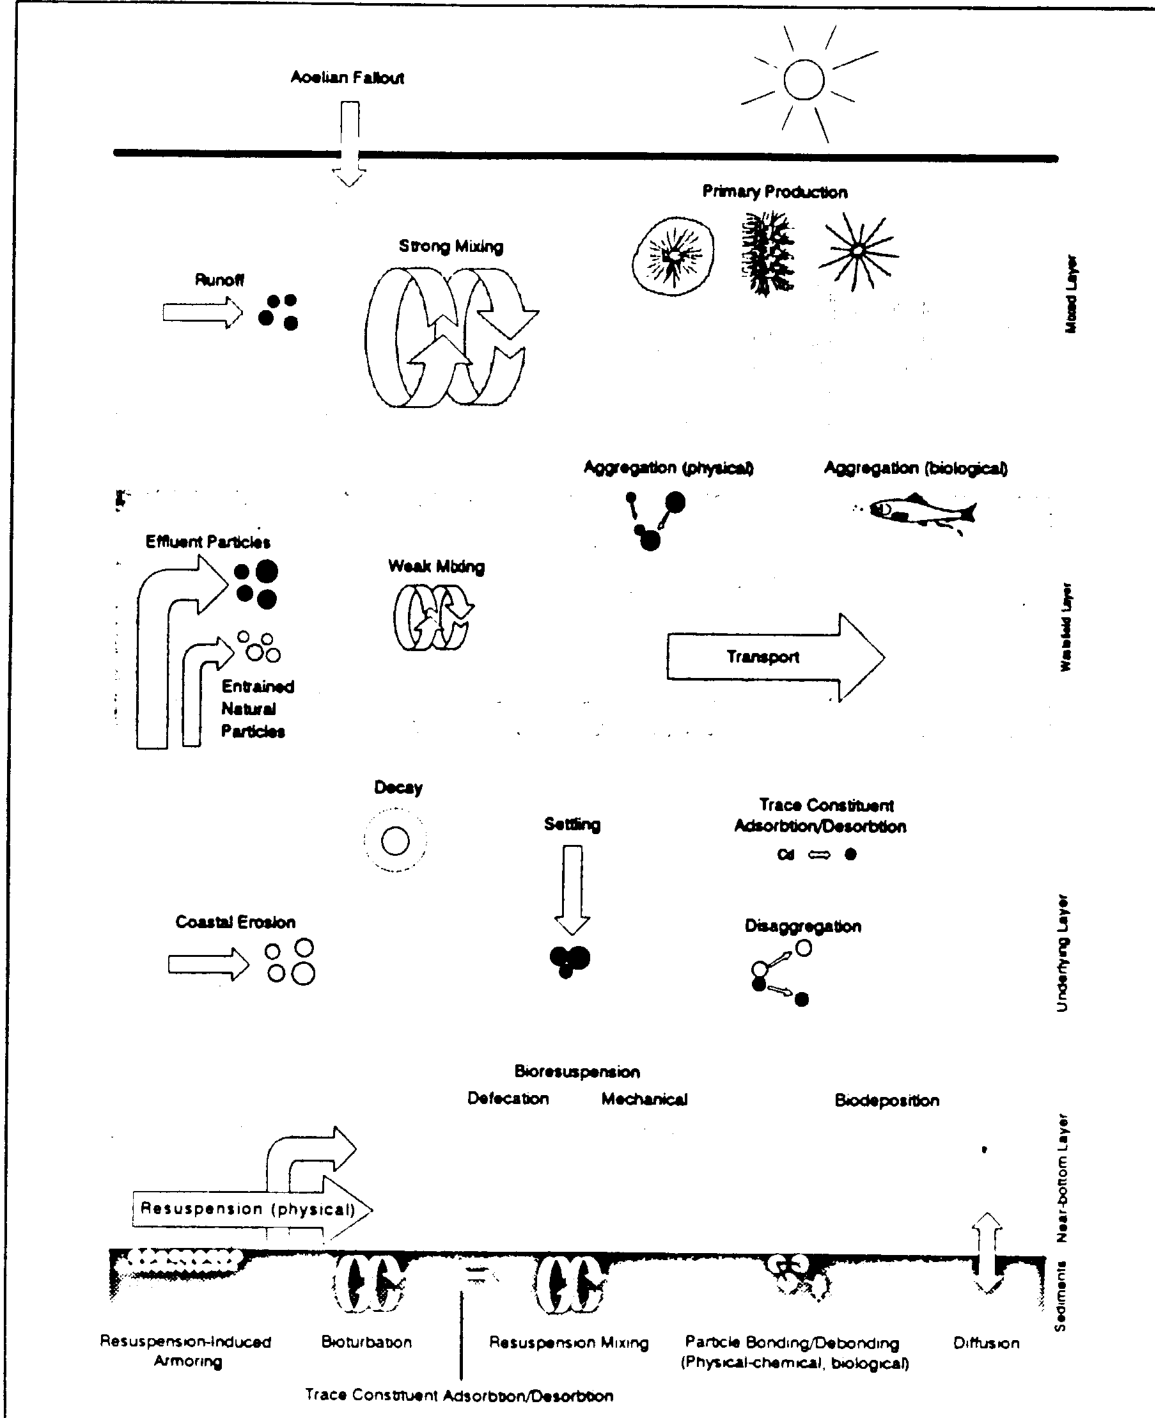
The sensitivity and self-consistency studies brought out several fundamental problems in assessing the importance of particle aggregation to the fate of particles discharged from outfalls. These uncertainties fall into four categories: 1) assumptions used to develop the aggregation rate and particle settling speed equations, 2) aggregation characteristics of natural suspended solids, 3) decay rates or fluxes of effluent and natural particles in Southern California coastal waters and sediments, and 4) quantitative representation of resuspension, transport, and redeposition of sediment particles. We discuss some of the predicted consequences and implications of particle aggregation for wastewater discharge, and the sensitivity of the predictions to those uncertainties.

Effects of Natural Suspended Solids in the Ocean

Natural and effluent particles can aggregate in the simulations generated by DECAL and SED2D. The aggregation of phytoplankton cells produced in the surface waters above the wastefield can generate particles that settle into the wastefield. Natural suspended solids entrained into the wastefield during initial dilution are another source of particles.

Both models included sedimentation of aggregate phytoplankton cells from the overlying water. The DECAL simulations assumed that the concentration of natural suspended solids in the layer of receiving water beneath the wastefield (i.e., entrainment

Figure 1
Processes that determine the fate of natural and wastewater effluent particles in the ocean.



VOL 12

2

0765

R0054065

region during initial dilution) was negligible (Farley and Castro 1990). The SED2D simulations used measurements of natural suspended solids in the water column as the concentration of natural suspended solids entrained into the wastefield. Concentrations measured off White Point, Dana Point (Myers 1974), Encinitas (Kinnetic Laboratories, Inc. 1989), and San Diego (Point Loma Laboratory, City of San Diego, unpublished data) were about 2 mg/L at representative entrainment depths.

The two models estimated initial dilution and the initial concentration of suspended solids in the water column by different methods. Dilutions predicted by SED2D simulations were substantially greater than those predicted by DECAL simulations. For example, SED2D simulations for the Point Loma outfall (San Diego) predicted an average initial dilution of 281:1, while DECAL predicted an initial dilution of 116:1. If we assume an initial dilution of 150:1 and an effluent suspended solids concentration of 70 mg/L (1988 effluent), the initial concentration of effluent suspended solids in the wastefield will be about 0.5 mg/L, or about 25% of the initial concentration of natural suspended solids in the wastefield.

If all natural particles can aggregate, their predominance in wastefield total suspended solids has important consequences for wastewater discharge. In the presence of effluent-natural and natural-natural particle aggregation in our example above, 80% of the mass of wastefield particles that settled to the bottom were natural particles and 20% were effluent particles. Analyses of sediment cores collected in 1981 at 60 m near the outfalls on the Palos Verdes Shelf (Stull *et al.* 1986) provide support for aggregation of wastefield and natural particles. The background natural flux was about 200 mg/cm^2/yr, and each unit mass of effluent particles that accumulated in the sediments was accompanied by approximately one unit mass of natural particles over and above the background flux (Figure 2).

The magnitude of the background flux, and the ratio between the additional flux of natural particles and effluent particles, depend on assumptions about the effects of bioturbation on the distribution of effluent particles in the core horizon influenced by effluent discharge. Background fluxes ranged from about 100 to 300 mg/cm^2/yr in limiting cases, and the ratio of natural flux to effluent flux ranged between 1 and 3. A background natural flux of 200 mg/cm^2/yr is 7 to 20 times greater than published estimates for natural particle accumulation in this region (Emery 1960, Schwalbach and Gorsline 1985).

We examined the predicted change in peak sedimentation of wastefield particulates if treatment removed all suspended solids from the effluent. The initial concentration of total suspended solids in the San Diego wastefield example would decrease from 2.5 mg/L (2.0 mg/L natural + 0.5 mg/L effluent) to 2.0 mg/L. For discharges into Southern California coastal waters, the peak sedimentation rate of wastefield suspended solids on the bottom varies roughly with the square of the initial wastefield concentration (Hendricks and Eganhouse 1990). Total removal of suspended solids from the San Diego effluent (i.e., discharge of distilled water) only reduced the peak sedimentation rate near the outfall diffuser by about one-third. The remaining flux of natural particles from the wastefield was predicted, however, to remain roughly an order-of-magnitude greater than the flux of natural particles in the absence of the discharge.

Why did the model predict such a large enhancement of the sedimentation rate of natural particles in the presence of a particle-free discharge? One possibility is that most of the natural particle mass was associated with particles that did not aggregate. The concentration associated with this mass should not be included in the particle aggregation computations. However, we do not know if cohesive and non-cohesive natural particles exist, or what partitioning may occur. An alternate explanation is that enhanced vertical mixing within the wastefield increased the flux of particles.

Vertical Mixing within the Wastefield

The development of the aggregation equations assumed that all size classes of aggregate particles were uniformly distributed throughout a fully mixed wastefield. Particles undergoing aggregation by settling through the wastefield could be recycled to the top of the wastefield by mixing, allowing them to fall through the wastefield many times. During each fall, they could collide with smaller, slower settling particles, thus increasing aggregate particle mass and settling speed. As particle settling speed increased, the likelihood of the particle settling from the wastefield increased. Ultimately, the settling speed of aggregate particles became so large that turbulence could not carry them upward in the wastefield and they settled to the bottom. In the absence of discharge, the reduced turbulence in the water column did not permit vertical recycling of large, fast-settling particles, so the rate of particle production and settling speed decreased.

We assumed that the 2 mg/L ambient concentration of natural particles in the water column was the steady-state condition in the absence of discharge. The flux of aggregate phytoplankton cells settling from the surface layer into the "wastefield" region of the water column matched the loss of particles from the wastefield region due to aggregation and sedimentation. We did not assume that the wastefield region was fully mixed. Instead, we estimated the thickness of the mixing layer in the aggregation equations that would produce the steady-state.

The results depended on the rate of production of phytoplankton mass in the surface layer. We used 600 mg/m²/day as the typical production rate, and 2400 mg/m²/day as the maximum production rate, for Southern California coastal waters (Tetra Tech 1987). The "effective" mixing layer thickness for the aggregation equations was 0.4 m for the typical rate and 1.9 m for the maximum rate. These values are an order of magnitude smaller than normal wastefield thickness (15-30 m). Because aggregate particle production rate varied as the 1.2-power of wastefield thickness (i.e., effective mixing layer thickness) and particle settling speeds varied as the 1.7-power, greatly enhanced production rates and increased settling speeds were predicted in the presence of discharge.

The assumption that complete vertical mixing occurred within the wastefield may be inappropriate. Temperature, salinity, dissolved oxygen, and light transmissivity are generally not uniform between the upper and lower boundaries within wastefields (Hendricks and Harding 1974, Hendricks 1977, 1987, Thompson 1992). Laboratory studies of vertical mixing for conditions analogous to wastewater discharge into a stratified water column indicate a rapid dissipation of vertical turbulence (Lin and Pao 1979). Stratification in these studies, however, was greater than in the ocean.

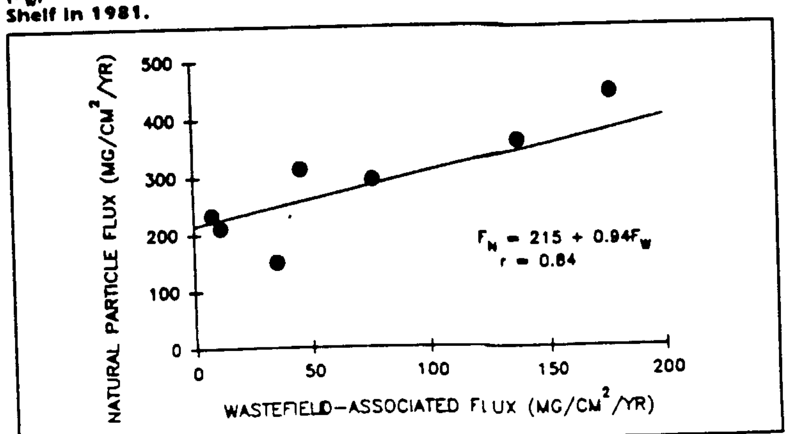
We also compared the density structure within the wastefield to the structure in the surrounding ambient water. Despite uncertainties introduced by internal waves and tides, density gradients existed within the wastefield that may be comparable to the density gradient in the ambient water. This suggests that using the full thickness of the wastefield in the aggregation equations may substantially overestimate the rate of aggregate particle production and their settling speeds.

The effective mixing layer thickness in the absence of discharge provides a lower bound for the effective mixing layer thickness within a wastefield. Simulations based on this assumption predicted a substantial increase in the time between particle discharge from the outfall and particle arrival on the sediments (from about one hour to about six days; Hendricks and Eganhouse 1992). The reduced production rate of aggregate particles, and the dispersion of settling particles by currents during longer water column residence times, greatly reduced the sedimentation flux to the bottom. It also minimized or eliminated the normal local enhancement of sedimentation rate near outfalls.

Sediment Resuspension

Once particles settle to the bottom, they can be mixed with sediments, buried, and resuspended; the organic material can decay; and trace constituents can be mobilized. Both models pro-

Figure 2
The relation between natural particle flux (F_N) and wastefield particle flux (F_W) estimated from sediment cores collected at 60 m from the Palos Verdes Shelf in 1981.



turbulence could not carry them upward in the wastefield and they settled to the bottom. In the absence of discharge, the reduced turbulence in the water column did not permit vertical recycling of large, fast-settling particles, so the rate of particle production and settling speed decreased.

We assumed that the 2 mg/L ambient concentration of natural particles in the water column was the steady-state condition in the absence of discharge. The flux of aggregate phytoplankton cells settling from the surface layer into the "wastefield" region of the water column matched the loss of particles from the wastefield region due to aggregation and sedimentation. We did not assume that the wastefield region was fully mixed. Instead, we estimated the thickness of the mixing layer in the aggregation equations that would produce the steady-state.

The results depended on the rate of production of phytoplankton mass in the surface layer. We used 600 mg/m²/day as the typical production rate, and 2400 mg/m²/day as the maximum production rate, for Southern California coastal waters (Tetra Tech 1987). The "effective" mixing layer thickness for the aggregation equations was 0.4 m for the typical rate and 1.9 m for the maximum rate. These values are an order of magnitude smaller than normal wastefield thickness (15-30 m). Because aggregate particle production rate varied as the 1.2-power of wastefield thickness (i.e., effective mixing layer thickness) and particle settling speeds varied as the 1.7-power, greatly enhanced production rates and increased settling speeds were predicted in the presence of discharge.

The assumption that complete vertical mixing occurred within the wastefield may be inappropriate. Temperature, salinity, dissolved oxygen, and light transmissivity are generally not uniform between the upper and lower boundaries within wastefields (Hendricks and Harding 1974, Hendricks 1977, 1987, Thompson 1992). Laboratory studies of vertical mixing for conditions analogous to wastewater discharge into a stratified water column indicate a rapid dissipation of vertical turbulence (Lin and Pao 1979). Stratification in these studies, however, was greater than in the ocean.

We also compared the density structure within the wastefield to the structure in the surrounding ambient water. Despite uncertainties introduced by internal waves and tides, density gradients existed within the wastefield that may be comparable to the density gradient in the ambient water. This suggests that using the full thickness of the wastefield in the aggregation equations may substantially overestimate the rate of aggregate particle production and their settling speeds.

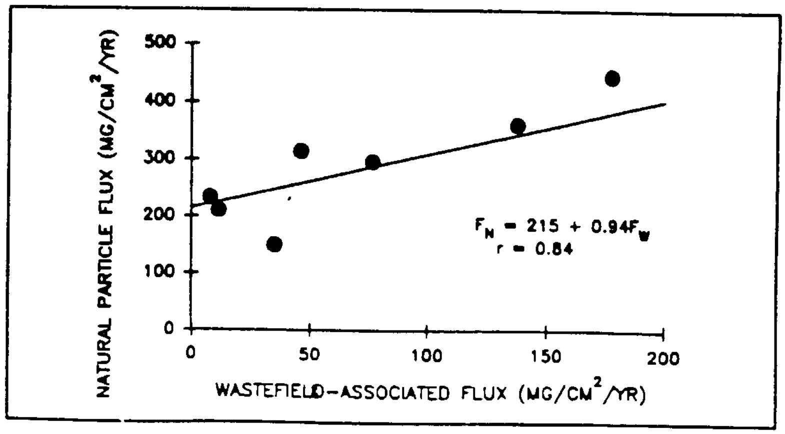
The effective mixing layer thickness in the absence of discharge provides a lower bound for the effective mixing layer thickness within a wastefield. Simulations based on this assumption predicted a substantial increase in the time between particle discharge from the outfall and particle arrival on the sediments (from about one hour to about six days; Hendricks and Eganhouse 1992). The reduced production rate of aggregate particles, and the dispersion of settling particles by currents during longer water column residence times, greatly reduced the sedimentation flux to the bottom. It also minimized or eliminated the normal local enhancement of sedimentation rate near outfalls.

Sediment Resuspension

Once particles settle to the bottom, they can be mixed with sediments, buried, and resuspended; the organic material can decay; and trace constituents can be mobilized. Both models pro-

Figure 2

The relation between natural particle flux (F_N) and wastefield particle flux (F_W) estimated from sediment cores collected at 60 m from the Palos Verdes Shelf in 1981.



vided only primitive representations of these processes. The processes were combined into two first-order rate equations in DECAL (one for organic material and one for a trace constituent). Under steady-state conditions, the rate of loss (or gain) of these processes was proportional to the mass of organic material (or trace constituent) deposited on the sediment surface. The magnitude of this parameter was determined either by choosing a value that minimized the difference between the predicted and observed sediment characteristics, or a value estimated from previous simulations for similar ocean environments.

The SED2D simulations used a different representation for sediment decay processes and did not simulate trace constituent concentrations. The simulations estimated fluxes of material into and out of the sediments as a result of resuspension, transport by near-bottom currents, and redeposition. Observations with sediment traps deployed off Southern California at 0.5, 2.0, 5.0 m above the bottom formed the conceptual framework of the resuspension submodels.

The material collected in sediment traps is primarily resuspended sediments (Hendricks and Eganhouse 1992, unpublished data). Most of the resuspended material is found within 3 m of the bottom and is transported out of the immediate area by near-bottom ocean currents (Hendricks 1987). In the absence of discharge, fluxes of resuspended sediments into the sediment traps are one to two orders of magnitude greater than the rate of accumulation of particle mass in the sediments (SCCWRP 1986, 1987, Hendricks 1987, Hendricks and Eganhouse 1992).

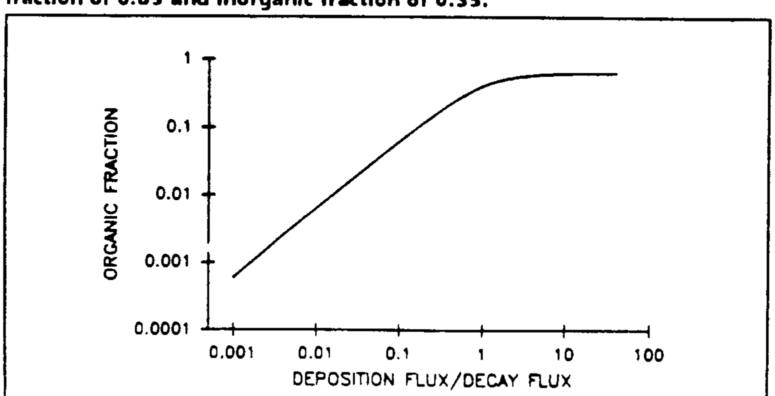
Knowledge of the ocean conditions leading to sediment resuspension and redeposition are required to conduct SED2D simulations of sediment resuspension, transport, and redeposition. These conditions are not well known for the three test sites. However, studies by Washburn *et al.* (1991) near the outfalls on the Palos Verdes Shelf provide some empirical data.

Resuspension begins at current speeds of about 10 cm/sec and no material is resuspended at current speeds of a few cm/sec. (Resuspension also occurs under the combined stress of waves and currents.) We used a threshold resuspension speed of 9 cm/sec and a threshold deposition speed of 4.5 cm/sec for the simulations.

The other required piece of information for SED2D is the average number of resuspensions a particle undergoes before it is buried in the sediments. In the absence of wastewater discharge, this is approximately equal to the deposition flux of mass into a near-bottom sediment trap divided by the accumulation flux of mass into the sediments (approximately 10 to 100 resuspensions). However, changes in the composition of the sediments associated with wastewater discharge, or alterations of the sediments by benthic and epibenthic biota, may affect this number in a way that cannot now be determined *a priori*. For example, SED2D simulations suggested that the average number of resuspensions was lower in the area affected by the Los Angeles County discharge than in the other two test areas. (This could explain the high rate of accumulation of natural particles estimated from the Palos Verdes Shelf cores.)

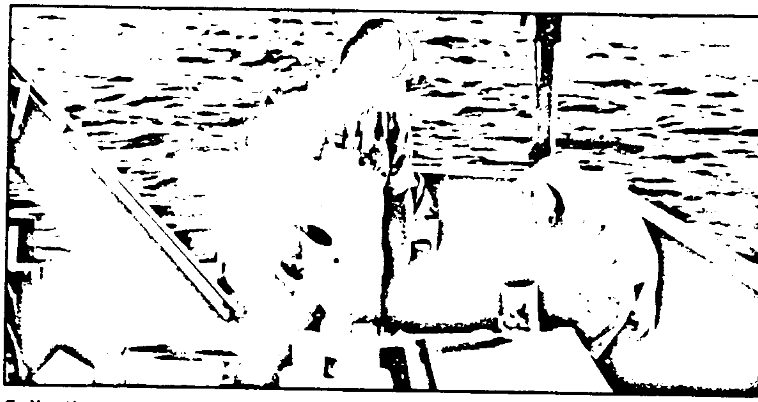
We used sensitivity simulations to examine the ratio between the peak sedimentation flux of wastefield particles to the bottom and the net deposition of wastefield particles in sediments at that location after resuspension. As used herein, "sedimentation" is the initial deposition of particles from the water column; "deposition" is the deposition of particles after resuspension. This ratio was approximately inversely proportional to the average

Figure 3
The relation between the organic content of sediments and the ratio of the deposition flux to the limiting decay flux for particles with an initial organic fraction of 0.65 and inorganic fraction of 0.35.



number of resuspensions experienced by a particle—provided that the number of resuspensions was in excess of about 10. Estimates of the peak accumulation rate of sediments were sensitive to errors in estimates of the average number of resuspensions of sedimenting particles. Sensitivity varies away from the area of peak sedimentation, where effects of the deposition of sediments resuspended from adjacent areas are more important.

Other simulations suggested that the average distance a resuspended particle traveled before redeposition was sensitive to threshold resuspension and redeposition speeds. Changes in transport distance had only minor effects on peak deposition rates around outfalls, but influenced deposition fluxes in areas on the fringes of wastefield sedimentation. Uncertainties in the effects of sediment resuspension in areas most heavily impacted by discharge were more sensitive to the average number of resuspensions and less sensitive to the threshold speed.



Collecting sediment trap material

Decay of Organic Material

The discussion so far has implicitly assumed that particle mass is inert. If the particle contains labile organic material, loss due to decay can affect the initial deposition flux to the bottom, the rate of accumulation of particle mass in the sediments, and sediment composition. Approximately 70% of effluent particle mass is organic material (Hendricks and Eganhouse 1992); effects of decay may alter particle fate predictions. We examined the sensitivity of the results to uncertainties in the decay rate of organic material in the water column and in the sediments.

The decay of organic material as a particle settles through the water column reduces the organic content, total mass, and deposition flux of material to surface sediments. Loss of mass reduces particle settling speed, increases residence time in the water column, and magnifies the effects of decay. The decay of organic material has the potential to produce large changes in particle composition and sedimentation fluxes if settling time becomes comparable to, or greater than, the characteristic decay time (inverse of the decay rate). Unfortunately, the decay rate of organic material in the ocean is not well known. Estimates based on treatment plant observations are about 0.1/day (Tetra Tech 1987). Laboratory and *in situ* studies suggest 0.52/day (Myers 1974). Simulations were carried out for values of 0.1 and 0.52/day.

When the decay rate was reduced from 0.52 to 0.1/day in DECAL, the predicted peak fluxes of total suspended solids to the sediments increased by about two (Los Angeles County) to four (Orange County). The effects were smaller in the SED2D simulations for two reasons. First, entrainment of natural suspended solids during initial dilution increased the wastefield concentration and particle settling speeds, thus reducing residence time in the water column. Second, particles consist of inorganic as well as organic material, so all of the particle mass was not subject to decay and the change in particle settling speed was less than in similar DECAL simulations.

Decay can continue after particles settle to the ocean bottom. In the SED2D model, decay was assumed to be confined to a layer of surface sediments. Hence there is a limit to the rate of loss of organic material (per unit area)—even if the sediments consist entirely of organic matter. For sediments with reduced concentrations of organic material, the rate of loss was correspondingly reduced below the limiting value. The decay flux can determine the rate of accumulation of mass in sediments, the organic content of sediments, and the rate at which sediment composition changes in response to changes in treatment method or changes in the ocean environment. No estimates of the "limiting" decay flux were available for sediments at the three test sites. Estimates from offshore basins and other geographical areas vary over several orders of magnitude.

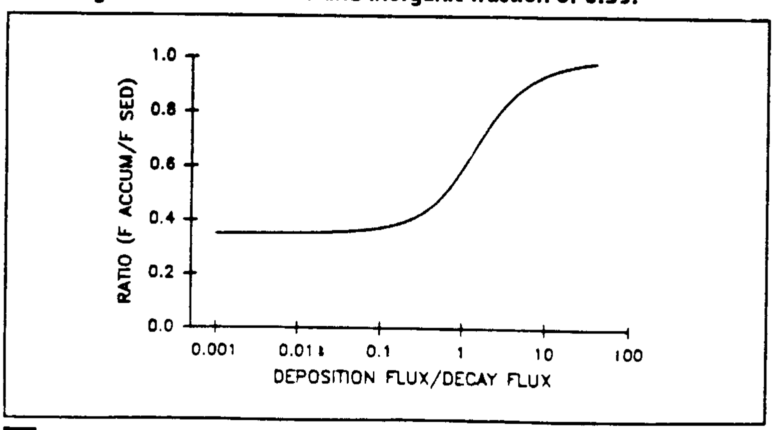
The organic content of sediments was related to the ratio of the deposition flux to the limiting decay flux (Figure 3). Once the deposition flux exceeded the limiting decay flux ($F_{depos}/F_{decay} > 1$), the composition of the sediments became nearly the same as the settling particles (because particles only spent a short time in the sediment layer where decay occurred). At lower deposition rates however, the organic fraction of the sediments was proportional to the deposition flux.

The material remaining after decay contributed to the accumulation of particle mass in the sediments and to sediment burial. The ratio of accumulation flux to deposition flux was less than unity ($F_{accum}/F_{depos} < 1$) and depended on the ratio of the deposition flux to the limiting decay flux (Figure 4). For deposition fluxes that were ten or more times the limiting decay flux ($F_{depos}/F_{decay} > 10$), the accumulation flux was virtually equal to the deposition flux (because little decay occurred before the particles were buried below the decay layer). Conversely, if the limiting decay flux was ten or more times greater than the deposition flux ($F_{depos}/F_{decay} < 0.1$), nearly all of the organic material was lost to decay and accumulation was due primarily to particle inorganic material. At intermediate deposition fluxes, the ratio between accumulation flux and deposition flux varied between these limits. Our best estimate for the decay flux was 180 mg/cm^2/yr, so the region of variability in the accumulation-deposition flux ratio corresponded to deposition fluxes of 18 to 1800 mg/cm^2/yr. This roughly corresponds to the range of accumulation rates (natural + effluent) estimated from cores taken on the Palos Verdes Shelf (Figure 2).

Large uncertainties in estimates of deposition flux were due to uncertainties in: 1) the contribution of natural particles to the aggregation process, 2) the effective mixing layer thickness for particle aggregation, 3) the rate of loss of organic material in the water column due to decay, and 4) the average number of resuspensions of a particle settling to the bottom. Similarly, the limiting decay flux of organic material in the sediments is unknown. These uncertainties magnify the potential for error in estimates of the composition of sediments and their rate of accumulation (i.e., burial).

Figure 4

The relation between the ratio of accumulation flux to deposition flux and the ratio of deposition flux to the limiting decay flux for particles with an initial organic fraction of 0.65 and inorganic fraction of 0.35.



Conclusion

There are substantial uncertainties in the predictions of the fates of wastewater effluent particles based on the DECAL and SED2D simulation models. Both models predicted areas of high rates of sedimentation near outfalls that were surrounded by areas of lower rates of sedimentation. The models predicted an increase in sedimentation of natural particles as a result of a discharge lacking particulate matter.

Uncertainties in the predictions arise from: 1) questions about the validity of aggregation equation assumptions, 2) lack of data on vertical mixing within the wastefield, 3) lack of knowledge about the aggregation characteristics of natural suspended solids, 4) poor understanding of sediment resuspension processes, and 5) lack of estimates of the decay rate of organic material in the water column and sediments. Until these uncertainties are addressed, it will be difficult to assess the validity of the predictions of the two models and the process representations contained in them. However, the models provide qualitative insight into the dynamics of the interaction of a wastefield and natural waters and the localized effects on sedimentation from the discharge of wastewater effluent. ■

EXTENSION OF POINT LOMA OUTFALL

In 1983, the State revised the California Ocean Plan and applied body contact standards for bacterial concentrations to beds of giant kelp *(Macrocystis pyrifera)*. This doubled the depth of protected inshore waters from 35 ft (10.7 m) to 70 ft (21.3 m) near the Point Loma ocean outfall (City of San Diego). At the same time, the distance between the outer boundary of the protected area (historical extent of the kelp bed) and the outfall diffuser was reduced from 2.6 km to 1.6 km.

These changes substantially reduced the isolation of the wastefield from areas where the body contact standard must be met and resulted in violations of the standard. An extension of the existing outfall offshore and into deeper water (85-105 m) is a potential way of meeting the bacterial standards in the kelp bed. Increased isolation is achieved by the greater depth of the wastefield in the water column, and by the increased distance between the outfall diffuser and the kelp beds.

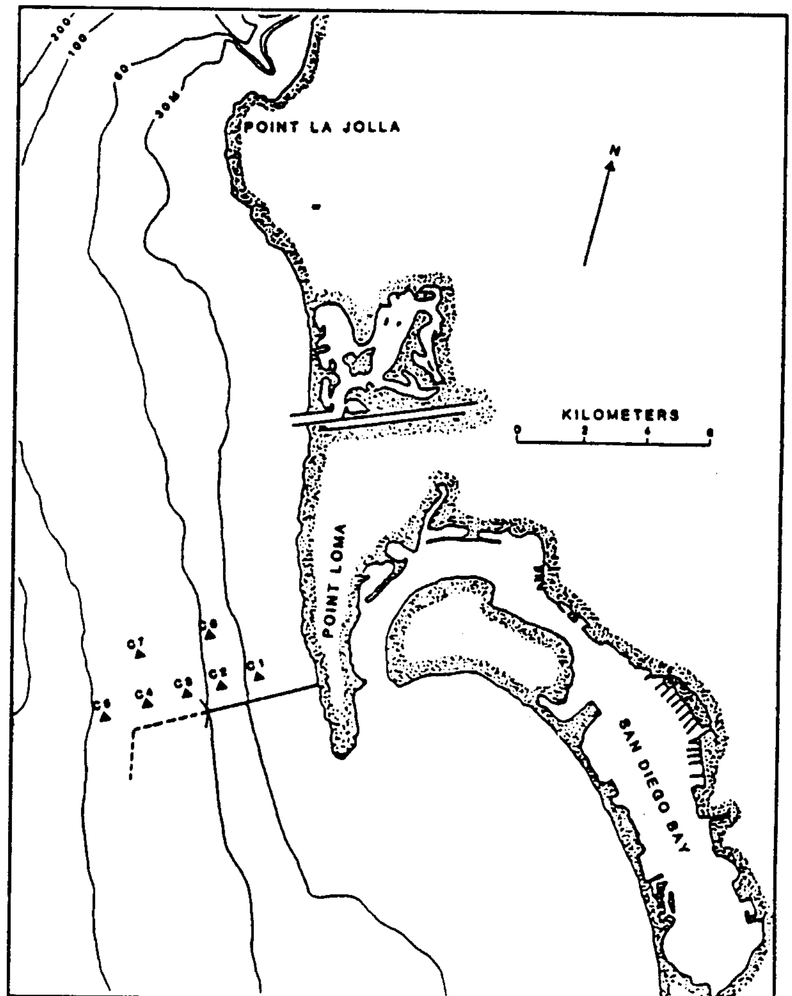

Figure 1
Location of current meter and thermistor moorings (C1-C7) off Point Loma (adapted from Engineering Science, Inc. 1991). Dashed line is potential outfall extension.

Methods

Engineering Science, Inc. subcontracted with SCCWRP to study the feasibility of the proposed extension. We examined the characteristics of water column density stratification and the properties of currents with current meter and thermistor data collected by Engineering Science. The data were collected between March and September 1990 near the Point Loma outfall (Figure 1) by 17 current meters on seven moorings and 51 thermistors on 5 moorings (Figure 2; Appendix 1). The results were incorporated into time-dependent models of initial dilution and transport of wastewater by ocean currents (Appendix 2). Analyses of the oceanographic data and formulation of the simulation models are discussed in Hendricks (1990) and Engineering Science (1991).

Two approaches were used in the simulations. The first approach considered isolation provided solely by density stratification of the water column. Density stratification suppresses vertical diffusion and advection, and "traps" the diluted wastewater in the water column. If the submerged wastefield is formed sufficiently deep so that its upper boundary always lies below the bottom of the outer edge of the kelp bed, the wastefield will not intrude into the kelp bed. However, because the ocean is a dynamic environment, it is not sufficient to simply ensure that the top of the wastefield lies below the kelp bed depth at the time of formation. Internal tides, internal waves, and slowly varying changes in density structure of the water column can change the depth of the wastefield after its formation. For example, during simulations of a discharge in deep water, vertical excursions of the wastefield of 10 m were common and occasional excursions of 30 m were observed.

The temperature of ambient water at the top of the wastefield at the time of formation was used as a surrogate indicator of water density. This temperature was compared with water temperature measured at the bottom of the outer edge of the kelp bed at later times. If the kelp bed temperature was warmer than the wastefield indicator temperature, the wastefield would not intrude into the kelp bed. If the kelp bed temperature was colder than the wastefield indicator temperature, density stratification of the water column would not prevent an intrusion. The occurrence of an *actual* intrusion, however, depended on ocean currents between the time the wastewater was discharged and when the *potential* intrusion could occur.

Results and Discussion

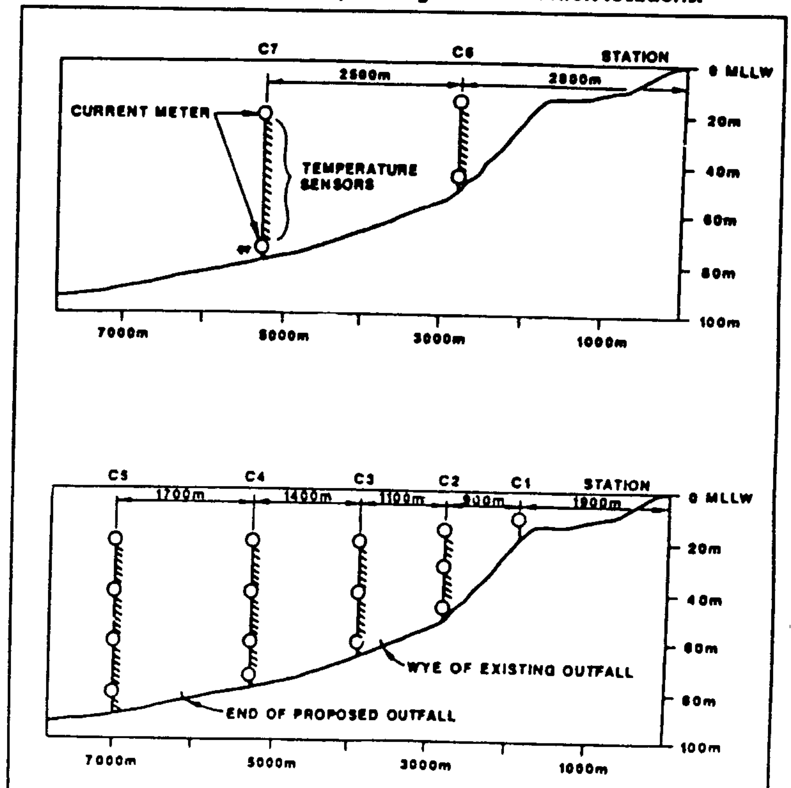
The fraction of time that a "density window" was "open" for potential intrusions was simulated for seven periods for discharge from a line source (0.05 mgd/ft, or 0.007 m^3/sec-m, of diffuser) in 83 and 95 m of water. We assumed that only wastewater discharged within the preceding five days could result in potential intrusions and that wastewater discharged earlier had been carried out of the area.

The density window was open from 18 to 38% of the time in 83 m, and from 4 to 12% of the time in 95 m (Figure 3). We assumed that data from individual moorings could be used to estimate intrusions at locations between, or offshore from, current meter and thermistor moorings. This assumption is supported by the similarity of the curves for the fraction of time the density window was open as a function of discharge depth (Figure 4).

The actual occurrence of an intrusion during an open density window also depends on ocean currents. During the second phase of the modeling effort, we added time-series measurements of ocean currents and water temperature to a data-driven, time-dependent, three-dimensional model of wastewater transport.

Figure 2

Location of current meters and thermistors on the moorings (adapted from Engineering Science, Inc. 1991). See figure 1 for station locations.



The model predicted that wastewater intrusions into the kelp bed would peak at 15% of the time 1 to 2 km upcoast from an outfall in 83 m of water (Figure 5a). Actual intrusions were predicted for about 40% of potential intrusions. The peak probability was reduced to 7.5% of the time 4 km upcoast from an outfall in 95 m of water (Figure 5b). The increased upcoast displacement for the deeper discharge is the result of increased wastefield transport time from the diffuser to the kelp bed. Actual intrusions were predicted for about 60% of potential intrusions.

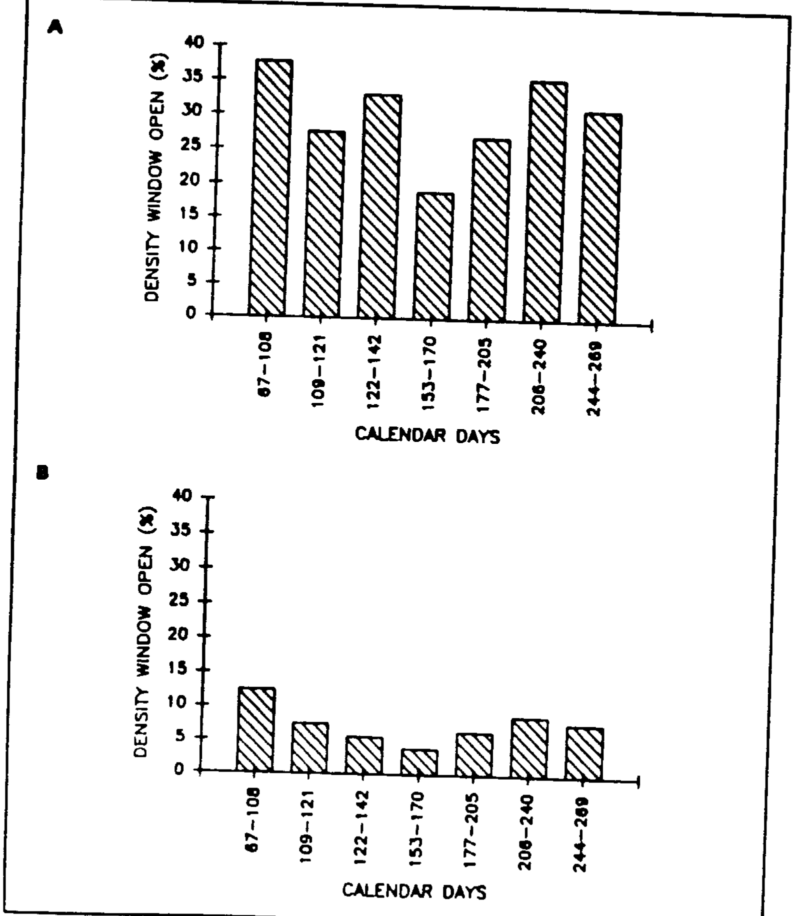
The probability of a potential intrusion leading to an actual intrusion was 50% greater for the deeper discharge, i.e., the effectiveness of transport alone in isolating the wastefield from the kelp bed was *reduced* by extending the outfall farther offshore and into deeper water. This somewhat surprising result is probably due to the formation of a deeper wastefield, which leads to an increase in onshore transport by ocean currents at deeper depths (Appendix 1). However, despite increased onshore transport, extending the outfall farther offshore into deeper water reduced the number of actual intrusions.

Intrusion probabilities are not directly convertible into probabilities of regulatory violations. Bathing water standards for total coliform (TC) bacteria require that concentrations not exceed 1000 TC/100 ml more than 20% of the time within a 30-day period. The probability of exceeding the standard depends on the intrusion probability, the distribution of intrusions in a 30-day period, the concentration of TC within the wastefield, and the number of samples collected during the period. For example, let us assume that intrusions occur randomly with a probability of 0.05 in a 30-day period, and that TC concentrations exceed 1000 TC/100 ml when the wastefield is present. If only four samples are collected during a 30-day period, the probability of exceeding the regulatory standard is 0.18 (roughly one out of every five 30-day periods). If 10 samples are collected, the probability falls to about 0.01 (one out of every 100 30-day periods).

These probability estimates may possess considerable uncertainty, particularly for predictions based on the combination of density stratification and wastewater transport. Results of simulated transport were sensitive to the details of cross-shore transport during upwelling and downwelling, including the details associated with internal tides. These processes are not well understood. For example, a shallower isotherm (an indicator

Figure 3

Percent of time the density window was open for discharges in (a) 83 m and (b) 95 m of water from March to September 1990.



of upwelling) was not always accompanied by onshore flow in waters below that isotherm. This suggests more complex flow patterns for ocean currents than could be resolved from the field measurements.

Similarly, the simulated cross-shore transport associated with a "gravitational collapse" of the wastefield (Wu 1969, Roberts *et al.* 1989a) contributed significantly to onshore transport of wastewater. Gravitational collapse results from relaxation of imbalances between density structures in the wastefield and in the adjacent ambient water, even though average densities in the two regions are equal. However, the measured density stratification in the ocean was much less than in laboratory studies. As a result, frictional effects may be important and the rate of collapse may be much lower than computed in the simulations (e.g., Amen and Maxworthy 1980). In this case, cross-shore transport would be substantially overestimated in the simulation, leading to an overestimate of the intrusion probability.

Estimates based on density considerations are more straight forward and provide an upper bound for intrusion probabilities. The primary uncertainties associated with estimates of potential intrusion probabilities are: 1) changes in the height-of-rise during initial dilution associated with differences between the simulated line-source and the final configuration of the outfall diffuser, 2) lack of oceanographic data for late fall and winter conditions, 3) interannual variability in the oceanographic environment, and 4) neglect of the opposing mechanisms of gravitational collapse of the wastefield and vertical mixing.■

Appendix 1:

Receiving Water Characteristics

Current meter and thermistor data were collected at 30 min intervals between March and October 1990. Fluctuations in the currents and temperature structure of the water column were separated by their temporal properties. A 24.75 hr running-average filter was used to divide the time-series into: 1) net current and current fluctuations that vary more slowly than tidal changes ("subtidal" component) and 2) tidal and higher frequency fluctuations ("tidal" component). Flows associated with subtidal fluctuations were predominantly longshore; the principal axis averaged 351-359° magnetic. Transport associated with tidal fluctuations was roughly isotropic (independent of direction), but with a small longshore enhancement. Transport distances characterizing tidal fluctuations were 1-3 km; distances characterizing subtidal fluctuations were tens of kilometers in the longshore direction.

Net flows at depths greater than 40 m were upcoast and ranged from 1.3 to 4.0 cm/sec depending on the distance offshore. The net flow at 20 m had weaker upcoast transport and ranged from 1.4 to 2.4 cm/sec. Net flows in the cross-shore direction were weakly onshore at a depth of 20 m (-0.1 to 0.8 cm/sec). The tendency for onshore flow increased with depth and peaked at 60 m (0.7 to 1.9 cm/sec). Within a few meters of the bottom, net cross-shore movement was offshore (-0.1 to -1.1 cm/sec).

Although data were collected from a large number of current meters and thermistors, the instruments covered only a fraction of the area around the Point Loma outfall. Previous measurements off San Diego (Hendricks 1977) and 30-80 km upcoast (Winant 1983) indicate coherence length-scales of 30-50 km for the subtidal longshore component of the currents. In this study, the coefficient of determination (r^2) for the subtidal longshore component for moorings 2 km apart ranged from 0.42 to 0.85 (increasing offshore). For vertical separations of 20 m on one mooring, r^2 ranged from 0.35 to 0.79 (increasing offshore). For the longshore component of tidal fluctuations, r^2 ranged from 0.14 to 0.72 for horizontal separations of 2 km, and 0.11 to 0.42 for vertical separations of 20 m on one mooring; r^2 generally increased offshore. The dominant pattern for fluctuations in both frequency ranges was a mode in which changes occurred in the same direction at all depths (barotropic mode).

Correlation length-scales for cross-shore motions were shorter than for longshore motions. In the tidal band, r^2 for horizontal separations of about 2 km typically ranged from 0.16 to 0.66, but fell to 0.003 between the innermost pair of moorings (Figure 1). Cross-shore motions are dominated by top and bottom currents in the opposite direction (baroclinic mode). Coefficients of determination between currents at 20 m and currents near the bottom ranged from 0.07 to 0.23. For fluctuations in the subtidal band, r^2 ranged between 0.13 and 0.62 for cross-shore motions at horizontal separations of about 2 km. For the tidal band, r^2 between the innermost two moorings was 0.03. Coefficients of determination between subtidal fluctuations for a vertical separation of 20 m were 0.01 to 0.14 and the flow tended to be barotropic. The

short correlation length-scales for cross-shore motions illustrate the difficulty and uncertainty in estimating cross-shore transport from the current meter data, especially in view of vertical wastefield excursions associated with internal tides and internal waves.

Fluctuations in water temperatures had longer correlation length-scales than did currents, especially for vertical separations (Figure 6). As a result, we could estimate the position of a segment of the wastefield in the water column from temperature data better than we could estimate the cross-shore transport of the same segment from current measurements.

Appendix 2:

Model Formulation

The first stage of modeling simulated formation of a wastefield in the water column after initial dilution. Simultaneous measurements of water column temperature structure and ocean currents in the entrainment region were used to compute characteristics of the wastefield at 30 min intervals. Of particular significance for the intrusion analysis was estimation of ambient water temperature at the depth of the top of the wastefield.

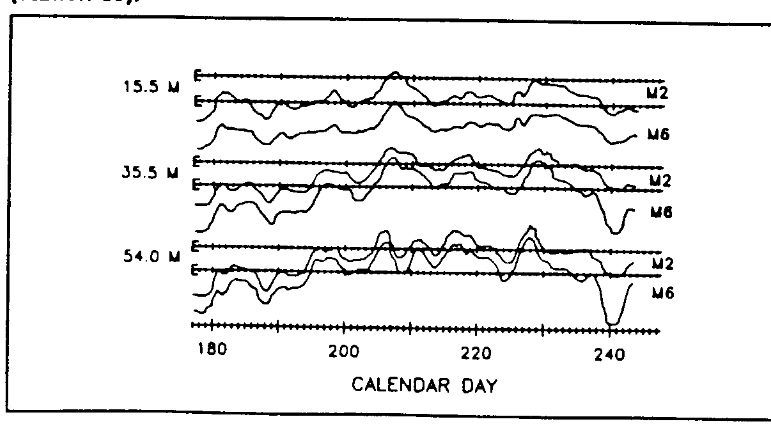
The initial dilution model (TSLINE) was developed from physical model studies by Roberts *et al.* (1989a,b,c), which used a constant density gradient ("linear density profile") in the receiving water. The density gradient in the ocean, however, generally increased with decreasing depth until reaching the pycnocline. The equilibrium depth of the wastefield in the water column was calculated iteratively by assuming a linear density gradient between diffuser port depth and equilibrium depth. The density at each depth was estimated by interpolation from thermistor measurements. Temperature was converted into density using temperature-salinity-density relationships from CTD (conductivity-temperature-depth) data collected on monthly hydrocast surveys.

Once the equilibrium depth of the wastefield was determined, the ambient water temperature at the top of the wastefield ("wastefield temperature") was computed from the average temperature gradient. The depth of the top of the wastefield was estimated using relations in Roberts *et al.* (1989a,b,c) for a line source discharge. In the presence of an increasing temperature gradient with decreasing water depth, the approximations tended to overestimate height-of-rise of the plume, but may have underestimated wastefield temperature.

Ambient water temperature was used as a surrogate indicator of the location of the top of the wastefield in the intrusion analysis and was stored in a time-series (along with other wastefield indicators such as length of each wastefield segment). The wastefield was represented by a collection of individual segments, each of which had a temperature, and hence a position in the water column. At each time step during the *potential* intrusion simulations, the temperature at the bottom of the kelp bed was compared with the temperature of each wastefield segment formed earlier during the simulation. In practice, the comparison was limited to segments formed within the preceding 5 days (earlier segments were assumed to have been carried out of the area). Since the wastefield was either present or absent at a given time, the comparison with wastefield segments for a specific time during the simulation was terminated as soon as a potential intrusion was detected. The probability of a potential intrusion occurring within the simulation area was the total number of potential intrusions during the simulation period divided by the number of time steps during the period.

In the second stage of modeling, the transport of each segment of the wastefield was simulated as it moved away from the diffuser. The first step was to establish the position of each segment in the water column. The cross-shore position at each time step was used to determine the pair of thermistor moorings that bracketed the position. Water temperatures recorded at the two closest thermistor moorings were examined to find the depths that corresponded to wastefield temperature. These depths were used to determine the pair of current meters on each of the two closest moorings that bracketed the depth associated with the wastefield

Figure 6
Temperature fluctuations in the subtidal frequency mode from June to August 1990 at three depths on moorings M2 (Station C2; Figure1) and M6 (Station C6).



temperature. Velocities measured at the pair of moorings were used to estimate the velocity components at the wastefield depth at each mooring. These were interpolated to estimate the velocity at the location of the wastefield segment. This velocity was used to estimate the position of the segment at the beginning of the next time step. This process was repeated for each wastefield segment at each time-step until the segment moved beyond the boundaries of the simulation area (16 km upcoast and downcoast from the diffuser), or the current meter data were exhausted. If the segment was transported out of the simulation area, it was removed from further computations.

Since measured flows generally had a net onshore movement, the simulated transport eventually moved a wastefield segment onshore. This cannot occur in the real ocean. To prevent this, the depth and position of each wastefield segment was checked at the end of each time step. If the depth of the segment was greater than the water depth at its predicted location, the segment was in deeper water farther offshore. Therefore, the predicted position of the wastefield segment was moved offshore until its depth was equal to the water depth.

An *actual* intrusion occurred whenever a wastewater segment moved inshore of the 25 m isobath (although kelp beds are absent from some sections of the coast). To calculate intrusion probabilities, the coast was divided into 1 km intervals. The fraction of each coastal interval affected by the intrusion was determined from the longshore position of the segment and segment length. For example, if a 1 km coastal interval was included within a wastefield segment, the probability of an intrusion was unity. If the segment only spanned one-quarter of the coastal interval, the intrusion probability was 0.25. The probability of an intrusion within a coastal interval at any given time in the simulation was equal to the sum of the probabilities associated with each wastefield segment at that time. The intrusion probability for the coastal interval for an entire simulation period was equal to the sum of the probabilities for each computation time divided by the number of these times during the period.

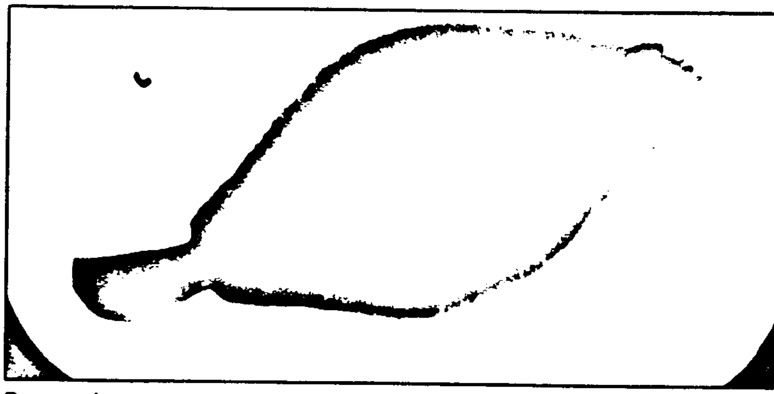
Response of Dover Sole to Termination of Sludge Discharge in Santa Monica Bay

Dover sole *(Microstomus pacificus)* commonly occur on the upper slope off Southern California at depths to about 1000 m (Allen and Mearns 1976). Most of the fish migrate into shallow water in summer related to feeding and back into deep water in the winter for reproduction (Hagerman 1952).

Dover sole are more abundant near municipal wastewater outfalls and the incidence of fin erosion and epidermal tumors is also higher in these areas (Cross 1985, 1986). Fish in contaminated areas may be more susceptible to these diseases due to elevated body burdens of contaminants, which may interfere with the immune system of the fish.

A major dietary component of Dover sole is polychaetes, especially *Capitella* spp. (Pearcy and Hancock 1978). The high levels of total organic carbon (TOC) in the sediments near the Joint Water Pollution Control Plant (Los Angeles County) outfall support high abundances of deposit feeding polychaetes like *Capitella*, and this probably supports the higher abundance of Dover sole in these areas (Cross *et al.* 1985).

The Hyperion sewage treatment plant terminated discharge of solid waste into the Santa Monica Bay in November 1987. Termination of sludge discharge caused changes in the biology of the macrofauna in the area near the outfall (Thompson 1991). The objective of this study was to examine changes in the abundance of Dover sole as a result of termination of sludge discharge.



Dover sole

Materials and Methods

Biologists from the Environmental Monitoring Division (City of Los Angeles) and SCCWRP collected fish at 12 stations in Santa Monica Bay from July 1986 to August 1990. Fish were collected by dragging a 7.6 m otter trawl for 10 min along a depth isobath at approximately 2 knots. Trawls were made during the summer (Jul-Aug) and winter (Jan-Feb) at two stations at 100 m and two stations at 200 m in each of three zones; there were no trawl collections in winter 1987. Fish were counted, measured (standard length) to the nearest centimeter, and examined for diseases (fin erosion and tumors). The catch was weighed to the nearest 0.1 kg by species.

Raw abundance data were not normally distributed and variances increased with increased means. Log transformation of abundance produced a normal distribution with homogeneous variances. The transformed data were analyzed by analysis of variance for effects of depth (100 and 200 m), season (winter and summer), location relative to the outfall (reference, transition, and contaminated zones), and pre- and post-sludge discharge. Disease incidence and sediment TOC data were transformed with the arcsin. The transformed TOC data were analyzed by analysis of variance for effects of depth, season, location relative to the outfall, and pre- and post-sludge discharge.

Three zones differing in the effect of sludge discharge were identified by benthic macrofauna assemblages: contaminated, transition, and reference. Sediment and infauna samples were collected using a modified Van Veen grab with an area of 0.1 m^2 along the 100 m and 200 m isobaths; two stations at each depth were located in each zone (Thompson 1991).

Results

The abundance of Dover sole in the trawls was significantly affected by season, distance of collection from the outfall (zone), and termination of sludge discharge (Table 1). Dover sole were generally more abundant in the summer (Table 2). Dover sole were most abundant in the contaminated zone near the outfall, least abundant in the reference zone, and intermediate in abundance in the transition zone. The abundance of Dover sole declined after the termination of sludge discharge. There was no significant difference in abundance of fish at 100 m and 200 m.

Epidermal tumors and fin erosion occurred in 5% of all Dover sole collected and the proportion of disease decreased with distance from the sludge outfall (Table 3). The highest incidence of disease occurred among fish collected on the 100 m isobath in the contaminated zone. There was little or no disease among fish collected in the reference and transition zones, although they were significantly different from each other.

Discussion

The seasonal patterns of Dover sole abundance observed in this study are consistent with the seasonal migration patterns of Dover sole reported by others (Hagerman 1952, Cross 1985, Hunter *et al.* 1990). The higher abundance of Dover sole, and the increased prevalence of fin erosion and epidermal tumors, in the contaminated zone near the sludge outfall is similar to the pattern observed among fish collected near the municipal wastewater outfalls on the Palos Verdes Shelf (Cross 1985, 1986). Of the nearly 60 species collected on the Palos Verdes Shelf, Dover sole were the most susceptible to tumors and fin erosion (Cross 1985).

The decrease in Dover sole abundance and disease prevalence after termination of solid waste discharge indicates that benthic conditions are improving near the outfall. The decline in fish abundance may be related to decreased organic content and prey abundance in the sediments. The abundance of Dover sole was correlated with the organic carbon content of the sediments. The concentrations of TOC in surface sediment was significantly higher near the outfall and declined somewhat after termination of solid waste discharge (Table 4). The abundance of polychaetes in grab samples was also correlated with TOC ($r=0.214$, $n=95$, $0.02<p<0.05$). Sediments with high organic content support large populations of deposit feeders such as polychaetes, which are the main prey item of Dover sole (Gabriel and Pearcy 1981, Cross *et al.* 1985).

Further evidence for the link between Dover sole abundance, sediment organic content, and polychaete abundance was observed during an anomalous incident. During the summer of 1989, the abundance of fish at the contaminated stations declined well below abundances recorded in previous summers. By the summer of 1990, abundances had returned to pre-1989 levels. In the summer of 1989, sediment TOC levels and polychaete abundances decreased, and the sand content of the sediments increased, at canyon stations close to the sludge outfall. High down-canyon currents were also measured during this period. These currents may have been responsible for increased levels of sand and decreased levels of TOC in the contaminated zone. Burial of the high organic sediments by shelf sediments entrained in the high currents, or resuspension of the organic material, may have increased the amount of sand and decreased the number of

Table 1

Analysis of variance of Dover sole abundance (log transformed number per 10 min trawl). Main effects are before and after termination of sludge discharge (pre/post), season (winter and summer), zone (contaminated, transition, and reference), and depth of collection (100 and 200 m). Interactions were not significant ($p>0.05$); N = 108, R^2 = 0.585. SS = sum of squares, DF = degrees of freedom, MS = mean square, F = MS main effect/MS error, P = probability.

VOL 12 2 0782

polychaetes. Reduced prey availability may account for the decline in the number of Dover sole collected. By the winter of 1990, the characteristics of the sediments had returned to pre-1989 conditions and the relative abundances of Dover sole and their prey species increased to former levels.

Conclusions

Termination of sludge discharge has significantly changed the marine environment in the area of the sludge outfall in Santa Monica Bay. The decreased incidence of disease in the Dover sole population is a positive sign of improving conditions. This trend of improvement will likely continue in the future. ■

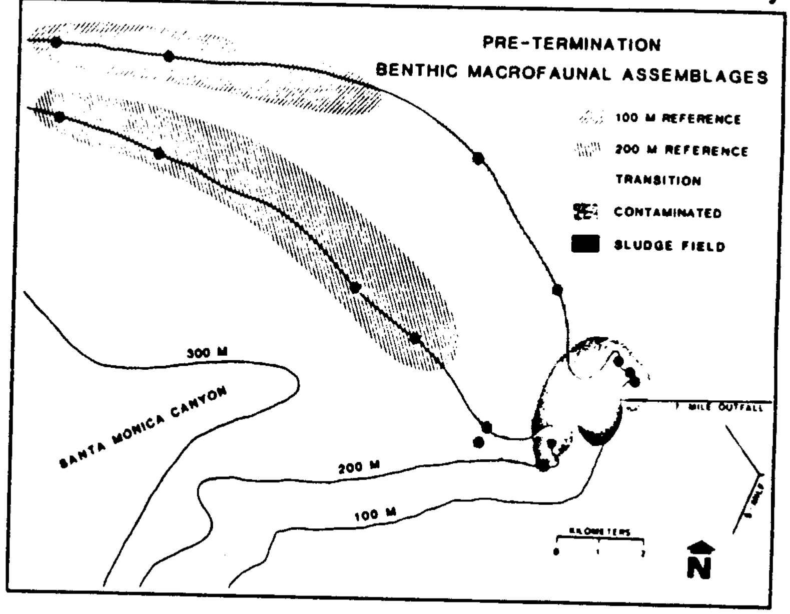
Temporal and Spatial Changes in Sediment Toxicity in Santa Monica Bay

The City of Los Angeles stopped discharging sludge into Santa Monica Bay in November 1987. As a result, the mass emissions of solids and contaminants into the bay have declined substantially (SCCWRP 1989). The effect of this event on the sediment quality and marine life in Santa Monica Bay was examined by SCCWRP from 1986 to 1990 (Thompson 1991).

This report describes the results of one component of the study, sediment toxicity in Santa Monica Bay. The objectives were to document temporal changes in sediment toxicity at the sludge discharge site, and to compare the relative sediment toxicity with the chemical characteristics of the sediments.

Figure 1.
Locations of sampling stations and the Hyperion sludge outfall in Santa Monica Bay.



Methods

Sediment samples were collected from eight stations in Santa Monica Bay (Figure 1). A pair of stations was located in each of four zones characterized by different benthic macrofaunal assemblages: reference (Stations 5 and 6), transition (3 and 4), contaminated (1 and 2), and canyon (sludge field; 50 and 51) (Thompson 1991). All stations, except those in the canyon, were located at a depth of 100 m.

