Diffuse-pollution problems are ubiquitous, their dimension and origin not well established, often fitting watershed boundaries rather than political ones (Viessman, 1988). By analyzing the problems of diffuse pollution in a regional rather than a local context, it is possible to identify more efficient options that might not be recognized or available otherwise. For example, successes with the regional approach to diffuse pollution management in the Washington, D.C., area demonstrated that gains can be substantial (Viessman and Welty, 1985). Other examples of successful regional water and water quality management organizations include the Florida Water Management Districts,³ the Water Pollution

³The Florida Water Resources Act of 1972 provided for the creation of water management districts. These regional management agencies have broad powers relative to the allocation and use of Florida's waters. In the early days the districts were largely concerned with water quantity issues, water supply, flood control, and drainage. With the passage of time, however, they have moved solidly into the water quality management area. Furthermore, they have taken on an environmentally slanted orientation.

For example, the core mission of the South Florida Water Management District is:

Management Associations in the Ruhr industrial district of Germany (Kneese and Bower, 1968), the Nebraska Natural Resources Districts and British Water Authorities.

These regional organization, which have the broad authority to raise revenues and implement management, would be more efficient than fragmented local and state organizations, which in many cases have limited authority to regulate, but do not have the authority to conduct in-stream water quality management (e.g., wetland restoration or low-flow augmentation) or collect user fees from the beneficiaries of improved water quality. Also discharge permit trading (the bubble approach to pollution discharge permitting) can only be accomplished if a regional watershedwide authority is a "referee" in the trading process and the same authority will make sure that the final discharge loads agreed upon by the polluters do not exceed the waste-assimilative capacity. Subsequently, the agency will continually reissue the permits.

The management of diffuse pollution also requires interagency cooperation and integrated approaches. Programs currently or potentially related to diffuse pollution in coastal areas are carried out by the U.S. Environmental Protection Agency, NOAA, U.S. Department of Agriculture, and many state and local agencies. The Florida Water Management Organizations again provide a good example of how a regional umbrella watershed management organization can cooperate and coordinate these multiagency efforts. Organizational arrangements and responsibilities of the regional water quality management organizations should be incorporated in the planning process (for example, Section 319 planning).

The core mission of the South Florida Water Management District is to manage water and related resources for the benefit of the public and in keeping with the needs of the region for the purpose of providing:

- Environmental protection and Enhancement
- Water Supply
- Flood Protection
- Water quality protection

This is being implemented through the coordination of operations, planning, public involvement, regulation, and construction. Inherent in the mission is the responsibility to assist the public and government officials in growth management by identifying water resource impact of land-use decisions and by advising on options for reducing adverse impacts and protecting water resources.

The water management districts have dealt with a variety of nonpoint pollution problems and in doing so have employed a number of nonconventional approaches, including Save Our River programs, Lake Okeechobee restoration, and the Lake Apopka land swamp proposal (Viessmann, 1988).

Water quality management today is heavily influenced by regulatory measures, all of which come from several directions (the EPA, Department of Interior programs and authorizations, Department of Agriculture, states, etc.). Viessman (1988) correctly pointed out that water management guided by narrowly devised regulatory measures, that is, by regulatory actions that only call for "planning," but do not provide for implementation (such as the planning activities of Section 208 of the Clean Water Act), are destined to be mediocre at best and destructive at worst.

Strategy of Abatement

Generally, mitigation of diffuse pollution from urban and nonurban areas relies on structural and nonstructural measures, or the so-called best management practices. These are well known and have been published in numerous EPA and state manuals, as well as in several chapters of this book. The strategy, however, means selecting the most optimal alternatives under the given legislative and fiscal constraints.

As pointed out in many articles (for example, see Novotny [1988] for a summary), as well as earlier in this chapter, abatement requires regulation and enforcement. As we have also seen, under the current legislative means of enforcement, only those diffuse sources that have been legally classified as "point sources" have a reasonable chance for clean-up. Furthermore, additional mitigation and land protection can be achieved using present or near-future wetland protection laws. This still leaves a large number of sources for which chances of abatement are minimal.

It is evident that the land-disturbing activities (construction, wetland drainage, stream channelization, etc.) during land-use transition are responsible for the highest loads of pollutants. Hence the strategy of mitigation should first focus on their control. However, enforcement is not available or is insufficient.

In established urban lands without significant construction, the NURP study established that there is not much difference between the strength (EMCs) of urban runoff from the major land uses (see Chapter 8). However, since the degree of imperviousness affects the runoff volume, the highest loads can be expected from highly impervious urban lands. Therein, structural facilities, such as detention-retention, followed by treatment, seem the most appropriate. For more pervious areas, typically for low- to medium-intensity residential areas with storm sewers, less structurally intensive measures, such as buffer strips along the streams; floodplain management; retention, storage, and sedimentation in sub-

urban ponds and lakes; and public education to reduce or eliminate (by switching to xeriscape) the use of fertilizers and pesticides on suburban lawns, are appropriate.

In suburban zones that are served by septic tanks and do not have sewers, controls aimed at the reduction of ground-water protection from nitrate contaminations and surface pollution by surfacing septic tank effluents, should be strengthened. Since construction activities yield the highest number of sediments, effective construction erosion-control regulations must be implemented on a national scale.

The best and most efficient results in controlling pollution by urban diffuse sources is achieved if the management is incorporated into the development plans. However, the recent report to the Congress by the General Accounting Office (U.S. GAO, 1990) pointed out that the EPA regulations aimed at the control of pollution by urban runoff are not sufficient. Many areas of the country experiencing the most rapid growth are not included, and by delaying the implementation of storm-water control programs, the U.S. Environmental Protection Agency "is losing a valuable opportunity to prevent stormwater problems rather than rely on expensive structural controls after development has occurred."

In agricultural areas, the programs mandated by the Food Security Act (the Farm Bill) should concentrate on lands and practices that have the most adverse water quality impact, with soil and water conservation as a constraint. Reliance on purely voluntary approaches is ineffective and typically results in very low participation of polluters in the programs.

Epilogue

People can be attracted by new ways of ordering their lives, as well as driven by the recognition of what will happen if they do not change.

Herman Daly and John Cobb (quoted in
State of the World 1990, L. R. Brown)

We began this book with the gloom of threatening environmental problems caused by some forms of diffuse pollution. We would like to end with a more optimistic closure.

In 1992/1993 a two-year experiment was conducted in Arizona. In the experiment eight scientists lived in a hermetically sealed environmental structure called *Biosphere II*. Supposedly the world outside of this structure is Biosphere I. During the experiment living processes generated waste; however, the waste and energy in it were recycled back in the ecological cycle. Essentially, Biosphere II did not generate a substantial net increase of waste.

It was not a precisely scientific experiment and some criticized it as a commercialized, publicity project. Nevertheless, this experiment has brought us to the third millennium. If man is to survive on this planet, a sustainable ecology is a must. Figures 1 and 2 show the contrast between the ecological cycles before the year 2000 and those expected to occur after the year 2000. They show change from the traditional energy-demanding and waste-producing living process to a sustainable low-waste, less energy-demanding ecology. Ecological engineering introduced in the Prologue and Chapter 1 will be a key in achieving this goal.

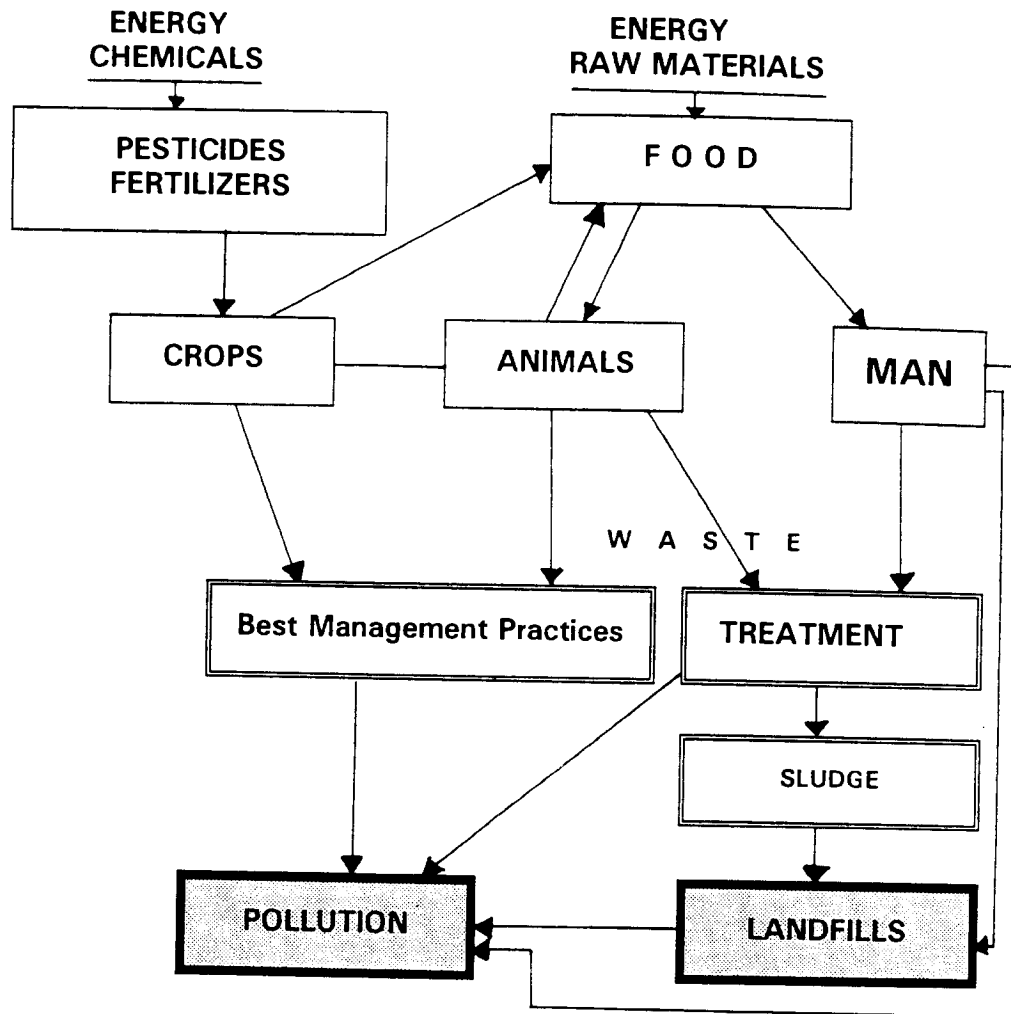

FIGURE 1. Ecological cycles of intensive mass flows of energy, raw materials, and waste, producing high levels of pollution.

Hence, the environmental policies of the third millennium will be different from those of the second millennium, and especially of the second half of the twentieth century. The fact that diffuse pollution is now both global as well as local requires broad international cooperation. With the adoption of the *sustainable development imperative* by the OECD nations, the overall approach to environmental policy is changing. Attention is now being focused on ensuring that all dimensions of environmental problems are considered, including pollution control, resource management, and broad quality of life; on developing more effective institutional arrangements for the formulation and implementation of environmental policies; on promoting technological changes

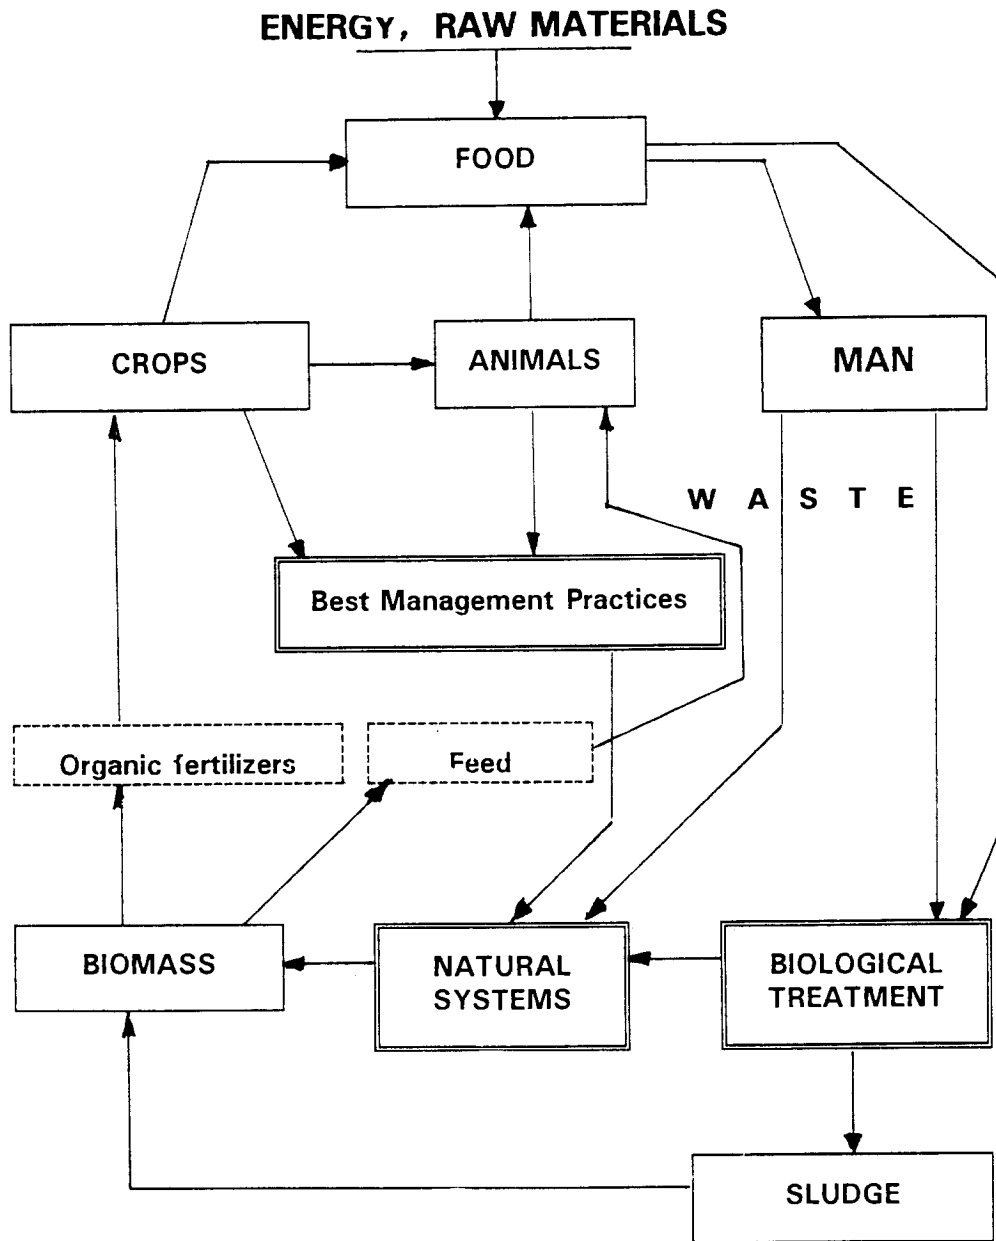

FIGURE 2. Ecological cycle of mass flows of energy, raw materials, and byproducts in a closed-loop sustainable mode with minimum pollution.

toward “clean, green” growth; on using economic instruments to provide market signals for environmental protection that better reflect relative scarcities; on streamlining the regulatory instruments for greater efficiency and cost effectiveness; on modifying production/consumption patterns to maintain a stock of scarce resources and reduce pollution; and on analyzing linkages between the environment and the economy and de-

veloping environmental indicators for measuring environmental performance. Today's and future approaches also emphasize (OECD, 1991):

- Broader objectives for environmental policy based upon the concept of sustainable development, and focus upon resource conservation as well as pollution control
- More effective institutional arrangements for the formulation and implementation of environmental policy
- More use of economic instruments to provide appropriate market signals for environmental protection; and improvements to the efficiency and cost effectiveness of regulatory instruments
- Wider use of anticipatory approaches to the formulation and implementation of environmental policy
- Development of more integrated approaches to environmental controls, both within the environmental sector and between the environmental sector and other sectors of the economy.

As pointed out in the *State of the World 1990* (Brown, 1990), building a more environmentally stable (sustainable) world society requires a vision of it. If the acid rain producing fossil-fuel power plants are to be replaced, then with what? If forests are not to be cleared for intensive agriculture, then where will the food be coming from? If a throwaway culture leads to pollution, then what should replace it? All these activities produce diffuse pollution.

A sustainable society is the one that satisfies its needs without jeopardizing the prospects of future generations. It is becoming increasingly apparent that the future economy cannot be driven by fossil-fueled power plants, heating, and vehicular traffic that can have catastrophic climatic consequences. It has been estimated that to stabilize the climate the per capita fossil-fuel consumption must be cut to about one-eighth of what it was in the late 1980s. If this is achieved, it obviously will also reduce in about the same proportion associated acid rainfall and toxic (mostly diffuse) emissions. Most likely solar, geothermal, and to a lesser degree (safe) nuclear energy sources will replace fossil fuel. Electric automobiles and people movers have already been introduced and successfully tested. Electric trains have long been the dominant means of transportation in many advanced countries (however, note that the production of electricity for electric trains and cars causes acid rain and other forms of diffuse pollution).

Reuse and recycling will replace throwaway waste. Biological and natural treatment systems provide the link between the waste production and reusable biomass. Biomass harvested from buffer strips and lands put into the conservation reserve (wood and hay) can be reused. Similarly,

organic fertilizers and soil conditioners can be produced from the biomass that is harvested from the wetlands and aquaculture systems used for assimilating the waste. Organic fertilizers are less likely to pollute ground-water aquifers and, with proper management, their use will not threaten surface-water resources. In some other ecological waste-disposal systems the produced organic biomass may immobilize and help to decompose residual toxic chemicals that will still be used.

In the third millennium, land could be used in accordance with the rules and laws of sustainability. There should be no loss of wetlands. As a matter of fact, lowlands surrounding bodies of water that have been drained will be restored to their wetland status. High slope eroding lands will be reforested or terraced. Agriculture will rely more on nitrogen-fixing plants and organic fertilizers and less on chemicals.

Farmers could be planting less monoculture crops and will be relying more on crop rotation and soil conservation to maintain soil moisture and to reduce soil loss and pesticide and fertilizer application rates. It is already apparent that farming in arid and semiarid areas, which relies heavily on mining ground-water aquifers, will cease in a few decades. New, less water-demanding crops will replace the thirsty and polluting crops in arid areas. This will result in less discharge of heavily polluted irrigation return flows.

In urban areas, diffuse-pollution-generating urban sprawl should be controlled, and suburbanites in developed countries will consider xeriscape rather than planting environmentally damaging lawns. Diffuse-pollution abatement will be incorporated into the landscape of urban environments, along with the retardance and water-conservation drainage.

As pointed out in this book, the solution of the problem of diffuse pollution is closely tied to political and economic factors. The new political order now emerging will spend less on military and more on environment, less on heavy polluting industries, oil refineries, and vehicular traffic and more on solar energy, recycling, and environmental protection. The *State of the World 1990* concluded that "as the transition to a more environmentally benign economy progresses, sustainability will gradually reclipse growth oriented economy as the focus of economic policy making." As far as the environmental engineering aspects of this change is concerned, the present book has tried to open the door.

APPENDIX B

U.S. EPA Water Quality Criteria for Dissolved Oxygen Concentrations

	Cold-Water Biota		Warm-Water Biota	
	Early Life Stages ^{a,b}	Other Life Stages	Early Life Stages ^b	Other Life Stages
30-day mean	NA ^c	6.5	NA	5.5
7-day mean	9.5 (6.5)	NA	6.0	NA
7-day mean minimum	NA	5.0	NA	4.0
1-day minimum ^d	8.0 (5.0)	4.0	5.0	3.0

^a Recommended water column concentrations to achieve the required intergravel dissolved oxygen concentrations shown in parentheses. The 3-mg/l difference is discussed in the criteria document. The figures in parentheses apply to species that have early life stages exposed directly to the water column.

^b Includes all embryonic and larval stages and all juvenile forms to 30 days following hatching.

^c NA—not applicable.

^d All minima should be considered as instantaneous concentrations to be achieved at all times. Further restrictions apply for highly manipulative discharges.

Criteria for Ammonia

Acute Toxicity Criterion (1 hr average, once in 3 yr exceedence)

$$\text{Criterion (in mg/l)} = \frac{0.52}{2 * FT * FPH}$$

where $FT = 10^{0.03(20 - TCAP)}$ for $TCAP \leq T \leq 30$
and

$$FT = 10^{0.03(20 - T)} \quad \text{for } 0 \leq T \leq TCAP$$

$TCAP = 20^\circ\text{C}$ where salmonids or other sensitive coldwater species are present and 25°C
where salmonids and other sensitive coldwater species are absent

$T =$ water temperature, $^\circ\text{C}$

Chronic Toxicity Criterion (4 day average, once in 3 yr exceedence)

$$\text{Criterion (in mg/l)} = \frac{0.8}{\text{Ratio} * FT * FPH}$$

where FT and FPH are calculated using the same formula as given above. $TCAP$ is determined as follows:

$TCAP = 15^\circ\text{C}$ where salmonids or other sensitive coldwater species are present and 20°C
where salmonids and other coldwater species are absent

$$\text{Ratio} = 16 \quad \text{for } 7.7 \leq \text{pH} \leq 9$$

and

$$\text{Ratio} = \{(24)[10^{(7.7 - \text{pH})}]\} / [1 + 10^{(7.4 - \text{pH})}] \quad \text{for } 6.5 \leq \text{pH} \leq 7.7$$

Key to Rate Summary: 0 = No significant degradation rate. 1 = 0.05 day⁻¹ < k_B < 0.5 day⁻¹; use 0.05 day⁻¹. 2 = k_B > 0.5 day⁻¹; use 0.5 day⁻¹

Notes: Unless noted, data (except K_p data) obtained from U.S. EPA Risk Reduction Engineering Laboratory (RREL), Cincinnati, Ohio, Treatability Database. K_p data obtained from Michael A. Callahan et al., *Water-related Environmental Fate of 129 Priority Pollutants*. EPA-440/4-79-029, 1980. NA = Data not available; IN = Insoluble; LV = little/somewhat volatile; V = moderately volatile; HV = highly volatile; LS = little/somewhat sorbed; S = moderately sorbed; HS = highly sorbed; LB = little/slowly biodegradable; B = moderately biodegradable; HB = highly biodegradable.

^aData obtained from U.S. EPA, *Processes, Coefficients, and Models for Simulating Toxic Organics and Heavy Metals in Surface Waters*. EPA/600/3-87/015, June 1987.

^bNo specific data on V nor B found in the literature.

^cBiodegradation demonstrated in soil samples and acclimated sewage sludge, but uncertain in ambient surface waters.

^dB = information inconclusive.

^eV = unknown.

^fB = unknown.

^gS and B = importance not determined.

^hV = unknown—information contradictory; B = varies with environment.

ⁱV and S = no information.

^jB = only in anaerobic sediments.

^kV = depressed by presence of organic solids; S = strongly adsorbed by solids, especially with high organic content; B = only important for those with fewer than 4 chlorines per molecule.

^lBiomethylation may occur.

^mMetabolized by a number of organisms to organic arsenicals having increased mobility.

ⁿSome copper complexes may be metabolized. Organic ligands are important in sorption and complexation processes.

^oBiomethylation in sediments can remobilize lead.

^pSorption strongest onto organic materials. Can be metabolized by bacteria to methyl and dimethyl forms that are quite mobile.

^qMost mobile of heavy metals.

^rVolatilization via biomethylation or formation of H_2Se . Hydrous metals strongly sorb Se. Metabolism may result in methylation with subsequent volatilization.

^sStrongly sorbed by hydrous Mn and Fe oxides, clay minerals, and organics.

^tAdsorbed to clay minerals and hydrous metal oxides.

^uStrong affinity for hydrous metal oxides, clays, and organic matter. Sorption increases with pH.

^vAt pH ≤ 10 , most free cyanide is HCN, which is quite volatile.

BEWARE THE SEDIMENT SCARE

JONATHAN JONES

Under the Resource Conservation and Recovery Act, sediments that accumulate in storm water may be classified as hazardous waste. Here's what to do to limit the risk.

Your municipal or industrial storm-water facility meets best management practices (BMPs) as outlined by EPA, and is designed to meet requirements under the Clean Water Act and the accompanying National Pollutant Discharge Elimination System (NPDES). So it's protected from hazardous-waste sanctions, right? Maybe not. Because of the breadth and complexity of the Resource Conservation and Recovery Act (RCRA), a number of unusual and perhaps unintended regulatory consequences can arise. For instance, retention ponds, infiltration basins, buried concrete vaults, created wetlands and other facilities not intended to contain or manage hazardous wastes could be characterized or identified as hazardous-waste—treatment, —storage and —disposal facilities.

Under current RCRA regulations, the "mixture" and "derived-from" rules may cause sediments with extremely low concentrations (barely above the detection limit) of certain constituents to be classified as hazardous waste. The problem has been accentuated by EPA's "contained-in" policy, which dictates that any environmental media (such as water, soil and sediment) containing any amount of listed hazardous waste must be handled entirely as a hazardous waste.

In spite of aggressive source-control efforts at municipal and industrial settings, pollutants listed under RCRA (such as from vehicle/equipment maintenance and yard care) will inevitably find their way into BMP facilities. Designers and facility owners must recognize this and plan for it. There are several protective measures to consider:

- Take reasonable steps to reduce the likelihood that listed chemicals under RCRA will come into contact with precipitation or storm water. Educate workers and the public about the problem. Tell them to cover the hazardous materials or place them indoors. The owner of a 3 acre vehicle-

maintenance facility, for example, which receives no runoff from adjoining properties, should be able to implement rigorous source controls with little difficulty. All work on vehicles can occur indoors. Floor drains and sumps can be connected to pretreatment facilities that discharge into the sanitary sewer. Parking areas can be separated from storm-water conveyances by vegetated "filter strips."

- Take inventory of hazardous chemicals on a regular basis and keep track of their use. Encourage the use of replacement compounds that are not listed by RCRA. Formulate, implement and regularly monitor an aggressive spill-control program.

- Consider installing storm-water-pretreatment facilities to localize the problem. For example, try installing a sedimentation basin immediately upstream from a storm-water wetland. Even with a short retention time, a significant fraction of the total sediment load can be removed from the storm water prior to its discharge into the wetland. This not only localizes sediments and the pollutants that adsorb them, but also benefits the receiving water (stream or wetland) and results in decreased long-term maintenance costs.

- Adopt measures to reduce the quantity of sediment that will enter the BMP over time. The smaller the accumulated sediment load, the less frequently it has to be removed. This is of vital importance because RCRA, in most instances, is relevant only when sediments actually need to be removed. Rigorous erosion and sediment-control practices and judicious use of sand during the winter months can make a big difference.

- Evaluate BMP facility design characteristics and implement techniques that will enhance the likelihood of pollutant loss within the BMP. The incorporation of fountains into retention ponds, for example, enhances the volatilization of many volatile and semi-

volatile organic compounds listed by RCRA. However, a permit is required to treat an RCRA hazardous waste, and "treatment" is defined as any method, technique or process—including neutralization—designed to change the chemical, physical, or biological character or composition of a hazardous waste.

- Ensure that facility designers discuss potential problems with regulators and their clients prior to an assignment. Professional liability can be reduced and the owner and engineer can agree, in advance, on mitigation measures. Discussions with regulators are equally important. Designers should cite regulations that force the implementation of storm-water BMPs; delineate the full range of functions that the BMP will fulfill (flood hazard reduction, storm-water quality management and so on); describe structural and nonstructural measures to be taken to reduce the probability that hazardous chemicals will enter the BMP; and suggest a regulatory agreement, in advance, that will address the issue in a reasonable, cost-effective manner if and when the sediments must be removed.

- Design an oversized sediment storage volume in the BMP. Instead of assuming that the BMP should undergo sediment removal once every five to 10 years, assume that sediment removal should occur no more frequently than once every 20–30 years. This will be impractical and excessively expensive in certain instances, but feasible in situations where additional sediment storage can be achieved economically. Recognize that in most instances RCRA actions will not be triggered until sediments need to be removed from the BMP. So every reasonable step should be taken to avoid sediment removal.