Temporal changes in the toxicity of canyon zone sediments were determined by laboratory tests on samples collected five times between November 1987 and August 1990. Spatial changes in toxicity among the four zones were investigated by laboratory tests with sediments collected in August 1989 and August 1990.

Surface sediment (upper 2 cm) was removed from the Van Veen grab sample, placed in a plastic jar, and stored refrigerated for up to two weeks before the toxicity tests. Short-term (10 days) and long-term (28 days) tests were conducted with the amphipod, *Grandidierella japonica*, using methods described in Nipper *et al.* (1989). Survival was measured in the short-term test, while survival and growth (change in body length per 28 days) were measured in the long-term test. Sediment from the amphipod collection site in Newport Bay was included in each test as a laboratory control.

The stations sampled and the number of replicates varied between collections because of sampling difficulties and limited availability of amphipods. Three replicates of one composite sediment sample from station 50 were tested in 1987 and 1988.

Single grab samples (not replicated) from Stations 1, 2, 4, 5, 6, 50, and 51 were tested in August 1989. Replicate grab samples from stations 50 and 51 were tested in February 1990. Replicate grab samples from stations 1, 2, 3, 4, 5, 6, 50, and 51 were tested in August 1990.

The sediment samples were analyzed for grain size (sand, silt, and clay), total organic carbon (TOC), total nitrogen (TN), dissolved sulfides, cadmium, copper, zinc, silver, DDT, DDE, DDD, Aroclor 1242, Aroclor 1254, hexachlorobenzene, and 22 polynuclear aromatic hydrocarbons (PAHs). Sediment analyses and toxicity tests were conducted on subsamples of sediment from the same grab sample. The chemistry data and analytical methods are found in Anderson *et al.* (1988) for the 1987-88 samples and Thompson (1991) for the 1989-90 samples.

Data for chlorinated hydrocarbons and polynuclear aromatic hydrocarbons were normalized to sediment organic carbon content prior to statistical analyses. Nonionic hydrocarbon concentration data are more highly correlated with biological effects when normalized to organic carbon than when expressed on a dry weight basis (Di Toro *et al.* 1991). Trace metal concentrations, grain size, TOC, and TN were expressed on a dry weight basis.

The data were tested for differences among zones and the laboratory control by single factor analysis of variance and Dunnett's multiple comparison test. The relations between changes in sediment characteristics and toxicity were examined with Spearman rank correlation coefficients.

Results

Temporal Changes in Toxicity

The 10-day survival of amphipods in laboratory control sediment (Newport Bay) varied between experiments, especially in February 1990 (Table 1).

Table 1.
Survival of Grandidierella japonica following 10-day exposure to sediments from the Canyon Zone (Stations 50 and 51) in Santa Monica Bay. Data are mean and one standard deviation (in parentheses). Three samples from each station were analyzed in 1987 and 1988, two samples were analyzed in 1989, and four samples were analyzed in 1990.

	10-Day Survival (%)				Adjusted survival % of control
	Canyon Zone		Lab Control		
Nov. 1987	35	(35)*	92	(7)	38
Apr. 1988	8	(14)*	88	(7)	9
Aug. 1989	90	(0)	98	(4)	92
Feb. 1990	53	(10)	65	(6)	82
Aug. 1990	72	(21)*	94	(6)	76

*Means significantly different from lab control (ANOVA and Dunnett's test, $p<0.05$).

Survival was expressed as percent of the laboratory control to compensate for variability in control survival. The adjusted survival of *G. japonica* doubled between 1988 and 1989 suggesting a dramatic reduction in the toxicity of canyon zone sediment (Table 1). Survival in canyon sediment remained high in subsequent experiments, although survival in the August 1990 experiment was significantly less than the laboratory control.

Spatial Changes in Toxicity

Amphipod growth rates were similar between the 28-day exposures in 1989 and 1990 (Table 2) and were not significantly different among the zones (ANOVA, $p>0.05$). Growth rates in 1990 were less variable among zones than growth rates in 1989. Growth rates were expressed as percent of the laboratory control to compensate for variations between experiments.

Amphipod survival during the 28-day tests was variable and not significantly different among the zones (Table 2). Animals exposed to reference zone sediment in 1990 had the lowest survival, while amphipods exposed to contaminated zone sediment had the highest survival.

Toxicity and Sediment Characteristics

The relation between toxicity and sediment characteristics was examined with the data from five experiments with canyon zone sediments. Correlations and *post hoc* hypotheses were used to identify which of the measured sediment variables corresponded with reductions in toxicity during the course of the study.

Spearman rank correlations were calculated between amphipod toxicity and sediment characteristics (Table 3). We assumed that sediment constituents exerting toxic effects would have negative coefficients; a correlation of -1.0 is the strongest possible relation (i.e., reduced concentration accompanied by increased survival). Organic carbon, organic nitrogen, naphthalene, C1 substituted naphthalenes, and sulfide had high negative correlations. Hexachlorobenzene was the only chlorinated hydrocarbon that was negatively correlated with survival. Correlation coefficients for DDTs and PCBs were positive, indicating that amphipods had higher survival at higher concentrations. Zinc had the largest negative correlation among the trace metals.

In the second analysis, sediment data for the canyon zone were divided into low toxicity samples (1989 and 1990 tests) and high toxicity samples (1987 and 1988 tests) (Table 3). Mean chemical concentrations in the low toxicity group were compared to those in the high toxicity group (hydrocarbons were TOC normalized). We assumed that only contaminants with a substantial concentration reduction from 1987/88 to 1989/90 would have played a role in temporal toxicity changes.

The greatest change between the high and low toxicity groups was the reduction in sulfide concentration (Table 3). Concentrations of anthracene, C2 and C3 substituted phenanthrenes, and perylene declined by more than 50%. Concentrations of 29 of the 36 measured constituents declined

Figure 2.
Scatterplot of Spearman rank correlations and relative concentration change for canyon zone sediments in the 10-day amphipod survival test. The correlations were calculated between toxicity and sediment chemistry. The concentration change compared sediments collected in 1989/90 to sediments collected in 1987/88. Labelled points in the lower left quadrant are the sediment characteristics that had the greatest relation to temporal toxicity changes. C1NAPH = C1 substituted naphthalenes, C1-C3PHEN = C1-C3 substituted phenanthrenes, HCB = hexachlorobenzene, NAPH = naphthalene, PCB42 = Aroclor 1242, PCB54 = Aroclor 1254, PERY = perylene, PPDDD = p,p'DDD, S = dissolved sulfide, TN = total nitrogen, TOC = total organic carbon.

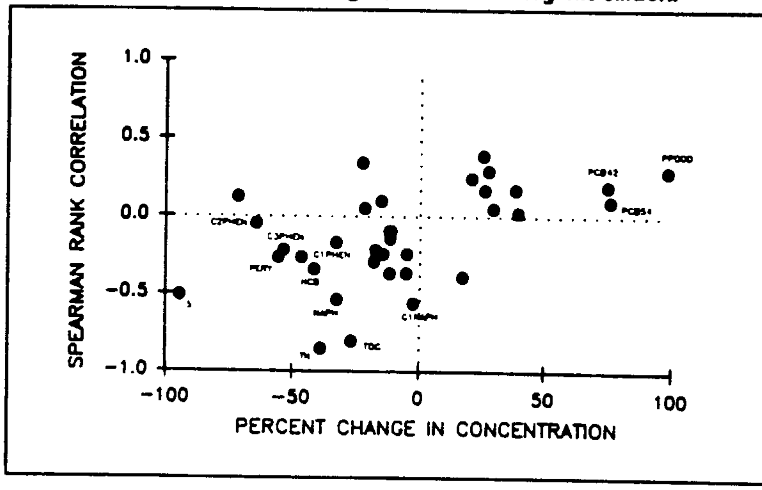


Table 2
Mean growth (mm/28 days) and survival (percent) of Grandidierella japonica following 28-day exposure to sediments from Santa Monica Bay and Newport Bay (laboratory control). N = 2 for each zone in 1989; N = 4 for each zone in 1990 (except transition where N = 2). Data are mean and one standard deviation (in parentheses).

	Growth				Survival			
	mm/28 day		% of control		Percent		% of control	
	1989	1990	1989	1990	1989	1990	1989	1990
Lab control	3.4 (0.1)	2.8 (0.3)	100	100	42 (12)	74 (6)	100	100
Reference	2.2 (0.5)	2.0 (0.8)	65	71	50 (8)	26 (21)	119	35
Transition	2.3 (0.7)	1.6 (0.4)	68	57	20 (19)	31 (29)	48	42
Contaminated	2.9 (0.2)	1.8 (0.4)	85	68	22 (8)	47 (13)	52	64
Canyon	1.8 (0.3)	1.8 (0.4)	53	64	25 (4)	44 (50)	60	59

by less than 25%. The mean concentrations of 16 contaminants, including DDTs, PCBs, and silver, increased.

Ten contaminants had the greatest expected responses (negative correlation and reduced concentration): sulfide, TOC, TN, hexachlorobenzene, naphthalene, C1 substituted naphthalenes, phenanthrene, C2 and C3 substituted phenanthrenes, and perylene (Figure 2). The patterns of change in sulfide and organic enrichment (TOC) at Station 50 matched the temporal change in toxicity (mortality) most closely (Figure 3). The change in TN was similar to that of TOC (data not shown). The concentrations of the hexachlorobenzene, naphthalenes, phenanthrenes, and perylene declined between 1987 and 1988, a period during which amphipod toxicity remained high (Figures 4 and 5).

Figure 3.
Temporal changes in 10-day amphipod (*Grandidierella japonica*) mortality, dissolved sulfide, and sediment TOC for Station 50 (canyon zone).

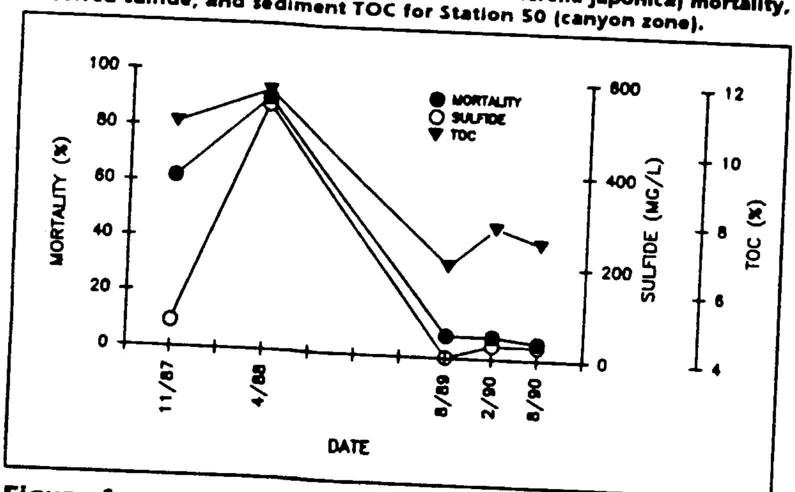

Figure 4.
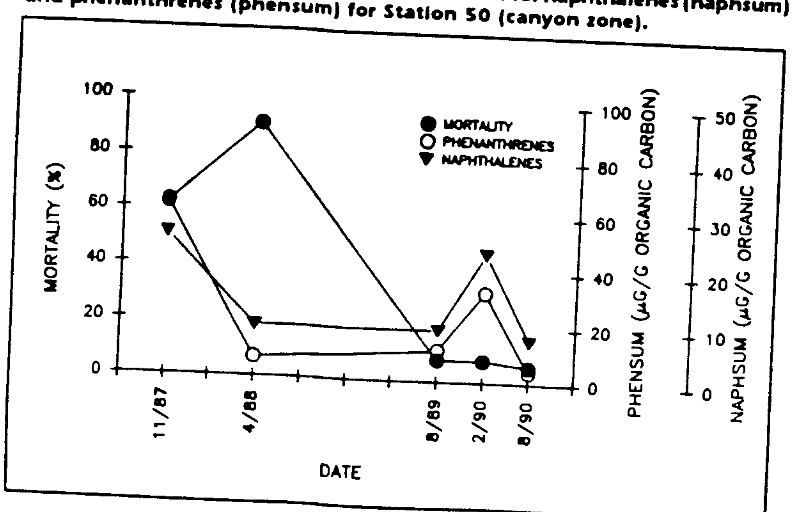
Temporal changes in 10-day amphipod (*Grandidierella japonica*) mortality and the TOC-normalized sediment concentrations for naphthalenes (naphsum) and phenanthrenes (phensum) for Station 50 (canyon zone).



Discussion

Laboratory tests with *Grandidierella japonica* documented: 1) a decrease in the toxicity of sediments in the canyon zone (sludge field) between April 1988 and August 1989, and 2) sediment quality at 100 m in the transition, contaminated, and canyon zones in 1989 and 1990 was similar to sediment quality in the reference zone. The reduction in toxicity of sediments in the sludge field occurred during a period of marked changes in animal species composition and abundance (Thompson 1991). This indicates that laboratory toxicity tests with *G. japonica* included relevant sediment qualities that were important to organisms living in Santa Monica Bay.

Changes in the concentration of hydrogen sulfide, TOC, and TN (sediment characteristics associated with organic enrichment) were strongly related to the changes in toxicity (Table 3). Sea urchins exposed to sulfide at concentrations comparable to those measured in canyon zone sediments suffer reduced growth and increased mortality (Thompson *et al.* 1991).

Naphthalenes, phenanthrenes, perylene, and hexachlorobenzene were identified as potential

Table 3

Changes in Santa Monica Bay canyon sediment characteristics and their correlation (Spearman rank correlation coefficient, r_s) to 10-day amphipod survival. Percent change in sediment concentration is the difference between means of the high toxicity group (Station 50 in 1987 and 1988) and the low toxicity group (Station 50 in 1989 and 1990). Negative change indicates a reduction in concentration from the high to the low toxicity group. Reference concentrations are means for Stations 5 and 6 between 1987 and 1990. Hydrocarbon concentrations are expressed relative to the organic carbon (oc) content of the sediment; remaining sediment constituents are expressed on a dry weight basis.

contributors to reductions in the toxicity of canyon zone sediments. Hexachlorobenzene concentrations, however, were similar in all four zones (Table 3) and were unlikely to have a significant influence on toxicity.

Draft sediment quality criteria have been proposed for phenanthrene based on equilibrium partitioning theory. Concentrations less than 120 μg/g organic carbon (95% confidence limits: 74-340 $\mu g/g_{oc}$) are "protective" of marine benthic organisms. Phenanthrene concentrations in excess of 3,000 $\mu g/g_{oc}$ produce 50% amphipod mortality in spiked sediment experiments (U.S. E.P.A. 1992). The mean phenanthrene sediment concentration in the high toxicity group in this study was 2.2 $\mu g/g_{oc}$, three orders of magnitude below the toxic levels in spiked sediment tests. The combined concentrations of naphthalenes and phenanthrenes in the high toxicity group was 52 $\mu g/g_{oc}$, approximately half of the draft E.P.A. criterion.

It is unlikely that the low molecular weight PAH compounds were the principal factor in the temporal toxicity changes in Santa Monica Bay sediments. These compounds may have contributed to the reductions, but additional laboratory testing with pure chemicals is needed before conclusions can be drawn. Insufficient data were available to evaluate the influence of perylene on toxicity in this study.

The lack of negative correlations between toxicity and DDT and PCB concentrations was not surprising; TOC-normalized concentrations in the canyon zone were similar to concentrations in the reference area (Table 3).

Conclusions

The reductions in sediment toxicity in 1989 and 1990 did not indicate that the effects of sludge discharge had disappeared in Santa Monica Bay. The assemblages of benthic macrofauna in the canyon, contaminated, and transition zones were still adversely affected in 1990 (Thompson 1991) and the concentrations of many contaminants in the canyon zone were 5-10 times higher than in reference areas (Table 3). We do not know if the differences in composition of macrofauna among the zones were caused by toxic sediments, or if they were the product of variables not represented in the toxicity test (e.g., sediment preferences, interactions among species, etc.). In any case, sediment toxicity tests with *G. japonica* were a less sensitive indicator of sediment quality in Santa Monica Bay than the composition of the benthic macrofauna.

Results based on chemical analyses of field sediments are not definitive, but can guide the selection of contaminants for laboratory research. Additional laboratory tests with sediments from Santa Monica Bay are planned to complement the data reported herein. We will use longer exposures to examine effects on reproduction of *G. japonica* and we will examine the effects of organic enrichment and grain size on benthic organisms. This research will provide some of the data needed to determine the relative influence of the various sediment characteristics on the benthic macrofauna in Santa Monica Bay. ■

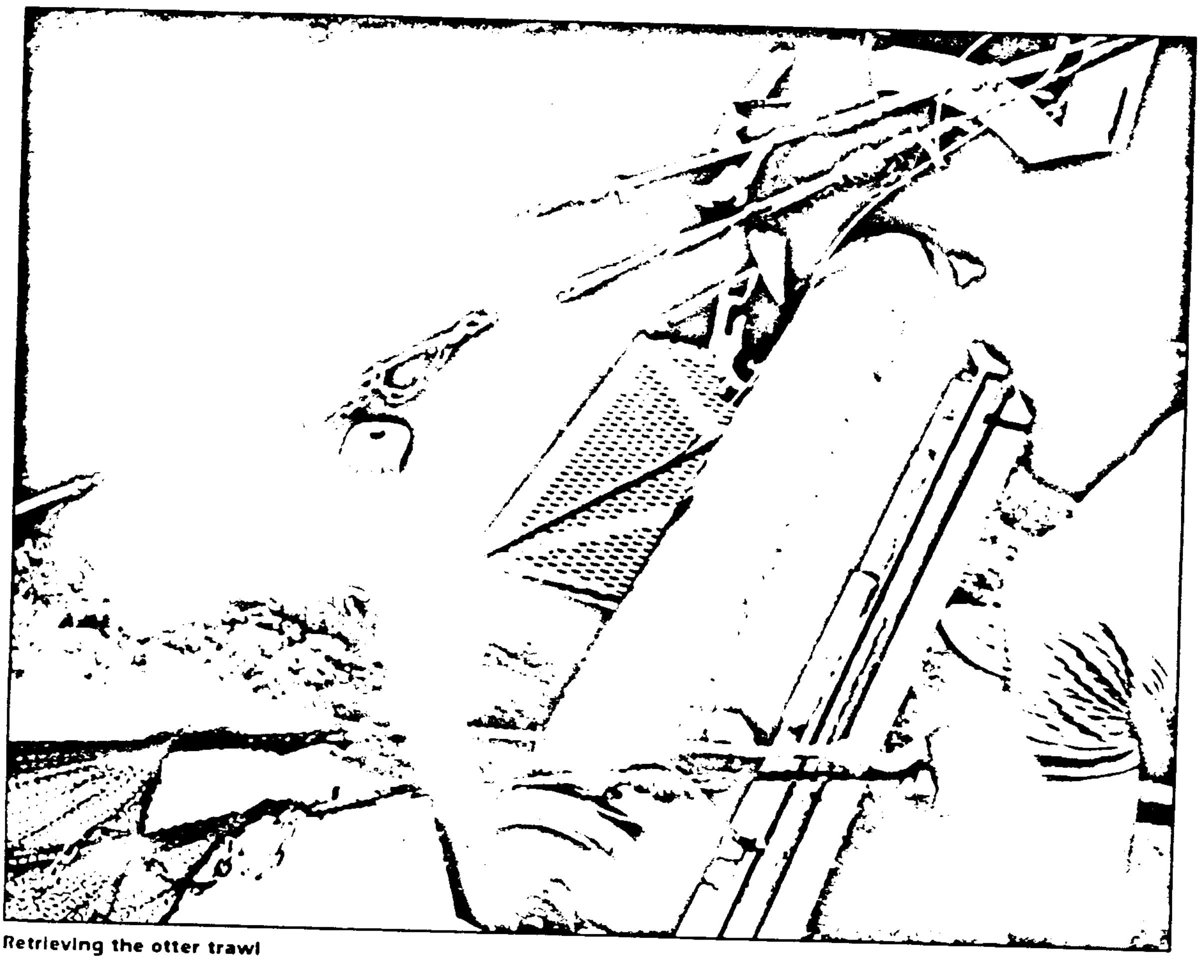
Long-Term Trends in Trawl-Caught Fishes Off Point Loma, San Diego



Retrieving the otter trawl

The mainland shelf off Point Loma is narrow; at roughly 140 m, it drops away into the San Diego Trough. The municipal wastewater outfall for the City of San Diego extends 4 km across the shelf and discharges approximately 256×10^9 L annually (186 mgd) into 60 m of water. Shelf sediments range from sand to sandy-silt; the sand content of the sediments ranges from 37% near the outfall to 52% off Mission Bay (Word and Mearns 1979). Water temperatures are generally cool during the winter and the water column is characterized by weak thermal stratification. Water temperatures are generally warm during the summer and the water column is characterized by strong thermal stratification. Major oceanographic events like El Niño significantly affect water characteristics.

Pacific sanddab, pink surfperch, stripetail rockfish, and longspine combfish were the most abundant fishes collected off Point Loma in the early 1970s (Voglin 1975). Pacific sanddab, English sole, and Dover sole occurred at most stations. Pacific sanddab, white croaker, longfin sanddab, and calico rockfish were the most abundant species at two reference sites near San Diego in 1985 and 1990 (Thompson *et al.* 1987, 1992).

Information on long-term trends in demersal fish populations on the mainland shelf off Southern California is uncommon. Most studies last less then three years (Cross and Allen 1992). The objective of this study was to examine temporal and spatial changes in trawl-caught fishes on the 60 m isobath off Point Loma over a 10-year period. Fish catches were examined in relation to water temperatures.

Materials and Methods

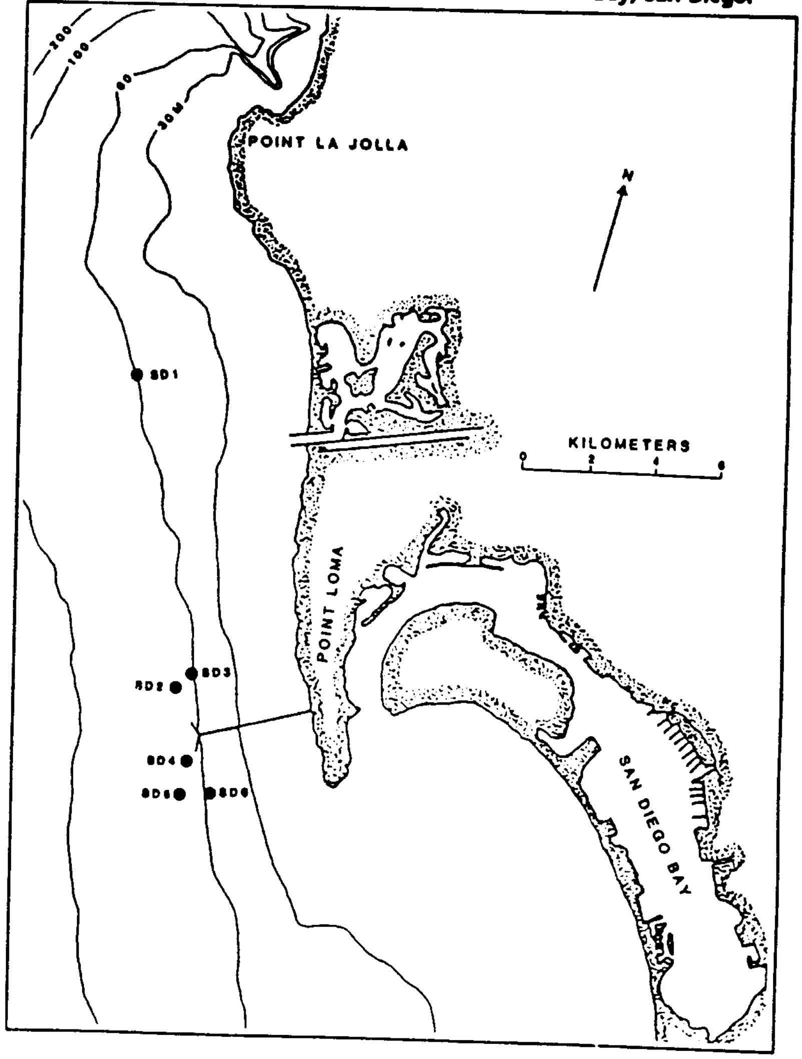
Biologists from the Point Loma Wastewater Treatment Laboratory and SCCWRP collected fishes by otter trawl at six stations off Point Loma near the municipal wastewater outfall for the city of San Diego (Figure 1). Station depths ranged from 55 to 70 m. Sampling began in the summer of 1982 and usually occurred in January (winter) and June (summer). From 1982 and 1992, 120 trawls were made.

One 10-min tow using a 7.6 m (headrope length) otter trawl was made at each station at a scope ratio (towing cable length versus water depth) of 3:1 (Word and Mearns 1979). When more then one trawl was made, the first one was used in the analyses. Vessel speed was approximately 2 knots and roughly 0.7 km were trawled at each station.

All fish in the trawl were identified, counted, measured to the nearest millimeter, and weighed aboard ship. If more than 20 fish of one species were collected, all fish were measured to the nearest centimeter. Unknown fish were returned to the lab and identified to genus and species whenever possible. Fish length data were converted to 1 cm size classes for the analyses.

Temperature data were averaged from four to five Point Loma water quality stations along the 60 m contour. From January 1980 to July 1987, water temperature was measured with a Martec

Figure 1.
Location of trawl stations off Point Loma and Mission Bay, San Diego.



XMS Mark 7. From 1988 on, the water column was profiled with a Seabird CTD (conductivity, temperature, and depth).

The similarity of trawl catches among stations was examined by cluster analysis of abundances standardized to Z-scores. Species occurring in less than 10% of the collections were eliminated. The similarity measure was Euclidean distance and the clustering method was single linkage (nearest neighbor) (Wilkinson 1990). The similarity in species lists was examined with average rank correlations (Mosteller and Rourke 1973) and the relation between trawl catch parameters and temperature was examined with Spearman rank correlations (Zar 1974).

Figure 2.
Mean monthly surface water temperature for 1980 to 1992, and annual deviations from the mean, along the 60 m isobath off Point Loma.

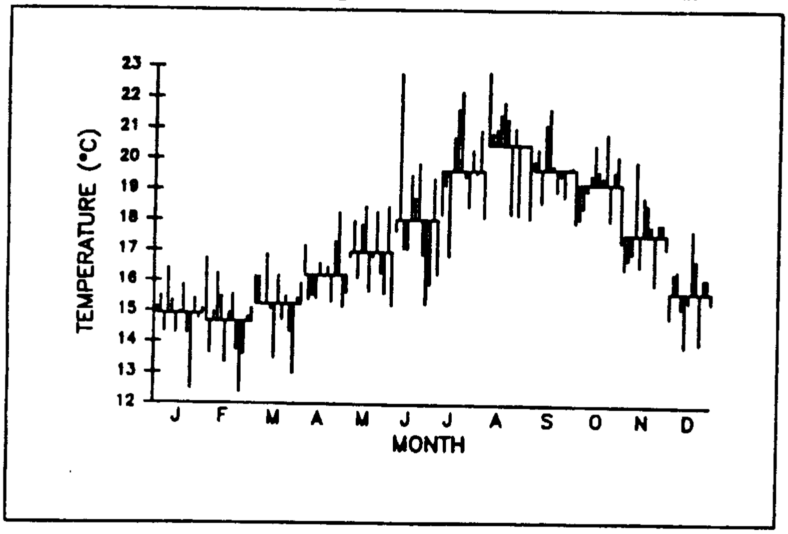


Figure 3.
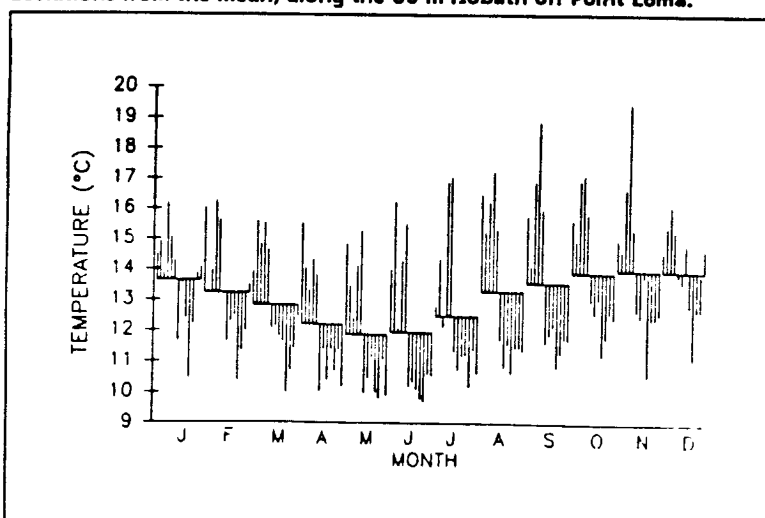
Mean monthly bottom water temperature for 1980 to 1992, and annual deviations from the mean, along the 60 m isobath off Point Loma.



Results

Water temperature

Surface water temperatures were warm during the summer months (June to September) and cool during the winter months (December to February) (Figure 2). During some years, cool temperatures that occurred in May and June were related to upwelling. The water column was weakly stratified in the winter and strongly stratified in the summer. Average bottom temperatures declined after 1984 (Figure 3). The difference between surface and bottom temperatures increased from 1980-84 (0-6.5°C) to 1985-92 (1-11°C).

Trawl catch

Ten years of semi-annual trawling at six stations off Point Loma produced 57 species from 28 families and 26,839 individuals (Table 1). Plainfin midshipman, longspine combfish, yellowchin sculpin, California tonguefish, and longfin sanddab occurred in over 90% of the trawls and accounted for 55% of the individuals collected. The 10 most abundant species accounted for 83% of the fish captured. Two rare fishes were collected in January 1988: spotted batfish and slender snipefish (Miller and Lea 1972).

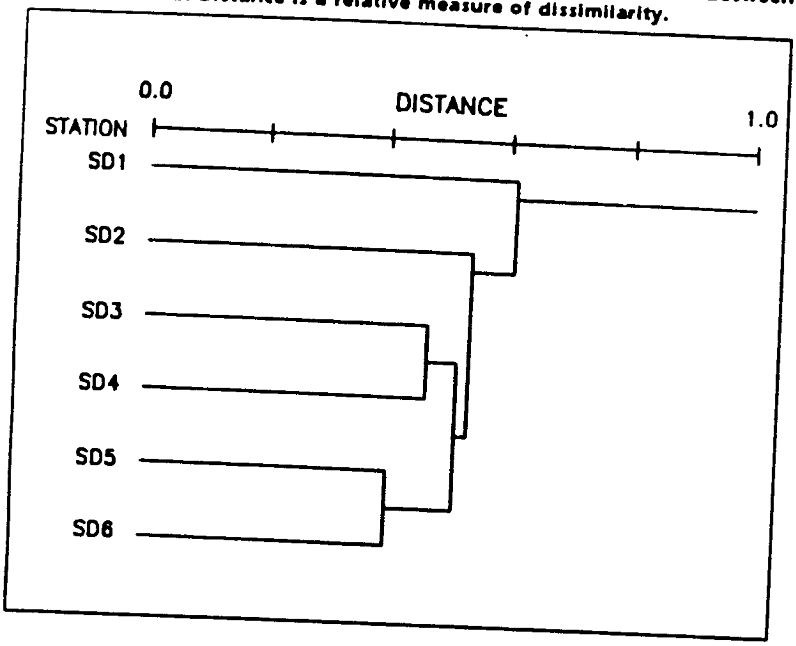
Figure 4.
Tree diagram of relations among trawl stations off Point Loma (SD1 to SD6) based on the composition and abundance of fishes in trawl catches between 1982 and 1992. Distance is a relative measure of dissimilarity.



The composition and rank order of abundance of trawl-caught fishes were similar among the six stations (Table 2). The average rank correlation among the species in Table 2 was 0.64 ($p<0.01$) indicating that the conditions that resulted in their dominance were similar among the stations. The control station (SD1) was the most dissimilar of all the stations, while the downcoast stations (SD5 and SD6) were the most similar (Figure 4). Eliminating SD1 from the calculations only raised the average rank correlation to 0.69.

Trawl catches were the smallest at SD1 (Figure 5). The mean number of species per trawl was 12% lower, the mean number of individuals was 39% lower, and the mean biomass was 60% lower at SD1 compared to the mean for the five remaining stations. The abundance of yellowchin sculpin,

Table 1

List of fish species and numbers collected and percent occurrence (PO) in 120 trawls off Point Loma, San Diego between 1982 and 1992.

Family	Common Name	Scientific Name	Number	PO
Myxinidae	Pacific hagfish	*Eptatretus stoutii*	1	< 1
Squalidae	spiny dogfish	*Squalus acanthias*	6	3
Torpedinidae	Pacific electric ray	*Torpedo californica*	2	2
Rajidae	big skate	*Raja binoculata*	2	2
	California skate	*Raja inornata*	23	17
	longnose skate	*Raja rhina*	3	< 1
	unidentified skate	*Raja* spp.	1	< 1
Myliobatididae	bat ray	*Myliobatus californica*	1	< 1
Chimaeridae	ratfish	*Hydrolagus colliei*	15	7
Engraulididae	northern anchovy	*Engraulis mordax*	4	3
Argentinidae	Pacific argentine	*Argentina sialis*	647	34
Synodontidae	California lizardfish	*Synodus lucioceps*	1,012	68
Batrachoididae	specklefin midshipman	*Porichthys myriaster*	6	2
	plainfin midshipman	*Porichthys notatus*	3,962	92
Ophidiidae	spotted cuskeel	*Chilara taylori*	44	14
Merlucciidae	Pacific hake (whiting)	*Merluccius productus*	1	< 1
Ogcocephalidae	spotted batfish	*Zalieutes elater*	1	< 1
Centriscidae	slender snipefish	*Macrorhamphosus gracilis*	1	< 1
Syngnathidae	kelp pipefish	*Sygnathus californiensis*	1	< 1
Scorpaenidae	scorpionfish	*Scorpaena guttata*	274	48
	bocaccio	*Sebastes paucispinis*	1	< 1
	calico rockfish	*Sebastes dallii*	1,118	63
	cowcod	*Sebastes levis*	1	< 1
	greenblotched rockfish	*Sebastes rosenblatti*	10	6
	greenspotted rockfish	*Sebastes chlorostictus*	1	< 1
	halfbanded rockfish	*Sebastes semicinctus*	42	8
	unidentified rockfish	*Sebastes* spp.	40	17
	splitnose rockfish	*Sebastes diploproa*	1	< 1
	stripetail rockfish	*Sebastes saxicola*	1,444	48
	vermilion rockfish	*Sebastes miniatus*	24	13
Zaniolepididae	longspine combfish	*Zaniolepis latipinnis*	2,701	93
	shortspine combfish	*Zaniolepis frenata*	1	< 1
Hexagrammidae	lingcod	*Ophiodon elongatus*	1	< 1
Cottidae	roughback sculpin	*Chitonotus pugetensis*	106	31
	yellowchin sculpin	*Icelinus quadriseriatus*	2,829	93
Agonidae	pigmy poacher	*Odontopyxis trispinosa*	48	15
Sciaenidae	queenfish	*Seriphus politus*	62	5
	white croaker	*Genyonemus lineatus*	803	33
Embiotocidae	pile surfperch	*Damalichthys vacca*	1	< 1
	pink surfperch	*Zalembius rosaceus*	2,267	74
	shiner surfperch	*Cymatogaster aggregata*	4	3
Uranoscopidae	smooth stargazer	*Kathetostoma averruncus*	8	6
Gobiidae	bay goby	*Lepidogobius lepidus*	354	51
	blackeye goby	*Coryphopterus nicholsii*	1	< 1
	unidentified goby	Gobiidae spp.	1	< 1
Stromateidae	Pacific butterfish	*Peprilus simillimus*	2	2
Cynoglossidae	California tonguefish	*Symphyrus atricauda*	1,670	93
Bothidae	bigmouth sole	*Hippoglossina stomata*	341	76
	fantail sole	*Xystreurys liolepis*	54	26
	gulf sanddab	*Citharichthys fragilis*	63	14
	longfin sanddab	*Citharichthys xanthostigma*	3,687	97

in the 1985 Reference Survey, but common thereafter; 3) English sole, which were abundant in 1975, were rare in both Reference Surveys and the present study; and 4) Pacific argentine were not collected before 1985.

Changes in dominance among trawl-caught fishes are not uncommon in the Southern California Bight. Stripetail rockfish dominated rockfish catches on the mainland shelf throughout the SCB from 1971 to 1975. Significant recruitment occurred in 1971, 1973, and 1975 when average annual water temperatures were 16°C or less. Significant recruitment of calico rockfish occurred in 1975 and 1977 when average annual water temperatures were 17°C or higher. Calico rockfish dominated rockfish catches from 1975 to 1978 (Mearns *et al.* 1980). The ranges of both species extend south to central Baja California, but calico rockfish are rare north of Santa Barbara and sripetail rockfish occur as far north as Alaska (Eschmeyer *et al.* 1983). The switch in dominance from stripetail rockfish to calico rockfish spanned 100 km of coast south of Point Dume and was linked to changing oceanographic conditions.

Bottom water temperatures off San Diego were above the 12 year mean (13.1°C) from 1980 to the end of 1984. The greatest deviations occurred in summer of 1983 coincident with the 1982-1983 El Niño. Trawl catches declined during the El Niño. The mean number of species per trawl declined 16-32% and the mean number of individuals and mean catch weight declined 57-65% over the periods immediately before and after the El Niño (Cross and Allen 1992). Immediately following the El Niño, catches of longfin sanddab, yellowchin sculpin, Dover sole, California lizardfish, and plainfin midshipman increased by 50-75%, while catches of longspine combfish, pink surfperch, calico rockfish, and stripetail rockfish increased by 80-99%. More species of fish were collected when bottom water temperatures were lower. Mearns (1978),

Figure 7

Relation between the mean number of species caught by trawl at all stations on one sampling date (n=6 trawls/date) and bottom water temperature. r_s is Spearman rank correlation.

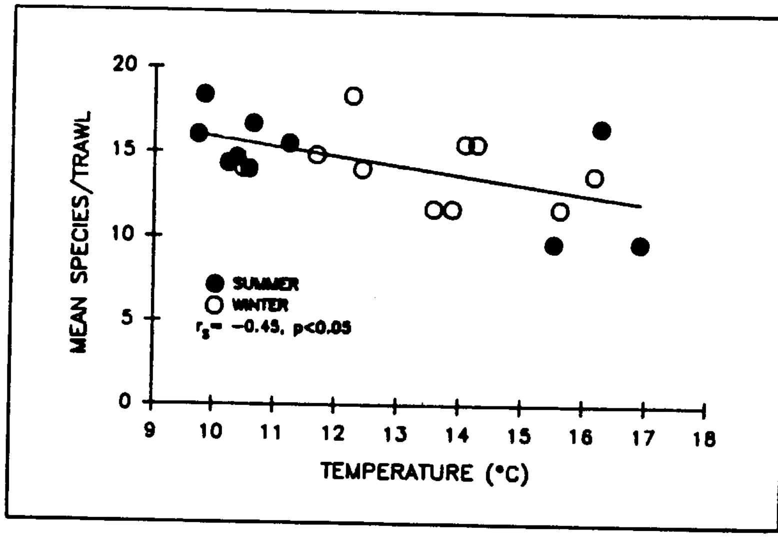

Figure 8

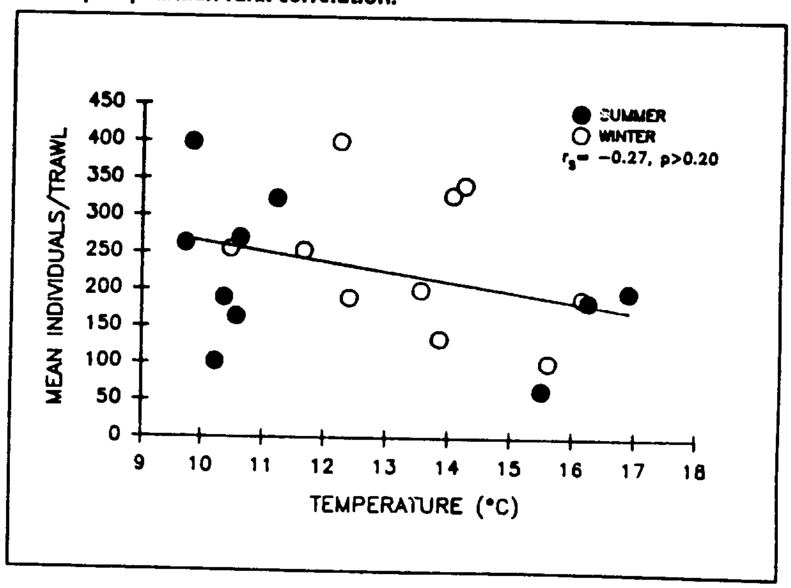
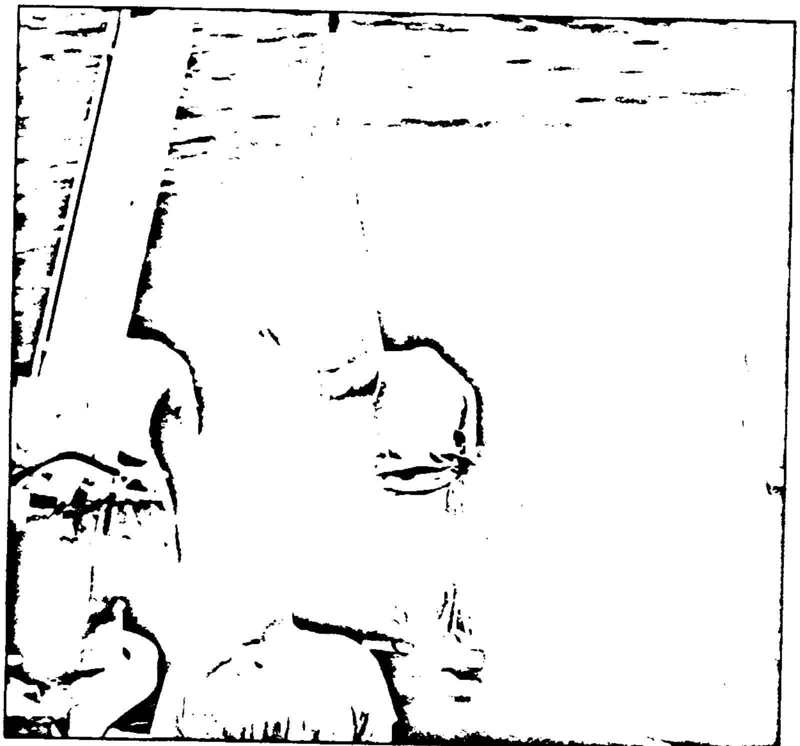
Relation between the mean number of individuals caught by trawl at all stations on one sampling date (n=6 trawls/date) and bottom water temperature. r_s is Spearman rank correlation.





Cod end of otter trawl containing the catch

using surface water temperature, found a similar correlation between trawl catches and water temperature. Many demersal species had poor recruitment during the warm-water years of 1957 to 1959 (Carlisle 1969) and 1974 to 1975 (Allen and Voglin 1976).

Cluster analysis separated the control station (SD1) from the remaining stations based on the composition and abundance of the trawl catches. The control station had the lowest catches of the six stations and lower catches than the 60 m stations in the 1990 Reference Survey (Figure 5). The organic content of sediments off Mission Bay (0.45% total organic carbon) is lower than the organic content of sediments close to the Point Loma outfall (0.54-0.65%) (see *Total Organic Carbon and Total Nitrogen in Marine Sediments, Sediment Trap Particles, Municipal Effluents, and Surface Runoff* in this report). The organic content of sediments close to the outfall was similar to the organic content of sediments collected at 60 m in the 1990 Reference Survey (0.57%; Thompson *et al.* 1992).

Changes in the composition of fish assemblages around some outfalls may be the result of alterations in the sediments caused by the discharge of wastewater solids. Changes in sediment properties, particularly increases in organic content, lead to alteration in benthic invertebrate assemblages. As the infauna changes, so does the assemblage of demersal fishes that prey on them (Cross *et al.* 1985).

Conclusions

The abundance and composition of the trawl catches, as well as the sediment organic content, at stations close to the Point Loma outfall were similar to the values obtained for the 60 m stations in the 1990 Reference Survey (Thompson *et al.* 1992). The control station (SD1) had the lowest trawl catches and sediment organic content. Either the control station is located in an area that is not typical of mainland shelf conditions, or the shelf off San Diego is similar to SD1 and there are not enough data to verify it. The similarity of trawl fish abundance and composition among the six stations, and the similarity in abundance and composition between this study and the 1990 Reference Survey, suggest that the effects of wastewater discharge on the fish assemblage off Point Loma are minimal.

It is not surprising that the fish assemblage off Point Loma responds to oceanographic events such as El Niño. The coupling of environmental changes and biological responses underscores the importance of long-term data collection (Wolfe *et al.* 1987). The data generated by monitoring programs should be adequate to differentiate between the natural variability of the biota and anthropogenic impacts on the biota (e.g., Stull *et al.* 1987). ■

Acknowledgements

Author Dario Diehl thanks Harold Stubbs for his hard work and many years of invaluable logistic coordination and ship navigation. He also thanks Tim Rothans, Lori Vereker, and all the past and present biologists from the Point Loma Treatment Plant for collecting the data. Lastly, he thanks Jeff Cross for his patience, persistence, and guidance.

1990 Reference Survey

Longspine combfish

We recently completed the third survey of chemical and biological conditions in reference areas on the mainland shelf off Southern California. Seven stations from the 60 m Survey (Word and Mearns 1979) and 1985 Reference Survey (Thompson *et al.* 1987) were sampled in July and August 1990. The objective was to provide estimates of sediment characteristics, contaminant levels, and biological conditions from the least impacted areas on the mainland shelf. A detailed account of sampling protocols, analytical methods, and the results are available as a SCCWRP Technical Report (Thompson *et al.* 1992).

Materials and Methods

Field Collections

Sediments, invertebrates, and fish were sampled at 30, 60, and 150 m at each of the seven stations; however, one 30 m station (R61 off La Jolla) had to be abandoned due to the presence of kelp. Water column salinity, temperature, and dissolved oxygen were measured at each station by hydrocast with a SeaBird CTD.

Sediment samples were collected with a 0.10 m^2 chain-rigged Van Veen grab sampler. Subsamples from the top 2 cm of the grab sample were taken with a 26 mm diameter syringe and immediately frozen for laboratory analyses. Macrobenthic infauna were collected from a separate Van Veen grab sample sieved through a 1.0 mm screen. The animals and debris were fixed in 10% borax buffered formalin in seawater, returned to the lab, and transferred to 70% ethanol. The samples were sorted to major taxa and identified to the lowest taxon practical. Megafaunal invertebrates and fish were collected at each station with a 7.6 m otter trawl towed for 10 min along an isobath at approximately 2 knots.

Laboratory Analyses

Total Organic Carbon and Nitrogen.

Sediments were analyzed for total organic carbon (TOC) and total nitrogen (TN) by high temperature (flash) combustion using a Carlo Erba EA1108 elemental analyzer (methods are detailed in *Total Organic Carbon and Total Nitrogen in Marine Sediments, Sediment Trap Particles, Municipal Effluents, and Surface Runoff* in this report).

Sand, Silt, Clay.

Sediment samples were homogenized, organic material was digested with 10% hydrogen peroxide, and the sample was wet sieved through a 63 µm stainless steel sieve. The sand fraction retained on the screen was dried and the sieving repeated. Particles that passed through the sieve were dried and added to the silt fraction. The sand fraction was weighed.

The silt/clay fraction that passed through the sieve was transferred to a 1000 ml graduated cylinder. After 24 hr, the water was decanted into 500 ml polypropylene bottles and centrifuged for 20 min at 1000 RPM. The water was siphoned from the centrifuge bottles and the residue was washed back into the graduated cylinder. Twenty-five ml of 1% Calgon solution were added to the silt/clay fraction to prevent flocculates and the sample was adjusted to 1000 ml with distilled H_2O and vigorously mixed. A 25 ml sample was drawn 20 cm from the top 20 sec after mixing (=silt fraction). The sample and pipet were rinsed with distilled water into an aluminum dish. A 25 ml sample was taken from a depth of 5 cm at the times tabulated by Plumb (1981) and transferred to an aluminum dish (=clay fraction). The samples were dried and weighed, and the weights were corrected for the addition of Calgon.

Trace Metals.

Sediments were analyzed for silver, cadmium, chromium, copper, nickel, lead, zinc, iron, and manganese by Global Geochemistry Corp. of Canoga Park, California. Wet sediment was digested in nitric acid and hydrogen peroxide. The digestate was then refluxed with either nitric acid or hydrochloric acid and then diluted to a volume of 50 ml (EPA procedure SW 846 3050). Percent moisture was determined on a separate sample. Digestates were analyzed on an inductively coupled plasma emission spectrometer (Baird simultaneous PST installed with 27 element channels). Concentrations were determined by comparison with standards. Samples were spiked after digestion and recoveries were used to correct data affected by the sample matrix.

Trace Organics.

Polynuclear aromatic hydrocarbons (PAHs) and chlorinated hydrocarbons (CHCs) were analyzed by Global Geochemistry Corp. Extraction and clean up of sediment samples were conducted according to modified SCCWRP methods (Eganhouse *et al.* 1990). Wet sediment was extracted three times with methylene chloride by sonication for 30 min. The combined extracts were concentrated and cleaned up on a silica gel column. The PAHs were analyzed on an Incos 50 GC-MS by a modified EPA 8270 method. The CHCs were analyzed on a Varian 3700 GC with an ECD. The DDT compounds (o, p'-DDE, p,p'-DDE, o. p'-DDT, and p, p'-DDT) and the Arochlors (1242 and 1254) were quantified by the internal standard method with PCB congener 207 (Ballschmiter and Zell 1980). One peak was used for quantitation of 1242 and two peaks for 1254 (Eganhouse and Gossett 1991).

VOL 12

2080

Statistical Analyses

The contaminant concentrations and biological variables (species, individuals, and biomass) were tested for differences among groups of stations, depths, and surveys by one-way analysis of variance (ANOVA) and the HSD multiple comparisons test (Tukey 1951). The patterns in species composition among the stations were examined using classification analysis of species abundance data (Clifford and Stephenson 1975). Proportion data were arcsine transformed and abundance data were $\log_{10}$ transformed. A value of 0.5 times the detection limit was used to calculate sample statistics for contaminants with masses below detection limit.

Results

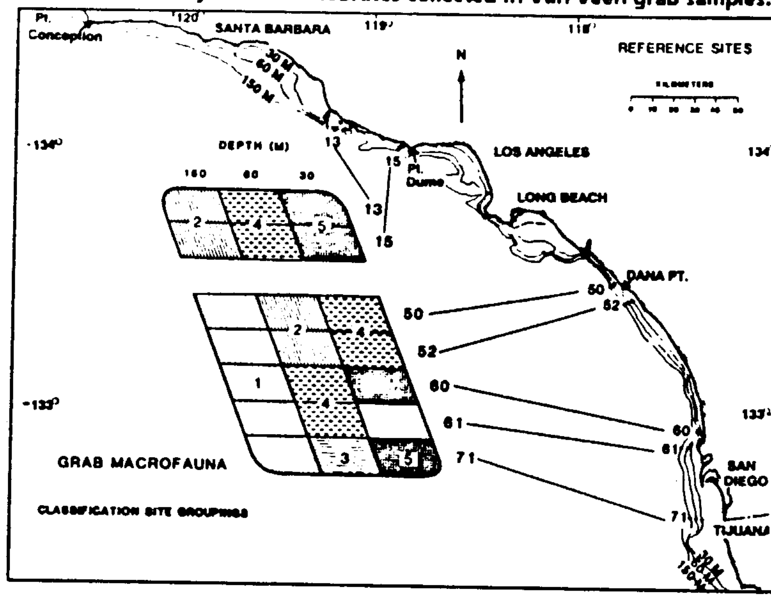
Water column and sediments

Temperatures near the bottom ranged between 9.9° and 13.8°C. Salinities ranged between 33.2 and 33.8 ppt. The lowest salinities were measured at the head of the La Jolla submarine canyon. Dissolved oxygen concentrations ranged between 3.1 and 9.0 mg/L. Temperature and dissolved oxygen were generally lowest at the 150 m stations and highest at the 30 m stations.

Shelf sediments were predominantly sandy-silt. As water depth increased, the amount of sand in the sediments decreased and the amount of clay increased, except off Imperial Beach where sand increased in deep water. Total organic carbon (TOC) ranged from 0.15% to 1.52% and was highly correlated with clay content ($r = 0.786$).

Sediment trace metal concentrations were generally low at all stations (Table 1) and were not significantly different among depths. Total DDT ranged between <0.5 to 39 ppb; concentrations were highest at the northern 60 and 150 m sites. Total PCBs ranged from <5 to 31 ppb; concentrations were highest off Point Dume and Dana Point. Total PAHs ranged from <0.09 to 69 ppb; concentrations were highest off Oxnard. The mean concentrations of trace organic contaminants were not significantly different among depths.

Figure 1.
Distribution of benthic macrofaunal assemblages (site groups) determined by classification analysis of invertebrates collected in Van Veen grab samples.



Macrobenthos

Classification analysis of the macrobenthos (>1 mm) identified five groups of stations (Figure 1; Table 2). Groups 1, 2, and 5 were variations of the *Amphiodia urtica-Spiophanes missionensis* assemblage (Group 4) that inhabits the entire Southern California mainland shelf. The benthos at station R71-60 formed a distinct assemblage. The number of species, number of individuals, and biomass were not significantly different among depths (Table 2).

Two species of amphipods, *Amphideutopus oculatus* and *Ampelisca brevisimulata*, dominated most of the grab samples collected at the 30 m stations. *Amphiodia urtica*, and to a lesser extent the polychaete, *Myriochele* sp. M., dominated samples collected at 60 m. The 150 m stations were dominated by the polychaetes, *Spiophanes fimbriata* and *Myriochele* sp. M, and *Amphiodia urtica*. The station in 60 m of water off Imperial Beach (R71) was dominated by the gastropod, *Micranellum crebricinctum*, and the ostracod, *Euphilomedes carcharodonta*.

Megabenthos

Classification analysis of the large, motile invertebrates (megabenthos) in otter trawl samples identified four groups of stations (Figure 2; Table 3). The asteroid, *Astropecten verrilli*, dominated trawl collections at 30 m, but decreased in abundance with increasing depth. The sea urchin, *Lytechinus pictus*, and the prawn, *Sicyonia ingentis* dominated collections at 60 m. The sea urchins, *Allocentrotus fragilis*, a common slope species, and *Lytechinus pictus* dominated the 150 m stations.

The number of species, individuals, and biomass per trawl were significantly higher at the 60 and 150 m stations compared to the 30 m stations (Table 3). The 60 m stations (Group 2) were inhabited by typical southern California mainland shelf megabenthos. The number of species was similar among the sites. Group 4a resulted from a small trawl catch at Station R52-30.

Demersal Fishes

Classification analysis of the demersal fishes identified three groups of stations (Figure 3; Table 4). The speckled sanddab *(Citharichthys stigmaeus)* and longfin sanddab *(Citharichthys xanthostigma)* dominated trawl catches at the 30 m stations. Pacific sanddab *(Citharichthys sordidus)* and longfin sanddab dominated trawl catches at the 60 m stations. Slender sole *(Eopsetta exilis)* and plainfin midshipman *(Porichthys notatus)* dominated trawl catches at the 150 m stations.

The number of fish species, individuals, and biomass increased with increasing depth

(Table 4). However, due to the variability among stations, there were no significant differences in species or biomass among the depths. The number of individuals was significantly greater at the 150 m stations compared to the 30 m sites.

Discussion

The mainland shelf (30-150 m) was composed primarily of sandy-silt sediments with an average TOC content of about 0.6%. The benthic invertebrates and demersal fishes collected at the 20 stations were typical of Southern California reference areas. Sediments at Station R71-60 contained about 94% sand and the macrofauna was distinct from the remaining stations (Table 2). Water depth and sediment type contribute to the differences among the assemblages identified by classification analysis.

The data from the 1977 60 m Survey (Word and Mearns 1979), the 1985 Reference Survey (Thompson *et al.* 1987), and the present study provide information about long-term temporal variation at reference sites. The chemical methods (sediment extraction and instrumental analysis) differed among the surveys. The number of DDT isomers and PAH compounds quantified changed between surveys. Nevertheless, silver was the only sediment characteristic measured that was significantly different among the three surveys (Table 5).

The same grab and trawl gear and methods were used in the 1977, 1985, and 1990 surveys. The assemblages of macrobenthic

R0054105

and megabenthic invertebrates sampled in 1990 were similar to the assemblages sampled in 1977 and 1985. The macrobenthic grab and megabenthic trawl statistics were highest in 1990, but there were no significant difference among surveys (Table 5). Megabenthic individuals were two orders of magnitude lower in 1985 than in 1977 and 1990. However, due to the large variation within years, the difference was not significant.

The assemblage of demersal fishes sampled in 1990 was similar to assemblages sampled in 1977 and 1985; seven of the ten most frequently occurring species were common to all three surveys. In contrast to the invertebrate data, fish trawl statistics were significantly lower in 1985 (Table 5). This may have resulted from altered environmental conditions following the 1982-83 El Niño and the severe storms in the winter of 1983.

Conclusions

The data collected during this survey complement the 1977 60 m Survey (Word and Mearns 1979) and the 1985 Reference Survey (Thompson *et al.* 1987). The seven reference areas (20 stations) sampled in 1990 were comparable to the major shelf habitats off Southern California and bracketed the major ocean municipal wastewater discharges. This is probably the minimum number of stations needed to describe reference conditions on the mainland shelf. With the renewed interest in bight-wide monitoring (National Research Council 1990), these reference stations could be incorporated into a regional monitoring program for the Southern California Bight. ■

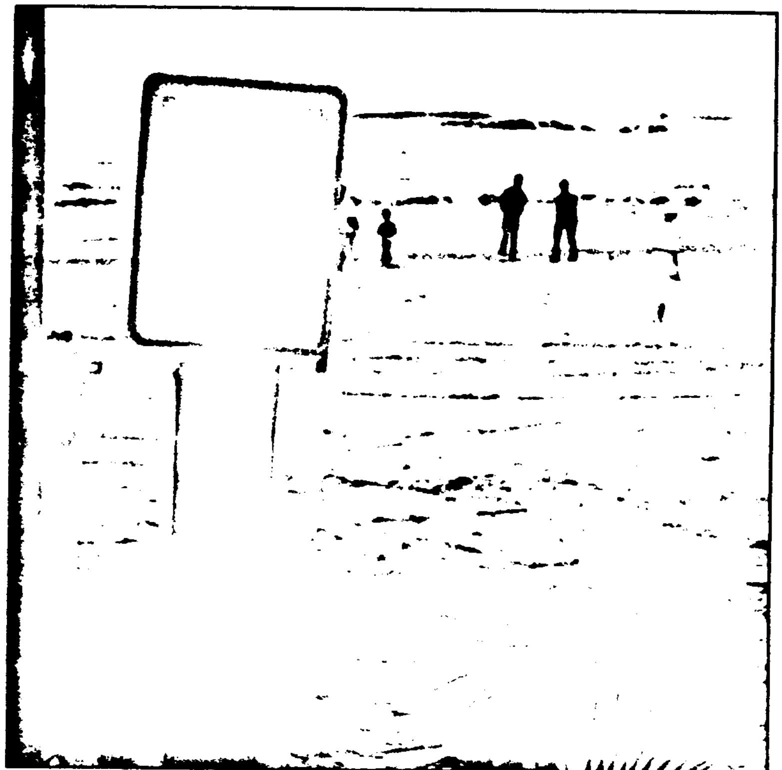
Toxcity of Dry Weather Flow in Ballona Creek

Ballona Creek is one of the few flood control channels that flows throughout the year into Santa Monica Bay. In addition to receiving surface runoff from streets and commercial and industrial properties during storms, Ballona Creek receives discharges from a variety of sources throughout the year (e.g., groundwater pumping and decontamination, swimming pool drainage, and dehumidifier condensate).

Previous studies by SCCWRP measured the chemical composition and toxicity of samples collected from Ballona Creek during storms. The concentrations of oil and grease, cadmium, chromium, copper, and nickel in stormwater samples from Ballona Creek are higher than concentrations in stormwater samples from several other channels in southern California (Schafer and Gossett 1988), and are comparable to concentrations in sewage effluents discharged into Santa Monica Bay. The concentrations of lead, zinc, total DDT, and total PCB in stormwater samples from Ballona Creek are greater than concentrations in sewage effluents discharged into the bay. The toxicity of Ballona Creek stormwater samples is similar to the toxicity of stormwater samples from the Los Angeles River, the largest source of gauged runoff in Southern California (SCCWRP 1989).

Elevated levels of contaminants are also present in Ballona Creek dry weather flow (SCCWRP, unpublished data), but we have not measured the toxicity of dry weather discharge to marine animals. The object of this study was to determine the toxicity of dry weather flow in Ballona Creek to sea urchin gametes and embryos. We compared the sensitivity of the two toxicity tests and examined the variability in toxicity over different temporal scales (hours and months). Sea urchin toxicity tests provide data useful for assessing impacts in the environment because sea urchins inhabit rocky intertidal areas of Santa Monica Bay and their larvae are found in the water column.



Storm drain warning

Materials and Methods Sampling

Three water samples were collected at hourly intervals on the afternoon of December 10, 1990 below the Inglewood Street overpass of Ballona Creek (Figure 1). Samples were collected

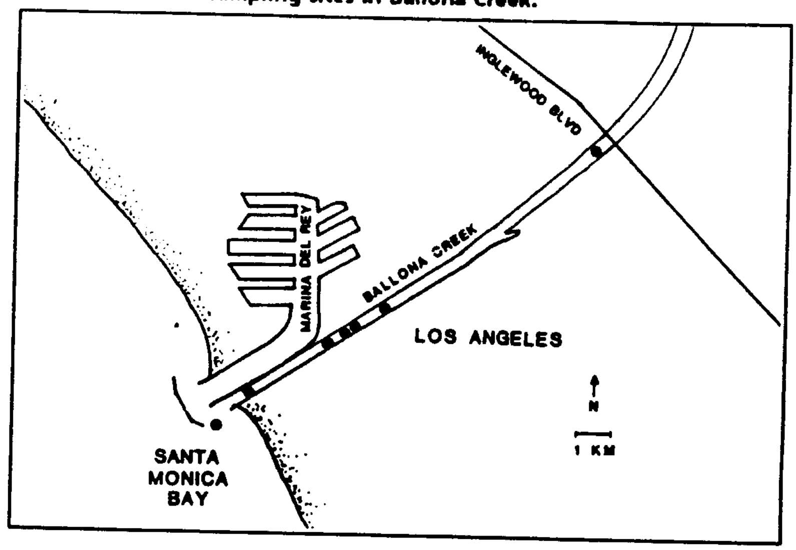
VOL 12 2 0 8 1 0

R0054110

from the center of the channel with a glass bottle. The collection site was above the tidal prism and contained undiluted dry weather flow; samples from this site had a salinity of 0 mg/g. Two additional water samples were collected from this location on February 25, 1991. Sampling in December was preceded by 21 days of dry weather, while sampling in February was preceded by 47 days of dry weather.

Surface water samples from six areas near the mouth of Ballona Creek were also collected on February 25 (Figure 1). These stations were within the mixing zone of Ballona Creek discharge with ocean water. Conductivity measurements indicated that the water samples contained 0-22% creek water.

Figure 1
Location of water sampling sites in Ballona Creek.



Sample preparation

The water samples were stored at 5°C and tested for toxicity within 24 h. Each of the Inglewood Street samples was diluted with filtered natural seawater (34 ppt salinity) to produce concentrations of 2-32% dry weather flow. Dilutions of distilled water with natural seawater were used to test the effects of variable salinities. Receiving water samples from the mouth of Ballona Creek were tested at full strength.

Seawater controls were used to document the health of the test organisms and to provide a reference for identifying toxic effects. We also used a series of reference toxicant dilutions ($CuCl_2 \cdot 2H_2O$ in seawater) in each toxicity test to document relative sensitivity between test dates. The pH of some Ballona Creek samples was adjusted by adding either 0.1 N HCl or 0.1 N NaOH.

Test procedures

Purple sea urchins *(Strongylocentrotus purpuratus)* were collected from the intertidal near Point Dume in northern Santa Monica Bay. The urchins were held in recirculating seawater aquaria at 13-15°C until the tests were performed.

Three or four replicates of each sample were tested for toxicity at 15°C. All samples were tested with the sea urchin fertilization test; one sample from December was also tested with the embryo development test. The fertilization test followed the procedures of Dinnel *et al.* (1987) and consisted of a 60 min exposure of sperm to the test samples. Eggs were then added to the samples and allowed 20 min for fertilization to occur. Preserved samples were examined under a microscope and the percent of eggs fertilized was determined. Reduced fertilization is an indicator of toxic effects.

The embryo development test consisted of a 48 h exposure and followed the procedures described in Long *et al.* (1990). Preserved embryo samples were examined under a microscope to detect developmental abnormalities, indicators of toxic effects. Normal embryos have a pyramid shape, differentiated gut, and well-developed skeletal rods. Abnormal embryos exhibit either a delayed rate of development, or pathological conditions such as aberrant cleavage and cell death.

Statistical significance was determined by analysis of variance and Dunnett's multiple comparison test of the toxicity data (relative to controls). Raw proportion data were transformed by the arcsine for the analyses. The concentration of sample producing the median toxic response (EC50) was estimated using probit analysis.

Results

Relative sensitivity

Dilutions of the December 1990 Ballona Creek sample were toxic to both sea urchin sperm and embryos (Figure 2). The fertilization test was more strongly affected than the development test by sample concentrations of 10% and greater.

Control percent fertilization was high in the December and February sea urchin sperm tests (95-98%; Table 1). There was little variability in toxicity among the Inglewood Street samples, or among samples collected on the same day (Table 1). The February Ballona Creek samples were slightly more toxic (EC50 = 6%) than the December samples (EC50 = 10%).

Results of the copper reference toxicant were similar between experiments (Table 1). The fertilization test in February was slightly more sensitive to copper (EC50 = 13 µg/L) than the fertilization test in December (EC50 = 19 µg/L).

The fertilization test results were unaffected by salinity changes over the range of 28-34 mg/g (Table 1). Large reductions in fertilization were produced by Ballona Creek dry weather flow dilutions with salinities of 30-32 mg/g, well within the range tolerated by the sperm.

The pH of undiluted dry weather flow was unexpectedly high in both sets of samples (pH 10.1). Consequently, the pH of test samples containing more than 5% Ballona Creek effluent was greater than the control (pH = 8.1; Table 1). The effect of pH on fertilization was tested on dilutions of a dry weather flow sample collected in February. The sample pH was adjusted to 8.1, the pH of the dilution seawater. Both the pH-adjusted and non-adjusted samples were toxic (Figure 3). However, the non-adjusted sample produced stronger effects on the sperm. At a concentration of 5.6%, fertilization in the non-adjusted sample was 53%. Fertilization in the adjusted sample was 89%, which was not significantly different from the control (Dunnett's test, $p>0.05$).

Figure 2

Response of sea urchin sperm (fertilization test) and embryos (development test) to various concentrations of Ballona Creek dry weather flow collected in December 1990. Data are mean ± 1 standard error.

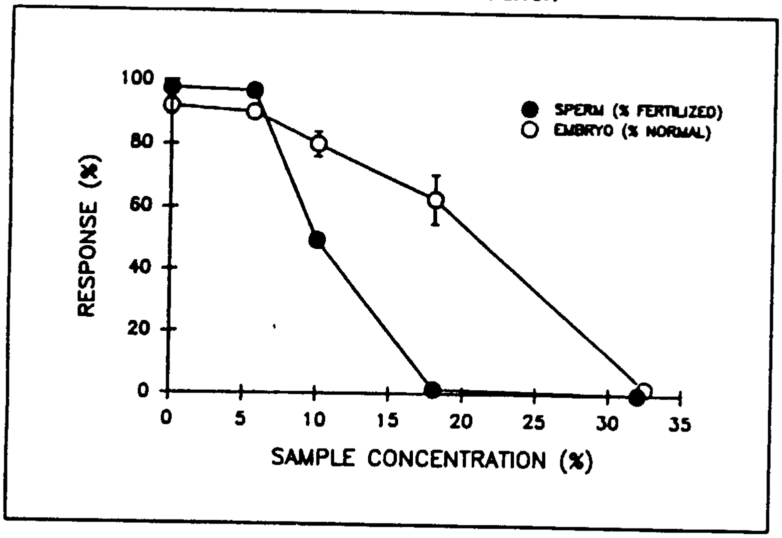


Figure 3

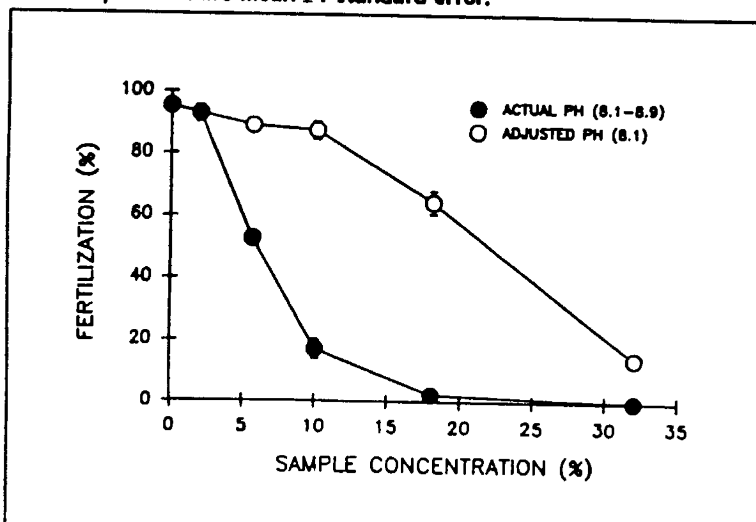
Influence of pH on fertilization test results of a February 1991 dry weather flow sample. Data are mean ± 1 standard error.



Most of the receiving water samples from the mouth of Ballona Creek were toxic to sea urchin sperm (Table 2). High toxicity was present in samples from the upstream and downstream ends of the mixing zone. Samples from the middle of the mixing zone were the least toxic. The pattern of toxicity in Ballona Creek did not correspond to the amount of creek water in the sample; the greatest effects were produced by water samples containing no dry weather flow.

Discussion

Ballona Creek dry weather flow was toxic to sea urchin sperm and embryos at low concentrations. The level of toxicity was similar among samples taken the same day and among samples taken several months apart. The greater toxic effects of the February samples may have been the result of variations in test sensitivity, rather than changes in dry weather flow toxicity. This conclusion is supported by the reference toxicant and salinity control data; tests conducted in February were more sensitive than tests conducted in December.

Variation in sensitivity among tests is an inherent characteristic of most biological test methods. The acceptability of test results is based on the magnitude of sensitivity changes measured by reference toxicants. Results of reference toxicant tests should be interpreted cautiously, however. Variations in sensitivity to one reference toxicant may not be an accurate indicator of overall test performance, unless the reference material possesses the same mode of toxic action and chemical characteristics (e.g., changes in speciation with pH) as the unknown material(s) exerting toxicity in the samples. The differences in sperm sensitivity to copper in this study were relatively small in comparison to other data (SCCWRP 1990) and unlikely to have had a large influence on the results for the Ballona Creek water samples.

Sea urchin fertilization was more sensitive to Ballona Creek water samples than embryo development. The relative sensitivity of these toxicity tests depends on the toxicant(s) present. In this study, elevated pH was responsible for much of the toxicity. Sea urchin sperm are sensitive to pH; fluctuations as small as 0.2 units (e.g., pH 8.2 to 8.4) produce declines in percent fertilization (Bay *et al.* 1992). The embryo development test is similar in sensitivity to the fertilization test for other toxicants (e.g., copper) and is more sensitive in some cases (e.g., ammonia; Bay *et al.* 1992).

Table 1

Water quality characteristics and results of sea urchin fertilization tests of dry weather flow from Ballona Creek at Inglewood Street. Results are also presented for diluted seawater (salinity control) and dissolved copper (reference toxicant) tests. Fertilization (Fert) is mean ± 1SE (N = 3-4). Conc = percent of dry weather flow or distilled water in test sample; Sal = salinity; Rep = replicate sample.

The toxicity detected in Ballona Creek dry weather flow is the result of toxic constituents in addition to altered pH. Salinity variations of 28-34 mg/g did not exert a major influence on test results.

The cause of high pH in Ballona Creek is unknown. None of the NPDES-permitted discharges to the creek has a high pH (S. Birosik, Los Angeles Regional Water Quality Control Board, personal communication). Altered pH may be the result of the normal metabolic activity of algae (uptake of dissolved CO_2 during photosynthesis) lining the concrete channels of the Ballona Creek drainage system. Algal metabolism raises pH in other waterbodies (Lee and Jones-Lee 1991).

The results of the receiving water tests indicated that water quality was reduced near the mouth of Ballona Creek. The spatial pattern of toxicity results suggested that there were upstream (dry weather flow) and downstream (Santa Monica Bay) sources of toxicity. Sources contributing to the toxicity of the receiving water may be contamination from nearby Marina del Rey or the release of toxicants from Ballona Creek sediments into the water.

This is the first of our efforts to understand the biological effects of nonpoint source pollutants on the marine environment. The toxicity of Ballona Creek dry weather flow and the receiving water was comparable to the toxicity of Southern California sewage effluents (SCCWRP 1990), yet much less effort has been expended to study the composition and toxicity of this and other urban drainages. In the future, more intensive studies of the potential effects of discharge from channels like Ballona Creek will be conducted by agencies such as the Santa Monica Bay Restoration Project. ■

CALIFORNIA REGIONAL WATER QUALITY CONTROL BOARD

Resolution No. 89-002

Regional Board Acceptance of Storm Runoff Report

WHEREAS:

1. The Los Angeles Regional Water Quality Control Board and the Southern California Coastal Water Research Project conducted a cooperative study of storm runoff in Los Angeles and Ventura Counties.

2. Pursuant to terms of the cooperative agreement, the Southern California Water Research Project has completed and submitted a final report entitled Storm Runoff in Los Angeles and Ventura Counties.

3. The study provides new information on the contaminant load that enters the coastal waters off Los Angeles and Ventura Counties.

4. A significant reduction in pollutant discharge to coastal waters can be achieved through better management and control of urban runoff.

NOW, THEREFORE, BE IT RESOLVED:

1. That the Regional Board accepts the report, Storm Runoff in Los Angeles and Ventura Counties; and

2. That the report be distributed to all affected agencies and interested parties; and

3. That staff be directed to work with all appropriate agencies to develop an urban runoff management strategy to control pollutant discharges to coastal waters.

I, Robert P. Ghirelli, Executive Officer, do hereby certify that the foregoing is a full, true and correct copy of a resolution adopted by the California Regional Water Quality Control Board, Los Angeles Region, on February 27, 1989.

Robert P. Ghirelli

ROBERT P. GHIRELLI, D.Env.
Executive Officer

SUMMARY

Forty-nine samples of runoff were collected from eight sites in Los Angeles and Ventura Counties on September 23-25, 1986, during the first rain after the dry season. Six sites were near the mouths of major storm channels and three were spread along the Los Angeles River, the largest source of gaged runoff in Southern California. Suspended solids, oil and grease, total extractable organics (TEO), trace metals, DDT, polychlorinated biphenyl compounds (PCBs), polycyclic aromatic hydrocarbons (PAHs), and n-alkanes were measured. Fifteen-minute flow data were obtained for most sites from the county flood control districts. Because the storm was unpredicted and so early in the rain season, samples were not taken as regularly as planned, but low-flow, high-flow, and post high-flow samples were taken at each site.

In general the highest contaminant concentrations occurred near the peak flows and not at the first increase in flow. With few exceptions the highest concentrations appeared at the channels with the greatest flows also making them the greatest sources of contaminant mass emissions.

The two Ventura sites showed minimal increases in flows, probably due to a limited amount of impermeable surface area and the dry status of the soils. The Santa Clara River samples had the highest suspended solids concentrations and DDT levels of any site, but the low volumes produced very low mass emissions.

Accurate flow measurements at the four Los Angeles County sites were obtained only for Ballona Creek and the three sites on the Los Angeles River. There was no gage on the Dominguez Channel and one of two gages required to determine the total flow for the San Gabriel River failed during the storm.

Flows from the Los Angeles River, Ballona Creek and the San Gabriel River were large; each exceeded the daily flow of the largest municipal wastewater treatment plant in the county. The runoff of the Los Angeles River at Willow Street and Ballona Creek had the highest mean concentrations of almost all contaminants. Concentrations of oil and grease, cadmium, chromium, copper, and nickel were similar to Hyperion 1985 five-mile effluent values, while lead, zinc, DDT, and PCB concentrations were higher.

Within the Los Angeles River system, runoff contaminant concentrations increased from the headwaters at Tujunga Wash through the mid-river site at the San Fernando Valley to the mouth near Long Beach. Most contaminants were below detectable limits at Tujunga Wash above any land development.

Downtown Los Angeles and the commercial and industrial area of south Los Angeles County added less than one-half the flow of the upstream drainage but three to five times the mass of contaminants.

Petroleum hydrocarbon characteristics in runoff were not very consistent within or between channels. However gas chromatograms for most samples contained unresolved complex mixtures (UCMs) humps characteristic of crankcase oil inputs. The relative abundances of polycyclic aromatic hydrocarbons (PAHs) in runoff samples at several sites indicated the input of unweathered petroleum and combustion by-products with the latter in greater amounts.

Previous studies found that the mean concentrations of contaminants in the Los Angeles River did not change much between 1971/72 and 1979/80, except for lead and PCBs. Our preliminary results for the Los Angeles River do not indicate much change since 1979 with the exception of a fourfold decrease in DDT concentrations.

INTRODUCTION

This report is the result of a cooperative study with the Los Angeles Regional Water Quality Control Board to measure runoff contaminant concentrations and to estimate mass emissions during storm flow conditions at several important channels in Los Angeles and Ventura Counties. Three to ten samples were taken at each of seven sites (49 samples total) during a 48-h period in order to sample peak and decreasing flow stages. We measured concentrations of suspended solids, percent volatile solids, oil and grease, TEO, cadmium, chromium, copper, nickel, lead, zinc, DDT, DDD, DDE, PCBs, n-alkanes and PAHs in whole water samples. A subset of samples was analyzed for triterpanes and steranes by UCLA. Rainfall and flow data were obtained from the County Flood Control Districts.

Results from a second storm sampled in January 1987 at these sites are not included in this report but will be reported when complete data become available. This study is part of a long-term Southern California Coastal Water Research Project (SCCWRP) program to update and improve past estimates of contaminant inputs to the Southern California Bight. By the summer of 1988 we will have sampled storm runoff from the largest storm channels in four of the coastal counties of Southern California.

Background Studies

Southern California Bight

Beach closures, pelican reproduction failures, fin rot, contaminated fish seizures, and kelp bed disappearances off the Southern California coast have stimulated interest in anthropogenic inputs of contaminants to Southern California coastal waters since the 1960's. Extensive monitoring of trace metals and chlorinated organics in municipal wastewater effluents, the principal source of most anthropogenic contaminants to the Southern California Bight (20, 26), began around 1970 and has expanded through the 1970's and 1980's. By 1985, source control, improved sludge handling, and increased treatment (additional advanced primary and secondary treatment) combined to reduce wastewater emissions significantly. Silver, cadmium, chromium, copper, mercury, nickel, lead, and zinc discharges were an average of 65% lower than peak (mid-1970's) emissions. DDT and PCB discharges were 99 and 90% lower, respectively. These reductions occurred despite increases in population and effluent flows (21). Recently, completed and planned municipal wastewater effluent improvements should continue to reduce outfall inputs while continued population growth and land development have made and will continue to make runoff a more important pollutant source of contaminants than it was 10 years ago.

Studies of contaminants in Southern California runoff are scarce compared with those available for municipal wastewater outfalls. Among possible reasons are (1) no agency has been responsible for storm drain water quality; (2) storm flow (which is responsible for most runoff volume and contaminant emissions) is unpredictable, highly variable and limited to a few months of the year; and (3) representative samples of storm flow are not easily obtained.

One of the first studies to measure runoff impacts in Southern California was conducted by Chen in the early 1970's at Marina del Rey (4). Water and sediment samples were taken from the marina near two storm drains and Ballona Creek over several stormy periods. It was determined that storm runoff had little direct effect on trace metal and pesticide levels in the water column within the marina. In contrast, sediments near the runoff channels were highly contaminated; sediments near the storm drains with DDE levels up to 5.5 mg/dry kg were 60 times more contaminated than sediments near the Hyperion five-mile outfall.

The most detailed and complete study of runoff emissions was conducted by SCCWRP during 1971/72, an unusually dry year (43% of average annual runoff). Wet and dry weather flows were sampled at four major rivers, and dry flow was sampled at an additional 11 streams in Southern California (20). Based on this limited survey it was concluded that the contribution of contaminants via runoff was less than 10% of that discharged by municipal outfalls in southern California. Exceptions to this generalization included suspended solids, nitrate, nitrogen, iron, manganese, lead, and cobalt. Two contaminants of note were suspended solids (274,000 metric tons, 99% of effluent emissions) and lead (90 metric tons, 43% of effluent emissions). DDT (0.12 metric tons) and PCB (0.25 metric tons) emissions were about 1 and 3%, respectively, of the combined outfall values.

Using the same sampling technique, Young et al. (25) repeated a similar study of three storms at the largest source of runoff in Southern California, the Los Angeles River (30% of the total average annual gaged flow from Southern California) in 1979/80. In that year low flow was responsible for only 5% of the annual discharge, and low-flow contaminant concentrations were approximately one-half of the storm concentrations. This indicates that storm runoff was by far the most important source of mass emissions. The 1979/80 study and the 1971/72 study also showed that with the exception of nickel, 88-99% of the trace metal and chlorinated hydrocarbons were associated with particulates (>0.4 m). A comparison of flow-proportioned mean concentrations of 10 trace metals, DDT, and PCBs between two storms in 1971/72 and three storms in 1979/80 showed that the standard error of 10 of the 12 contaminants was less than 50% (six of the twelve were less than 20%). This suggests that there was not a large difference in mean concentration values between years. Differences in lead and PCB concentrations were much larger than those of the other contaminants, and mean concentrations (between 1971/72 and 1979/80) showed a six- and eightfold reduction, respectively. These reductions were most likely due to legal restrictions on the industrial use of both compounds.

The Los Angeles County Flood Control District (now called the Department of Public Works) has conducted detailed monitoring of storm channel contaminants since the late 1960's. Monthly samples from 30 channel sites were collected from 1967 through 1984 (5). Biochemical oxygen demand (BOD) and levels of oil and grease, nutrients, trace metals, pesticides, and bacteria were measured (5). In 1985, the monthly monitoring program was reduced to 7 stations plus 14 additional stations monitored bimonthly or quarterly and 15 stations sampled twice annually during storm flows (6). Although this is the largest storm channel data base for Southern California and may reveal trends in low flow concentrations, it was not designed for the estimation of mass emissions because corresponding flows have not been recorded. In addition, runoff was rarely sampled during peak flows when

VOL 12

2 0 8 3 1

VOL 12

20832

concentrations are most variable and emissions are most significant. Despite limitations of this data set, Garber (12) has made some preliminary estimates of long-term emissions rates to Santa Monica Bay. He used the annual average concentrations from Flood Control contaminant data and annual flow measurements from four gaged channels and assumed individual storm drains contribute about 40% of the gaged runoff. The single greatest cause of variation in annual emissions is variation in annual water discharge volume.

Figures 1 and 2 show the annual flow and lead emissions between 1967 and 1982 for the Los Angeles River, the total runoff to Santa Monica Bay, and the Hyperion combined outfalls. From the available data, Garber (12) estimated that Santa Monica Bay runoff inputs (1967-1982) of lead, selenium, nickel, copper, mercury, chromium, and total identifiable hydrocarbons to be 40%, 17%, 14%, 6%, 52%, 9%, and 7%, respectively, of the 1987 emissions from Hyperion's two outfalls. These estimates are probably low because storm conditions (which normally lead to much higher contaminant concentrations) were not proportionally sampled. As of the end of 1987 the sludge outfall discharges have been terminated reducing many outfall contaminant inputs by 50% and further increasing the importance of runoff as a source of contaminants.

The Pico-Kenter storm drain in Santa Monica delivered a small but regular flow that accumulated on the beach. This site has been the focus of attention because of petroleum-like discharges that have closed the beach and because of high incidences of cancer in lifeguards who have worked in the area (7). The linkage of storm drain constituents to the incidences of cancer has been investigated (and discounted) and chemical values (nutrients, BOD, chemical oxygen demand (COD), oil and grease, phenols, cyanide, and 14 metals) have been reported (7). Estimates of mass emissions have been made by using Pico-Kenter contaminant data and County Flood Control flow data for all of Santa Monica Bay (18). These calculations estimate that runoff to the bay is responsible for 10% of the oil and grease and 10-50% of the trace metals that the seven-mile sludge line discharged in 1981.

Studies of water and sediment quality in Marina del Rey, the adjacent mouth of Ballona Creek, and storm drains entering the harbor (13) have shown higher levels of contaminants at sites near the storm drains and creek mouth than in the harbor. Elevated contaminant concentrations and reduced dissolved oxygen were detected at most stations after storm runoff. Interestingly, measurements of oil and grease in runoff to Marina del Rey showed no decrease in the concentration ranges through three consecutive storms indicating a large reserve.

Eganhouse and Kaplan (9-11) characterized organics in Los Angeles River water from an early season storm in 1978 and compared constituents and masses of runoff inputs with municipal emissions. They found that 60% of the extractables were petroleum derived, whereas the non-hydrocarbons were mostly biogenic. Although runoff inputs of hydrocarbons were estimated to be one-half of municipal outfall inputs to Southern California, they were estimated to represent 2% of the global inputs from all sources to the ocean.

In 1986 Anderson and Gossett (1) reported on PAHs in marine sediments from the outfall and harbor areas between San Diego and Los Angeles. They found some of the highest levels near the mouths of the Los Angeles River, and the Dominguez Channel and near storm drains in San Diego Bay.

Background Outside Southern California

In comparison to Southern California runoff, the east coast of the United States has been extensively studied (2, 15, 16, 17, 23). There is also considerably more information about sources of contaminants. However, these studies were carried out in areas that receive much more frequent rain than Southern California does, and in most cases rainfall occurs throughout the year with short intervals between runoff events.

In a three-year study of contaminant sources and mass emissions to Narragansett Bay, Hoffman and Quinn (15) determined that runoff was the largest source of petroleum hydrocarbons, high molecular weight PAHs, lead, and zinc to the bay. Municipal outfalls were the major source of low-molecular-weight PAHs. Although highways and industrial areas occupied a relatively small portion of the drainage basin they were important sources because of their very high concentrations. Highways and industrial runoff contained, respectively, 40 and 80 times the petroleum hydrocarbons, 40 and 12 times the copper, 100 and 7 times the lead, and 160 and 15 times the zinc as residential runoff concentrations.

In Richmond, California, Stenstrom et al. (22) measured oil and grease emissions from five different land use areas in a basin that drains into San Francisco Bay. The authors concluded that runoff emissions were an important and growing problem and that 50% of the oil and grease emissions from the studied basin could be eliminated if emissions from industrial and parking facilities (11% of land in the basin) were controlled.

Ebbert and Wagner (8) examined 35 collection sites from eight urban areas throughout the United States, compared rain concentrations of contaminants with runoff concentrations, and found that rain could be a significant source of contaminants. The mean contributions of rain to runoff emissions were 74% for nitrate plus nitrite, 12% for COD, 12% for copper, 6% for lead, and 2% for suspended solids.

Richards and Holloway (19) used Monte Carlo techniques to evaluate the accuracy and precision of tributary load estimates using a 4000 data point sampling set. Hypothetical annual sampling programs with 12 to 600 samples were examined. The results showed that the bias and precision of loading estimates were influenced not only by the frequency and pattern of the sampling plan but also by the size of the drainage basin (smaller channels need more frequent sampling) and the behavior of the constituent measured. Stratified sampling with the bulk of the samples taken during the highest flow will produce the most accurate estimates. Estimates within 20% accuracy are suggested with only a few low flow measurements and careful concentrated sampling during the 2 or 3 greatest flows of the year (24).

OBJECTIVES

The primary objective of this study was to determine the concentrations of contaminants from major runoff sources and to estimate their mass emission rates to the ocean. These data are compared to past estimates of runoff emissions as well as other sources of contamination to the Southern California Bight.

We also determined how the concentration and mass of contaminants varied throughout the storm events to see if significant portions of the mass emissions were concentrated in a small part of the flow. We sampled sites to see how contaminant levels varied with land use. In addition, we measured polycyclic aromatic hydrocarbons (PAH) concentrations for the first time for several channels to determine which compounds were present in Southern California runoff.

METHODS

Six large runoff sources in Ventura and Los Angeles Counties were sampled (Figure 3). Each channel has a unique drainage basin, and most of the channels (Santa Clara River, Calleguas Creek, Los Angeles River, and San Gabriel River) receive wastewater effluent from one or more municipal wastewater treatment plants. This contributes significantly to dry weather flows.

Sampling locations on each channel were selected for the following reasons: (1) to provide safe sampling; (2) to be used under adverse weather conditions; (3) to provide access to the center channel of the flow; and (4) to be downstream from the major sources of runoff contaminants. In an attempt to sample downstream from potential major sources we located three of our stations (Calleguas Creek, Dominguez Channel, and San Gabriel River) in the upper reaches of the tidal prism.

Santa Clara River

The Santa Clara River drains the second largest basin in Southern California (4,200 km^2) and has produced some of the largest peak flows (165,000 cfs) in Southern California's history. However, the flow near the mouth is poorly correlated with natural weather conditions because water is imported from the California Water Project and flow in the upper and middle river is regulated by releases from the dams at Lake Piru, Lake Pyramid, and Lake Casitas. Diversions and groundwater recharge prevent upstream flows from reaching the ocean except during large storms. Even below the last water diversion the dry sandy riverbed is capable of absorbing most of the flow from early season and small storms.

We sampled on the north side of the channel where Highway 101 crosses the river (H on Figure 3). This site is located about 8 km above the mouth of the river, which is at McGrath State Beach. Our site is the last accessible, safe location to sample moderate or high flow conditions. The channel is over 300 ft wide, and the bed is unlined.

Calleguas Creek

Calleguas Creek drains 650 km^2, including the southern part of the Hueneme Plain, and receives secondary effluent discharge from several treatment plants. This sampling site on Highway 1 is in the middle of the tidal prism and above Mugu Lagoon (I on Figure 3). We decided to sample here because it would allow us to obtain runoff from Calleguas Creek as well as Revlon Slough, which also drains a large portion of the Hueneme Plain that is used intensively to grow vegetables and other cash crops. Unfortunately, between the time we selected this site and when it was sampled, the channels were separated and the junction point moved below our site location. Therefore we collected separate samples from only

Calleguas Creek. Flow data were obtained from the Ventura Department of Public Works from their station at Camarillo, which is about 6 km above the sampling site.

Ballona Creek

Ballona Creek drains 232 km^2 of highly urbanized land in West Los Angeles. The main channel is concrete lined. Oil and tar lines on the banks of the channel are evidence of the occasional discharge of petroleum from freeway tanker spills and other sources. Our sampling station (D on Figure 3) is located 4 km above the mouth of the creek, between the entrance to Marina del Rey and the beach at Playa del Rey. The station on the Inglewood Avenue bridge is above tidal influence except during the highest tides; however, we saw no visual or chemical evidence of saltwater intrusion during any sampling period. Flow data were obtained from the Los Angeles County Department of Public Works recording gauge F 38C-R, which is located near Sawtelle Avenue about 1 km above the sampling site.

Dominguez Channel

The Dominguez Channel drains about 100 km^2 of industrial and urban land in south Los Angeles. In the past, the upper reaches received runoff from the Montrose Chemical Plant. This plant was the source of most of the DDT discharged from municipal outfalls or dumped into Southern California marine waters between the late 1940's and mid-1970's (3). The sides of the Dominguez Channel are covered with riprap, and the lower 10 miles are within the tidal prism and continuously filled with water. There is no recording flow gage in the lower reaches of the channel. The sampling site (C on Figure 3) is located on the railroad bridge just south of Anaheim Street, which was as close to the channel's termination in Los Angeles/Long Beach Harbor as possible. Although this sampling site lacked adequate flow data and was in the lowest section of the tidal prism, we decided to sample here because the 5-6 km of channel immediately above this site is lined with oil refineries. In addition, the harbor sediment just below our sampling site has been shown to have very high levels of petroleum hydrocarbons and pesticides (1). Justification for selecting this site comes from its high potential for producing environmentally significant concentrations of contaminants under rapid flow conditions.

Los Angeles River

The Los Angeles river was sampled because it is responsible for about 30% of the total annual gaged runoff from Southern California and it has been studied twice before by using similar techniques. Three sites were selected in an attempt to separate sources of contaminants to the river. The upper river basin is slightly developed, the middle portion drains the San Fernando Valley and is largely residential, while the lower half of the river drainage is more commercial and industrial. The three sites sampled were Big Tujunga Wash (F on Figure 3), Fletcher Avenue Bridge (E on Figure 3), and the Willow Street Bridge (B on Figure 3).

Big Tujunga Wash is one of three major tributaries draining the foothills above Los Angeles. Our sampling site was located below the Big Tujunga Dam which collects runoff from undeveloped steep-sloped hills. Although the flow in this area is small, we decided to sample here because anthropogenic contaminants in this area could only have been deposited by aerial fallout.

The Fletcher Avenue Bridge crosses the Los Angeles River about halfway between the headwaters and the mouth. Drainage above this site is mostly from the suburban San Fernando Valley and the less developed foothills. The Los Angeles County Public Works Department maintains a recording gage that records flow at 15-min intervals at this site.

The Willow Street sampling site is located in Long Beach at the end of the concrete-lined channel about 2 km above the river mouth in Long Beach Harbor. The total area drained above this site is about 3200 km^2. Past flows at this site have reached over 100,000 cfs. This section of the channel receives runoff from downtown Los Angeles and the commercial/industrial developments of east and southeast Los Angeles. The Rio Hondo Channel is approximately 16 km above this site and is capable of transferring water from the San Gabriel River to the Los Angeles River at the discretion of the Public Works Department.

Flow data for the three sites were obtained from the Los Angeles County Department of Public Works for stations F168-R, F57C-R, and F319-R (Figure 3). These are within 1 km of their respective sampling sites.

San Gabriel River

The San Gabriel River drains approximately 1600 km^2, but its discharge to the ocean is relatively small. During low flow and small storm flows much of the upper river water is retained for groundwater recharge. Most of the dry weather flow in the lower river is from advanced wastewater effluents.

We intended to sample two sites on the San Gabriel River; however, the first storm occurred so early in the season that we missed sampling the upper station at San Gabriel Parkway.

The lower San Gabriel River was sampled at College Park, (A on Figure 3), which is about 3 km above the river mouth in Long Beach Harbor. Unfortunately, this site was also located about 1 km below the upper end of the tidal prism. The site was selected because it was the nearest point of access below the confluence of the San Gabriel River and Coyote Creek. Storm flows from Coyote Creek to the San Gabriel River can constitute more than one-half of the total flow. We selected this site under the assumption that any significant flow would flush saltwater out even at the highest tides. However, salinity measurements of a few low flow samples taken at high tide indicated the presence of marine water. Consequently, trace metals were not measured for those samples nor were they included in emission estimates. Two Los Angeles County Department of Public Works flow gages were required to measure the total flow from both channels for our site. Gage F428-R on the San Gabriel River malfunctioned during the storm and no data were collected. Gage F354-R, below Spring Street, measured Coyote Creek flow about 3 km above the sampling site. Mass emission estimates are based only on the Coyote Creek flow.

Samples were collected from the center of flow for each channel by lowering an acid-washed kilned 1-gallon bottle in an epoxy covered metal sampler that was equipped with a horizontal and vertical tail stabilizer that kept the bottle opening facing upstream. The bottles passed through the surface layer uncapped. The sampler was submerged about 0.5 meter below the surface, and was filled in about 90 seconds. The sampler was deployed twice for each sampling period, and the sample was proportionally divided into the sample containers for organics (4 liters), trace metals (1 liter), suspended solids (1 liter), oil and grease (1 liter), and toxicity (20 ml).

Cumulative rainfall data from 17 sites (Table 1) located within the drainage basins that we were studying were collected from Los Angeles County Department of Public Works files.

River Flow Data

Figure 3 shows gaging stations for Los Angeles County. The gages on Ballona Creek, the Los Angeles River, the San Gabriel River, and Coyote Creek can provide flow data at 15-min intervals. Continuous flow data for Calleguas Creek were provided by the Ventura County Department of Public Works. Data for the Santa Clara River flow are based on field crews observations, which we believe to be acceptable since the flow was low and did not change much during the storm.

RESULTS AND DISCUSSION

A complete listing of flow rates, flow volume, interval volume, contaminant concentrations, and mass emissions for each sample is listed in Appendix A.

Differences Between Sites

Mean concentrations

Flow-proportioned mean contaminant concentrations and ranges for eight sites are summarized in Table 2. Histograms of mean concentrations at the sampling sites are shown in Figure 4, A-N.

Suspended solids mean concentrations for seven sites are shown in Figure 4, C. The highest (1250 mg/liter at the Santa Clara River) and lowest (30 mg/liter at Calleguas Creek) concentrations were found in Ventura County. The sites in Los Angeles County ranged between 200 and 750 mg/liter.

The Los Angeles River at the Willow Street site (Figure 4; B, D-H). generally had the highest concentrations of hydrophobic (oil and grease, total extractable organics, PAH, n-alkanes, PCBs, and DDT) contaminants. Exceptions occurred at Ballona Creek, which had 50% more oil and grease and a DDT concentration 4 times that of the Willow Street site, and Santa Clara, which had a DDT concentration 11 times that of the Willow Street site.

The trace metals concentrations (cadmium, chromium, copper, nickel, lead, and zinc) were all highest at Ballona Creek followed by the LA River at Willow (Figure 4, I-N). Concentrations at Tujunga Wash were consistently below detection, while the other sites had roughly equal levels.

Within the LA River system contaminants increased between upper and lower stations. The Willow runoff had about twice the amount of suspended solids as the upper two stations did. Oil and grease and TEO concentrations quadrupled between Tujunga and Fletcher and again between Fletcher and Willow. Metal concentrations were below detection limits at Tujunga, but metal concentrations at Willow were two to four times higher than those at Fletcher (Figure 4, I-N).

Mean concentrations per gram of suspended solid

Past studies have shown that most of the contaminants are associated with suspended particulates (9, 21). We have calculated contaminant concentrations per gram of suspended solid in Table 3 assuming that all of the contaminants are particulate bound. This could be a misleading supposition if contaminant levels are very low and dissolved contaminants constitute a significant percent of the total concentration. However, with this caution in mind Table 3 (and Figure 5, A-L) gives an indication of quality of particulates that may accumulate in sediments or be spread in near-shore waters.

Oil and grease measurements at Tujunga and Santa Clara were an order of magnitude less than at the other sites (Figure 5, A). The four sites with moderate to high flows (Willow, Fletcher, Ballona, and San Gabriel) had similar values between 10.5 and 23.6 mg/g. The very high concentrations at Calleguas Creek were a result of the very low concentrations of suspended solids.

DDT and PCBs had two different patterns (Figure 5, E-F). Santa Clara River and Ballona Creek particulates were more contaminated with DDT than were particulates at the other sites, while PCBs were more uniformly distributed at all sites except Tujunga Wash.

The Los Angeles River and Ballona Creek had much higher concentrations of PAHs and n-alkanes than the other sites.

The trace metals concentrations on suspended solids (Figure 5, G-L) were reasonably uniform at four stations (Willow, Fletcher, Ballona, and San Gabriel), while concentrations of metals at Tujunga and the Santa Clara River were much lower.

Los Angeles River System

Within the Los Angeles River stations, the Tujunga samples had the lowest contaminant concentrations but moderately high suspended solids levels. This resulted in very low concentrations per gram of suspended solid. The trace metals, pesticides, PCBs and PAHs were below detection limits while oil and grease and n-alkanes were 4 and 9 times higher than at mid-river. Concentrations of metals, pesticides and PCB on suspended solids are similar for samples from mid-river (Fletcher) and lower river (Willow). However, the lower river samples are 2 to 9 times high in TEO, PAHs and n-alkanes.

Mass Emissions

Calculated flow-proportioned mass emissions are listed in Table 4 and shown in Figure 6, A-N.

The Los Angeles River is the largest source of runoff to the Southern California Bight. The highest flows combined with the high concentrations caused the Willow Street site to have the highest mass emissions of all constituents except DDT.

For all constituents except DDT there is a consistent pattern of greatest emissions coming from the Los Angeles River, then Ballona Creek followed by Fletcher and San Gabriel. The remaining stations have minimal inputs.

Within the LA River stations, Tujunga emits a miniscule volume of runoff and contaminants. The flow at the Willow site is about 30% greater than that at Fletcher, but contaminant emissions are 3 to 10 times greater, indicating a much greater source, in the lower basin.

The Ballona Creek drainage is only about 10% of the Los Angeles drainage basin, but during this storm its flow was about 40% of the LA River flow. The emissions of most contaminants were approximately 40% of the LA River emissions. Exceptions were lead and zinc, which were about equal to Willow emissions, and DDT and n-alkanes which were twice and one-sixth of the Willow emissions.

We have underestimated the emissions from the San Gabriel River because we only have flow data from Coyote Creek, so our estimates could be low by a factor of 2 or more. The measured flow is three-fourths the size of the Ballona Creek flow, but emissions of oil and suspended solids, oil and grease, TEO, trace metals, and chlorinated hydrocarbons are between 3 and 20% of Ballona's emissions, while PAH and n-alkane emissions are 1 and 3%, respectively.

Trends in flow and contaminant concentrations with time

Figure 7, A-H, shows the flow and concentrations of suspended solids, oil and grease, TEO, lead, total PAHs, total PCBs, and volatile solids for the Los Angeles River during the 48-h of sampling.

There were two peaks in flow about 6 h apart; the first peak exceeded 10,000 cfs, whereas the second peak returned to 9,000 cfs after dropping to 5,000 cfs.

The peak contaminant concentrations (except percent volatile solids) occurred in either sample 6 or 7 before the first peak in flow. Although sample 8 had the highest flow, the concentrations of all contaminants dropped. This may be due to a washout of contaminants.

Trends in Cumulative Emissions

As an example of when contaminant emissions occur, Figure 8, A-D, shows the cumulative percent flow with cumulative percent emissions of suspended solids, oil and grease, combined trace metals, and chlorinated hydrocarbons for the Willow station, and Figure 9, A-D, shows that approximately 80% of the flow and suspended solids were discharged within a 10-h period. Contaminant emissions lagged during the first 5% of flow but rapidly increased after 10% of the flow occurred. In general the first 25% of flow produced 50% of the contaminant emissions, and when 50% of the flow had occurred, 75% of the contaminant emissions had occurred. This pattern is representative of the other sites studied.

Petroleum hydrocarbon characterization

Aliphatic hydrocarbons

Figure 10a represents a typical chromatogram of the aliphatic fraction from our stormwater runoff samples. Generally, most of the samples contained a single hump of varying size (known as the unresolved complex mixture-UCM) and numerous resolved peaks which represent simple alkanes containing from 10 to 30 carbons. The presence of a UCM maximizing at n-C21-C35 is indicative of crankcase oil in the runoff. The n-alkanes, which are the resolved peaks labelled with their respective number of carbons, showed maxima at n-C17 as well as the higher molecular weight n-alkanes with odd numbers of carbons (i.e., n-C27, C29 and C31). The odd-even carbon chain length predominance of these higher molecular weight species indicates the presence of waxes characteristically associated with the cuticles of higher plants.

There were two notable exceptions to the pattern illustrated in Figure 10a. First, samples taken from Ballona Creek at 6 and 47 hours contained two UCM humps, the first hump being larger and maximizing at n-C18 (Figure 10b). It has been suggested by some researchers that this pattern may be representative of bacterial degradation products. Second, the 31 hour sample taken from the Los Angeles River at Willow Street contained no UCM at all. It did, however, exhibit the highest concentrations of n-alkanes (mostly from the C23-C39 range) with little apparent odd-even predominance. This sample was taken during the second peak in flow at approximately 8500 cubic feet/second (Figure 7a). The distribution we observed is not consistent with a recent biogenic origin, but may be related to dewaxing of petroleum. Similar distributions were not observed in samples taken before or after this one. Therefore, it is unclear whether these results are anomalous, representing the inclusion of a small particle of pure wax, or an indication of a short-term input to the river.

Aromatic hydrocarbons

Figure 11 presents a relative abundance plot for the 26 PAHs measured in this study (see Appendix A for a list of the compounds and their individual concentrations). This sample was taken from the Los Angeles River at Willow Street after 30.8 hours and is indicative of the most common distributional pattern. Most of the samples contained some naphthalenes (compounds 1-4) and phenanthrenes (compounds 9-12) which are the dominant PAHs in unweathered petroleum. However, the compounds with four or more rings (fluoranthene through benzo[g,hi,i]perylene; compound 14-26), which are combustion products, were frequently present at higher concentrations. Therefore, results of this study showed a mixture of both types of hydrocarbons being discharged during this storm with a larger amount of combustion products present.

The PAH composition was variable throughout the storm at a single point on the channel and in samples taken contemporaneously during a storm at different sites in the channel. However, the plot from the Los Angeles River station at Willow Street (Figure 8) is comparable to those obtained by Anderson and Gossett (1) for bottom sediments collected at the mouth of the Los Angeles River as well as those for sediments from the vicinity of Los Angeles County's outfall, suggesting that stormwater runoff and municipal effluent may contain PAHs of similar composition.

CONCLUSION

As the emissions of contaminants from outfalls continue to decrease, runoff emissions become a more important source of marine inputs. Outfall emissions have been steadily reduced over the last 10 years (21), but little has been done to reduce contaminants. Young et al. (25) concluded that variations in runoff concentrations were not significantly different in the Los Angeles River between 1971 and 1979 except for lead and PCBs, which were reduced by factors of 6 and 8, respectively. There do not appear to be many major changes in concentration since

1979. Table 5 shows concentrations for the five storms measured in 1971 and 1979 and the present 1986 results. Between 1979 and 1986 copper and lead concentrations increased by about a factor of 2, while suspended solids and chromium were reduced by two-thirds and one-half, respectively. The rest of the trace metals and PCBs varied by less than one-third. DDT had the largest change and was reduced by a factor of 4.

How the volume of runoff affects contaminant emissions is not clear. Los Angeles River runoff in 1971/72 was about one-half of normal runoff, while 1979/80 produced runoff five times the 15-year average; yet Young and his co-workers found most contaminant concentrations to be similar. Five of the twelve highest concentrations in the year did not occur in the first storm of 1979, and the third storm had cadmium and lead concentrations higher than those of the first storm. Data from the storm we sampled in January 1987 should allow us to determine the changes between storms within a year.

We did have some indication of a washout of contaminants in the Los Angeles River in this year's study because almost all of the contaminant concentrations peaked before our highest flow sample was taken. If the distribution of rain on land use areas did not change significantly there may have been a reduction in available contaminants. Hoffman et al. (14) found that residential, highway, commercial, and industrial areas had different rates of washout during a storm with residential concentrations of petroleum hydrocarbon approaching zero after less than 2 cm of rain, while industrial sites showed no reductions in concentrations after 2 cm of rain.

Large flows from Ballona Creek, Los Angeles River Willow, Los Angeles River Fletcher, and the San Gabriel River exceeded 3.5×10^9 liters (920 million gallons) during the storm, while flows of less than 0.32×10^9 liters (84 million gallons) occurred at the Santa Clara, Tujunga, and Calleguas sites.

During the storm, flows changed very little at Big Tujunga Wash, the Santa Clara River, and Dominguez Channel, while at Ballona Creek, Los Angeles River Willow, and San Gabriel flows varied by about 100x.

The highest concentrations of contaminants are associated with peak flows. Because we sampled the two Ventura sites while they had relatively low flow, this data may be less representative annual emissions of contaminants.

The two channels with the highest flows, Los Angeles River Willow and Ballona Creek, had the highest mean contaminant concentrations and consequently had the highest emissions of oil and grease, TEOs, cadmium, chromium, copper, nickel, lead, zinc, PCBs, PAHs, resolved hydrocarbons, and n-alkanes.

Annual estimate of runoff should be viewed with the awareness of certain limitations, some relevant to all runoff studies and others relevant only to this study. Factors that need further examination include annual variations in total rainfall within a drainage basin, the intentional retention of runoff for groundwater recharge, and diversions between drainage basins. The factors can combine to make each storm and year difficult to compare with other storms and years.

ACKNOWLEDGMENTS

We appreciate the financial and field support that was provided by the Los Angeles Regional Water Quality Control Board, especially Allen Chartrand and Michael Sowby. The Hyperion Laboratory kindly allowed us to use their facilities to measure oil and grease. We thank our fellow staff members who interrupted their work and sleep patterns to make this study possible.

Newport Bay Watershed: Construction Activities Best Management Practices Plan for Sedimentation Control

Enclosed is the Final Technical Memorandum for Task 8015.03, Newport Bay Watershed: Construction Activities Best Management Practices Plan for Sediment Control.

This technical memorandum describes the best management practices that are suitable for construction sites within the watershed. The report also compares the grading ordinances, and administrative and enforcement practices of five jurisdictions in the watershed. The study concludes that in general the present system is working effectively to reduce erosion and sediment at construction sites, but recommends some modifications in the ordinances and their administration.

We appreciate your cooperation during the course of this project.

SUMMARY

The rapid sedimentation of Upper Newport Bay has become the concern of many agencies and individuals. The bay is currently the focus for a series of studies to develop sedimentation control plans. This study investigates the reduction of sediment produced at construction sites by the application of best management practices (BMPs). These BMPs consist of structural measures used at the site and nonstructural measures involving administrative and regulatory processes.

Construction site BMPs are described in section 3.0 of the report. Twenty-seven of the practices are found to be appropriate for occasional-to-frequent use within the watershed. No single set of measures is recommended because selection must be site specific.

Section 4.0 of the report describes the procedures used by local governments to promote erosion and sediment control measures at construction sites. Five jurisdictions in the watershed were studied: Irvine, Newport Beach, Orange, Tustin, and Orange County. The five grading ordinances were compared with each other and with model ordinances. The administrative and enforcement procedures used by Irvine were studied in detail and compared with those of Newport Beach and Orange County. The study concludes that generally the present system is working effectively to reduce erosion and sediment produced from construction sites. Nevertheless, some modifications in the ordinances and in administration are recommended.

Section 5.0 describes the institutional arrangements used to achieve water quality goals relating to construction sites. The emphasis is on land use regulation by local governments, with supervisory review by the Regional Water Quality Control Board.

The conclusions and recommendations of the study appear in detail in sections 3.0, 4.0 and 5.0, and are summarized in section 2.0. Sections 1.0 and 2.0 will serve as the basis for the 208 plan amendment.

1.0 INTRODUCTION

1.1 Background

Sediment that is eroded from a watershed and deposited downstream reduces water quality and impairs the beneficial use of natural habitats and man-made facilities. All watersheds produce sediment under natural conditions. However, sediment production may increase temporarily by several thousand times if the natural vegetation is disturbed and the soil exposed. This temporary increase in sediment may have serious, longterm impacts if it is deposited in sensitive areas such as Upper Newport Bay.

1.2 Study Objective and Scope

The objective of this study is to develop a sedimentation control plan for construction activities in the Upper Newport Bay watershed employing best management practices. This plan defines and recommends specific practices to be used on construction sites, suggests changes in existing grading ordinances and administrative procedures, and describes the framework for regulating the erosion and sedimentation aspects of construction activities. The report is to be used in conjunction with current studies of other sediment sources in the watershed.

The information presented in the study is based on published materials and personal interviews. The grading ordinances and administrative procedures of five juisdictions within the watershed were studied: Irvine, Newport Beach, Orange, Tustin, and Orange County. Construction site best management practices applied throughout the country were examined, and those appropriate to conditions in the watershed were recommended.

This study updates and expands earlier work conducted as part of the areawide 208 planning process. (See Pomeroy, Johnston & Bailey, July 1978: and J.B. Gilbert & Assocs., Aug. 1978.)

VOL 12

2 0925

2.0 FINDINGS, CONCLUSIONS & RECOMMENDATIONS

Public officials, developers and contractors in the Upper Newport Bay watershed are well aware of the problems caused by increased sediment runoff from construction sites. This concern for sedimentation in Upper Newport Bay has led to regulation of construction sites that is among the most strict in the state. Based on conversations with knowledgeable people in the public and private sectors, it appears that the present system is working effectively. Major reasons are the close communication between local governments and developers/contractors, and the voluntary cooperation shown by local developers such as The Irvine Company.

Conclusions

1. Erosion control plans specifying appropriate best management practices can lead to a reduction in accelerated sediment production from construction sites.
2. The three major jurisdictions in the watershed--Irvine, Newport Beach and Orange County--maintain relatively uniform ordinances, standards and procedures.
3. The city of Tustin currently does not have an erosion/sedimentation control policy.
4. The city of Orange is applying an extensive set of standards in its approach to erosion/sedimentation control. The success or failure of this approach will have little effect on Upper Newport Bay because the drainage area within the city is small compared to the total watershed.
5. None of the jurisdictions studied specifies water quality protection as a goal of its grading ordinance.

Recommendations

1. Best Management Practices. Twenty-seven BMPs are recommended as appropriate for occasional-to-frequent use in the watershed (Table 2). Four of these practices are now rarely used.

2. Grading Ordinances. It is recommended that the jurisdictions in the watershed adopt water quality protection as a goal of their grading ordinances. Additional changes in the ordinances are not recommended because it appears that changes can be more easily incorporated into existing administrative standards and procedures.

3. Administrative Standards and Procedures. The following actions are recommended:

- that the present uniformity in standards be maintained among Irvine, Newport Beach and Orange County;
- that the present positive working relationship with developers and contractors be maintained;
- that the jurisdictions actively promote and participate in erosion control training programs for their staff;
- that efforts be made to improve communication between plan checkers and site inspectors;
- that Irvine and Orange County institute collection of a debris deposit similar to that of Newport Beach, and
- that the city of Tustin begin developing an erosion/sediment control program at the earliest possible time.

4. Regulatory Process. It is recommended that the local governments continue to take the lead responsibility for erosion and sediment control at construction sites. The Regional Water Quality Control Board should maintain an active supervisory role by performing periodic site inspections and by requesting annual reports from local governments when water quality goals are not being met.

VOL 12

20928

3.0 BEST MANAGEMENT PRACTICES

3.1 Definition

Best management practices (BMPs) are defined broadly in the Code of Federal Regulations.

> BMPs are those methods, measures, or practices to prevent or reduce water pollution and include but are not limited to structural and nonstructural controls, and operation and maintenance procedures. BMPs can be applied before, during, and after pollution-producing activities to reduce or eliminate the introduction of pollutants into receiving waters. (40 CFR 35.1521-4(c))

BMPs therefore include many responses to erosion and sedimentation ranging from regulations and enforcement (section 4.0 of this report), to specific measures applied at construction sites as part of a sediment control plan. This section discusses the latter category of BMPs.

BMPs that reduce sediment produced from construction sites can be divided generally between temporary and permanent measures. The expected life of temporary measures can vary from one day to eighteen months. After that time, substantial maintenance or reconstruction is required to retain the efficiency of most temporary measures. Permanent measures have a longer expected life, usually dependent on construction materials. Both temporary and permanent measures require some degree of design and construction expertise. Even placing gravel bags on a graded roadway requires an estimate of flow rate to determine optimum placement.

The goal of BMPs should be to obtain a significant reduction of sediment at a reasonable cost. The definition of "significant" and "reasonable" will vary depending on the source--public agency or private developer. However, disagreements may be reduced by keeping in mind the following principles.

1. Use land according to its capability and treat it according to its needs.

2. Leave soil bare for the shortest time possible.

3. Reduce the velocity and control the flow of runoff.

4. Detain runoff at the site to trap sediment.

5. Release runoff safely to downstream areas.
(John Muir Institute, June 1979, p. 27)

These principles illustrate the need to develop control measures on a site-by-site basis. There is no single BMP or combination of BMPs that will always be effective.

Even the best planned erosion and sediment control measures will not totally eliminate the temporary increase in sediment runoff from construction sites. Nevertheless, those measures that reduce erosion, such as diversions or vegetation, are important in preventing silts and clays from entering the stream system. These fine-grained particles are the most difficult to trap in downstream sediment-control devices. Therefore, any site plan should concentrate first on erosion control within the site, and then second on trapping sediment before it leaves the site.

3.2 Description of Practices

This section describes 36 best management practices that could be applied to the Newport Bay watershed. Sources for the information are cited in the text. When no page number appears, the previous citation applies. Sample drawings and specifications are included for information only, and are not intended for use in formal design.

BEST MANAGEMENT PRACTICES

R0054232

TEMPORARY GRAVEL CONSTRUCTION ENTRANCE

Definition. A stabilized pad of crushed stone located at any point where traffic will be entering or leaving a construction site to or from a public right-of-way, street, alley, sidewalk or parking area. (USDA, SCS, July 1975, p. 16.01)

Purpose. To reduce or eliminate mud and sediment transported onto public rights-of-way by vehicles or runoff. (USDA, SCS, July 1975, p. 16.01)

Conditions Where Practice Applies. Wherever traffic will be leaving a construction site and moving directly onto a paved surface. Should be used in conjunction with other practices to stabilize construction site roadways, and prevent offsite movement of sediment. Standard applies where the entrance will be removed or paved within 12 months after construction. (ABAG, Aug. 1980, p. I-107)

Design and Maintenance Considerations.

1. Two to three-inch stone, at least 6 inches thick (Virginia, 1980, p. III-2), or

   1-1/2 to 2-1/2-inch stone at least 8 inches thick (ABAG, Aug. 1980, p. I-107; also USDA, SCS, July 1975).

2. The width shall extend the full width of all points of ingress and egress. (ABAG, Aug. 1980, and Virginia, 1980)

3. The length of the pad shall be as required, but not less than 50 feet. (ABAG, Aug. 1980, and Virginia, 1980)

4. The entrance shall be maintained in a condition which will prevent tracking or flowing of sediment onto public rights-of-way. This may require periodic top dressing with additional stone as conditions demand and repair and/or cleanout of any measures used to trap sediment. All sediment spilled, dropped, washed or tracked onto public rights-of-way must be removed immediately. (ABAG, Aug. 1980)

5. When necessary, wheels must be cleaned to remove sediment prior to entrance onto public rights-of-way. When washing is required, it shall be done on an area stabilized with crushed stone which drains into an approved sediment trap or sediment basin. All sediment shall be prevented from entering any storm drain, ditch or watercourse through use of sand bags, gravel, or other approved methods. (ABAG, Aug. 1980)

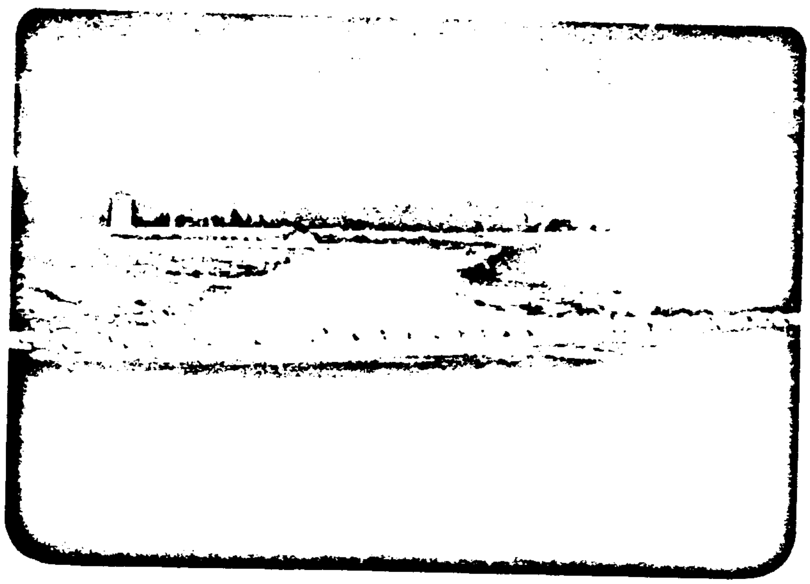

FIGURE 1. A temporary gravel construction entrance with filter berm in place when entrance is not being used. (Courtesy The Irvine Company)

CONSTRUCTION SITE ROAD STABILIZATION

Definition. The temporary stabilization of access roads, subdivision roads, parking areas, and other on-site vehicle transportation routes with stone or asphalt immediately after grading. (Virginia, 1980, p. III-5)

Purposes.

1. To reduce the erosion of temporary roadbeds by construction traffic during wet weather, and to reduce dust during dry weather.

2. To reduce the erosion and therefore regrading of permanent roadbeds between the time of initial grading and final stabilization. (Virginia, 1980, p. III-5)

Conditions Where Practice Applies. Wherever stone-base roads or parking areas are constructed, whether permanent or temporary, for use by construction traffic. Associated practices are vegetation establishment and protection, and dust control.

Paved areas should be constructed immediately after completion of building foundations and all subsequent motorized travel on the site should be limited to these areas except for completion of roadwork. Materials delivery should also be conducted on these stabilized areas. (Panhandle Area Council, April 1978, p. I-4)

Design Considerations.

1. Temporary roads and parking areas shall follow the contour of the natural terrain to the extent possible. A 6-inch course of 2-to-3-inch aggregate shall be applied immediately after grading or completion of utility installation within the right-of-way. Filter fabric may be applied to the roadbed for additional stability in accordance with fabric manufacturer's specifications. (Virginia, 1980, p. III-6)

2. Permanent roads and parking areas shall be designed and constructed in accordance with applicable standards. If areas are not paved immediately after grading, additional gravel base may be required. (Virginia, 1980)

Maintenance. Both temporary and permanent roads and parking areas may require periodic top dressing with new gravel. (Virginia, 1980, p. III-7)

SANDBAG, GRAVEL BAG, OR STRAW BALE BARRIERS

Definition. A temporary sediment barrier consisting of a row of entrenched and anchored straw bales, or stable, interlocking sand- or gravel-filled bags. (Virginia, 1980, p. III-9; and Panhandle, Apr. 1978, p. VI-7)

Purpose. To intercept and detain small amounts of sediment from disturbed areas of limited extent, and to decrease the velocity of sheet flow and low-to-moderate channel flows (bags only). (Virginia, 1980)

Conditions Where Practice Applies. Below disturbed areas subject to sheet and rill erosion where size of drainage is no greater than one-half acre. (ABAG, Aug. 1980, p. I-109; and USDA SCS, Dec. 1970, p. 13.01) Straw bale barriers can be used on slopes that do not exceed 50 percent (2:1) or around drainage inlets. Filtering capabilities are improved when used in conjunction with filter fabric. Sandbags or gravel bags can be used on slopes (not exceeding 50 percent), around drainage inlets, and in small swales or ditches subject to low-to-moderate-level flows. Sandbags do not provide sediment filtration, but cause deposition by detaining and diverting flows. (Panhandle, April 1978, p. VI-7) Gravel bags provide some filtration, and also detain flows.

The maximum life expectancy of bale or bag barriers is one rainy season. Because maintenance can be a problem, this measure should not be used where other sediment control practices are feasible. (ABAG, Aug. 1980, p. I-109)

Design Considerations.

1. Dikes of bags or bales constructed across a right-of-way or immediately below the site of construction activities should have a low spillway-embankment section of sand and gravel that serves as a filter outlet. (Amimoto, May 1978, p. 151)

2. The gravel bags should contain 1/4-inch aggregate, or pea gravel.

3. The barriers must be installed so that runoff cannot escape freely under the straw bales or sand/gravel bags. (Amimoto, May 1978)

4. Straw bales bound with nylon or wire are more durable than twine-bound bales. (Amimoto, May 1978)

5. Straw bales should be anchored to the ground with steel rods, fence posts, rebars, or wood pickets. Two anchors per bale are required. (Amimoto, May 1978)

6. The barrier shall be entrenched and backfilled. A trench shall be excavated the width of a bale and the length of the proposed barrier to a minimum depth of 4 inches. After the bales are staked, the excavated soil shall be backfilled against the barrier. Backfill soil shall conform to the ground level on the downhill side and shall be built up to 4 inches against the uphill side of the barrier. (Virginia, 1980, p. III-12)

VOL 12

2

0936

7. Sandbags exceeding two bags in height must be pyramided and may require anchoring with steel rods, rebars, or similar supports. (Amimoto, May 1978, p. 152)

Maintenance Considerations.

1. Straw bale barriers shall be inspected immediately after each rainfall and at least daily during prolonged rainfall. (Virginia, 1980, p. III-12)
2. Close attention shall be paid to the repair of damaged bales, end runs and undercutting beneath bales. (Virginia, 1980)
3. Sediment deposits should be removed after each major rainfall. (Virginia, 1980, p. III-15; also Panhandle, April 1978, p. VI-7)

SILT FENCE

Definition. A temporary sediment barrier consisting of a filter fabric (either burlap or synthetic filter fabric) stretched across and attached to supporting posts and entrenched.