- Construct facilities, where practical, that are "off-line" rather than "on-stream." This is certainly not a panacea, but at least the facility sediments will not be located in "wa-

SEDIMENT FOREBAYS AND OTHER DESIGN TECHNIQUES CAN PROTECT FACILITIES FROM RCRA REGULATIONS.

ters of the state or the United States," which could be a complicating factor.

AFTER THE FACT

Sediments in existing BMPs may already contain RCRA-listed chemicals. If that's the case, consider the following steps:

- Conduct additional sampling to confirm the presence of the contaminants. Sample at multiple locations to assure adequate horizontal and vertical coverage. Critically analyze the data collected and determine whether additional actions are required.
- If the drainage area is small, thoroughly search the area for the source of the chemicals that have been detected in the sediments. Once sources are found, check their waste characteristics against the RCRA definition of hazardous waste (40 CFR Part 261) to ensure the wastes are, in fact, RCRA-regulated wastes. A thorough search of this kind is obviously feasible only in smaller drainage basins.
- If the search indicates that RCRA-regulated wastes have mixed with the storm-water facility sediments, take immediate action to ensure that the chemical will not continue to be discharged into the storm-water drainage system. Simply because a chemical or constituent regulated by RCRA is detected in BMP sediments, however, does not

necessarily render the sediment a hazardous waste. If, for example, a spent halogenated solvent listed as hazardous waste is detected in detention pond sediments, those sediments would be hazardous waste under the mixture rule only if the sources of the spent solvent contained more than 10% of that solvent by volume. If no product containing more than 10% of the listed solvent is found, or if contact with precipitation/runoff (including via spills) is unlikely, the pond sediments would not be classified as hazardous waste. The distinction between having one or more discernable point sources of hazardous waste (with suitable characteristics) vs. no clearly defined sources with suitable characteristics is a critical one.

- If a distinct source is not found, convey the information to the regulators. RCRA regulators will be less inclined to control sediments contaminated by diffused sources.
- Note that in many cases, a risk assessment will demonstrate that no practical risk is posed to the public or other life forms by constituent levels within the sediments. This is important information for the regulators because they can exercise some discretion in evaluating regulatory options. If volatile or semivolatile compounds are in the sediments, the risk assessment should

account for the sediment dredging and disposal process, which will cause substantial volatilization and reduce the risk.

- Evaluate modifications to the storm-water facility that may help you avoid excavation of the contaminated sediments. Raising a detention pond outlet structure, for example, increases sediment storage space. Any actions of this kind need to be carefully evaluated, however, because they can have implications related to dam safety, flood attenuation and water-quality performance.

RCRA is undergoing reauthorization and there is a possibility that the updated law may exempt storm-water BMP facilities from RCRA coverage. Early indications, however, are that most RCRA changes will focus only on hazardous-waste definitions. It is prudent to be aware of the potential problem and take steps to limit the risks to BMPs that you design or operate. At times, it may be necessary to confer with qualified legal counsel.

LANDSCAPE ARCHITECTS AND URBAN EROSION CONTROL

Libbe S. Halevy

Where better to address urban runoff than at a project's front end, where landscape architects can control more than runoff.

All too often, landscape architects are the last to be called in to work on urban projects, allowing them little input in siting, master planning, or other tasks for which they have been trained.

Doug Wagner works as the only landscape architect on staff at Precedent Development, a residential subdivision developer in Indianapolis, IN. He's currently involved with Windemere, a 1,100-home site development northeast of Indianapolis in Fisher. "Windemere mixes first home buyers with those looking to buy \$400,000 custom homes," he explains. "Also there's a commercial area with an elaborate community park, two tennis courts, a basketball court, an extensive playground area, and an Olympic-sized swimming pool." Two hundred home sites are currently occupied, another 200 are being actively marketed, and 700 are in the planning and building stages.

In developing an erosion control plan for the site, Wagner works directly with the civil engineers. "They have to submit other plans to municipalities," he says, "so it makes sense to have them design the erosion control plan along with everything else." Wagner looks at what the engineers come up with and makes changes or recommendations to fit company needs. "We need to make certain their plan fits the pattern of what we do because when you submit your erosion control package to the state, you sign that you're going to implement, monitor, and maintain it. That's a long-term commitment for us."

According to Wagner, municipalities are becoming more aware that siltation from developments goes into storm lines. Local governments have started to require developers to flush the dirt and vacuum it out to keep the storm lines open, Wagner says. "It's more cost-effective to do a good job of preventing erosion from the outset rather than coming back and cleaning out the lines before you can get final municipal acceptance."

For Windemere, Precedent Development was turning farmland into home sites and needed to institute a total erosion control plan. Most of the subdivision is flat with a few wooded areas. "Every lot we develop has to have positive drainage," says Wagner. "Typically, water drains from the pad area where the home is built to the side yard, which then drains toward the rear yard of most homes. We place storm inlets in the back of these yards to accept storm runoff."

Once the water gets into the storm inlets, it runs underground through concrete pipes to one of several 0.2 ha to 0.8 ha (0.5-

"It's more cost-effective to do a good job of preventing erosion from the outset rather than coming back and cleaning out the lines"

ac. to 2-ac.) retention ponds. "Retention ponds are required so you have a mechanism for controlling storm runoff. You are not allowed to release stormwater from your site faster than it was being released before you developed it. Because of the streets, roofs, sidewalks, and drives, water runs off your site much quicker than when the land was being farmed, so you have to have a mechanism for holding the water back and releasing it at a calculated rate. That's what the retention ponds do."

While the minimum required depth of any retention pond is 24 m (8 ft.), typically Precedent digs its ponds 3 m to 5.5 m (10 ft. to 18 ft.) deep. "We like to overdig ours so that if there is any silt leaving the lot and being caught in our retention pond, it's not actually leaving the site. But, ultimately, your target is to stop it from getting into the

pond. You want to keep the dirt on-site."

Ultimately water is released from the ponds into legal drains, streams, or rivers. "It's put back into nature, allowed to go back into the watershed that it was meant to run to. It just happens at a slower rate than it would, given the amount of construction that has taken place."

To keep siltation from happening, Precedent is required to put in seeding material from the edge of the curb to the building. "You try to do this as soon as you can after construction," Wagner says. "Usually you wait until after the utilities are installed because otherwise they'll tear it back up." After gas and phone lines are in, Wagner has each lot seeded 4.6 m to 7.6 m (15 ft. to 25 ft.) from the curb into the right-of-way. "That keeps the soil from being washed directly into the street," Wagner explains. "We also seed rear-yard swales that have direct access to backyard inlets."

One of the biggest erosion problems for Precedent has been dirt tracked out onto streets during construction. To control this, Precedent scrapes the streets with front-end loaders and uses its own street cleaners to sweep the streets. "If you don't," Wagner admits, "the municipality gets after you. But we also need to do it because a cleaner site helps with retail marketing of the home."

Other erosion control measures include woven-fabric erosion control fences along the back of curbs to filter solid material before it gets into the drains, and straw-bale dams around backyard inlets. Many of these measures are required by the Indiana Department of Natural Resources. "We are governed by our state," Wagner says. "Indiana has a mechanism for controlling erosion off-site, and its guidelines must be followed. We like to think we follow those guidelines and do more."

Wagner believes that the worst oversight on any residential-subdivision development is failure to maintain erosion control plans. "You need to come back and replace straw bales, and check the beehive

swarm inlets and erosion control fences that protect curb inlets. If you don't, you risk losing valuable topsoil and incurring fines or delays from the local municipality regulators until the problem is solved."

Frequently the landscape architect's creative impulse becomes stifled by a lack of money. "Most people's appetites are bigger than their pocketbooks," says A. Devitt Day, currently chief building official for Hines County, MS. While still in private practice, Day worked on the grounds behind the old state capitol building in Jackson.

"The building sits on a hill 12 m (40 ft.) above the Illinois Central railroad tracks, with a 15% gradient," Day explains. The state wanted the old gravel parking lot on the hill replaced with a hard-surface parking lot and a bus turnaround/loading area, with cement stairs leading all the way down the slope. Erosion already had begun eating away at the slope, and though the state capitol was built on pylons and was not in immediate danger, stabilization of the slope carried a high priority.

"In order to grade the area and get the parking lot on that slope, we had to use just about every erosion control technique we knew to stabilize the slope until we could get substantial ground cover to hold

it in place," Day explains. Work proceeded between intermittent showers, requiring soil-stabilization efforts throughout construction. "We get better than 137 cm (54 in.) of rain a year here," Day states, "and if you don't consider the rain, you lose your soil." He laid down burlap matting held in

"When you submit your erosion control package to the state, you sign that you're going to implement, monitor, and maintain it"

place with uncoated metal pins, materials that could be left in place to biodegrade after the project was completed.

"But in hard rains you still get dirty water coming across the mat, proof that your soil is washing away." Hay bales lined up at the base of the graded area work as filters to hold back the soil. "When the site dries out, we haven't lost any soil and we haven't put any

sediment on anyone else's property."

After construction Day seeds and mulches separately "because we get a better distribution of the seed that way." For mulch, he uses hay mixed with a slight slurry of asphalt, which is then blown onto the slope under several hundred pounds of pressure. "The asphalt makes the hay stick together, and it becomes an additional mat over the seeds," Day explains. "It will hold long enough for the seeds to germinate, at which point the roots begin to hold the slopes."

Urban erosion not only happens in cemented-over cities. Some of it takes place in formerly rural or country areas when urban dwellers, bent on "getting away," take urban problems along with them.

Bob Wentz Park at Windy Point, 80 km (50 mi.) west of Austin, TX has been a popular windsurfing area for more than a decade. But the actual Windy Point launching site for windsurfers was battered by overuse. Traditionally, people pulled their cars up to the edge of the water, trampled grasses, and wore away the topsoil in pursuit of their sport. Unwittingly they were destroying the environment they came to enjoy.

In 1991, Diane Winterowd of Winterowd Associates in Austin, was asked to partici-

The Building Blocks Of A Beautiful Wall.

No Pins. No Mortar. No Problem.

The Anchor Wall pinless, mortarless retaining wall system makes a beautiful difference in your design. With maximum design flexibility and no height limitations, our walls accent the surroundings with warm earthtones and natural textures in maintenance-free, environmentally friendly units. Every segmental block is molded with an integral rear lip or top locator to automatically guide each course, ensuring proper alignment and set back. The best choice for hard to accommodate areas, Anchor Wall is the right fit for your project. You can't beat our system for design adaptability, easy installation and lasting performance. For the Anchor Wall dealer nearest you, call 1-800-473-4452.

JULY/AUGUST 1995

pate in a biorevetment program at Windy Point. "By the time we got started," she says, "ninety-nine percent of the land had been denuded. All we had left was exposed stone, rock, and gravel with a few scruffy old trees near the top." The point itself is not steep, more like a gently sloping rise that manages to stick out of the water. Reconstruction began with three layers of circular terraces a few feet high that went around the point. Winterowd says, "That way we would be able to fill behind them with about 0.6 m (2 ft.) of soil gradually tapering off to the next terrace level, bringing soil back and at the same time creating a way to keep it from sliding back into the lake." The boulders and soil used in the reconstruction came from other construction locations at Windy Point and from an off-site project in similar hilly country.

The new topsoil was seeded with a variety of native grasses and what Winterowd calls "good riparian kinds of trees, such as sycamores, pecan, bald cypress, and Texas ash." As important as the revegetation to the project's success were new restrictions on public access to the site. "People are no longer allowed to drive their vehicles all the way out onto the point," she explains. "We created an area for them to unload their gear, but then they have to park in a nearby lot." The park also imposed a limit to the number of people allowed into the facility.

Winterowd is currently involved in another park project, one that is serving as a bioengineering pilot program for Austin. "A stream running through two parks (Bartholomew and Givens) in Austin has been eroding the banks badly," Winterowd states. "We've lost land and trees to it. The banks are being undercut to less stable gravel layers. As a result, it sloughs off very easily. In other areas there's debris clogging the creek and backing it up, which forces the creek to cut a route for the overflow. This secondary channel may isolate as much as an acre of land from the rest of the park."

Using a bioengineering approach has confronted Winterowd with special problems. "Bioengineering relies a lot on the use of willow and dogwood as pioneer species," she states, "but only one variety of willow and one variety of dogwood are native to the Austin area. Species used successfully in the East and Northeast do not exist in Austin. And while the city receives an average of 86 cm (34 in.) of rainfall a year, it also has long dry periods." Anxious to see if bioengineering techniques are able to cope successfully with the climate, the city still is using the Bartholomew/Givens restoration as a pilot program.

Another problem is that work can only be done on 152 m (500 lineal ft.) at a time.

"It's a permitting situation," Winterowd explains. "For the city, 152 m (500 ft.) is considered a maintenance operation. If we exceed that, it would be considered 'new construction' and we would have to go through the city's whole permitting process. It wouldn't change anything we're doing, but it would slow down the process. This way we get a general permit to do repairs and maintenance on the property, requiring some small level of construction, without having to go through the submittals, staff reviews, and resubmissions."

Even the most creative landscape archi-

tects are called upon to do what Bill Young labels "cookie-cutter work." Young, owner of Restoration Partners in West Palm Beach, FL, decries the lack of imagination usually required by the job. "It's all dictated by standards and regulations," he says. "Frequently developers are out to do the bare minimum, and you find yourself stuck with the situation."

Young worked on the installation of street trees in the Staten Island [NY] Hillside Preservation District, a project tightly controlled by pre-existing statutes and regulations. "The City Planning Department was

The Ultimate Solution for Tough Erosion Control Problems.

NEW

PYRAMAT™ Erosion Matrix

Specify PYRAMAT for:

- ▲ Landfill Caps, Slopes & Diversion Structures
- ▲ Dams, Dike & Levee Protection
- ▲ Bank & Shoreline Stabilization
- ▲ High Flow Channels
- ▲ Geosynthetic Reinforced Earth Structures
- ▲ Slope Facings
- ▲ Veneer Cover Soil Stabilization

PYRAMAT is a tough 3-dimensional woven geotextile with unique up and down cavities. These cells interlock with soil to provide dimensional stability even under the most demanding erosion conditions.

looking to preserve trees both for aesthetic and erosion control purposes, which was a noble idea," he says. But the city had a rigid formula for determining how many trees were "owed" in each location.

"Every tree you saved on a site was worth points determined by its size. For every tree cut down, you owed an equivalent amount of caliper-inches in on-site and street trees. The City Planning Department provided a very limited list of acceptable trees. Your only option was to select which ones were to be installed—a task that did nothing to stimulate innovative design."

Tales from the North Woods

"Not all big-city projects get smothered in institutionalized details," Young concedes. "A good example is the Central Park renewal project," the comprehensive program undertaken by New York City's Central Park Conservancy (CPC), a non-profit organization formed in 1980 to restore and maintain this vital urban wildland. Working in close coordination with the city's Department of Parks and Recreation (DPR), CPC has attracted public involvement, raised significant funds, and overseen the renovation of dozens of sites throughout the park. In 1984, when efforts to restore

the park's woodland areas were mired down in a sea of endless debate, Andropogon Associates, an outside landscape architect firm from Philadelphia, PA, was called in to develop a workable restoration and management plan.

"You can't have 32 million feet pounding the trails without turning the soil to concrete," points out Andropogon's principal, Leslie Sauer, whose task was to provide direction. "We realized we had to tap into the insight, skills, and enthusiasm of the key players—users and caretakers alike—and rely on them to find and implement solutions." Thus, she cast herself in the role of facilitator rather than author of subsequent efforts... an inspired tack as it turned out. "Involvement is crucial," she says. "You want the users doing the restoration, but it's not just a case of getting groups to work together. We wanted to develop a new constituency armed with real scientific information about what's at stake and what the options are."

Faced with such factors as the success of exotic species, the effects of air pollution, and the continuous compaction by traffic of all sorts, all parties could agree that the park would need far more than a gardening approach of simply replanting

native species. Rather, they wanted to restore the conditions under which native species would once more reproduce naturally on their own. "We experimented with control plots before taking any wholesale action on the ground," Sauer says. Accurate records have been maintained to assess the success of their efforts. Even more important, in Sauer's mind, was recognizing the need to substantially upgrade the care of the landscape and to include training for staff and volunteers in the program.

"Controlling erosion is prerequisite to stabilization," Sauer says. "Volunteers are schooled in the use of various techniques including decompacting surface soil, the use of organic erosion blankets, and refilling ravines and rutted trails." But stewardship is more than that. Sauer believes that an active and enthusiastic corps of volunteers is crucial, not just as a productive labor force, but as a conduit to various user communities and the public at large. People who are involved, they have found, are able to pass along their hands-on knowledge to others, in effect multiplying the impact of their program's efforts. EC

LANDSCAPE ARCHITECTS AND URBAN EROSION CONTROL

Libbe S. HaLevy

Where better to address urban runoff than at a project's front end, where landscape architects can control more than runoff.

Too often, landscape architects are the last to be called in to work on urban projects, allowing them little input in siting, master planning, or other tasks for which they have been trained.

Doug Wagner works as the only landscape architect on staff at Precedent Development, a residential subdivision developer in Indianapolis, IN. He's currently involved with Windemere, a 1,100-home site development northeast of Indianapolis in Fisher. "Windemere mixes first home buyers with those looking to buy \$400,000 custom homes," he explains. "Also there's a commercial area with an elaborate community park, two tennis courts, a basketball court, an extensive playground area, and an Olympic-sized swimming pool." Two hundred home sites are currently occupied, another 200 are being actively marketed, and 700 are in the planning and building stages.

In developing an erosion control plan for the site, Wagner works directly with the civil engineers. "They have to submit other plans to municipalities," he says, "so it makes sense to have them design the erosion control plan along with everything else." Wagner looks at what the engineers come up with and makes changes or recommendations to fit company needs. "We need to make certain their plan fits the pattern of what we do because when you submit your erosion control package to the state, you sign that you're going to implement, monitor, and maintain it. That's a long-term commitment for us."

According to Wagner, municipalities are becoming more aware that siltation from developments goes into storm lines. Local governments have started to require developers to flush the dirt and vacuum it out to keep the storm lines open, Wagner says. "It's more cost-effective to do a good job of preventing erosion from the outset rather than coming back and cleaning out the lines before you can get final municipal acceptance."

For Windemere, Precedent Development was turning farmland into home sites and needed to institute a total erosion control plan. Most of the subdivision is flat with a few wooded areas. "Every lot we develop has to have positive drainage," says Wagner. "Typically, water drains from the pad area where the home is built to the side yard, which then drains toward the rear yard of most homes. We place storm inlets in the back of these yards to accept storm runoff."

Once the water gets into the storm inlets, it runs underground through concrete pipes to one of several 0.2 ha to 0.8 ha (0.5-

"It's more cost-effective to do a good job of preventing erosion from the outset rather than coming back and cleaning out the lines"

ac. to 2-ac.) retention ponds. "Retention ponds are required so you have a mechanism for controlling storm runoff. You are not allowed to release stormwater from your site faster than it was being released before you developed it. Because of the streets, roofs, sidewalks, and drives, water runs off your site much quicker than when the land was being farmed, so you have to have a mechanism for holding the water back and releasing it at a calculated rate. That's what the retention ponds do."

While the minimum required depth of any retention pond is 24 m (8 ft.), typically Precedent digs its ponds 3 m to 5.5 m (10 ft. to 18 ft.) deep. "We like to overdig ours so that if there is any silt leaving the lot and being caught in our retention pond, it's not actually leaving the site. But, ultimately, your target is to stop it from getting into the

pond. You want to keep the dirt on-site."

Ultimately water is released from the ponds into legal drains, streams, or rivers. "It's put back into nature, allowed to go back into the watershed that it was meant to run to. It just happens at a slower rate than it would, given the amount of construction that has taken place."

To keep siltation from happening, Precedent is required to put in seeding material from the edge of the curb to the building. "You try to do this as soon as you can after construction," Wagner says. "Usually you wait until after the utilities are installed because otherwise they'll tear it back up." After gas and phone lines are in, Wagner has each lot seeded 4.6 m to 7.6 m (15 ft. to 25 ft.) from the curb into the right-of-way. "That keeps the soil from being washed directly into the street," Wagner explains. "We also seed rear-yard swales that have direct access to backyard inlets."

One of the biggest erosion problems for Precedent has been dirt tracked out onto streets during construction. To control this, Precedent scrapes the streets with front-end loaders and uses its own street cleaners to sweep the streets. "If you don't," Wagner admits, "the municipality gets after you. But we also need to do it because a cleaner site helps with retail marketing of the home."

Other erosion control measures include woven-fabric erosion control fences along the back of curbs to filter solid material before it gets into the drains, and straw-bale dams around backyard inlets. Many of these measures are required by the Indiana Department of Natural Resources. "We are governed by our state," Wagner says. "Indiana has a mechanism for controlling erosion off-site, and its guidelines must be followed. We like to think we follow those guidelines and do more."

Wagner believes that the worst oversight on any residential-subdivision development is failure to maintain erosion control plans. "You need to come back and replace straw bales, and check the beehive

swarm inlets and erosion control fences that protect curb inlets. If you don't, you risk losing valuable topsoil and incurring fines or delays from the local municipality regulators until the problem is solved."

Frequently the landscape architect's creative impulse becomes stifled by a lack of money. "Most people's appetites are bigger than their pocketbooks," says A. Devitt Day, currently chief building official for Hines County, MS. While still in private practice, Day worked on the grounds behind the old state capitol building in Jackson.

"The building sits on a hill 12 m (40 ft.) above the Illinois Central railroad tracks, with a 15% gradient," Day explains. The state wanted the old gravel parking lot on the hill replaced with a hard-surface parking lot and a bus turnaround/loading area, with cement stairs leading all the way down the slope. Erosion already had begun eating away at the slope, and though the state capitol was built on pylons and was not in immediate danger, stabilization of the slope carried a high priority.

"In order to grade the area and get the parking lot on that slope, we had to use just about every erosion control technique we knew to stabilize the slope until we could get substantial ground cover to hold

it in place," Day explains. Work proceeded between intermittent showers, requiring soil-stabilization efforts throughout construction. "We get better than 137 cm (54 in.) of rain a year here," Day states, "and if you don't consider the rain, you lose your soil." He laid down burlap matting held in

"When you submit your erosion control package to the state, you sign that you're going to implement, monitor, and maintain it"

place with uncoated metal pins, materials that could be left in place to biodegrade after the project was completed.

"But in hard rains you still get dirty water coming across the mat, proof that your soil is washing away." Hay bales lined up at the base of the graded area work as filters to hold back the soil. "When the site dries out, we haven't lost any soil and we haven't put any

sediment on anyone else's property.

After construction Day seeds and mulches separately "because we get a better distribution of the seed that way." For mulch, he uses hay mixed with a slight slurry of asphalt, which is then blown onto the slope under several hundred pounds of pressure. "The asphalt makes the hay stick together and it becomes an additional mat over the seeds," Day explains. "It will hold long enough for the seeds to germinate, at which point the roots begin to hold the slopes."

Urban erosion not only happens in cemented-over cities. Some of it takes place in formerly rural or country areas when urban dwellers, bent on "getting away," take urban problems along with them.

Bob Wentz Park at Windy Point, 80 km (50 mi.) west of Austin, TX has been a popular windsurfing area for more than a decade. But the actual Windy Point launching site for windsurfers was battered by overuse. Traditionally, people pulled their cars up to the edge of the water, trampled grasses and wore away the topsoil in pursuit of their sport. Unwittingly they were destroying the environment they came to enjoy.

In 1991, Diane Winterowd of Winterowd Associates in Austin, was asked to partici-

The Building Blocks Of A Beautiful Wall.

No Pins. No Mortar. No Problem.

The Anchor Wall pinless, mortarless retaining wall system makes a beautiful difference in your design. With maximum design flexibility and no height limitations, our walls accent the surroundings with warm earthtones and natural textures in maintenance-free, environmentally friendly units. Every segmental block is molded with an integral rear lip or top locator to automatically guide each course, ensuring proper alignment and set back. The best choice for hard to accommodate areas, Anchor Wall is the right fit for your project. You can't beat our system for design adaptability, easy installation and lasting performance. For the Anchor Wall dealer nearest you, call 1-800-473-4452.

pate in a bioevetment program at Windy Point. "By the time we got started," she says, "ninety-nine percent of the land had been denuded. All we had left was exposed stone, rock, and gravel with a few scruffy old trees near the top." The point itself is not steep, more like a gently sloping rise that manages to stick out of the water. Reconstruction began with three layers of circular terraces a few feet high that went around the point. Winterowd says, "That way we would be able to fill behind them with about 0.6 m (2 ft.) of soil gradually tapering off to the next terrace level, bringing soil back and at the same time creating a way to keep it from sliding back into the lake." The boulders and soil used in the reconstruction came from other construction locations at Windy Point and from an off-site project in similar hilly country.

The new topsoil was seeded with a variety of native grasses and what Winterowd calls "good riparian kinds or trees, such as sycamores, pecan, bald cypress, and Texas ash." As important as the revegetation to the project's success were new restrictions on public access to the site. "People are no longer allowed to drive their vehicles all the way out onto the point," she explains. "We created an area for them to unload their gear, but then they have to park in a nearby lot." The park also imposed a limit to the number of people allowed into the facility.

Winterowd is currently involved in another park project, one that is serving as a bioengineering pilot program for Austin. "A stream running through two parks (Bartholomew and Givens) in Austin has been eroding the banks badly," Winterowd states. "We've lost land and trees to it. The banks are being undercut to less stable gravel layers. As a result, it sloughs off very easily. In other areas there's debris clogging the creek and backing it up, which forces the creek to cut a route for the overflow. This secondary channel may isolate as much as an acre of land from the rest of the park."

Using a bioengineering approach has confronted Winterowd with special problems. "Bioengineering relies a lot on the use of willow and dogwood as pioneer species," she states, "but only one variety of willow and one variety of dogwood are native to the Austin area. Species used successfully in the East and Northeast do not exist in Austin. And while the city receives an average of 86 cm (34 in.) of rainfall a year, it also has long dry periods." Anxious to see if bioengineering techniques are able to cope successfully with the climate, the city still is using the Bartholomew/Givens restoration as a pilot program.

Another problem is that work can only be done on 152 m (500 lineal ft.) at a time.

"It's a permitting situation," Winterowd explains. "For the city, 152 m (500 ft.) is considered a maintenance operation. If we exceed that, it would be considered 'new construction' and we would have to go through the city's whole permitting process. It wouldn't change anything we're doing, but it would slow down the process. This way we get a general permit to do repairs and maintenance on the property, requiring some small level of construction, without having to go through the submittals, staff reviews, and resubmissions."

Even the most creative landscape archi-

tects are called upon to do what Bill Young labels "cookie-cutter work." Young, owner of Restoration Partners in West Palm Beach, FL, decries the lack of imagination usually required by the job. "It's all dictated by standards and regulations," he says. "Frequently developers are out to do the bare minimum, and you find yourself stuck with the situation."

Young worked on the installation of street trees in the Staten Island [NY] Hillside Preservation District, a project tightly controlled by pre-existing statutes and regulations. "The City Planning Department was

The Ultimate Solution for Tough Erosion Control Problems.

NEW

PYRAMAT™ Erosion Matrix

Specify PYRAMAT for:

- ▲ Landfill Caps, Slopes & Diversion Structures
- ▲ Dams, Dike & Levee Protection
- ▲ Bank & Shoreline Stabilization
- ▲ High Flow Channels
- ▲ Geosynthetic Reinforced Earth Structures
- ▲ Slope Facings
- ▲ Veneer Cover Soil Stabilization

PYRAMAT is a tough 3-dimensional woven geotextile with unique up and down cavities. These cells interlock with soil to provide dimensional stability even under the most demanding erosion conditions.

looking to preserve trees both for aesthetic and erosion control purposes, which was a noble idea," he says. But the city had a rigid formula for determining how many trees were "owed" in each location.

"Every tree you saved on a site was worth points determined by its size. For every tree cut down, you owed an equivalent amount of caliper-inches in on-site and street trees. The City Planning Department provided a very limited list of acceptable trees. Your only option was to select which ones were to be installed—a task that did nothing to stimulate innovative design."