Purpose. To intercept and detain small amounts of sediment from disturbed areas during construction operations in order to prevent sediment from leaving the site; and to decrease the velocity of sheet flows, and low-to-moderate channel flows.

Conditions Where Practice Applies. Below disturbed areas where erosion would occur in the form of sheet and rill erosion, and where the size of drainage area is no more than one-half acre. (ABAG, Aug. 1980, p. I-112) Maximum slope above the barrier should not exceed 50 percent (2:1). (Virginia, 1980, p. III-18) Barriers should not be used where flow rate is expected to exceed one cubic foot per second (1 cfs). (Virginia, 1980) Maximum life expectancy is six months. (Virginia, 1980, III-19) This measure should be used only where no other practices, except a straw bale dike, are feasible. (ABAG, Aug. 1980, p. I-112)

Design Considerations.

FLOW RATES AND FILTERING EFFICIENCIES OF
VARIOUS SEDIMENT FILTER MATERIALS

Material	Flow Rate (gal./sq.ft./min.)	Filter Efficiency (%)
Straw	5.6	67
Burlap (10 oz. fabric)	2.4	84
Synthetic Fabric	0.3 (Avg.)	97 (Avg.)

Source: Virginia, 1980, p. III-18.

1. The fence posts shall be spaced a maximum distance of 10 feet center-to-center.

2. Woven wire fence shall be fastened securely to the upstream side of the fence posts by staples or wire ties.

3. A trench at least 6 inches deep shall be excavated on the upstream side of the fence.

4. The filter cloth shall be stapled or securely fastened to the upstream side of the woven wire. Sufficient filter cloth shall be allowed to extend to the bottom of the trench and back up to the upstream side of trench.

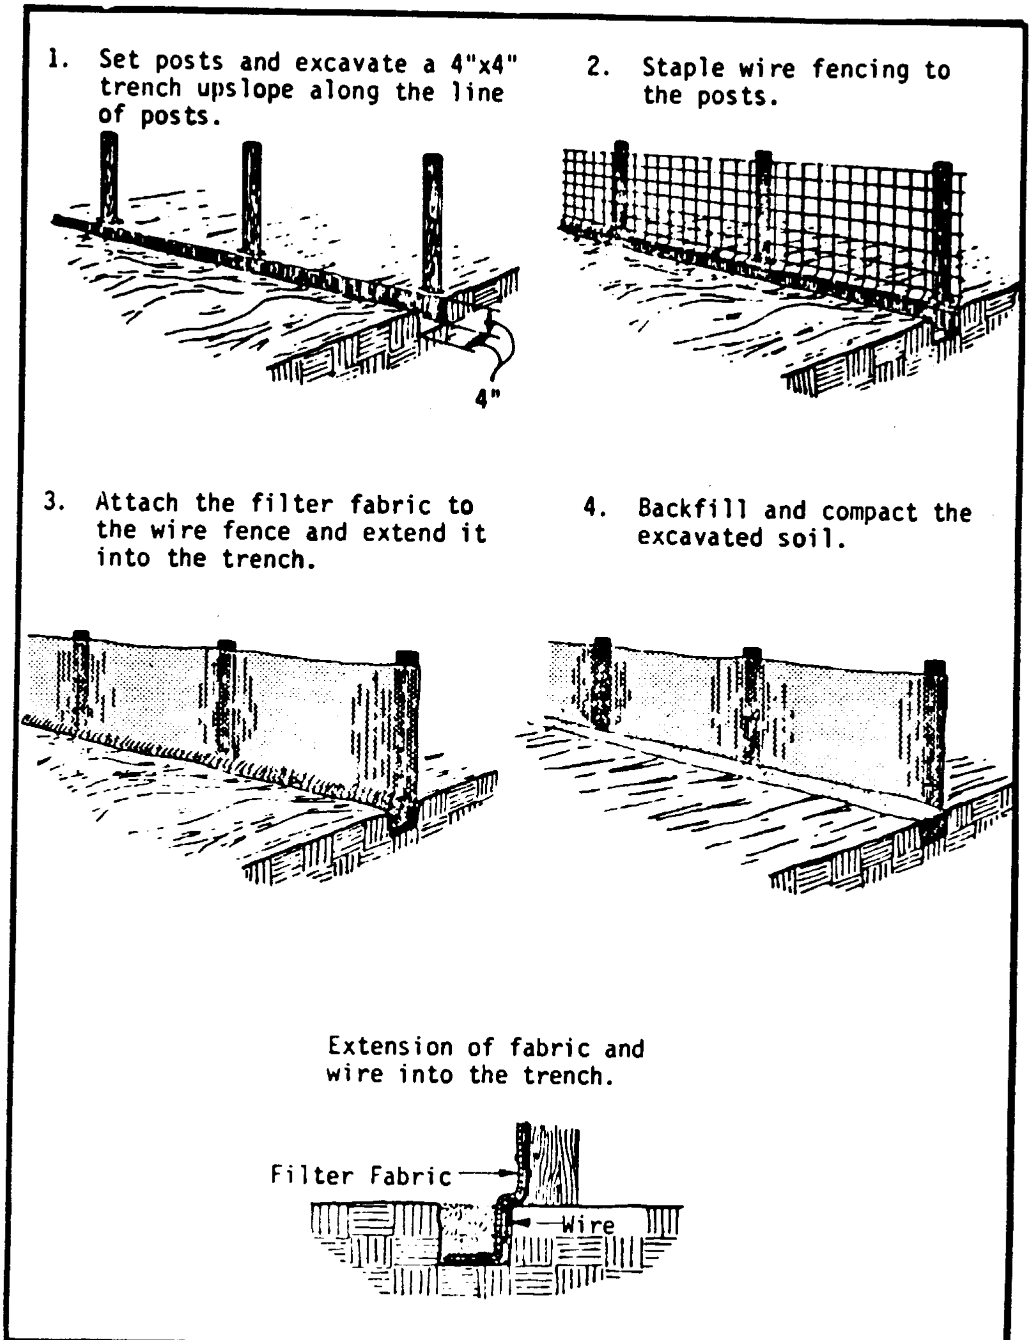
5. The trench shall be backfilled with soil and compacted to the original ground level. (ABAG, Aug. 1980, p. I-114)

Maintenance Considerations.

1. The fence shall be inspected during each storm and the filter cloth shall be replaced promptly as needed if it is torn.

2. Silt shall be removed periodically to keep the silt level from reaching halfway to the top of the fence. (ABAG, Aug. 1980, p. I-114)

SAMPLE DRAWING: SILT FENCE



Source: Virginia, 1980.

FIGURE 5

FILTER BERMS

Definition. A temporary sediment trap consisting of a ridge of gravel or crushed rock placed across a graded right-of-way, or at the point of discharge from a perimeter berm or other diversion device. (Amimoto, May 1978, p. 151)

Purpose. To retain sediment on-site by retarding and filtering runoff while at the same time allowing construction traffic to proceed along the right-of-way. (Amimoto, May 1978)

Conditions Where Practice Applies. Any graded right-of-way with slope greater than two percent; or an outlet from a diversion device with drainage area less than five acres. (Amimoto, May 1978, p. 157, and USDA SCS, July 1975, p. 17.01) Filtering capabilities can be enhanced by using a sand core or filter fabric. (White and Franks, 1978, p. 161) Maximum design life, with continuous maintenance, is one rainy season. (White and Franks, 1978, p. 148)

Design and Maintenance Considerations. Sample design standards (Amimoto, May 1978, p. 151):

1. Height: 1.5 - 2.0 feet;
2. Top width: 3 - 5 feet;
3. Side slopes: 3:1 or flatter;
4. Spacing: maximum distance 200 - 300 feet apart (when placed on right-of-way);
5. Material: 3/4 - 3-inch, well-graded gravel or crushed rock.

Where berm will be subjected to concentrated flows, gravel should be embedded at least four inches in the ground. (USDA SCS, July 1975, p. 17.03)

After each storm remove trapped sediment and clean out or replace clogged filter material. During dry weather inspect regularly and repair as needed when berm is damaged by vehicular traffic. (Panhandle, Apr. 1978, p. VI-9)

SAMPLE DRAWING: FILTER BERMS

2 0945

R0054245

VOL 12

BRUSH BARRIER

Definition. A temporary sediment barrier constructed at the perimeter of a disturbed area from the residue materials available from clearing and grubbing the site.

Purpose. To intercept and retain sediment from disturbed areas of limited extent, preventing sediment from leaving the site.

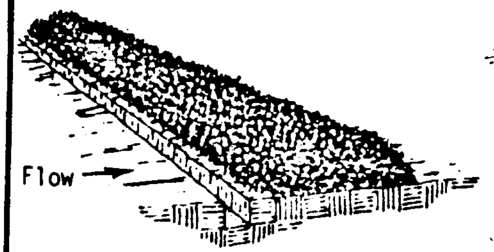
Conditions Where Practice Applies. Below disturbed areas subject to sheet and rill erosion, where enough residue material is available for construction of such a barrier.

Construction and Maintenance Considerations.

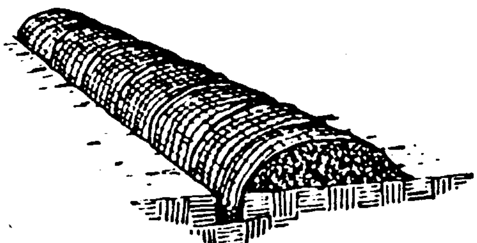
1. The height of a brush barrier shall be a minimum of 3 feet.
2. The width of a brush barrier shall be a minimum of 5 feet at its base. (The sizes of brush barriers may vary considerably based upon the amount of material available and the judgment of the design engineer).
3. The barrier shall be constructed by piling brush, stone, root mat and other material from the clearing process into a mounded row on the contour.
4. The mound slab shall be completely covered by filter fabric entrenched on the uphill side and secured with stakes on the downhill side.
5. Brush barriers shall be inspected after each rainfall and necessary repairs shall be made promptly.
6. Sediment deposits must be removed when they reach approximately one-half the height of the barrier. (Virginia, 1980, pp. III-25-27)

2 0946

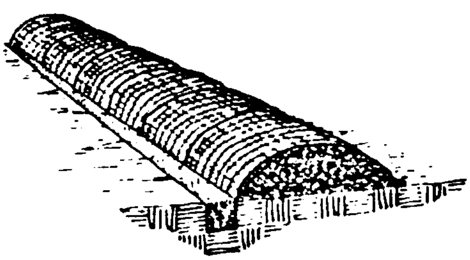
SAMPLE DRAWING: BRUSH BARRIERS



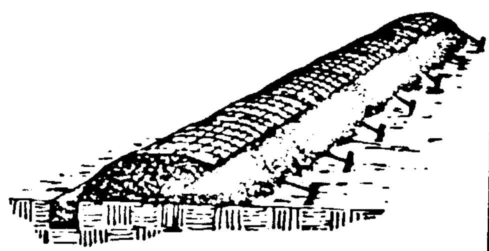
1. Excavate a 4" x 4" trench along the uphill edge of the brush barrier.



2. Drape filter fabric over the brush barrier and into the trench. Fabric should be secured in the trench with stakes set approximately 36" o.c.



3. Backfill and compact the excavated soil.



4. Set stakes along the downhill edge of the brush barrier, and anchor by tying twine from the fabric to the stakes.

Source: Virginia, 1980.

FIGURE 7

FILTER INLET

Definition. A temporary sediment filter or an impounding area around a stormdrain drop inlet or curb inlet. (Virginia, 1980, p. III-29)

Purpose. To prevent sediment from entering stormdrainage systems prior to permanent stabilization of the disturbed area. (Virginia, 1980)

Conditions Where Practice Applies. Where stormdrain inlets are operating before permanent stabilization of drainage area. The actual type of structure will vary with site conditions. (Virginia, 1980)

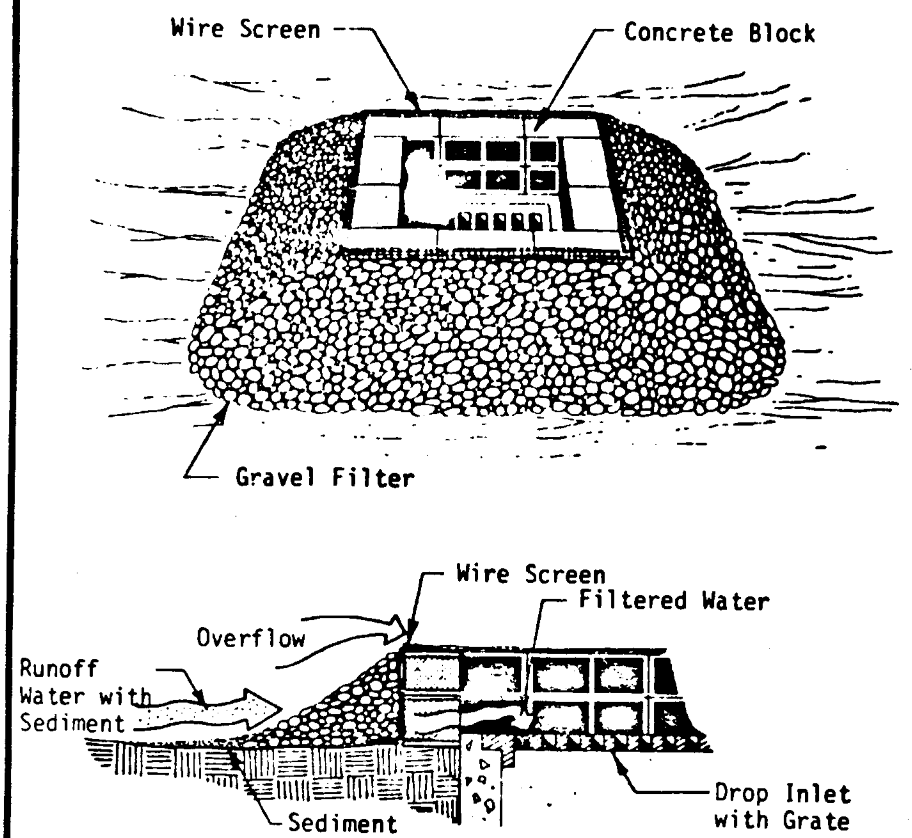
Design Considerations.

1. The contributing drainage area shall not exceed one acre.
2. Design should facilitate inspection and cleaning of filter material.
3. Do not use in streets where impounded water will create a safety hazard or endanger fill slopes.
4. Types of filter inlet designs:
   a. straw bale drop inlet structure -- bales must be anchored and staked; filtering ability enhanced by using filter fabric.
   b. burlap drop inlet sediment filter -- use 10-ounce-per-square-yard fabric; attach to stakes spaced a maximum of 3 feet apart, and entrench lower edge of fabric.
   c. gravel-and-wire-mesh drop inlet (or curb inlet) sediment filter -- place coarse gravel 12 inches deep over wire mesh covering inlet structure.
   d. block-and-gravel drop inlet (or curb inlet) sediment filter -- surround inlet with concrete block covered by wire mesh; pile gravel against wire mesh on the outside of the block barrier.
   e. excavated drop inlet sediment trap -- size to provide sufficient storage capacity and prevent overflow into inlet. (See Sediment Traps.)
   f. sod drop inlet sediment filter -- place sod to cover soil for a distance of four feet an each side of the inlet. (Virginia, 1980, pp. II-30-38)

Maintenance Considerations. Trapped sediment should be removed and the clogged filter material cleaned out or replaced after each storm. (Amimoto, May 1978, p. 152; also Panhandle, Apr. 1978, p. VI-13)

FIGURE 8. Inlet protection provided by gravel-bag berms. These are recommended only where ponding on the road will not cause a public hazard. (Courtesy The Irvine Company)

SAMPLE DRAWING: DROP INLET PROTECTION



Specific Application

This method of inlet protection is applicable where heavy flows are expected and where an overflow capacity is necessary to prevent excessive ponding around the structure.

Source: Virginia, 1980.

FIGURE 9

VOL 12

2 0950

R0054250

INTERCEPTOR DITCH

Definition. A permanent structure located at the top of a cut slope. Also known as a brow ditch.

Purpose. To divert water away from a cut slope.

Conditions Where Practice Applies. Wherever a cut slope is to be part of the final project design.

Design Considerations.

1. The interceptor ditches should be designed to convey the design flood from the contributing area above the cut.
2. The interceptor ditches should be protected against erosion by lining and also protected against clogging by vegetative debris.
3. The discharge area should be non-erodible or have energy dissipating structures.
4. The interceptor ditch should be completed before the cut is made to the final grade.

Maintenance Considerations. A permanent inspection and maintenance program should be established and followed. (Amimoto, May 1978, p. 90)

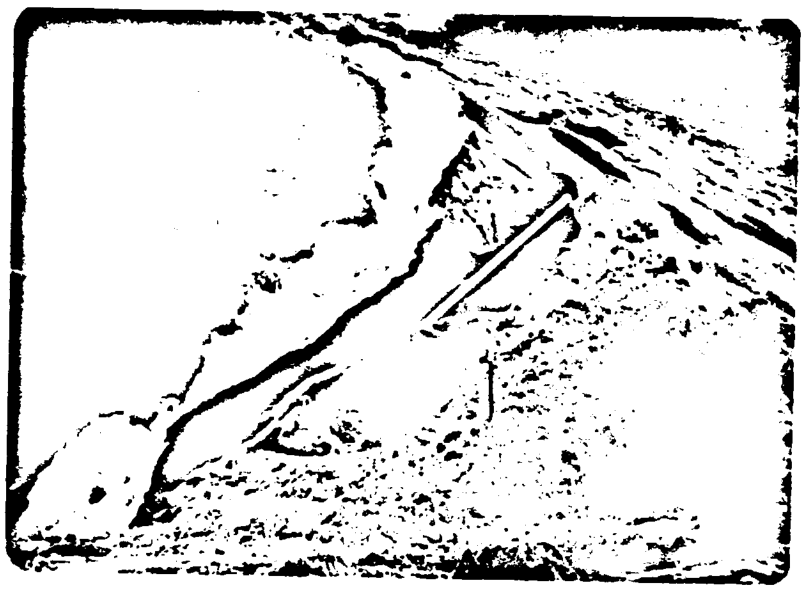


FIGURE 10. Permanent interceptor ditch. Improper design and/or maintenance of control measures can actually accelerate erosion. (Courtesy Dept. of Fish and Game)

DIVERSION DIKES

Definition. A ridge designed to redirect sheet flow, especially away from a slope. A temporary diversion dike is usually composed of compacted soil, whereas a permanent diversion dike is made of erosion-resistant material such as asphalt. (Virginia, 1980, p. III-39; and Amimoto, May 1978, p. 89)

Purpose. To divert storm runoff from higher drainage areas away from slopes to a stabilized outlet; or to divert sediment-laden runoff from a disturbed area to a sediment-trapping facility. (Virginia, 1980)

Conditions Where Practice Applies. Wherever stormwater runoff must be diverted to protect slopes or to retain sediments on site during construction. Temporary structures have a life expectancy of 18 months. (Virginia, 1980) Permanent diversions are used in rural areas where curbs and gutters are not required. An alternative measure may be an interceptor ditch or swale.

Design Considerations.

1. Sample design standards (Virginia, 1980, pp. III-40 & 41):

   - drainage area: less than five acres
   - minimum height: 18 inches
   - side slopes: 1.5:1 or flatter
   - grade: area upslope of dike must have positive grade to stabilized outlet. If slope is greater than two percent, stabilization of the drainage path with grouted rock or asphalt may be required.
   - outlet: diverted runoff, if free from sediment, must be released through a stabilized outlet; or if sediment laden, must be released through a sediment trapping facility.

2. Whenever feasible, the dike should be built before construction begins on the project.

3. The dike should be adequately compacted to prevent failure.

4. Temporary or permanent seeding and mulch shall be applied to the dike within 15 days of construction.

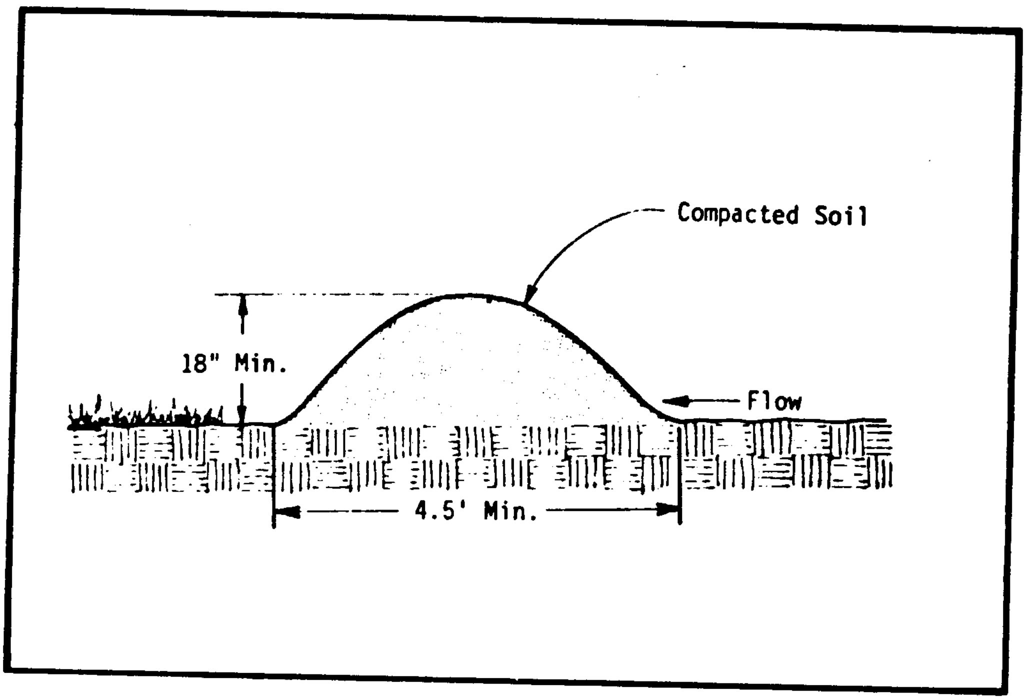
5. The dike should be located to minimize damages by construction operations and traffic. (Virginia, 1980, p. III-41)

Maintenance Considerations. The measure shall be inspected after every storm and repairs made to the dike, flow channel and outlet, as necessary. Approximately once every week, whether a storm has occurred or not, the measure shall be inspected and repairs made if needed. Damages caused by construction traffic or other activity must be repaired before the end of each working day. (Virginia, 1980, p. III-42)

VOL 12

2 0953

SAMPLE DRAWING: TEMPORARY DIVERSION DIKE



Source: Virginia, 1980.

FIGURE 11

ACTIVE FILL DIVERSION

Definition. A temporary channel with a supporting ridge on the downhill side, cut along the top of an active earth fill.

Purpose. To divert storm runoff away from the unprotected slope of an active fill to a stabilized outlet or sediment-trapping facility.

Conditions Where Practice Applies.

Where the drainage area at the top of an active earth fill slopes toward the exposed slope and where continuous fill operations make the use of a diversion dike unfeasible. This temporary structure should remain in place for less than one week.

Design Considerations.

1. Drainage area: less than five acres.

2. Height: minimum height of ridge will be nine inches.

3. Grade: the channel will have a positive grade to a stabilized outlet or sediment-trapping device, if needed.

4. The diversion shall be constructed at the top of the fill at the end of each work day as needed.

5. The diversion shall be located at least 2 feet inside the top edge of the fill.

6. The supporting ridge of the lower side shall be constructed with a uniform height along its entire length.

Maintenance Considerations. Because the practice is temporary and under most situations will be covered the next work day, the maintenance required should be low. If the practice is to remain in use for more than one day, an inspection will be made at the end of each work day and repairs made to the measure if needed. The contractor should avoid the placement of any material over the structure while it is in use. Construction traffic should not be permitted to cross the diversion. (Virginia, 1980, pp. III-43 - 45)

FIGURE 12

VOL 12

2 0956

R0054256

VOL 12

20957

PERMANENT DIVERSION

Definition. A channel constructed across a slope with a supporting ridge on the lower side. (Virginia, 1980, p. III-51)

Purpose. To reduce slope length and to intercept and divert stormwater runoff to stabilized outlets at non-erosive velocities. (Virginia, 1980)

Conditions Where Practice Applies.

1. Where runoff from higher areas may damage property, cause erosion, or interfere with the establishment of vegetation on lower areas.
2. Where surface and/or shallow subsurface flow is damaging sloping upland.
3. Where the slope length needs to be reduced to minimize soil loss. (Virginia, 1980)

Design Considerations.

1. Diversion location shall be determined by considering outlet conditions, topography, land use, soil type, length of slope, seepage planes (where seepage is a problem) and the development layout.
2. The channel may be parabolic, trapezoidal or vee-shaped, but must be able to carry the design storm with 0.3 feet of freeboard.
3. The supporting ridge shall incorporate the following design features:
    a. the side slopes shall be no steeper than 2:1;
    b. the width at the design water elevation shall be a minimum of 4 feet;
    c. the minimum freeboard shall be 0.3 foot; and
    d. the design shall include a 10 percent settlement factor.
4. Diversions shall have adequate outlets which will convey concentrated runoff without erosion.
5. Unless otherwise stabilized, the ridge and channel shall be mulched and seeded within 15 days of installation.
6. Disturbed areas draining into the diversion shall be mulched and seeded before or at the time the diversion is constructed. (Virginia, 1980, III-52 & 54)

Maintenance Considerations.

Before final stabilization, the diversion should be inspected after every rainfall. Sediment shall be removed from the ditchline and repairs made as necessary. Seeded areas which fail to establish a vegetative cover shall be reseeded as necessary. Thereafter, a permanent inspection and maintenance program should be followed. (Virginia, 1980)

SAMPLE DRAWING: PERMANENT DIVERSIONS

FIGURE 13

VOL 12

PERIMETER BERM OR SWALE

Definition. A temporary dike (berm) or excavated drainageway (swale) along the perimeter of a construction site or disturbed area. (USDA SCS, July 1975, p. 15.01; and Tahoe, Jan. 1978, p. VII-20)

Purpose. To prevent offsite stormwater runoff from entering disturbed areas, and to direct runoff from the sites to sediment-trapping devices. (USDA SCS, July 1975; and Tahoe, Jan. 1978)

Conditions Where Practice Applies. Throughout the entire construction period, from rough grading through permanent stabilization. (USDA SCS, July 1975)

Design Considerations.

1. Berms (Tahoe, Jan. 1978, pp. VII-20 & 21):

   a. .75 - 1.5-inch gravel, covered by plastic sheeting, 6 mils thick;

   b. side slopes not to exceed 2:1 (horizontal to vertical).

2. Swales (USDA SCS, July 1975, pp. 15.01 & 15.02)

   a. drainage area less than five acres.

   b. bottom width: seven feet minimum.

   c. side slopes: 2:1 (horizontal to vertical) or flatter.

   d. stabilization may be required when grade exceeds two percent or where regular traffic crossings occur.

3. Experience in Colorado has shown that hand-dug diversion ditches have less negative impacts on soil stability than machine-dug ditches, and that they are easier to maintain than berms. (Johnson & Fifer, undated, p. 41)

Maintenance Considerations. Periodic inspections should be made and repairs made as needed. More frequent inspections should occur during the wet season.

0961

RIGHT-OF-WAY DIVERSIONS

Definition. Temporary berms or swales located across disturbed areas or graded rights-of-way.

Purposes. To shorten the length of exposed slopes, thereby reducing the potential for erosion, by intercepting stormwater runoff and diverting it to a stabilized outlet or sediment-trapping device. (USDA SCS, July 1975, p. 14.01)

Conditions Where Practice Applies. Across disturbed rights-of-way, such as for roads or pipelines, or disturbed areas such as graded parking lots or earth fills. Drainage swales, or dips, are not recommended when the slope exceeds 10 percent (1:10). (Amimoto, May 1978, p. 108) The berms, also known as interceptor dikes or water bars, may be composed of compacted soil and stabilized with asphalt. (Amimoto, May 1978, pp. 105 & 106) An alternative measure is a filter berm.

Design Considerations.

1. Berms (Amimoto, May 1978, p. 105):

   a. minimum height: 1.5 feet;

   b. minimum top width: 2 feet;

   c. maximum side slopes: 2:1 (horizontal to vertical); and

   d. spacing: to vary with erosion hazard and uphill slope (White & Franks, 1978, p. 170).

2. Swales (USDA, July 1975, p. 14.01):

   a. minimum bottom width: 7 feet;

   b. minimum depth: 1 foot;

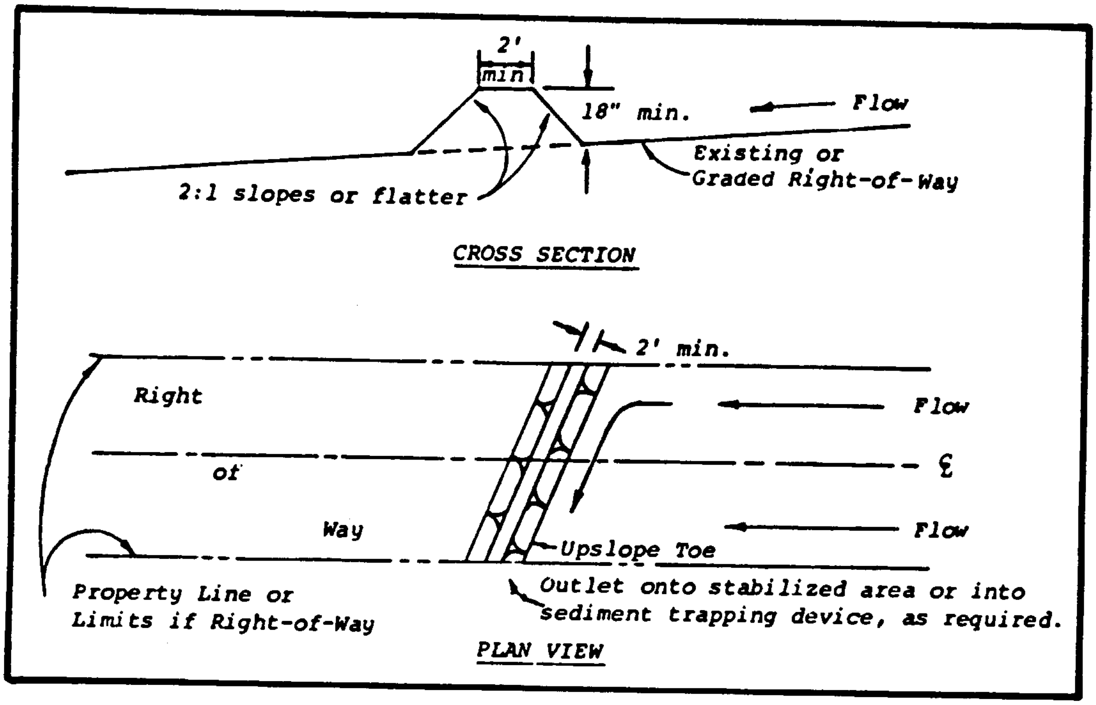
   c. maximum side slopes: 2:1; and

   d. stabilization: gravel or grass may be required.

3. All measures shall have a positive grade to a stabilized outlet or to a sediment-trapping device.

Maintenance Considerations. Periodic inspection shall be made as needed. More frequent inspections should be made during the rainy season.

SAMPLE DRAWING: INTERCEPTOR DIKE



SAMPLE DRAWING: INTERCEPTOR SWALE

FIGURE 15

ROADSIDE DITCHES

Definition. A permanent side ditch adjoining the shoulder of a road.

Purpose. To carry excess road runoff and to prevent erosion from uncontrolled surface flows along roadway.

Conditions Where Practice Applies. To be used only in limited locations where surface runoff from the adjacent roadway surface exceeds the gutter capacity or where gutters are inappropriate or not required. This method of drainage control is not be used as a major drainage channel. Associated practices are right-of-way diversions, and check dams.

Design Considerations. Ditch sections should be designed in conformance with applicable standards. Depending on expected velocity of flow, the ditch can be unlined (less than 2 cfs) or lined (greater than 2 cfs) with riprap, grouted stone, asphalt, concrete or vegetation, as appropriate.

Maintenance Considerations. Periodic inspections should be made as needed. (Tahoe, Jan. 1978, p. IX-17)

VOL 12

STORMWATER CHANNELS

Definition. A permanent, designed waterway, shaped and lined with appropriate vegetation or structural material to safely convey excess stormwater runoff away from a developing area. (Virginia, 1980, p. III-101)

Purpose. To provide for the disposal of concentrated surface runoff without damage from erosion. (Virginia, 1980)

Conditions Where Practice Applies. Generally applicable to man-made channels, including roadside ditches, and intermittent natural channels that are modified to accomodate increased flows generated by land development. This practice is not generally applicable to major natural streams. (Virginia, 1980)

Planning Considerations. The design of a channel cross section and lining is based primarily upon the volume and velocity of flow expected in the channel. If conditions are appropriate, grass, other vegetative linings or riprap channels may be used. Where high velocities cannot be avoided, structural stabilization with concrete will be required.

Besides the primary design considerations of capacity and velocity, a number of other important factors should be taken into account when selecting a cross section and lining. These factors include land availability, compatibility with land use and surrounding environment, safety, maintenance requirements, and outlet conditions.

1. Vee-shaped ditches are generally used where the quantity of water to be handled is relatively small, such as along roadsides. A grass or sod lining will suffice where velocities in the ditch are low. For steeper slopes where high velocities are encountered, a concrete or asphaltic concrete lining may be appropriate.

2. Parabolic channels are often used where the quantity of water to be handled is larger and where space is available for a wide, shallow channel with low velocity flow. Riprap should be used where higher velocities are expected and where some dissipation of energy (velocity) is desired. Combinations of grass and riprap are also useful where there is a continuous low flow in the channel.

3. Trapezoidal channels are often used where the quantity of water to be carried is large and conditions require that it be carried at a relatively high velocity. Trapezoidal ditches are generally lined with concrete or riprap.

4. Outlet conditions for all channels should be considered. This is particularly important for the transition from a man-made lining such as concrete to a vegetative lining. Appropriate measures must be taken to dissipate the energy of the flow to prevent scour of the receiving channel. (Virginia, 1980, p. III-102) (See Outlet Protection.)

2 0964

Maintenance Considerations.

Grass-lined Channels

During the initial establishment, grass-lined channels should be repaired immediately and grass re-established if necessary. After grass has become established, the channel should be checked periodically to determine if the grass is staying in place. If the channel is to be mowed, it should be done in a manner that will not damage the grass.

Riprap-lined Channels

Riprap-lined channels should be checked periodically to ensure that scour does not occur beneath the riprap layer. The channel should also be checked to determine that the stones are not dislodged by the flow.

Concrete-lined Channels

Concrete-lined channels should be checked periodically to ensure that there is no undermining of the channel or erosion adjacent to the side walls. Particular attention should be paid to the outlet of the channel. If scour is occurring at the outlet, appropriate energy dissipation measures should be taken.

Sediment Deposition

If the channel is below a high sediment-producing area, sediment should be trapped before it enters the channel. If sediment is deposited in grass-lined channels, it should be removed promptly to prevent damage to the grass. Sediment deposited in riprap and concrete-lined channels should be removed when it reduces the capacity of the channel. (Virginia, 1980, pp. III-109 & 110)

SAMPLE DRAWING: STORMWATER CHANNELS

FIGURE 16

VOL 12

20966

R0054266

INFILTRATION TRENCHES

Definition. A permanent ditch filled with gravel and rock used to increase infiltration of runoff from impervious surfaces.

Purpose. Increases infiltration and thereby reduces runoff volume and velocity from impervious surfaces.

Conditions Where Practice Applies. Where any extensive area of impervious surfaces is used, such as paved parking lots. The trench should be designed to operate as part of a total stormwater management system on a project. Not recommended for sediment trapping alone.

Design and Maintenance Considerations.

1. Provision should be made for overflow into a stormdrain system in case of failure of the trench because of clogging by deposited sediments, or storm intensities greater than the design storm.

2. Use of sediment traps upstream can increase life expectancy of the trench.

3. Provision should be made for periodic removal of gravel-rock backfill and sediment. (White and Franks, 1978, pp. 170 & 171)

FIGURE 17

SLOPE DRAIN

Definition. A temporary installation of conduit or flexible tubing extending from the top to the bottom of a cut or fill slope. (Virginia, 1980, III-89)

Purpose. To conduct concentrated stormwater runoff safely down the face of a slope without causing erosion problems on or below the slope. (Virginia, 1980)

Conditions Where Practice Applies. On cut or fill slopes before permanent stormwater drainage structures are installed. Can be used in association with diversion dikes above the slope, and outlet protection at the base. (Virginia, 1980)

Design and Maintenance Considerations.

1. It is important that these temporary structures be installed properly and maintained since their failure will often result in severe gully erosion. The entrance section must be securely entrenched, all connections must be watertight, and the conduit must be staked securely. (Virginia, 1980, p. III-90)

2. The outlet of the slope drain must be protected from erosion. Often an energy dissipating device is required. (The Irvine Company, 1975, p. 19)

3. Slope drains can be made of flexible tubing or corrugated metal pipe. The flexible tubing must be securely anchored to the slope at regular intervals not to exceed 10 feet, and must be inspected regularly to ensure that it has not been torn or twisted. (Virginia, 1980, III-90)

SAMPLE DRAWING: PIPE SLOPE DRAIN

VOL 12

2 0970

R0054270

CHUTES AND FLUMES

Definition. A temporary or permanent open, lined channel constructed on a slope. (Virginia, 1980, p. III-95)

Purpose. To conduct concentrated stormwater runoff safely down the face of a slope without causing erosion problems on or below the slope. (Virginia, 1980)

Conditions Where Practice Applies. Where flow must be conveyed down a cut or fill slope. The maximum recommended drainage area is 36 acres. (USDA SCS, July 1975, p. 18.01)

Design Considerations.

1. The width and depth of the chute or flume will depend on the contributing drainage area. (USDA SCS, July 1975, p. 18.02)

2. The outlet must be protected and an energy dissipating device installed if necessary to prevent downstream erosion. (USDA SCS, July 1975)

3. The channel must be lined with non-erosive material such as concrete. (USDA SCS, July 1975)

4. The structure shall be placed on a firm foundation such as undisturbed soil or compacted fill. It must be tied in with the appropriate diversion and outlet facilities. (USDA SCS, July 1975)

Maintenance Considerations. A permanent schedule for inspection and maintenance should be required for a permanent structure. Periodic inspections of temporary structures is also necessary.

FIGURE 19. Concrete chute. Proper design and maintenance of diversion facilities at chute entrance reduces the chance of undermining the structure. (Courtesy Dept. of Fish and Game)

VOL 12

OUTLET PROTECTION

Definition. Temporary or permanent structurally lined aprons or other acceptable energy dissipating devices placed at the outlets of pipes or paved channel sections. (Virginia, 1980, III-127)

Purpose. To prevent scour at stormwater outlets and to minimize the potential for downstream erosion by reducing the velocity of concentrated stormwater flows. (Virginia, 1980)

Conditions Where Practice Applies. Applicable to the outlets of all pipes and paved channel sections where the velocity of flow at design capacity of the outlet will exceed the permissible velocity of the receiving channel or area. (Virginia, 1980)

Planning Considerations.

1. The most commonly used device for outlet protection is a structurally lined apron. These aprons are generally lined with riprap, grouted riprap, or concrete. They are constructed at a zero grade for a distance which is related to the outlet flow rate and the tailwater level. (Virginia, 1980, III-128)

2. Experience in Colorado has shown that straw bales and silt fences were adequate protection below 8-inch pipes, but rock riprap was required even for temporary outlet protection below larger diameter culverts. (Johnson and Fifer, undated, p. 46)

3. If the outlet discharges into a well-defined channel, the side slopes of the channel should not be steeper than 2:1. (Virginia, 1980, III-130)

4. The apron should be located so that there are no bends in the horizontal alignment. (Virginia, 1980)

Maintenance Considerations. Inspection and repair requirements will vary depending on construction material.

VOL 12

LEVEL SPREADER

Definition. A temporary or permanent stable outlet for dikes and diversions consisting of an excavated depression constructed at zero grade across a slope. (Virginia, 1980, p. III-161)

Purpose. To convert concentrated runoff to sheet flow and release it onto areas stabilized by existing vegetation. (Virginia, 1980)

Conditions Where Practice Applies. Where sediment-free storm runoff is intercepted and diverted away from graded areas onto undisturbed stabilized areas. This practice applies only in those situations where the spreader can be constructed on undisturbed soil and the area below the level lip is stabilized by natural vegetation. The water should not be allowed to reconcentrate after release. (Virginia, 1980) Usually used in association with a temporary diversion dike or a temporary right-of-way diversion. Can also be used at outlet of stabilized area such as a paved parking area. Can be used in conjunction with stormwater management practices to increase infiltration, thereby reducing runoff volume and velocity.

Design Considerations.

1. Length is determined on the basis of expected flow (in cfs) from the design storm. (Virginia, 1980, III-162)
2. Minimum width is six feet, and minimum depth is six inches. (Virginia, 1980)
3. The grade of the channel entering the spreader shall be less than or equal to 1 percent for the last 20 feet before discharge. (Virginia, 1980)
4. The spreader should not be constructed on fill material. (Virginia, 1980, p. III-163; also USDA SCS, July 1975, p. 37.02)
5. Runoff should not be allowed to reconcentrate below the spreader. (Virginia, 1980, p. III-164)
6. Spreaders should not be constructed on slopes exceeding 3:1 (horizontal to vertical). (Tahoe, Jan. 1978, p. VIII-6)

Maintenance Considerations.

The measure shall be inspected after every rainfall and repairs made if required. The contractor should avoid the placement of any material on and prevent construction traffic across the structure. If the measure is damaged by construction traffic, it shall be repaired immediately. (Virginia, 1980, p. III-164)

FIGURE 21

RIPRAP

Definition. A permanent, erosion-resistant ground cover of large, loose, angular stone. (Virginia, 1980, p. III-137)

Purposes.

1. To protect the soil surface from the erosive forces of concentrated runoff.

2. To slow the velocity of concentrated runoff while enhancing the potential for infiltration.

3. To stabilize slopes with seepage problems and/or non-cohesive soils. (Virginia, 1980)

Conditions Where Practice Applies.

To soil-water interfaces where the soil conditions, water turbulence and velocity, or expected vegetative cover are such that the soil may erode under the design flow conditions. Riprap may be used, as appropriate, at stormdrain outlets, on channel banks and/or bottoms, roadside ditches, drop structures, and at the toe of slopes. (Virginia, 1980)

Design Considerations.

1. Graded vs. Uniform Riprap. Riprap is classified as either graded or uniform. A sample of graded riprap would contain a mixture of stones which vary in size from small to large. A sample of uniform riprap would contain stones which are all fairly close in size.

   For most applications, graded riprap is preferred to uniform riprap. Graded riprap forms a flexible self-healing cover, while uniform riprap is more rigid and cannot withstand movement of the stones. Graded riprap is cheaper to install, requiring only that the stones be dumped so that they remain in a well-graded mass. Hand or mechanical placement of individual stones is limited to that necessary to achieve the proper thickness and line. Uniform riprap requires placement in a more or less uniform pattern, requiring more hand or mechanical labor. (Virginia, 1980, p. III-138)

2. Sequence. Since riprap is used where erosion potential is high, construction must be sequenced so that the riprap is put in place with the minimum possible delay. Disturbance of areas where riprap is to be placed should be undertaken only when final preparation and placement of the riprap can follow immediately behind the initial disturbance. Where riprap is used for outlet protection, the riprap should be placed before or in conjunction with the construction of the pipe or channel so that it is in place when the pipe or channel begins to operate. (Virginia, 1980, p. III-139)

3. Filter Blankets. A filter blanket is a layer of material placed between the riprap and the underlying soil surface to prevent soil movement into or through the riprap. A filter blanket can be of two general forms:

a gravel layer or a plastic filter cloth. No filter blanket is necessary for riprap used as stormdrain outlet protection. (Virginia, 1980, pp. III-141 & 142)

Maintenance Considerations. Properly installed riprap should require very little maintenance. It should be inspected periodically, and repaired if needed. (Virginia, 1980, p. III-143)

STREAMBANK STABILIZATION

Definition. Methods of stabilizing the banks of streams using structural or vegetative measures, or a combination of both. (Virginia, 1980, p. III-175)

Purpose. To protect streambanks from erosion. (Virginia, 1980)

Conditions Where Practice Applies. Use in streambank sections that are subject to erosion because of disturbance during construction or increased flows after construction. (Virginia, 1980)

Design Considerations.

1. Types of structural measures:

   Riprap - heavy, angular stone placed or dumped onto the streambank to provide armor protection against erosion.

   Gabions - these rectangular rock-filled wire baskets are pervious, semi-flexible building blocks which can be used to armor the bed and/or banks of channels or to divert flow away from eroding channel sections.

   Deflectors (groins or jetties) - Structural barriers which project into the stream to divert flow away from eroding streambank sections.

   Reinforced Concrete - may be used to armor eroding sections of the streambank by constructing retaining walls or bulk heads. Positive drainage behind these structures must be provided. Reinforced concrete may also be used as a channel lining.

   Log Cribbing - a retaining structure built of logs to protect streambanks from erosion. Log cribbing is normally built on the outside of stream bends to protect the streambank from the impinging flow of the stream.

   Grid Pavers - modular concrete units with interspersed void areas which can be used to armor the streambank while maintaining porosity and allowing the establishment of vegetation. These structures may be obtained in precast blocks or mats, or they may be formed and poured in place. Design and installation should be in accordance with manufacturer's instructions. (Virginia, 1980, III-177)

   Revetments - a wall of stone or concrete, or a fence of flexible material, such as wire mesh, along the outside of stream bends; used to protect the bank from high velocity flows.

2. Types of vegetative measures:

   Sod Walls - sod blocks are piled, tilting slightly toward bank, and backfilled with soil. Used to stabilize terraces.

   Woven Willow (Wattling) - live willow branches are interwoven with anchored willow poles and sticks, forming short fences along the bank parallel to the streambed.

Brush Layers - live branches are planted in ditches dug parallel to stream. (Tourbier & Westmacott, Apr. 1974, pp. 107 and 108)

Sprigging - planting runners of mat-type grass, such as bermuda grass.

Maintenance Considerations. All structures should be maintained in an "as-built" condition. Structural damage caused by storm events should be repaired as soon as possible to prevent further damage to the structure or erosion of the streambank. Vegetation should be re-established if damaged during high flows or by other causes. (Virginia, 1980, p. III-177)

FIGURE 24

VOL 12

2 0982

R0054282

GRADE CONTROL STRUCTURES

Definition. Structures which reduce and maintain the channel gradient. Examples include drop structures, check dams, and erosion checks. (Amimoto, May 1978, p. 125)

Purpose. By reducing the channel gradient, the runoff velocities decrease, thus preventing erosion at higher flows. (Amimoto, May 1978)

Conditions Where Practice Applies.

1. Drop Structures - In man-made channels which must traverse long, relatively steep slopes without large increases in the flow velocity. In natural channels which have long or relatively steep sections and which, as a result of construction activities, are expected to experience channel erosion problems. (Virginia, 1980, p. III-155)

2. Check Dams - This practice is limited to use in small open channels which drain 10 acres or less. It should not be used in a live stream. Some specific applications are illustrated by the following examples.

   a. Temporary ditches or swales which, because of their short length of service, cannot receive a nonerodible lining but still need some protection to reduce erosion.

   b. Permanent ditches or swales which for some reason cannot receive a permanent nonerodible lining for an extended period of time.

   c. Either temporary or permanent ditches or swales which need protection during the establishment of grass linings. (Virginia, 1980, pp. III-151 and 152)

   Alternative measures in small drainageways are silt fences and sediment barriers such as sand or gravel bags.

3. Erosion Checks - Used in areas that are susceptible to rill erosion, such as swales or shallow ditches, or on critical slopes subject to severe sheetflow. They are generally located at stress joints in swales and ditches where the gradient changes or tributary inflow occurs. (The Irvine Company, 1975, pp. 20 & 21)

Design and Maintenance Considerations.

1. Drop Structures - Waterway drop structures are expensive, permanent structures and consequently should be designed by a qualified engineer. When locating the structure, attention should be given to changed water elevations which will result and their effect upon adjacent areas. Waterway drop structures of this type are most cost effective where the design flow is 100 cfs or greater and the drop in elevation across the structure is less than 10 feet. (Virginia, 1980, p. III-156)

   Once the drop structure is built and the area around it stabilized, maintenance should be minimal. Immediately after construction, the channel should be checked for scour above and below the structure. Periodic inspections should be made to check for cracking of the concrete, uneven settlement, and piping around the structure. (Virginia, 1980, p. III-160)

2. Check Dams - Check dams can be constructed of either stone or logs. Stone generally must be purchased, but is cheaper to install because it requires little hand labor. Stones should be a minimum 2 - 3-inch diameter. The cross section of the ditch or swale should be covered completely, with the center of the dam lower than the edges. (Virginia, 1980, p. III-152)

   Provision must be made for removal of the dam if it is used as a temporary structure. Regular inspections should be made of the dams during the rainy season, and sediment removed when it reaches half the height of the dam. (Virginia, 1980, p. III-154)

3. Erosion Checks - Composed of flexible, porous, long-lived mats of fiberglass, plastic or jute buried in vertical slit trenches. A cap strip should extend two feet upstream and downstream of the erosion check. They should be installed immediately after final grading and before seeding. The checks should be inspected for erosion, and replaced or repaired as necessary. (Amimoto, May 1978, p. 128; also The Irvine Company, 1975, pp. 20 & 21)

VOL 12

2 0986

VOL 12 2 0987

STREAM CROSSINGS

Definition. Temporary, nonerodible road crossings used by construction traffic. Structures may include bridges, culverts, pipe arches or paved fords. (Virginia, 1980, p. III-183; Amimoto, May 1978, p. 146)

Purpose. To provide a means for construction traffic to cross flowing streams without damaging the channel or banks; and to keep sediment generated by construction traffic out of a stream. (Virginia, 1980)

Conditions Where Practice Applies. Bridges, culverts and spans are generally applicable to small, flowing streams. (Virginia, 1980). Paved fords are frequently used at crossings subject to flash floods, seasonal storm runoff peaks, or frequent heavy passage of debris. This type of structure is less expensive than raising the grade of the road and installing a bridge or culvert. (Amimoto, May 1978, p. 146) However if a permanent bridge will be part of the completed project, it should be constructed as soon as possible, avoiding the need for a temporary stream crossing.

Design and Maintenance Considerations.

1. Bridges and culverts are channel constrictions which can cause flow backups or washouts during periods of high flow. For this reason, the temporary nature of stream crossings is stressed. They should be planned to be in service for the shortest practical period of time and to be removed as soon as their function is completed. The structures should be designed by a qualified civil engineer based on best available estimates of hydrology and sediment or debris hazard, and on adequate geotechnical information. (Virginia, 1980, p. III-184) Structures should be inspected after every rainfall and at least once a week, whether it has rained or not, and all damages repaired immediately. (Virginia, 1980, III-186)

2. A paved ford may cause less disturbance of stream flow regime, but it cannot be removed easily after construction. Because the roadbed is not raised above the channel, care must be taken to avoid the tracking or washing of sediment onto the paved ford. Associated practices could include gravelled approaches and filter berms. After construction, little maintenance of the ford should be required.

3. Permits to install stream crossings may be required by the Corps of Engineers and California Fish and Game.

FIGURE 28

VOL 12 2 09888

FIGURE 29. A temporary stream crossing using conduit and fill. Fill slopes should be stabilized with riprap. (Courtesy Dept. of Fish and Game)

VEGETATION PROTECTION

Definition. Temporary methods of preventing disruption by construction activities of natural or planted vegetation.

Purpose. To minimize the extent of land disturbance and retain natural sediment control.

Conditions Where Practice Applies. Any area where construction activity disturbs the land to the extent of reducing protective vegetation, compacting soil, or otherwise causing deterioration of the environment. (Tahoe, Jan. 1978, p. I-21) Vegetation protection can be especially important along streamcourses and drainage ways.

Design Considerations.

1. Trees can be protected from traffic with temporary measures such as fences. They can be protected from cut and fill activities by using dry wells, retaining walls or drain tiles as appropriate. (USDA SCS, July 1975, pp. 58.04 & 58.05)

2. Buffer strips, or vegetative filter strips, can act as a natural sediment trap. Filter strips can be either natural or planted. Tall, dense stands of grass are the most effective sediment traps. Minimum width of strips should be 15 feet plus 1/2 of channel width above diversions, and 100 feet along flowing streams. (Amimoto, May 1978, p. 152)

3. Traffic control is the restriction of construction traffic to predetermined routes according to types and numbers of vehicles anticipated. Associated practices are road stabilization and stream crossings. (Tahoe, Jan. 1978, p. I-21)

VOL 12

VEGETATION ESTABLISHMENT

Definition. The selection and use of appropriate plants as a temporary or permanent erosion control measure.

Purpose. To provide protection to slopes, drainageways or other disturbed areas that are subject to sheetflows or low-velocity flows.

Conditions Where Practice Applies.

1. Temporary plantings are used where grading operations are not completed and will be resumed within five years, or where grading operations are complete but a rapid-growing ground cover is needed before permanent vegetation can be established. (The Irvine Company, 1975, p. 32)

2. Permanent plantings are generally made after construction is completed. Irrigation may be required for establishing and sustaining vegetation.

3. If used alone, vegetative erosion control methods can be expected to achieve a considerable degree of success on less than severe slopes (less than 2:1) where drainage control is not a problem. However, on steeper slopes (greater than 2:1) or areas with drainage problems, permanent vegetative erosion control must be combined with drainage control and mechanical stabilization techniques. (White and Franks, 1978, pp. 148 & 149)

4. The associated practices of mulching, fertilizing, and slope preparation are usually necessary to establish successful plantings. At some sites, irrigation may also be required.

Design and Maintenance Considerations.

1. Selection of appropriate plants should be made by an experienced professional who is knowledgeable in vegetative erosion control measures. Periodic inspections should be made by the designer to ensure that plantings are installed, maintained, and are operating as conceived.

2. Guidelines for selection of appropriate plant materials are contained in Tahoe, Jan. 1978, Chapter XI and in Chan & Burgess, Jan. 1981. Advice on local planting conditions may also be available from the Soil Conservation Service and Caltrans district offices.

3. Methods of revegetation include:

   a. manual broadcasting,
   b. drilling,
   c. hydroseeding,
   d. spot seeding of shrubs,
   e. wattling (see also Streambank Stabilization),
   f. sodding, and
   g. sprigging.

   (Amimoto, May 1978, pp. 47-51, Virginia, 1980, pp. III-231-233)

2 0991

VOL 12

MULCHES

<u>Definition.</u> A temporary medium used to cover exposed soil in order to conserve soil moisture and reduce the erosive force of raindrops.

<u>Purpose.</u> To improve seed germination and plant establishment.

<u>Conditions Where Practice Applies.</u> Any construction area where temporary or permanent plantings will be made. It should be noted that a light application of mulch does not reduce erosion. (U.S. EPA, Dec. 1976, p. 17) Therefore, mulching should be looked on as an associated practice of vegetation establishment, not necessarily as an erosion control measure in itself.

<u>Design and Maintenance Considerations.</u>

1. Types of Mulches

   a. hydromulching (usually done at same time as hydroseeding),

   b. wood chips,

   c. fiberglass roving,

   d. straw,

   e. crushed stone or gravel,

   f. jute matting,

   g. wood excelsior matting

   h. plastic netting.
   (Tahoe, Jan. 1978, pp. V-i & ii; Amimoto, May 1978, p. 66)

   Chemicals and tackifiers are often considered mulches although they may inhibit plant growth by reducing soil porosity.

2. Mulches may have to be reapplied or repaired if vegetation is not successfully established.

2 0992

VOL 12

TOPSOILING

Definition. Methods of preserving and using topsoil to enhance final site stabilization with vegetation.

Purpose. To provide a suitable growth medium for final site stabilization with vegetation.

Conditions Where Practice Applies.

1. Where the preservation or importation of topsoil is determined to be the most effective method of providing a suitable growth medium.

2. Where the subsoil or existing soil presents the following problems:

   a. the texture, pH, or nutrient balance of the available soil cannot be modified by reasonable means to provide an adequate growth medium.

   b. the soil material is too shallow to provide an adequate root zone and to supply necessary moisture and nutrients for plant growth.

   c. the soil contains substances potentially toxic to plant growth.

3. Where high-quality turf is desirable to withstand intense use or meet aesthetic requirements.

4. Where ornamental plants will be established.

5. Only on slopes that are 2:1 or flatter.

6. Topsoiling, like mulching, should be viewed as an associated practice of vegetation establishment, not as a sediment control measure by itself.

Design Considerations. Topsoil is the surface layer of the soil profile, generally characterized as being darker than the subsoil due to the presence of organic matter. It is the major zone of root development, carrying much of the nutrients available to plants, and supplying a large share of the water used by plants.

Although topsoil provides an excellent growth medium, there are disadvantages to its use. Stripping, stockpiling, and reapplying topsoil, or importing topsoil, may not always be cost-effective. Topsoiling can delay seeding or sodding operations, increasing the exposure time of denuded areas. Most topsoil contains weed seeds, and weeds may compete with desirable species.

Advantages of topsoil include its high organic matter content and friable consistence, water-holding capacity, and nutrient content. (Virginia, 1980, pp. III-207 & 208)

2 0993

VOL 12

SLOPE PREPARATION--SCARIFYING

Definition. Providing a rough soil surface with horizontal depressions created by operating a tillage or other suitable implement on the contour. (Virginia, 1980, p. III-201) Also known as "grooving." (Virginia, 1980, p. III-204)

Purposes. To aid in establishment of vegetative cover with seed, and to reduce runoff velocity and increase infiltration. (Virginia, 1980)

Conditions Where Practice Applies. Slopes with grades less than 2:1 that are to be mulched and/or seeded. (Tahoe, Jan. 1978, p. VI-24) Scarifying alone does not significantly reduce erosion, and if improperly done, can even increase it. (U.S. EPA, Dec. 1976, p. 17) To be successful, the measure must be used in conjunction with other practices such as mulching, seeding and brow ditches or berms.

Design Considerations.

1. Scarifying shall be applied on cuts in cohensive soil or in soft rock which can be excavated without ripping. (Amimoto, May 1978, p. 53)
2. The steps shall be approximately square with horizontal dimensions of 8-10 inches. (Amimoto, May 1978)
3. Steps should be approximately horizontal, with a gradient not to exceed two percent. (Amimoto, May 1978)
4. Excavation of each step shall be in the opposite direction from the preceding one to minimize build-up of loose material at ends of steps. (Amimoto, May 1978)
5. Loose material which collects at the ends of steps shall be removed and ends blended into the natural ground. (Amimoto, May 1978)
6. Scarifying shall not be allowed in the lowest zone of the slope because loose material tends to slough onto toe. (Amimoto, May 1978)

2 0994

SLOPE PREPARATION - STAIR STEPPING

Definition. Construction of a continuous series of large horizontal steps on slopes by operating a tillage or other suitable implement on the contour. (Amimoto, May 1978, p. 54, and Virginia, 1980, p. III-201). Also known as "serrating." (Amimoto, May 1978, p. 54)

Purposes. To aid in establishment of vegetation, and to reduce runoff velocity and increase infiltration. (Virginia, 1980)

Conditions Where Practice Applies. Stair stepping applies to slopes greater than 2:1 (horizontal to vertical) composed of soft, rippable rock. (Amimoto, May 1978, p. 54) It creates benches partially filled with loose material (colluvium) which can support vegetation. To be successful, the measure must be used in conjunction with other practices such as mulching, seeding, and brow ditches or berms.

Design Considerations.

1. The steps may vary from 2-4 feet vertically, with the horizontal dimensions being a function of the staked slope ratio. (Amimoto, May 1978, p. 54) In no case should the percentage slope of the steps exceed the natural angle of repose for the colluvial material.

2. Steps shall be approximately horizontal, with a gradient not to exceed two percent. (Amimoto, May 1978)

3. Excavation of each step shall be in the opposite direction from the preceding one to minimize build-up of loose material at the ends of steps. (Amimoto, May 1978)

4. Loose material which collects at the ends of steps shall be removed and the ends blended into the natural ground. (Amimoto, May 1978)

FIGURE 30

VOL 12

20996

R0054296

SEDIMENT TRAPS

Definition. A small temporary ponding area, formed by constructing an earthen embankment with a gravel outlet, across a drainage swale.

Purpose. To detain sediment-laden runoff from small disturbed areas long enough to allow the majority of the coarse sediment to settle out.

Conditions Where Practice Applies.

1. Below drainage areas of 5 acres or less.
2. Where the sediment trap will be used no longer than 18 months. (The maximum useful life is 18 months.)
3. The sediment trap may be constructed either independently or in conjunction with a temporary diversion dike.

Design and Maintenance Considerations.

1. Sediment traps should be used only for small drainage areas. If the contributing drainage area is greater than five acres, then a sediment basin should be used.
2. Sediment must be periodically removed from the trap. Plans should detail how this sediment is to be disposed of, such as by use in fill areas on site or removal to an approved off-site dump.
3. Sediment traps, along with perimeter controls, should be installed before any land disturbance takes place in the drainage area.
4. If excavation is necessary to attain the required storage volume, side slopes should be no steeper than 2:1.
5. The outlet for the sediment trap should consist of a crushed stone section of the embankment located at the low point in the basin. The crest of the outlet should be at least one foot below the top of the embankment.
6. The structure should be checked regularly to ensure that it is structurally sound. Sediment shall be removed and the trap restored to its original dimensions when the sediment has accumulated to half the design volume of the trap.
7. Sediment traps must be removed after the contributing drainage area is stabilized. Erosion control plans should show how the site of the trap is to be graded and stabilized after removal.

(Virginia, 1980, pp. III-55-58; also USDA SCS, July 1975, pp. 20.01 - 20.08)

VOL 12

2/000

TEMPORARY SEDIMENT BASIN

Definition. A temporary basin with a controlled stormwater release structure, formed by constructing an embankment of compacted soil across a drainageway. (Virginia, 1980, p. III-59; also USDA SCS, July 1975, p. 19.01)

Purpose. To detain sediment-laden runoff from disturbed areas long enough for the majority of the sediment to settle out. A sediment basin will not necessarily reduce the peak rate of runoff. (Virginia, 1980)

Conditions Where Practice Applies. Below disturbed areas greater than 5 acres but less than 150 acres. There must be sufficient space and appropriate topography for the construction of a temporary impoundment. These structures are limited to a useful life of 18 months; otherwise they must be designed as permanent debris basins. (Virginia, 1980)

Design Considerations.

1. Effectiveness. Sediment basins are at best only 70-80 percent effective in trapping sediment which flows into them. Therefore, they should be used in conjunction with erosion control practices such as temporary seeding, mulching, diversion dikes, to reduce the amount of sediment flowing into the basin. (Virginia, 1980, p. III-60)

2. Location. To improve the effectiveness of the basin, it should be located so as to intercept the largest possible amount of runoff from the disturbed area. The best locations are generally low areas and natural drainageways below disturbed areas. Drainage into the basin can be improved by the use of diversion dikes and ditches. The basin should not be located where its failure would result in the loss of life or interruption of the use or service of public utilities or roads. (Virginia, 1980)

3. Design Elements.

   a. design capacity,

   b. embankment and/or excavation specifications,

   c. principal spillway,

   d. emergency spillway,

   e. soil erodibility and trap efficiency, and

   f. controlled access for safety. (ABAG, Aug. 1980, pp. I-87)

4. Stabilization. Stabilize embankment and emergency spillway using structural and vegetative stabilization, as appropriate. Stabilize inlet to the basin if velocities are high. (Tahoe, Jan. 1978, p. IX-43)

5. Permits should be obtained as necessary from the Army Corps of Engineers, California Department of Fish and Game, and California Department of

Water Resources (DWR). Dams within the jurisdiction of DWR are those having a height greater than 6 feet and storage exceeding 50 acre-feet, and those having a storage exceeding 15 acre-feet if the dam height is greater than 25 feet. (Dept. of Water Resources, Dec. 1979, p. xvii)

6. Methods of basin removal and site stabilization should be specified in the design plans.

Maintenance Considerations. Cleanout intervals should be specified in the initial plans. Sediment disposal shall not create a potential additional sediment source. All-weather access to the basin must be provided.

VOL 12

PERMANENT DEBRIS BASINS

Definition. A permanent earth dam designed for impounding and controlled release of water.

Purpose. To detain sediment-laden runoff from disturbed areas long enough for most of the sediment to settle out. A debris basin may also cause some flood-peak reduction.

Conditions Where Practice Applies. In disturbed watersheds, below areas greater than 150 acres, and wherever permanent sediment control is necessary and a major structure is economically feasible.

Design Considerations. Design elements are the same as those listed for temporary sediment basins. However, the level of design effort is greater. Safety considerations are of primary importance. Therefore, detailed analyses of hydrology and geology are necessary to ensure a properly designed structure. An example of design criteria appears in USDA SCS, June 1976.

Maintenance Considerations. Methods of and responsibility for maintenance sould be determined during initial design. The question of public safety will generally require some degree of public agency participation.

2

1005

FIGURE 37. Permanent debris basin. Vegetation should be removed immediately prior to the rainy season as a part of regular maintenance. (Courtesy Dept. of Fish and Game)

SUBSURFACE DRAINS

Definition. A perforated conduit such as pipe, tubing or tile installed beneath the ground to intercept and convey groundwater.

Purposes.

1. To prevent sloping soils from becoming excessively wet and subject to sloughing.

2. To improve the quality of the growth medium in excessively wet areas by lowering the water table.

3. To drain stormwater detention areas or structures.

Conditions Where Practice Applies. Wherever excess water must be removed from the soil. The soil must be deep and permeable enough to allow an effective system to be installed. Either a gravity outlet must be available or pumping must be provided. These standards do not apply to foundation drains.

Design Considerations. Subsurface drainage systems are of two types, relief drains and interceptor drains. Relief drains are used either to lower the water table in order to improve the growth of vegetation, or to remove surface water. They are installed along a slope and drain in the direction of the slope. They can be installed in a gridiron pattern, a herringbone pattern, or a random pattern.

Interceptor drains are used to remove water as it seeps down a slope, to prevent the soil from becoming saturated and subject to slippage. They are installed across a slope and drain to the side of the slope. They usually consist of a single pipe or series of single pipes instead of a patterned layout. (Virginia, 1980, pp. III-187 & 188; also USDA SCS, July 1975, pp. 40.01 - A40.14)

1009

DUST CONTROL

Definition. Reducing surface and air movement of dust during land disturbing, demolition and construction activities.

Purpose. To prevent surface and air movement of dust from exposed soil surfaces and reduce the presence of airborne substances which may be harmful or injurious to human health, welfare, or safety, or to animal or plant life.

Conditions Where Practice Applies. In areas subject to surface and air movement of dust where on-site and off-site damage is likely to occur if preventive measures are not taken.

Design Considerations. Construction activities inevitably result in the exposure and disturbance of soil. Fugitive dust is emitted both during the activities (i.e., excavation, demolition, vehicle traffic, human activity) and as a result of wind erosion over the exposed earth surfaces. Large quantities of dust are typically generated in "heavy" construction activities, such as road and street construction and subdivision, commercial or industrial development, which involve disturbance of significant areas of soil surface. Research at construction sites has established an average dust emission rate of 1.2 tons/acre/month for active construction. Earth-moving activities comprise the major source of construction dust emissions, but traffic and general disturbance of the soil also generate significant dust emissions. Most of this dust will be redeposited and eventually washed into the storm-drain or stream system.

Methods to reduce dust include:

1. Temporary measures:
   - mulches, especially tackifiers,
   - vegetative cover,
   - tillage,
   - irrigation,
   - barriers, and
   - calcium chloride.
2. Permanent measures:
   - permanent vegetation,
   - topsoiling, and
   - stone.

(Virginia, 1980, pp. III-299-301)

Maintenance Considerations. Dust control measures should be reapplied or repaired, as needed.

VOL 12

2

1010

STOCKPILE STABILIZATION

Definition. Temporary methods to prevent erosion of materials that are being stored at a construction site.

Purpose. To reduce sediment and dust that may be produced by temporary stockpiles.

Conditions Where Practice Applies. Whenever loose, unconsolidated material, such as topsoil, sand, or sediment that has removed from traps or basins, is being stored at a construction site. Associated practices are temporary diversion dikes, traffic control, and dust control.

Design and Maintenance Considerations. Stockpiles should not be placed on sloping ground, drainage ways, or areas subject to rapid sheetflow. Stockpiles should be placed on level terrain away from areas subject to ponding from sediment control or other devices. Temporary diversions made of compacted soil berms or sandbags may be required around the stockpile. Traffic should be diverted away from stockpiles. Stockpiles should not be disturbed unnecessarily after placement. Plastic netting or tackifiers may be required to stabilize fine materials. Stockpiles should be inspected frequently during the rainy season to ensure stability.

3.3 Findings, Conclusions and Recommendations

Table 1 shows the frequency of BMPs used in the watershed. The table was compiled from six responses to a questionnaire. The respondents were

- Irvine,
- Newport Beach,
- Orange,
- Orange County,
- Soil Conservation Service, and
- The Irvine Company.

In written and verbal comments, all respondents stressed the need for proper design, installation and maintenance. They pointed out that even a well-conceived practice will be ineffective, or actually worsen erosion, if not installed or maintained properly. They also stressed that good design and placement is required for even the most simple or temporary measure. Clearly there is a need for a continuing erosion control training program to educate everyone involved--designers, builders, plan-checkers, and inspectors--about BMPs. The program recently instituted by the Soil Conservation Service is a good beginning in this education process. It should be supported and supplemented by the jurisdictions within the watershed.

Based on a review of applicable BMPs and their present use, the following practices are recommended for occasional-to-frequent use:

1. temporary gravel construction entrance,
2. sandbag, gravel bag or straw bale barriers,
3. silt fences,
4. filter berms,
5. filter inlets,
6. interceptor ditches,
7. diversion dikes,
8. active fill diversions,
9. permanent diversions,
10. perimeter berms or swales,
11. right-of-way diversions,
12. stormwater channels,
13. slope drains,
14. outlet protection,
15. level spreader,
16. riprap,
17. streambank stabilization,
18. grade control structures,
19. vegetation protection,
20. vegetation establishment,
21. mulches,
22. temporary sediment traps,
23. temporary sediment basins,
24. permanent debris basins,
25. topsoiling,
26. dust control, and
27. stockpile stabilization.

Four of the practices are now used only rarely in the watershed: silt fences, level spreaders, vegetation protection, and topsoiling. The Soil Conservation Service also recommends that the use of vegetation protection and topsoiling be encouraged.

It is difficult to recommend more frequent use of practices now used only occasionally because of the site-specific nature of erosion and sediment control plans. However, a review of the responses to our questionnaire indicates that diversion structures may be underused at present. These structures include diversion dikes, active fill diversions, permanent diversions, perimeter berms or swales, and right-of-way diversions.

The lands currently under development in the cities of Orange and Tustin generally have gentle slopes. Future development in Tustin is expected to extend into the foothills as recently annexed land is urbanized. Lands under development in Newport Beach, Irvine and the areas under county jurisdiction vary in topography from gentle slopes to hilly areas. The BMPs recommended above can be used in all jurisdictions for those projects that have the conditions where the practice applies. These conditions are specified for each BMP in section 3.2. Table 2 summarizes the recommended best management practices and the control objectives to which they are applied.

The remaining BMPs not listed above may be useful under special circumstances. The following BMPs may be used rarely, but effectively, at appropriate sites:

1. construction site road stabilization,
2. brush barriers,
3. roadside ditches,
4. infiltration trenches,
5. chutes and flumes,
6. temporary stream crossings,
7. scarifying,
8. stair stepping, and
9. subsurface drains.

(1) Varies depending on site characteristics. Expertise in erosion control is assumed.

4.0 GRADING ORDINANCES

4.1 Comparison of Ordinances

Five grading ordinances currently applied in the Newport Bay drainage area were compared. The five jurisdictions considered were Irvine, Newport Beach, Orange, Tustin and Orange County. In importance of effect on sedimentation of the Upper Bay, the cities of Irvine and Newport Beach rank highest. Irvine is critical because the city covers nearly 30 percent of the watershed. Approximately 10 to 15 percent of the city's area is disturbed by construction every year (personal communication, Bob Storchheim, city of Irvine, July 27, 1981). This figure will probably remain high for some time as The Irvine Company continues to develop its land. Newport Beach is important to the Upper Bay because the city surrounds it. Sediment is transported from construction sites almost directly into the bay. The remaining jurisdictions produce less sediment from construction sites largely because there is less continuing construction activity within their boundaries. Only a small portion of the city of Orange lies within the watershed. The topography of the city of Tustin is relatively flat and construction sites are less susceptible to erosion. The intensity of development activites within the area under the jurisdiction of Orange County is much less than that within the cities of Irvine and Newport Beach. Nevertheless, erosion rates from Orange County sites may be high when construction occurs in the foothills.

Table 3 is a matrix comparing the grading ordinances of the five jurisdictions. Three ordinances are nearly identical in their major provisions: Irvine, Newport Beach, and Orange County. These three ordinances are based on the model grading ordinance in the Uniform Building Code (UBC) (Int'l Conf. of Bldg. Officials, 1979), but with an added emphasis on erosion and sediment control.

** no arbitrary limits established; decided for each site based on the natural topography, good engineering practices, and the recommendations of a geologist and soils engineer.

VOL 12

2

1023

Tustin has adopted the UBC ordinance directly, without any modifications. The UBC ordinance as written does not address erosion/sediment control on construction sites. Rather, it is directed at reducing hazards of cut and fill operations to adjacent property and to the public. However, many jurisdictions use the ordinance as the authority to require erosion/sediment control measures when they appear necessary. Other jurisdictions, such as Irvine, Newport Beach and Orange County, amend the ordinance to reflect local needs and concerns. In either case, however, the authority of the ordinance is sufficient to regulate erosion/sediment control practices at construction sites.

A detailed comparison of the ordinances for Irvine, Newport Beach, Orange County and Tustin reveals that the Tustin ordinance does not contain specific requirements for erosion control measures. Historically such controls were not required because the city occupies flat terrain which is not subject to severe erosion, even when disturbed. However, Tustin has recently annexed land which is owned by The Irvine Company and extends into the foothills. This land is in agricultural reserve. However, the city expects that it will be developed eventually. When The Irvine Company begins conceptual planning of its development, the city will review the need for requiring erosion control measures (personal communication, Alan Warren, city of Tustin, July 31, 1981). The absence of other major developments in the meantime and present staffing shortages may delay this review for a considerable period.

Comparison of the ordinances of Irvine, Newport Beach and Orange County indicates uniformity in their requirements. This uniformity is desirable from the developers' viewpoint because it facilitates preparation of grading and erosion control plans. The thresholds of the ordinances are described in item 1 of the matrix (Table 3). These thresholds, which determine the projects that are exempt from the ordinance requirements, are among the lowest in the state (Fitting, Nov. 1979; J.B. Gilbert & Assocs., Aug. 1978). This means that nearly all clearing or grading operations are subject to erosion control standards.

Item 2 of the matrix compares the authority of the agencies to require reports by a soils engineer and/or an engineering geologist. These reports may be required at the discretion of the responsible agency in every jurisdiction reviewed. However, such reports are not required for every grading project. In the case of the Newport Beach ordinance, all projects within the Newport Bay watershed must submit an erosion control plan, even if a soils or engineering report is not required.

All the ordinances require a bond or similar surety to cover the cost of repairing the contractor's grading work (item 3). In the cases of Irvine and Newport Beach, this bond is usually not released until the project site is ready for occupance and final landscaping is established. Retention of the bond for this entire period is desirable because erosion problems can occur at all stages of construction, not only during grading.

Items 5 and 6 show the final slope requirements for cuts and fills. The requirements are important for erosion control because certain practices, such as slope vegetation, are not effective on gradients steeper than 50 percent (2:1) (White and Franks, 1978).

All three ordinances require that runoff be diverted before reaching cut or fill slopes (item 6). Diversion swales must be paved to prevent erosion, have a minimum gradient of six percent, and drain an area not exceeding one-third acre. All diversion outlets must be protected from erosion by resistant material such as riprap.

Item 7 of the matrix lists the provisions for on-site erosion/sediment control. The three ordinances require vegetative slope stabilization and other best management practices (BMPs) where appropriate. The BMPs to be employed are chosen on a site-by-site basis, and are specified in an erosion and sediment control plan. No single BMP or group of BMPs is appropriate in all situations. Therefore, erosion and sediment control plans will vary among sites. The ordinances also specify that additional BMPs may be required during the rainy season. This provision improves the effectiveness of erosion control measures, and encourages land developers to perform a detailed project review prior to grading during the rainy season.

None of the existing ordinances specifically states that water quality protection is a purpose (item 8). However Irvine, Newport Beach and Orange County use their ordinances to implement 208 planning goals. Section 208(b)(2)(H), 86 Stat. 841, requires this planning process to "set forth procedures and methods (including land use requirements) to control to the extent feasible" water pollution related to construction activity. The existing grading ordinances have been a convenient way to require and enforce installation of best management practices. This reality could be reflected in the present grading ordinances by a minor amendment: "It is the intent of this code to safeguard life, limb, property, <u>water resources</u>, and the public welfare by regulating grading . . . ." (City of Irvine Grading Regulations) Although not necessary for enforcement, more elaborate wording could be borrowed from ordinances such as Solano County's.

> The purpose of this ordinance is to provide the means for controlling soil erosion, sedimentation, increased rates of surface runoff and related environmental damage by establishing minimum standards and providing regulations for the construction and maintenance of fills, excavations, cuts and clearing of vegetation, revegetation of cleared areas, drainage control, and the protection of exposed soil surfaces in order to protect downstream waterways and wetlands and to promote the safety, public health, convenience and general welfare of the community.

None of the three ordinances specifically requires a construction schedule (item 9). However, as a matter of practice all project schedules are filed with the reviewing agency so that those expected to extend into the rainy season can be closely monitored. Sites that are graded during the dry season, but left exposed during the rainy season, are thereby subject to the additional rainy-season requirements noted in item 7.

Item 10 indicates that the Newport Beach ordinance specifically requires an erosion and sediment control plan for projects subject to the ordinance. As a matter of policy, however, Irvine and Orange County also require erosion and sediment control plans for any proposed construction during the rainy season. The format of erosion and sediment control plans is similar in the three jurisdictions. Appendix C is a copy of Orange County's requirements for an erosion control plan. A typical plan would include:

1. a 24-hour telephone number of someone responsible for the construction site;
2. paved areas and drainage devices that will be completed by October 15 (the beginning of the rainy season);
3. type and placement of on-site erosion control devices; and
4. location of and access to desilting basins, if any.

As noted above, the specific best management practices included in the plan would vary depending on the site and the extent of grading.

Item 11 shows that only Newport Beach includes sizing criteria for desilting basins in its ordinance. The criteria used by Irvine and Orange County are specified in their standard plans, not in their ordinances. The advantage of omitting design criteria from the ordinance is that they can be easily modified and updated as conditions change, or technology and new information develop. A discussion of the design criteria for desilting basins and other BMPs appears in section 3.2.

Methods of enforcement are specified in the three ordinances. These methods include warnings by inspectors, stop-work orders, or withholding of building permits. However, the goal of all jurisdictions is to obtain voluntary cooperation from contractors without resorting to compulsory alternatives. The administrative and enforcement procedures used by Irvine, Newport Beach and Orange County are discussed in section 4.2.

The city of Orange is in the process of adopting a grading ordinance which contrasts sharply with those of the other four jurisdictions. The proposed ordinance is a series of brief resolutions which define the general scope and purpose of grading regulations. In addition to minimizing hazards to life and property, the purpose is to

> assure the proper development of the City in level and hillside terrain so as not to destroy the natural character and amenities of such land or deplete the scenic resources of the City. (Undated draft, Proposed Grading Ordinance, City of Orange.)

The resolutions refer to "Standards for Grading." The standards are contained in a 75-page document that is similar to other cities' grading ordinances.

VOL 12 2 1028

The advantage of this arrangement is flexibility: old standards can be modified and new ones adopted quickly in response to changing conditions and technologies. City Council approval is not required for these revisions. A Design Review Board is responsible for ensuring that the principles of the grading ordinances are applied to specific projects. The Board, which has been operating for three years, consists of representatives from various city agencies and private firms. The Board works with developers at the conceptual planning stage, leaving final plan checking and approval to qualified city staff. As with the other jurisdictions reviewed, the effectiveness of this approach depends on how the standards are applied to and enforced for specific projects.

An additional comparison was made among the five ordinances and two model ordinances (SCAG, April 1979; Amimoto, May 1978). Table 3 includes the major provisions of the South Coast 208-plan model ordinance and of the California Department of Conservation (CDC) model ordinance. The most notable differences between the existing ordinances (except Tustin's) and the CDC model ordinance are that the model does not require 1.) special rainy-season control measures and 2.) outlet protection where diverted runoff is discharged. Both are key elements in reducing erosion and sedimentation at construction sites, and should be retained in the existing ordinances. On the other hand, the CDC model calls for a construction schedule to be filed with a grading permit application. Although this is done for projects in the jurisdictions reviewed, except Tustin, it is not specifically required by the existing grading ordinances.

The 208-plan model ordinance is similar to the existing ordinances in Irvine, Newport Beach and Orange County in its erosion control elements. The exception is that the model ordinance does not specifically exempt erosion-resistant areas. Another difference is that the model ordinance specifies sizing criteria for desilting basins. As discussed above, a grading ordinance may not be the best place to specify design criteria because the requirement limits the agency's response to unique situations or new technologies.

Comparison was also made with the modifications of the UBC model code suggested by Pomeroy, Johnston & Bailey (July 28, 1978). These changes include:

1. adding the purpose of protecting water resources;
2. extending the scope of the ordinance to erosion control;
3. making erosion/sediment control plans mandatory unless specifically waived by the responsible agency;
4. adding special requirements for rainy-season operations; and
5. deleting the exemption from erosion control measures for erosion-resistant cut slopes.

Except for items 1 and 5, Irvine, Newport Beach and Orange County have made these changes, either in their ordinances or in administrative policy. It is suggested that these modifications would be appropriate for Tustin to consider.

The jurisdications in the Upper Newport Bay watershed have approached erosion and sediment problems through their grading ordinances and permit process. Some jurisdictions elsewhere in California have chosen to adopt a separate erosion control ordinance. Resource conservation districts in California are proposing county erosion and sediment control ordinances that address the problems of accelerated erosion on all categories of land use, including construction areas.

One example of this type of ordinance is the one amending the Santa Cruz County Code. The purpose of this ordinance "is to eliminate and prevent conditions of accelerated erosion that have led to, or could lead to, degradation of water quality, loss of fish habitat, damage to property, loss of topsoil and vegetation cover, disruption of water supply, and increased danger from flooding." It includes provisions that no person shall cause or allow to be continued a condition on any site that is causing or is likely to cause accelerated erosion as determined by the Planning Director. Such a condition shall be controlled and/or prevented by using appropriate measures as outlined in the code or by additional measures as specified by the Planning Director. Property owners will be given a reasonable amount of time, as determined by the Planning Director, to control the specified erosion problems.

The ordinance requires the development of erosion control plans; provides for the setting of fees for plan checking, inspection, violations, variance requests and for land clearing permits; provides for inspection and compliance; and provides for determination of violations, work stoppage, and the assessment and enforcement of penalties.

4.2 Administration and Enforcement

The following discussion concentrates on the city of Irvine. As noted in section 4.1, Irvine contains the largest area of land that will be developed in the near future, and has the potential to increase sediment from the watershed during the construction phase of development. The regulatory procedures used by Newport Beach and Orange County are discussed in relation to Irvine. Omitted from the report are Tustin, which does not currently have an erosion control program, and Orange, which has insignificant jurisdictional authority in the watershed (less than one-half square mile). Sources of information for this section include state and local government personnel, and local developers.

In the city of Irvine, an erosion control plan is required for every grading project covered by a grading permit if that project will extend into the rainy season (October 15 to April 15). No grading permit will be issued unless an erosion control plan has been approved, or the requirement specifically waived by the city. The permit is valid for one year, and a new plan must be submitted and approved if grading operations extend into subsequent rainy seasons. Every plan submitted to Community Development is checked for sufficiency by staff at the Regional Water Quality Control Board in Riverside. Review by city staff is minimal. The Regional Board may ask the city to have a specific control plan modified, or the city may require modification on its own.

After a permit is issued and grading begins, site inspections are made by city staff. At minimum, the following inspections occur:

1. pregrading inspection,
2. toe inspection,
3. excavation inspection,
4. fill inspection,
5. drainage device inspection,
6. rough grading, and
7. final grading.

None of these relates directly to the erosion control plan, but the condition of the site with respect to erosion control measures is checked on each visit. In addition, all sites are inspected for adequacy of erosion control during the month immediately preceding the rainy season. Spot checks are made during periods of heavy rain whenever they occur. Enforcement action is taken by the city to correct any deficiencies or inadequate maintenance observed on continuing basis during the rainy season. Yearly on August 15 and September 15, the city advises contractors with active grading permits about rainy-season requirements for erosion control. Measures and enforcement policies are discussed at open meetings held quarterly for contractors.

The same inspector follows a project through all grading stages. If the inspector finds the erosion control measures to be inadequate, then a 24-hour notice is issued. If the contractor does not make an effort to solve the problem in that time, then a stop-work order is issued by the city. The order can be enforced by city police, but such enforcement has not been necessary in the past. Another alternative open to the city is to do remedial work on a site and recover the cost from the bond all contractors must post. This alternative is used only in extreme emergencies because of time involved in recovering the cost. Nevertheless, the existence of the bonds is important in assisting enforcement of erosion control even after grading is completed. The bond is held until final project improvements are made. The period between final grading and project completion allows additional time to determine whether all required erosion control measures are operating as designed.

Finally, the city has a Standards Committee which regularly reviews city regulations and standards, including the grading ordinance and erosion controls. The committee consists of the managers of Inspection, Final Engineering, and Maintenance Services. This procedure indicates effective communication, and allows for the updating of standards and requirements, making them more responsive to actual field conditions. Standard reviews are initiated regularly by committee members, and additional reviews are made upon the request of developers and contractors.

The Newport Beach and Orange County systems are similar to Irvine's. Plan checking and inspections are divided between departments. However, Newport Beach and Orange County do not request routine plan checking from the Regional Board. Instead, only major projects are sent to the Board for review.

Newport Beach has an additional enforcement tool--the debris deposit. This deposit, usually made in cash, is required from a contractor before any building or grading permit is issued. The amount may range from $100 to $15,000, depending on either the value of proposed construction or the amount of proposed grading. If construction does not conform to permit requirements or the erosion control plan, the city issues a notice to the contractor giving a time limit for correction. If the problem is not corrected within the specified time, the deposit is forfeited and the permit is suspended until the problem is corrected and a new deposit is made. When the city issues its final project approval, the full remaining deposit is refunded to the contractor.

The major land developer in the Irvine-Newport Beach area is The Irvine Company (TIC). The company produces an annual erosion control program that complies with the cities' ordinances. The program serves to advise contractors on TIC projects about their erosion-control responsibilities during the rainy season. TIC takes an active part in site inspections, emergency service, and city-contractor liaison during the rainy season. Part of the success of erosion control in the Upper Newport Bay watershed is due to this active interest by TIC.

4.3 Conclusions and Recommendations

Conclusions

1. The jurisdictions of Irvine, Newport Beach and Orange County cover most of the area within the Newport Bay watershed.
2. These three jurisdictions maintain an excellent uniformity in the requirements of their grading ordinances, standards and procedures.
3. These requirements equal or exceed the model ordinances studied in terms of erosion control.
4. The city of Tustin has not incorporated erosion control requirements into its grading ordinance or administrative policy.
5. The city of Orange is approaching erosion control by using extensive standards that are separate from the grading ordinance. The success or failure of this new approach will have little effect on Upper Newport Bay because the drainage area within the city of Orange is small compared to the rest of the basin.
6. None of the jurisdictions specifies water quality protection as a goal of their grading ordinances. However, all but Tustin apply their ordinances to 208-planning goals.
7. Voluntary cooperation by developers and contractors is preferred. However, compulsory compliance is enforced when needed.
8. Irvine, Newport Beach and Orange County generally have good communication with developers. Notices sent to contractors prior to the rainy season help them comply with special erosion control requirements. Quarterly meetings, such as those held by Irvine, also improve contractors' understanding of city requirements.

9. According to developers' comments, lack of communication among the departments and staff within the jurisdictions appears to be an occasional problem. The source of the problem is generally a difference in interpretation between the plan checker and the site inspector.

10. There is an occasional shortage of qualified personnel for plan checking or site inspections because of the cyclical nature of erosion control measures. All plans must be approved and sites inspected during the month preceding October 15. During the winter, inspections must be made whenever there is significant rainfall. This shortage can be acute for Orange County because its jurisdiction is fragmented and scattered over a large area.

11. Enforcement measures available to Irvine, Newport Beach and Orange County are stop-work orders and contractor's bonds. In addition, Newport Beach requires a debris deposit.

Recommendations

1. That Irvine, Newport Beach and Orange County continue to maintain uniform ordinances, standards, and procedures. Regional training classes and occasional meetings of field supervisors from each jurisdiction would probably accomplish the necessary coordination.
2. That Tustin begin reviewing its grading ordinance and developing erosion control standards at the earliest possible time, but not later than proposed development of foothill land.
3. That the existing ordinances of Irvine, Newport Beach, Orange County and Orange be modified to include water quality protection as a goal.
4. That all jurisdictions continue to maintain positive working relationships with developers and contractors to encourage voluntary compliance with erosion control standards.

VOL 12

2 1036

5. That regular meetings be held with plan checkers and inspectors in attendance to improve communication and to ensure that standards remain consistent. Feedback on field conditions and actual effectiveness of BMPs would be especially useful for the plan checkers. Another way to increase communication is simply to place plan checkers and inspectors in adjacent or nearby offices, as is currently done in Irvine.

6. That temporary staff be partly offset by training other inspection personnel, such as building inspectors, in erosion control methods. These inspectors would supplement the regular staff during peak periods, as is currently done in Irvine. An added benefit is that the inspectors are then able to recognize and report erosion problems on any site they visit while performing their normal duties.

7. That, in order to increase knowledge among agency personnel, all jurisdictions support and participate in the Soil Conservation Service's local erosion control training program. Each jursidiction may also decide to organize supplementary in-house training, emphasizing field applications.

8. That the filing time for complete erosion control plans be modified in some cases. For example, a grading application may be filed in April or May, with the operation planned to extend into the rainy season. The initial erosion control plan should be required for permanent measures, or measures such as sediment basins, that will be constructed before or during rough grading. However, rainy-weather measures should not be filed with the agency until August or September. At that time, the contractor will have a more precise construction schedule and can make his erosion control plan more specific.

9. That permanent erosion control measures be carefully inspected before the release of the grading bond. A permanent maintenance schedule should be established and the responsible party should be designated. In addition,

all temporary measures and sediment should be removed and stabilized in accordance with the erosion control plan.

10. That Irvine and Orange County collect a debris deposit similar to that of Newport Beach.

5.0 REGULATORY PROCESS

5.1 Present Agency Responsibilities

The Federal Water Pollution Control Act is administered by the Environmental Protection Agency. Section 208 of the act applies to nonpoint sources of pollution, such as sediment. EPA has designated the State Water Resources Control Board as the state planning agency under section 208. California's Porter-Cologne Water Quality Control Act enables the board to carry out its designated functions. These functions include guiding the statewide planning process to identify nonpoint sources of pollution and methods of control. In addition, the Porter-Cologne Act authorizes the board to establish water quality policy for the state.

The state board acts through the Regional Water Quality Control Boards. These regional boards are directly involved in applying statewide water quality goals through the development of water quality plans and the use of waste discharge requirements. These requirements set water quality standards. For example, land use activities cannot reduce water quality beyond the established limits. However, the regional boards cannot specify the methods by which the standards are to be met. It, therefore, falls to cities and counties to regulate land use activities and promote best management practices that reduce sediment production. However, if local governments fail to regulate land use activities, the regional boards may step in and take necessary enforcement actions to prevent pollution. For instance, regional boards may order remedial work to be done directly, and then recover the cost from the polluter. (John Muir Institute, 1979, pp. 83-93.)

5.2 Revised Implementation Framework

The attached flowchart shows recommended changes in the 208 Construction BMPs Implementation Framework. The original framework is given in Appendix A. The chart emphasizes the role of the responsible local agencies and shows the Water Quality Board as having review responsibility. It is recommended that the regional board not become involved in individual plan preparation and approval, but that it concern itself with general policy, coordination among local agencies, and enforcement problems when they occur. The monitoring of agency performance would be by report from the jurisdictions, and/or by independent verification by board staff. Site inspections are the best way to ensure that the management agencies are fulfilling their duties. It is recommended, however, that all jurisdictions continue to advise the regional board and other appropriate agencies of major grading projects by sending them a copy of the proposed erosion control plans.

This change in emphasis is most likely to affect the present working relationship between Irvine and the regional board. The board currently reviews all erosion control plans submitted to the city. However, expected state budget cuts will likely prevent the regional board from maintaining this high level of involvement. Therefore, Irvine eventually will need to reduce its reliance on the regional board for review of all erosion control plans. The resulting increased costs to the city may have to be partially offset by additional charges to developers.

The regional board should also take an active part in the erosion control training program. The board's guidance would be helpful in developing a program consistent with water quality goals, and one which encourages uniform enforcement among jurisdictions.

In the revised implementation framework, the board may request periodic reports from the management agencies in accordance with the Porter-Cologne Act, section 13225(c). One such report may be requested in October and would list the locations of grading operations, divided between regular grading and engineered grading (greater than 5,000 cubic yards). This list would assist the board in making site inspections during the winter. Another report may be requested by the board in May or June, assessing the agency's enforcement procedures during the preceding rainy season. The following items may be included in the report:

1. type and location of regulated grading projects, divided between regular and engineered grading;
2. types and design standards of erosion and sediment control measures;
3. number of inspections for each site; and
4. any enforcement actions taken by agency.

The board may wish to forego this detailed report if independent site inspections during the winter indicate that the management agency is rigorously enforcing its grading ordinance.

BRASH INDUSTRIES

30 December 1995

Santa Monica Bay Restoration Project
101 Centre Plaza Drive
Monterey Park, CA 91754

Attention: Ms. Stephanie McDonald
Contract Manager

Subject: BRASH Industries PIE 94-015

Dear Ms. McDonald:

It is with a sense of sadness that I compose this last Official correspondence on the BRASH PIE Project. The project and all of its relevant forms Exhibit E, Deliverables, text, and general outline information is included. Much useful stormwater information was gathered from the various Santa Monica Watershed cities and cities in other states.

In summary, the program was finished on time and delivered a good product. Our hope is that the information presented at the workshops will be useable for subsequent programs and that we all have had an opportunity to make positive steps in storm(-)water pollution prevention.

This program evolved to a "Grander" reality then was originally anticipated in its conception. This was made possible through the efforts of those who supported this project: Liz Allen-PS Enterprises, Donna Toy-Chen, HTM Office, EAD City of LA, and of course Stephanie McDonald of SMBRP. Stephanie, I enjoyed working with you and appreciate your timely assistance and support. There are numerous agency representative, trade associations, and professional people whose assistance also made our workshops successful.

I hope this project will be regarded by those who judge progress and success as a worthwhile model for supporting industry efforts to implement pollution prevention programs, in a business friendly environment.

Sincerely,

M. H. Sachse

Marvin H. Sachse, P.E.
President

STORMWATER 2000

EDUCATION BEFORE REGULATION

15 NOVEMBER 1995

WORKSHOP I

INDUSTRIAL FACILITY COST EFFECTIVE NPDES COMPLIANCE

9:00 - 9:15 Opening
Marvin Sachse, P.E. BRASH Industries

9:15 - 9:35 The Real Results of Stormwater Pollution
Dean Smith, Los Angeles County Department of Beaches and Harbors

This section addressed the incontrovertible evidence of pollution and its financial impact on the community. The cost of clean-up plus qualitative and quantitative information dramatically emphasized the need for Stormwater Management Programs.

9:35 - 10:05 Trends, Techniques, and Facility Trouble Spots
Dan Radulescu, Santa Monica Bay Restoration Project

This section focussed on the regulatory aspects of Stormwater Management. It also placed a human face on the regulators. It provided insights into the regulatory process, established that every-body is in the process together, and the their are some very bad operators that make it difficult for those who are striving for compliance.

10:05 - 10:20 Stormwater Management Assistance Sources
Donna Toy-Chen, R.E.A., Hazardous and Toxic Material Program, City of L.A. Environmental Affairs Dept.

The availability of free or low cost assistance is an encouraging sign for industry, and lets industry know that their tax dollars are being utilized for their assistance, not just their regulation.

10:20 - 10:50 Do It Yourself Compliance-NOI, SWPPP, Reports, Sampling: **Marvin Sachse**, P.E. BRASH Industries

A brief explanation of the NOI/SWPPP process, providing self help information on the completion of the SWM paperwork and sampling. Forms were presented to assist in SWPPP and Annual Report completion. Between-the-lines insights on sampling and how to reduce its cost were presented. Locations and sources of testings labs were offered along with pricing and sample collection and preservation guidelines. Information on Annual report completion was also presented.

10:50 - 11:00 Questions and Answers

VOL 12

2 1048

WORKSHOP II

COMMERCIAL/RETAIL STORMWATER COMPLIANCE

2:00 - 2:15 Opening
Honorable Ruth Galanter: City of Los Angeles Council District Six

2:15 - 2:35 Stormwater Pollution Impacts
Dr. James Fawcett, Los Angeles County Department of Beaches and Harbors

This section addressed the incontrovertible evidence of pollution and its financial impact on the community. The cost of clean-up plus qualitative and quantitative information dramatically emphasized the need for Stormwater Management Programs.

2:35 - 2:50 Santa Monica Bay Progress
Marianne Yamaguchi, Santa Monica Bay Restoration *Project*

The overview of the S M B R P provided perspectives on the magnitude of the bay pollution challenge, and more importantly, indication that progress was being made -- in a reasonable time frame.

2:50 - 3:10 Restaurant Perspectives
***Gerry Breitbart**, California Restaurant Association*

The importance of proper restaurant training and procedures to reduce stormwater pollution. Specific areas of concern were parking log maintenance, proper facilities maintenance procedures, floor mat washing. Points were brought up that much pollution originates from the purchaser not the food provider.

3:10 - 3:30 Fast Food Industry Compliance Experiences
Dan Milojevich, In-N-Out Burger

First-hand experience in working with different municipalities and regulatory agencies. The difficulties that were encountered as well as some of the cost effective solutions found in the working with regulators. The importance of stakeholder involvement cannot be overlooked.

3:30 - 3:50 Auto Services Compliance
Ron Wilkniss, Western States Petroleum Association

The automotive service industry has distinct stormwater concerns. This presentation was to assist gasoline and service station operators understand the regulatory environment as well as pollution prevention alternatives. Data was presented indicating that service stations contamination levels were at, or near, background levels.

3:50 - 4:00 Self Regulation and Education Before Mandatory Regulation
Marvin Sachse, P.E., BRASH Industries

The importance of self inspections and networking within an industry was emphasized as a means of reducing regulatory scrutiny. A present day, business sensitive, attitude exists with many regulatory agencies and municipalities. The importance of dialog was stressed.

DELIVERABLE CHECK LIST

1) Summary report of watershed city interviews and copy of survey form:

Submitted: July 1995 Copy Available upon request:

2) Technical Information Package: Copies of applicable workshop information publications.

Enclosed.

3) Module-Script of general presentation, in presentation form.

To achieve maximum audience interest regulatory experts, industry spokespeople, and company representatives with first hand compliance experience, were utilized as - featured speakers. They were all asked to provide a copy of their presentation for our records. One did, it is enclosed. A detailed agenda is enclosed to define the subject area that were addressed. This should provide the form for subsequent forums.

Comments Enclosed.

3a) Text of press release for module user to submit to media.

See 3b).

3b) Text of two, one minute public service radio announcements for module user to submit to radio stations.

Stephanie McDonald has same in her possession. The same item was used for PSA as well Print media.

4) Two Work shops, list of attendees:

Enclosed.

P. O. BOX 957 • VENICE, CALIFORNIA 90294 • TELEPHONE: 310-305-8637

VOL 12

2

1051

5) Summary of:

1) Work shop evaluation and copy of survey form.

Reviewed by Stephanie McDonald, SMB Project Manager, at work shop. Blank form included. Completed forms are available.

2) Summary of test City's reactions to using the module.

Enclosed.

Three cities provided evaluations. The cities that were in attendance were: Culver City, Hawthorne*, Los Angeles*, and Manhattan Beach*, Santa Monica. (Many more cities were invited to attend, but were unable to participate.) The summary of three polled cities (*) were:

The following points were considered very positively:

- **The presentation was well put together.**
- **The mix of speakers.**
- **The quality of speakers.**
- **The information presented.**
- **First hand experiences as related to storm water compliance.**
- **Representation by the different impacted industries.**

Deficiencies were:

- **The total number of industry representatives in attendance.**
- **How does one secure attendance by the key audience?**

The three cities polled expressed an interest in utilizing the module for their city's Stormwater program.

APPENDIX A
FIELD MONITORING PROGRAM

A.1 INTRODUCTION

The field monitoring program was designed to provide data to characterize runoff concentrations and to estimate nonpoint source pollutant loads entering the Lower South Bay from Santa Clara County. Monitoring during storm events was conducted to provide data to calibrate and verify the hydrologic and pollutant simulation model. Hydrological and water quality data associated with base dry-weather streamflows were also collected to estimate dry-weather annual pollutant loads. A secondary objective was to obtain initial information on the toxicity of both storm-related and dry-weather flows in streams entering the Bay.

The field monitoring program utilized three types of stations, as follows:

- Land use stations - Small, relatively homogenous land use catchments were selected to represent major land use categories. Data from these catchments were used as input to the loading model.
- Stream stations - Stations that were located in the lower portions of watersheds and which received a composite of storm runoff waters from multiple land use categories. Stream stations were monitored to provide data to verify the loading model.
- Reservoir stations - Stations located immediately below the water supply reservoirs. These were utilized to provide data to establish upstream background water quality conditions and to estimate loads associated with reservoir releases.

The field program can be conveniently described in terms of the following elements:

- The hydrology monitoring element consisted of continuously monitoring flows at stream and land use stations at hourly intervals throughout the duration of the monitoring program in order to estimate the hydrological component of the load.

- Water quality monitoring was conducted in three program elements: wet weather, dry weather, and reservoir release. Wet-weather water quality monitoring consisted of monitoring water quality at land use and stream stations for seven storm events. Storm composite samples were collected. The purpose of this sampling was to provide a basis for estimating pollutant loads during winter storm events. In order to estimate loads during winter base flow periods and summer dry-weather periods, dry-weather water quality monitoring was conducted by obtaining grab samples at the stream stations eight times through the program. To provide information on the water quality of water released from reservoirs, one round of reservoir release water quality monitoring was conducted at six stations immediately downstream of reservoirs.

- Bottom sediment sampling was conducted at the four stream stations. This sampling was conducted quarterly throughout the first year of the study. The purpose of this monitoring was to evaluate the role of bottom sediments as both a source and sink of pollutants associated with nonpoint source runoff.

- The bioassay testing program was designed as an initial screening of toxicity exerted by wet-weather samples obtained from land use and stream stations and dry-weather samples from stream stations.

In addition to the above, a number of special studies were conducted to address specific concerns. These studies examined: (1) dissolved oxygen concentrations during storm events at selected stream stations, (2) dissolved metal concentrations in runoff, (3) settling rates of suspended particulates in stormwater collected from stream stations, and (4) concentrations of fecal streptococci bacteria in stormwaters.

A.2 SAMPLING STATIONS

The selection of appropriate sites for the field monitoring program was critical to characterize stormwater runoff pollutants. The following sections discuss the selection criteria and the characteristics of the selected catchments and stations.

A.2.1 Selection Criteria

Specific site selection criteria followed the general guidelines provided by Shelley (1979). Criteria used to select specific monitoring sites were (1) catchment characteristics, (2) hydraulic factors, and (3) accessibility and safety.

Catchment characteristics of primary concern in selection of land use stations were representativeness of land use, overall size of the catchment, and uniformity of land use. In practice, the latter two concerns tend to operate in an opposite fashion, thus constraining the suitability of many catchments for siting of monitoring stations. With increasing size of the catchment, it becomes more unlikely that the requirement for uniformity of land use can be met. In the case of stream stations, it was desirable that the stations be located as far downstream in the watershed as possible, yet upstream of any tidal influences that would adversely affect the rating curve.

Hydraulic factors were important considerations in selection of both land use and stream stations. In the case of open-channel stations, it was necessary that eath be located at a site with an existing stage-discharge rating or at a site where adequate stage-discharge ratings could be established. Similarly, it was essential that manhole stations have suitable hydraulic characteristics for installation (and calibration) of the weirs. Thus, the following hydraulic factors were important considerations in the site selection process:

- Location at a site with an existing stage-discharge rating or at a site having a suitable control where a reliable rating curve could be developed

- Uniform and stable channel conditions for a distance equal to at least six channel widths upstream of the station

- Lack of tidal influence or backwater effects caused by downstream obstructions

- No evidence of surcharging or submergence over the normal range of precipitation (manhole installations)

- Adequate distance from major tributaries in order to allow for complete mixing

Safety and accessibility were important considerations, primarily to avoid accidents and injury, but also to ensure that field crews felt sufficiently safe so they exercised due care in conducting the field effort. Considerations included avoiding heavily trafficked areas or areas where light and/or visibility created conditions conducive to an accident with passing cars or trucks. Choice of station locations was also influenced by accessibility and security, and wherever possible, stations were located on SCVWD right-of-way which was secured.

A.2.2 Catchment and Station Characteristics

The following describes the catchment and station characteristics for land use and stream stations. For reference, Table A-1 summarizes general information and Table A-2 gives estimates of the land use mix of each catchment.

A.2.2.1 Land Use Catchments. The land use catchments were selected to represent the following major land use categories: light and heavy industry, commercial, single- and multi-family residential, and open.

Station L1 was a light industrial site located on Junction Avenue. The catchment drains a 22-acre industrial park bordered by Charcot Avenue, Dado Avenue, and Coyote Creek (in San Jose). The station was located in a manhole on Junction Avenue near the Southern Pacific Railroad (SPRR) lines. The storm drain diameter was 30 inches, and a sharp-crested weir was placed in the manhole to facilitate flow measurements. Truck traffic on Junction Avenue was often heavy and on one occasion was sufficient to create vibrations that broke the 10-liter glass bottle in the automatic sampler suspended below the manhole.

Station L2 was a heavy-industrial site on a catchment that drains Walsh Avenue between the SPRR lines and Lafayette Street (in Santa Clara). This 28-acre catchment included warehouse distribution centers involving heavy truck traffic, a used-car parts distributor, a commercial carpet cleaning service, a printing shop, and small miscellaneous manufacturing and office facilities. Initially there was an open drum storage area that was associated with a carpet cleaning facility; however, the drums were found to have been removed on a field reconnaissance conducted on December 5, 1988. The station was located in the right-of-way east of the SPRR lines in a manhole with a 20-inch-diameter storm drain. A weir was installed in the manhole for flow measurements. There was evidence of an illicit discharge at this station in August 1988 that was analyzed and shown to be strongly caustic.

Table A-1. STATION DESCRIPTION

Designation	Type of Station	Location	Location	Jurisdiction	Principal Land Use	Drainage Area (acres)	Conveyance	Remarks
L1	Land Use	Junction Avenue, between Charcot and Dado Streets	San Jose	San Jose	industrial park	22	30" R.C.P.	Manhole station, with weir installed
L2	Land Use	Walsh Avenue, near SPRR	Santa Clara	Santa Clara	heavy industry	28	27" R.C.P.	Manhole station, with weir installed
L3	Land Use	Frances and Beemer streets, north of Sunny-vale Caltrans RR Station	Sunnyvale	Sunnyvale	commercial	265	42" R.C.P.	Manhole station, with weir installed
L4	Land Use	Hale Creek, near Magdalena Rd.	Santa Clara County	SCVWD	low-density single-family residential (hillside)	1,633	open channel	SCVWD gaging station No. 33
L5	Land Use	Sunnyvale East Channel, near Fremont Avenue	Sunnyvale	SCVWD	single-family residential (valley)	2,080	channelized	Highly-erodable channel, rating developed
L6	Land Use	Pasetta and Williams, near San Tomas Expressway and SPRR	Santa Clara	Santa Clara	multi-family residential	85	33" R.C.P.	Manhole station, with weir installed

a Based on county and city general land use plans as compiled by SCVWD (projections generally ranged between 1989 and 2000), field reconnaissances, and aerial photos.

b Does not include areas above upland reservoirs.

c Definition of low-, medium-, and high-density residential differed amongst municipalities, but generally was as follows: Low--1 to 5 dwelling units/acre; Medium--6 to 12 dwelling units per acre; High--greater than 12 dwelling units per acre.

d Light-industrial land use refers to industrial parks and high technology manufacturing. Heavy industry refers to more traditional manufacturing and distribution centers.

Station L3 was a manhole station located at the intersection of Frances and Beamer Streets, north of the Sunnyvale Caltrans Station. The 300-acre catchment represented commercial and single-family residential land use and included the Sunnyvale Town Center and the Caltrans station. The drainage area was approximately bounded by the SPRR lines (north), Mathilde Avenue (west), Bayview Avenue (east), and Olive Avenue (south). A weir was also installed at this station.

Station L4 was located on Hale Creek near Magdalena Road. It drains a 1633-acre, low-density (1-2 dwelling units/acre), single-family residential area in Los Altos Hills. The station corresponded to SCVWD gaging station No. 33, which employs a sloping concrete weir as a hydraulic control for flow measurement.

Land use Station L5 was located on Sunnyvale East Channel at Fremont Avenue. It drains a 2080-acre predominantly single-family residential area. The monitoring station, located in a short earthen reach between Fremont Avenue and Ashbourne Drive, was just upstream of a concrete apron and box culvert which pass under Fremont Avenue. The channel was subject to extensive bank and bottom erosion, especially in the area downstream of the box culvert below Ashbourne Drive.

Station L6 was a 85-acre catchment consisting of a multi-family residential area bounded by Passetta, Williams, and Monroe streets, and Deborah Drive, and a single-family residential area located along Sheraton Drive and El Capitan Avenue. This catchment also included a church and school. The station was located in a manhole near the San Tomas Expressway and the SPRR. The second manhole upstream of the station was located at the junction of Passetta and Williams streets. The storm drain in the manhole was 33 inches in diameter. A weir was installed at this station to better estimate flows.

VOL 12

Station L7 was on Stevens Creek, just upstream of Camp Castanoan Bridge, above Stevens Creek Reservoir. The 8410-acre drainage area consisted primarily of steep, heavily forested land in the Santa Cruz Mountains.

Station L8 was a second open land use catchment (6464 acres in area) located in the Diablo Range and draining primarily open ranchland. The station corresponded to the SCVWD gaging station No. 57 on Packwood Creek, upstream of Anderson Reservoir.

A.2.2.2 Stream Stations. Four stream stations were selected at locations near the Bay, but above the zone of tidal influence. The purpose of the stream stations was to provide a means of making loading estimates from large catchments solely with measured flow and water quality data. Such estimates could then be used as a check by comparing findings with the model predictions (based on the upstream land use characteristics). The following is a description of the stream stations.

2

Station S1 was located at the SCVWD gaging station No. 26A, located on Calabazas Creek near Wilcox school. The drainage area is 14 square miles and consists of approximately 80 percent residential/commercial and 20 percent open (Table A-2), the latter of which is located mostly in the upland portions of the catchment in the foothills of the Santa Cruz Mountains. The control is a sloping concrete weir.

1069

Station S2 was located on Sunnyvale East Channel, just upstream of Awhanee Avenue (a frontage road along Bayshore Freeway). This catchment has an area of 5.2 square miles and is wholly urbanized, consisting of residential (68 percent) and commercial (32 percent) land use on the valley floor. The station corresponds to the SCVWD gaging station No. 74. The control is a sloping concrete weir.

These two stations were selected to be representative of the smaller more urbanized watersheds on the west side of the Study Area.

Station S3 was the USGS station No. 1119000 on the Guadalupe River, located downstream of the confluence with Los Gatos Creek. This station has a total drainage area of 146 square miles and includes Los Gatos Creek and Lexington Reservoir, Guadalupe Creek and Guadalupe Reservoir, Ross Creek, Alamitos Creek and Almaden Reservoir, and Calero Creek and Calero Reservoir. This station was selected because it drains a large urbanized area that is accurately gaged. The area of the catchment below the reservoirs is approximately 85 square miles. The land use in this area is 30 percent open, 61 percent residential, 5 percent commercial, and 4 percent industrial (Table A-2).

Station S4 was located on Coyote Creek at Montague Expressway at the SCVWD high-flow gaging station No. 2060. This catchment includes Upper Penitencia and Silver and Thompson creeks, and Anderson and Coyote reservoirs. The catchment area below Anderson Reservoir is approximately 120 square miles, 64 percent of which is open ranch land located in the foothills of the Diablo Range. The remaining land use consists of 30 percent residential, 1 percent commercial, and 5 percent industrial (Table A-2). The SCVWD gaging station at this location was designed to record only flood stages, so this station had to be rated for more typical lower storm-event flows.

A.2.2.3 Reservoir Stations. The reservoir stations were located at SCVWD gaging stations below Stevens Creek, Lexington, Guadalupe, Almaden, Calero, and Anderson Reservoirs (Table A-1).

A.3 SAMPLING AND ANALYSIS PROGRAM

A.3.1 Hydrology

The field study was designed to collect accurate hydrological information at each station to quantify discharges throughout the year and to collect flow-weighted composite samples. Thus, monitoring of stage (water depth) was performed continuously throughout the year, at all stations that had year-round flow.

The majority of open-channel stations were located at sites which had previously-established stage-discharge curves. Two of the open-channel stations (L5 and L7) required establishment of new stage-discharge curves. A third station (S4) required establishment of the low-flow portion of the rating curve.

Flow ratings at all four manhole installations were initially calculated using a standard weir-rating formula. These ratings were later calibrated at manhole installations L2, L3, and L6 using dye-dilution methods.

A.3.2 Water Quality

Water quality constituents included in the field monitoring program were selected based on the following factors:

- Constituents previously identified to be a major concern in Lower South Bay and its tributaries
- Constituents previously identified as prevalent in urban runoff studies conducted as part of EPA's National Urban Runoff Program
- Pollutants expected to be present in surface runoff waters from the Study Area, based upon industrial sources, or other specific local knowledge

- Pollutants identified historically in nonpoint source runoff samples collected within the Study Area

The overall approach of the water quality studies was to examine a wide range (or "full suite") of potential pollutants in the early phases of the study and then develop a more refined list (or "reduced suite") of pollutants based upon results of the initial surveys (Table A-3). One analysis, organophosphate pesticides, was added to the reduced suite but was later eliminated, because none were detected.

A.3.3 Sediment Quality

The overall approach and list of sediment quality constituents (Table A-4) were similar to those described for the water quality testing program. The primary difference in the sediment quality program was that the reduced suite of constituents was originally expected to retain the broader scan of organic contaminants provided by the semi-volatile (EPA 625) GC/MS analysis. It was originally expected that a number of priority pollutant compounds would be detected in sediments, due to their low solubilities and their tendency to associate with fine particles. Due to low levels of these compounds detected, the final suite of constituents focused more directly on polynuclear aromatic hydrocarbons (PNA) that are produced as by-products of internal combustion engines.

Organophosphate pesticides were analyzed in the sediments on only one occasion. Since none were detected in the samples, this group of compounds was not included in later analyses.

A.4 SCHEDULE

The field monitoring program was initiated in February 1988 and completed in April 1989. Figure A-1 shows the schedule and Table A-5 gives specific sampling dates. A single survey was conducted to assess the quality of water discharged from six major reservoirs in the Santa Clara able A-3. SUITES FOR CHEMICAL ANALYSIS OF WATER QUALITY SAMPLES

Valley. The reservoir water quality survey was conducted on February 26, 1988, concurrently with the first dry-weather water quality survey.

A total of seven dry-weather water quality surveys were conducted during the 15-month field program. Four of these studies were conducted during winter months, two during the spring, and one in the autumn following a lengthy dry period.

Seven wet-weather (i.e., storm) events were sampled to obtain water quality data. The first and only storm event sampled in the 1987-88 wet-weather season occurred on April 20, 1988. The six remaining storm events that were sampled occurred in the 1988-89 wet-weather season. The first significant rainfall of the 1988-89 wet-weather season was sampled on November 23, 1988. The remaining five storm events monitored were in January, February, and March 1989.

Three wet-weather toxicity tests were conducted in February and March 1989. Dry-weather toxicity testing was coordinated with the December 12, 1988, and the February 1 and April 6, 1989, dry-weather water quality surveys.

The sediment sampling was fully completed during the first year of the study. The final quarterly sediment survey was completed on December 12, 1988.

A number of other program elements classified as "special studies" were completed in association with storm events sampled in early 1989. Detailed monitoring of dissolved-oxygen levels was performed at the four stream stations on February 9. Concentrations of dissolved metals were added to the suite of constituents measured in storm runoff during the March 25 and April 6 storm events. Experiments on settling rates of suspended particulates were conducted on samples collected on May 25. A special survey of concentrations of fecal streptococci bacteria was conducted in association with the January 23 storm event.

A.5 EQUIPMENT

A.5.1 Station Design

Two generalized station designs were employed in the field study. The most common design was for monitoring flow and water quality in open channels. This configuration varied slightly among the several stations, depending upon specific site characteristics. The second type of station was designed for monitoring flow and water quality within storm sewers.

The following design considerations were common to both station configurations:

- Intakes must be protected from large objects transported by the stormwater runoff.
- Intakes must be located in a well mixed area not subject to burial or emergence.
- Water velocity in the intake hose during sampling must be maximized to maintain particulate material in suspension.
- Intake hose material must be appropriate to avoid metals and organic contamination of samples.
- Sample container material must be compatible with holding samples to be analyzed for both trace metals and organic compounds.
- The peristaltic pumps must be capable of delivering consistent sample volumes, regardless of intake hose length and changes in head associated with the rise and fall of stage in the water body being sampled.

VCL 12 2/078

- Automatic samplers should not exceed a head difference of 20 feet above the water in order to prevent deterioration in water velocities within the intake and decreasing precision in sample volume.

All intakes were placed in cages constructed of quarter-inch stainless rod. These cages were designed to deflect moderate-sized objects around the intakes and the pressure sensors. Coarse stainless steel intake screens were used to reduce the likelihood of blockage within the sample tubing.

In most installations, intakes were positioned between 2 and 4 inches above the bottom, as recommended by Shelley (1979). This range was believed to be a reasonable compromise between avoidance of bedload transport and keeping the intake submerged. When base flow conditions allowed, the intake was positioned higher in the water column. For example, the base stage in Coyote Creek was typically around 3 feet, so the intake at this station was positioned 1.5 feet off the bottom.

The 3/8-inch (i.d.) intake hose was constructed of polyethylene on the outside and Teflon on the inside. The polyethylene provided the required physical strength while the Teflon provided a suitable material for handling samples which would be analyzed for either metals or organic compounds. The bore diameter of the intake hose was selected to maximize the velocity of flow within the hose (in order to prevent settling of suspended solids). An internal diameter of 3/8 inch was calculated to maintain the minimum velocities of 1 to 2 fps at head differences of up to 20 feet.

Consistent sample volumes were obtained over a wide range of head differences by development and use of an algorithm which could compensate for changes in head pressures. This algorithm was part of the specialized software developed to control the automatic samplers. The number of pump rotations necessary to obtain a sample volume of 500 ml was calculated as a function of intake hose length and an instantaneous measure of head pressure between the pump and surface of the water. This value could be calibrated in the field to compensate for specific station configurations.

The composite sample containers provided commercially by ISCO were inappropriate for collection of water for analysis of both trace metals and organic compounds. Borosilicate glass provided the best alternative for collection of water to be submitted for metals and organics. Thus 10-liter, borosilicate media bottles were used to replace the standard containers.

Although the open-channel and manhole installations shared common design criteria, the manhole installations were unique in that they required installation of a primary control device to increase accuracy of flow measurements, particularly at lower flows. Rectangular sharp-crested weirs were used, because they were found to be the most cost-effective primary control device to fabricate and install in this application.

A.5.2 Weirs

All weirs utilized in the manhole installations were rectangular weirs made from quarter-inch steel plate. The heights of the weirs were generally about one-half the diameter of each pipe. A rectangular cutout with a width equal to one-quarter of the pipe diameter and a depth equal to one-sixth of the diameter was placed in the center top portion of the weir to facilitate accurate measurement of lower flows (see Figure A-2).

Each weir was secured by stainless steel cable to eyebolts set in the wall of the manhole. This both prevented the weirs from becoming lodged in the pipe if they were to break loose during a storm event, and it allowed for quick removal of the weirs, if upstream flooding were to occur. Hoses were attached to the back of the weirs to aerate the nappe.

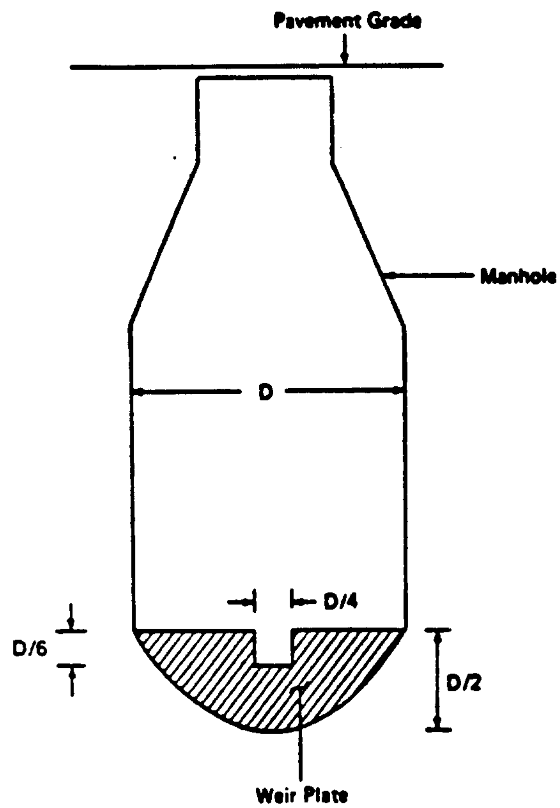

Figure A-2. WEIR SCHEMATIC

A.5.3 Automatic Samplers and Stage Recorders

Automatic samplers and stage recorders were deployed in all of the open-channel and manhole installations. Each system consisted of an ISCO Model 2700 composite sampler, a Campbell Scientific Model CR-10 Data Logger and Control Module, and a pressure sensor. GeoKon Model AVW-1 Vibrating Wire pressure/temperature sensors were initially installed at all stations. These sensors were selected for the study on the basis of their extreme durability and accuracy. Nevertheless, a number of these sensors were observed to drift out of specifications in the early stages of the study. These sensors were then replaced with the newly available Druck Model PDCR-830 titanium pressure sensors. These Druck sensors proved to have both excellent accuracy and stability characteristics under a variety of field conditions.

The ISCO composite samplers were used to pump, cool, and store water samples during storm events. The standard programmable read-only memory (PROM) units which contain the instruction set for the samplers were specially modified to allow full external control via the sampler's flowmeter input data port. All pumping functions could then be controlled externally by the Campbell Scientific CR-10.

A.5.4 Data Logger

Campbell Scientific CR-10s were used at each station to provide overall system control functions and to serve as a central data processor and data storage module. Two types of data, high-resolution storm data and continuous (dry- and wet-weather) hydrology data, were recorded by the data logger. Data were nondestructively retrieved by use of a standard, portable tape deck. The tapes were then read by an IBM-compatible microcomputer with a Campbell Scientific PC-201 card. If the data dump was defective, the station could be revisited and the data retrieved again.

The storm data memory register stored detailed information on the storm events, including the time the storm mode was initiated, the time each

VOL 12

2102

sample was taken, and the storm runoff volume represented by each sample. After completely filling a 10-liter sample container, 15-minute-averaged values for temperature, stage, and flow were stored in the storm memory register until the station was visited by the field crews to change sample containers.

The continuous hydrology memory register maintained hourly-averaged temperature and stage data. These data were continuously recorded during storm events and base flow conditions.

A.5.5 Software to Initiate and Terminate Flow Composite Sampling

Software installed in each CR-10 was designed to continuously monitor stage at each monitoring station and then automatically initiate flow-weighted composite sampling. Pressure sensors were interrogated every 15 seconds to determine stage. Fifteen-minute averages of the stage data were then stored and later used to evaluate whether storm sampling should be initiated.

The software enabled storm sampling to be initiated, based upon both relative and absolute criteria. At the end of every 15-minute interval, stage or flow data (using stage-discharge equations) were compared to those obtained during the prior 15-minute interval. Storm sampling was initiated, if percentage increases in one of these parameters exceeded a given criterion, typically 20 percent. This criterion could be modified to adjust sensitivity of the "trigger," based upon the specific hydrological characteristics of each station.