Tales from the North Woods

"Not all big-city projects get smothered in institutionalized details," Young concedes. "A good example is the Central Park renewal project," the comprehensive program undertaken by New York City's Central Park Conservancy (CPC), a non-profit organization formed in 1980 to restore and maintain this vital urban wildland. Working in close coordination with the city's Department of Parks and Recreation (DPR), CPC has attracted public involvement, raised significant funds, and overseen the renovation of dozens of sites throughout the park. In 1984, when efforts to restore

the park's woodland areas were mired down in a sea of endless debate, Andropogon Associates, an outside landscape architect firm from Philadelphia, PA, was called in to develop a workable restoration and management plan.

"You can't have 32 million feet pound-ing the trails without turning the soil to concrete," points out Andropogon's principal, Leslie Sauer, whose task was to provide direction. "We realized we had to tap into the insight, skills, and enthusiasm of the key players—users and caretakers alike—and rely on them to find and implement solutions." Thus, she cast herself in the role of facilitator rather than author of subsequent efforts...an inspired tack as it turned out. "Involvement is crucial," she says. "You want the users doing the restoration, but it's not just a case of getting groups to work together. We wanted to develop a new constituency armed with real scientific information about what's at stake and what the options are."

Faced with such factors as the success of exotic species, the effects of air pollution, and the continuous compaction by traffic of all sorts, all parties could agree that the park would need far more than a gardening approach of simply replanting

native species. Rather, they wanted to restore the conditions under which native species would once more reproduce naturally on their own. "We experimented with control plots before taking any wholesale action on the ground," Sauer says. Accurate records have been maintained to assess the success of their efforts. Even more important, in Sauer's mind, was recognizing the need to substantially upgrade the care of the landscape and to include training for staff and volunteers in the program.

"Controlling erosion is prerequisite to stabilization," Sauer says. "Volunteers are schooled in the use of various techniques including decompacting surface soil, the use of organic erosion blankets, and refilling ravines and rutted trails." But stewardship is more than that. Sauer believes that an active and enthusiastic corps of volunteers is crucial, not just as a productive labor force, but as a conduit to various user communities and the public at large. People who are involved, they have found, are able to pass along their hands-on knowledge to others, in effect multiplying the impact of their program's efforts. EC

$$^{\circ}\text{F}=1.8(^{\circ}\text{C})+32.$$

Vertical Datum

Sea Level: In this report, "sea level" refers to the National Geodetic Vertical Datum of 1929—a geodetic datum derived from a general adjustment of the first-order level nets of the United States and Canada, formerly called Sea Level Datum of 1929.

Abbreviations

°C/min	degrees Celsius per minute
dpm	disintegrations per minute (radioisotope activity)
GC-FID	gas chromatography with flame-ionization detection
GC-MS	gas chromatography with mass spectrometric identification
keV	thousand electron volt
M	molar
meq/L	milliequivalents per liter
mBq	millibecquerels
MWL	global meteoric water line
NURP	Nationwide Urban Runoff Program (established in 1978 by U.S. Environmental Protection Agency)
permil	parts per thousand
pCi/L	picocuries per liter
TU	tritium unit (1 tritium atom per 10 ¹⁸ hydrogen-1 atoms [approximately equal to 3.2 picocuries per liter])
µm	micrometer (3.937 × 10 ⁻⁵ in.)

Water-Quality Information

Electrical conductivity is expressed as specific conductance, in microsiemens per centimeter at 25°C (µS/cm).

Trace-element and pesticide concentrations in water samples are given in micrograms per liter (µg/L). One thousand micrograms per liter is equivalent to 1 milligram per liter (mg/L). Micrograms per liter is approximately equivalent to "parts per billion" (ppb). Trace-element concentrations in sediment are given in micrograms per gram (µg/g). Micrograms per gram is equivalent to "parts per million" (ppm). Pesticide concentrations in sediment are given in micrograms per kilogram (µg/kg). One thousand micrograms per kilogram is equivalent to 1 microgram per gram (µg/g). Micrograms per kilogram is equivalent to "parts per billion" (ppb).

Well-Numbering System

Wells are identified and numbered according to their location in the rectangular system for the subdivision of public lands. Identification consists of the township number, north or south; the range number, east or west; and the section number. Each section is divided into sixteen 40-acre tracts lettered consecutively (except I and O), beginning with "A" in the northeast corner of the section and progressing in a sinusoidal manner to "R" in the southeast corner. Within the 40-acre tract, wells are sequentially numbered in the order they are inventoried. The final letter refers to the base line and meridian. In California, there are three base lines and meridians: Humboldt (H), Mount Diablo (M), and San Bernardino (S). All wells in the study area are referenced to the Mount Diablo base line and meridian (M). Well numbers consist of 15 characters and follow the format 014S020E24L001M. In this report, well numbers are abbreviated and written 14S/20E-24L1. Wells in the same township and range are referred to only by their section designation, 24L1. The following diagram shows how the number for well 14S/20E-24L1 is derived.

POTENTIAL FOR CHEMICAL TRANSPORT BENEATH A STORM-RUNOFF RECHARGE (RETENTION) BASIN FOR AN INDUSTRIAL CATCHMENT IN FRESNO, CALIFORNIA

By Roy A. Schroeder

Abstract

A wide variety of chemicals from urban runoff were found at elevated concentrations in sediment that accumulated in a storm-runoff recharge basin in an industrial part of the city of Fresno. The chemicals include as many as 20 inorganic elements and about the same number of organic compounds, primarily organochlorine pesticides and polycyclic aromatic hydrocarbons. Most of these contaminants were found to be sorbed to the upper 4 centimeters of sediment, which also is the maximum depth to which atmospheric lead-210 penetrated. None of the contaminants were detected above background concentrations in the sediment at depths greater than 16 centimeters. In shallow sediment, zinc is the inorganic element that was most enriched; its concentration was 38 times higher in surface sediment (0–1 centimeter) than in deeper strata (below 16 centimeters). Similarly, organic carbon enrichment was nearly 1,000 times higher in the surface sediment.

Although batch-elutriation experiments demonstrated the potential for leaching of contaminants attached to sediments, a sharp decrease in concentrations with increasing sediment depth, and the extremely low level of contaminants in two monitor wells adjacent to the basin, confirmed the absence of contaminant transport to the water table. Continued long-term protection for ground water is afforded by an approximately 8-meter-thick unsaturated zone beneath the basin. Zinc, on the basis of its hundredfold-higher concentration in water from the recharge basin than in ground water, is indicated as the most sensitive surrogate for monitoring possible ground-water degradation by inorganic cations.

Results from this study were compared with previously published results from comprehensive monitoring of urban runoff to the basin during 1981–83. The comparison revealed remarkably similar patterns of chemical contamination, although estimates of sediment quantity delivered to the basin differed by a factor of 1.8. The higher estimate of sediment quantity delivered obtained by this study likely reflects imprecision in the determination of sediment depths and an unusual open texture of the thin veneer that accumulated during the 4-year period the basin had been in existence. A technique using lead-210 is illustrated that could, with adequate data collection, provide estimates of sediment and contaminant quantity delivered to recharge basins without the numerous analyses and sample-collection effort necessary to monitor runoff.

INTRODUCTION

URBAN HYDROLOGY STUDIES

In response to concerns that urban runoff may be a significant nonpoint source of contaminants, the U.S. Environmental Protection Agency (EPA) established the Nationwide Urban Runoff Program (NURP) in 1978 to characterize the quality of urban runoff and to determine the extent to which urban runoff might contribute to impairment of water quality in receiving water bodies (U.S. Environmental Protection Agency, 1983). Studies were done at 28 urban areas throughout the Nation, and the U.S. Geological Survey (USGS) participated in 11 of the studies (Driver and others, 1985). At two study areas—in Fresno, California (Oltmann and Shulters, 1989), and Long Island, New York (Ku and Simmons, 1986)—urban stormwater runoff is routed to constructed retention/recharge basins where it then percolates through the soil and recharges the aquifer.

In the studies at Fresno and Long Island, it was concluded that properties of the soil beneath the basins are highly effective in retaining urban runoff contaminants, although the ability of the soil to continue to retain contaminants was said to be unknown (U.S. Environmental Protection Agency, 1983).

Nightingale (1975; 1987a,b,c; 1989) showed that concentrations of several trace elements and synthetic organic compounds from urban runoff were elevated above background levels in near-surface sediments in recharge basins in residential and commercial parts of the city of Fresno, but that the concentrations decreased rapidly with increasing sediment depth and also generally were very low in interstitial water from the unsaturated zone and in ground water beneath the basins. The study reported here extends these previous investigations to a recharge basin in an industrial catchment where the Fresno NURP study found most contaminant concentrations to be several times higher than in runoff from residential and commercial catchments (Oltmann and Shulters, 1989). This study thereby completes the evaluation of these recharge basins in each of the major urban land-use categories (industrial, commercial, and residential). This investigation included analyses of numerous synthetic organic compounds, a broad suite of more than 40 elements, and some stable and radiogenic isotopes. This study was done by the USGS in cooperation with the Fresno Metropolitan Flood Control District.

PURPOSE AND SCOPE

This report presents the results of a study during 1986-87 whose purpose was to determine whether stormwater runoff to a recharge basin in an industrial part of the city of Fresno has caused, or has the potential to cause, degradation of the ground-water quality. The study included three approaches:

1. Comparison of chemical concentrations in water from the recharge basin to concentrations in water from an aquifer beneath the recharge basin,
2. Determination of chemical-concentration profiles in sediment beneath the recharge basin, and
3. Laboratory elutriation tests in which water was mixed with contaminated basin sediment or clean aquifer soil and reanalyzed.

This study builds on previous results of the Fresno NURP study for which contaminants in urban runoff were monitored during 1981-83. Results of the NURP study were published by Brown and Caldwell Consulting Engineers (1984), Fresno Metropolitan Flood Control District (1987), Nightingale (1987a,b,c; 1989), Nightingale and others (1985), Oltmann and Shulters (1989), and Oltmann and others (1987).

ACKNOWLEDGMENTS

The author thanks Harry Nightingale of the U.S. Department of Agriculture in Fresno and Doug Harrison and Gerald Lakeman of the Fresno Metropolitan Flood Control District for helpful suggestions before and during the study. Removal of water from the recharge basin by the Fresno Metropolitan Flood Control District prior to sampling greatly facilitated the collection of sediment samples.

DESCRIPTION OF THE STUDY AREA

The city of Fresno is about 260 km southeast of San Francisco (about 180 km east of the Pacific coastline at Monterey Bay), in the San Joaquin Valley and between the San Joaquin River to the north and the Kings River to the south (fig. 1). Average annual rainfall in Fresno is about 25 cm, nearly all of which falls between October and April (Page and LeBlanc, 1969). Topographic relief is low with an average gradient of only about 1.6 m/km. Because of the flat terrain and the lack of adequate water courses through the city, almost 100 stormwater retention/recharge basins (hereinafter referred to as "recharge basins") have been constructed to dispose of surface runoff and to recharge an aquifer that has been designated as a sole-source aquifer by the U.S. Environmental Protection Agency. The average size of the basins is 4 to 6 ha, and the average size of the urban catchments served by the basins is about 2.6 km².

The industrial-catchment basin that was the subject of this study is in the southeast part of the Fresno metropolitan area (fig. 1). The area of the catchment is 113 ha, of which 34.2 percent is idle or vacant and 65.8 percent is used for industrial purposes. Impervious surface covers 52.5 percent of the catchment (Oltmann and Shulters, 1989). Industries present in the catchment include cotton mills, food processing, petroleum operations, chemical storage, carpet manufacturing, and light trucking (Brown and Caldwell Consulting Engineers, 1984).

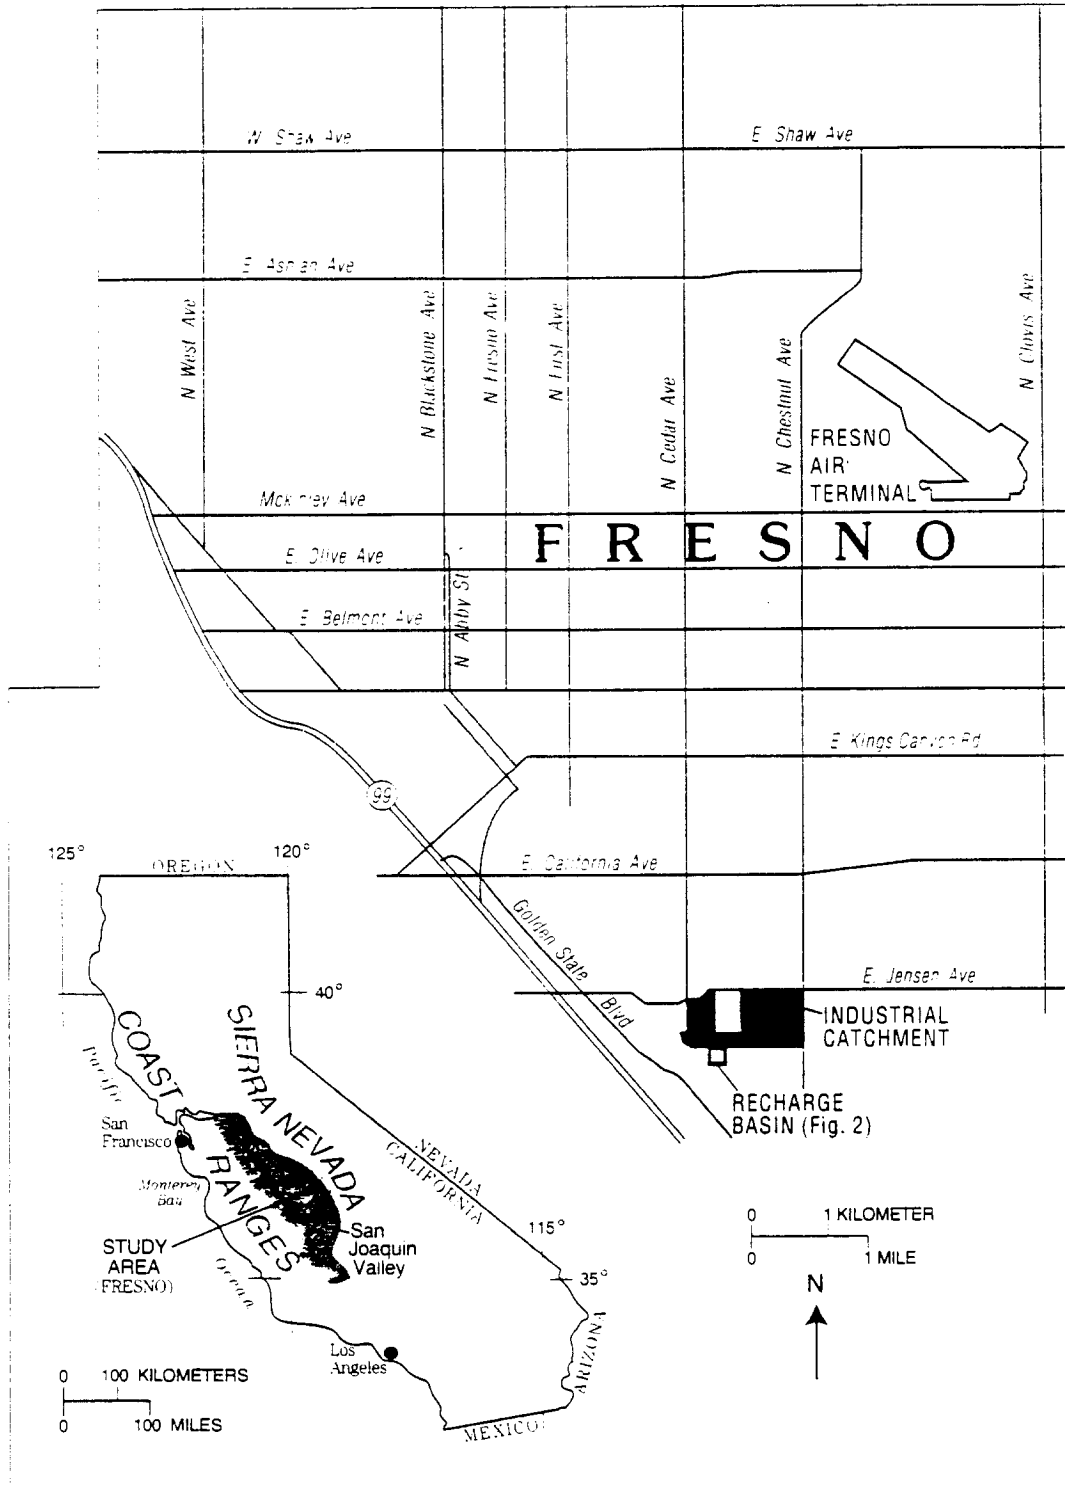

Figure 1. Location of study area.

Runoff is routed to a basin (approximately one-half hectare) on the south side of the catchment. A detailed diagram of the basin and its immediate surroundings as they existed at the time of this study (1986) is shown in figure 2. Prior to this study, the basin was last dredged (scraped) in 1982, when it was deepened and rechannelized to its present form to facilitate sample collection for the NURP study (G.E. Lakeman, Fresno Metropolitan Flood Control District, oral commun., 1992). Although excavation of the basin exposed a highly permeable coarse sand, the very fine texture of muds that soon accumulate on the basin's floor may considerably reduce the effective area through which percolation takes place by restricting it to the sloping sides of the basin at high-water stages. Over a period of time, the structure increasingly functions as an evaporation (retention) pond as opposed to a recharge basin and must be scraped to again expose a more permeable bottom.

Vegetation on the rim of the basin is sparse and the water itself contains algae but no macrophytes. The area surrounding the basin is disked periodically to maintain a generally barren environment so as not to attract wildlife. The basin normally contains water to a depth of a meter or more, even during the dry summer months; however, it was pumped dry in July 1986 to permit subbottom sampling on August 4, 1986.

GEOLOGY, HYDROLOGY, AND GROUND-WATER QUALITY NEAR THE STUDY AREA

A general description of the geology, hydrology, and ground-water quality at the study area is inferred from Page and LeBlanc's (1969) summary for Fresno and its surrounding area. Their summary, in turn, was based on data and interpretations resulting from several regional studies in the Central Valley of California (Lippincott, 1902; Mendenhall and others, 1916; Davis and Poland, 1957; Davis and others, 1959, 1964; Olmsted and Davis, 1961; Meade, 1967; and Croft and Gordon, 1968).

The study area is in the Kings River high alluvial fan geomorphic unit. The water-bearing unconsolidated deposits of this unit (and of the adjacent units)

are underlain by a basement complex of consolidated rocks of pre-Tertiary age. Depth to bedrock at the study area is about 1,200 m. The unconsolidated fine-grained continental deposits of Tertiary and Quaternary age, derived from weathering of crystalline rocks in the Sierra Nevada to the east, are overlain by coarser oxidized granitic alluvium of Quaternary age. Thickness of the alluvium is about 150 m at the study area, where it is capped by a veneer (a few meters thick, or less) of heavily reworked fine-grained soil.

Prior to development of the ground-water resources, the direction of ground-water movement in the Fresno area was toward the southwest; however, pumping has created a permanent cone of depression beneath the city of Fresno that now deflects ground-water movement toward the north in the vicinity of the study area (Mitten, 1984). A hydraulic gradient of 2 m/km toward the west-northwest is inferred at the study site from water-level contours for 1963 and regional maps that show similar conditions prevailing in 1975 (Page, 1975). Although ground water is unconfined on a regional scale, local areas of confinement or partial confinement may exist beneath intercalated clay and silt lenses.

A trend toward higher dissolved-solids concentration, and dominance of sodium and chloride ions, with increasing depth probably exists throughout the Fresno area, particularly in the older, fine-grained continental deposits. The base of the freshwater (defined as water in which ionic concentration is less than 2,000 mg/L in NaCl equivalents) is estimated to be 400 m below sea level (about 500 m below land surface) at the study area. However, nearly all wells in the area penetrate only the younger alluvium, in which the alkaline earths (calcium or magnesium) and bicarbonate are the predominant ions. Ground water from a 65-m-deep (perforated to only 51 m) agricultural production well, 14S/20E-24K1, about 0.4 km east of the study area probably is representative of regional ground-water quality; data from a 1957 analysis of water from this well are reproduced in table 1. Predominant ions are calcium, magnesium, and bicarbonate, and the dissolved-solids concentration of 226 mg/L is equivalent to a specific conductance of about 350 μ S/cm (microsiemens per centimeter).

FIELD AND ANALYTICAL METHODS

SITE SELECTION, WELL INSTALLATION, AND SOIL CORING

Two test holes (fig. 2) were drilled: at latitude 36°41'54"N, longitude 119°44'57"W; and at 36°41'51"N, 119°44'56"W (about 100 m south of the first test hole). The holes were drilled with a 6-inch-diameter (15 cm) hollow-stem auger, and 2-inch-diameter (5 cm) PVC monitor wells, 14S/20E-24L1 and 14S/20E-24L2, were installed in the holes.

As auger flights were pulled up and removed following insertion of the well casing in the hollow stem, the annulus between the walls of the test hole and the casing quickly was filled with a slurry of native material from the saturated zone. During this procedure the casing sank, exposing a much longer perforated interval (6 m) to the saturated zone than was intended (1–2 m). The wet, cohesionless sand (Durnford and others, 1991) below the water table rose several meters above the water table in the annulus. The remaining annulus above this sand was backfilled with a layer of bentonite pellets, then with drill cuttings from the unsaturated zone, and finally with a 1.5-m cement seal to land surface. Altitude of land surface is 86.5 m at well 14S/20E-24L1 (test hole 1) and 85.5 m at well 14S/20E-24L2 (test hole 2). Both monitor wells are perforated (slotted) from

12 to 18 m below land surface. Because the casing sank during installation, the top of the perforated interval was only about 0.6 m above the water table at well 14S/20E-24L1 and was actually about 0.3 m below the water table at well 14S/20E-24L2 when samples for water-quality analysis were collected during summer and autumn 1986.

Both monitor wells are adjacent to the recharge basin (fig. 2) and, on the basis of regional ground-water-flow patterns discussed in the previous section, the first well installed (14S/20E-24L1) is believed to be downgradient of the basin. Irregular topography at this location precluded drilling the first test hole closer than about 50 m from the recharge basin. Flatter terrain to the south permitted drilling of the second test hole within a few meters of the edge of the recharge basin, thereby increasing the probability of intercepting any small ground-water mound should one extend only a short distance beyond the basin area. The second well also decreases the chance that a contaminant plume would be missed if the local hydraulic gradient were toward the southwest (the direction of the regional gradient prior to pumping in Fresno) for any reason, including pumping from any wells near the study area itself (see Mitten and Guay, 1986, for a summary of municipal pumpage and location of wells). Although a monitor well upgradient of the basin would have provided information about the local hydraulic gradient and confirmation that water from the basin is reaching the water table and producing a ground-water mound, this study did not have sufficient resources to install a third well. Installation of lysimeters beneath the recharge basin itself, as in a previous study, would have been especially valuable but was precluded by concern that they would provide a pathway for enhanced transport of contaminants through the unsaturated zone.

Soil cores were recovered from selected depths during drilling of the test holes by lowering a 2-ft (0.6 m), split-spoon steel corer through the hollow drill stem. The depths selected for coring in test hole 1 were based on field observations of change in texture as determined from drill cuttings brought to the surface by the auger and from the drill operator's perception of changes in drilling characteristics. Depths for coring in test hole 2 were chosen to confirm the presence of low-permeability zones found in test hole 1. Particle-size distribution in the core soils was determined using sieves for the sand-size fraction and hydrometers for the fine fraction using methods described by Guy (1969). The data are given in table 2.

Particle-size data were used in conjunction with field observations to compile the lithologic logs given in table 3. Depths were recorded with a precision of 0.03 m during drilling; however, they were measured relative to land surface that was highly irregular because soil excavated to form the recharge basin had been deposited near the test holes. Therefore, accu-

racy of the logs relative to a fixed benchmark probably is no better than 0.3 m.

Although changes in color and texture commonly are gradual and subtle, three distinct zones of silty clay were found and correlated between the test holes: at 7.2-7.3 m, 10.7-10.9 m, and 15.5-15.8 m in test

Table 3. Geologic log for test hole 1 adjacent to the recharge basin

[Rock-color terms are from Goddard and others, 1948. m, meter; mm, millimeter]

Depth (m)	Thickness (m)	Description
0.6	0.6	Fine sand, silt, and clay in about equal proportions, moderate-yellowish-brown (10 YR 5/4). Surface soil heavily reworked and mixed with soil excavated in construction of recharge pond.
2.5	1.9	Sand, fine to coarse, silty, moderate-yellowish-brown (10 YR 5/4) tending to dark-yellowish-orange (10 YR 6/6). Numerous small concrete chips decreasing in abundance with depth, thin (1 mm) calcareous stringers and bands.
5.8	3.3	Sand, fine to coarse, pale-yellowish-brown (10 YR 6/2) with some moderate-yellowish-brown (10 YR 5/4) marbling. Biotite, quartz, and mica grains abundant. Measured 10-percent silt and 90-percent sand. Becoming finer below 5.6 m.
6.2	.4	Silt, fine sand, pale-yellowish-brown (10 YR 6/2) with numerous small (1-3 mm) light-brown (5 YR 5/6) blebs. Measured 70-percent silt.
6.4	.2	Sand, fine to medium, silt, pale-yellowish-brown (10 YR 6/2). Measured 15-percent silt.
7.2	.8	Sand, fine, silty, moderate-yellowish-brown (10 YR 5/4). Measured 30-percent silt.
7.3	.1	Silt, clayey, moderate-yellowish-brown (10 YR 5/4) tending to dark-yellowish-brown (10 YR 4/2). Measured 70-percent silt and 20-percent clay.
10.7	3.4	Fine sand, some silt, color fluctuating between moderate-yellowish-brown (10 YR 5/4) and light-brown (5 YR 5/6) throughout interval. Measured 80-percent fine sand and 10-percent silt.
10.9	.2	Silt, clayey, pale-yellowish-brown (10 YR 6/2) to dark-yellowish-brown (10 YR 4/2). Measured 60-percent silt and 20-percent clay.
13.0	2.1	Sand, fine to medium, with silt and clay, poorly sorted, light-brown (5 YR 5/6) blebs at top of interval blending entirely into moderate-brown (5 YR 4/4) matrix below 11.6 m. Clay and silt decreasing and fine sand increasing slightly with depth. Measured 15-percent clay and 20- to 30-percent silt. Bottom of interval in saturated zone.
15.5	2.5	Sand, fine to coarse, with silt and clay, (slightly coarser than interval above), changing gradually from moderate-yellowish-brown (10 YR 5/4) at top of interval to light-brown (5 YR 5/6) at bottom of interval.
15.9	.4	Sand, silty with greyish clay blebs, moderate-yellowish-brown (10 YR 5/4). Measured 35-percent silt and 15-percent clay.
18.3	2.4	Sand, fine to coarse, becoming coarser with increasing depth, moderate-yellowish-brown (10 YR 5/4) tending to light-brown (5 YR 5/6). Biotite, quartz, and mica grains abundant (similar to 2.5-5.8 m interval). Measured 10-percent silt.

¹Finer, less-permeable zones visually identified during coring.

hole 1; and at 6.4-6.5 m, 9.7-9.8 m, and 14.4-14.6 m in test hole 2 (table 4). Difference in the depth below land surface of these three zones matches closely the difference in land-surface altitude at the test holes. The water table was between the middle and deepest of these zones in each test hole.

SAMPLING OF SEDIMENT FROM THE RECHARGE BASIN

To facilitate sampling of accumulated sediment in the recharge basin, all water was pumped from the basin in mid-July 1986, and the exposed sediment was allowed to dry for about 3 weeks prior to sampling. As the fine-grained sediment covering the floor of the basin dried, shrinkage cracks formed thin polygonal plates. The plates were about 1 cm thick (although actual thickness is somewhat imprecise because the bottom surface of the plates was irregular) and represent the most recently deposited sediment that accumulated in the recharge basin.

Removal of the plates (the 0- to 1-cm depth samples) exposed an unusual geometric surface that bore a striking resemblance to a honeycomb, the individual cells of which were several millimeters across and deep. The sediment was strongly reduced, as indicated by its black color, except for a thin veneer of brown (oxidized) clay rimming the edge of each cell wall. It is suggested that the cells were formed by escape of gas bubbles as the mud was drying. Gas bubbles, accompanied by a small oil sheen, commonly were seen breaking the water's surface when the basin was flooded. This gas is presumed to be hydrogen sulfide, carbon dioxide, methane, and (or) nitrogen generated by microbial activity within the sediments. After the basin's water had been removed, the underlying sediment was exposed to air entering through cracks at the sediment surface, and oxidation produced the thin brown rind on the cells.