In addition to comparing relative increases in either stage or flow, storm sampling could be automatically initiated if the 15-minute average stage measurement exceeded a set value. This trigger was particularly useful for stations that, under certain conditions, did not increase rapidly enough in stage to exceed the relative criteria or where no base flows were present.

Flow-weighted composite sampling could also be terminated by software control of the system. The data loggers were programmed to terminate the storm sampling mode once the stage dropped below a level 20 percent greater than the storm initiation or trigger stage. Sampling would not terminate automatically without first filling a sample container.

A.5.6 Equipment and Installation

Instrumentation for all open channel installations was contained in custom-built 2-ft x 4-ft x 30-inch steel enclosures mounted on concrete pads. In natural channels, conduits for containment of pressure sensor leads and water intake tubing were installed through the concrete pad and led underground to the channel. In some cases, a short conduit (approximately 0.5 to 1.0 feet) was installed between the instrument enclosure and adjacent stilling wells. The pressure sensor could then be installed in the stilling well where it was well protected from potential vandalism. For installations where both stilling wells and concrete channels existed, both the pressure transducer and intake hose were run into the stilling well. The intake tubing was then fished through the lower communication port and mounted at the bottom of the channel.

Each storm sewer installation was completely contained within the existing manhole chambers. All equipment was suspended by metal cable slings from eyebolts installed in the concrete wall just under the manhole cover. A two-person field crew was required to conduct routine monitoring involving removal of the sampling equipment from the manhole. Data dumps and routine monitoring of station operation could be performed by one person, since the systems communication port was located immediately below the manhole cover.

A.6 SAMPLING METHODS

A.6.1 Field Procedures and Training

A detailed set of Standard Operating Procedures (SOP) were developed for all phases of the field monitoring program. The SOP contained the following procedural instructions:

- Standard Observations
- Initial setup of the composite samplers
- Storm monitoring station software initiation
- Battery replacement
- Data retrieval
- Sample removal and handling
- Grab sampling
- Sample transfer and tracking

Field training sessions were held prior to each storm season for personnel expected to participate in storm monitoring. The training sessions involved review of the SOP and hands-on experience in interrogating a model storm monitoring station.

Additional training was provided in the field during station maintenance visits. Less experienced field personnel were routinely deployed with key project personnel. This enabled greater dissemination of important station-specific knowledge (e.g., location and special handling needs) and provided an opportunity to practice station interrogation skills that would be needed during the intensive storm monitoring events.

A.6.2 Grab Samples

Grab samples were taken for all water samples that were not appropriate for analysis from the pumped composite sample. Grab samples were necessary for bacteria, volatile organics, pH, and dissolved oxygen.

Two methods were used to obtain grab samples of water. The primary method involved direct collection of the water sample in the sample container. The open container was attached to a stainless steel rod. This enabled the open container to be fully immersed as near as possible to the centroid of flow and eliminated potential contamination of the sample. This method was applied to samples collected for bacteria, volatile organics, and pH. Van Dorn (1.5-liter) bottle samplers were used for collection of samples for measurement of dissolved oxygen.

The guidelines followed by Kinnetic Laboratories field personnel for grab sampling during storm events calls for collection of samples in the early phase of the storm, certainly during the rising limb of the hydrograph. Most of the grab samples collected in this program were performed in the early phase of the storm.

Sediment grab samples were collected either by use of clean stainless steel scoops or by scraping the sediments directly into the sample containers. Four to five different scrapes were taken to comprise a single sample. A conscious effort was made to sample finer-grained sediments in depositional areas of the stream bed. In several cases, appropriate sediments were difficult to locate. In such cases, professional judgement was used to locate the most appropriate sediments along a given reach.

A.6.3 Automatic Samplers

Sampling of stormwater runoff was accomplished primarily by use of modified ISCO composite samplers. The automatic samplers were designed to take 500-ml aliquots of runoff water at time intervals corresponding to a given volume of water flowing by the monitoring station. The volume of runoff represented by each 500-ml sample was a user-specified value. The default setting for each site was 1/20 of the expected runoff volume for a 0.25-inch storm. The sampling rate at a given station could be altered in the field by increasing or decreasing this value. It was necessary to adjust this variable based upon both sample volume requirements (e.g., additional analytical and bioassay water requirements) and anticipated rainfall in excess of 0.25 inches.

The percentage of the total storm represented by each composite sample varied widely among storm events and stations (Table A-6). The precipitation, runoff, and required sample volumes were important factors in determining the percentage of the storm from which flow-weighted composites were attained. After depositing 19 samples (9.5 liters) into the composite sample container, the monitoring system would go into standby mode until visited by the field crew. High sampling rates or brief, intense periods of rainfall occasionally caused the composite samplers to fill too rapidly and enter the standby mode. This would cause loss of storm coverage until the station was revisited by the field crew. Low sampling rates or lower than anticipated rainfall would result in good storm coverage but inadequate sample volumes.

A.6.4 <u>Effects of Partial Storm Capture on Load Estimates</u>

In the field monitoring efforts, it was not always possible to secure samples over the entire runoff period, for use in the flow-weighted composites that were analyzed. In some cases, this was due to the inability of field crews to reach all stations before runoff began. In most cases, it resulted from the sample collection container filling before runoff from the event had terminated. A record was maintained of the fraction of the total runoff volume that was sampled and incorporated in the samples for water quality analysis. This information is summarized in Table A-6 which lists, for each event at each station, the ratio of the sampled volume to the total volume of runoff.

As the listing indicates, the storm fraction sampled varied from event to event at any site, and the pattern was not consistent from site to site for a specific storm event. Fifty-seven (57) of a possible 70 station-events produced composite samples that were analyzed for water quality. Four station-events were missed due to equipment malfunction (SM). The

Table A-6. PERCENT OF STORM EVENT RUNOFF SAMPLED[a]

Event No.	Date of Storm Event	L1	L2	L3	L4	L5	L6	S1	S2	S3	S4
		Stations[b]

7	3-23-89	NS	NS	78	60	100	95	36	50	SM	67

a The ratio of the volume sampled to the total volume of runoff is the percentage of the runoff sampled.

b Samples were not obtained at Station L8 because of lack of runoff; samples were obtained at Station L7, but the rating curve was affected by downstream activities.

c The percent sampled was considered too small for the data to be considered representative.

NS Not sampled (often because of lack of runoff).

SM Sampling equipment malfunctioned.

* Volume sampled did not include the storm peak.

remaining nine (NS) produced no water quality samples, often due to lack of runoff.

An evaluation of the potential effect of the percentage of an event sampled on the estimate of the site median concentration (SMC) which was used in developing pollutant load estimates was structured on the basis of the following considerations.

- The data set as a whole covers a wide range of sampled fractions, and a significant spread in percent sampled also applies generally to individual stations.
- The quality data exhibit significant variability, with each station having a different mean or median.
- Concentrations of different pollutants have different orders of magnitude.
- Working separately with individual pollutants at individual sites provides too small a sample for reliable analysis.

To evaluate the effect of the fraction of the storm sampled, each EMC (event mean concentration for the site-event for each pollutant) was first normalized by computing the ratio of the individual concentration value to the SMC for the corresponding pollutant and site. Individual EMCs are tabulated in the Volume I Appendix document. The SMC values used are those presented in report Tables 6-2 and 6-3. Pollutants used in this analysis were those for which nearly all measurements were above detection limits. This set included six metals (Cd, Cr, Cu, Pb, Ni and Zn), plus TSS, BOD and Total Hardness (TH), to have several different basic pollutant types represented. The normalization procedure reduced all the data to a common basis, and provides a sample size of about 500 values for analysis.

A comparison of the normalized pollutant concentrations in relation to the percentage of the storm event that was sampled is displayed by Figure A-3 for the Land Use Sites, and by Figure A-4 for the Stream Stations.

Pollutant concentrations for the Land Use Sites provided the primary basis for the load estimates. A good basis for comparison exists here, because 42 percent of the site-events captured 90 to 100 percent of the runoff (65 percent captured more than 70 percent). The display indicates that the variability in measured concentrations of the nine different pollutants is unrelated to the fraction of total runoff volume captured. There are a small number of individual values that deviate substantially from the median, but the bulk of the results (all pollutants, all sites, all percent captures) fall into a relatively narrow band either side of the site median (Ratio = 1). Note that each SMC reflects a series of events with an appreciable range of percent captures.

On this basis, we conclude that the pollutant site median concentrations, which provided the principal basis for load estimates, are not distorted by the lower percentages of total runoff that were sampled for some events. This situation, therefore, has not influenced the load estimates that were developed.

Results for the Stream Stations are generally similar, but with the difference that less than 10 percent of the values apply to events where more than 90 percent of the runoff was captured. For these stations, 85 percent of the values apply to events which captured between 30 and 70 percent of the storm flow. There is no trend indicated either within this range, or compared with the limited data at 100 percent runoff capture. The single set at 3 percent capture (event 3 at station S-1) would be appropriate to exclude, although this single set of values will not have a significant effect on the overall study results.

Fig. A-3. Effect of Percentage of Total Storm Sampled on Event Mean Concentration Land Use Sites

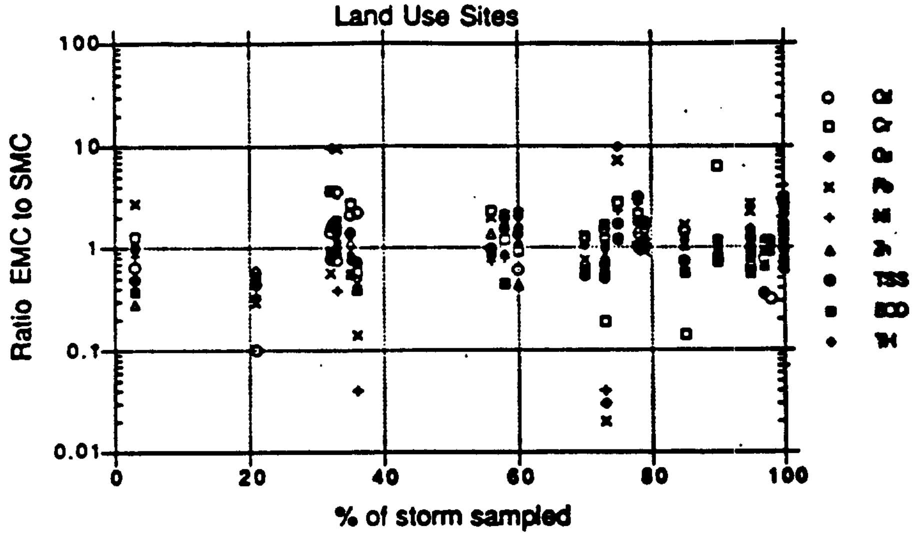

Fig. A-4. Effect of Percentage of Storm Sampled on Event Mean Concentration Stream Stations

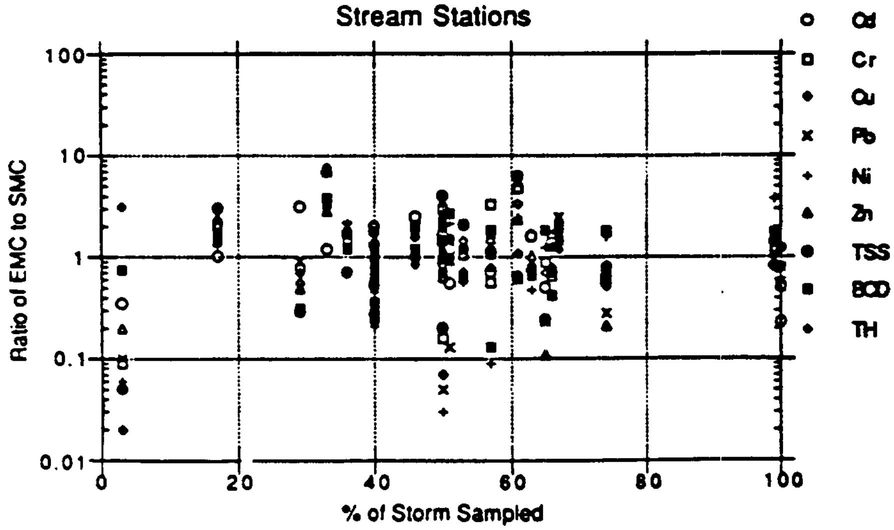

VOL 12

2 1091

R0054391

The stream concentrations were utilized in the study for comparison with projected in-stream concentrations computed from the land use runoff. The differences (measured concentrations were consistently greater than projections based on land runoff) provided the basis for a correction factor. The variation in percent capture of event runoff is not indicated to influence estimates of stream concentrations. However, because the bulk of this data is based on 30 to 70 percent capture of the total event values, there is a somewhat greater uncertainty in the concentration estimates for the Stream Stations, than is the case for the Land Use Sites.

A.6.5 Flow-Rating

Development of new stage-discharge relationships was required at three open channel stations and three manhole stations. In manhole stations, rectangular notched weirs were installed. Flow was then estimated based on the theoretical sharp-crested contracted weir equation (ISCO 1979):

$$Q = 3.33\ (L - 0.2H)H^{1.5}$$

where

Q = flow (cfs)
L = width of the weir crest (ft)
H = stage (feet)

This equation was verified by performing low-flow dye dilution measurements at the manhole stations. These tests indicated that some calibration of the weir equation was required for flow within the weir notch at stations L2 and L3. As a result, the following rating curves were used for low flows in these weirs:

$Q = 1.73H^{.85}$ (Station L2)
$Q = 1.83H^{1.79}$ (Station L3)

VOL 12 2 1092

R0054392

Rating curves for stations L5, L7, and S4 were developed from discharge measurements. Rating curves were developed only for low flows at station S4, since a high flow rating curve had previously been developed by the SCVWD. Figures A-5, A-6, and A-7 show the rating curves for these three stations. Discharge measurements for these stations were generally good. For station S4, the rating curve was developed from 10 flow measurements, and a good fit was obtained to these data. However, the rating curves for stations L5 and L7 are at best of fair quality, given the low number (three) of discharge measurements used at each station.

Current-meter surveys were conducted to develop stage-discharge data at the three open-channel stations. Discharge methods were made using standard USGS methods (USGS 1970). It was desired that at least six discharge measurements be taken over a full range of stages in order to obtain reliable rating information at each site.

Dye-dilution methods were used to verify weir equations at three of the four manhole stations. (At these stations, provisions for a water supply could be arranged with the local water supplier.) Intra-acid Rhodamine WT was used as the tracer. Rhodamine WT is a nontoxic, fluorescent tracer dye that is commonly used in applications such as this. This dye is stable and is not easily adsorbed to particulates.

Flow was established at each station by use of upstream fire hydrants. Dye of a known concentration was injected into the turbulent flow at an upstream manhole by use of FMI constant displacement piston pumps. Stage, temperature, and dye concentration were then measured just upstream of the weir at the subject station. Periodic water samples were obtained for later laboratory verification of dye concentrations in order to provide backup to the field fluorometer and to make certain that concentrations were in the linear response range of the fluorometer. Due to the limited flow capacity of fire hydrants, verification of the theoretical weir equations was only possible for low-flow conditions.

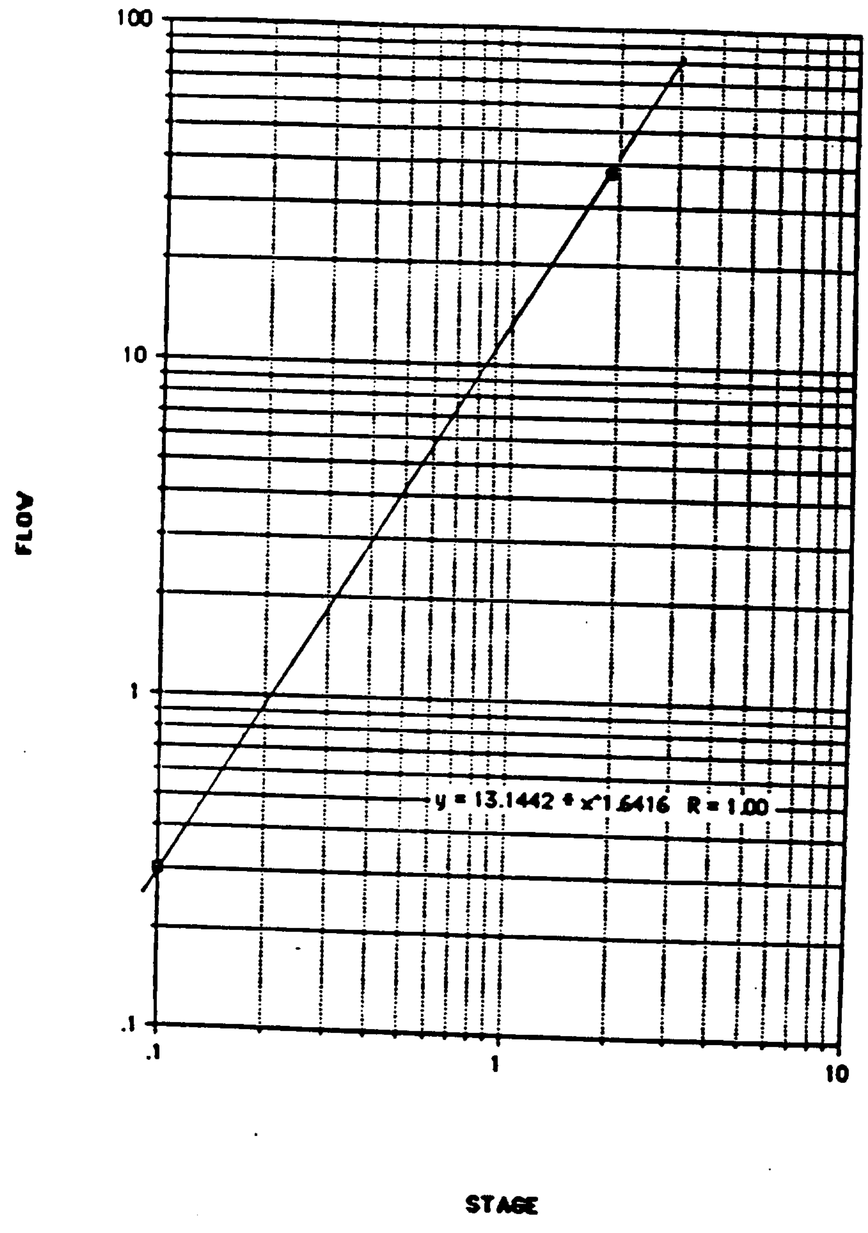

Figure A-5. Rating Curve for Station L5

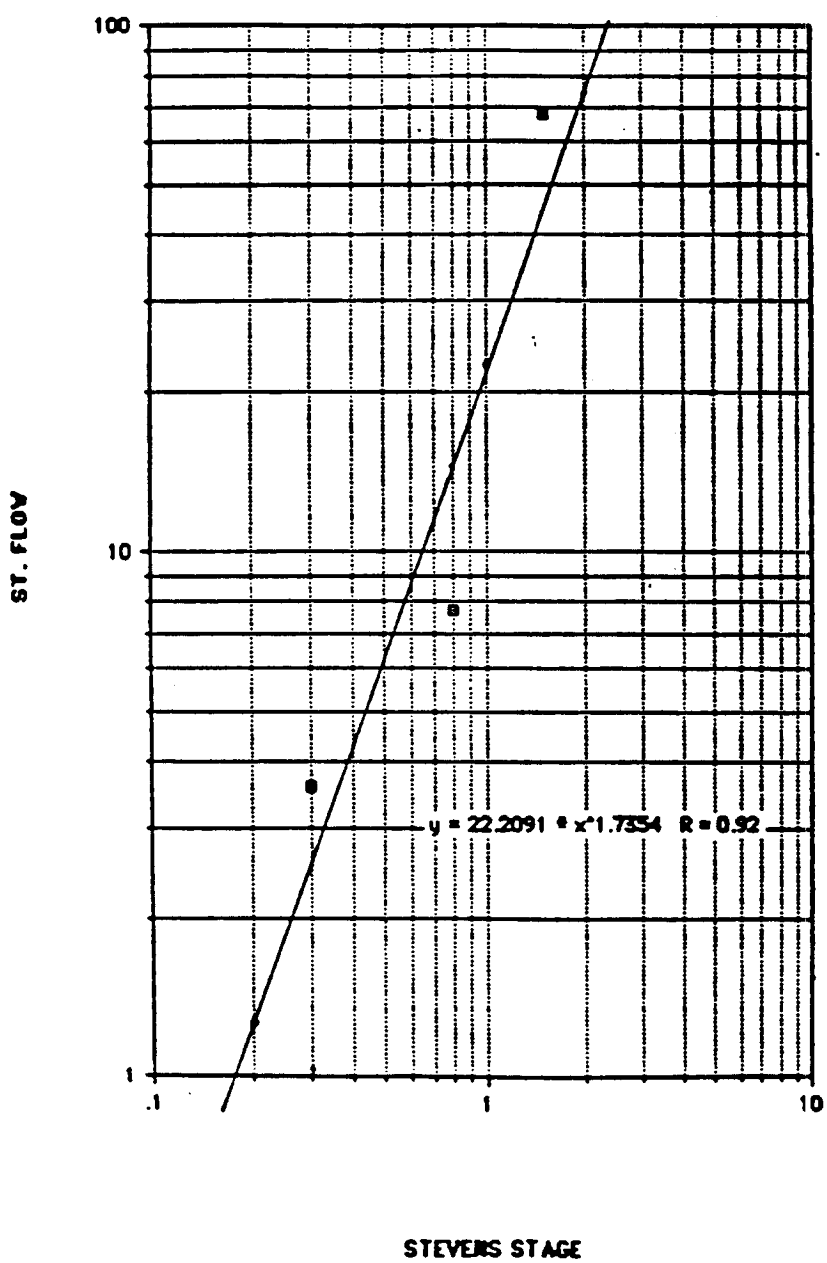

Figure A-6. Rating Curve for Station L7

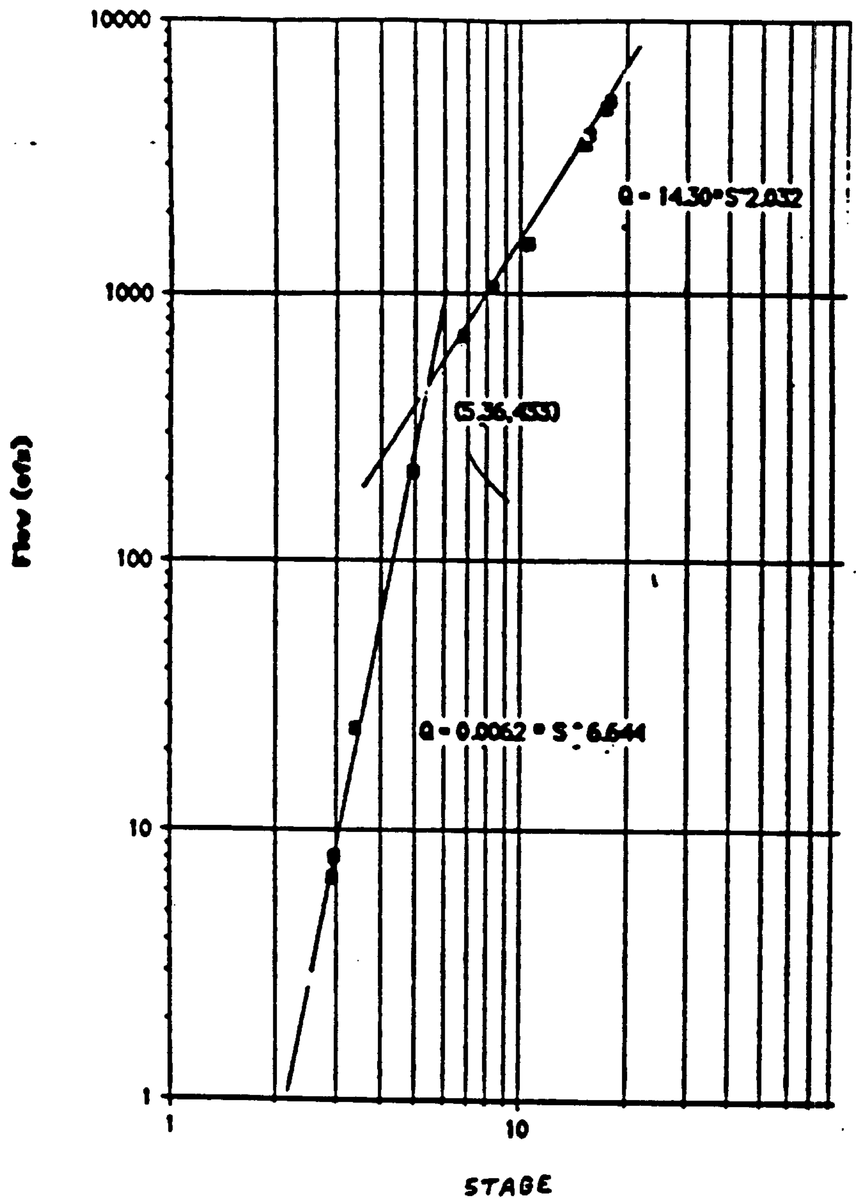

Figure A-7. Rating Curve for Station S4

A modification of the channel occurred at one station, L7 (Stevens Creek at Camp Castanoan Bridge), midway through the study. That alteration required establishment of a second rating curve. A small rock dam was constructed just below the station in order to enhance the water supply system for Camp Castanoan. This dam was breached during a storm in early March, at which time the initial flow rating was reinstated.

A.6.6 Special Studies - Dissolved Oxygen

Many of the previous studies involving nonpoint source water quality have been concerned about depression of dissolved oxygen levels in the receiving waters. A single intensive study was conducted at each of the four stream stations to measure dissolved oxygen concentrations during and after stormwater discharges.

Dissolved oxygen was measured for a period of approximately 35 hours using duplicate Winkler titrations in lieu of polarographic membrane probe techniques. The titrations provide a much more accurate estimate of dissolved oxygen, particularly in the presence of oil and grease. Polarographic oxygen probes can become rapidly desensitized if contaminated with oil and grease.

Dissolved oxygen results did not show any signs of depression for all four stations studied. The DO results are summarized here and shown in Appendix D.8. For station S-1, DO ranged from 8.9 to 11.8 mg/L, and DO levels ranged from 8.6 to 12.2 for station S-2. The DO concentrations were similar for stations S-3 (9.7 to 10.4 mg/L) and S-4 (8.5 to 9.6 mg/L).

A.6.7 Special Studies - Dissolved Metals

Two sampling rounds were conducted to evaluate the relative contributions of dissolved metals and particulate-associated metals in stormwater runoff. Both dissolved and total metal concentrations were measured in all stormwater samples obtained during each storm event.

VOL 12

2 / 1097

VOL 12

Dissolved metal samples were subsampled from the composite storm samples in the same manner as the total metal samples. Prior to fixation, the dissolved metal samples were filtered through 0.45-micron polycarbonate filters. The filtrate was subsequently acidified with HNO_3 to a pH of less than 2.

A.6.8 Special Studies - Settling Column Tests

A preliminary screening of the settling characteristics of particulates present in the NPS discharges from the study area was made by conducting settling tests on samples taken from each of the stream stations (S-1, S-2, S-3, and S-4) during the storm runoff event in March 1989.

This effort was designed to provide information on settleability, for reference and potential use in the consideration of issues such as detention basin controls, sediment accumulation and scour in stream beds, and pollutant accumulations in bay sediments.

Because of the nature of the test procedure and the variability expected of particle size distributions in stormwater runoff, the results obtained should only be considered to provide a general approximation of the settling characteristics of particulates that are introduced to the South San Francisco Bay by nonpoint sources in the study area.

The tests were performed using a settling column constructed from an 8-inch in diameter by 5-foot, 1-inch-long lucite tube. Four sample ports are located at 1-foot intervals.

The column is filled to the top with a sample of the water to be tested, and then stirred to distribute the settleable solids uniformly throughout the column.

2 1098

A sample at time zero is analyzed to establish initial conditions. Total suspended solids (TSS) was selected as the pollutant analyzed for these tests.

Samples are then withdrawn from each port at selected time intervals after the start of the test. They are analyzed to determine the concentration of TSS that remains at the sample location after the elapsed time interval.

The difference between each such concentration and the amount present initially is used to compute a percent removal.

Since each combination of depth to a sample port and elapsed time to the sample reflects a specific distance settled in a specific interval of time, each sample corresponds to a settling velocity (feet per hour). Each such value corresponds to a percent removed value computed from the measured concentration.

The results can be interpreted as the percentage of the TSS in the sample that have settling velocities equal to or greater than the value represented by the port depth and sample time. The results are then plotted to provide an indication of the frequency distribution of pollutant settling velocities in the sample.

Test results are summarized in Table A-7. This table lists both the measured concentration and also the percentage of the initial concentration that each value represents. It also lists the set of settling velocities (in feet per hour) that are computed from the various combinations of depth and sample time. Note that the combinations employed result in multiple measurements for some settling velocities. In the table, the settling velocities are listed in increasing rank order, and for each of these the corresponding removal percentage is tabulated for each of the four samples.

VOL 12 2/1/01

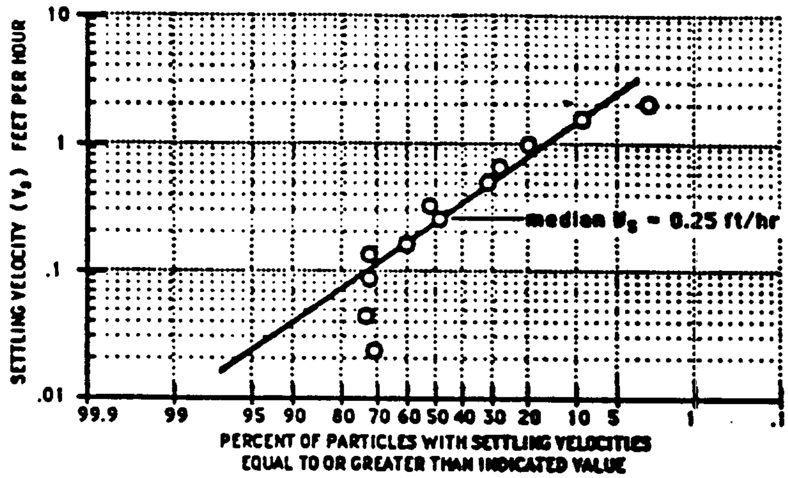

Figure A-9. Distribution of Settling Velocities of Pooled Data for Stream Stations

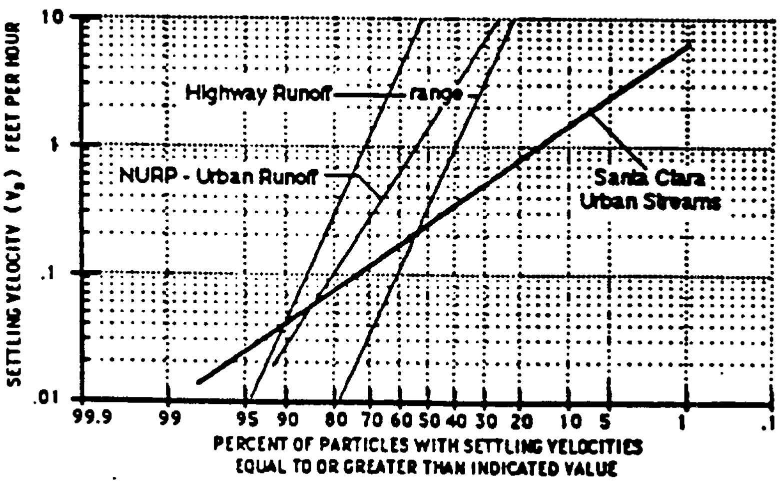

Figure A-10. Comparison of Settling Velocity Distribution from Different Sources

VOL 12

2 1102

Each of the samples shows a difference in particle sizes, reflected by the median settling velocities for the test, which range between 0.15 and 0.45 ft/hr. Because of the variability and the nature of the test, it would be inappropriate at this point to simply observe that the stream samples tested indicate a median settling velocity on the order of approximately 0.25 ft/hr, and having a distribution approximately as shown by Figure A-9.

These results are compared with the results of similar tests reported in other studies in Figure A-10. The principal indication is that the particulates in the Santa Clara wet weather stream samples are appreciably smaller in size (lower settling velocities) than those measured in direct runoff from urban or highway sites. This type of relationship can be expected if one considers that most of the bigger particles will have settled out rapidly in the stream, and as a result do not show up in these samples.

A.6.9 Special Studies - Fecal Streptococci

Analysis of fecal streptococci, together with fecal coliform, provide insight on possible sources of fecal contamination. Ratios of fecal coliform to fecal streptococci provide some indication as to whether the contamination was of human or nonhuman origin. Ratios in excess of 4.1 are sometimes considered to be primarily of human origin, whereas ratios less than 0.7 are considered to be of nonhuman origin. Ratios between 0.7 and 4.1 may be indicative of mixed human and nonhuman fecal contamination (Standard Methods 1980).

A survey of fecal streptococci and coliform bacteria was conducted at the four stream sites in order to assess possible sources of fecal contamination in nonpoint source runoff during storm events. Grab samples were taken at stream sites S1 through S4 during the third Wet-Weather Water Quality event in January 23, 1989. The analyses for both types of bacteria were conducted in accordance with Standard Methods for the Examination of Water and Wastewater (1980).

2/103

VOL 12

Results of the fecal streptococci are presented in Appendix D.2-1. Ratios of fecal coliform to fecal streptococci show values ranging from about 1 (S3 and S4) to 10 (S1 and S2).

A.6.10 Subsampling Procedures, Sample Containers, and Preservatives

The 10-liter composite samples collected from the autosamplers during storm events were sealed with Teflon-lined polyethylene caps, packed in ice, and transported to Kinnetic Laboratories, Inc., in Santa Cruz for further processing. When multiple 10-liter bottles were collected for a single station, it was first necessary to thoroughly blend the samples. Blending of the composite samples was accomplished by use of a peristaltic pump and Teflon hose.

The peristaltic pump was also used to draw samples for each set of analyses. Samples for each analyses were placed in prelabeled containers with appropriate preservatives (see Table A-9). Whenever possible, analyses requiring common containers and preservation were placed in the same container in order to minimize sample handling.

2 1104

Grab samples for analysis of sediment were placed directly into appropriate sample containers (see Table A-10). In most situations, common containers were used for collection and holding of sediments to be analyzed for (1) trace metals and inorganics and (2) volatile and semi-volatile organics. Single containers were utilized for organochlorine pesticides, chlorinated herbicides, and polynuclear aromatic hydrocarbons.

A.6.11 Field QA/QC

Several external or field quality control procedures were used to evaluate potential errors which could have been introduced during sample collection and subsequent analytical procedures. These external quality control checks were performed by blind submission of blanks and duplicates.

Blanks used in the field QA/QC procedures consisted of both field blanks and trip blanks. Field blanks were used to assess errors due to bottle contamination and field sampling procedures. Field blanks were obtained by sampling contaminant-free waters (furnished by the laboratory) using procedures identical to those used for collection of field samples. The field blanks for samples taken from the composite samplers were obtained by pumping contaminant-free waters into sample containers. This same procedure was used to extract field samples from the composite sample. Field blanks for grab samples were obtained by pouring blank water into a sample container. Trip blanks were utilized to assess potential contamination from both sample containers and coolers used for sample transportation. These blanks consisted of contaminant-free water provided in a standard sample container by the laboratory. These blanks remained unopened in the coolers and were returned to the laboratory for analysis.

Field duplicates were utilized to evaluate data precision. Analysis of these types of control samples provide a measure of the variability due to natural factors in the water body, sampling procedures and analytical procedures. Field duplicates were collected in the same manner as the primary samples and submitted blind to the laboratory.

A third quality control check conducted as part of the field program was quarterly analysis of external spike samples. Samples containing certified levels of contaminants were purchased from ERA laboratories in Colorado and the National Bureau of Standards (PNAs only). These samples were received by the project QA/QC officer. The QA/QC officer then removed certification information and submitted the samples to each laboratory under chain-of-custody.

A.7.2 Laboratory QA/QC

Laboratory procedures used to monitor bias and precision in analytical measurements included the following:

- Use of full-range internal calibration standards
- Analysis of laboratory blank water for every 10 samples analyzed by each methodology
- Analysis of a laboratory spike for every 10 samples
- Laboratory splits on 10 percent of the field samples submitted to the laboratory

Spikes were intended to evaluate the overall accuracy of the data set. Although spiking of either field samples or contaminant-free blank water was permitted by the project QA/QC plan, all spikes were performed using field samples in order to account for possible matrix interferences.

The laboratory blanks were conducted as part of each participating laboratories quality assurance plans. These blanks provided a measure of potential sources of contamination to the samples.

Laboratory splits were utilized to evaluate the precision of the analytical measurements. The duplicate data were used to calculate relative percent difference (RPD) values for each constituent. Upper and lower control limits based upon 95 percent confidence limits of historical laboratory splits were used to evaluate analytical precision and acceptability of the data.

A.8 DATA MANAGEMENT

Hardcopies of analytical chemistry results received from each contract laboratory were entered into a spreadsheet database using Lotus 1-2-3. Separate spreadsheets were maintained for each major chemical analysis (e.g., PNAs, organochlorine pesticides) or class of analyses (e.g., physical data-TSS, pH).

Each spreadsheet contained information on the type of sample (e.g., dry-weather, wet-weather), station identification, a sequential event number, date of sampling, analytical laboratory sample identifier, and target detection limits for each analyte. Reported values and actual detection limit on the laboratory report were recorded for each analyte.

Copies of the individual laboratory reports (hardcopy), chain-of-custody documents, and the complete Lotus 1-2-3 database were provided to Woodward-Clyde Consultants by Kinnetic Laboratories, Inc.

APPENDIX B
HYDROLOGIC MODEL CALIBRATION AND VERIFICATION

Stormwater quality loads for 11 watersheds were estimated by first determining the loads from each land use in each watershed, and then summing loads from all land uses to produce loads to the bay. Because land use loads were calculated as the product of flow volume and concentration, this methodology required estimates of 1) the volume of runoff from each land use category, and 2) the average concentration of pollutants from each land use category.

This Appendix describes the procedures used to estimate flow volumes. Section B.1 provides an overview of the Stormwater Management Model (SWMM), the rainfall-runoff model used to estimate flow volumes. Section B.2 describes the model setup for the Santa Clara Valley, Section B.3 discusses model calibration and verification, and Section B.4 presents estimates of stormwater runoff volumes for the Santa Clara Valley.

2 / / / / / / 7 /

B.1 OVERVIEW OF SWMM

The review of hydrologic data presented in Section 5.0 provides insight into the historical magnitude and variability of rainfall and runoff in the Santa Clara Valley. However, to estimate nonpoint source loads, knowledge of the sources of storm runoff is required. Runoff from undeveloped areas will differ in terms of water quality from runoff in urban areas on the valley floor, and little can be learned about the apportionment of runoff between developed and undeveloped areas through analysis of existing streamflow records alone. Unless one is willing to install and operate many more stream gages for several years, the preferred way to estimate runoff from individual land uses and from ungaged areas is by using a rainfall-runoff model.

Rainfall-runoff models use physical and land use information about a catchment to calculate storm runoff from a given rainfall record. Rainfall-runoff models vary in complexity from relatively simple models such as the Rational Method (Linsley et al. 1982), to models which attempt to represent in detail the physical mechanisms through which rainfall is converted to runoff.

In this study, the U.S. EPA Stormwater Management Model Version IV (Huber et al. 1988) was used to estimate runoff volumes from land use areas for loads calculations. This model, referred to as SWMM, contains a detailed mathematical description of the hydrologic cycle, including runoff from impervious and pervious areas, infiltration, percolation to the water table, groundwater flow into channels, losses due to evapotranspiration, interception, and depression storage, and routing of runoff down stream channels. The model also has water quality and treatment components which are useful in evaluating the effects of control measures. Thus, SWMM is sufficiently detailed and general in scope to model the processes which are relevant to the estimation of nonpoint source loads.

SWMM represents a watershed as a set of hydrologic units referred to as subcatchments. Each subcatchment is assumed to have a unique set of runoff properties, including rainfall, area, width, slope, infiltration characteristics, and percent of impervious areas. The model simulates runoff over time using time steps determined by the interval at which rainfall data are available. For accurate simulation of storm hydrographs, this time step is typically on the order of 15 to 60 minutes. At each time step, the model performs a water balance on all subcatchments, as illustrated in Figure B-1. The volume of water available for surface runoff is determined by first subtracting losses for depression storage, infiltration, and evaporation from rainfall. The remaining water is routed

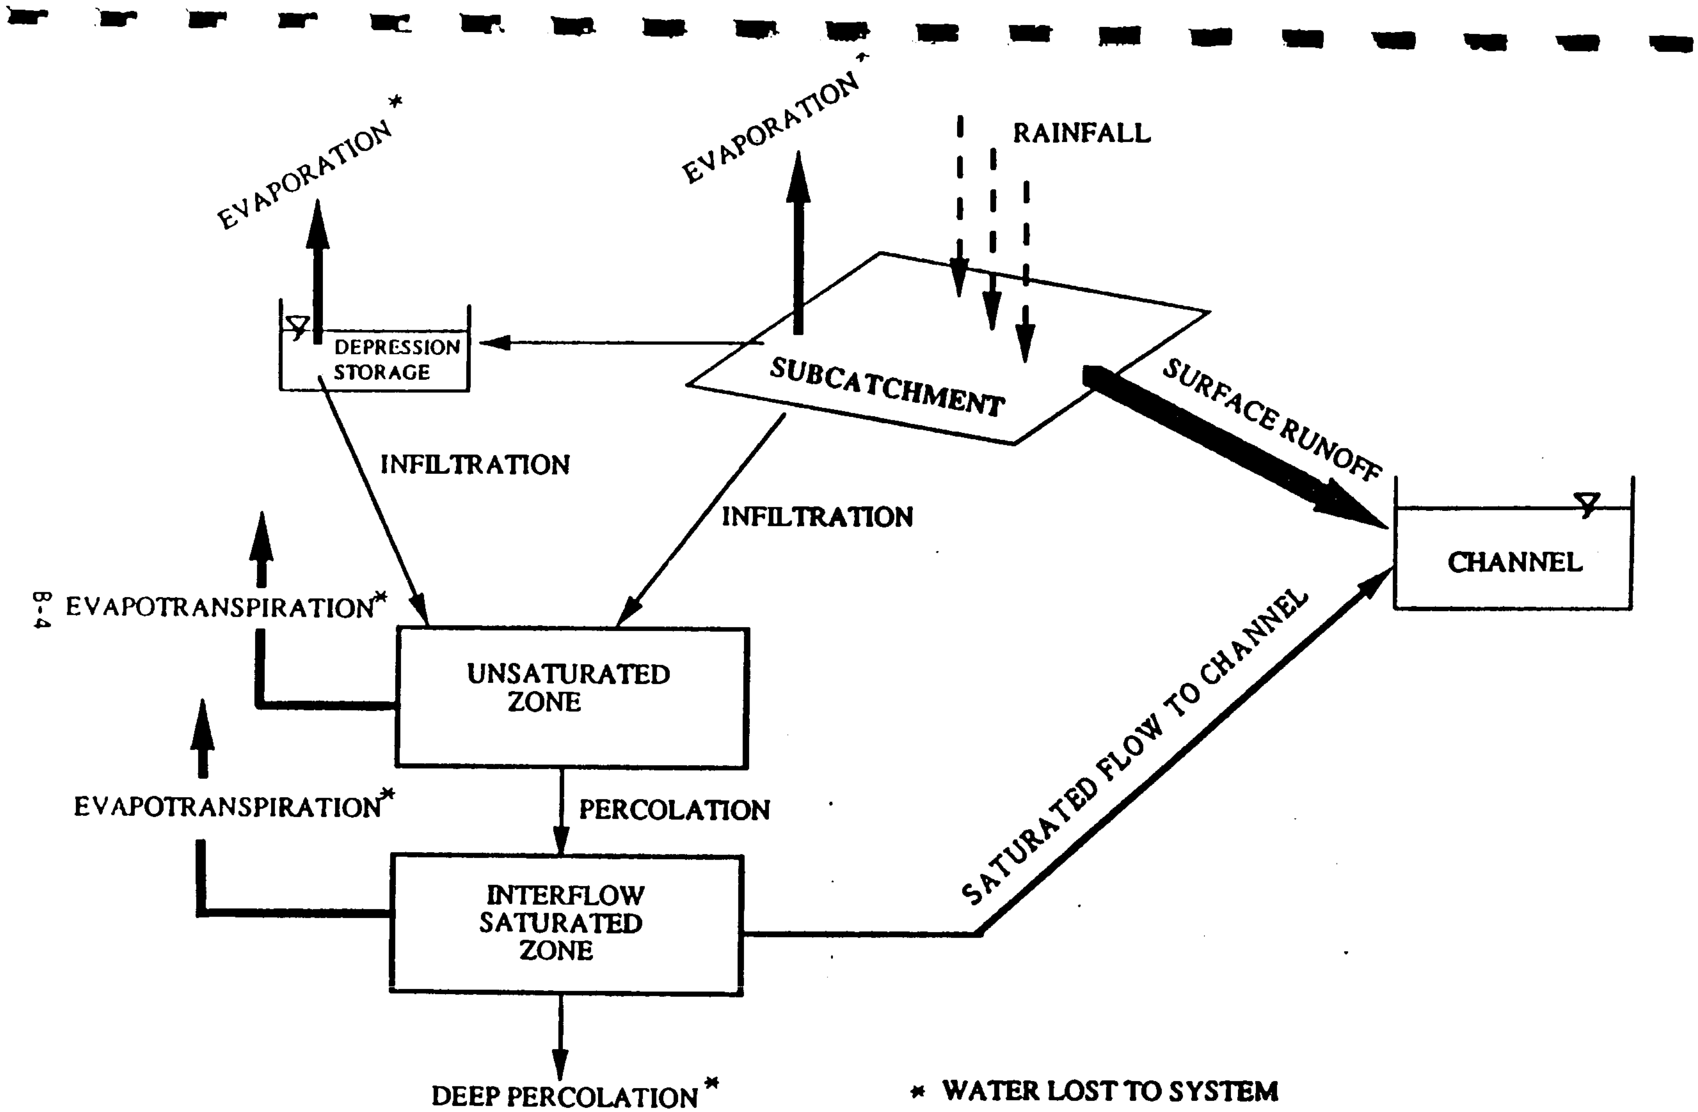

FIGURE B-1. SWMM Water Balance For a Subcatchment as runoff from the subcatchments into channels using a non-linear reservoir routing scheme, with the outflow rate determined by Manning's equation. Each subcatchment contains both pervious and impervious areas; runoff is more rapid from impervious areas because rainfall on these areas is not subject to infiltration losses. Water in depression storage, used to simulate storage in depressions on the ground surface, may either infiltrate or evaporate.

The subsurface component of the hydrologic cycle is represented in SWMM by two storage reservoirs, one for the unsaturated zone and one for the saturated zone. The volume of infiltration is determined using either a Horton or a Green-Ampt infiltration model. Infiltrated water then moves into the unsaturated zone, where it may either remain in storage, evapotranspirate, or percolate into the saturated zone. Water in the saturated zone may either remain in storage, flow into channels, or percolate out of the system. Flow from the saturated zone to channels is determined based on the difference in elevation between the water table and the channel water surface; the water table elevation is recalculated each time step based on the current volume of water in the saturated zone and the porosity of the saturated zone.

B.2 MODEL SETUP FOR THE SANTA CLARA VALLEY

The goal of this study was to estimate total nonpoint source loads from the Santa Clara Valley. Thus, SWMM was used to model runoff from the entire valley. For data management and calibration purposes, the valley was subdivided into the 11 major watersheds shown in Figure B-2. Streamflow data for calibration were available at the downstream ends of six of these watersheds; runoff from the remaining watersheds was estimated using SWMM without calibration.

Prior to using SWMM, a conceptual model of the important runoff processes occurring in the valley was developed. Based on the analysis of

1123

measured flow and precipitation data presented in Section 5.0, the following concepts were used to guide the application of SWMM to the study area:

1) Orographic effects on rainfall are strong, especially in the Santa Cruz Mountains.

2) Runoff on the valley floor occurs primarily from impervious areas associated with urban development.

3) Runoff from pervious areas occurs primarily in the Santa Cruz Mountains where rainfall intensities are sufficient to exceed soil infiltration capacities.

4) Runoff from pervious areas has a seasonal component, with the strongest runoff response occurring in the late wet season when antecedent soil moisture levels are highest.

5) Storm hydrographs typically have a 2- to 3-day recession component derived from subsurface flow rather than from surface runoff. This subsurface flow is probably interflow through temporarily saturated areas and perched groundwater in the unsaturated zone.

These concepts were used in determining how the SWMM runoff, infiltration, and groundwater algorithms were configured for this study, and will be referred to in terms of specific model parameters in the following sections. Section B.2.1 discusses how watersheds were subdivided into SWMM subcatchments, and Section B.2.2 describes procedures used to estimate model input parameters.

B.2.1 Watershed Discretization

The number and size of subcatchments used by SWMM should be determined by (1) the level of detail required in the model results, and (2) the level of detail at which data are available. For this study, complete data were available for relatively small subcatchments used by the Santa Clara Valley Water District (SCVWD) for their flood hydrograph modeling. However, this level of detail, while important for flood modeling, is not necessary for estimating annual-scale runoff and water quality loads. Huber and Dickenson (1988) present data and examples showing that small subcatchments can be lumped into larger SWMM subcatchments with little loss of information, as long as input parameters are scaled appropriately.

Because orographic effects on rainfall are so important in the Study Area, the first step in setting up subcatchments for this study was to divide each watershed into subareas over which rainfall was assumed to be uniformly distributed. The number of subareas were selected such that the variability of rainfall within watersheds was adequately represented. Figure 8-3 illustrates the subarea breakdown for the Calabazas Creek watershed. The subareas shown are typical of those used in the smaller watersheds in the western part of the valley, with three subareas representing rainfall on 1) the lower valley floor, 2) the upper valley floor, and 3) the Santa Cruz Mountain foothills. Table 8-1 summarizes the rain gages used to model runoff for all of the watersheds in the Study Area.

SWMM performs water balance calculations and estimates flows for areas represented by subcatchments. Thus, to estimate flows from individual land uses each rain gage subarea was divided into subcatchments for up to six land use categories (open, low density residential, medium density residential, high density residential, commercial, and industrial). These land use subcatchments represented "lumped areas" in that all of the areas of a given land use were modeled as a single contiguous subcatchment. In the example shown in Figure 8-3, rain gage subarea 100 was subdivided into an open subcatchment, a low residential subcatchment, and a medium residential subcatchment. Because the land use breakdown for the area was 43 percent open, the open subcatchment had an area equal to 43 percent of

1126

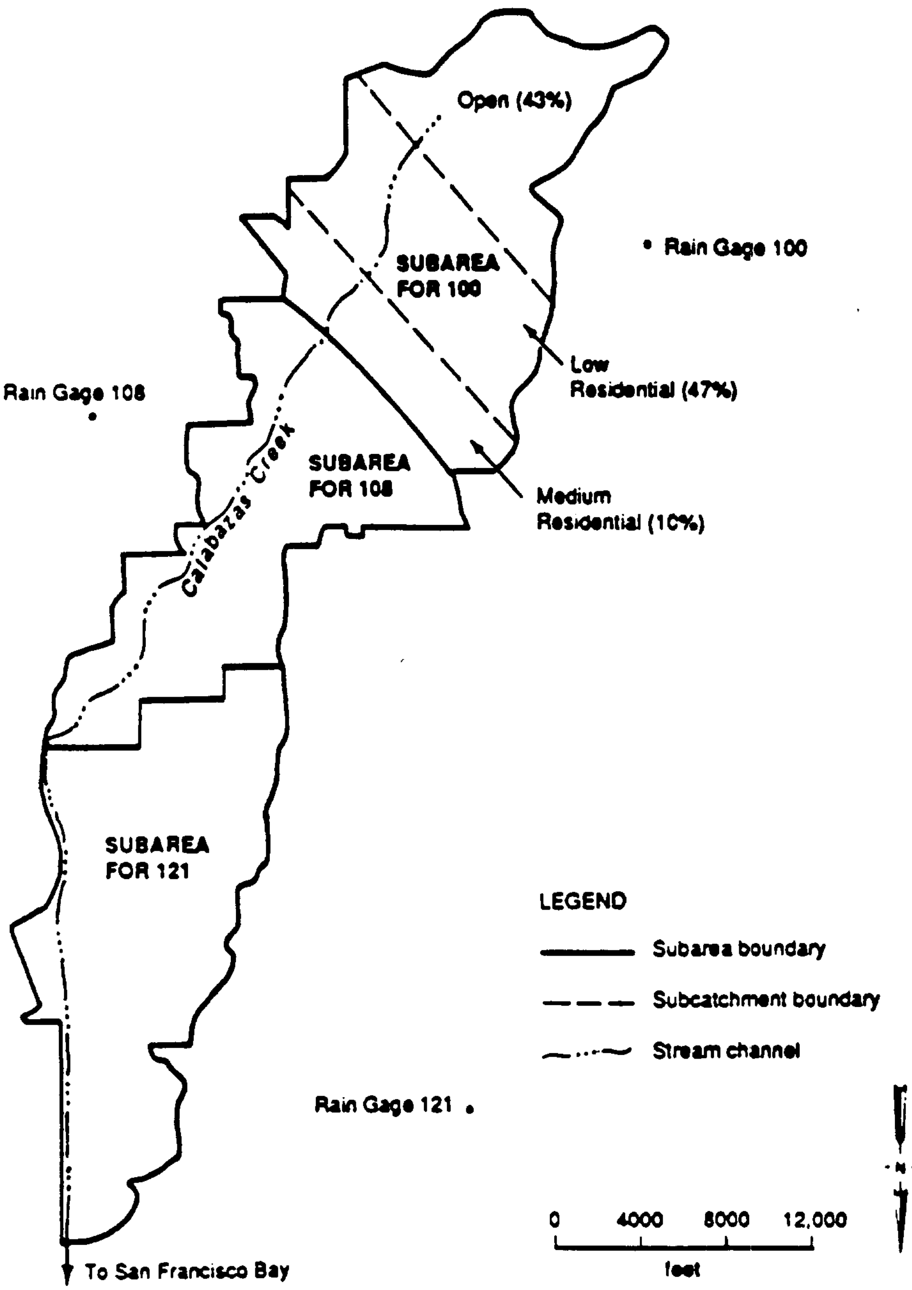

Figure B-3. SUBCATCHMENT BREAKDOWN FOR CALABAZAS CREEK the total area represented by rain gage 100. In general, physical properties such as rainfall, subcatchment width, and soil infiltration parameters were identical for all land use subcatchments in a given rain gage subarea. Land use properties such as impervious area were allowed to vary between land use subcatchments to reflect different levels of development.

B.2.2 Model Parameter Estimation

SWMM requires a number of parameters describing meteorology, catchment geometry, and runoff characteristics. The accuracy at which parameters can be estimated without model calibration varies. Thus, parameters can be grouped as follows:

1) Parameters which can be accurately estimated with no calibration (i.e., catchment area)

2) Parameters which can be estimated with reasonable accuracy, but must be refined through calibration (i.e., infiltration parameters)

3) Parameters which can be estimated only through model calibration (i.e., interflow outflow coefficients)

Table B-2 summarizes the important model input parameters and the corresponding estimation procedures; these are discussed in detail in the following paragraphs.

B.2.2.1 Rainfall. Rainfall is the driving force in the model, and is by far the most important input parameter. SWMM in this case was run continuously for multiple-year simulations, and required continuous records of 15-minute or hourly rainfall. Therefore, the continuous rainfall records available for SCVWD and NWS gages in the valley were used as inputs to the model. The SCVWD gages are weighing gages which record at 15-minute intervals with a precision of 0.1 inch. The one NWS gage, located in San

VOL 12

2/1/28

Table 8-2. SUMMARY OF SWMM RUNOFF INPUT PARAMETERS

Parameters	Estimation Procedure	Varies by Land Use?	Calibration Parameter?
Rainfall (in.)	NWS hourly and SCVWD 15-minute recording weighing gages (1974-1989). To correct for orographic effects, rainfall records were multiplied by isohyetal correction factors based on the ratio of average annual rainfall for subareas to the average at the gage.		
Potential Evapotranspiration Rate (in./day)	Average monthly pan evaporation data at the Alamitos Recharge facilities, multiplied by monthly pan coefficients provided by the SCVWD.		
Area (acres)	Drainage areas were measured from drainage maps provided by the SCVWD.		
Slope (fraction)	Slopes were determined by area-weighting slopes for those SCVWD catchments contained in model subcatchment.	•	
Land Use (%)	Land use percentages were determined by area-weighting values for SCVWD catchments contained within each SWMM subcatchment.	•	
Catchment Width (feet)	Drainage area divided by the maximum length of overland flow.		•
Impervious Area (%)	Derived from calibration of SWMM for monitored land use catchments (Station L1-L7) for the 1988-89 season.	•	•
Surface Roughness	Values for each land use were derived from tables for grassy, paved, and forested surfaces in the SWMM User's Manual.	•	
Depression Storage (in.)	Values for each land use were derived from tables for grassy and paved surfaces in the SWMM User's Manual.	•	•
Infiltration Parameters	Hydrologic soil groups were mapped from Soil Conservation Service (SCS).	•	•
Interflow Parameters	Soil surveys (1941). Typical values for each soil group were then selected from tables in the SWMM User's Manual. The average for a SWMM subarea was determined by area-weighted averaging.		
Unsaturated zone	From typical values tabulated in SWMM user's manual for soil types surveyed by the SCS (1941).		•
Saturated zone	From typical values tabulated in SWMM user's manual for soil types surveyed by the SCS (1941).		•
Outflow coefficients	By calibration to match measured hydrographic recessions.	•	•

Jose, is an hourly gage with a precision of 0.01 inch. A detailed description of these data is provided in Section 5.1.

The rainfall record for each subcatchment was selected by first identifying the rain gage located nearest to the centroid of the subcatchment area. The record for this rain gage then became the base rainfall record for the subcatchment. In selecting a base rainfall record, we also compared the elevation of the rain gage to that of the subcatchment (i.e., if the nearest gage were on a high ridge above the subcatchment, another gage at an elevation closer to that of the subcatchment was sometimes selected as a more representative record).

Once a base record was established for the subcatchment, the rainfall record was adjusted for the average difference between rainfall volumes in the subcatchment and at the rain gage. To accomplish this, rainfall records were multiplied by correction factors based on the ratio of average annual precipitation in the subcatchment to average annual precipitation in the rain gage:

$$R_{sc} = R_g * (P_{sc}/P_g) \qquad \text{(B-1)}$$

where

R_{sc} = 15-minute rainfall values used in modeling the sub catchment (in)

R_g = the corresponding 15-minute rainfall in the rain gage (in)

P_{sc} = the mean annual rainfall in the subcatchment (in)

P_g = the mean annual rainfall in the rain gage (in)

The mean annual rainfall for the catchment was estimated from annual average rainfall isohyets. Rainfall isohyets were derived from isohyetal maps provided by the SCVWD.

VOL 12

2/130

VOL 12

Storm patterns within a year can be highly variable, and this correction of rainfall records based on long-term annual average rainfall totals will certainly not capture all of the spatial variability within an individual storm. However, the method does ensure that, on average, the rainfall record used in modeling runoff will have the correct cumulative volume. This method should therefore be sufficiently accurate for estimating annual flow volumes and loads.

8.2.2.2 Potential Evapotranspiration Rate. The potential evapotranspiration rate determines how much water could be lost to evaporation and transpiration. SWMM uses an average rate for each month of the year; for this study, these rates were estimated using the average monthly pan evaporation rates measured by the SCVWD at the Alamitos Recharge Facility. These pan evaporation rates were corrected by pan coefficients provided by the SCVWD.

8.2.2.3 Catchment Area, Slope, and Land Use. These data were available for catchments used by the SCVWD in their flood modeling. These catchments were smaller than the SWMM subcatchments used in this study. Consequently, model subcatchment areas were determined from the SCVWD catchment maps by summing the areas for the appropriate SCVWD catchments. Similarly, slopes and land use breakdown were determined by area-weighting the values for the SCVWD catchments comprising a SWMM subcatchment.

8.2.2.4 Catchment Width. SWMM represents each subcatchment as a rectangle defined by an area and width; the length of overland flow is then the area divided by the width. Catchment width is therefore an important parameter in determining the timing of runoff. This width is difficult to measure, since the actual shapes of subcatchments are rarely rectangular. As recommended in the SWMM Users Manual (Huber and Dickensen 1988), a first estimate of this parameter was obtained by dividing the subcatchment area by the maximum distance from catchment boundary to the main channel.

2 (1131)

B.2.2.5 Impervious Area. This parameter is defined as the percentage of an area that has no infiltration, i.e., paved areas, rooftops, etc. Impervious areas must also be connected, and paved areas that drain onto pervious areas should not be considered impervious. This parameter could conceivably be measured directly from aerial photos, but this would be extremely costly and of questionable accuracy for an area as large as the Santa Clara Valley.

The approach used here was to determine representative impervious areas for each land use by calibrating SWMM on storm data at the single land use catchments sampled in this study. These values were then adjusted during calibration of the larger watersheds to match observed runoff volumes.

B.2.2.6 Surface Roughness Coefficients and Depression Storages. These were estimated for pervious and impervious areas using values tabulated in the SWMM user's manual for various types of surfaces. Values tabulated for either paved, grassy, or forested surfaces were selected based on land use. Depression storages were also calibrated in forested areas to represent interception on vegetation.

B.2.2.7 Infiltration Parameters. For this study, the Green-Ampt option in SWMM was selected for modeling infiltration during storm events. The Green-Ampt infiltration model, while certainly idealized, is mechanistically rather than empirically based and has input parameters that can easily be related to known soil properties. For infiltration during storms, the model uses three parameters: 1) the saturated hydraulic conductivity, 2) a suction parameter, and 3) the maximum soil moisture deficit. The saturated hydraulic conductivity represents the infiltration rate at saturation. The suction parameter is used to model the effects of capillary suction in the soil. The maximum moisture deficit is analogous to porosity and determines the storage capacity of the soil layer that controls infiltration. Values of these parameters are tabulated for each of the four Soil Conservation Service (SCS) hydrologic soil groups in the SWMM User's Manual. Therefore,

VOL 12

2 1132

values for this study were determined by overlaying SCS soil survey maps (SCS 1941) onto maps of the SWMM subcatchments. The area of soils in each SCS hydrologic group were measured, and the average parameters for the watershed were determined by area weighting. The following calculation illustrates the method for the saturated hydraulic conductivity:

$$K = (\%A)(KA) + (\%B)(KB) + (\%C)(KC) + (\%D)(KD) \qquad \text{(B-2)}$$

where:

K = the average saturated hydraulic conductivity for a subcatchment
A, B, C, D = the four SCS hydrologic soil groups
%A = the percentage of the total area that are A soils
KA = the value of saturated hydraulic conductivity for A soils

In general, soils in the area ranged from B to D, where D soils have the lowest infiltration rates.