The 1-cm-thick surface-sediment plates were removed for analysis from six sites on the basin floor. The basin floor slopes gently downward from the

¹Finer, less-permeable zones visually identified during coring.

northeast corner, where the storm runoff enters the basin, toward the south (fig. 2), therefore, a spatial gradation of increasing fines toward the south was anticipated. The particle-size data from the six sites that are presented in table 5 provide some evidence for such a trend, although the difference in percentage of fine fraction is small. Clay-plus-silt content ranges from 67 percent at sediment-sampling site 2 to 77 percent at site 4; however, clay contents are about 10 percent greater at sites 5 and 6 in comparison with the other four sites. In addition to the 0-1 cm (surface-sediment plate) samples, two successive thin layers, estimated to each be only about 1 mm thick, were scaped from the surface near site 5. Both were found to contain approximately equal proportions of clay and silt and virtually no sand (table 5). Accordingly, the small differences in the percentage of fine fraction between surface samples at the six sites could simply be due to varying proportions from the very thin layer of fine sediment at the surface (top few millimeters) and the coarser sediment immediately below the surface (to a depth of 1 cm).

In addition to surface samples from the five sites, sediment and native soil to a depth of 1.5 m were collected at site 5 in the recharge basin. This site, which seemed to be the deepest part of the basin, was 4.9 m below the top of the cement seal at well 14S/20E-24L1 (test hole 1). Successive layers of sediment were exposed and collected at site 5 by excavating a rectangular pit with a small hand trowel. The pit was "telescoped" inward in a staircase arrangement to eliminate sloughing of overlying sediment as successive layers were uncovered. Excavation continued in this manner to a depth of 64 cm; the deepest sample, from 120 to 150 cm, then was obtained with a manually operated 2-inch-diameter (5 cm) steel auger. Although the color of sediment samples lightened considerably with increasing depth, even the deepest sample had a grayish-tan color indicative of an anaerobic environment.

The particle-size-distribution data (table 5) for the subbottom-deposit samples collected at site 5 show the existence of a shallow zone, from the sediment surface to a depth of 8 cm, in which silt and clay predominate, and a deeper zone, below 16 cm, in which sand predominates (with little silt and clay present). The interval between 8 and 16 cm is a transition zone between the overlying sediment derived from outside the basin, presumably brought in by runoff from the catchment, and the underlying natural alluvium referred to throughout this report as "soils" or "substrata."

On the basis of the difference in altitude between test hole 1 and basin sediment-sampling site 5, one would expect the lithology of the basin deposits immediately below 16 cm to be similar to that of the test hole between 4.9 and 5.5 m. However, minor differences in particle-size distribution and in element concentrations suggest that the basin deposits below 16 cm more closely resemble those from 5.5 to 5.8 m in test hole 1 (for which chemical data exist but particle-size data do not). Specifically, the basin deposits below 16 cm consist predominantly of a fine-to-medium sand, whereas the soil from 4.9 to 5.5 m in test hole 1 consists predominantly of a coarse-to-medium sand (compare data in tables 2 and 5). In addition, comparison of selected element (Fe, Mg, Mn, Th, Ti, and V) concentrations (data given in tables 7 and 9 and discussed in later sections of this report) shows that basin deposits below 16 cm are closer in chemical composition to soils between 5.5 and 5.8 m than to soils between 4.9 and 5.5 m in test hole 1. It should be noted, however, that chemical differences between the two soil samples are small and that the element arsenic presents a pattern opposite to that of the aforementioned six elements.

CHEMICAL ANALYSIS OF WATER, SOIL, AND SEDIMENT

A Teflon bailer with Teflon ball-check valve was used to collect ground-water samples from the two monitor wells installed for this study. Aliquots for analysis of inorganic constituents and nutrients were filtered through a membrane with 0.45- μ m pores. Aliquots for analysis of gross organic indicators (such as methylene blue active detergents, tannin plus lignin, and oil and grease) and specific organic compounds were not filtered. Samples for analysis of organic compounds were stored at temperatures near 0°C and analyzed within a few days of their collection. Samples for analysis of cations and trace elements were stabilized by addition of nitric acid to pH approximately 2 and nutrients were preserved by addition of mercuric chloride and storage at temperatures near 0°C. Samples for trace-element analysis in the low-concentration (sub-ppb) range were acidified with ultrapure nitric acid and stored in Teflon bottles.

Grab samples of water from the recharge basin, and samples from the laboratory elutriation study (discussed in detail later in the "Laboratory Elutriation Experiments" section) were processed and analyzed in a manner similar to that used for the ground-water samples, except that collection and sample-preservation techniques for low-level (sub-ppb) trace-

element samples described above were used for only some of the samples (readily recognized in data tables 6, 12, and 13 by the reporting of significant digits to the tenths microgram-per-liter (sub-ppb) level for several trace elements). Solutions from the elutriation test were centrifuged rather than filtered.

Aqueous chemical constituents were analyzed by the USGS National Water Quality Laboratory in Arvada, Colorado, using methods described by Wershaw and others (1987) and Fishman and Friedman (1989). Tritium initially was analyzed at the University of California, San Diego, and these analyses later were confirmed at the USGS Isotope Laboratory in Reston, Virginia, using a liquid-scintillation counting method. Stable isotopes of hydrogen and oxygen also were analyzed in the Reston laboratory.

Sediment and soil samples for determination of organic constituents were stored in glass jars at temperatures near 0°C until their analysis a few days after collection, or they were frozen for later use in the laboratory elutriation tests. Organic constituents and nutrients were analyzed by the USGS National Water Quality Laboratory using methods described by Wershaw and others (1987) and Fishman and Friedman (1989). Groups of organic compounds that were analyzed include the organochlorines, organophosphorous insecticides, chlorophenoxy-acid herbicides, and extractable priority pollutants. In addition to these specific compounds, extractable nonspecific organic compounds were analyzed by gas chromatography with flame ionization detection (GC-FID).

The GC-FID scans provide only a general indication of organic contaminant concentrations because total concentrations determined by GC-FID amount to only about 1 percent of total organic carbon (analyzed by combustion) in near-surface sediments from the basin. For GC-FID analysis, a 25-g (approximate dry weight) subsample of sediment was extracted with a methanol plus methylene chloride solvent mixture for 12 hours using continuous Soxhlet extraction. The extract then was concentrated using a Kuderna-Danish apparatus. Surrogate compounds were added prior to extraction to check recovery, and perdeuterionaphthalene ($C_{10}D_8$) was added as an internal standard to the extract just prior to GC-FID analysis. Chromatographic separation was done using a 25-m by 0.21-mm SE-54 fused silica capillary column held initially at 50°C for 5 minutes then increased to 300°C at 6°C/min. Concentrations were calculated relative to the response of the internal standard (as " $C_{10}D_8$ equivalents").

For the gas chromatography-electron impact mass spectrometric (GC-MS) analysis of two sediment samples (0-1 cm and 8-16 cm depths) from site 5, approximately 25 g (dry weight) of sediment was processed and chromatographed in the same way as for GC-FID analysis. However, the chromatography column was coupled directly to a mass spectrometer, which was set to analyze from 45-450 atomic mass units with a scan time of 0.25 second. Compound identifications were based on comparison of the gas chromatographic peak retention time and mass spectrum with similar data for standard compounds. In addition to priority pollutants, a computerized library search for nontarget compounds was done. Although many compounds were detected, especially in the surface sample, only a few could even be identified by the compound class to which they belong.

Analysis of soil and sediment samples for element concentrations was done in the USGS Analytical Facility in Denver using methods (Severson and others, 1987) identical to those also used for a multisite reconnaissance of irrigation drainage effects that was done concurrently with this study (see, also, Schroeder and others, 1988, and Arbogast, 1990, for details on analytical methods). The samples were prepared for analysis by drying at about 30°C and grinding to pass an 80-mesh (180 μ m) sieve. Virtually complete mineral digestion was effected with a combination of strong acids. Inductively coupled argon-plasma atomic emission spectrometry (ICP) was used to analyze a broad suite of about 40 elements. Arsenic and selenium were analyzed using hydride-generation atomic absorption. Mercury was analyzed using flameless cold-vapor atomic absorption. Boron was analyzed on a hot-water extract. Uranium and thorium were analyzed using delayed-neutron activation.

Lead-210 (^{210}Pb) and radium-226 (^{226}Ra) were analyzed in 13 sediment samples from the recharge basin and in 2 soil samples from test hole 1. J.K. Cochran, at the State University of New York, Stony Brook, analyzed these samples using a non-destructive gamma-counting technique. About 90 to 150 g dried sediment (or soil) was sealed in 100 cm^3 aluminum cans and stored for 2 weeks to allow gaseous radon-222 (^{222}Rn) to reach decay equilibrium with ^{226}Ra . Gamma emissions were counted on a 1,000 mm^2 , 10-mm-thick, Canberra Electronics planar germanium detector. The 46.5 keV (thousand electron volt) ^{210}Pb peak and the 352 keV ^{214}Pb peak were used to measure ^{210}Pb and ^{226}Ra activity, respectively. Counting time was about 24 hours. Detector efficiencies were determined using laboratory as well as National Bureau of Standards sediment standards.

Corrections for sample self-absorption of gamma rays were made by measuring the attenuation of ^{210}Pb and ^{226}Ra sources placed on the sample cans. Concentrations are reported in disintegrations per minute per gram dry sediment (dpm/g) with precision based on counting statistics.

QUALITY OF RECHARGE-BASIN WATER AND GROUND WATER

The most direct way of determining whether recharge from the study basin has impaired ground-water quality is to measure chemical concentrations in the basin sediment and concentrations in nearby ground water. Nightingale (1975, 1987a,b,c, and 1989) found that several trace elements and synthetic organic compounds were strongly sorbed by soils beneath five recharge basins in residential and commercial parts of the city of Fresno and that their concentrations were low in soil moisture from the unsaturated zone and in ground water immediately below a basin. Accordingly, although contaminant levels in sediment were expected (and found) to be higher at the recharge basin in the commercial catchment that was the subject of this study, little or no effect on ground-water quality was anticipated.

An important consideration in evaluating the potential for ground-water contamination by urban-runoff chemical constituents is establishing whether runoff in the basin actually reaches the water table below the basin in significant amounts. Measurement of soil-moisture content in the unsaturated zone and installation of several monitor wells to determine the local hydraulic gradient would provide direct evidence of recharge but were beyond the resources available for this study. Nevertheless, water-budget calculations indicate that the potential for substantial recharge exists. On the basis of mean annual rainfall of 26 cm, measured rainfall-runoff coefficient, soil-water capacity, and physical dimensions of the catchment and recharge basin (Oltmann and Schulters, 1989), mean annual runoff should be sufficient to saturate soil above the water table for a distance of about 100 m beyond the basin's boundaries. Of course, this simplified calculation assumes symmetrical spreading beneath the recharge basin. On the basis of saturated hydraulic conductivities calculated from measured soil characteristics, Nightingale (1989) concluded that subsurface silt and clay strata (lenses) would cause lateral movement of water beneath a Fresno recharge basin that had a measured infiltration rate of 16 cm/d (almost 60 m/yr). If the soil deposits in the recharge area above the lenses are assumed to be isotropic and

homogeneous and the recharge rate is constant, then the radius of the area infiltrated must vary inversely with the square root of vertical hydraulic conductivity (Freeze and Cherry, 1979, p. 16). On the basis of this relation and the inferred variation in hydraulic conductivities (Nightingale, 1989), the water would be expected to spread laterally a distance of about three times the basin's diameter. The likelihood that recharge reaches the water table directly beneath and near (as opposed to some great distance from) the basin is inferred on the basis of arguments given above, along with the absence of significant lithologic discontinuities at the test holes.

Additional evidence that ground water at the water table has mixed with a substantial volume of water from the recharge basin was obtained from analysis of tritium and the stable isotopes of hydrogen and oxygen.

ISOTOPIC EVIDENCE FOR RECHARGE

Tritium, the radioactive isotope of hydrogen having a half-life of 12.43 years, is produced naturally by cosmic-ray interactions with the upper atmosphere. Atmospheric detonation of thermonuclear weapons produced large quantities of tritium with the result that tritium concentrations in precipitation began increasing above natural levels about 1950, reaching a peak that was 10^2 - 10^3 times natural levels in the mid-1960's, and then gradually declining following the international treaty that banned atmospheric testing by the major nuclear powers. Tritium in precipitation today remains several times higher than natural levels. It is this bomb-produced tritium transient that can be used to distinguish post-1950 water from older water.

On the basis of nationwide maps of tritium deposition (Michel, 1989), it is estimated that average annual tritium concentration in precipitation at the city of Fresno was slightly greater than 10 TU (tritium units) at the time of this study. (One tritium unit is one tritium atom per 10^{18} hydrogen-1 atoms and equals approximately 3.2 picocuries per liter.) On the basis of physical properties of the aquifer (Williamson and others, 1989, and Hugh Mitten, USGS, written commun., 1986), it is concluded that regional ground water in the city of Fresno that originates as recharge in the Sierra Nevada foothills is unlikely to contain any tritium. The measured tritium concentration of 10.2 TU in the recharge basin (table 6) is close to the estimated tritium concentration in local precipitation. It is presumed that the

basin contains a mixture of ground water used by industries in the catchment area and not discharged to a municipal treatment plant in addition to precipitation runoff, and that it is the precipitation runoff that was the principal source of tritium in the sample from the recharge basin collected January 29, 1986.

Tritium concentrations of about 6 TU in both monitor wells (table 6) seem to indicate significant recharge from the basin. However, the evidence is compromised by the recent finding of tritium in many wells throughout the San Joaquin Valley, including 46 TU in well 14S/20E-34G1, a 124-foot well about 3 km southwest of the study site (Shelton and Miller, 1991). Recharge by extensive irrigation with surface water likely is the source of tritium in ground water throughout the San Joaquin Valley; in the city of Fresno, artificial recharge also is a potential source of tritium.

Stable-isotope ratios of hydrogen (²H/¹H or D/H) and oxygen (¹⁸O/¹⁶O) also can be used to infer

recharge and possibly to place constraints on the timing of such recharge from the basin. Both isotope ratios are expressed here as permil in the commonly used δ (delta) notation relative to the Vienna-Standard Mean Ocean Water (V-SMOW) standard. The general relation between hydrogen- and oxygen-isotope ratios in precipitation is shown by the global meteoric-water line (MWL) in figure 3 (Craig, 1961). This line has a slope of 8, and the isotopic composition of waters that have undergone evaporation typically fall to the right of this line; that is, they are enriched in ¹⁸O relative to deuterium. This deviation from the MWL, as well as relatively high values of δD and δ¹⁸O, indicates that water in the recharge basin at the time of sampling for stable isotopes on July 11, 1986, was highly evaporated.

The hydrogen-isotope ratio of precipitation in the city of Fresno can be inferred, from regional-scale data along an east-west traverse between the Pacific Coast and Nevada, to be about -80 permil (Ingraham and Taylor, 1991). Ground water from most wells in

Figure 3. Relation between hydrogen and oxygen stable-isotope ratios in recharge-basin water and nearby ground water.

the vicinity of the city of Fresno has a δD slightly less than -90 permil. Even the isotopic composition of water from well 14S/20E-34G1 (alluded to in the earlier discussion on tritium), at $\delta D = -91.5$ permil and $\delta^{18}O = -12.3$ permil, does not differ greatly from the composition expected for ground water free of local recharge by surface water or irrigation—apparently because the local recharge has not undergone substantial evaporation. As can be seen in figure 3 (dashed lines), there is no way the isotopic composition measured in the two monitor wells can be obtained by mixing regional ground water or local precipitation with recharge-basin water in varying proportions. On the basis of this departure from a simple two-member mixing model, it is concluded that one or more of the following conditions are necessary to explain the isotopic composition found in the monitor wells:

1. The δD of precipitation may have been higher (less negative) at the time of this study than the inferred estimate of -80 permil.
2. The D and ^{18}O contents of regional ground water at the study site may be higher than represented by well 14S/20E-34G1. D and ^{18}O contents are reported to be higher in some wells several kilometers from the study area (Shelton and Miller, 1991).
3. Recharge in the basin might be occurring during periods when the basin's water has undergone less evaporation, such as during the winter; as a result, 1H and ^{16}O concentrations

ordinarily would be considerably higher (2H and ^{18}O would be lower) than during summer when the basin was sampled. It is reasonable that recharge should be much greater following winter storms when the basin was observed by the author to be fuller than during the dry summer season when it contains less water.

Although the relative importance of each of the above explanations cannot be evaluated without frequent monitoring over a period of time, the fact that δD and $\delta^{18}O$ values in the monitor wells generally are less negative than in other wells in the Fresno area argues strongly that recharge from the basin is reaching the water table locally.

The stable-isotope data, together with the tritium data, suggest that basin recharge is comparable in importance at the study site to regional ground-water flow from the Sierra Nevada foothills, so that any storm-runoff contaminants not effectively removed by the soil beneath the basin should be easily detectable by means of shallow monitor wells such as those that were installed for this study. Nevertheless, the sparse isotope data presented do not support quantitatively apportioning ground water at the monitor wells between regional flow and basin recharge. Apart from the limitations discussed above, seasonal and annual isotope variations in precipitation are likely to be quite large. For example, mean annual tritium concentration in precipitation during 1980-81 is nearly double that of the near-record wet period of 1982-83 (Michel, 1989). Also, mean annual δD in precipitation was found to vary as much as 40 permil between 1981 and 1989 at some sites in a monitoring network that included 32 locations in southeastern California and adjacent parts of Nevada and Arizona (Friedman and others, 1992).

MAJOR IONS AND TRACE ELEMENTS

Comparison between water samples from the recharge basin and the monitor wells (table 6), and comparison of both with regional ground-water composition listed in table 1, reveals little difference in such broad measures of water quality as dissolved-solids concentration and specific conductance. For chloride, which is an ideal unreactive tracer (as are isotopes), differences are larger but still too small to be useful. Although differences are large for silica and bicarbonate (alkalinity), precipitation and dissolution reactions make both unsuitable as tracers. Of the major ions, potassium (K) is the most useful indicator of whether cationic contaminants in the re-

charge basin reach the water table. Aqueous potassium concentrations are about 5 times higher in the recharge basin than in either regional ground water (table 1) or the nearby monitor wells (table 6)—indicating that there is no discernible transport of this cation to the water table. Profiles of dissolved- and exchangeable-cation concentrations beneath a recharge basin in the city of Fresno show that removal of dissolved potassium in percolating recharge water occurs through ion-exchange reactions with clay minerals in the soil (Nightingale, 1989).

Zinc is potentially an even more sensitive surrogate than is potassium, as the concentration of zinc is more than 100 times higher in the recharge basin than in the monitor wells (table 6). Motor vehicles, and especially motor oil, have been implicated as the major source of zinc in the urban environment (Wigington and others, 1983). The reason for such a large enrichment (comparative concentration ratio) for aqueous zinc in the recharge basin is unknown; however, it may be related partly to its role as a biological micronutrient and partly to its greater solubility than other heavy metals with large anthropogenic inputs (Harter, 1983; Wigington and others, 1983). (These same reasons can be used to explain the high concentrations of potassium.) In any case, because the available data show that trace metals in urban runoff have not affected ground-water quality at this site, monitoring for zinc would be very effective in demonstrating continued absence of impairment by trace-metal cations.

ORGANIC PRIORITY POLLUTANTS AND PESTICIDES

Water from the recharge basin and from monitor wells was analyzed for three gross organic indicators: tannin and lignin, total phenols, and methylene blue active surfactant (MBAS) detergents. All were reported present in the recharge basin and some also were detected in the monitor wells (table 6). However, the baseline for colorimetric detection of these analytes in dissimilar waters is likely to be variable and is sufficiently uncertain that their reported detection at very low levels in the monitor-well samples is not conclusive evidence for their actual presence (that is, the levels detected likely represent "false positives").

Several groups of synthetic organic chemicals also were analyzed: purgeable and extractable priority pollutants, organochlorine compounds, and organophosphorous insecticides. Only a few were found and, because their reported aqueous concentrations were at

the laboratory reporting limit, their presence should not be inferred without further sampling.

Organic (and trace-metal) concentrations generally are much higher in sediments than in water and, for this reason, the sediment (soils) data presented in the next section of this report provide a much more sensitive indicator of organic contaminant migration than do the aqueous-phase data.

CHEMICAL CONCENTRATIONS IN SEDIMENT AND SOIL

Chemical analysis of sediment beneath the recharge basin and of soil from test holes provides this study with the strongest evidence that sorption by the solid phase is a very effective mechanism for removal of inorganic and organic contaminants, and that only a very small fraction of the available capacity for removal is used after a few years. Results of these analyses are presented in tables 7 to 10, and in table 14 (results reported in table 14 are discussed later, in the "Laboratory Elutriation Experiments" section). The results given in these tables indicate marked attenuation in concentration of numerous elements and synthetic organic chemicals within the top few centimeters beneath the recharge basin.

INORGANIC ELEMENTS

The determination of "background levels" is more difficult for inorganic elements than for synthetic organic chemicals; whereas the former occur naturally in variable concentrations, the latter are completely absent in soil and sediment known to be free of human influence.

Comparisons of trace-element data show that natural variability far exceeds any differences resulting from sampling and analytical imprecision. The range in concentration for 43 elements analyzed in five soil cores from test hole 1 exceeds 10 percent for all 32 of the elements whose concentrations exceed reporting limits (table 7). This contrasts markedly with the nearly identical concentrations measured for sediment samples collected immediately adjacent to one another from depths of 0 to 1 cm (table 8) and 120 to 150 cm (tables 8 and 9) at site 5 in the recharge basin. For the highly contaminated surficial samples, measurable concentrations are identical for 20 elements and differ by more than 10 percent for only 4 elements (molybdenum, potassium, thorium, and ytterbium). For the background-level

¹Two adjacent samples at site 5 were analyzed.

samples from the deepest interval, measurable concentrations are identical for 13 elements and differ by more than 10 percent for only 3 elements (nickel, niobium, and thorium).

Such small differences between duplicate sediment analyses provides strong evidence that the much larger site-to-site differences in surface sediments from the recharge basin (table 8) are real. Many of the trace elements whose concentrations are highest at the surface have concentrations at sites 5 and 6 that are about double those at sites 1 and 2. This trend of increasing concentration toward the south end of the recharge basin and away from the discharge pipe is consistent with a similar trend of increasing percentage of clay (table 5) to which these contaminants could be expected to adsorb.

Although the sediment at site 5 shows a marked decrease in many chemical concentrations with increasing depth (table 9 and fig. 4), the rather large variability in natural abundances and sharp change in lithology (from fine to coarse sediment) several centimeters below the recharge basin makes the assignment of background values somewhat uncertain. This variability in background concentrations is

especially evident from the chemical differences between soil cores at five different depths (table 7), all of which must represent uncontaminated natural conditions. The concentrations of several elements are highest in the core interval from 10.9 to 11.3 m, which likely is related to the increased proportion of clay and silt in this sample relative to the other four samples (table 4). Radium-226 provides similar evidence of natural variability that probably implies differences in mineral assemblage. Concentrations of this naturally occurring radioisotope differ substantially between two of the soil cores (table 7), between the six surface-sediment sites in the recharge basin (table 8), and at different subbottom depths from site 5 beneath the recharge basin. On the basis of the particle-size distributions and selected chemical concentrations, as was noted in the section "Sampling of Sediments from the Recharge Basin," it was concluded that recharge-basin sediment below 16 cm is chemically most similar to soil between 5.5 and 5.8 m in test hole 1. However, the fact that chemical concentrations for a number of elements vary by a factor of 2 or more in uncontaminated soil from various depths in test hole 1 indicates that "background" for fine-grained basin deposits above 16 cm may be quite different from "background" for coarse-

grained basin deposits below 16 cm. Sampling of near-surface soil in the vicinity of the study basin that could have established more suitable background levels for the shallower basin sediment was not done. Extensive tilling and grading in the area indicated that

nearby soil would not have been suitable for direct comparison because reworking is likely to have mixed contaminated (by atmospheric deposition) and uncontaminated soil, and soil of differing texture, in variable proportions.

Figure 4. Enrichment ratios for selected constituents in subbottom sediment at site 5 in the recharge basin.

ORGANIC CHEMICALS

The results for organic carbon, oil and grease, GC-FID organic carbon, and organochlorine compounds in near-surface (0-1 cm) sediments at the six recharge-basin sites are given in table 8. Table 9 gives results for the same suite of organic constituents with increasing subbottom depth at site 5. Results for analysis of extractable priority pollutants, organochlorine compounds, organophosphorus insecticides, and chlorophenoxy-acid herbicides at depths of 0 to 1 cm and 8 to 16 cm at site 5 are given in table 10. The pattern of results for organic chemicals generally

is similar to that shown by inorganic elements, although there exists considerably less uniformity in either the areal trend (table 8) or the profile (table 9) for the organic chemical constituents. No pesticides were detected below 16 cm at site 5, and only two, chlordane and DDE, were identified (at their reporting limits of 0.001 $\mu\text{g/g}$ and 0.0001 $\mu\text{g/g}$, respectively) in sediment from the 8- to 16-cm interval.

The only pesticides that were found in basin sediment are the long-lived organochlorine compounds. It was anticipated that some of the more widely used organophosphorus insecticides, on the

basis of their abundance in rainfall and runoff (Oltmann and Shulters, 1989), also might be present in sediment, but none were detected (table 10). Similarly, their absence in sediment from five recharge basins in residential and commercial catchments during the Fresno NURP study was attributed to probable degradation (Nightingale, 1987c). A large number of phosphorus-containing organic compounds were reported during the gas-chromatographic analyses for this study, but they could not be specifically identified because of poor resolution and many interferences (M.P. Schroeder, USGS, oral commun., 1987). High organic content and the anaerobic nature of the sediment—which made cleanup of the sample extracts difficult and may have interfered with detection of organophosphorus insecticides—is the cause of the variable analytical reporting limits for the organochlorine compounds that are listed in the tables.

Chlordane was the organochlorine compound reported in highest concentration, a finding similar to that obtained during monitoring for the NURP study (Oltmann and Shulters, 1989). However, one of the more puzzling results obtained by this study is the finding of DDT itself as opposed to only its metabolites, DDD and DDE, which are more commonly present in environmental samples today. The highest DDT concentration of 0.10 $\mu\text{g/g}$ was found not in surface sediment but rather in sediment from a depth of 1 to 2 cm at site 5. Use of DDT was banned in the United States about 10 years prior to the Fresno NURP study and the operation of this recharge basin in its present configuration. Confirmation of DDT's presence is strong, as shown by its detection in several of the sediment samples analyzed (tables 8 and 9). Furthermore, the Fresno NURP study found that DDT concentrations consistently exceeded DDD and DDE concentrations in street sweepings from residential, commercial, and industrial catchments (Oltmann and Shulters, 1989).

Of 50 extractable organic priority pollutants analyzed, 13—including 12 polycyclic aromatic hydrocarbons and 1 phthalate ester—were detected in surficial sediment from site 5 (table 10). None were detected in sediment from the 8- to 16-cm interval. Total concentration of all the identified organic compounds in the surficial interval is slightly less than 100 $\mu\text{g/g}$, nearly all of which consists of the polycyclic aromatic hydrocarbons listed in table 10. Comparison with data given in table 9 shows that this represents only about 5 percent of the organic carbon reported by the GC-FID analysis, and less than 0.1 percent of total organic carbon. Although two addi-

tional polycyclic aromatic hydrocarbons (dimethyl-substituted naphthalenes) and at least 20 compounds belonging to the broad classes of alkanes and alkenes (or cycloalkanes) were identified by GC-FID analysis, virtually all the organic matter in the basin sediment remains uncharacterized. It seems likely that much of it may be generated by biological activity in the overlying water column; however, the organic nitrogen data that might have supported this assertion with the observation of low carbon/nitrogen ratios are lacking because all sediment samples but one listed in table 9 were accidentally destroyed in the laboratory during analysis.

ASSESSMENT OF ANTHROPOGENIC INPUTS

Chemical profiles that show a decrease in concentration with increasing sediment depth not only are strong evidence for sorptive removal of contaminants but also can be used, with some assumptions, to quantify the relative importance of anthropogenic (human-related) and natural (background) sources. The concept of enrichment ratios, defined herein as the concentration in a particular sediment interval divided by the mean concentration for all intervals below a depth of 16 cm (considered background concentration), is useful for this discussion. Profiles of enrichment ratios for selected constituents are shown in figure 4. If the surficial (0 to 1 cm) sediment is presumed to represent the combined inputs of current anthropogenic and natural sources, then decreases below this depth represent removal of contaminants, and possibly dilution by mixing with deeper soil that is free of anthropogenic influence. As expected, for rare-earth elements such as lanthanum, which has very few industrial uses, the concentration profile shows no change and represents only the natural abundance of this element. Two other rare earths that are present above reporting limits, cerium and neodymium, also show no change in concentration with depth (table 9).

Surface-enrichment ratios for all elements were calculated and are reported to the nearest whole number in table 11 for those values that differ from 1. These values include about half the elements analyzed. For those elements not listed in table 11, either there is no anthropogenic source or (1) concentrations are uniformly below detection, (2) natural levels are so high that they mask any anthropogenic input, or (3) variability in mineralogy or lithology exerts the predominant influence on concentrations. Just as an enrichment ratio of 1 does not preclude an anthropogenic component—conversely, an

Table 11. Surface-enrichment ratios for selected elements and radioisotopes in sediment at site 5 in the recharge basin

Radium-226	²²⁶ Ra	2

enrichment ratio greater than 1 is not necessarily conclusive proof of anthropogenic contamination, especially when these ratios are low. Such results could be an artifact of natural variability, as already discussed, or the results could be unique to the geochemical behavior of individual elements.

Despite these limitations on interpretation, it is clear from some of the very large enrichment ratios listed in table 11 that anthropogenic fluxes to the recharge basin far exceed natural fluxes for several trace metals that are in widespread industrial use. Results for three elements at this recharge basin (copper=25, lead=9, and zinc=38) can be compared with the enrichment ratios for these same elements (Cu=6, Pb=15, and Zn=5) in sediment from Irondequoit Bay, New York (Schroeder, 1985), which also was one of the NURP study sites (Kappel and others, 1986).

The results for four elements (As, Cu, Pb, and Ni) from this study also can be compared with those from a previous investigation at five other recharge basins in the city of Fresno, the oldest of which has been in use for about 20 years. The five basins are in

predominantly residential catchments that include some commercial land use and minimal industry. Surface-enrichment ratios, calculated by comparing published data for depths of 0-2 and 90-120 cm in the five basins (Nightingale, 1987b), range from 1 to 18 for arsenic, 3 to 13 for copper, 60 to 400 for lead, and 2 to 4 for nickel. Values for this study (table 11) are arsenic = 16, copper = 25, lead = 9, and nickel = 7. Enrichments are greater for the trace metals copper and nickel and much less for lead in the industrial catchment in comparison with the residential/commercial catchments, a pattern which is similar to that found during direct monitoring of runoff in the NURP study (Oltmann and Shulters, 1989).

Surface-enrichment ratios can be calculated similarly for organic priority pollutants and organochlorine compounds; however, the calculations yield only minimum estimates of 10^2 and 10^3 , respectively, because these compounds are below detection levels in the deeper sediment. Organic carbon, analyzed by combustion and by GC-FID (fig. 4 and table 9), also yields surface-enrichment ratios of almost 10^3 ; for organic carbon, detectable concentrations exist below 16 cm for both methods of analysis.

The data presented and the foregoing discussion indicate that a wide variety of trace elements and synthetic organic chemicals from the industrial catchment are removed within the top 16 cm of sediment in the recharge basin. Given the existence of nearly 8 m of soil between the basin and the water table and such effective removal of contaminants for the 4 years of operation in the basin's current configuration (since last scraped), local ground-water quality should be afforded protection during continued operation of the basin for a very long time. A similar inference can be made on the basis of results of studies at five other recharge basins in the city of Fresno (Nightingale, 1987a,b,c, and 1989)—although it was suggested by Nightingale (1989) that periodic monitoring of organic contaminants in soil would be advisable because of their known presence in storm runoff.

LABORATORY ELUTRIATION EXPERIMENTS

The potential for movement of urban-runoff contaminants through the unsaturated zone can be evaluated by means of laboratory experiments that simulate processes of sorption from the aqueous onto the solid phase and desorption from the solid into the aqueous phase. Both types of experiments were done for this study. As conducted, the experiments were intended to provide only a qualitative rather than a quantitative assessment. They were adapted from

methods commonly used to determine sorption isotherms (Harter, 1983) and from elutriation tests used to determine short-term water-quality conditions associated with dredging operations (Fuhrer and Rinella, 1983; Palermo, 1986). In one set of experiments, samples of highly contaminated surface sediment from the recharge basin were mixed with water from the recharge pond to test the ability of the sediments to desorb contaminants into the water with which it is in contact. In another experiment, water from the recharge basin was mixed with clean soil from the unsaturated zone deep beneath the recharge basin to examine the potential for removal of aqueous contaminants by the soil.

Water for the experiment was collected from the recharge basin on April 29, 1986, and stored frozen until its use 4 months later. It generally was similar in composition to water collected from the basin on January 29, 1986, as indicated by comparison of chemical concentrations in tables 6 and 12 (in table 12, see values for zero-day equilibration time). The most obvious difference between the two samples is the absence of nitrate (plus nitrite, which likely is negligible) in the water used for the laboratory experiment. Although this difference may be a consequence of seasonal variations, it seems more likely that it is the result of biological degradation because the water used for the laboratory experiment

was neither preserved with the mercuric chloride biocide nor filtered prior to its storage for later use.

One experiment was carried out by using a magnetic stirrer to continuously mix recharge-basin water and recharge-basin surficial sediment, in an approximately 10-to-1 gravimetric ratio, for as long as 4 days. The sediment-water slurry was contained in a covered, cylindrical glass chromatography jar and was continuously bubbled with nitrogen gas to maintain an oxygen-free environment throughout the experiment. Aliquots for chemical analysis were removed after 1, 2, and 4 days. The aliquots (also the initial, or zero-day, water) were centrifuged for 1 hour at 5,000 times

gravity, but they were not filtered. Although the solutions appeared visually to be free of suspended solids, the possible presence of colloidal material cannot be excluded. The increase in specific conductance from 346 to 638 $\mu\text{S}/\text{cm}$ after 1 day, and a smaller increase to only 696 $\mu\text{S}/\text{cm}$ after 4 days (table 13) shows that dissolution is initially rapid and then slows.

Calcium and sulfate were the main contributors to the increase in specific conductance. Despite a very large increase in dissolved (supernatant after centrifugation) iron and manganese during the experiment, the increase in all other cationic trace-metal concen-

trations, with the exception of zinc, was comparatively modest. Most chemical concentrations changed little between days 1 and 4. Iron is an obvious exception—its concentration decreased from 6.3 to 1.0 mg/L during this period. Failure of the needle valve that regulated release of nitrogen gas several hours before termination of the experiment may have allowed entrance of some oxygen to the chamber, with the consequent precipitation of iron.

Increases were measured in tannin and lignin, total phenols, and MBAS detergents during the 4-day experiment. However, given the potential for analytical artifacts in the colorimetric methods used for these broad-indicator constituents (Wershaw and others, 1987), their precise concentrations and detection at these low concentrations is uncertain. Nightingale (1989) reported the movement of phenols in soil moisture beneath one recharge basin in the city of Fresno that had very coarse substrata. The solubility and negative polarity of phenols make them one of the few relatively mobile classes of compounds analyzed for in this study. However, specific phenols were not detected in sediment samples from the recharge basin (table 10) and, therefore, their presence and downward transport remain uncertain.

Surficial sediment for the laboratory experiment was taken from a location near site 5 in the recharge basin and was collected in a slightly different manner than was used for all other samples of surficial sediment described elsewhere in this report. Instead of removing the entire 1-cm-thick polygonal plate, the sample was obtained by scraping the sediment surface with a Teflon-coated spatula at several locations over a wide area near site 5. Chemical composition of this composite sample (table 14) is remarkably similar to composition of the duplicate samples from 0 to 1 cm at site 5 (tables 8 and 9). For 35 detectable elements, the average (unsigned) difference in concentration is 5.4 percent between the duplicate samples and only slightly larger at 7.7 percent between the composite sample and the mean value of the duplicate samples.

In addition to the equilibration between surface sediment and water from the recharge basin, the sediment also was mixed with deionized water for about 4 days as a further check for desorption of contaminants into the aqueous phase. The results given in table 13 (results for a deionized-water blank also are shown in the table) lead to the conclusion already stated that evidence exists for possible transfer of some chemical constituents from sediment to the aqueous phase. Wigington and others (1983) also reported the potential for leaching of four inorganic

Table 14. Concentrations of elements in recharge-basin sediment and in aquifer soil used for the laboratory elutriation tests

urban contaminants (Cd, Cu, Pb, and Zn) from sediment in a recharge basin in Washington, D.C. They found that as much as 2 percent of these

elements was removed by a 0.01M $\text{Ca}(\text{NO}_3)_2$ solution, of the four elements tested, zinc was the most readily solubilized. Because solid-phase concentrations typically exceed aqueous concentrations by three orders of magnitude or more, the amount leached during the experiment represents a very large input to the aqueous phase. However, their experimental procedure likely overstates the potential for leaching in the environment because $\text{Ca}(\text{NO}_3)_2$ is expected to hydrolyze to form a weakly acidic solution.

For the laboratory experiment in which water from the recharge basin was mixed with natural uncontaminated soil, the core from a depth of 10.9-11.3 m in test hole 1 was selected. Soil from this depth was chosen because its generally higher silt-plus-clay content—in comparison with other, sandier, core samples (table 4)—would be expected to favor increased sorption. Results from this experiment to check for removal of aqueous contaminants by clean soil were inconclusive. An increase in mineral dissolution, as indicated by the increase in specific conductance from 346 (table 12) to 548 $\mu\text{S}/\text{cm}$ (table 13), was measured. The major ions that showed the largest increase are calcium, sulfate, and bicarbonate (alkalinity).

Concentrations of many minor constituents, including tannin and lignin and MBAS detergents, changed little. Some constituents, such as phenols and arsenic, actually show substantial increases. The increase from 2 to 6 $\mu\text{g}/\text{L}$ for phenols is, if anything, another indication of the uncertainty in the colorimetric test for phenols at this low level. And the increase in arsenic from 3 to 35 $\mu\text{g}/\text{L}$ indicates the potential for leaching of selected trace elements from even uncontaminated soil.

In summary, the batch-elutriation experiments done for this study demonstrate the potential for leaching of urban-runoff contaminants as water in recharge basins infiltrates the basin's sediment. However, the results of similar experiments to test the ability of uncontaminated substrata to remove those contaminants were inconclusive—in part, because of the significant natural abundances of some inorganic elements; because of limitations on the colorimetric methods used to analyze broad organic indicators; and because of the possible presence of colloidal material

in the centrifuged elutriate itself. Theoretical considerations based on the physical and chemical properties of contaminants in a circumneutral (or slightly alkaline) environment and monitoring of soil moisture and ground-water chemistry provide more reliable support for evaluating transport of urban-runoff contaminants to the water table than do the results of these elutriation experiments. The observation that concentration gradients show a sharp decrease in sediment beneath the recharge basin, and the likelihood that water-infiltration rates are sufficiently slow for the soil moisture to, in effect, undergo a series of "batch-removal" processes as it percolates downward through the soil, ensures the effective removal of all urban runoff contaminants, with the possible exception of those having negative charge (anions) or negative polarity.

Perhaps the most important finding obtained from these laboratory experiments comes from analyses of the sediment and soil before (table 14) and after (table 15) the elutriation tests. The data in table 14 were obtained from complete mineral digestion with strong acids, whereas those in table 15 are based on oxidation of organic matter with H_2O_2 followed by only partial digestion with 0.3M HCL (Fishman and Friedman, 1989). The mild-acid digestion is intended to remove only surface layers while leaving the aluminosilicate mineral matrix itself largely intact. Among the alkali- and alkaline-earth elements, the mild-acid treatment removed virtually no calcium, magnesium, and sodium but did leach a substantial proportion of the total potassium. Percent recoveries from the contaminated basin sediment at 0 to 1 cm near site 5 and from clean aquifer soil at 10.9-11.3 m in test hole 1 can be obtained by dividing concentrations for partial digestion (table 15) by concentrations for complete digestion (table 14). Results of this calculation for several elements are summarized in table 16. These results show that a number of elements having high enrichment ratios (the contaminants in urban runoff) are almost entirely recoverable by the mild treatment and therefore are presumed to be present in surface coatings on mineral grains and in organic matter (Horowitz and Elrick, 1987). Percent recoveries for mild-acid digestion of the uncontaminated aquifer soil are somewhat less, but they also indicate that a substantial proportion of selected trace elements is likely associated with

Table 15. Concentrations of chemical constituents in recharge-basin sediment and aquifer soil after the laboratory elutriation tests

hydrous ferromanganese oxides present either as coatings on mineral grains or disseminated throughout the uncontaminated soil.

TRANSPORT AND LOADING OF CONTAMINATED SEDIMENT

When results of this study are compared with results from the NURP study, some differences emerge that raise questions about how contaminants in the urban environment are delivered to the recharge basin and about the quantity of contaminants actually present in the basin. Although these are important questions, it is emphasized that they do not change this study's principal conclusion that urban contaminants are not reaching the ground water, nor do they affect sediment-disposal considerations (following periodic scraping of the basin's floor) that are based on compliance with sediment-quality criteria or standards.

Table 17. Annual loads to the industrial recharge basin determined from runoff monitoring and sediment inventories

[Annual loads in kilograms per year. Inventory loads are converted to values based on mild-acid, partial digestion (see text) for direct comparison with runoff loads, adjusted to mean annual rainfall in Fresno, obtained by Olman and Shulters (1989)]

Element	Annual load, determined from:		Inventory/runoff ratio
	Runoff	Inventory

COMPARISON OF BASIN-SEDIMENT INVENTORIES AND STORM-RUNOFF LOADS

Storm-runoff loads to the industrial basin, calculated from average-annual constituent loads estimated by Olmann and Shulters (1989, table 25) on the basis of monitoring for the NURP study during the 1981-82 and 1982-83 wet seasons, are given in table 17. Quantities of constituents found in this study to have accumulated in the recharge-basin's sediment during operation in its present configuration from 1982 to 1986 also are given in the table. In order to compare annual loads estimated by means of the two methods, it is necessary to adjust the sediment inventories for differences in recovery between the mild-acid digestion used during the NURP study to analyze runoff samples and the complete mineral digestion used in this study to analyze basin sediment. This was done by multiplying total-constituent amounts measured in the sediment by recovery percentages from the "Basin sediment" column in table 16, thereby providing a comparison that is based on element recoveries from the partial-digestion analytical method. [Alternatively, an equivalent comparison could be based on loads determined from complete-digestion methods by dividing the runoff-load values of Olmann and Shulters (1989) reproduced in table 17 by the recovery percentages.] Complete recovery (100 percent) was used in the calculation for organic carbon, copper, lead, and zinc. The concentration

profiles at site 5, given in table 9, were used to calculate constituent quantities in the basin sediment. Quantities are calculated by multiplying concentrations, basin area, sediment dry-bulk density, and subbottom depth. The error that is propagated by uncertainty in each of these parameters is discussed below.

The uncertainty in element concentrations that results from analytical imprecision is small: an average of only about 5 percent on the basis of analysis of duplicate samples. The error that results from spatial variability in concentration is much greater: as much as a factor of about 2 (100 percent) for many of the urban contaminants in surface sediment (0-1 cm) at six locations in the recharge basin (table 8). However, the effect of such large spatial variability is deceptive because nearly all of the basin floor's area is in the south end, where the variability obtained by comparing surficial concentrations at sites 5 and 6 is only about 5 percent (table 8), and by comparing concentrations at site 5 with those from a broad area near site 5 (table 13) is only about 8 percent. The area of the basin floor that contains contaminated sediment is difficult to estimate because the sediment reaches an indeterminate distance up the sloping sides of the basin. The basin-floor area was measured in the field to be about 3.72×10^7 cm² (40,000 ft² or about 1 acre) with a possible error of about 25 percent.

Sediment dry-bulk density (ρ in equation 1 later) was not measured in this study, but a value of 1.5 g/cm^3 was chosen because it was measured by Nightingale (1989) for a sediment with similar grain-size distribution from another recharge basin in the city of Fresno. True density of well-homogenized sediment samples is likely to differ little from this estimate, although minor fluctuations with depth can be expected. A far greater error arises from the unusual open texture of sediment in the top few centimeters referred to in the "Sampling of Sediment from the Recharge Basin" section of this report.

These irregularities in sediment texture, and thinning of the contaminated zone along the sideslopes and channel in the northern part of the basin, create a rather large uncertainty in precise assignment of subbottom depths as well as some ambiguity in choosing the maximum depth to be used in calculating sediment inventories. Four centimeters was chosen as the maximum depth to use because sediment below this depth contained no excess (atmospheric) lead-210 ($^{210}\text{Pb}_{\text{ex}}$).

When each of the various sources of error is considered, the accuracy of calculated annual-contaminant inventories in the sediment is thought to be no better than a factor of 2 or 3. As noted, most of the imprecision is attributable to uncertainty in the determination of depth and bulk density related to the unusual sediment texture. Guay and Smith (1988) also recognized the large error in simulating a relation between quantity and quality of storm runoff in the industrial catchment and therefore developed simulations for residential and commercial catchments only. Failure of their model for the industrial catchment may be caused by discharge from large point sources unrelated to rainfall, in contrast to residential and commercial catchments, where nonpoint (as numerous small-point) contributions predominate. Median errors using data from individual storms for their simulation in a commercial catchment were 11 percent for lead and 54 percent for suspended sediment. However, even these rather large errors in estimating urban-runoff loads are much less than differences between the results obtained using the two methods described in this report. The differences for selected constituents are expressed as a ratio between the sediment-inventory and runoff-monitoring load and are given in table 17. Possible reasons for the differences include: (1) errors in one, or both, of the methods used to estimate annual loads; (2) real differences between the period of storm monitoring during 1981-83 and the period of sediment

accumulation during 1982-86; and (3) substantial delivery of sediment containing urban contaminants by some mechanism in addition to storm runoff, such as overland flow and erosion on the perimeter of the basin or atmospheric transport (dryfall).

Contaminated sediment contained in the recharge basin exceeds the amount delivered as suspended sediment in storm runoff by a factor of 1.8 (table 17). The difference is only slightly less for several elements (Cr, Cu, Pb, Mn, Ni, and Zn), possibly reflecting minor dilution with sediment (soils or substrata) containing little or no urban contaminants. The close similarity in loading patterns for these elements and for sediment is especially surprising given the very different procedures and assumptions used to obtain the two estimates. These results suggest that a single explanation may exist for the differences, such as a systematic error in the estimated quantity of sediment. Furthermore, there are simple explanations to reconcile inventory-runoff differences that are either much greater (aluminum and iron) or much less (arsenic, organic carbon, and mercury) than 1.8 for five other elements.

The amount of recoverable aluminum and iron contained in basin sediment relative to runoff apparently is overestimated because the digestion procedure produced uncharacteristically high recoveries for the strongly anaerobic sediments from the basin in comparison with the much lower recoveries of both aluminum and iron for clean aquifer soil (table 16). Possible explanations for those elements that appear to be depleted in the basin sediment (arsenic, organic carbon, and mercury) are much more varied.

The subbottom concentration profile from site 5 (table 9 and fig. 4) clearly shows that some arsenic has migrated beyond the 4-cm depth. The amount of arsenic that migrated was not included in the inventory calculation, which was cut off at 4 cm to maintain internal consistency among all elements. The greater mobility for arsenic, in comparison with many other trace elements that exist as cations, may be attributed to its possible existence as the more soluble oxyanion.

Mercury concentrations are so low that analytical errors and loss during storage and processing of the sediment samples must be considered; however, natural loss by volatilization of the element or its methylated form within the basin (Compeau and Bartha, 1985) also is possible.

Because the concentration of dissolved organic carbon in soil water (and ground water) generally is low and sorption of organic carbon to solid-particle surfaces typically is high, transport of organic carbon with downward-percolating recharge is likely to be a minor mechanism for its removal. The main removal mechanism for organic carbon is believed to be biological degradation within the subbottom sediment; the data in table 17 indicate that at least one-half the organic carbon delivered in runoff must be decomposed. In fact, the fraction of organic carbon actually mineralized (degraded) must be even greater than one-half because not only allochthonous carbon in runoff but also autochthonous carbon produced biologically within the pond itself is delivered to the subbottom sediment. The basin receives an average annual load of 730 kg total nitrogen. Dissolved phosphorus also was noted to be especially high in runoff from the industrial catchment in comparison with runoff from the residential and commercial catchments (Oltmann and Shulters, 1989). It is this rich supply of nutrients which results in the deep green color (from algae) of the pond itself and in the existence of strongly anaerobic sediment beneath the basin, and which provides an environment that supports extensive degradation of organic carbon.

LEAD-210 CONSTRAINTS ON ORIGIN AND LOADING OF CONTAMINATED SEDIMENT

Lead-210 occurs naturally as a product of the uranium-238 decay series and has a half-life of 22 years. Lead-210 has been used widely for dating lacustrine and coastal sediments that have accumulated during the last 100 years (Faure, 1977). For this study, the primary purpose in obtaining ^{210}Pb data was to ascertain the maximum depth at which inorganic elements from urban runoff occur in basin sediment. This radioisotope is especially well suited to this purpose because (1) its chemical and physical properties are expected to be similar to those of other inorganic cations, especially nonradiogenic lead, and thus it would be expected to transport similarly and (2) that portion of the sedimentary ^{210}Pb derived from atmospheric fallout, the $^{210}\text{Pb}_{\text{xs}}$ (excess lead-210), will be completely absent in the much older substrata that lie beneath the basin's recently deposited sediment if no downward transport of the isotope has occurred. Lead-210 also may provide useful insight into the origin (mechanism of delivery) and loading of urban-contaminated sediment to recharge basins.

Atmospheric ^{210}Pb is produced when ^{226}Ra in the Earth's crust decays to ^{222}Rn , an inert gas that effuses into the atmosphere, where it subsequently decays through a series of very-short-lived daughters to ^{210}Pb and falls back to the Earth's surface. Because secular (long-term) equilibrium is presumed to exist between sedimentary (or soil) ^{226}Ra and its decay products, the $^{210}\text{Pb}_{\text{xs}}$ activity can be calculated as total ^{210}Pb activity minus ^{226}Ra activity (see Graustein and Turekian, 1986, for a more complete discussion). For this study, activities are given in dpm (disintegrations per minute), which can be converted to other units of activity commonly used in the literature with the relation: 1 pCi (picocurie) = 2.2 dpm = 37 mBq (millibecquerels). Crustal variations in concentration of the parent isotope from which ^{210}Pb is derived and rapid removal of ^{210}Pb from the atmosphere in comparison with global circulation times causes regional variations in the flux of atmospheric ^{210}Pb . On the basis of measurements in soil and precipitation, Moore and Poet (1976) reported values of 0.53 to 1.0 (dpm/cm²)/yr for oceanic fluxes, 0.3 to 2.0 (dpm/cm²)/yr for continental fluxes in the north temperate zone, and 1.6 (dpm/cm²)/yr from surface-soil profiles in Colorado, Texas, and Kansas. Graustein and Turekian (1986) reported values ranging from 0.6 to 1.2 from undisturbed soil in 19 locations throughout the central and eastern United States. Published data from several locations on the west coast yield a range of about 0.2 to about 0.7 (dpm/cm²)/yr, with latitude, longitude, and precipitation quantity influencing the flux (Fuller and Hammond, 1983)—and a value of about 6 (dpm/cm²)/yr in Emerald Lake (calculated from data in Holmes and others, 1989, fig. 2). Although Emerald Lake is only 110 km east-southeast of Fresno in an alpine watershed on the west slope of the Sierra Nevada, its high ratio of watershed to lake area (almost 50) and the steep slopes of this cirque lake are likely to result in an anomalously high atmospheric-flux estimate. Although data are not available for the city of Fresno, proximity to the Pacific Ocean suggests that the ^{210}Pb flux should be near the low end of the range of continental values and likely no greater than about 1 (dpm/cm²)/yr. Data from undisturbed soil or from atmospheric precipitation (wet and dry deposition) in the Fresno area would be needed to determine the local flux more accurately.

Annual deposition of $^{210}\text{Pb}_{\text{xs}}$ in a sediment profile can be calculated from:

$$^{210}\text{Pb}_{\text{xs}} \text{ flux} = \frac{\sum_i [^{210}\text{Pb}_{\text{xs}}]_i L_i \rho}{1 - e^{-\lambda t}} \quad (1)$$

where λ is the decay constant (0.0311 yr^{-1}), ρ is dry-bulk density (1.5 g/cm^3), t is 4 years, and the other terms are defined in the following paragraph. The above formulation yields the same result as an alternative method chosen to illustrate more clearly the effect of errors in basin area and sediment mass on the result. The method also is analogous to that used for calculating element inventories in table 17.

Annual deposition of $^{210}\text{Pb}_{\text{xs}}$ to the basin also can be calculated by substituting data (in table 9) from site 5, where a complete activity profile exists, into the equation:

$$^{210}\text{Pb}_{\text{xs}} \text{ flux} = \frac{M}{t \cdot A \cdot L} \sum_i [^{210}\text{Pb}_{\text{xs}}]_i L_i \quad (2)$$

where

- $[^{210}\text{Pb}_{\text{xs}}]$ is the activity in sediment interval i ,
- L_i is the length of sediment interval i
- L is the sediment depth (4 cm) to which $^{210}\text{Pb}_{\text{xs}}$ is present,
- M is mass of sediment in the basin,
- t is length of time (4 years) the basin has been operated since last scraped, and
- A is area of the basin ($3.72 \times 10^7 \text{ cm}^2$).

Using the estimated sediment-accumulation rate (M/t) of 56,000 kg/yr given in table 17, and adjusting upward for the small amount of decay that took place during 4 years, yields a $^{210}\text{Pb}_{\text{xs}}$ deposition rate of 6.4 $(\text{dpm/cm}^2)/\text{yr}$. This value is markedly higher than the expected atmospheric flux of about 1 $(\text{dpm/cm}^2)/\text{yr}$. Fluxes determined from sediment data in surface-water bodies often are higher than atmospheric deposition rates and the difference is attributed to sediment "focusing"—the preferential scavenging on fine-grained material at the location of the cored sediment. For example, in four cores from the NURP study site in Irondequoit Bay, New York, fluxes were found to range from about 1 to 3 $(\text{dpm/cm}^2)/\text{yr}$ (Schroeder, 1985). The spatial trend shown by surficial activities that are given in table 8 provides evidence that focusing occurs in the recharge basin.

However, the equation above hints at a simpler explanation that reconciles the difference—a decrease in the sediment mass by a factor of 2 and an increase in the effective basin area by a factor of 3.

Monitoring of suspended-sediment concentration in runoff yielded the lower estimate (in relation to inventory estimate) for average annual sediment delivered to the recharge basin, and because total rainfall in Fresno during 1982-86 was only a little above average, annual sediment deliveries during this period also should be near the annual average. Erosion from the sideslopes and perimeter to the floor of the recharge basin plausibly could increase the effective area of deposition by a factor of 3 (compare total basin area to bottom area in figure 2). Such sediment may have been deposited initially as dryfall, whose contribution must be small in comparison with that of runoff, or the pattern and level of contamination in the dryfall and overland flow on the sideslopes must be similar to that in runoff in order to maintain the similarity in pattern shown by several different elements that is indicated in table 17.