Between storms, SWMM uses a simple empirical algorithm to determine how dry soils are at the start of the next storm. As previously discussed, the antecedent soil moisture level is an important factor in determining runoff response in the Study Area, especially in the later months of the rainy season. Initial calibration of SWMM indicated that the empirical SWMM soil moisture depletion algorithm was not adequately reproducing the seasonality of soil moisture levels; soils were generally saturating during every storm and then drying out to the maximum moisture deficit within a few days. Thus, the model predicted that storms in February responded the same to rainfall as storms in November. The SWMM soil moisture depletion algorithm was therefore modified so that the depletion rate and storage capacity of the soil layer controlling infiltration could be adjusted during calibration. The depletion rate was defined as a fraction of the potential evapotranspiration rate:

$$R_i = (F_d)(PET_i) \quad \text{(B-3)}$$

where:

R_i = the soil moisture depletion rate for month i
PET_i = the potential evapotranspiration rate for month i
F_d = the soil moisture depletion factor

This modification allowed depletion rates to vary seasonally, and F_d was added as a calibration parameter for the model. To control the storage capacity of the soil, the thickness of the soil layer controlling infiltration was also added as a calibration parameter. This storage parameter could then be adjusted along with the depletion factor to match the observed seasonality in runoff.

B.2.2.8 Interflow Parameters. To model the interflow recession observed in many storm hydrographs in the Study Area, the SWMM groundwater model was configured as shown in Figure B-4. The bottom of the saturated zone was set at a relatively shallow depth (10 to 15 feet) so that the saturated zone rose rapidly during storm events and released stored water into channels within 1 to 7 days. This interflow system was modeled only in steep areas with high rainfall volumes; interflow was generally not observed in valley floor catchments.

Model input parameters in the unsaturated zone include storage parameters such as field capacity and wilting point, and parameters describing hydraulic conductivity as a function of soil moisture. These were generally estimated from tables of typical values for the appropriate SCS soil types. Similarly, the saturated zone is defined by storage parameters such as porosity and rate parameters such the saturated zone outflow coefficients. Flow from the saturated zone into the channel was calculated using the following model based on head differences between the channel and the saturated zone:

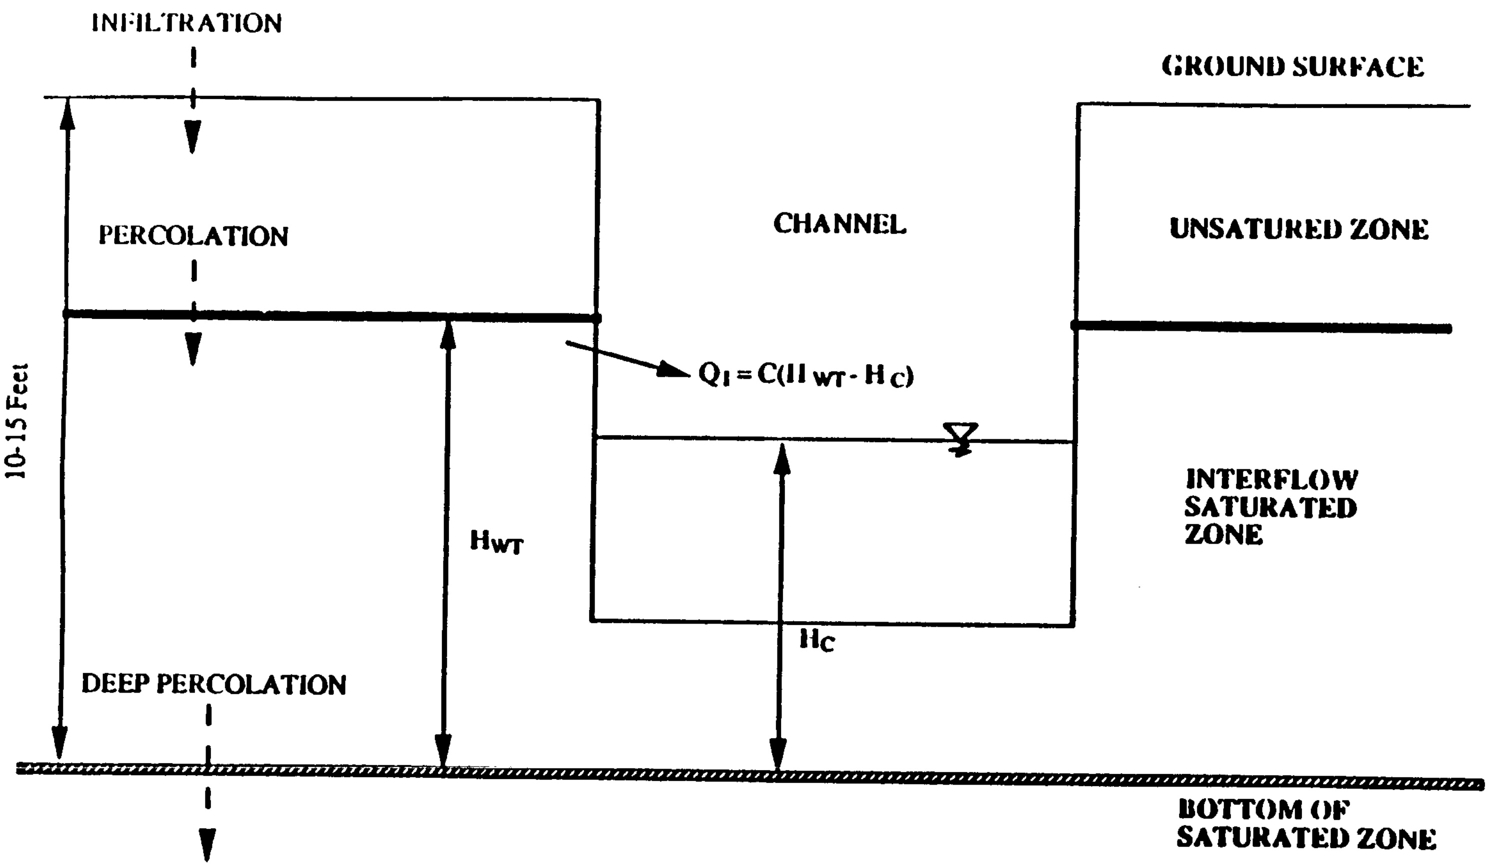

FIGURE B-4. SWMM Interflow Model

$$Q_I = C(H_{wt} - H_c) \quad (B\text{-}4)$$

where:

Q_I = interflow rate into the channel (cfs)
H_{wt} = elevation of the water table (ft)
H_c = elevation of water in the channel (ft)
C = interflow coefficient (ft^2/sec)

The interflow coefficient C is a calibration parameter which was primarily used to determine the magnitude of interflow into the channel. An additional calibration parameter, representing deep percolation out of the saturated zone, was used to steepen predicted hydrograph recessions to match observed recession curves.

B.2.2.9 Channel Data. Runoff and interflow from SWMM subcatchments were routed down channels using the SWMM non-linear routing algorithm. For this study, one channel was defined for each rain gage subarea, and input data were required specifying the slope, Manning's roughness coefficient, and cross section of each channel reach. Cross-sectional data for all streams were provided by the SCVWD in the form of HEC-2 input files used in flood modeling. From these, representative cross sections were selected and approximated as trapezoids for SWMM (defined by a bottom width and two side slopes). Manning's roughness coefficients and slopes were averaged for each channel reach modeled.

B.3 SWMM CALIBRATION AND VERIFICATION

Although SWMM is a state of the art model of rainfall-runoff processes, it, like all runoff models, represents an idealization of the actual processes occurring in a catchment. In addition, the spatial variability of model input parameters is difficult to account for in large catchments with many types of geology and land uses. Therefore, the model must be calibrated against measured streamflow data to produce reliable results. The calibration consists of running the model, comparing model prediction to measured streamflows, and adjusting the model calibration parameters to better match the observed flows. The process is repeated until the comparison between measured and predicted flows is deemed adequate. Calibration is then followed by verification, in which the calibrated model is run and compared to streamflow records for a period not included in the calibration period.

The following sections describe 1) calibration criteria, 2) selection of calibration periods, 3) calibration parameters, and 4) results for individual watersheds.

B.3.1 Calibration Goals and Criteria

To capture the year to year variability of runoff, SWMM was run continuously over several years during calibration and verification. Since the emphasis of this study was on annual loads from storm runoff, the primary goal of calibration was to match measured wet-season total runoff volumes. The runoff volume for a season consists primarily of runoff from relatively few storm events (typically less than 15), and matching wet-season runoff volumes required accurate simulation of individual storm events.

For calibration purposes, predicted flows were compared to measured flows at SCVWD and USGS stream gages. See Section 5.2 for a discussion of stream gages in the Study Area. A number of parameters were calculated to measure the quality of calibration. For comparing predicted versus measured wet-season totals, the following statistics were calculated:

$$\text{RMSE} = \frac{100\left(\sum_{i=1}^{n}(P_i - M_i)^2/n\right)^{1/2}}{M} \qquad \text{(B-5)}$$

$$\text{BIAS} = 100(P - M)/M \qquad \text{(B-6)}$$

where:

P_i = predicted wet-season runoff volume for year i (in.)

M_i = measured wet-season runoff volume for year i (in.)

n = the number of years in the calibration period.

M = the mean measured wet-season runoff volume (in.)

P = the mean predicted wet-season runoff volume (in.)

The RMSE, or root mean square error, is a measure of the absolute magnitude of calibration errors expressed as a percentage of mean runoff. The BIAS indicates whether the model is on average over- or under-predicting runoff volumes, and is also expressed as a percentage of the mean wet-season runoff volume. The goal of calibration was to minimize both the RMSE and the BIAS.

Results of calibrations performed for comparable studies were consulted to derive specific calibration acceptance criteria. Alley (1986) summarizes calibration results from the USGS rainfall-runoff model DR3M for 37 catchments nationwide. In this study, calibration errors were measured by the mean absolute deviation (MAD) between predicted and observed flow volumes. On average, the MAD was on the order of 20 percent for the 37 simulated catchments. In a modeling study of three small urban catchments, Guay and Smith (1988) calibrated the USGS model DR3M to runoff data for 10 to 13 storms in one season. Prediction errors in total annual runoff volume for these three single land use catchments ranged from 10 to 25 percent. In a study performed on Permanente Creek in Santa Clara County, Nolan and Hill (1989) obtained calibration errors in total annual flow volume of 3 to 33 percent.

These studies indicate that calibration errors are generally on the order of 20 percent, but may range as high as 30 or 40 percent. The studies cited above generally focused on small (less than 100 acre) urban catchments with a single well-defined land use. None of these studies

VOL 12 2/1/38

calibrated using more than 3 years of flow data. Thus, one would expect that the calibration errors obtained in modeling the large watersheds in the Santa Clara Valley for up to 10 years of flow data would be somewhat higher. Nonetheless, for this study a relatively ambitious calibration goal of 15 percent RMSE was used for annual flow predictions. Given the difficulties inherent in simulating large open areas, this goal was often not achieved. However, the RMSEs summarized in Table B-3 range from 1 to 40 percent, and are consistent with calibration errors obtained in other studies. More importantly, the biases in the model predictions are small, and range from 1 to 16 percent.

Daily predicted flows were compared to measured flows in two ways. First, daily predicted flows and measured flows were plotted together over time and visually compared. These plots were used for detailed analyses of the sources of calibration errors, particularly in terms of matching seasonal runoff patterns and hydrograph recessions. Finally, a Kolmogorov-Smirnov hypothesis test was used to compare the frequency distributions of measured and predicted daily flows. This test first calculates the maximum difference between measured and predicted cumulative probabilities. This difference is then compared to a test statistic based on the number of daily flows and the confidence level. If the maximum difference is less than the test statistic, the hypothesis that the predicted and measured flows are from the same population is accepted. This test, while it does not check that the flow on a given day is accurately predicted, does measure how well the model is reproducing the day to day variability of flows.

B.3.2 Selection of Calibration and Verification Periods

Runoff in the Study Area varies greatly from year to year, and the annual runoff volume for a wet year can be ten times greater than in a dry year. A calibration based on only one dry year would therefore not accurately represent runoff in wet years. Therefore, SWMM was calibrated and verified against as many years of streamflow data as were available,

Table B-3. SUMMARY OF SWMM CALIBRATION/VERIFICATION

Watershed	Calibration Period	Verification Period	Calibration: Mean Wet-Season Runoff (in.)	Calibration: RMSE (%)	Calibration: Bias (%)	Verification: Mean Wet-Season Runoff (in.) [a] RMSE measures the average error in predicted wet-season runoff, as a percentage of the mean wet-season runoff volume.

[b] BIAS measures the average bias (tendency to under- or over-predict) in predicted wet-season runoff, as a percentage of the mean wet-season runoff volume.

with approximately two thirds of the record used for calibration and one third for verification. As discussed in Section 5.0, concurrent streamflow and rainfall data are generally available for the period 1974 through 1989, with occasional gaps due to gaging errors, data storage problems, and damage to stream gages. Table B-3 summarizes the calibration and verification periods for the various watersheds; calibration periods were typically 4 to 9 years in length, while verification periods were 3 to 5 years long. Both calibration and verification periods were selected to contain a mix of wet, dry, and average years. Note that there was only one year of data available for calibration of the Coyote Creek watershed.

B.3.3 Calibration Parameters

Table B-4 summarizes the values of parameters derived from calibration of SWMM for each watershed. For adjustment of runoff volumes in urban areas, the most important parameters were the percent of impervious area and depression storages. These parameters were especially important in dry years when almost all runoff was from impervious areas; the percent impervious area for each of the various land uses was therefore determined primarily through calibration on dry years. In open and low-residential areas, the most important parameters were the Green-Ampt infiltration and soil depletion parameters. The saturated hydraulic conductivity was used to determine the overall rate of infiltration (and therefore reduction in runoff). The soil moisture depletion parameters L and F_d were used to model the seasonality of infiltration (and runoff) by adjusting the rate at which soils dried out between storms. The interflow coefficient A1 and deep percolation factor DF were used to match hydrograph recessions, while CET, POR, and GRELEV defined the storage characteristics of the saturated zone.

B.3.3.1 Calibration of the Percent Imperviousness. One of the most sensitive model parameters in urban areas is the percent imperviousness. Runoff volumes are often directly proportional to the value of the percent imperviousness, meaning that if this parameter is doubled, runoff volumes

will nearly double. This is especially true in urban areas with low rainfall intensities.

Estimation of the percent imperviousness can conceivably be performed by direct measurement from areal photographs. However, this is usually impractical for large areas such as the Santa Clara Valley. The usual practice is therefore to derive general values of this parameter for each land use category. However, even values tabulated in the literature for individual land uses may vary by as much as 100 percent. For instance, Table B-5 compares values tabulated for Santa Clara County by (1) the SCVWD, and (2) the U.S. Geological Survey (1977). In general, the USGS values are considerably lower than the SCVWD values. The USGS data also indicate considerable variability within land use categories, with values ranging from 6 percent in hillside residential areas to 10 percent in valley floor low-density residential areas. An important conclusion that can be drawn from this is that no one value can be realistically used to represent all low-density residential areas, since not all areas within the low-density category are paved or developed to the same extent.

For our calibration of SWMM, we initially used the percent imperviousness values developed by the SCVWD (shown in Table B-5). However, use of these values resulted in consistent overestimation of runoff. That this overestimation was derived from the imperviousness estimate became apparent when examining predicted runoff from small early season storms. Runoff from these storms comes primarily from paved areas, and the model consistently overpredicted runoff from these storms even when infiltration parameters were adjusted to prevent any pervious area runoff from occurring. We therefore adjusted the percent impervious values downward to match storm volumes for these types of events.

Clearly, percent imperviousness is a very sensitive calibration parameter, and should not be adjusted to account for processes that may be better represented by the pervious area infiltration parameters. To ensure

2 1148

that we were not adjusting percent imperviousness when calibration of infiltration parameters would have been more appropriate, calibration of this parameter was performed only to match runoff volumes from small storms where little runoff was occurring from pervious areas. The resulting calibrated percent imperviousness values are shown in Table B-4 for each watershed, and are summarized in Table B-5. As shown in Table B-5, the calibrated values are much lower than the original SCVWD values, but are consistent with percent imperviousness values tabulated by the USGS for Santa Clara County.

B.3.3.2 Sensitivity of the Model to Green-Ampt Infiltration Parameters. An important component of the SWMM rainfall-runoff calibration was the calibration of the Green-Ampt infiltration parameters. These parameters control infiltration of water on pervious surfaces, and thus play a critical role in predicting runoff from open areas. The Green-Ampt infiltration algorithm has three parameters: the saturated hydraulic conductivity, a capillary suction parameter, and the maximum soil moisture deficit. Sensitivity analyses of the model indicated that the controlling infiltration parameter was the saturated hydraulic conductivity, defined as the infiltration rate at saturation. Our calibration efforts therefore focused on this parameter, while leaving the values of the suction parameter and soil moisture deficit constant. As a result, occasionally the final calibrated value of the hydraulic conductivity was not consistent with the values of the suction parameter and maximum soil moisture deficit.

To test whether this inconsistency had a significant effect on the model results, a model run for Calabazas Creek was performed to demonstrate SWMM's insensitivity to the suction parameter and maximum soil moisture deficit. In this run, the values of these two parameters (which formerly corresponded to a moderately permeable "C" soil) were forced to be consistent with the calibrated hydraulic conductivity value (which corresponded to a low permeability "D" soil). Table B-6 summarizes the results of this analysis. In general, annual flow volumes were insensitive

Table B-6. SENSITIVITY OF ANNUAL LOADINGS TO THE SUCTION AND INITIAL MOISTURE DEFICIT PARAMETERS

to these parameters. Annual loading results between the new run and the original run differed by as little as .02 percent in 1988-89, and by as much as 4 percent in 1978-79. Total loadings for the 1977-1989 period change by about 3 percent.

B.3.3.3 Sensitivity of the Model to Time Series Potential Evapotranspiration Data. Potential evapotranspiration (PE) was represented in the model by average pan evaporation rates for each month of the year. Evaporation data are used in the model to simulate (1) changes in depression storage between storms and (2) seasonal changes in soil moisture storages. These processes primarily affect the antecedent soil moisture levels before storms, and therefore are most important in nonurban areas. Soil moisture levels change on a monthly or seasonal time scale, indicating that predicted annual runoff volumes are not sensitive to day to day changes in evaporation rates.

Table B-7 summarizes the mean monthly evaporation rates used in the model, and also shows the standard deviation and range of observed monthly values for the period 1976 to 1988. Note that the standard deviation of monthly values is on the order of 20 percent or less of the mean, indicating that monthly evaporation shows little year to year variation. To test the sensitivity of the annual loading predictions to the use of monthly average PE data, a model simulation was performed for Calabazas Creek using time series PE data. Table B-8 compares the resulting flow predictions to those obtained using monthly average evaporation data. Annual loads predicted from the two data sets differed by 1 to 6 percent, while the mean annual load differed by only 1.6 percent. Thus, it is reasonable to conclude that monthly average PE data are adequate for annual loads prediction.

B.3.4 Calibration and Verification Results

Table B-3 summarizes the calibration and verification statistics for all of the watersheds for which flow data were available. Figures B-5

through B-11 plot predicted wet-season volumes against measured volumes. These statistics and plots measure how well the model was able to predict total wet-season runoff volumes. During calibration, RMSEs ranged from 1 to 38 percent, and the BIAS ranged from ±1 to ±12 percent. During verification, RMSEs ranged from 3 to 45 percent, and the BIAS ranged from ±1 to ±16 percent. For the combined period, RMSEs ranged from 1 to 40 percent of mean wet-season runoff, while the BIAS ranged from ±0.1 to ±6 percent. The flow-weighted average RMSEs for the Study Area were 25, 22, and 25 percent for the calibration, verification, and combined periods, respectively. Average BIASes were -4, 5, and -1 percent for these three periods. Details on the calibration and verification process for individual watersheds are presented below.

B.3.4.1 <u>Calabazas Creek</u>. Calabazas Creek originates in the foothills of the Santa Cruz Mountains and drains into Guadalupe Slough. Mean annual rainfall ranges from 12 inches near the Bay to 32 inches in the foothills. For SWMM, the catchment was divided into three rain gage subareas corresponding to SCVWD rain gages 100, 108, and 121. Model calibration was performed primarily against streamflow data for SCVWD streamgage 26a, located on the valley floor and representing about three-fourths of the total watershed area. In addition, streamflow data at SCVWD streamgage 31 were used to refine estimates of pervious runoff parameters in the upper portion of the watershed.

Calibration and verification results for Calabazas Creek, in terms of wet-season runoff, are illustrated in Figure B-5. The calibration for Calabazas Creek was generally accurate and unbiased, with a RMSE for the combined calibration/verification period of 11 percent of the mean volume and a BIAS of 1 percent. The predicted daily flow distribution passed the Kolmogorov-Smirnov distribution test at the 95 percent confidence level. The most important calibration parameters were the Green-Ampt infiltration parameters, used to model seasonal runoff. Matching the seasonal patterns of runoff required an infiltration layer with a thickness of 8 to 10

inches, so that the soil did not saturate until after the first or second major storm of the season.

B.3.4.2 Stevens Creek. Stevens Creek is in the western part of the valley, and extends from the county boundary in the Santa Cruz Mountains down to the Bay. Most of the undeveloped portion of the watershed flows into Stevens Creek Reservoir. This reservoir, while designed to store flows in the winter for release in the summer, does commonly release stormwater during wet years. Mean annual rainfall ranges from 12 inches near the Bay to 24 inches just below the reservoir, and is as high as 60 inches above Stevens Creek Reservoir.

Calibration of SWMM was performed only for the portion of the watershed below Stevens Creek Reservoir; flows out of the reservoir were represented by the record for SCVWD gage 44. Rain gage subareas were designated for SCVWD rain gages 100,48, and 121. The model was calibrated against measured flows at SCVWD gage 35, just north of the Central Expressway. To determine the amount of runoff occurring below the reservoir, flows from gage 44 (immediately below the reservoir) were subtracted from flows at gage 35. Also subtracted from the gage 35 record were diversion flows from Permanente Creek into Stevens Creek (measured by the difference between SCVWD gages 32a and 37). Calibration was limited to the period 1975 to 1983, when the diversion gage 37 was discontinued.

Figure B-6 shows the calibration results for Stevens Creek (areas downstream of Stevens Creek Reservoir). The RMSE for the combined calibration/verification period was 34 percent of the mean annual flow, and the BIAS was 1 percent. The model generally performed well, except in the 1981-82 season, when the model overpredicted runoff by about 60 percent. The predicted daily flow distribution passed the Kolmogorov-Smirnov distribution test at the 95 percent confidence level. Because the area downstream of the reservoir is mostly urbanized, the percent impervious area was the most important calibration parameter, although the Green-Ampt

VOL 12

2/162

infiltration parameters were also important in modeling seasonal effects on runoff.

8.3.4.3 Sunnyvale East Channel. This watershed is a small urban area extending from the City of Cupertino down to the Bay. Mean annual rainfall in the basin ranges from 12 to 16 inches. The entire area was modeled using SCVWD rain gage 48. Calibration and verification were performed for the 1977 to 1989 record at SCVWD streamgage 74.

Calibration results are shown in Figure B-7. The RMSE in this case was 9 percent of the mean wet-season volume, while the BIAS was -1 percent. The predicted daily flow distribution passed the Kolmogorov distribution test at the 95 percent confidence level. The most important calibration parameters in this mostly urban, low rainfall catchment was the percent of impervious area; little or no seasonality was observed in runoff response to rainfall.

8.3.4.4 Saratoga Creek. Saratoga Creek extends from the county boundary in the Santa Cruz Mountains to its confluence with San Tomas Aquinas Creek. Mean annual rainfall ranges from 50 inches in the uplands to 12 inches near the Bay. For SWMM modeling, SCVWD rain gage 77 was used to represent the undeveloped upland areas, while rain gage 108 was used in the urban valley floor areas. Calibration and verification were performed on the record for SCVWD gage 25. The 1984-85 season was not included in the calibration or verification periods because the measured flow data for this year indicated an annual runoff coefficient of 0.95, which is unreasonable for a watershed which includes significant open and low-density residential areas.

Calibration and verification results for Saratoga Creek are shown in Figure B-8. The RMSE for the combined calibration/verification period was 22 percent of the mean wet-season volume, while the BIAS was .1 percent. The calibration of this watershed was complicated due to 1) the strong

VOL 12

2/1/63

infiltration parameters were also important in modeling seasonal effects on runoff.

8.3.4.3 Sunnyvale East Channel. This watershed is a small urban area extending from the City of Cupertino down to the Bay. Mean annual rainfall in the basin ranges from 12 to 16 inches. The entire area was modeled using SCVWD rain gage 48. Calibration and verification were performed for the 1977 to 1989 record at SCVWD streamgage 74.

Calibration results are shown in Figure 8-7. The RMSE in this case was 9 percent of the mean wet-season volume, while the BIAS was -1 percent. The predicted daily flow distribution passed the Kolmogorov distribution test at the 95 percent confidence level. The most important calibration parameters in this mostly urban, low rainfall catchment was the percent of impervious area; little or no seasonality was observed in runoff response to rainfall.

8.3.4.4 Saratoga Creek. Saratoga Creek extends from the county boundary in the Santa Cruz Mountains to its confluence with San Tomas Aquinas Creek. Mean annual rainfall ranges from 50 inches in the uplands to 12 inches near the Bay. For SWMM modeling, SCVWD rain gage 77 was used to represent the undeveloped upland areas, while rain gage 108 was used in the urban valley floor areas. Calibration and verification were performed on the record for SCVWD gage 25. The 1984-85 season was not included in the calibration or verification periods because the measured flow data for this year indicated an annual runoff coefficient of 0.95, which is unreasonable for a watershed which includes significant open and low-density residential areas.

Calibration and verification results for Saratoga Creek are shown in Figure 8-8. The RMSE for the combined calibration/verification period was 22 percent of the mean wet-season volume, while the BIAS was .1 percent. The calibration of this watershed was complicated due to 1) the strong interflow recession component observed in many storms, and 2) the extremely strong response to runoff in wet years. To match observed storm response, it was necessary at times to force the model to shut off infiltration through saturation of the soil profile from below. Thus, the important model parameters were 1) the interflow recession constants, and 2) the soil and groundwater storage parameters.

B.3.4.5 San Tomas Aquinas Creek. This watershed is adjacent to Saratoga Creek and extends from the Santa Cruz Mountain foothills to its discharge point into Guadalupe Slough. Rainfall ranges from 12 to 40 inches per year on average. SCVWD rain gage 79 was used to represent the foothills and upper valley, gage 108 was used on the central valley floor, and the San Jose National Weather Service gage was used in the lower valley floor. Calibration was performed primarily at SCVWD streamgage 24, although data at SCVWD streamgage 29 were used to refine estimates of parameters in the upper portion of the catchment.

Calibration and verification results are shown in Figure B-9. The RMSE for wet-season volumes was 21 percent, while the BIAS was -2 percent. San Tomas Aquinas Creek was very similar to Saratoga Creek in terms of runoff, with storm hydrographs exhibiting a very strong interflow recession component and unusually strong response to rainfall. Again, the most important parameters were (1) interflow recession constants, and (2) soil and groundwater storage coefficients. An additional problem encountered here was the very different behavior of runoff between post-1983 and pre-1983 data. Measured flow data at gage 24 generally indicated less response to rainfall (i.e., lower runoff coefficients) after 1983, and we were unable to arrive at a calibration which could match both periods. One possible explanation for this is a change in the rating curve at gage 24 after the floods of the 1982-83 season.

B 3.4.6 Coyote Creek. This is the largest watershed in the valley, and drains the entire eastern side of the valley. Included are large

VOL 12 2/165

undeveloped areas above Anderson Reservoir, Silver-Thompson Creek, Upper Penitencia Creek, and Berryessa Creek. For SWMM, Coyote Creek was modeled only between SCVWD streamgage 58 (below Anderson Reservoir) and the Bay; most of the area upstream of gage 58 either drain into reservoirs or are undeveloped areas. Storm runoff from these areas was therefore represented by the actual record for streamgage 58. The drainage area below this point is mixed urban and non-urban, with most of the non-urban areas located in the upper portions of Silver-Thompson and Upper Penitencia Creek.

The only streamgage on Coyote Creek below gage 58 is a high-flow gage which records only when stage is above 8.5 feet; the record here is consequently of limited usefulness. However, a continuous stage recorder was installed at this location for the 1988-89 sampling period as part of this study. Thus, Coyote Creek was calibrated for one year only (1988-89). This period was relatively dry, and use of the model for wetter years should be less reliable than if it had been calibrated over a variety of hydrologic conditions. The predicted wet-season volume for this period was 1 percent lower than measured. Because of the dryness of the calibration period, the most important calibration parameter was the percent of impervious area.

B.3.4.7 Berryessa Creek. The Berryessa Creek watershed is located on the eastern side of the valley on the slopes of the Diablo Range, and flows into Coyote Creek near the Bay. Rainfall in this area is much lower than in the Santa Cruz Mountains, and ranges from 14 to 20 inches on average per year. SCVWD rain gage 23 was used to model the upper parts of the catchment, and the San Jose National Weather Service gage was used to model the lower portions of the catchment. Calibration and verification were performed at SCVWD streamgage 64.

Figure B-10 show the calibration and verification results for this watershed. The overall RMSE was 29 percent of the mean annual flow, and the BIAS was 6 percent. The calibration was adequate in most years, with most of the RMSE resulting from the 2-inch overprediction of runoff in 1982-83.

B.3.4.8 Guadalupe River. The Guadalupe River is the second largest watershed in the valley, and extends from the Santa Cruz Mountains to the Bay. Major tributaries include Los Gatos Creek, Ross Creek, Calero Creek, Alamitos Creek, and Canoas Creek. Mean annual rainfall in the basin ranges from 12 inches near the Bay to about 50 inches on the Santa Cruz Mountain ridgeline. Rain gages used to model the watershed are shown in Table B-1.

The SCVWD operates an extensive reservoir and recharge system on the Guadalupe River. Most of the areas in the Santa Cruz Mountains drain into Lexington, Guadalupe, Almaden, and Calero reservoirs. Water released from Lexington Reservoir is also stored in Vasona Reservoir. For the most part, these reservoirs are designed to store runoff in the winter and release in the summer for groundwater recharge. However, during wet years the reservoirs do release significant volumes of winter storm runoff. Outflows from each reservoir are measured by stream gages located immediately below the reservoir spillways. Much of the water released by reservoirs during dry weather is diverted downstream into groundwater recharge ponds. Water can also be diverted into the watershed from Coyote Creek through the Coyote-Alamitos Canal.

Calibration and verification of SWMM on the Guadalupe River was performed using the flow record for the U.S. Geological Survey (USGS) gage immediately below the confluence with Los Gatos Creek. This gage is downstream of the recharge ponds, and represents all of the major Guadalupe tributaries. It does not measure runoff from much of the urban San Jose portion of the watershed. Calibration was performed for runoff from areas downstream of reservoirs; runoff above the reservoirs was represented in loads calculations by the actual reservoir release records. To determine the volume of runoff occurring downstream of reservoirs, reservoir releases were subtracted from the USGS gage record using the following rules:

VOL 12

2/1/67

1) During storms, all of the water released from reservoirs reaches the USGS gage.

2) Between storms, all of the flow recorded by the USGS gage consists of reservoir releases minus diversions to recharge ponds.

These rules basically assume that released water is not diverted during storms, and that dry-weather reservoir releases are much larger than natural baseflow.

Calibration efforts on the Guadalupe River were less successful than at other watersheds, primarily because the Guadalupe River watershed is a highly managed system with numerous storage reservoirs and diversions. Because there were insufficient data to account for all of the stored and diverted water in the watershed, it was difficult to differentiate between storm runoff and water released from other sources. In several years, these data indicated storm runoff coefficients (runoff/rainfall) greater than 1.0 in February and March. As a results, SWMM was calibrated only during periods in which the measured flow data appeared to be reasonable (i.e., had reasonable runoff coefficients). Even focusing on these periods, the calibration/verification resulted in a wet-season RMSE of 40 percent and a BIAS of -2 percent. Calibration and verification results are plotted on Figure B-11. The predicted daily flow distribution passed the Kolmogorov-Smirnov test at the 95 percent confidence level. This calibration could have been improved by using parameter values which were completely inconsistent with those used in other basins. For instance, to match observed dry year totals (when all runoff is from impervious areas), the model would require percent impervious areas ranging from 1 to 20 percent in urban areas. In other simiiar basins, this parameter generally ranged from 10 to 80 percent. Given the mass balance problems observed in the measured flow data, the final calibration was determined using the best combination of parameters that was consistent with values used on Calabazas, Saratoga, San Tomas Aquinas, and Stevens Creek.

B.3.4.9 Comparisons of Predictions with Observed Flows for Selected Storms. An important component of any calibration is visual comparison of predicted hydrographs with measured hydrographs. Analysis of calibration statistics alone is not sufficient; visual comparison must also be made to ensure that the model predictions are consistent with our understanding of the relevant physical processes. In this section, selected predicted and measured hydrographs are presented to give the reader some idea of how well we were able to simulate storm hydrographs.

Figures B-12, B-13, and B-14 are examples of the range of hydrograph comparisons we were able to obtain. Figure B-12 shows the measured and predicted daily average flows for February 1980 storms in Calabazas Creek, and is an example of an excellent match between the model and the observed flows. Both the peak and storm recession are accurately predicted by the model. Figure B-13 illustrates a poor match between predicted and observed flows for a December 1977 storm on San Tomas Aquinas Creek. In this case, the model significantly overpredicted the peak flow rate and total storm volume. Figure B-14 shows a perhaps more typical hydrograph comparison for a March 1979 storm on San Tomas Aquinas Creek. Here, the model overpredicts the peak flow rate by about 20 percent, but is able to accurately simulate the total storm volume.

B.4 WATERSHED RUNOFF PREDICTIONS

The goal of the SWMM calibration discussed in the previous section was to produce a model which could 1) estimate runoff in ungaged areas, and 2) estimate the contributions of various land uses to runoff. This section summarizes storm runoff predictions for the Santa Clara Valley. These predictions were made for all watersheds for water years 1977-78 through 1988-89, the period for which rainfall data are available for all catchments.

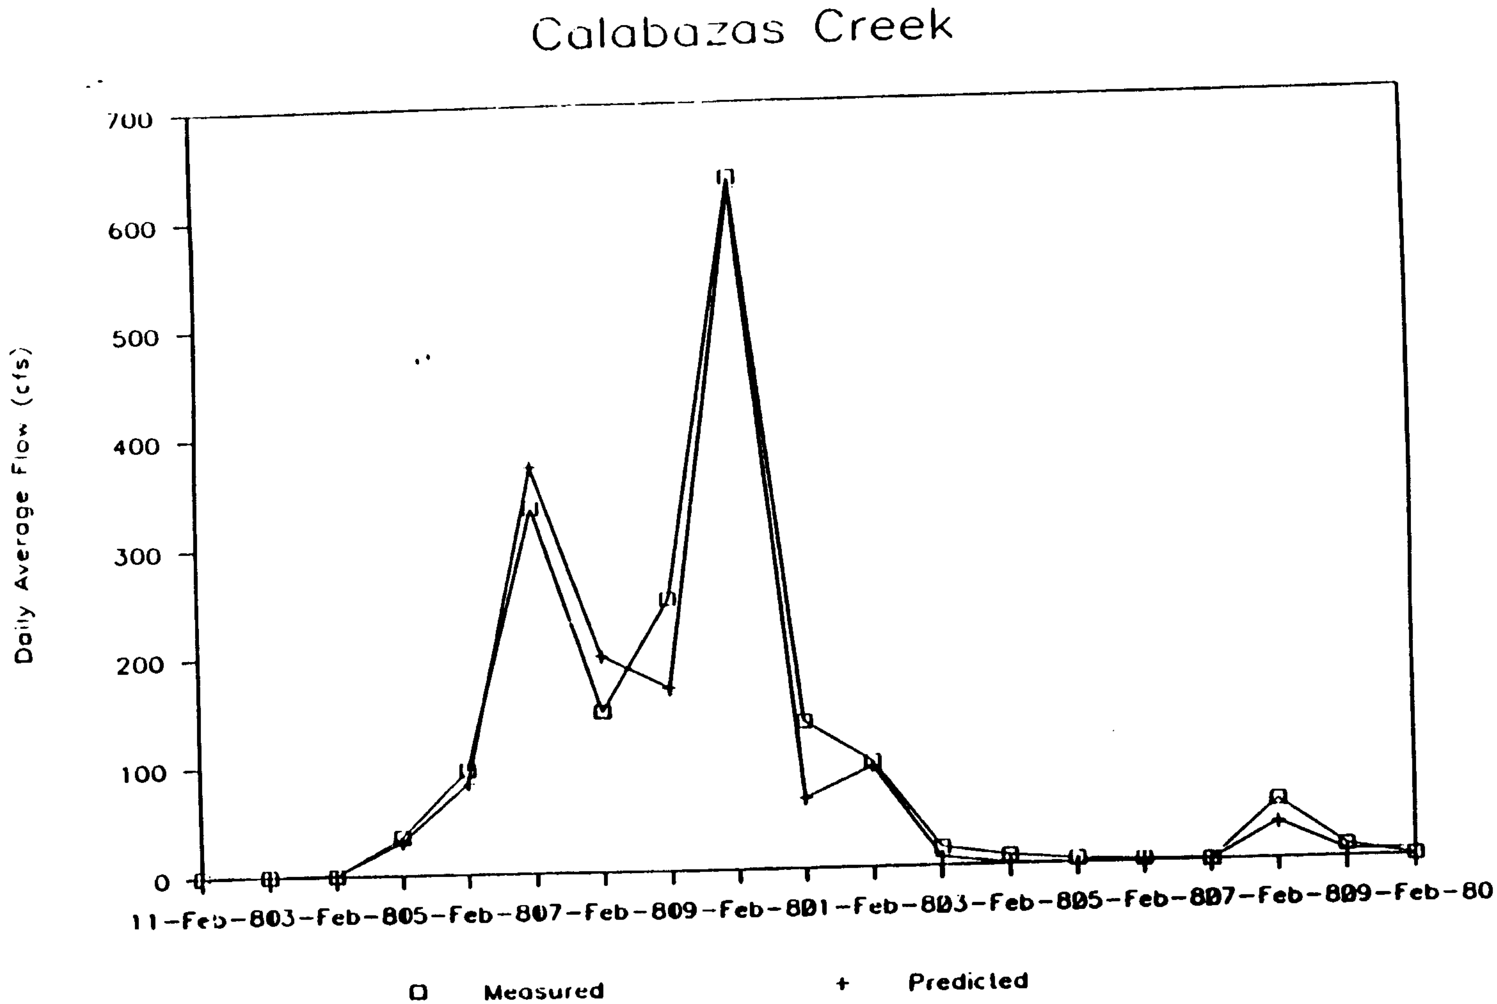

Figure B-12. Comparison of Predicted and Measured Hydrographs for Calabazas Creek, February 1980

Figure B-14. Comparison of Predicted and Measured Hydrographs for San Tomas Aquinas Creek, March 1979

SWMM was used to predict runoff in three types of areas:

1) Areas for which the model was calibrated against measured streamflow data

2) Areas in calibrated watersheds that are downstream of the calibration gage

3) Watersheds for which no flow data are available for calibration

For areas in which the model was calibrated, flow predictions were made by simply running the calibrated version of the model for the projection period. To account for model errors in calibration/verification years, the predicted flows for each land use were then multiplied by the ratio of wet-season measured runoff to predicted runoff for that year. This correction scaled the predicted flows to match measured totals exactly, and assumed that the correction factor was the same for all land uses.

For watersheds with streamflow data for calibration, there were usually uncalibrated urban areas in the lower portions of the watersheds. This applies to the following watersheds: Coyote Creek, Guadalupe River, Calabazas Creek, Saratoga Creek, San Tomas Aquinas Creek, Sunnyvale East Channel, and Stevens Creek. Because Sunnyvale East Channel best represents typical northern valley urban areas, parameters calibrated for this watershed were used in other uncalibrated urban areas. Soils parameters were estimated based on soil type and calibration in areas with similar soils.

Most of the western portion of the valley has little or no flow data for calibration. This includes Permanente Creek, Adobe, Matadero, and Barron creeks, and Sunnyvale West Channel. In addition, as only the portion of the San Francisquito Creek watershed in Santa Clara County was modeled, flow data could not be used for calibration. In these areas, parameters were estimated from similar calibrated watersheds. In urban

VOL 12 2/1/73

areas on the lower valley floor, parameters were estimated based on the calibration for Sunnyvale East Channel. In areas on the upper valley floor, parameters were estimated from the calibrations for Stevens Creek and Calabazas Creek. Finally, in upland areas calibration results for Stevens, Calabazas, and San Tomas Aquinas creeks were used to estimate parameters.

Table 8-9 summarizes the predicted annual storm runoff volumes for each watershed in the valley. As would be expected based on the relative drainage areas, 50 percent of storm runoff on average comes from Coyote Creek and the Guadalupe River. The highest runoff volume occurred during the 1982-83 season, while the lowest occurred in the 1988-89 season.

8.5 DETERMINISTIC WATER QUALITY MODELING OF CALABAZAS CREEK

As described in Section 8, loads in this study were derived as the product of annual runoff volume (from SWMM modeling) and annual mean concentration for each constituent and land use. These mean concentrations were obtained from statistical analysis of the water quality data collected at the land use and stream sampling stations. An alternative approach to estimate loads is to use the semi-empirical buildup-washoff models included in SWMM to predict runoff water quality. While these models are highly empirical and largely unverified, they do attempt to represent a number of the physical processes that are thought to determine runoff water quality. To compare this approach to the statistical mean concentration approach used in this study, the SWMM buildup washoff model was applied to estimate annual load from the Calabazas Creek watershed. A description of the model, calibration results, and predicted loads are provided in this section, as well as a comparison of the buildup-washoff load predictions to those derived from the statistical mean concentration model.

8.5.1 Model Description

The SWMM runoff water quality model is based on the concept of pollutant buildup and washoff. The concept behind this model is that a

VOL 12

supply of constituents builds up on the land surface during dry periods and is subsequently washed off during a storm. Pollutant buildup is assumed to occur as a function of time between storms. During a storm, washoff is assumed to occur as a function of the available mass of pollutants on the land surface and the rate of runoff. While the buildup-washoff concept does explain some of the mechanisms thought to produce runoff water quality, the model itself is highly empirical and requires substantial calibration to produce reasonable results.

Many studies have been conducted to determine rates of buildup on city streets. Sartor and Boyd (1972), among others, found that buildup appears to be non-linear, developing rapidly at first and then leveling off to a limit. This form of buildup is implemented in SWMM using an exponential buildup function:

$$P_{Shed} = P_{lim}*(1-\exp(-K_b*t)) \qquad (8\text{-}7)$$

2 1176

where

P_{Shed} = mass of constituent in watershed at time t (lbs/acre)
P_{lim} = upper limit on constituent mass that can accumulate (lbs/acre)
K_b = buildup rate constant ($days^{-1}$)
t = time between storms (days)

Washoff is the process that mobilizes the accumulated constituents into runoff and streamflow. In stream channels and other areas of significant flow, this process is described by sediment transport theory, where flow rate and bottom shear stress are important factors. For thin overland flows (sheet flows) common during storms in urban environments, rainfall energy can also mobilize particles. Therefore, more intense storms are able to washoff more of a constituent than a less intense storm. Whatever mechanisms are involved, it is obvious that as rainfall and washoff continue the amount of constituen. remaining in the watershed diminishes.

supply of constituents builds up on the land surface during dry periods and is subsequently washed off during a storm. Pollutant buildup is assumed to occur as a function of time between storms. During a storm, washoff is assumed to occur as a function of the available mass of pollutants on the land surface and the rate of runoff. While the buildup-washoff concept does explain some of the mechanisms thought to produce runoff water quality, the model itself is highly empirical and requires substantial calibration to produce reasonable results.

Many studies have been conducted to determine rates of buildup on city streets. Sartor and Boyd (1972), among others, found that buildup appears to be non-linear, developing rapidly at first and then leveling off to a limit. This form of buildup is implemented in SWMM using an exponential buildup function:

$$P_{Shed} = P_{lim}*(1-\exp(-K_b*t)) \qquad (8\text{-}7)$$

where

P_{Shed} = mass of constituent in watershed at time t (lbs/acre)
P_{lim} = upper limit on constituent mass that can accumulate (lbs/acre)
K_b = buildup rate constant ($days^{-1}$)
t = time between storms (days)

Washoff is the process that mobilizes the accumulated constituents into runoff and streamflow. In stream channels and other areas of significant flow, this process is described by sediment transport theory, where flow rate and bottom shear stress are important factors. For thin overland flows (sheet flows) common during storms in urban environments, rainfall energy can also mobilize particles. Therefore, more intense storms are able to washoff more of a constituent than a less intense storm. Whatever mechanisms are involved, it is obvious that as rainfall and washoff continue the amount of constituen. remaining in the watershed diminishes.

VOL 12

2/1/77

This observation, combined with the results of several empirical studies leads to the washoff formula used in SWMM:

$$Poff(t) = K_w * r^c * P_{shed} \qquad (B-8)$$

where

Poff = amount washed off at time t (lbs/acre)
K_w = washoff coefficient
r = runoff rate (in/hr)
c = empirical washoff exponent

Thus, the model has four input parameters: the limiting buildup rate (P_{lim}), the buildup rate constant (K_b), the washoff coefficient (K_w), and the washoff exponent (c). The buildup limit sets an upper limit on the availability of the constituents, and has a linear effect on the total mass load. The buildup rate constant sets the time scale of buildup between storms and thus attempts to capture the effects of "antecedent conditions." It can therefore be used to match observed water quality variations between sequential storm events. The washoff coefficient has a linear effect on the total mass that washes off during a storm. The washoff exponent primarily controls how load varies with time during a storm.

B.5.2 Model Calibration

None of the buildup-washoff model parameters can be measured directly, and all must be estimated by calibrating the model against measured water quality data. Few data on initial estimates of the buildup parameters are available in the literature for the types of constituents of concern in this study, although there are data on buildup rates of "dust and dirt" on parking lots and streets. The SWMM manual suggests an initial estimate of the washoff coefficient K_w of 4.6 in_{-1}, although other studies have used values ranging from .052 to 6.6 in_{-1}. The washoff exponent is suggested to range from 1.0 to 2.0, with a median value of 1.5.

VOL 12

2/179

8.5.2.1 Data Used for Calibration. The buildup washoff model was calibrated against water quality data collected at the Calabazas Creek monitoring station (S1) for five storms in the 1988-89 season. The available water quality data consisted of Event Mean Concentrations (EMCs) derived from composite samples; no data on the time-dependence of concentrations within a storm were available. Three constituents, Total Suspended Solids (TSS), copper and lead, were chosen for this test of the water quality model portion of SWMM. Measured EMCs used in calibration are listed in Table B-10.

8.5.2.2 Calibration Methods. The goal of calibration was to match to the extent possible the observed EMCs for the five storms for each constituent. Calibration was performed by systematically changing the values of the four buildup washoff parameters to minimize the difference between the simulated and observed EMCs. A number of parameters were used to measure the accuracy of the calibration. The root mean square error (RMSE) of predicted vs. observed EMCs was used to quantify the magnitude of model calibration errors. This was reported as a percentage of the mean measured concentration. The BIAS, or sum of errors, was used to indicate if the model was systematically under or overpredicting EMCs. To verify that the model was reproducing the statistics of the measured data, the predicted mean and coefficient of variation of the EMCs for the five storms were compared to the mean and coefficient of variation of the observed data. Finally, the data for each storm were tabulated and plotted as a function of time to verify whether or not the model was reproducing the observed trends in the data.

8.5.2.3 Calibration Results. Table B-10 compares the calibrated model to the measured data, and lists the calibration statistics for each constituent. Final calibrated values of the model input parameters are shown in Table B-11. RMSEs for the calibrations ranged from 19 percent for copper to 25 percent for TSS, and were relatively unbiased. The model was able to accurately reproduce the means of the observed data, but consistently underestimated the coefficient of variation of the data.

Figure B-15 compares the predicted and observed EMCs as a function of time for Copper. The model was able to reproduce the relatively high concentrations observed in the first November storm, but was unable to simulate the low concentrations found in the January and February storms. Much of the rainfall in 1988-89 occurred in the last week of December 1988, and the low concentrations observed in January may be a result of heavy washoff of constituents from street surfaces in December. However, the model did not reproduce this effect. The model also could not reproduce the rapid drop in concentration that was measured in the second of the two March storms. Overall, although the model was on average able to match observed concentrations with an RMSE of about 20 percent, it was not particularly successful at matching the observed sequence and timing of storm concentrations.

B.5.3 Comparison of Annual Load Estimates for Deterministic and Constant Concentration Water Quality Models

The calibrated water quality model was used to estimate annual loads for the 12 year simulation period (water years 1977-78 to 1988-89). Table B-12 compares these results to the annual load predictions obtained from the statistical mean concentration model. In dry years such as the 1988-89 calibration period the two models give comparable estimates of annual load. However, the deterministic water quality model predicts loads that are 2-3 times lower in wet years such as 1982-83. Overall, the deterministic water quality model predicts significantly lower concentrations than does the mean concentration model.

The reasons behind this difference between the two methods lie primarily in the assumptions behind the buildup-washoff model. During wet years, the buildup-washoff model assumes that the increased number of storms will reduce the mass of pollutant available on the street surfaces for washoff. Thus, although flow volumes may be an order of magnitude higher in wet years than in dry years, predicted concentrations in runoff are lower due to this source limitation effect. On the other hand, the

1184

mean concentration method assumes no difference in average water quality between wet and dry years. There is of course no direct evidence that the "dilution" effect predicted by the buildup-washoff model actually occurs. In this study, little or no correlation was found between the time between storms and runoff concentration, implying that the number of storms in a year should have little effect on water quality concentrations.

In summary, the deterministic water quality model predicts significantly lower loads and concentrations in wet years. The model does account for a number of mechanisms that one would intuitively believe to occur during and between storms. However, the model requires substantial calibration, and was not able to accurately simulate observed patterns in water quality during the 1988-89 monitoring period. The mean concentration model used in loads estimation in the remainder of this study makes direct use of the observed water quality data, and requires little calibration. The mean concentration model, however, is unable to account for possible differences in water quality during wet and dry years. Currently, there are no data available to determine which (if either) of these models is best able to simulate water quality in wet years.

SUMMARY OF LABORATORY QA/QC

VOL 12

2/1/88

APPENDIX C
SUMMARY OF LABORATORY QA/QC

Evaluation of the quality of the analytical data included:

1) Precision of laboratory duplicates (Table C.1)
2) Precision of field duplicates (Table C.2)
3) Precision of matrix spike and matrix spike duplicate recoveries (Table C.3)
4) Potential contamination of field and laboratory (method or reagent) blanks (Table C.4)
5) Laboratories performance on Environmental Resources Associates (ERA) quality control samples (Table C.5)

C.1 WATER SAMPLES

C.1.1 Laboratory Duplicates

Laboratory duplicates were routinely performed by the laboratory for a reduced suite of parameters. The only exception was for dry-weather 3 (May 12, 1989) and wet-weather 1 sampling events (May 5, 1989), where laboratory duplicate analyses were not generated. Results of laboratory duplicate analyses are presented in Tables C.1-1 to C.1-12. The precision of the laboratory duplicates is an indication of the variability in the extraction and analytical procedures in the laboratory. This precision is commonly expressed as a relative percent difference (RPD). The RPD was calculated by the following equation:

$$|Conc\ (A) - Conc\ (B)| / \{[Conc\ (A) + Conc\ (B)]/2\}$$

where

Conc (A) = Concentration of primary duplicate sample

Conc (B) = Concentration of secondary duplicate sample

|Conc (A) - Conc (B)| = Difference between concentrations of primary and secondary duplicates expressed as absolute values

For the dry-weather sampling events 1, 2, 4, 5, 6, and 7, the RPD ranged from 0 to 29%, with a mean value of 6%. The RPDs for all wet-weather sampling events (2 to 7) were between 0 to 40% (mean of 16%), with the exception of two elevated RPDs for lead (55%) and mercury (100%) analyses for wet-weather 2 duplicate samples. Thus the reported RPDs for both dry and wet-weather samples are considered to be within laboratory acceptable limits.

C.1.2 Field Duplicates

Results of field duplicate samples are an indication of overall field variability, precision of field sampling and laboratory analyses. As such, the results of field duplicates have more variability than laboratory duplicates, which measure only laboratory performance. Field duplicate samples were collected and analyzed for a reduced parameter suite for all dry and wet-weather sampling events, with the exception of wet-weather 1 (May 5, 1989). The results of field duplicate analyses are presented in Tables C.2-1 to C.2-13. For all dry-weather field duplicate samples, the RPD ranged from 0 to 100%, with a mean of 23%. The RPD ranged from 0 to 94% for all wet-weather field duplicate samples; the mean value was 31%. These mean field duplicate RPDs are higher than the laboratory duplicate RPDs by about a factor of two to three, and likely represent the additional variability from field sampling.

C.1.3 Matrix Spike and Matrix Spike Duplicates

Matrix spike (MS) and matrix spike duplicate (MSD) recovery data are performed to evaluate accuracy and precision of each individual analytical method. The results of MS and MSD recoveries and also the RPD of these matrix spikes are summarized in Tables C.3-1 to C.3-10. Matrix spike recoveries for specific compounds analyzed under each method evaluated in this program were within acceptable limits according to the current EPA guidance for laboratory analyses (EPA, Test Methods for Evaluating Solid Waste, SW846, Third Edition). The RPD between MS and MSD recoveries were generally less than 30%, and therefore considered to be within EPA acceptable limits.

C.1.4 Laboratory (Method or Reagent) and Field Blanks

The purpose of laboratory and field blank analysis is to detect potential contamination from the laboratory and/or field sampling. All laboratory method blanks and field blanks were generally free of contaminants, with the exception of the detections of some organic compounds and metals.

C.1.4.1 Metals. It is important to note that the collection of field blanks in this sampling program was different for the dry- and wet-weather sampling events. Field blanks were obtained using procedures identical to those for collection of field samples. Dry-weather samples were collected by dipping sample containers in the sampling stream. Correspondingly, field blanks were collected by pouring laboratory reagent water (Milli-Q purified) into sample containers at each sampling station. Wet-weather composite samples were collected in the ISCO samplers in 10-liter borosilicate bottles, which were then taken to the laboratory. In the laboratory, a peristaltic pump with Teflon hose was used to fill individual sample bottles required for the various analyses (e.g., metals, pesticides, etc.). The Teflon hose was flushed with laboratory reagent water every time a new 10-liter sample bottle from each of the sampling stations was to be drained. At the end of this process, the Teflon hose was flushed and then laboratory reagent water was used to fill sample bottles for the blank analysis. This method of blank collection is commonly known as an

VOL 12

2/1/90

equipment blank. Hereinafter, all "field blanks" collected in the wet-weather period will be referred to as equipment blanks.

For the dry-weather samples, field blanks showed low levels of zinc contamination in dry-weather 4 (0.011 mg/L), dry-weather 5 (0.014 mg/L), dry-weather 6 (0.010 mg/L), and dry-weather 7 (0.006 mg/L). These levels of zinc were generally equal to or lower than the actual zinc levels found in the stream samples (Stations S1 to S4). No zinc contamination was found in the method blank analyses for the above-listed dry-weather sampling rounds. Because the method blanks were free of contamination, the source of the zinc contamination in the field blank is not the laboratory reagent water or the acid-preservative.

In addition, mercury and lead were detected at 0.0003 mg/L and 0.003 mg/L in dry-weather 4 and 6, respectively. The impact of mercury and lead contamination on the actual concentrations found in water samples is minimal because of the following reasons:

1) Mercury and lead were not detected in method blanks.

2) Mercury and lead concentrations in the field blank are close to the detection limit of 0.0001 mg/L and 0.001 mg/L, respectively.

3) Mercury levels detected in actual water samples are about 10 times higher than those found in the field blank.

4) Lead was not detected in actual water samples except for a lead concentration of 0.004 mg/L detected in one stream sample.

For the wet-weather samples, low levels of some metals were detected in the equipment blanks from wet-weather 2 (Table C.4-8), wet-weather 3 (Table C.4-10), wet-weather 5 (Table C.4-12), and wet-weather 7 (Table C.4-14). The source of contamination is potentially from carryover of residual metals found in the hose used with the peristaltic pump. The concentrations found in the actual water samples were not corrected for these metal contaminants because all method blanks were generally free of metal contamination for the above-listed wet-weather sampling events with the exception of wet-weather 2, in which cadmium was detected in the method blank at the detection limit of 0.0002 mg/L.

For wet-weather 6, five metals--chromium (0.052 mg/L), copper (0.011 mg/L), lead (0.001 mg/L), nickel (0.06 mg/L), and zinc (0.018 mg/L)--were detected in the equipment blank. The source of these elevated metals is probably from the laboratory water. Because the Milli-Q purification system was broken during this sampling event, laboratory water was obtained from the solar still, which probably contained the elevated metals. Although the equipment blank was contaminated, the metals results for the actual water samples should not be affected because the samples did not come in contact with the solar still water except perhaps for a very small volume that may have adhered to the tubing from the flushing operation. The method blank analysis generally did not detect any metals concentrations that were comparable to those found in the equipment blank. For wet-weather 6, the only metal detected above the detection limit in the method blank was chromium. Chromium was detected at 0.002 mg/L in the first method blank and at a lower level of 0.001 mg/L in the second method blank.

C.1.4.2 Organics. Two volatile organics, methylene chloride and acetone, were detected in method blanks. Methylene chloride was detected at 6, 11, and 7 μg/L in method blanks for dry-weather 1 and 2, and wet-weather 1, respectively. Acetone was detected twice at 27 and 20 μg/L for dry-weather 2 and wet-weather 1, respectively. These volatile organics are commonly used solvents in the laboratory for sample extractions. Therefore, the detections of methylene chloride and acetone in storm runoff samples during dry-weather 1 and 2, and wet-weather 2, are suspect and most probably due to laboratory contamination.

VOL 12 2/1/92

A semi-volatile organic, bis(2-ethylhexyl)phthalate (BEHP), was detected in method blanks from dry-weather 1 and 2, and wet-weather 1 and 2. The concentrations of BEHP ranged from 11 to 800 µg/L. The presence of BEHP is common in plastic material such as gloves and tubing. According to the current guidance from EPA on evaluation of phthalate data (EPA 1988), phthalates are common laboratory contaminants at levels of less than 100 µg/L. Based on evidence of BEHP contamination in the laboratory and EPA's current position on phthalate compounds, the detections of BEHP in storm runoff samples from L1, L2, and L6 are therefore suspect and most probably due to laboratory contamination.

A detection of 4,4'-DDE at 0.077 µg/L was found in a field blank from wet-weather 3. Since this organochlorine compound, 4,4'-DDE, was not detected in any of the storm runoff samples for wet-weather 3, this one-time detection of 4,4'-DDE in a field blank is likely due to field or laboratory contamination, and does not impact the results of organochlorine analyses of water samples collected from wet-weather 3.

C.2 SEDIMENT SAMPLES

Results of QC analyses for sediment samples are presented in Tables C.1-13, C.2-14 to C.2-16, and C.3-11 to C.3-14. Generally, the RPDs for laboratory and field duplicates were similar to those reported for the water samples. Matrix spike recoveries and RPDs of these matrix spike recoveries were also within acceptable limits.

As with the water samples, BEHP was detected in method blanks in the second and third sampling rounds. BEHP concentrations ranged from 940 to 2400 µg/kg The ubiquitous presence of BEHP in both laboratory and field environments is discussed earlier in Section C.1.4. Detections of BEHP in actual sediment samples from sampling events 2 and 3 are therefore suspect and likely due to laboratory artifacts.

VOL 12

C.3 EXTERNAL REFERENCE SAMPLES

External reference samples were submitted to the laboratories by the Project Quality Control Officer. These samples were supplied by Environmental Resource Associates (ERA), Arvada, Colorado, with certified analyses of target parameters. External reference samples were selected by the project quality control officer to match specific method analyses, expected concentration ranges, and sample matrices as closely as possible. The analytical results supplied with the reference samples were not disclosed to the individual laboratories. Samples were submitted a total of five times on a quarterly basis throughout the study. A summary of the results of comparisons between laboratory performance and ERA results for selected constituents is presented in Table C.5.1. Results of each quarter are presented in Tables C.5.2 through C.5.6.

C.3.1 First Quarter ERA Quality Control Samples, 1988

All laboratory reported concentrations were within the advisory ranges of the external reference samples except for arsenic, semi-volatiles (1,2,3-trichlorobenzene), and pesticides (gamma-BHC and PCBs, Aroclor 1242). The advisory range is the range of values that an experienced laboratory can expect to attain using the most precise methods and equipment. In determining advisory ranges, ERA considers both the parameter and the most commonly used method of analysis for the parameter. The arsenic value was outside the advisory range, but was determined to be an acceptable level of performance by the individual laboratory. True and advisory values for ERA organic quality control samples (volatiles, semi-volatiles, pesticides and PCBs, and herbicides) are based on analytical results from applicable EPA reference methods. True values represent 100% recoveries for the analyses. Since many organic analytical methods do not yield 100% recoveries, ERA advisory ranges reflect typical recoveries from water samples for the applicable EPA methodologies. The semi-volatile and pesticides and PCBs values were within an acceptable level of performance by the laboratory.

VOL 12

2/1/95

C.3.2 Second Quarter ERA Quality Control Samples

Laboratory reported values were within the advisory ranges except for the conventional constituents (BOD and TKN), and organic quality control samples such as volatiles (chloroform) and semi-volatiles (acenaphthene, benzo(a)pyrene, 2-chloronaphthalene, 1,3-dichlorobenzene and hexachlorobutadiene). The conventional constituent values were within acceptable levels of performance. The organic sample values were low due to laboratory contamination problems experienced during sample preparation.

C.3.3 Third Quarter ERA Quality Control Samples

Laboratory reported values outside the advisory ranges were for conventional constituents (TKN, ammonia, and phosphate) and organic quality control samples including:

1) Semi-volatiles (hexachloroethane, 1,2,4-trichlorobenzene, 2-chloronaphthalene, acenaphthylene)
2) Pesticides (aldrin and heptachlor epoxide)
3) PCBs (Aroclor 1242)

The pesticides and PCBs true values were near or below the detection limits for the laboratory, which caused recovery values to be unattainable by the laboratory.