The discussion above illustrates how, with relatively few measurements in comparison with much more intensive monitoring of runoff, reasonable estimates can be obtained for the quantity of contaminated sediment in an urban-runoff recharge basin. More detailed studies are needed to refine and test the validity of the method. Such studies might preferably be done in turfed basins that have been operated for a much longer time than was the subject basin in this study, thereby minimizing possible effects of erosion from the sides of the basin and providing a much thicker sediment veneer in which depths and bulk density could be measured more accurately.

SUMMARY AND CONCLUSIONS

Previous monitoring of storm-runoff quantity and quality, during 1981-83, in Fresno revealed elevated concentrations of urban contaminants in residential, commercial, and industrial catchments. The monitoring was accompanied by studies that confirmed the presence of these contaminants within the top few centimeters of sediment beneath recharge basins constructed to dispose of runoff from residential and commercial catchments. This study extends those previous studies to a 0.4-ha industrial-catchment basin where some urban contaminants were expected to be

present at even higher concentrations than in residential- and commercial-catchment basins. This study also shows that a wide variety of inorganic and organic contaminants generated in the 1.13-km² industrial catchment are removed by sorption within the top 4 cm of sediment in the recharge basin, and that the contaminants have not degraded ground-water quality beneath the basin.

The absence of local ground-water-quality impairment is documented by comparing chemical concentrations in two water-table monitoring wells to aqueous concentrations in the recharge basin. Shallow ground water near the basin contains a significant proportion of partly evaporated runoff from the basin as shown by measured delta-deuterium values of about -50 permil in both monitor wells in comparison with reported values of about -90 permil in regional ground water and -16 permil in the recharge basin itself. Because aqueous zinc concentration is about 100 times higher in the recharge basin than in the monitor wells, this element is an especially sensitive surrogate for assessing potential ground-water degradation by inorganic cations. Organic contaminants either were absent or were detected at such low concentrations (near reporting limits) that evidence for their presence in the monitor wells is questionable.

The range in chemical concentration of many urban contaminants in surface (0-1 cm) sediment from six locations on the floor of the recharge basin was a factor of about 2. Concentrations were lowest in channels at the north end of the basin nearest the pipe from which runoff discharges, and highest at the south end in the broad, topographically lowest part of the basin. The proportion of fine sediment also is highest at the south end, as would be expected. Profiles at a representative location in the south end of the basin show that concentrations of nearly all contaminants decrease to background levels at a depth of 4 cm, which also was the maximum depth to which atmospheric ²¹⁰Pb (excess ²¹⁰Pb) penetrates; no contaminants generated in the urban environment were detected below a depth of 16 cm.

Surface-enrichment ratios, defined as the ratio of concentrations in the top centimeter to concentrations in substrata below 16 cm, provide a quantitative means to compare anthropogenic (human related) and natural sources. Accordingly, a ratio of 2 is consistent with equal inputs from human and natural sources. Twenty inorganic elements were found to have enrichment ratios of 2 or greater. The value for zinc, which had the highest ratio, was 38. Values for several other elements were: arsenic=16, chromium=5,

copper=25, lead=9, mercury>11, nickel=7, phosphorus=5, and organic carbon=10³.

Enrichment ratios cannot be calculated for the approximately 20 organic compounds identified in sediment because the compounds are absent at depth. Nearly all the organic compounds detected in sediment are either organochlorine pesticides or polycyclic aromatic hydrocarbons. Among compounds in these two groups, chlordane and pyrene show the highest concentrations. Curiously, concentrations of the banned pesticide DDT exceed those of its possible metabolites DDD and DDE, a finding also noted in previous studies of urban runoff in the city of Fresno.

Estimates of sediment quantity and element load (total recoverable by mild-acid digestion) loads obtained in this study from a single core in the recharge basin exceed previously published estimates that were based solely on storm-runoff monitoring by a factor of 1.8. Possible explanations for this study's higher estimates are imprecision in the determination of sediment depths, the unusually open texture of the sediment veneer that had accumulated during the 4-year period the basin was operating, and thinning of the sediment layer in parts of the basin.

The flux of atmospheric ²¹⁰Pb, calculated to be 6.4 (disintegrations per minute/cm²)/yr using data from the only core obtained in the basin, is much higher than the maximum expected atmospheric flux of about 1 (disintegrations per minute/cm²)/yr. This difference can be reconciled if 1982-86 sediment contained in the basin is reduced by half and if the effective area of deposition is increased to 3 times larger than the approximately 0.4-ha floor of the basin. Erosion from the perimeter and sideslopes of the basin could provide the additional area required. This discussion illustrates how acquisition of ²¹⁰Pb data can be used to check estimated loads of sediment and urban contaminants delivered to recharge basins without the numerous analyses and intensive sample collection necessary to monitor runoff itself. However, additional data collection is needed to confirm and refine the method.

Water Quality of Storm Runoff and Comparison of Procedures for Estimating Storm-Runoff Loads, Volume, Event-Mean Concentrations, and the Mean Load for a Storm for Selected Properties and Constituents for Colorado Springs, Southeastern Colorado, 1992

By Paul von Guerard and William B. Weiss

Abstract

The U.S. Environmental Protection Agency requires that municipalities that have a population of 100,000 or greater obtain National Pollutant Discharge Elimination System permits to characterize the quality of their storm runoff. In 1992, the U.S. Geological Survey, in cooperation with the Colorado Springs City Engineering Division, began a study to characterize the water quality of storm runoff and to evaluate procedures for the estimation of storm-runoff loads, volume and event-mean concentrations for selected properties and constituents.

Precipitation, streamflow, and water-quality data were collected during 1992 at five sites in Colorado Springs. Thirty-five samples were collected, seven at each of the five sites. At each site, three samples were collected for permitting purposes; two of the samples were collected during rainfall runoff, and one sample was collected during snowmelt runoff. Four additional samples were collected at each site to obtain a large enough sample size to estimate storm-runoff loads, volume, and event-mean concentrations for selected properties and constituents using linear-regression procedures developed using data from the Nationwide Urban Runoff Program (NURP). Storm-water samples were analyzed for as many as 186 properties and constituents. The constituents measured include total-recoverable metals, volatile-organic compounds, acid-base/neutral organic compounds, and pesticides.

Storm runoff sampled had large concentrations of chemical oxygen demand and 5-day biochemical oxygen demand. Chemical oxygen

demand ranged from 100 to 830 milligrams per liter, and 5-day biochemical oxygen demand ranged from 14 to 260 milligrams per liter. Total-organic carbon concentrations ranged from 18 to 240 milligrams per liter. The total-recoverable metals lead and zinc had the largest concentrations of the total-recoverable metals analyzed. Concentrations of lead ranged from 23 to 350 micrograms per liter, and concentrations of zinc ranged from 110 to 1,400 micrograms per liter.

The data for 30 storms representing rainfall runoff from 5 drainage basins were used to develop single-storm local-regression models. The response variables, storm-runoff loads, volume, and event-mean concentrations were modeled using explanatory variables for climatic, physical, and land-use characteristics. The r^2 for models that use ordinary least-squares regression ranged from 0.57 to 0.86 for storm-runoff loads and volume and from 0.25 to 0.63 for storm-runoff event-mean concentrations. Except for cadmium, standard errors of estimate ranged from 43 to 115 percent for storm-runoff loads and volume and from 35 to 66 percent for storm-runoff event-mean concentrations. Eleven of the 30 concentrations collected during rainfall runoff for total-recoverable cadmium were censored (less than) concentrations. Ordinary least-squares regression should not be used with censored data; however, censored data can be included with uncensored data using tobit regression. Standard errors of estimate for storm-runoff load and event-mean concentration for total-recoverable cadmium, computed using tobit regression, are 247 and 171 percent.

Estimates from single-storm regional-regression models, developed from the Nationwide Urban Runoff Program data base, were compared with observed storm-runoff loads, volume, and event-mean concentrations determined from samples collected in the study area. Single-storm regional-regression models tended to overestimate storm-runoff loads, volume, and event-mean concentrations. Therefore, single-storm local- and regional-regression models were combined using model-adjustment procedures to take advantage of the strengths of both models while minimizing the deficiencies of each model.

Procedures were used to develop single-storm regression equations that were adjusted using local data and estimates from single-storm regional-regression equations. Single-storm regression models developed using model-adjustment procedures had standard errors of estimate smaller than the standard errors of estimate for the regional-regression equations. Reduction of standard error in percent ranged from -1,980 to -10.

Regression models that had been developed from the Nationwide Urban Runoff Program data base for estimating the mean load for a storm were evaluated. Mean load for a storm was estimated for selected constituents. Ninety-percent confidence intervals were computed for each mean load estimate. Estimated mean load for a storm was compared to mean load of a storm that was computed based on daily mean water discharge and land-use characteristics and was compared to the mean load from six samples collected during rainfall runoff. Generally, mean load for a storm, computed based on daily mean water discharge and land-use characteristics and on mean load from samples collected during rainfall runoff, was near or within the 90-percent confidence intervals for estimates of mean load for a storm.

INTRODUCTION

Urbanization usually increases the impervious area of a watershed, which increases storm-runoff rates and, subsequently, total volume of storm runoff. Associated with storm runoff are properties and constituents that can cause the degradation of water quality locally and in receiving waters downstream. Because of concerns about the effects of urban runoff on water quality, the Water Quality Act of 1987 contains provisions that specifically address storm-runoff discharges. The U.S. Environmental Protection Agency, under section 319

of the Water Quality Act of 1987, requires that States "assess the nature and extent of nonpoint sources of pollution." Section 402(p) of the same act requires that municipalities that have a population of 100,000 or greater obtain National Pollutant Discharge Elimination System (NPDES) permits to improve the quality of storm runoff.

Final rules published by the U.S. Environmental Protection Agency (1990) require that municipalities prepare permit applications to include, among other information, the following:

1. Characterization of the quantity and quality of storm runoff for three or more major storms at selected storm-water-discharge sites that represent different combinations of commercial, industrial, and residential land uses.
2. Estimates of annual-pollutant loads and event-mean concentrations for selected constituents for the cumulative discharges of storm-runoff discharge points in the study area.

In 1992, the U.S. Geological Survey, in cooperation with the Colorado Springs City Engineering Division, began a study to characterize the water quality of storm runoff in Colorado Springs and to compare techniques for the estimation of storm-runoff loads, volume, event-mean concentrations, and mean load for a storm for selected properties and constituents.

Purpose and Scope

This report presents water-quality data collected during 1992 to characterize the water quality of storm runoff in Colorado Springs. These data were collected to help meet the requirements of the NPDES permitting process. Precipitation, streamflow, and water-quality data were collected during 1992 at five sites in Colorado Springs (fig. 1, table 1). This report presents procedures for estimating storm-runoff loads, volume, and event-mean concentrations for selected properties and constituents at unmonitored sites in Colorado Springs and to make a comparison of several procedures for estimating storm-runoff loads, volume, and event-mean concentrations. In addition, the report presents estimates of a mean load for a storm.

Thirty-five samples were collected, seven at each of the five sites. At each site, three samples were collected for NPDES permitting purposes; two of these samples were collected during rainfall runoff, and one sample was collected during snowmelt runoff. Four additional samples were collected at each site to obtain a large enough sample size to estimate storm-runoff

loads, volume, and event-mean concentrations for selected properties and constituents using linear-regression procedures developed using data from the Nationwide Urban Runoff Program (NURP). Storm-water samples were analyzed for as many as 186 properties and constituents (tables 16–21 in the "Supplemental Data" section at the back of this report). Some of the properties and constituents measured include pH, specific conductance, water temperature, chemical oxygen demand, biochemical oxygen demand, bacteria, dissolved and suspended solids, major ions, nutrients, residual chlorine, total-recoverable metals, oil and grease, phenols, volatile-organic compounds, acid-base/neutral organic compounds, and pesticides.

Computed, hereinafter called observed, values for storm-runoff loads, volume, and event-mean concentrations are compared by using root-mean-square error with the results from regional-regression models developed from data collected for the NURP (Ellis and others, 1984; Driver and Tasker, 1990). Procedures are presented for using local data to adjust estimates from single-storm regional-regression models.

Description of Study Area and Sampling Sites

The study area, the city of Colorado Springs, is located in and along the eastern slope of the southern

Rocky Mountains (fig. 1). The climate of the study area is semiarid. Annual precipitation for 1948–87 at the Colorado Springs airport ranged from 8.6 to 25.4 in. Mean annual precipitation at the airport was 15.2 in. Convective thunderstorms contribute most of the rainfall during May through September. Thunderstorms occur an average of 70 days each year (U.S. Geological Survey, 1970). Mean air temperatures are about 29°F in January and 70°F in July (Hansen and others, 1978).

Soils in the study area tend to be sandy, moderately deep to deep, and well drained to excessively well drained. The study area is underlain mainly by sandstone and shale and by alluvial and windlain deposits. The landform dominating the study area is the Colorado Piedmont. A more detailed description of the study area is discussed in von Guerard (1989). Another important aspect of the study area is the rate of growth associated with Colorado Springs. Population increased from 45,472 in 1950 to 281,140 in 1990. Additionally, total area of Colorado Springs increased from 9.4 mi² in 1950 to 181.4 mi² in 1990 (Christine Lytle, Colorado Springs City Engineering Division, written commun., 1992).

Each of the sampling sites, except for site 4, is located near the outfall of a drainage basin. Drainage-basin areas range from 0.049 to 0.327 mi², and a predominant land use can be attributed to each basin (table 1). However, all sites have a mixture of land

4 Water Quality of Storm Runoff and Comparison of Procedures for Estimating Storm-Runoff Loads, Volume, Event-Mean Concentrations, and the Mean Load for a Storm for Selected Properties and Constituents for Colorado Springs, Southeastern Colorado, 1992

uses, which is typical of Colorado Springs. For the purposes of this report, a drainage basin is defined by the local municipal storm-sewer network and is not necessarily delineated by the topography of the drainage basin. Selected descriptive data for the five drainage basins are listed in table 1. Except for site 4, all sites discharge into another part of the Colorado Springs storm-sewer system. Site 4 discharges directly into Monument Creek.

Site 1 is in southeastern Colorado Springs (fig. 1). The sampling site is in a 60-in. reinforced concrete pipe (RCP) and is accessed by a manhole. The manhole is located about 200 ft upstream from Spring Creek along the southern boundary fence of the Valley-Hi Golf Course and is south of the sixteenth hole. The sampling site is directly upstream from an 18-in. side drain entering the RCP from the south. Site 1 has a drainage-basin area of 0.125 mi², of which 58.1 percent is impervious area (table 1). Predominant land use in the drainage basin is commercial (table 1) and includes retail stores and two automobile dealerships that have repair facilities.

Site 2 is in northwest Colorado Springs (fig. 1). The sampling site is in a 72-in. RCP accessed by a manhole. The manhole is located about 100 ft southeast of the intersection of Garden of the Gods Road and Chestnut Street and is about 200 ft upstream from Douglas Creek. Site 2 has a drainage-basin area of 0.165 mi², of which 37.5 percent is impervious area (table 1). Predominant land use is industrial and includes tool and machine forging, computer software, heating and air-conditioning manufacturing, and metallurgy companies.

Site 3 is located in north-central Colorado Springs (fig. 1). The sampling site is in a 48-in. RCP and is accessed by a manhole. The manhole is located on the northwest corner of Beacon Street at Buchanan Street and is about 400 ft east of Monument Creek. Site 3 has a drainage-basin area of 0.173 mi², of which 55.9 percent is impervious area. Land use predominantly is industrial (table 1) and includes auto repair, machining, manufacturing, food-processing, welding, computer software, metal-fabrication, and paper-distribution companies.

Site 4 is in central Colorado Springs (fig. 1). The sampling site is in a 66-in. RCP accessed by a manhole. The manhole is about 0.7 mi upstream from Shooks Run and 75 ft from the southeast corner of Wahsatch Street and Cross Lane. Site 4 has a drainage-basin area of 0.327 mi², of which 34.2 percent is impervious area. Land use primarily is low-density residential (table 1) but includes some commercial businesses.

Site 5 is in southwest Colorado Springs (fig. 1). The sampling site is in a 42-in. RCP and is accessed by a manhole. The manhole is located about 30 ft upstream from a drainage channel leading to Bear Creek and is about 300 ft east of the southeast corner of a retail store. The sampling site is directly upstream from an 18-in. side drain entering the RCP from the northwest. Site 5 has a drainage-basin area of 0.049 mi² of which 40.1 percent is impervious area (table 1). Land use in the drainage basin predominantly is undeveloped (43 percent); however, commercial land use composes 39.9 percent of the drainage-basin area (table 1). The undeveloped area is in the upper part of the drainage basin and did not contribute runoff during the events sampled; therefore, runoff sampled is considered to be representative of commercial land use. Commercial land use includes two automobile dealerships that have repair facilities, a gas station, and several retail stores.

Acknowledgments

The authors appreciate the support and cooperation provided by Christine Lytle, Leonard Miller, and Bruce Thorson of the city of Colorado Springs. The authors thank Daniel Bunting, El Paso County Regional Floodplain Administrator, for providing precipitation duration data. The authors also thank Seth Bacon, Evan Howe, and Dennis Young, student employees of the U.S. Geological Survey, for their untiring efforts in collecting and processing storm-water samples.

DATA-COLLECTION TECHNIQUES, WATER-QUALITY-SAMPLING PROCEDURES, AND QUALITY-ASSURANCE PROCEDURES

Collection of storm-runoff data in the urban environment and for the purposes of NPDES requires specialized techniques and procedures. The following is a description of the data-collection techniques and sampling procedures used for this study.

Precipitation and Flow Data-Collection Techniques

Two to four precipitation storage gages were installed in each drainage basin. These gages were inspected at least daily from May 25 to August 16, 1992, and periodically, thereafter, until the completion

of the snowmelt sampling. Precipitation for each drainage basin was area weighted using Thiessen polygons (Chow, 1964). In addition to providing total precipitation for each storm sampled, data collected at precipitation storage gages were used to determine precipitation conditions for 6 to 72 hours prior to the collection of a sample. To meet NPDES requirements for sampled storms, precipitation could not exceed 0.10 in. during the 72 hours preceding the collection of samples. For the four additional samples collected for selected properties and constituents, precipitation could not exceed 0.05 in. during the 6 hours preceding sample collection.

The hydraulics of flow in storm-sewer systems is extremely complex, and when coupled with the safety and logistical problems associated with accessing storm sewers, the complex hydraulics make the accurate measurement of storm-water discharge difficult. Palmer-Bowles flumes were installed at each site to measure flow in the storm sewers (Kilpatrick and others, 1985). The Palmer-Bowles flume causes flow in the RCP to be subcritical at the flume approach and forces flow through critical depth in the flume throat. Kilpatrick and others (1985) developed calibration curves for the Palmer-Bowles flumes. These calibration curves are within ± 10 percent of measured flow. Depth of flow in the RCP was measured using a gas-purge conoflow pressure-regulating system and a pressure transducer. Flow depth was recorded using dataloggers.

Water-Quality-Sampling Procedures

Thirty samples were collected during rainfall runoff, and five samples were collected during snowmelt runoff. Prior to sample collection, all sample-collection bottles were washed using a nonphosphate detergent and were rinsed using tap water, 1-percent hydrochloric acid solution, and pesticide-grade methanol. Initially, and after each storm was sampled, pumping-sampler-intake lines were cleaned, using the procedure just described; in addition, the lines were given a final rinse of organic-free water. Glass mason jars used for the collection of samples for bacteria analysis were sterilized using an autoclave.

Storm-runoff samples were obtained by manually collecting grab samples and by using automatic-pumping samplers. Grab samples were collected for pH, bacteria, residual chlorine, total-recoverable cyanide, oil and grease, phenols, and volatile-organic compounds. Water temperature was measured from a grab sample immediately after collection. Grab samples were collected as depth-integrated point sam-

ples and were collected using Teflon USDH-81 samplers (Federal Inter-Agency Sedimentation Project, written commun., 1992) that were equipped with 1-qt glass jars. At all sites and at all flow depths, flow in the RCP was turbulent and well mixed.

Composite samples were collected for chemical oxygen demand, biochemical oxygen demand, specific conductance, alkalinity, dissolved and suspended solids, major ions, nutrients, total-recoverable metals, acid-base/neutral organic compounds, and pesticides. Composite samples were first collected discretely using automatic-pumping samplers equipped with Teflon intake lines and four 1-gal glass bottles. The samplers were activated by the datalogger when a predetermined flow in the RCP was exceeded. After the sampler was activated, samples were collected at intervals of 5 to 30 minutes, depending on the flow in the RCP. Samples were collected until the water level in the RCP dropped below the sampler orifice. After the bottles were filled, they were capped with Teflon-lined lids, put on ice, and transported to a field laboratory for flow-weight compositing. Flow-weighted aliquots were split from the sample into a stainless-steel Teflon-lined churn, using a Teflon cone-splitter that was equipped with Teflon tubing. The aliquot needed from each discrete sample used for flow weighting was determined using an arithmetic weighting formula:

$$S_v = (QSAMP \cdot TVSR) / TQSC \quad (1)$$

where

S_v = the aliquot from a particular discrete sample;

$QSAMP$ = instantaneous flow when the particular discrete sample was collected;

$TVSR$ = the total volume of flow-weighted sample needed for processing; and

$TQSC$ = is the sum of instantaneous flows for all discrete samples from which aliquots will be drawn.

After compositing, samples were shipped to the U.S. Geological Survey National Water-Quality Laboratory in Arvada, Colorado, for analysis.

The concentration of the flow-weighted composite sample is used to represent the storm-runoff event-mean concentration. Storm-runoff load, in pounds, was computed by multiplying the event-mean concentration by the volume of storm runoff for the storm sampled and by a unit conversion constant.

Quality-Assurance Procedures

Trip blanks and field-equipment blanks were collected and analyzed for all properties and constituents to evaluate potential field contamination. Trip blanks are sample bottles filled with water devoid of any organic or inorganic constituents. Field and laboratory spikes were used to evaluate recovery and potential loss of concentration of organic compounds. Field and laboratory spikes are sample water spiked with a constituent of a known concentration.

Trip blanks were collected to evaluate any possible contamination occurring during transport of the sample from the field to the analytical laboratory. Values and concentrations in trip blanks were almost equal to or less than the analytical detection limit for all properties and constituents. Values and concentrations in field-equipment blanks were almost equal to or less than the analytical detection limits for every property and constituent except for chemical oxygen demand and total-organic carbon indicating there was little or no field contamination.

Field and laboratory spikes for organic compounds were done to evaluate potential analytical recoveries and possible degradation of constituents from the time of collection to when samples were analyzed. Average percent recoveries for volatile organic compounds were 43 percent for field spikes and 67 percent for lab spikes. The percent recoveries of less than 100 percent for the spikes indicate some loss of constituent concentration between sample collection and analysis. Average percent recoveries for acid-base/neutral organic compounds were 80 percent for field spikes and 97 percent for laboratory spikes. For pesticide compounds, average percent recoveries were 80 percent for field spikes and 82 percent for laboratory spikes. Generally, recovery of constituents was less than 100 percent, especially for volatile organic compounds. However, percent recovery was greater than 100 percent for certain constituents. This large percent recovery can be accounted for by the possible matrix effects on certain spiked concentrations and by the precision of the analytical technique used in the analysis (Mary Olsen, U.S. Geological Survey, oral commun., 1993).

WATER QUALITY OF STORM RUNOFF

Storm-runoff water-quality data were collected at sites that represent commercial (sites 1 and 5), industrial (sites 2 and 3), and residential (site 4) land uses (table 1). The water-quality properties and constituents collected can be separated into the following major categories:

1. Properties—pH, specific conductance, temperature, chemical oxygen demand, and biochemical oxygen demand,
2. Bacteria—fecal coliform and fecal streptococci,
3. Dissolved and suspended solids and major ions,
4. Nutrients—nitrogen and phosphorus,
5. Total-recoverable metals,
6. Total-organic carbon,
7. Organic compounds—volatile, acid-base/neutral, and pesticides.

Three samples were collected at each site for NPDES permitting purposes. Four additional samples were collected for selected constituents that also were collected for NPDES purposes. The additional four samples were collected to provide a large enough sample size (seven samples per site) to estimate storm-runoff loads and event-mean concentrations for selected constituents using linear-regression procedures developed using data from the NURP. These data are summarized in table 2.

Median concentrations of chemical and 5-day biochemical oxygen demand were highest for site 4 (table 2); the median concentration for chemical oxygen demand for site 4 was 330 mg/L and for 5-day biochemical oxygen demand was 86 mg/L. Storm runoff generally had a neutral pH. The median value of pH for commercial sites was 7.5, for industrial sites was 7.3, and for the residential site was 7.4. Specific conductance of storm runoff was largest for samples collected during snowmelt runoff. Median specific conductance for all samples collected during snowmelt runoff was 385 $\mu\text{S}/\text{cm}$; during rainfall runoff, the median specific conductance was 104 $\mu\text{S}/\text{cm}$. Water temperatures ranged from 0.0 (during snowmelt runoff) to 24.5°C (table 17).

The maximum counts of fecal coliform and fecal streptococci were measured at sites 1 and 4 (table 17). Median counts for all samples at sites 1 and 4 were 4,900 and 17,000 col/100 mL. However, largest median counts for bacteria were in samples from site 4 at 4,900 col/100 mL for fecal coliform and 20,500 col/100 mL for fecal streptococci.

Dissolved-solids concentrations ranged from 34 to 4,240 mg/L (table 19) for all land uses, and the range of concentrations was similar for all sites. The largest concentrations of dissolved solids were measured from snowmelt samples. The largest concentration of suspended solids, 1,400 mg/L, was measured for site 5 (table 19). The largest median concentration of suspended solids was 826 mg/L at site 5.

Samples were collected to characterize concentrations of nutrients (nitrogen and phosphorous) in storm runoff. Sites 3 and 5 had the largest median concentrations for ammonia as nitrogen and nitrate plus nitrite as nitrogen, 1.0 and 1.2 mg/L. Site 4 had the largest median concentrations for total ammonia plus organic nitrogen as nitrogen, and total and dissolved phosphorus at 3.8, 0.72, and 0.27 mg/L.

Generally, concentrations of total-recoverable metals were similar for all sites (table 19). Concentrations of total-recoverable lead were largest for sites 2 and 5 and had a median concentration of 180 µg/L. Concentrations of total-recoverable copper, nickel, and zinc were largest for sites 2 and 5 and had median concentrations of 18.0, 16.0, and 500 µg/L.

The largest median concentration of total-organic carbon was 100 mg/L at site 4. The median concentration of total-organic carbon for sites 1, 2, 3, and 5 was 52 mg/L.

Each sample collected for volatile-organic compounds (VOC) was analyzed for 61 constituents. The largest number of VOC's detected were 21 at site 4 and 31 at site 5. The number of VOC's detected, the number of samples collected, and the number of times each VOC was detected are listed for each site in table 3. Generally, volatile organic compounds were detected more often in samples collected during snowmelt runoff than in samples collected during rainfall runoff. A possible explanation for the higher number of detections of volatile organic compounds in snowmelt-runoff samples is that these samples were collected at a lower temperature than were the samples collected during rainfall runoff. Volatile organic compounds volatilize at a slower rate at the lower temperatures during snowmelt runoff. The volatile organic compounds detected generally were associated with gasoline and other petroleum products.

Each sample collected for acid-base/neutral organic compounds was analyzed for 57 constituents. The largest number of acid-base/neutral organic compounds detected was 21 at sites 1 and 3 and 26 at site 2. The number of acid-base/neutral compounds detected, the number of samples collected, and the number of times each compound was detected is listed in table 3. Except for chlordane in the sample collected at site 4 on June 12, concentrations of pesticides were less than the analytical detection limits for all samples.

PROCEDURES FOR ESTIMATING SINGLE-STORM-RUNOFF LOADS, VOLUME, AND EVENT-MEAN CONCENTRATIONS

The NPDES permitting process requires the estimation of total annual pollutant loads and event-mean concentrations for 12 properties and constituents. The

12 properties and constituents are chemical oxygen demand (COD), 5-day biochemical oxygen demand (BOD), dissolved solids (DS), suspended solids (SS), total nitrogen (TN), total ammonia plus organic nitrogen as nitrogen (TKN), total phosphorus (TP), dissolved phosphorus (DP), total-recoverable cadmium (CD), total-recoverable copper (CU), total-recoverable lead (PB), and total-recoverable zinc (ZN). In a simplistic assessment, seasonal or annual storm-runoff loads, volume, and event-mean concentrations could be estimated using mean concentrations of properties and constituents from the set of sampled storms. However, better estimates of single-storm-runoff loads and event-mean concentrations can result by using multiple-regression analysis to relate these response variables to climatic, physical, and land-use characteristics (Driver and Tasker, 1990). These regression models could be used with precipitation data and physical and land-use information to estimate single-storm-runoff loads, volume, and event-mean concentrations for individual storms at ungaged storm-runoff sites.