C.3.4 Fourth Quarter ERA Quality Control Samples

Laboratory reported values were within the advisory ranges except for trace metals (arsenic, mercury, selenium, and silver), conventional constituents (ammonia, nitrate, phosphate), and organic quality control samples including semi-volatiles (1,4-dichlorobenzene and bis(2-chloroisopropyl)ether), PCBs (Aroclor 1221), and herbicides (2,4-D and 2,4,5-TP). The true values for PCBs and herbicides were below the detection limits for the laboratory and recovery values were unattainable. The herbicides ERA sample was no longer analyzed because the concentration levels of the analyte were always below laboratory detection limits. Due to complications during sample preparation for the metals analysis, low recoveries were reported by the laboratory. The conventional constituent values were acceptable levels of performance.

C.3.5 First Quarter ERA Quality Control Samples, 1989

Laboratory reported values were within the advisory ranges except for trace metals (lead and cadmium), and the organic quality control samples: pesticides (endrin aldehyde) and PCBs (Aroclor 1221). The concentration of endrin aldehyde and Aroclor 1221 were below the laboratory detection limits. The conventional constituent values and the trace metal values were acceptable levels of performance.

C.4 CONCLUSIONS

In summary, the QA/QC data are of acceptable quality according to the current EPA guidelines for laboratory analyses. Based on this QA/QC evaluation, the chemical data (water and sediment) collected in this program are therefore considered of good and reliable quality.

The precision of the data, represented by the relative percent difference (RPD), was evaluated for both field and laboratory duplicates. For field duplicates collected during wet and dry weather periods, the RPD ranged from 0 to 100 percent with an associated mean of 27 percent. For laboratory duplicates, the RPD ranged from 0 to 29 percent (mean of 6 percent) for dry weather samples, and 0 to 40 percent (mean of 16 percent) for wet weather samples. Results of field duplicate samples are an indication of overall field variability, and precision of field sampling techniques and laboratory analyses. As such, the results of field duplicates show more variability than laboratory duplicates, which measure only the precision of laboratory methods.

VOL 12

2/1/96

The accuracy of the data is represented by the results of (1) matrix spike recoveries, and (2) external reference standards. Matrix spike recoveries for all constituents were within acceptable limits. Based on the results of five rounds of external reference standards, most of the metals concentrations (arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc) and other conventional pollutants (TKN, nitrate, phosphate, BOD, and total suspended solids) were within the "true" concentrations, therefore indicating that they are reliable values. It is important to note that cadmium, chromium, copper, lead, nickel, and zinc are the five metals used for estimates of metals loads to the Bay. For selenium and silver, however, the actual measured concentrations appear to underestimate the "true" concentrations by about 10 to 30 percent. These two metals were not used in the loading estimates, and were consistently found at low levels with a few values above the detection limit.

APPENDIX D
SANTA CLARA NONPOINT SOURCE WATER
AND SEDIMENT QUALITY DATA

1277

VOL 12 2 1278

APPENDIX D
SANTA CLARA NONPOINT SOURCE WATER AND SEDIMENT QUALITY DATA

The following section presents the water and sediment quality data collected for the Santa Clara Valley Nonpoint Source study. The data are organized by parameter type (e.g., metals, conventional, etc.) and are titled D.1 through D.7. Under each parameter type the data are further subdivided into water samples and sediment samples. In addition, the metals include subgroups for total and dissolved concentrations in the wat r column. Following is a list of the parameter types and the corresponding appendix section:

- D.6 Polynuclear aromatic hydrocarbons
  - D.6-1 Polynuclear aromatic hydrocarbons in water column
  - D.6-2 Polynuclear aromatic hydrocarbons in sediment
- D.7 Volatiles and semi-volatiles
  - D.7-1 Volatiles and semi-volatiles in water column
  - D.7-2 Volatiles and semi-volatiles in sediment
- D.8 Dissolved oxygen data from stream stations and settling data

Within each parameter subgroup, the data are further organized by sample I.D. along rows and with the parameters sampled along columns. The sample I.D. corresponds to the sampling station identification number (e.g., L1 through L7 for land use stations, S1 through S4 for stream stations, and R1 through R6 for reservoir release stations). Under each sample I.D. the data are again subdivided into samples collected during dry (DRY) and wet (WET) weather, when appropriate. Also shown under sample I.D. are field duplicate (FD), lab replicates (LR), and field blanks (FB).

Under each parameter type are the measured concentrations (or ND if non-detected) and the value of the detection limit for the sample collected. Blanks in the data set mean that an analysis was not performed for certain parameters (such as hexavalent chromium) during a particular sampling event.

ORGANOCHLORINE PESTICIDES

Abbreviated Name	Actual Name
6CL-CHX-A	Alpha-BHC (hexachlorocyclohexane
6CL-CHX-B	Beta-BHC (hexachlorocyclohexane)
6CL-CHX-D	Delta-BHC (hexachlorocyclohexane)
6CL-CHX-G	Gamma-BHC (hexachlorocyclohexane)
G-CHLORDANE	Gamma-chlordane
ENDOSULFAN-A	Endosulfan I
ENDOSULFAN-B	Endosulfan II
ENDOSULFAN-S	Endosulfan sulfate
ENDRIN-ALD	Endrin aldehyde
HEPCL EPOX	Heptachlor epoxide
METHOXYCL	Methoxychlor
tPCB	Total polychlorinated biphenyls
DDD	4,4'-DDD
DDE	4,4'-DDE
DDT	4,4'-DDT

APPENDIX A

Summary of Test Conditions

square root transformed weight data. There was no significant decrease in mean larval weight in samples L-4 and L-7 when compared with the weight of laboratory water controls. There was significantly decreased larval weight in samples S1, S2 and L5.

Environmental monitoring data for fathead minnow larvae are summarized in Table 6.

<u>Selenastrum</u>

Growth and environmental monitoring data are summarized in Table 7.

Because of the large number of samples, the test was run in two batches. Run #1 included samples L3, L4, L5, L6 and L7. Run #2 included samples S1, S2, S3, L1 and L2. Each sample set had its own control.

For Run #1, cell number data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 3.653 vs tabled χ^2 value at p=0.01 and 5 d.f. = 15.09). ANOVA and Dunnetts analyses were done on the untransformed data. There was no significant decrease in mean cell numbers in samples L3 and L4 when compared with growth in lab water controls. There were significantly decreased cell numbers in sample L5, L6 and L7.

For Run #2, cell number data were normally distributed (Shapiro-Wilkes), but were not homogeneous. Square root transformation corrected the homogeneity (Bartlett's B = 14.88 vs tabled critical value for p=0.01 and df=5 of 15.09). ANOVA and Dunnett's tests were done on the square root-transformed data. There was no significant decrease in mean cell numbers in samples S1, S2 and S3 when compared with growth in lab water controls. There were significantly decreased cell numbers in samples L1 and L2.

Results and Conclusions

Ceriodaphnia

On 14 February, testing was initiated on all samples. Within 8 hours, all daphnids in samples S1, S2, S3, L2, L3, L4, L5 and L6 had died. Ten percent dilutions of those samples were prepared using laboratory water, and the entire test was re-started on 15 February. The reproduction and survival data summarized in Tables 1 and 2 are the results of testing 100% concentrations of samples L1 and L7, and 10% concentrations of the samples listed above. Data were statistically analyzed using the laboratory water controls as the comparative data.

Analysis of survival data by Fisher's Exact Test showed that samples S1, L1 and L3 produced statisticelly significant mortality when compared with laboratory water controls. Following protocol guidelines, reproduction data for those samples was excluded from subsequent statistical analysis.

Reproduction data were found to be non-homogeneous, with a Bartlett's B value of 19.86 (tabled Bartletts value at P = 0.01 for 7 df = 18.48). This non-homogeneity could not be corrected by data transformation (square root, log, arcsin), and subsequent analysis was done by Steel's Many-One Rank Test. The tabulated critical rank sum value for n= 10 and K=8 at P=0.05 is 73. Rank sums for samples S-2 (55) and L3 (55) were less than 73, indicating that reproduction in these samples was significantly lower than in the laboratory control water.

Environmental monitoring data are tabulated and presented in Table 3.

Fathead Minnow Larvae

Survival and growth (dry weight) data are summarized in Table 4, and data for individual replicate test containers are presented in Table 5.

Mortality in samples L1 and L2 was significantly higher than in control water, and these data were excluded from further statistical analysis.

Larval weight data were normally distributed (Shapiro-Wilkes) but were not homogeneous (Bartletts B = 22.42). Data transformation (square root, log, arcsin) did not correct the non-homogeneity. Protocol guidance suggests that Steel's Many-One Rank Test be used to analyze growth data, but Steel's cannot be used when there are less than 4 replicates. Telephone guidance from EPA Cincinnati directed us to transform the data to produce the Bartletts B value closest to the critical number, and use that transformed data set to perform Dunnett's test. Square root transformation produced a Bartlett's B value of 17.64, compared with a critical B at 0.05 with 5 df of 15.09. Dunnett's analysis was done on the

Introduction

As part of the Santa Clara Valley Non-Point Source Program, toxicity testing must be carried out on water samples collected during both dry weather (four times) and wet weather (three times). Dry weather tests require daily collection of water samples at the four stream stations (S1-S4). Wet weather tests are conducted using a single composite sample of runoff water for the daily renewals. This test is the first of three wet weather tests. Three toxicity tests are conducted, utilizing Ceriodaphnia dubia (invertebrate), Pimephales promelas (fish) and Selenastrum capricornutum (plant).

The Ceriodaphnia and Pimephales tests are seven days in duration, and are static-renewal protocols, requiring daily replacement of test solutions. Collections of runoff water are made by MBL personnel and stored at 4°C. Aliquots of this stored water are used for daily renewals.

The three bioassays were performed concurrently. Daphnids and fish were run on 15-21 February, 1989. Algae were tested in two batches, 14-18 February and 15-19 February, 1989. Methods, results and data are presented in the following pages.

The samples were collected and delivered to MBL by Kinnetic Laboratories Inc. personnel. The experimental design called testing only undiluted (100%) stream water. A lab water control (EPA moderately-hard) was run to provide quality assurance data. The lab water results were also used as the comparative data for statistical comparisons.

Most of the runoff samples proved to be acutely toxic to Ceriodaphnia, producing 100% mortality within 8 hours of test initiation. Those acutely toxic samples were S1, S2, S3, L2, L3, L4, L5 AND L6. After consultation with our client, we prepared 1:10 dilutions of each of those samples and started the Ceriodaphnia test again using 10% concentrations.

Fathead minnow and Selenastrum bioassays were done with undiluted runoff samples.

1399

Methods

Ceriodaphnia

Test organisms were neonates derived from in-house cultures. Original broodstock was from EPA Duluth, received 11 May, 1988 and cultured in EPA moderately hard water prepared with Milli-Q water. Samples of stream test water were collected daily during the test, and lab control water was EPA moderately hard (Milli-Q).

The test was initiated with 4-8 hour old neonates derived from third broods of individually maintained broodstock. Testing was conducted with 10 individuals per treatment, each in individual plastic cups containing 15 ml of test solution. Test temperature was 25 $\pm$ 1°C and photoperiod was 16 hour light:8 hour dark. Test solutions were renewed daily, concurrent with transfers, water quality measurements and assessment of survival and reproduction. At each daily transfer, new media were inoculated with food (2 drops of *Ceriodaphnia* chow and 1 drop of *Selenastrum* culture, density approximately 2.5 X 10^6 cells/ml). Following the 7-day test period, survival data was statistically evaluated using the probit method to calculate the 96-hour LC50. Reproductive data was evaluated using ANOVA and Dunnett's Test after confirming data homogeneity by Bartlett's Test. Test conditions and organism data are summarized in Appendix Table A-1.

Fathead Minnow Larvae

Test organisms were larvae, less than 24 hours old, obtained from in-house culture. All larvae were from the same spawning substrate, but probably from multiple spawns. Original broodstock was purchased from Thomas Fish Farms, San Rafael, California, approximately March of 1988. Stream test water samples were collected fresh each day. Control water was EPA moderately hard (Milli-Q). Ten larvae were used in each test container and there were three replicate containers per concentration. Each larval container was fed three times daily with 750-1000 newly-hatched *Artemia* nauplii. Test temperature was 25 $\pm$ 1°C, and photoperiod was 16:8. Daily renewal of 80% of the test volume coincided with daily environmental monitoring and assessment of survival. After seven days of exposure, the test was terminated by addition of formalin to each container. Surviving larvae were dried and weighed, and weight data were statistically evaluated using Bartlett's Test followed by ANOVA and Dunnett's Test. Probit analysis of survival data was used to calculate the 96-hour LC_1. Test conditions and organism data are summarized in appendix Table A-2.

Selenastrum

Algal assays were conducted in sterile 250 ml Erlenmeyer flasks. Preparation of the nutrient medium followed guidelines set forth in EPA-600/9-78-018.

VOL 12

Introduction

As part of the Santa Clara Valley Non-Point Source Program, toxicity testing must be carried out on water samples collected during both dry weather (four times) and wet weather (three times). Dry weather tests require daily collection of water samples at the four stream stations (S1-S4). Wet weather tests are conducted using a single composite sample of runoff water for the daily renewals. This test is the second of three wet weather tests. Three toxicity tests are conducted, utilizing Ceriodaphnia dubia (invertebrate), Pimephales promelas (fish) and Selenastrum capricornutum (plant).

The Ceriodaphnia and Pimephales tests are seven days in duration, and are static-renewal protocols, requiring daily replacement of test solutions. Collections of runoff water are made by MBL personnel and stored at 4°C. Aliquots of this stored water are used for daily renewals.

The three bioassays were performed concurrently. Daphnids and fish were run on 14-21 March, 1989. Algae were tested in two batches, 11-15 March and 12-16 March, 1989. Methods, results and date are presented in the following pages.

The samples were collected and delivered to MBL by Kinnetic Laboratories Inc. personnel. The experimental design called for testing only undiluted (100%) stream water. A lab water control (EPA moderately-hard) was run to provide quality assurance data. The lab water results were also used as the comparative data for statistical comparisons.

Some of the runoff samples proved to be acutely toxic to Ceriodaphnia, producing 100% mortality within 8 hours of test initiation. Those acutely toxic samples were S1, S2, L5 and L6. We prepared dilutions of each of those samples and started the Ceriodaphnia test again using 25% or 50% concentrations.

Fathead minnow and Selenastrum bioassays were done with undiluted runoff samples.

2

Methods

Ceriodaphnia

Test organisms were neonates derived from in-house cultures. Original broodstock was from EPA Duluth, received 11 May, 1988 and cultured in EPA moderately hard water prepared with Milli-Q water. Samples of stream test water were collected daily during the test, and lab control water was EPA moderately hard (Milli-Q).

The test was initiated with 4-8 hour old neonates derived from third broods of individually maintained broodstock. Testing was conducted with 10 individuals per treatment, each in individual plastic cups containing 15 ml of test solution. Test temperature was 25 ± 1°C and photoperiod was 16 hour light:8 hour dark. Test solutions were renewed daily, concurrent with transfers, water quality measurements and assessment of survival and reproduction. At each daily transfer, new media were inoculated with food (2 drops of Ceriodaphnia chow and 1 drop of Selenastrum culture, density approximately 2.5×10^6 cells/ml). Following the 7-day test period, survival data was statistically evaluated using the probit method to calculate the 96-hour LC50. Reproductive data was evaluated using ANOVA and Dunnett's Test after confirming data homogeneity by Bartlett's Test. Test conditions and organism data are summarized in Appendix Table A-1.

Fathead Minnow Larvae

Test organisms were larvae, less than 24 hours old, obtained from in-house culture. All larvae were from the same spawning substrate, but probably from multiple spawns. Original broodstock was purchased from Thomas Fish Farms, San Rafael, California, approximately March of 1988. Stream test water samples were collected fresh each day. Control water was EPA moderately hard (Milli-Q). Ten larvae were used in each test container and there were three replicate containers per concentration. Each larval container was fed three times daily with 750-1000 newly-hatched Artemia nauplii. Test temperature was 25 ± 1°C, and photoperiod was 16:8. Daily renewal of 80% of the test volume coincided with daily environmental monitoring and assessment of survival. After seven days of exposure, the test was terminated by addition of formalin to each container. Surviving larvae were dried and weighed, and weight data were statistically evaluated using Bartlett's Test followed by ANOVA and Dunnett's Test. Probit analysis of survival data was used to calculate the 96-hour LC_1. Test conditions and organism data are summarized in appendix Table A-2.

1413

Selenastrum

Algal assays were conducted in sterile 250 ml Erlenmeyer flasks. Preparation of the nutrient medium followed guidelines set forth in EPA-600/9-78-018.

All algal counts were made manually with a hemacytometer and microscope. Treatment groups and controls were set up with a minimum of three replicates. Testing was conducted in an environmental chamber with continuous illumination of 400 ft/candles at 24 $\pm$ 2°C for 96 hours. All test flasks were innoculated with approximately 1 X 10^4 cells/ml from a 4 day old stock culture. Cultures were shaken twice daily by hand. Upon conclusion of testing, statistical analyses were made of final cell densities to determine EC50 concentrations using the Probit Method. Bartlett's test was used to confirm homogeneity of variance after which Dunnett's test was used.

Results and Conclusions

Ceriodaphnia

On 13 March, rangefinder acute testing was initiated on all samples. Within 8 hours, all daphnids in samples S1, S2, L5 and L6 had died. Dilutions of those samples were prepared using laboratory water, and the entire test was re-started on 14 February. The reproduction and survival data summarized in Tables 1 and 2 are the results of testing 100% concentrations of samples L1, L3, L4 and L7, 50% concentrations of samples S1 and L5 and 25% concentrations of samples S2 and L6. Data were statistically analyzed using the laboratory water controls as the comparative data.

Analysis of survival data by Fisher's Exact Test showed that all samples except L7 produced statistically significant mortality when compared with laboratory water controls. Following protocol guidelines, reproduction data for those samples was excluded from subsequent statistical analysis.

Mean young production for Sample L7 was higher (25.8 per adult) than laboratory water controls (17.3 per adult). No statistical analysis was necessary to determine that Sample L7 did not inhibit reproduction when compared with controls.

Environmental monitoring data are tabulated and presented in Table 3.

Fathead Minnow Larvae

Survival and growth (dry weight) data are summarized in Table 4, and data for individual replicate test containers are presented in Table 5.

Mortality in sample L1 was significantly higher than in control water, and these data were excluded from further statistical analysis.

Larval weight data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 7.324). Dunnett's analysis was done on the untransformed weight data. There was no significant decrease in mean larval weight in samples S1, S2, L5, and L7 when compared with the weight of laboratory water controls.

Environmental monitoring data for fathead minnow larvae are summarized in Table 6.

VOL 12 2 1414

Selenastrum

Growth and environmental monitoring data are summarized in Table 7.

Because of the large number of samples, the test was run in two batches. Run #1 included samples S1, S2, S3, S4 and L1. Run #2 included samples L3, L4, L5, L6 and L7. Each sample set had its own control.

For Run #1, cell number data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 8.606 vs tabled X^2 value at p=0.01 and 4 d.f. = 13.28). There were no visible cells in sample L1 after four days of incubation, so these data were excluded from further statistical analysis. There were significantly decreased cell numbers in sample S1, S2, S3 and S4 when compared with growth in lab water controls.

For Run #2, cell number data were normally distributed (Shapiro-Wilkes) and homogeneous. (Bartlett's B = 9.736 vs tabled critical value for p=0.01 and df=5 of 15.09). ANOVA and Dunnett's tests were done on the untransformed data. There was no significant decrease in mean cell numbers in samples L3, L6 and L7 when compared with growth in lab water controls. There were significantly decreased cell numbers in samples L4 and L5.

Introduction

As part of the Santa Clara Valley Non-Point Source Program, toxicity testing must be carried out on water samples collected during both dry weather (four times) and wet weather (three times). Dry weather tests require daily collection of water samples at the four stream stations (S1-S4). Wet weather tests are conducted using a single composite sample of runoff water for the daily renewals. This test is the third of three wet weather tests. Three toxicity tests are conducted, utilizing Ceriodaphnia dubia (invertebrate), Pimephales promelas (fish) and Selenastrum capricornutum (plant).

The Ceriodaphnia and Pimephales tests are seven days in duration, and are static-renewal protocols, requiring daily replacement of test solutions. Collections of runoff water are made by MBL personnel and stored at 4°C. Aliquots of this stored water are used for daily renewals.

The three bioassays were performed concurrently. Daphnids and fish were run on 28 March - 4 April, 1989. Algae were tested in two batches, both run on 30 March - 4 April, 1989. Methods, results and data are presented in the following pages.

The samples were collected and delivered to MBL by Kinnetic Laboratories Inc. personnel. The experimental design called for testing only undiluted (100%) stream water. A lab water control (EPA moderately-hard) was run to provide quality assurance data. The lab water results were also used as the comparative data for statistical comparisons.

Based upon previous wet weather test results, we expected many of the runoff samples to produce rapid and complete mortality in Ceriodaphnia tests. After one day of exposure in this test, however, most Ceriodaphnia were still alive, so we did not prepare dilutions of any of the test samples. All species were tested with undiluted runoff samples.

VOL 12

2 1434

Methods

Ceriodaphnia

Test organisms were neonates derived from in-house cultures. Original broodstock was from EPA Duluth, received 11 May, 1988 and cultured in EPA moderately hard water prepared with Milli-Q water. Samples of stream test water were collected daily during the test, and lab control water was EPA moderately hard (Milli-Q).

The test was initiated with 4-8 hour old neonates derived from third broods of individually maintained broodstock. Testing was conducted with 10 individuals per treatment, each in individual plastic cups containing 15 ml of test solution. Test temperature was 25 ± 1°C and photoperiod was 16 hour light:8 hour dark. Test solutions were renewed daily, concurrent with transfers, water quality measurements and assessment of survival and reproduction. At each daily transfer, new media were inoculated with food (2 drops of <u>Ceriodaphnia</u> chow and 1 drop of <u>Selenastrum</u> culture, density approximately 2.5 X 10^6 cells/ml). Following the 7-day test period, survival data was statistically evaluated using the probit method to calculate the 96-hour LC50. Reproductive data was evaluated using ANOVA and Dunnett's Test after con' ing data homogeneity by Bartlett's Test. Test conditions and org. sm data are summarized in Appendix Table A-1.

Fathead Minnow Larvae

Test organisms were larvae, less than 24 hours old, obtained from in-house culture. All larvae were from the same spawning substrate, but probably from multiple spawns. Original broodstock was purchased from Thomas Fish Farms, San Rafael, California, approximately March of 1988. Stream test water samples were collected fresh each day. Control water was EPA moderately hard (Milli-Q). T.. larvae were used in each test container and there were three replicate containers per concentration. Each larval container was fed three times daily with 750-1000 newly-hatched <u>Artemia</u> nauplii. Test temperature was 25 ± 1°C, and photoperiod was 16:8. Daily renewal of 80% of the test volume coincided with daily environmental monitoring and assessment of survival. After seven days of exposure, the test was terminated by addition of formalin to each container. Surviving larvae were dried and weighed, and weight data were statistically evaluated using Bartlett's Test followed by ANOVA and Dunnett's Test. Probit analysis of survival data was used to calculate the 96-hour LC_1. Test conditions and organism data are summarized in appendix Ta'le A-2.

Selenastrum

Algal assays were conducted in sterile 250 ml Erlenmeyer flasks. Preparation of the nutrient medium followed guidelines set forth in EPA-600/9-78-018.

All algal counts were made manually with a hemacytometer and microscope. Treatment groups and controls were set up with a minimum of three replicates. Testing was conducted in an environmental chamber with continuous illumination of 400 ft/candles at 24 ± 2°C for 96 hours. All test flasks were innoculated with approximately 1 X 10^4 cells/ml from a 4 day old stock culture. Cultures were shaken twice daily by hand. Upon conclusion of testing, statistical analyses were made of final cell densities to determine EC50 concentrations using the Probit method. Bartlett's test was used to confirm homogeneity of variance after which Dunnett's test was used.

Results and Conclusions

Ceriodaphnia

Testing was initiated on 28 March, 1989. Reproduction and survival data are summarized in Table 1 and are presented in full in Table 2. Data was statistically analysed using the laboratory water as the comparitive dictum ("control").

Analysis of survival data by Fisher's Exact Test showed that all samples except L-2 and L-7 produced statistically significant mortality when compared with laboratory water controls. Following protocol guidelines, reproduction data for those samples was excluded from subsequent statistical analysis.

Reproduction data for control, L-2 and L-7 samples were found to be normally distributed (Shapiro-Wilkes test) and homogeneous (Bartlett's B = 2.760). Subsequent ANOVA and Dunnett's tests showed that there was significantly decreased young production in sample L-2 when compared with lab water controls. Sample L-7 was not significantly diferent from controls.

Environmental monitoring data are tabulated and presented in Table 3.

Fathead Minnow Larvae

Survival and growth (dry weight) data are summarized in Table 4, and data for individual replicate test containers are presented in Table 5.

Larval weight data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 11.89). Dunnett's analysis was done on the untransformed weight data. Mean larval weight in all samples tested was significantly decreased in comparison with larval weight of laboratory controls. For this data set, the minimum significant difference was 0.145 grams, representing a 17.9% reduction in larval weight from the control.

Environmental monitoring data for fathead minnow larvae are summarized in Table 6.

VOL 12 2 1437

Selenastrum

Growth and environmental monitoring data are summarized in Table 7.

Because of the large number of samples, the test was run in two batches. Run #1 included samples L4, L5, L6 and L7. Run #2 included samples S1,S2,S4,L2,and L3. Each sample set had its own control.

For Run #1, cell number data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 8.941 vs tabled X^2 value at p=0.01 and 4 d.f. = 13.28). There were significantly decreased cell numbers in samples L4, L5, L6 and L7 when compared with growth in lab water controls.

For Run #2, cell number data were normally distributed (Shapiro-Wilkes) but were not homgeneous (Bartletts B = 16.84). Data transformation (square root, log, arcsin) did not correct the non-homogenity. Protocol guidance suggests that Steel's Many-One Rank Test be used to analyze growth data, but Steel's cannot be used when there are less than 4 replicates. Telephone guidance from EPA Cincinnati directed us to transform the data to produce the Bartletts B value closest to the critical number, and use that transformed data set to perform Dunnett's test. Square root transformation produced a Bartlett's B value of 15.58, compared with a critical B at 0.05 with a 5df of 15.09. Dunnett's analysis was done on the square root trasformed data. There was no significant decrease in cell number in samples S1, S2, and L3 when compared with laboratory water controls. There were significantly decreased cell numbers in samples S4 and L2.

Introduction

As part of the Santa Clara Valley Non-Point Source Program, toxicity testing must be carried out on water samples collected during both dry weather (four times) and wet weather (twice). Dry weather tests require daily collection of water samples at the four stream stations (S1-S4). Wet weather tests will be conducted using a single composite sample of runoff water for the daily renewals. This test is the first of four dry weather tests. Three toxicity tests are conducted, utilizing Ceriodaphnia dubia (invertebrate), Pimephales promelas (fish) and Selenastrum capricornutum (plant).

The Ceriodaphnia and Pimephales tests are seven days in duration, and are static-renewal protocols, requiring daily replacement of test solutions with newly-collected test water samples. Daily collections of stream water are made by MBL personnel.

The three bioassays were performed concurrently. Daphnids and fish were run on 13-20 December,1988 while algae were tested on 13-17 December, 1988. Methods, results and data are presented in the following pages.

The samples were collected and delivered to MBL by MBL personnel. The experimental design called testing only undiluted (100%) stream water. A lab water control (EPA moderately-hard) was run to provide quality assurance data. The lab water results were also used as the comparative data for statistical comparisons.

VOL 12 2 1462

Methods

Ceriodaphnia

Test organisms were neonates derived from in-house cultures. Original broodstock was from EPA Duluth, received 11 May, 1988 and cultured in EPA moderately hard water prepared with Milli-Q water. Samples of stream test water were collected daily during the test, and lab control water was EPA moderately hard (Milli-Q).

The test was initiated with 4-8 hour old neonates derived from third broods of individually maintained broodstock. Testing was conducted with 10 individuals per treatment, each in individual plastic cups containing 15 ml of test solution. Test temperature was 25 ± 1°C and photoperiod was 16 hour light:8 hour dark. Test solutions were renewed daily, concurrent with transfers, water quality measurements and assessment of survival and reproduction. At each daily transfer, new media were inoculated with food (2 drops of Ceriodaphnia chow and 1 drop of Selenastrum culture, density approximately 2.5 X 10^6 cells/ml). Following the 7-day test period, survival data was statistically evaluated using the probit method to calculate the 96-hour LC50. Reproductive data was evaluated using ANOVA and Dunnett's Test after confirming data homogeneity by Bartlett's Test. Test conditions and organism data are summarized in Appendix Table A-1.

Fathead Minnow Larvae

Test organisms were larvae, less than 24 hours old, obtained from in-house culture. All larvae were from the same spawning substrate, but probably from multiple spawns. Original broodstock was purchased from Thomas Fish Farms, San Rafael, California, approximately March of 1988. Stream test water samples were collected fresh each day. Control water was EPA moderately hard (Milli-Q). Ten larvae were used in each test container and there were three replicate containers per concentration. Each larval container was fed three times daily with 750-1000 newly-hatched Artemia nauplii. Test temperature was 25 ± 1°C, and photoperiod was 16:8. Daily renewal of 80% of the test volume coincided with daily environmental monitoring and assessment of survival. After seven days of exposure, the test was terminated by addition of formalin to each container. Surviving larvae were dried and weighed, and weight data were statistically evaluated using Bartlett's Test followed by ANOVA and Dunnett's Test. Probit analysis of survival data was used to calculate the 96-hour LC_1. Test conditions and organism data are summarized in appendix Table A-2.

Selenastrum

Algal assays were conducted in sterile 250 ml Erlenmeyer flasks. Preparation of the nutrient medium followed guidelines set forth in EPA-600/9-78-018.

VOL 12

2 1463

All algal counts were made manually with a hemacytometer and microscope. Treatment groups and controls were set up with a minimum of three replicates. Testing was conducted in an environmental chamber with continuous illumination of 400 ft/candles at 24 ± 2°C for 96 hours. All test flasks were innoculated with approximately 1 X 10^4 cells/ml from a 4 day old stock culture. Cultures were shaken twice daily by hand. Upon conclusion of testing, statistical analyses were made of final cell densities to determine EC50 concentrations using the Probit Method. Bartlett's test was used to confirm homogeneity of variance after which Dunnett's test was used.

VOL 12 2 1464

Results and Conclusions

Ceriodaphnia

Reproduction and survival data for *Ceriodaphnia* are summarized in Table 1, and are presented in full in Table 2. Data were statistically analyzed using the laboratory water as the comparative datum ("control").

No stream sample produced ≥ 50% mortality of *Ceriodaphnia* after 96 hours exposure. The 96-hour LC_{50} for *Ceriodaphnia* is >100% for all samples.

Reproduction data were determined to be homogeneous by Bartlett's test, with a B value of 0.5476. Tabled X^2 value for 4 d.f. at p=0.05 was 9.488. ANOVA and Dunnett's test were performed on the untransformed reproduction data. For these data, the minimum significant difference is 8.15 young per adult, representing a 45.3% reduction of mean young production from control levels. There was no significant reduction in young produced between any stream water and the lab water controls.

Environmental monitoring data are tabulated and presented in Table 3.

Fathead Minnow Larvae

Survival and growth (dry weight) data are summarized in Table 4, and data for individual replicate test containers are presented in Table 5.

There was no effluent concentration tested in which survival was less than 83%. The 96-hour LC_{50} values, therefore, are >100% for all samples.

Larval weight data were determined to be homogeneous, with a Bartlett's B value of 4.674. The tabled X^2 value for 4 d.f. at p=0.05 is 9.488. Subsequent ANOVA and Dunnetts analyses were done on the untransformed weight data. There was no significant decrease in mean larval weight in samples S-1, S-2 and S-3 when compared with the weight of dilution water controls. There was significantly decreased larval weight in the S-4 sample.

Environmental monitoring data for fathead minnow larvae are summarized in Table 6.

Selenastrum

Growth and environmental monitoring data are summarized in Table 7.

The lab water growth (cell number) data were set equal to 100% growth, and cell numbers in each stream sample were transformed to

VOL 12

2 1465

percentage of the lab water values. The 96-hour EC_{50} was calculated to be >100% of all stream samples.

Cell number data were homogeneous (Bartletts B = 0.9274 vs tabled X^2 value at p=0.05 and 4 d.f. = 9.488). ANOVA and Dunnetts analyses were done on the untransformed data. There was no signficant decrease in mean cell numbers in any of the stream samples when compared with growth in lab water controls.

All algal counts were made manually with a hemacytometer and microscope. Treatment groups and controls were set up with a minimum of three replicates. Testing was conducted in an environmental chamber with continuous illumination of 400 ft/candles at 24 $\pm$ 2°C for 96 hours. All test flasks were innoculated with approximately 1×10^4 cells/ml from a 4 day old stock culture. Cultures were shaken twice daily by hand. Upon conclusion of testing, statistical analyses were made of final cell densities to determine EC50 concentrations using the Probit Method. Bartlett's test was used to confirm homogeneity of variance after which Dunnett's test was used.

VOL 12

1478

Results and Conclusions

Ceriodaphnia

Reproduction and survival data for *Ceriodaphnia* are summarized in Table 1, and are presented in full in Table 2. Data were statistically analyzed using the laboratory water as the comparative datum ("control").

Analysis of mortality data by Fisher's Exact Test showed that sample S-2 produced statistically significant mortality when compared with laboratory water controls (Fishers b value = 3). Following protocol guidance, reproduction data from S-2 were not included in subsequent statistical analyses.

Reproduction data were found to be not normally distributed (D'Agostino's D value = 0.2397). Critical D values are 0.2655 to 0.2874. Data could not be normalized by any transformation (Square root, log, or arcsin $\sqrt{x}$), and subsequent analysis was done by the non-parametric Steel's Many-One Rank Test. The tabulated critical rank sum value for n=10 and k=4 is 76. Rank sums for S-1, S-3, S-4 and S-5 all exceeded 76, indicating that reproduction in these samples was not significantly lower than in the laboratory control water.

Environmental monitoring data are tabulated and presented in Table 3.

Fathead Minnow Larvae

Survival and growth (dry weight) data are summarized in Table 4, and data for individual replicate test containers are presented in Table 5. There was not enough sample from S-5 to do the fathead minnow bioassay, and only S-1 through S-4 were included.

Larval weight data were determined to be normally distributed (Shpiro-Wilkes test), and homogeneous, with a Bartlett's B value of 0.979. The tabled X^2 value for 4 d.f. at p=0.01 is 13.28. Subsequent ANOVA and Dunnetts analyses were done on the untransformed weight data. There was no significant decrease in mean larval weight in samples S-1, S-2, S-3 and S-4 when compared with the weight of dilution water controls.

Environmental monitoring data for fathead minnow larvae are summarized in Table 6.

Selenastrum

Growth and environmental monitoring data are summarized in Table 7.

Cell number data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 0.9274 vs tabled X^2 value at p=0.01 and 5 d.f.

VOL 12 2 1479

Introduction

As part of the Santa Clara Valley Non-Point Source Program, toxicity testing must be carried out on water samples collected during both dry weather (four times) and wet weather (twice). Dry weather tests require daily collection of water samples at stream stations. Wet weather tests will be conducted using a single composite sample of runoff water for the daily renewals. This test is the second of four dry weather tests. Three toxicity tests are conducted, utilizing Ceriodaphnia dubia (invertebrate), Pimephales promelas (fish) and Selenastrum capricornutum (plant).

The Ceriodaphnia and Pimephales tests are seven days in duration, and are static-renewal protocols, requiring daily replacement of test solutions with newly-collected test water samples. Daily collections of stream water were made only during the first two days of the test period. On the second day it became clear that an unexpected rainstorm was imminent, and the inclusion of storm runoff in our "dry weather" samples was not appropriate in terms of the study objectives. The decision was made, therefore, to collect enough sample on Day 2 (our last dry day) to perform daily renewals for the remainder of the 7-day test period. In summary, water collections were made only on Days 1 and 2 of the test period. Water collected on Day 2 was stored at 4°C for the remainder of the 7-day test period, and daily renewals on days 2-7 were done using this stored water.

The three bioassays were performed concurrently. Daphnids and fish were run on 3-10 February, 1989 while algae were tested on 3-7 February, 1989. Methods, results and data are presented in the following pages.

The samples were collected and delivered to MBL by MBL personnel. The experimental design called testing only undiluted (100%) stream water. A lab water control (EPA moderately-hard) was run to provide quality assurance data. The lab water results were also used as the comparative data for statistical comparisons.

VOL 12 2

1480

VOL 12 2 1481

Methods

Ceriodaphnia

Test organisms were neonates derived from in-house cultures. Original broodstock was from EPA Duluth, received 11 May, 1988 and cultured in EPA moderately hard water prepared with Milli-Q water. Samples of stream test water were collected daily during the test, and lab control water was EPA moderately hard (Milli-Q).

The test was initiated with 4-8 hour old neonates derived from third broods of individually maintained broodstock. Testing was conducted with 10 individuals per treatment, each in individual plastic cups containing 15 ml of test solution. Test temperature was 25 ± 1°C and photoperiod was 16 hour light:8 hour dark. Test solutions were renewed daily, concurrent with transfers, water quality measurements and assessment of survival and reproduction. At each daily transfer, new media were inoculated with food (2 drops of *Ceriodaphnia* chow and 1 drop of *Selenastrum* culture, density approximately 2.5×10^6 cells/ml). Following the 7-day test period, survival data was statistically evaluated using the probit method to calculate the 96-hour LC50. Reproductive data was evaluated using ANOVA and Dunnett's Test after confirming data homogeneity by Bartlett's Test. Test conditions and organism data are summarized in Appendix Table A-1.

Fathead Minnow Larvae

Test organisms were larvae, less than 24 hours old, obtained from in-house culture. All larvae were from the same spawning substrate, but probably from multiple spawns. Original broodstock was purchased from Thomas Fish Farms, San Rafael, California, approximately March of 1988. Stream test water samples were collected fresh each day. Control water was EPA moderately hard (Milli-Q). Ten larvae were used in each test container and there were three replicate containers per concentration. Each larval container was fed three times daily with 750-1000 newly-hatched *Artemia* nauplii. Test temperature was 25 ± 1°C, and photoperiod was 16:8. Daily renewal of 80% of the test volume coincided with daily environmental monitoring and assessment of survival. After seven days of exposure, the test was terminated by addition of formalin to each container. Surviving larvae were dried and weighed, and weight data were statistically evaluated using Bartlett's Test followed by ANOVA and Dunnett's Test. Probit analysis of survival data was used to calculate the 96-hour LC_1. Test conditions and organism data are summarized in appendix Table A-2.

Selenastrum

Algal assays were conducted in sterile 250 ml Erlenmeyer flasks. Preparation of the nutrient medium followed guidelines set forth in EPA-600/9-78-018.

Introduction

As part of the Santa Clara Valley Non-Point Source Program, toxicity testing must be carried out on water samples collected during both dry weather (four times) and wet weather (twice). Dry weather tests require daily collection of water samples at stream stations. Wet weather tests will be conducted using a single composite sample of runoff water for the daily renewals. This test is the third of four dry weather tests. Three toxicity tests are conducted, utilizing *Ceriodaphnia dubia* (invertebrate), *Pimephales promelas* (fish) and *Selenastrum capricornutum* (plant).

The *Ceriodaphnia* and *Pimephales* tests are seven days in duration, and are static-renewal protocols, requiring daily replacement of test solutions with newly-collected test water samples. Daily collections of stream water were made by Kinnetic Laboratories (KLI) personnel.

The three bioassays were performed concurrently. Daphnids and fish were run on 9-16 April, 1989 while algae were tested on 8-12 April, 1989. Methods, results and data are presented in the following pages.

The experimental design called for testing only undiluted (100%) stream water. A lab water control (EPA moderately-hard) was run to provide quality assurance data. The lab water results were also used as the comparative data for statistical comparisons.

VOL 12 2 1497

Methods

Ceriodaphnia

Test organisms were neonates derived from in-house cultures. Original broodstock was from EPA Duluth, received 11 May, 1988 and cultured in EPA moderately hard water prepared with Milli-Q water. Samples of stream test water were collected daily during the test, and lab control water was EPA moderately hard (Milli-Q).

The test was initiated with 4-8 hour old neonates derived from third broods of individually maintained broodstock. Testing was conducted with 10 individuals per treatment, each in individual plastic cups containing 15 ml of test solution. Test temperature was 25 ± 1°C and photoperiod was 16 hour light:8 hour dark. Test solutions were renewed daily, concurrent with transfers, water quality measurements and assessment of survival and reproduction. At each daily transfer, new media were inoculated with food (2 drops of Ceriodaphnia chow and 1 drop of Selenastrum culture, density approximately 2.5 X 10^6 cells/ml). Following the 7-day test period, survival data was statistically evaluated using the probit method to calculate the 96-hour LC50. Reproductive data was evaluated using ANOVA and Dunnett's Test after confirming data homogeneity by Bartlett's Test. Test conditions and organism data are summarized in Appendix Table A-1.

Fathead Minnow Larvae

Test organisms were larvae, less than 24 hours old, obtained from in-house culture. All larvae were from the same spawning substrate, but probably from multiple spawns. Original broodstock was purchased from Thomas Fish Farms, San Rafael, California, approximately March of 1988. Stream test water samples were collected fresh each day. Control water was EPA moderately hard (Milli-Q). Ten larvae were used in each test container and there were three replicate containers per concentration. Each larval container was fed three times daily with 750-1000 newly-hatched Artemia nauplii. Test temperature was 25 ± 1°C, and photoperiod was 16:8. Daily renewal of 80% of the test volume coincided with daily environmental monitoring and assessment of survival. After seven days of exposure, the test was terminated by addition of formalin to each container. Surviving larvae were dried and weighed, and weight data were statistically evaluated using Bartlett's Test followed by ANOVA and Dunnett's Test. Probit analysis of survival data was used to calculate the 96-hour LC_1. Test conditions and organism data are summarized in appendix Table A-2.

Selenastrum

Algal assays were conducted in sterile 250 ml Erlenmeyer flasks. Preparation of the nutrient medium followed guidelines set forth in EPA-600/9-78-018.

All algal counts were made manually with a hemacytometer and microscope. Treatment groups and controls were set up with a minimum of three replicates. Testing was conducted in an environmental chamber with continuous illumination of 400 ft/candles at 24 $\pm$ 2°C for 96 hours. All test flasks were innoculated with approximately 1 X 10^4 cells/ml from a 4 day old stock culture. Cultures were shaken twice daily by hand. Upon conclusion of testing, statistical analyses were made of final cell densities to determine EC50 concentrations using the Probit Method. Bartlett's test was used to confirm homogeneity of variance after which Dunnett's test was used.

Results and Conclusions

Ceriodaphnia

Reproduction and survival data for Ceriodaphnia are summarized in Table 1, and are presented in full in Table 2. Data were statistically analyzed using the laboratory water as the comparative datum ("control").

Analysis of mortality data by Fisher's Exact Test showed that sample S-4 produced statistically significant mortality when compared with laboratory water controls (Fishers b value = 3). Following protocol guidance, reproduction data from S-4 were not included in subsequent statistical analyses.

Reproduction data were found to be normally distributed (D'Agostino's D test) and homogeneous (Bartlett's B = 9.81).

None of the samples produced significantly decreased young production when compared with laboratory water controls.

Environmental monitoring data are tabulated and presented in Table 3.

Fathead Minnow Larvae

Survival and growth (dry weight) data are summarized in Table 4, and data for individual replicate test containers are presented in Table 5. There was not enough sample from S-5 to do the fathead minnow bioassay, and only S-1 through S-4 were included.

Larval weight data were determined to be normally distributed (Shapiro-Wilkes test), and homogeneous, with a Bartlett's B value of 3.85. The tabled X^2 value for 4 d.f. at p=0.01 is 13.28. Subsequent ANOVA and Dunnetts analyses were done on the untransformed weight data. There was no significant decrease in mean larval weight in samples S-1, S-2, and S-4 when compared with the weight of dilution water controls. There was significantly decreased larval weight in sample S-3.

Environmental monitoring data for fathead minnow larvae are summarized in Table 6.

Selenastrum

Growth and environmental monitoring data are summarized in Table 7.

Cell number data were normally distributed (Shapiro-Wilkes) and homogeneous (Bartletts B = 5.86 vs tabled X^2 value at p=0.01 and 4 d.f. = 13.28). ANOVA and Dunnetts analyses were done on the untransformed data. There was no signficant decrease in mean cell numbers in samples S1, S2 and S3 when compared with growth in lab water controls. There were significantly decreased cell numbers in sample S-4.

APPENDIX A

Summary of Test Conditions

TABLE A-1

Ceriodaphnia Bioassay

Test Type:	Static Daily Renewal
Test Endpoints:	Survival, Reproduction
Test Duration:	7 days - 168 hours
Temperature:	25 ± 1°C
Photoperiod:	16 L: 8 D
Start:	9 April, 1989, 11:00 hours
Finish:	16 April, 1989, 11:00 hours
Test Containers:	1 oz plastic cups
Test Volume:	15 ml
Dilution Water:	Not Applicable
Test Material:	Santa Clara Valley NPS - Dry Weather #3
Test Concentrations:	100%, controls
# Replicates:	10
Organisms per replicate:	1
Test Species:	Ceriodaphnia dubia
Source:	in-house culture
Age:	4-8 hours
Acclimation/Culture Water:	EPA Moderately Hard (Milli-Q)
Diet:	Selenastrum, Ceriodaphnia chow

VOL 12

1513

TABLE A-2

Fathead Minnow Bioassay

Test Type:	Static Daily Renewal
Test Endpoints:	Survival, Growth
Test Duration:	7 days - 168 hours
Temperature:	25 ± 1°C
Photoperiod:	16 L: 8 D
Start:	9 April, 1989, 12:00 hours
Finish:	16 April, 1989, 12:00 hours
Test Containers:	1 liter glass jars
Test Volume:	500 ml
Dilution Water:	Not Applicable
Test Material:	Santa Clara Valley NPS - Dry Weather #3
Test Concentrations:	100%, control
# Replicates:	3
Organisms per replicate:	10
Test Species:	*Pimephales promelas* (Fathead minnow)
Source:	in-house culture
Age:	<24 hours
Culture Water:	Dechlorinated Tap
Diet:	*Artemia* nauplii

VOL 12

TABLE A-3

Selenastrum Bioassay

Test Type:	Static
Test Endpoints:	Growth, (cell number)
Test Duration:	4 days, 96 hours
Temperature:	24 ± 2°C
Photoperiod:	Continuous light
Light Intensity:	400 ± 40 FC
Start:	8 April, 1989, 13:00 hours
Finish:	12 April, 1989, 13:00 hours
Test Containers:	250 ml Erlenmeyer flasks
Test Volume:	100 ml
Dilution Water:	Not Applicable
Test Material:	Santa Clara Valley NPS - Dry Weather #3
Test Concentrations:	100%, Control
# Replicates:	3
Organisms per replicate:	10,000/ml innoculated
Test Species:	*Selenastrum capricornutum*
Source:	In-house culture
Age:	4 days
Culture Water:	EPA Moderately Hard

APPENDIX G
POINT SOURCE LOADS

G.1 WASTEWATER TREATMENT PLANT LOADS

Annual loads were estimated for the three Lower South Bay wastewater treatment plants (San Jose/Santa Clara, Sunnyvale, Palo Alto) based on self-monitoring data provided by the Regional Board for 1987 and 1988. The data, shown in Table G-1, give for each year the number of samples, the number of samples below the detection limit, the average concentration, and the load for each plant. The total annual load is then computed in the right-hand column. Loads were estimated using synoptic rather than average flow measurements. The mean annual flows for each treatment plant are also provided at the top of each table.

When the majority of samples are below detection, the estimated load is uncertain and conservative because the concentration was assumed to equal the detection limit, whereas the actual concentration is between zero and the detection limit. Comparisons with nonpoint source loads were made only for those constituents which were consistently measured at levels well above detection limits.

G.2 OTHER POINT SOURCES

There are a number of point source discharges to the area streams, operating under NPDES Permits. These are facilities which pump contaminated groundwater from the aquifer, subject it to treatment to remove contaminants, and then discharge to a stream, often via a storm drain. All of the identified discharges are upstream of the stream

monitoring stations used in the study, and would therefore influence the conditions at the station, primarily during dry weather periods.

As part of their permit requirements, these plants submit regular reports providing information on discharge quantity and quality. For this study, WCC obtained and reviewed these reports for each of the facilities which discharge, covering a substantial portion of 1987. This source was useful in establishing the approximate rate and total volume of discharge by these point sources. There are usually a large number of flow observations reported, and the degree of fluctuation between observations is nominal, so that the average that was computed for use in the load estimates is considered to provide a suitable indicator of the quantity of treated groundwater discharged to the streams.

Characterization of the quality of these discharges is a different matter. The principal constraint imposed by the data in the Permit reports is that the laboratory analyses performed examined only organic compounds (the pollutants of concern at these sites), and, following treatment, all concentrations reported (with isolated occasional exceptions) were below detection levels.

To address this limitation, the RWQCB requested the facilities involved to conduct a special supplementary survey to provide information on heavy metal levels in the discharge. Heavy metals are a normal component of urban runoff and this information would provide a common element to use for comparisons of sources. Results from the single sample analyzed by these special studies were reviewed, and the concentrations observed were combined with the discharge flows from the more comprehensive flow records, to compute estimates of the pollutant loads from the point sources.

These results are summarized by Table G-2. Facilities are organized by stream, and the discharge rate and concentrations of observed pollutants are listed. Copper and zinc are selected for load computations because

they are the only metals that appear to be present often enough to include in a watershed summary. Coyote Creek is a partial exception, in that nickel, rather than copper is present. Zinc appears to be the only heavy metal that is observed in most of the discharges.

The flows are assumed to be uniform throughout the year, and the mass loads computed from the listed flows and concentrations are shown for the wet and dry seasons. These results are presented for each discharge, as is the total for all the discharges upstream of each stream monitoring station. The concentrations shown for the PS total for the watershed are the flow weighted concentrations for the composite point source discharges above each station, which could be compared with the measured concentrations at the station. Chapter 8 of the report discusses the influence of the presence of pollutants from upstream point sources on the projections of loads from watersheds that do not contain such facilities.

ANALYSIS OF UNCERTAINTY IN LOAD ESTIMATES

VOL 12

APPENDIX H
ANALYSIS OF UNCERTAINTY IN LOAD ESTIMATES

The annual nonpoint source load estimates presented in Section 8 were derived from simulated flows and measured concentration data. Because the exact values of flows and concentrations are not known, annual load estimates have some degree of uncertainty associated with them. In this appendix we describe and quantify this uncertainty, so that future decisions and analyses can be based on both the loads estimates and their associated confidence levels.

The sources of uncertainty in loads estimates are summarized and discussed in Section H.1. Section H.2 then presents the procedures used to quantify uncertainty. Section H.3 discusses the results of the quantitative uncertainty analysis in terms of confidence bounds on annual load estimates for the entire valley.

2 1620

H.1 SOURCES OF UNCERTAINTY

For the purposes of this study, annual loads are estimated as the product of annual flow volume and mean concentrations for each land use. Thus, uncertainty in the load arises from (1) uncertainty in the estimate of flow from each watershed and land use, and (2) uncertainty in the estimate of mean concentrations for each land use.

H.1.1 Uncertainty in Flow Estimates

Storm runoff flow volumes were estimated in this study using the rainfall-runoff model SWMM, as described in Appendix B. In watersheds where flow data were available, the model was calibrated to match observed flow volumes. In watersheds where no flow data were available, the model was applied using input data from similar calibrated watersheds. The following factors contribute to uncertainty in flow estimates:

1. Model input parameters are not known exactly,
2. The model itself is an inexact representation of the actual hydrologic processes,
3. The measured flows used in calibration of the model are not exact.

Calibration of the model against observed flows attempts to minimize the first two components of flow uncertainty. However, as described in Appendix B it is not possible to arrive at a perfect calibration for any one watershed. Root Mean Square Errors (RMSEs) in annual load estimates generally ranged from 15 to 25 percent, but were as high as 40 percent in some watersheds. Errors in uncalibrated watersheds would be expected to be higher.

Even if the calibration resulted in a perfect match with observed flows, there would be some uncertainty associated with errors in flow measurements. The magnitude of these errors is currently unknown, but is assumed to be small relative to calibration errors in most watersheds. A possible exception to this is the Guadalupe River, where flow measurements were found to be inconsistent with reservoir release data (see Section 5.3.2 for a detailed discussion).

H.1.2 Uncertainty in the Mean Concentration

The annual mean concentrations for each land use and constituent were estimated from the sampling data collected during the 1987-88 and 1988-89 monitoring periods. The following factors contribute to the uncertainty in the estimated mean concentrations:

VOL 12 2 1622

1. Mean concentrations for each land use were estimated from a finite number of water quality samples (generally less than 25). Statistically, the degree of uncertainty in the mean decreases with large samples sizes, and increases as the sample variance increases. For industrial and open land uses, mean concentrations were estimated based on 5 or fewer samples.

2. Measured concentrations are subject to laboratory and field sampling errors. As discussed in Section C.4, laboratory QA/QC data indicated the data collected in this study are of good and reliable quality. Relative percent differences (RPDs) between field duplicates were on average 29 percent, and ranged from 0 to 100 percent. For laboratory duplicates, relative percent differences were on average 16 percent, and ranged from 0 to 40 percent.

3. Data collected during the 1987-88 and 1988-89 monitoring periods may not be representative of other years with higher rainfall. The monitoring period for this study unfortunately coincided with several years of drought in California. Thus, there is the concern that water quality in wet and normal years might differ significantly from data collected during dry years. As discussed in Section 8.6.4, dry years differ from wet years primarily in terms of the number of storms, not the volume of storms. Data collected during the monitoring period suggest little relationship between runoff volume, storm frequency, and concentration. However, buildup-washoff, water quality modeling results for Calabazas Creek (Appendix B) suggest that water quality is significantly different in wet years such as 1982-83 than in dry years such as the monitoring period. This component of uncertainty cannot be quantified until monitoring data are collected in wet years.

4. Land use concentrations were corrected by loads correction factors to compensate for differences between land use and stream station concentrations. As discussed in Section 8.6.2, the processes that might be explained by these loads correction factors are currently unknown. We

believe that these factors probably account for processes occurring within the stream bed. This component of uncertainty cannot be quantified until more data are collected on stream processes and stream bed water quality.

H.2 PROCEDURES USED TO QUANTIFY UNCERTAINTY

For this analysis, uncertainty is quantified by deriving confidence bounds on annual loads estimates, given the uncertainty in flow and concentration. A first-order, second moment approach is used, assuming that the distribution of load estimates for a given year can be described completely by the mean and variance of the estimates. Alternative methods for uncertainty analysis (e.g., Monte Carlo simulation) can give a more precise evaluation of uncertainty, but generally require more data and computational time than is practical for a modeling study of this scale.

The following sections describe the procedures and equations used in the analysis. Key assumptions include:

- Flow and concentration are assumed to be independent of each other.
- Uncertainty due to differences between water quality during the dry monitoring period and wetter years is not quantified, due to the lack of data. This component of uncertainty should be evaluated when wet-year water quality data are collected.
- Uncertainty due to stream bed processes is not evaluated, again due to lack of quantitative data on the effects of these processes.
- The mean and variance in flow estimates can be quantified using the model calibration errors, expressed as the ratio of observed to predicted annual flow volumes.

VOL 12 2 1623

87

- The distribution of load estimates can be described completely by the mean estimate and the variance in estimates.

- In deriving confidence bounds, the distribution of errors in loads estimates is assumed to be Log Normal.

H.2.1 Uncertainty in Loads from a Single Land Use in a Watershed

The estimate of annual load from a single land use within a watershed is computed from the following model:

$$L_{ij} = Q_{ij}\, C_j \qquad \text{(H-1)}$$

where

L_{ij} = the estimated load for a given year from watershed i, land use j

Q_{ij} = the estimated flow volume from watershed i, land use j

C_j = the estimated mean concentration for land use j

Because Q_{ij} and Cm_j are not precisely known, the expected value (or mean estimate) of L_{ij} is estimated by correcting the estimated flow by the mean calibration error:

$$E[L_{ij}] = E[Q_{ij}]\, E[C_j] = (Q_{ij}\bar{e}_i)C_j \qquad \text{(H-2)}$$

where

E[ ] = expected value (or mean) of [ ]

$\bar{e}_i$ = the mean flow model calibration error for watershed i, expressed as the mean ratio of observed to predicted flows

VOL 12 2 1624

R0054924

The variance of load estimates about this mean has two components. The first component, referred to as the intrinsic variance, accounts for the variability of flow and concentration estimates, assuming that the mean estimates of flow and concentration are known exactly:

$$Var[L_{ij}]_{int} = (Q_{ij}\bar{e}_i)^2 Var[C_j] + \bar{C}_j^2 Var[Q_{ij}] + Var[Q_{ij}] Var[C_j] \qquad (H\text{-}3)$$

where

$$Var[\,] = \text{variance of } [\,] \qquad (H\text{-}4)$$

The variance in C_j is simply the variance in the measured water quality samples for land use j, and accounts for both natural storm to storm variability and variability due to measurement (QA/QC) errors. The variance in Q_{ij} can be derived from the model calibration errors as follows:

$$Var[Q_{ij}] = Q_{ij}^2 \; Var[e_i] \qquad (H\text{-}5)$$

where e_i is the ratio of observed to predicted flows for watershed i.

The second component of the uncertainty in load estimates is the parametric variance. The parametric variance accounts for the fact that the mean estimates of flow and concentration are derived from limited data sets, and are therefore uncertain:

$$Var[L_{ij}]_{par} = Var[\; E[Q_{ij}] \; E[C_j] \;] \qquad (H\text{-}6)$$

$$= (Q_{ij}\bar{e}_i)^2 Var[C_j]/n_c + \bar{C}m_j^2 Q_{ij}^2 Var[e_i]/n_e + Q_{ij}^2 Var[e_i] \; Var[C_j]/(n_e n_c)$$

where

n_c = number of concentration data
n_e = number of years of data used to estimate the mean model error

The total variance in load estimates for a given year is then given by the sum of the intrinsic and parametric variances:

$$Var[L_{ij}] = Var[L_{ij}]_{int} + Var[L_{ij}]_{par} \tag{H-7}$$

H.2.2 Uncertainty in Annual Loads Estimates for the Entire Study Area

The expected value of annual load estimates for the study area in year t is the sum of the mean load estimates for each watershed and land use in year t:

$$E[L_t] = \Sigma_i \Sigma_j E[L_{ij}] \tag{H-8}$$

where
$E[L_t]$ = the expected value of the load estimate for the study area in year t

Similarly, the variance in the estimate of the total annual load is the sum of the variances of load from each watershed and land use:

$$Var[L_t] = \Sigma_i \Sigma_j Var[L_{ij}] \tag{H-9}$$

H.2.3 Uncertainty in the Mean Annual Load Estimate

The mean annual load is the mean of the annual loads for the 12 year simulation period, and is estimated as follows:

$$E[L] = \Sigma_t E[L_t] / n_t \tag{H-10}$$

where

n_t = the number of years in the simulation period

The estimated mean is uncertain due to (1) the limited number of years of data used to estimate E[L], and (2) the parametric uncertainty in the mean estimates of flow and concentration. As a result, the variance in the mean annual load estimate is the sum of the sample variance of annual loads and the parametric variance:

$$Var[\ E[L]\ ] = \Sigma_t[(L_t - E[L])^2/(n_t-1) + Var[L_t]_{par}]/n_t \qquad (H-11)$$

H.2.4 Estimation of Confidence Bounds

The equations given above allow for the estimation of the mean estimate and the variance in estimates for (1) study area loads for any year t, and (2) the mean annual study area load. The next step in the analysis is to derive confidence bounds by assuming a distribution of estimates about the mean estimate. For this study, a log normal distribution of loads estimates was assumed. While there is no direct evidence that load estimates should be log normally distributed, this distribution is commonly observed in environmental data, and has the advantage of being bound by zero. Log normal distributions are described completely by the mean and variance.

H.2.5 Data Used in the Uncertainty Analysis

The uncertainty analysis described above requires (1) estimates of the flow model calibration errors, and (2) estimates of the mean and variance of concentrations for each land use and constituent.

Table H-1 summarizes the mean and variance of the model calibration error ratios (e_i) for each calibrated watershed. These were derived directly as the ratio of observed to predicted annual flow volumes for each calibration period. To quantify error ratios for uncalibrated watersheds, simulation experiments were conducted in which data from one calibrated

Table H-1. SUMMARY OF FLOW CALIBRATION ERROR RATIOS FOR EACH WATERSHED

1628

watershed were used to simulate runoff from a second calibrated watershed. Thus, the second watershed was treated as if it were uncalibrated. For these experiments, Sunnyvale East Channel was simulated using Calabazas Creek model data, and San Tomas Aquinas Creek was simulated using Saratoga Creek data. The resulting error ratios are summarized in Table H-1.

The means and variances of concentrations for each land use were obtained from statistical analysis of the sampling data, as described in Section 6. Table H-2 summarizes these for each land use and constituent.

H.3 RESULTS OF THE UNCERTAINTY ANALYSIS

Results of the uncertainty analysis for total loads from the study area are presented here as confidence bounds about the estimated load. Confidence bounds define the region in which one believes the true estimate of load lies, at a given level of confidence. Thus, 90 percent confidence bounds define the bounds between which one is 90 percent certain that the true value lies. Narrow confidence bounds imply a low level of uncertainty in an estimate, while wide confidence bounds imply high uncertainty.

Table H-3 summarizes the 90 percent confidence bounds for the mean annual total load estimate for each chemical parameter. In general, the 90 percent bounds are about plus or minus 50 to 60 percent away from the mean estimate. The relative widths of the bounds vary little among the different chemical parameters.

Note that these confidence bounds account only for uncertainty in flow estimates and in mecn concentration estimates for land uses. Thev do not account for possible differences in water quality between wet and dry years, nor do they account for possible stream bed processes.

As an example of how this information can be interpreted, the estimated mean annual copper loading is 14,600 lbs. Uncertainty results indicate that we can be 50 percent certain the actual mean annual load is between 11,500 and 17,600 lbs. We can be 90 percent certain the actual mean annual load is between 8400 and 24,000 lbs.

As an indication of how uncertainty varies year to year, Figure H-1 presents the confidence bounds about the estimated annual copper load for each of the twelve simulated years. As would be expected, confidence bounds tend to be wider for individual years than they are for the mean (i.e., we are more certain about the mean of the 12 annual load estimates than we are of any one year's load). 90 percent bounds are about plus or minus 95 percent away from the estimated value.