The form of the regression equation used for estimating single-storm-runoff loads, volume, and event-mean concentrations is a linear function of the logarithmic-transformed variables:

$$\log Y = \log B_0 + B_1 \log X_1 + B_2 \log X_2 + \dots + B_N \log X_N \quad (2)$$

Taking the antilogs, the equation becomes:

$$Y = B_0 X_1^{B_1} X_2^{B_2} \dots X_N^{B_N}, \quad (3)$$

where

- Y = estimated storm-runoff load, volume, or event-mean concentration (response variable);
- B₀, B₁, B₂, B_N = regression coefficients;
- X₁, X₂, ..., X_N = climatic, physical, or land-use variables (explanatory variables); and
- N = number of climatic, physical, and land-use variables in the regression model.

A transformation bias is produced when logarithms of the estimated mean response (log of the response variable) is retransformed (equation 3). This transformation bias usually results in the underestimation of the estimated mean response. However, the major part of this transformation bias may be eliminated by multiplying the estimated mean response by a correction factor (Duan, 1983):

$$BCF = \frac{1}{n} \sum_{i=1}^n 10^{e_i} \quad (4)$$

the calibration data set, in log units.

Single-Storm Local-Regression Models

Using data collected for 30 rainfall-runoff storms, single-storm local-regression models were developed for the Colorado Springs area for estimating storm-runoff loads for the 12 NPDES properties and constituents and for estimating storm-runoff volume and event-mean concentrations for the 12 NPDES properties and constituents. The data for 30 storms from 5 drainage basins (6 storms in each drainage basin) are listed in tables 16 and 19. Data collected for snowmelt samples (the November and December samples) were not available at the time of this analysis and, thus, were not included in the development of the local-regression models. Also, techniques for estimating storm-runoff loads, volumes, and event-mean concentrations were developed using data for rainfall-runoff conditions (Ellis and others, 1984; Driver and Tasker, 1990), and the snowmelt samples represent different hydrologic processes and need to be considered separately. The models were developed using ordinary least-squares regression, except for total-recoverable cadmium (CD). The CD data set had 11 of the 30 analyses reported as less than (censored) values. Ordinary least-squares regression should not be used with censored data. However, censored data can be included with uncensored data using tobit regression, which is similar to least-squares regression, in which the parameter estimates are fit using maximum-likelihood estimation (Helsel and Hirsch, 1992). Except for two, all CD concentrations were 3 $\mu\text{g/L}$ or less (table 19); however, the CD concentration of 21 $\mu\text{g/L}$ was not included in this analysis because it is not considered representative of storm runoff in the study area. Storm-runoff loads, volume, and event-mean concentrations (response variables) were modeled using the following climatic, physical, and land-use characteristics (explanatory variables):

1. Total rainfall (TRN), in inches,
2. Total contributing drainage-basin area (DA), in
3. Impervious area (IA), as a percent of total contributing drainage-basin area,

4. Industrial land use (LUI), as a percent of total contributing drainage-basin area,
5. Commercial land use (LUC), as a percent of total contributing drainage-basin area,
6. Residential land use (LUR), as a percent of total contributing drainage-basin area,
7. Nonurban land use (LUN), as a percent of total contributing drainage-basin area,
8. Period (in days) preceding collection of a sample having less than 0.10 in. of precipitation (DD).

The RSQUARE procedure (Statistical Analysis System Institute, Inc., 1990) was used to determine which combination of explanatory variables composed the most suitable regression model. The RSQUARE procedure performs all possible linear regressions for all possible combinations of explanatory variables and determines the subsets of explanatory variables that have the largest r^2 value (Statistical Analysis System Institute, Inc., 1990). For the models to have a hydrologic and physiographic basis, only subset regression models including the explanatory variables TRN and DA were evaluated. The most suitable regression model was selected on the basis of the statistical significance of explanatory variables in the regression, the values of r^2 , and checked using other model selection criteria (Statistical Analysis System Institute, Inc., 1990). An r^2 value is the proportion of the total variation of the response variable that is explained by the explanatory variables. For certain properties and constituents, all of the possible regressions included explanatory variables that were not significant at the 5-percent confidence level. Therefore, some regression models that were selected as the most suitable included explanatory variables that were not significant at the 5-percent confidence level (tables 4 and 5). However, inclusion of these variables in the models improved the computed r^2 and were considered useful predictors of the dependent variables. For event-mean concentrations for BOD, the local-regression model was not significant at the 5-percent confidence level (table 5). For evaluating all possible regression models (RSQUARE procedure) for storm-runoff loads and for event-mean concentrations for CD, only uncensored data were used (19 of the 30 values for CD were uncensored).

Plots of residual (observed values minus estimated values) compared to estimated values were analyzed to evaluate the constant variance (homoscedasticity) of the residuals. Residual plots for all of the most suitable models indicate that the variance of the residuals generally is constant throughout the entire

range of prediction. Because hydrologic data usually are skewed when using parametric statistical techniques, such as RSQUARE, data need to be transformed to minimize the heteroscedasticity of residuals and to linearize the x,y relation. Response and explanatory variables used in the RSQUARE procedure were log transformed (base 10).

The local-regression models for storm-runoff loads, volume, and event-mean concentrations and the corresponding BCF, r^2 values, and the standard error of estimate are listed in tables 4 and 5. The standard error of estimate is an estimate of the standard deviation about the regression. The smaller the standard error of estimate, the more precise will be the predictions (Driver and Tasker, 1990). The standard error of estimate, in percent, was calculated for all the local-regression models using the following equation (Driver and Tasker, 1990):

$$SE = 100 \{ [e^{(mse \times 5.302)} - 1] \}^{0.5} \quad (5)$$

where

SE = the standard error of estimate, in percent;

mse = the mean square error, in log (base 10) units; and

5.302 = the square of the conversion of log base-10 values to natural logs.

The values of r^2 that use ordinary least-squares regression ranged from 0.57 to 0.86 for storm-runoff loads and volume (table 4) and from 0.25 to 0.63 for storm-runoff event-mean concentrations (table 5). Except for CD, standard errors of estimate range from 43 to 115 percent for storm-runoff loads and volume and 32 to 66 percent for storm-runoff event-mean concentrations (tables 4 and 5). Standard errors of estimate for storm-runoff load and event-mean concentration for CD were 247 (table 4) and 171 percent (table 5). The accuracy of the load, volume, and concentration models cannot be compared on the basis of standard error of estimate because the units of the response variable for each model are different (Hoos and Sisolak, 1993).

The explanatory variables generally had signs (positive or negative) that were hydrologically logical. However, occasionally, the signs on individual explanatory variables seem to be counter intuitive. Driver and Tasker (1990) list the following explanations for why the signs of some regression coefficients (explanatory variables) may be counter intuitive:

1. Significant cross-correlation between explanatory variables causes multicollinearity problems in the local-regression models, however, this is accounted for in the RSQUARE procedure.

2. The process involving the effect of the explanatory variables on the water-quality constituent is not well understood.
3. The explanatory variable is a surrogate for another variable.
4. The apparent significance of an explanatory variable may be due to chance and, therefore, the relation may be spurious.

Use of the local-regression models listed in tables 4 and 5 need to be limited to the ranges of climatic, physical, and land-use (explanatory) variables listed in table 6. If values outside these ranges are used in the local-regression models, the standard errors may be considerably larger than the values reported in tables 4 and 5. As the local-regression models are applied to drainage-basin areas and to storms larger than the average drainage-basin area or storm volume of the observation sites, the accuracy of estimates of storm-runoff loads, volume, and event-mean concentrations decreases.

Single-Storm Regional-Regression Models

Procedures for estimating single-storm runoff loads, volume, and event-mean concentrations were developed by Ellis and others (1984) and Driver and Tasker (1990) for 11 of the 12 properties and constituents required for the permitting process. Regional-regression equations for BOD were not developed. Linear-regression equations were developed from data collected by the NURP. Equations developed by Ellis and others (1984) were developed using NURP data collected in the Denver metropolitan area. The Driver and Tasker (1990) equations were developed from the NURP data base and include sets of equations for three geographically distinct regions delineated by mean annual rainfall. The Colorado Springs area is included in Region 1. Comparison of estimates from these regional-regression models with observed storm-runoff loads, volume, and event-mean concentrations for samples collected in the study area will be useful in selecting the most appropriate method for estimating single-storm runoff loads, volume, and event-mean concentrations.

regression models were compared to observed values from data collected at five sites in the study area in 1992 (fig. 1, table 1). The response variables estimated by Driver and Tasker (1990) are storm-runoff loads for COD, SS, DS, TN, TKN, TP, DP, CD, CU, PB, and ZN; storm-runoff volume, and event-mean concentrations for COD, SS, DS, TN, TKN, TP, DP, CD, CU, PB, and ZN. The response variables estimated by Ellis and others (1984) are storm-runoff loads for COD, SS, TN, TP, PB, and ZN and storm-runoff volume. Driver and Tasker (1990) developed two sets of single-storm regional-regression models for storm-runoff loads and volume. The first set of models was based on a stepwise regression analysis of 13 explanatory variables including TRN, DA, IA, land-use, and regional climatic variables. The second set of models was based on three explanatory variables—TRN, DA, and IA. The single-storm regional-regression models for storm-runoff event-mean concentrations are based on stepwise regression analysis of the same 13 explanatory variables used to develop models for storm-runoff load and volume. Single-storm regional-regression models developed by Ellis and others (1984) for storm-runoff loads and volume were based on three explanatory variables—TRN, DA, and IA.

Comparisons of observed and estimated storm-runoff loads, volume, and event-mean concentrations were made using the root-mean-square error (RMSE) of estimate from the equation:

$$RMSE = \left[\frac{1}{n} \sum_{i=1}^n (\log O_i - \log E_i)^2 \right]^{\frac{1}{2}} \quad (6)$$

where

RMSE = the root-mean-square error in log units (base 10);

O_i = *i*th observed value;

E_i = *i*th estimated value from the regional-regression model; and

n = the number of observations in the data set.

Generally, when compared to observed values, the 3-variable models that were developed by Driver and Tasker (1990) for estimating storm-runoff loads had the smallest RMSE (table 7). For estimates of storm-runoff volume, when compared to observed values, the multivariate model developed by Driver and Tasker (1990) had the smaller RMSE (table 7).

An evaluation of residuals from a comparison of observed and estimated storm-runoff loads, volume, and event-mean concentrations can be used to determine the direction of bias of estimated values compared to observed values. Compared to observed values, most regional-regression models tended to overestimate (negative sign in table 8) storm-runoff loads, volume, and event-mean concentrations. However, the direction of bias was not consistent for all properties and constituents and runoff volume (table 8).

R0024103

Differences between the observed and estimated storm-runoff loads, volume, and event-mean concentrations can be explained by the following:

1. Hydrologic conditions controlling the detection of properties and constituents specific to Colorado Springs are not explained by the Driver and Tasker (1990) models.
2. Data collected for certain properties and constituents for the NURP studies might not be representative of the Colorado Springs area.
3. Regional-regression models were developed using a larger range of drainage-basin areas than the drainage-basin areas used for this study (tables 1 and 6). Therefore, regional-regression models might be biased and might be overestimating storm-runoff loads, volume, and event-mean concentrations for smaller drainage basins.

Procedures for Adjustment of Estimates from Single-Storm Regional-Regression Models Using Local Data

When compared to observed data, single-storm regional-regression models tended to overestimate storm-runoff loads, volume, and event-mean concentrations. As a result, single-storm local-regression models would be the preferred method for estimating storm-runoff loads, volume, and event-mean concentrations because the single-storm local-regression models were developed using local data based on the climatic, physical, and land-use characteristics of the Colorado Springs area. However, only a small number of observations (30--snowmelt samples not included) were available for the development of the single-storm local-regression models, and the use of the single-storm local-regression models need to be limited to estimates within the ranges of the explanatory variables used to develop the model (table 6). Single-storm regional-regression models are based on a large number of observations (65 to 348), and the explanatory variables have a wider range than the explanatory vari-

¹Computed using uncensored data.

ables used in the single-storm local-regression models (table 6). It would be useful if single-storm local- and regional-regression models could be combined to take advantage of the strengths of both regression models while minimizing the respective deficiencies of the regression models.

Hoos (1991) presented a procedure to adjust single-storm regional-regression models using local data. Hoos and Sisolak (1993) evaluated different model-adjustment procedures (MAP's) and established criteria for selecting the appropriate MAP. The MAP is in the form of a regression analysis. Local data are used as the calibration data set. In one MAP (MAP-R-P), log-transformed local (observed) data (response variables) are regressed against the log-transformed estimates from the single-storm regional-regression models (explanatory variables). The resulting equations are the adjusted regression models used to predict storm-runoff loads, volume, or event-mean concentrations at an unmonitored site. Another form of MAP (MAP-W) is simply the weighting of log-transformed estimates from

local- and regional-regression models. The equations for the two MAPs for adjusting the regional-regression equations are Hoos and Sisolak, (1993):

1. MAP-R-P calibration equation:

$$\log O_i = \log B_o + B_1 \log R_{Ei} \quad (7)$$

where

- O_i = the observed value of storm-runoff load, volume, or event-mean concentration at site i ;
- B_o and B_1 = coefficients fitted from a simple linear-regression analysis of the calibration data set (observed data); and
- R_{Ei} = the regional estimate; estimated value of storm-runoff load, runoff volume, or event-mean concentration from the unadjusted single-storm regional-regression model at site i .

The adjusted regional-regression model (from the detransformation of eq. 7) is then:

$$AR_{Ei} = B_o R_{Ei}^{B1} \text{ (BCF)} \quad (8)$$

where

AR_{Ei} = the adjusted single-storm regional-regression estimate.

2. MAP-W calibration equation:

$$\log O_i = \{ (J \times \log RE) [(1-J) \times \log LOC] \} \quad (9)$$

where

$$J = \{ (SE_{loc}^2) / [(SE_{loc}^2) + (SE_{reg}^2)] \} \quad (10)$$

where

SE_{loc} = the standard error of estimate, in log units for the single-storm local-regression model;

SE_{reg} = the standard error of estimate, in log units as reported in Driver and Tasker (1990) for the single-storm regional-regression model; and

LOC = estimated value from the single-storm local-regression equation.

The weighted single-storm regional-regression model (the detransformation of eq. 10) then is:

$$WE = \{ (RE^J) \times (LOC^{(1-J)}) \} \times BCF, \quad (11)$$

where

WE = adjusted (weighted) single-storm regional-regression estimate.

Selection of the appropriate MAP needs to be made based on whether or not observed and estimated data are correlated and on if there is a consistent bias between the local-data (observed) and estimated-data pairs (fig. 2, step 3). Correlation between observed and estimated data was evaluated by analyzing the significance of Spearman's rho (Iman and Conover, 1983), and bias was determined using the signed-rank test on the paired data (Iman and Conover, 1983). If the null hypothesis (a significant correlation does not exist between observed and estimated values or a consistent bias does not exist between observed and estimated values) for either test is not rejected at a selected level of significance, then correlation between observed data and explanatory variables is determined by examining correlation coefficients, r^2 (fig. 2, step 4) (Hoos and Sisolak, 1993).

After evaluating Spearman's rho and the signed-rank test for the Colorado Springs data set, the appropriate MAPs were selected for adjusting the regional-regression models using local data based on the flow chart in figure 2. The RMSE was large for all comparisons between observed values and values estimated using single-storm regional-regression equations (tables 7, 9, and 10). Because observed values and estimated values from single-storm regional-regression equations were highly correlated and had a consistent direction of bias, MAP-R-P (fig. 2, steps 2 and 3) was selected for adjusting storm-runoff-load equations for TN, TKN, TP, DP, CU, and PB and for adjusting the storm-runoff event-mean concentration equations for TP, CU, and PB. Observed and estimated values for the remaining storm-runoff loads and event-mean concentrations of the remaining constituents were not highly correlated or did not have a consistent direction of bias, or both; however, the remaining observed values were significantly correlated with some explanatory variables. Therefore, MAP-W (fig. 2, step 3) was selected for adjusting storm-runoff-load equations for COD, DS, SS, CD, and ZN; for adjusting equations for estimating volume of runoff; and for adjusting event-mean concentration equations for COD, DS, SS, TN, TKN, DP, CD, and ZN.

When compared to observed storm-runoff loads and volume, the three-variable single-storm regional-regression models for storm-runoff loads and the multivariate single-storm regional-regression models for storm-runoff volume that were developed by Driver and Tasker (1990) had the smallest RMSE of all of the single-storm regional-regression models tested. These models and the 13-variable single-storm regional-regression models for event-mean concentration were adjusted using MAPs.

The MAP's decreased model error in estimating storm-runoff loads, volume, and event-mean concentrations, except for the equation for event-mean concentration for CD. Reduction of error, in percent, ranged from -1,980 to -10 percent (based on data in tables 9 and 10). The effect of MAP's on estimated storm-runoff loads and event-mean concentrations can be illustrated by plotting observed values, estimates from regional-regression models, and estimates from regional-regression models adjusted using MAPs. Two examples from site 2 are presented, one for each MAP—MAP-R-P (TP) and MAP-W (TKN) (figs. 3 and 4). In both cases, the estimates of storm-runoff load and event-mean concentration obtained using MAP-R-P (fig. 3) and MAP-W (fig. 4) were closer to the observed value than the estimate from the regional-regression equation. Adjusted models, developed using MAP-R-P and MAP W, for estimating storm-runoff loads, volume, and event-mean concentrations are listed in tables 11 and 12.

ESTIMATES OF A MEAN LOAD FOR A STORM

In addition to developing single-storm regional-regression models for storm-runoff loads, volume, and event-mean concentrations, Driver and Tasker (1990) developed regression models for estimating the mean load for a storm, hereafter called mean load. Mean load is the estimate of mean load for a particular drainage basin. With the estimate of mean load, seasonal or annual loads for a particular drainage basin can be estimated by multiplying the mean load by the average number of storms for the season or year. Regression models for estimating mean load were based on drainage-basin area, percent of impervious area, mean annual rainfall, mean minimum January temperature, and a variable (dummy variable) indicating whether commercial and industrial land uses exceeded or did not exceed 75 percent of the drainage-basin area (Driver and Tasker, 1990). Regression models for estimating mean load were developed for COD, DS, SS, TN, TKN, TP, DP, CU, PB, and ZN. These regression models were developed from the NURP data base and are based on rain storms. The range of explanatory variables used in the regression models for estimating mean load are listed in table 13. In general, use of the models to estimate mean load at sites that have characteristics much beyond the range of values listed in

table 13 need to be avoided (Driver and Tasker, 1990). Using the Driver and Tasker (1990) models, mean loads were estimated for COD, DS, SS, TN, TKN, TP, DP, CU, PB, and ZN for sites 1 through 5. A 90-percent confidence interval was computed for each mean load of a storm estimated using the models from Driver and Tasker (1990) (table 14). For example, there is a 90-percent confidence level that the true mean load for TP for all storms at site 1 lies between 0.06 and 0.87 lb (table 14). Confidence intervals were not computed for single-storm regression models because matrix information was unavailable.

Estimated mean loads from the Driver and Tasker (1990) models (MLDT) were compared to mean loads estimated for 1992, based on daily mean water discharge and land-use characteristics, hereafter referred to as MLDWD, and on loads that are the mean storm-runoff load of the six storms sampled at each of the five sites in 1992 (table 14).

Linear regression was used for estimating mean loads based on daily mean water discharge. The most suitable regression models for estimating mean load from daily mean water discharge were selected using the procedures described in the section "Single-Storm Local-Regression Models." Values of r^2 ranged from 0.59 to 0.84, and standard error of estimate, in percent, for the regression models, ranged from 45 to 93 (table 15).

R0024114

Records of daily mean water discharge were collected at all sites from about June 1 to December 6, 1992. For periods of missing record, daily mean water discharge was estimated using the following equation:

$$DMWD = 19,941 TRN^{1.08} LUI^{-1.26} LUC^{-0.98} LUR^{-1.78} \quad (12)$$

where

DMWD = daily mean water discharge, in cubic feet per second;

TRN = total rainfall, in inches;

LUI = industrial land use, in percent;

LUC = commercial land use, in percent; and

LUR = residential land use in percent.

For this equation, the value of r^2 was 0.77, and the standard error of estimate was 78 percent.

Generally, MLDWD were within the 90-percent confidence intervals of MLDT (table 14). However, estimates of COD, DS, SS, and CU, at selected sites were not within the 90-percent confidence intervals from Driver and Tasker (1990) mean load equations. At sites 1, 2, and 5, estimates of MLDWD for COD exceeded the upper 90-percent confidence interval (table 14); and at sites 1 and 2, MLDWD for SS exceeded the upper 90-percent confidence limit (table 14). At sites 3 and 4, estimates of MLDWD for DS and CU were less than the 90-percent confidence interval, and at site 2, estimates of mean load based on daily mean water discharge for ZN exceeded the upper 90-percent confidence interval (table 14).

At all sites, estimates of MLDWD for COD and SS were larger than MLDT (table 14). At all sites, estimates of MLDWD for DS, TN, and CU were less than MLDT (table 14). Estimates of MLDWD for TKN, TP, DP, PB, and ZN based on daily mean water discharge when compared to MLDT had no consistent direction of bias (table 14).

Differences between the two types of estimates of mean load may be explained by the following:

1. Hydrologic conditions controlling the occurrence of properties and constituents, especially COD and SS, that are specific to Colorado Springs are not accounted for in the Driver and Tasker (1990) models.
2. Data collected for certain properties and constituents for the NURP studies may not be representative of the Colorado Springs area.

Generally, the mean load of six storms at each site was within the 90-percent confidence interval of the Driver and Tasker (1990) mean load equations (table 14). The mean load of the six storms exceeded

the upper 90-percent confidence interval for COD and SS at site 1 (table 14). The mean load of the six storms was less than the lower 90-percent confidence interval for DS at sites 2, 3, 4, and 5; for CU at sites 3, 4, and 5; and for PB at site 3 (table 14).

The mean load of the six storms at each site compared well with the estimates derived using the Driver and Tasker (1990) mean load equations. However, these mean loads represent only 6 storms, whereas the Driver and Tasker (1990) models were developed using between 200 and 1,000 storms that represent drainage basins having a wider range of drainage-basin area and percent impervious area (table 6). Therefore, the Driver and Tasker (1990) mean load equations might provide a better estimate of annual and seasonal loads for engaged drainage basins in Colorado Springs.

COMPARISON OF PROCEDURES FOR ESTIMATING STORM-RUNOFF LOADS, VOLUMES, EVENT-MEAN CONCENTRATIONS, AND THE MEAN LOAD FOR A STORM

Various procedures for estimating storm-runoff loads, volume, and event-mean concentrations have been discussed in this report. The following is a more concise comparison of the value and limitations of these procedures. The procedures discussed include:

1. Single-storm local-regression models for storm-runoff loads, volume, and event-mean concentration (tables 4 and 5).
2. Single-storm regional-regression models for storm-runoff loads, volume, and event-mean concentration (Ellis and others, 1984; Driver and Tasker, 1990).
3. Adjustment of single-storm regional-regression models for storm-runoff loads, volume, and event-mean concentration using local data (tables 11 and 12) (Hoos and Sisolak, 1993).
4. Estimates of mean load (table 14).

The use of single-storm local-regression models needs to be limited to the ranges of explanatory variables (table 6) used to develop the model. If values outside these ranges are used in the single-storm local-regression models, the standard errors may be considerably larger than the values reported in tables 4 and 5. As the single-storm local-regression models are applied to drainage-basin areas and to storm volumes larger than the values from the observation sites, the accuracy of estimates of storm-runoff loads, volume, and event-mean concentrations decreases.

Single-storm regional-regression models were developed using explanatory variables that have a wider range than the single-storm local-regression models (table 6). When compared to observed data, single-storm regional-regression models tended to overestimate storm-runoff loads, volumes, and event-mean concentrations (table 8). Model adjustment procedures (MAPs), which use local data to decrease the model error, were applied to selected single-storm regional-regression models. The MAPs decreased model error in estimating storm-runoff loads, volume, and event-mean concentrations—model error decreased from -1,980 to -10 percent (based on data in tables 9 and 10).

A prediction of annual or seasonal storm-runoff loads, volume, and event-mean concentration at an unmonitored site can be obtained by applying the single-storm models described to a series of storms and producing a synthetic record of storm loads and volume. Values of storm characteristics used as explanatory variables listed in table 6 and in Ellis and others (1984) and Driver and Tasker (1990) may be determined for a series of storms from the long-term rainfall record for a station near an unmonitored site. The synthesized record of storm loads may be reduced to an estimate of mean annual or mean seasonal load by summing loads from each storm, then dividing by the number of years in the period of the synthetic record.

The mean load estimated for individual sites for selected constituents generally compared well to mean load estimated based on daily mean water discharge and land-use characteristics and to the mean load of six storms, for each site, sampled in 1992 (table 14). The use of the mean load procedure should be limited to the range of values of variables used to develop the models (table 13). However, the mean load procedure can be applied to larger drainage basins by dividing the drainage basin into segments that fall into the range of drainage-basin areas used to develop the mean load model and computing the mean load for each drainage-basin segment. The mean load for the drainage basin would be the sum of the loads computed for each drainage-basin segment. Annual or seasonal loads could be computed by multiplying the estimated mean load by the average, or total for a specific year, number of storms for a drainage basin.

SUMMARY

The U.S. Environmental Protection Agency requires that municipalities that have a population of 100,000 or greater obtain National Pollutant Discharge Elimination System permits to control the quality of storm runoff. In 1992, the U.S. Geological Survey, in cooperation with the Colorado Springs City Engineer-

ing Division, began a study to characterize the water quality of storm runoff and to compare techniques for the estimation of storm-runoff loads, volume, and event-mean concentrations for selected properties and constituents.

Precipitation, streamflow, and water-quality data were collected during 1992 at five sites in Colorado Springs. Thirty-five samples were collected, seven at each of the five sites. At each site, three samples were collected for National Pollutant Discharge Elimination System permitting purposes; two of the samples were collected during rainfall runoff, and one sample was collected during snowmelt runoff. Four additional samples were collected at each site to obtain a large enough sample size to estimate storm-runoff loads, volume, and event-mean concentrations for selected properties and constituents using linear-regression procedures developed using data from the Nationwide Urban Runoff Program (NURP). Storm-water samples were analyzed for as many as 186 properties and constituents. Some of the properties and constituents measured include pH, specific conductance, water temperature, chemical oxygen demand, biochemical oxygen demand, bacteria, dissolved and suspended solids, major ions, nutrients, residual chlorine, total-recoverable metals, oil and grease, phenols, volatile-organic compounds, acid-base/neutral organic compounds and pesticides.

Storm runoff sampled had large concentrations of chemical oxygen demand and 5-day biochemical oxygen demand. Chemical oxygen demand ranged from 100 to 830 mg/L, and 5-day biochemical oxygen demand ranged from 14 to 260 mg/L. Total-organic carbon concentrations ranged from 18 to 240 mg/L. The total-recoverable metals lead and zinc had the largest concentrations of the total-recoverable metals analyzed. Concentrations of lead ranged from 23 to 350 $\mu\text{g/L}$, and concentrations of zinc ranged from 110 to 1,400 $\mu\text{g/L}$.

Single-storm local-regression models for estimating storm-runoff loads, volume, and event-mean concentrations were developed. Results from these models and observed values for storm-runoff loads, volume, and event-mean concentrations are compared with the results from regional-regression models developed from the Nationwide Urban Runoff Program for the purposes of determining which regression models provide the best estimates of storm-runoff loads, volume, and event-mean concentrations.

Single-storm local-regression models were developed for estimating storm-runoff loads and event-mean concentrations for the 12 National Pollutant Discharge Elimination System properties and constituents and for estimating storm-runoff volume. The data for

30 storms representing rainfall runoff from 5 drainage basins were used in this analysis. Except for total-recoverable cadmium, the models were developed using ordinary least-squares regression. Because some cadmium concentrations were censored (less than values), tobit regression, which is similar to ordinary least-squares regression, was used to estimate storm-runoff load and event-mean concentration for total-recoverable cadmium. The response variables, which are storm-runoff loads, volume, and event-mean concentrations, were modeled using climatic, physical, and land-use characteristics.

The values of r^2 for models that use ordinary least-squares regression ranged from 0.57 to 0.86 for storm-runoff loads and volume and from 0.25 to 0.63 for storm-runoff event-mean concentrations. Standard errors of estimate ranged from 43 to 115 percent for storm-runoff loads and volume and from 32 to 66 percent for storm-runoff event-mean concentrations. Standard errors of estimate for storm-runoff load and event-mean concentration for total-recoverable cadmium were 247 and 171 percent.

Single-storm linear-regression models for estimating storm-runoff loads, volume, and event-mean concentrations were developed for 11 of the 12 properties and constituents required for the National Pollutant Discharge Elimination System permitting process. Regional-regression equations for BOD were not developed. Linear-regression equations were developed from data collected by the NURP. Equations were developed from the NURP data base and include sets of equations for three geographically distinct regions delineated by mean annual rainfall. The Colorado Springs area is included in Region I. Estimates from these regression models were compared with observed storm-runoff loads, volume, and event-mean concentrations from samples collected in the study area.

Single-storm regional-regression models tended to overestimate storm-runoff loads, volume, and event-mean concentrations observed at the five Colorado Springs sites. Because regression models developed using local data are based on the climatic, physical, and land-use characteristics of the Colorado Springs area, single-storm local-regression models would be the preferred method for estimating storm-runoff loads, volume, and event-mean concentrations. As a result, single-storm local-regression models would be the preferred method for estimating storm-runoff loads, volume, and event-mean concentrations because the single-storm local-regression models were developed using local data based on the climatic, physical, and land-use characteristics of the Colorado Springs area. However, only a small number of observations (30) were available for the development of the single-storm

local-regression models, and the use of the single-storm local-regression models needs to be limited to estimations within the ranges of the explanatory variables used to develop the model. Although the single-storm regional-regression models tended to overestimate storm-runoff loads, volume, and event-mean concentrations, these single-storm regional-regression models are based on a large number of observations (65 to 348), and the explanatory variables have a wider range than the explanatory variables used in the single-storm local-regression models. Single-storm local- and regional-regression models were combined using model-adjustment procedures to take advantage of the strengths of both models while minimizing the respective deficiencies of the models.

When compared to observed storm-runoff loads and volume, the adjusted three-variable single-storm regional-regression models for storm-runoff loads and the multivariate regional-regression model for volume of runoff had the smallest root-mean-squared error of all of the single-storm regional-regression models tested. These models and the single-storm regional-regression models for event-mean concentration were adjusted using model-adjustment procedures.

Except for the equation for event-mean concentration of total-recoverable cadmium, all model-adjustment procedures decreased the error for models estimating storm-runoff loads, volume, and event-mean concentrations. Reduction of standard error, in percent, ranged from -1,980 to -10 percent.

In addition to developing single-storm regional-regression models for storm-runoff loads, volume, and event-mean concentrations, regression models for estimating mean load for a storm were developed for ten of the National Pollutant Discharge Elimination System properties and constituents. With the estimate of the mean load, seasonal or annual loads can be estimated by multiplying the mean load by the mean number of storms for the season or year. These regression models were developed from the NURP data base and are based on rain storms.

Mean loads were estimated for ten of the National Pollutant Discharge Elimination System properties and constituents for sites 1 through 5. Estimated mean loads from the regional-regression equations were compared to mean loads estimated for 1992, based on daily mean water discharge, and on loads that are the mean storm-runoff load of the six storms sampled at each of the five sites in 1992.

Except for selected estimates of chemical oxygen demand, dissolved solids, suspended solids, and total-recoverable copper, mean loads based on daily mean water discharge were within the 90-percent confidence interval of results from the mean load equa-

34 Water Quality of Storm Runoff and Comparison of Procedures for Estimating Storm-Runoff Loads, Volume, Event-Mean Concentrations, and the Mean Load for a Storm for Selected Properties and Constituents for Colorado Springs, Southeastern Colorado, 1992

tions. At sites 1, 2, and 5, estimates of mean load based on daily mean water discharge for chemical oxygen demand, and at sites 1 and 2, estimates of mean load based on daily mean water discharge for suspended solids exceeded the upper 90-percent confidence intervals. At sites 3 and 4, estimates of mean load based on daily mean water discharge for dissolved solids and total-recoverable copper were less than the 90-percent confidence interval.

At all sites, estimates of mean load based on daily mean water discharge for chemical oxygen demand and suspended solids were larger than mean loads estimated by the mean load equations. At all sites, estimates of mean load based on daily mean water discharge for dissolved solids, total nitrogen, and total-recoverable copper were smaller than mean loads estimated by the equations. Estimates of mean load for total ammonia plus organic nitrogen as nitrogen, total phosphorus, dissolved phosphorus, total-recoverable lead, and total-recoverable zinc based on daily mean water discharge when compared to mean loads estimated by the mean load equations had no consistent direction of bias. Generally, the mean load of six storms was within the 90-percent confidence interval of the mean load equations. The mean load of the six storms for each site exceeded the upper 90-percent confidence interval for chemical oxygen demand and suspended solids at site 1. The mean load of the six storms was less than the lower 90-percent confidence interval for dissolved solids at sites 2, 3, 4, and 5; for total-recoverable copper at sites 3, 4, and 5; and for total-recoverable lead at site 3.

The mean load of the six storms at each site compared well with the estimates derived using the mean load equations. However, these mean loads represent only 6 storms, whereas the equations were developed using between 200 and 1,000 storms that represent drainage basins having a wider range of drainage-basin area and percent impervious area. Therefore, the mean load equations might provide a better estimate of mean loads, and hence annual and seasonal load, for ungaged drainage basins in Colorado Springs.

May 29, 2001	Steve McAuley, Project Chief	(412) 490-3801	(412) 490-3828
	Robert Anderson, Biologist	(412) 490-3810	

Water quality in the Allegheny and Monongahela River Basins is generally good – with some exceptions

Stream and groundwater quality in many areas of the Allegheny and Monongahela River Basins is improving and is, in many respects, better than or comparable to what is found nationally, according to the results of a 5-year investigation by the U.S. Geological Survey (USGS).

“The quality of rivers around Pittsburgh has really improved in the last 20 years, especially for fish,” said USGS biologist and principal author, Robert Anderson. “A lot of people still think of these rivers as polluted as they were in the 1960’s, but if someone wanted to go fishing for bass or walleye, they could do very well right in downtown Pittsburgh.”

Compliance with regulations that control water discharged from active coal mines has been a factor in the improvement. In addition, government agency and citizens groups have been very active in focusing funding and energy on treatment of water from abandoned coal mines in Pennsylvania, West Virginia, New York, and Maryland.

“Coal mining remains the largest single factor affecting water quality in a large part of the Allegheny and Monongahela River Basins,” said Steve McAuley, Project Chief. “We are not seeing new sources of highly acidic discharges but the water leaving coal mines does differ from water in unmined areas.” Where treatment has not occurred, the water is generally acidic (low pH), and contains elevated concentrations of metals and sulfate. Sulfate concentrations are five times greater in streams draining mined areas than in streams draining unmined areas. In addition, the diversity and abundance of aquatic organisms remain reduced in comparison to areas where there has been no coal mining. These results are based on well and stream samples from more than 180 sites in the coal-bearing region.

The region’s water quality is influenced by more than coal mining. Past pollution still lingers in the form of PCBs, chlordane, and DDT. The use of these compounds has been prohibited for two decades but they remain in fish tissue samples and in river sediments. For example, PCB’s were detected in 43 percent of the total stream sediment and fish samples tested.

Mixtures of currently used pesticides were detected in some agricultural and urban streams and well water. Concentrations of the individual compounds were usually lower than guidelines for drinking water or protection of aquatic life. The potential risk, however, can only be partially

addressed because standards and guidelines are not available for all measured compounds, and they do not consider exposure to mixtures of chemicals.

"Some areas in the Allegheny and Monongahela River Basins appear to be of much better quality than the national average. The amount and types of life living in some forested and agricultural areas are among the most diverse in the Nation," said Anderson, "which is something to be proud of."

Copies of the 38-page, color report, "Water Quality in the Allegheny and Monongahela River Basins, 1996-98," by Robert M. Anderson, Kevin M. Beer, Theodore F. Buckwalter, Mary E. Clark, Steven D. McAuley, James I. Sams, III, and Donald R. Williams, published as USGS Circular 1202, are available free of charge from the USGS Branch of Information Services, Box 25286, Denver Federal Center, Denver, CO 80225. (303) 202-4700 (fax request to (303) 202-4693). The Circular may be viewed on the World Wide Web at <http://water.usgs.gov/nawqa>.

This assessment is part of the National Water Quality Assessment (NAWQA) Program conducted by USGS investigating water-quality conditions in more than 50 major river basins and aquifers. This program is currently releasing results on surface and ground water in 15 additional major river basins. Access the individual basin reports on the NAWQA website, in addition to other NAWQA publications and national data sets and maps.

Further detail on the effects of coal mining in the Allegheny and Monongahela River Basins can be obtained in USGS Water-Resources Investigations Report 99-4208, "Effects of Coal-Mine Drainage on Stream Water Quality in the Allegheny and Monongahela River Basins – Sulfate Transport and Trends," by James I. Sams, III, and Kevin M. Beer, and in Water-Resources Investigations Report 98-4258, "Stream Water Quality in Coal Mined Areas of the Lower Cheat River Basin, West Virginia and Pennsylvania, During Low-Flow Conditions, July 1997," by Donald R. Williams, Mary E. Clark, and Julianne Brown.

Further detail regarding pesticides and nutrients can be obtained from Water-Resources Investigations Report 00-4061, "Nutrients and Organic Compounds in Deer Creek and South Branch Plum Creek in Southwestern Pennsylvania, April 1996 through September 1998," by Donald R. Williams and Mary E. Clark. These reports are available on the web at http://pa.water.usgs.gov/pa_pubs.html. A limited supply is available at the USGS office in New Cumberland at 215 Limekiln Road, New Cumberland, Pennsylvania 17070; telephone (717) 730-6916 and the USGS office in Pittsburgh at 1000 Church Hill Road, Suite 200, Pittsburgh, Pennsylvania 15205; telephone (412) 490-3800.

As the nation's largest water, earth, and biological science and civilian mapping agency, the USGS works in cooperation with more than 2,000 organizations across the country to provide reliable, impartial, scientific information to resource managers, planners, and other customers. This information is gathered in every state by USGS scientists to minimize the loss of life and property from natural disasters, contribute to the sound conservation, economic and physical development of the Nation's natural resources, and enhance the quality of life by monitoring water, biological, energy, and mineral resources.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM	IV
SUMMARY OF MAJOR FINDINGS	1
Stream and river highlights	1
Ground-water highlights	2
INTRODUCTION TO THE ALLEGHENY AND MONONGAHELA RIVER BASINS	3
MAJOR FINDINGS	5
Coal mining dominates water quality	5
Sulfate is an indicator of coal-mining activity	6
Aquatic communities are affected in streams receiving large amounts of mine drainage	7
NATIONAL PERSPECTIVE—Invertebrate index status is among the best in the Nation in forested settings	8
Ground-water quality is affected near mined areas	9
Concentrations of trace elements in bed sediment exceed aquatic-life guidelines	9
NATIONAL PERSPECTIVE—Trace elements may limit aquatic life in urban streams and mined areas	10
Water quality of the large rivers of the Allegheny and Monongahela River Basins is improving	10
Persistent pesticides and PCBs were more prevalent in fish tissue than in sediment	11
Low concentrations of numerous pesticides were detected in an agricultural stream and an urban stream	12
Pesticides are at low concentrations when detected in ground water	13
NATIONAL PERSPECTIVE—Pesticides in the Allegheny and Monongahela River Basins are similar to those found nationally	15
Volatile organic compounds were detected at low concentrations in an urban stream	15
Low levels of volatile organic compounds were detected in most domestic wells sampled	16
Nitrate is common in streams and ground water	17
Radon in ground water is common but highly variable	19
REGIONAL STUDIES: Sulfate concentrations and biological communities in Appalachian coal areas indicate mining-related disturbances despite a general water-quality improvement between 1980 and 1998	20
Water-quality characteristics targeted by SMCRA improved in streams, but sulfate and metals remain high at some sites	20
Invertebrate-community impairment appears related to amount of mining	21
Sulfate and some metal concentrations were higher in ground water near surface coal mines	21
STUDY UNIT DESIGN	22
GLOSSARY	24

APPENDIX—WATER-QUALITY DATA FROM THE ALLEGHENY AND MONONGAHELA RIVER BASINS IN A NATIONAL CONTEXT	27

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Allegheny and Monongahela River Basins that emerged from an assessment conducted between 1996 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Allegheny and Monongahela River Basins assessment. Study-area residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

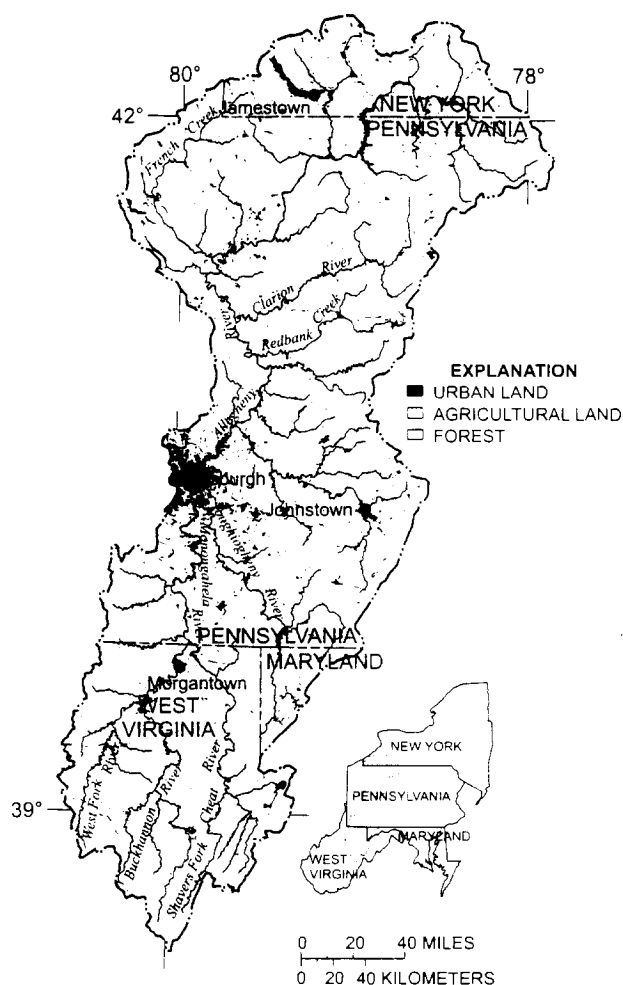

The Allegheny and Monongahela River Basins are one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Stream and River Highlights

Streams and rivers in the Allegheny and Monongahela River Basins range from those of high quality that support diverse aquatic life to those that are seriously degraded and support few aquatic species and few human uses of the water. Higher quality stream reaches are generally in the northern one-third of the study area and in mountainous areas in eastern sections. These areas are dominated by forest, low-intensity agriculture, and rural communities. Urban development and coal-mining activities through much of the basins have had a significant influence on water quality and aquatic life. Industrial activity in small and large towns has resulted in contaminated streambed sediments and contaminated fish. Acid- and/or mineral-laden mine drainage from abandoned coal mines is one of the most serious and persistent water-quality problems in the basins, limiting water use and aquatic resources.

- Sulfate concentrations were 5 times greater in streams draining mined areas than in streams draining unmined areas. Sulfate concentration is closely related to coal production in the sampled basins but not as clearly related to pH or dissolved metal concentration. (See page 6.)
- Since 1980, treatment of drainage from active and abandoned mines has generally resulted in improved water quality, with increased pH and lower metal and sulfate concentrations, but diversity and abundance of aquatic organisms remain reduced in comparison to unmined areas. (See pages 7, 20, and 21.)
- Zinc in bed sediment exceeded aquatic-life guidelines at 15 of 50 sites. (See page 9.)
- Arsenic concentrations most often exceeded aquatic-life guidelines in bed sediment in streams draining northern, once glaciated areas, and high concentrations appear to be unrelated to human activity. (See page 10.)
- Streams in forested settings are among the most diverse nationally with respect to aquatic insects among NAWQA sites sampled between 1996 and 1998. (See page 8.)
- A group of now-banned industrial chemicals, polychlorinated biphenyls (PCBs), was detected in 43 percent of sediment and fish-tissue samples. Consumption advisories are in place for several fish species because of PCB and chlordane contamination in some large river reaches. (See pages 11 and 12.)
- Some of the most degraded stream reaches have, since the early 1900s, supported few aquatic organisms. Yet, the quality of many reaches is now improving, and abundant fish and invertebrate populations include sensitive species not seen here in decades. (See page 11.)

The Allegheny and Monongahela River Basins drain 19,145 square miles of Pennsylvania, West Virginia, New York, and Maryland. About 64 percent of the study area is forested; the remainder is a patchwork of land uses. Agriculture (30 percent) is commonly low intensity pasture, dairy, and hay. Urban areas account for about 4 percent of the area, but they include many forested ridges. Coal-mining activities influence water quality in most of the study area but are not visible on this surface land-use map. (Land-use coverage is based on 1991, 1992, and 1993 land-use data.)

Major Influences on Streams and Rivers

- Surface, underground, reclaimed, and abandoned coal mines
- Impoundments and maintenance of navigation channels
- Increased urban development
- Reductions in agriculture, industrial activity, and coal production

- In sampled streams in basins dominated by urban or agricultural land, pesticides and volatile organic compounds (VOCs) were commonly detected, although generally at concentrations meeting drinking-water and aquatic-life standards and guidelines. (See pages 12–13 and 15–17.)
- Pesticide concentrations in stream water exceeded drinking-water guidelines in single samples from each of two basins, one dominated by agriculture and the other dominated by urban land use. (See pages 12 and 13.)

Ground-Water Highlights

Although not regulated, the quality of water from domestic wells—the predominant water source for residents of rural areas—meets Federal standards for drinking water for most substances analyzed in this study. Ground-water supply generally meets or exceeds expectations from wells in the highly permeable glaciofluvial deposits of the valley-fill aquifers in the northwest. Ground-water supply often meets needs but can be meager from wells tapping the water-filled fractures of the fractured-rock aquifers present throughout much of the rest of the study area.

- Compared to ground water in unmined areas of the coal-bearing rocks, water in shallow private domestic wells near reclaimed surface coal mines had higher concentrations of sulfate, iron, and manganese, even after all mining and reclamation had been completed. (See pages 9 and 21.)
- Pesticides were detected more frequently in the valley-fill aquifers of the glacial sediments than in fractured-rock aquifers. (See pages 13-15.)
- Overall, VOCs were detected at very low levels in the 95 ground-water samples analyzed. Gasoline-related compounds were detected slightly more frequently and at slightly higher concentrations in ground water near reclaimed surface coal mines than near unmined areas. (See pages 16 and 17.)
- Nitrate was detected in 62 percent of sampled wells, although only one domestic-well sample exceeded the drinking-water standard for nitrate. (See pages 17 and 18.)
- Radon was detected at levels exceeding the proposed Federal drinking-water standard of 300 pCi/L (picocuries per liter) in 56 percent of the ground-water samples. The proposed alternative standard (4,000 pCi/L) was exceeded in 2 percent of the samples. (See page 19.)

Major Influences on Ground Water

- Coal mining
- Pesticide and fertilizer application
- Widespread use of gasoline and oxygenates
- Naturally occurring concentrations of radon

INTRODUCTION TO THE ALLEGHENY AND MONONGAHELA RIVER BASINS

The Allegheny and Monongahela Rivers join at Pittsburgh, Pa., forming the Ohio River. Historically, these rivers served as a transportation corridor to the West and were of strategic military significance. The Allegheny and Monongahela River Basins were at the focus of the industrial revolution in the United States. In 1990, approximately 4.2 million people lived in the area, and although the land and water uses have changed many times, the legacy of past activities is evident. Today's stream quality reflects a blend of past and present land uses and the natural quality and quantity of the water in these basins.

Topography and Geology

The Allegheny and Monongahela River Basins (ALMN) lie almost entirely within the Appalachian Plateaus Physiographic Province. The entire study area is underlain by sedimentary rocks that have been fractured in many places by folding and faulting. These rocks carry ground water in much of ALMN and are referred to as fractured-rock aquifers. The northwestern parts of the Allegheny River Basin were glaciated. The glaciers deposited sand, gravel, silt, and clay in the valleys and eroded the hills, leaving a terrain of more consistent altitude (Becher, 1999; McAuley, 1995). The glaciofluvial and alluvial deposits overlying the sedimentary rocks are generally much more permeable and comprise the valley-fill aquifers (Risser and Madden, 1994). Glaciofluvial deposits include sediments left by water flowing within, under, or out of glaciers. In contrast, the Appalachian highlands to the east and southeast have steep, high

Figure 1. The Allegheny and Monongahela River Basins lie almost entirely within the Appalachian Plateaus Physiographic Province. The eastern parts of the basins are more mountainous, the west is characterized by “rolling hills,” and the northwest has relatively low relief as a result of being covered by glaciers in the last ice age. The topography affects land use, exposed geologic formations, and stream habitat—all of which, in turn, affect the quality and uses of water.

peaks, ridges, and plateaus that are deeply divided by valleys (fig. 1). Land use is limited by the rough terrain and nutrient-poor soil in much of ALMN, both of which make large agricultural fields impractical. Urban areas generally

lie along river valleys. Ridgetops are commonly forested, even in otherwise urban settings.

Ecologically, the streams of these basins present a diversity of habitats. Mountainous areas are generally dominated by streams

that are very low in nutrients and remain cold all year. These streams support trout and a few other cold-water fish species but commonly include diverse aquatic-invertebrate populations. Streams along the western side of ALMN are generally warm-water systems with a much greater diversity of fish species.

Water Use

Most water (94 percent) used in ALMN is drawn from surface-water sources. In 1995, 82 percent of water withdrawn in ALMN was for industrial uses or thermoelectric power generation. Although ground-water withdrawals are proportionally small, they are important for public supply or domestic use, especially in rural areas (fig. 2).

Reservoirs have been in place in the study area for more than 150 years for flood control (fig. 3), recreation, navigation, power generation, water quality, and water supply. Nearly all major tributaries have reservoirs constructed on them. The entire

Figure 3. One of the most devastating floods in United States history occurred in the Allegheny River Basin on May 31, 1889. A dam upstream from Johnstown, Pennsylvania, failed. Downstream, 2,209 people were killed and thousands more were injured. (Photograph used with permission from the National Park Service.)

Figure 2. In 1995, water withdrawn averaged 3,284 million gallons per day. In the Pittsburgh area, nearly all water used for public supply is surface water. Ground water provides water for domestic use in most rural areas.

length of the Monongahela River and the lower 72 miles of the Allegheny River are maintained for navigation by dams. During dry periods, low streamflows are augmented by reservoir releases to dilute degraded water (Ohio River Basin Commission, 1980).

Nonconsumptive use of the water resource also is extensive in ALMN. Some streams are managed for whitewater sports, boating, or fishing, and some high-quality stream reaches are important for conservation and

management of endangered species.

Hydrologic conditions

Although streamflow roughly followed normal patterns during 1996–98, flows were substantially higher or lower than normal for short periods in response to weather extremes (fig. 4). Hence, the ALMN water-quality data set includes responses to a wide range of flows while still being largely representative of normal conditions.

Figure 4. Streamflow was above average in 1996–97 and below average in summer 1998.

MAJOR FINDINGS

The quality of streams, rivers, and ground water reflects complex interactions of natural and human-induced conditions. Natural watershed scale factors such as climate, geography, and topography influence water chemistry and aquatic biological communities. Broad-scale land uses, as well as localized human activities combine with background conditions to influence overall water quality.

Within ALMN, the interaction of a diverse geography and an equally diverse set of land uses influence the quality of the water resource. Surface-water sampling sites were selected in a variety of land-use settings including forest, urban, agriculture, mining, and mixed land use. The study design for ground water focused on assessing the water-quality conditions of major aquifers in ALMN, with emphasis on the quality of recently recharged ground water associated with ongoing and recent human activities (see page 22) (Gilliom and others, 1995). Specific findings from particular land uses and geographic settings are presented in the rest of this part of the report.

Coal Mining Dominates Water Quality

Although not easily represented on land-use maps, mining has the greatest influence on surface and ground-water quality and aquatic habitat of any single land use in ALMN. The area of surface mined land is difficult to quantify because of revegetation: deep-mine activity leaves virtually no trace on the surface.

Coal has been mined in ALMN for more than 200 years and has been central to the economy and lifestyle of many communities. Extensive commercial coal mining

began with almost no concern for the protection of the land surface and water resources. Consequently, stream-water quality in much of ALMN was severely degraded—streams became virtually unusable and supported few aquatic species. Mine-related influences have long been recognized as among the most serious and persistent water-quality problems in Pennsylvania (Pennsylvania Department of Environmental Protection, 1996) and West Virginia (West Virginia Department of Environmental Protection, 1998), as well as throughout Appalachia, extending from New York to Alabama (Biesecker and George, 1966).

Surface and underground coal mining and coal-cleaning processes expose many elements to weathering. Pyrite and marcasite (iron disulfides also known as “fool’s gold”) are naturally occurring compounds commonly found in coal

Nearly all basins greater than 100 square miles within the coal-bearing region of ALMN have been mined at one time or another, many with several coal-extraction techniques.

and in overburden rock. Pyrite is the major source of acid mine drainage (AMD) in the Eastern United States (Rose and Cravotta, 1998). During or after mining, AMD can be formed by a series of complex geochemical and bacterial reactions that occur when pyrite is exposed to air and water (Pennsylvania Department of Environmental Protection, 1999) (fig. 5). Through these reactions, some dissolved ferrous iron will precipitate out of solution in the form of insoluble ferric hydroxide (fig. 6).

Secondary reactions of the acidic water can bring into solution other constituents in the coal and the overburden rock, such as manganese, aluminum, zinc, arsenic, bar-

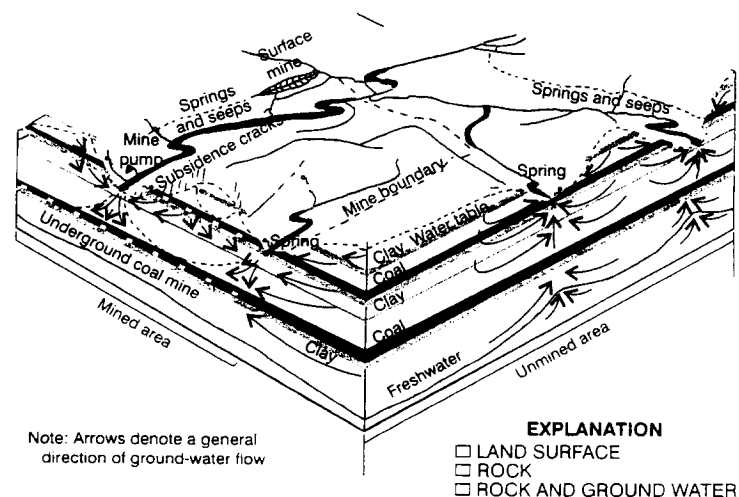

Figure 5. Coal mines disrupt existing flow patterns of ground water and surface water. Oxygen dissolved in surface water is transported to rock strata containing pyrite. Sulfuric acid is produced, which may then emerge in springs, seeps, and streams carrying large amounts of dissolved metals. (Figure adapted from Puente and Atkins, 1989.)

Figure 6. Reddish-orange iron precipitate is commonly seen in streams affected by acid mine drainage.

ium, cadmium, cobalt, copper, and silver. Some reach concentrations potentially dangerous to wildlife and may exceed drinking-water standards (table 1). These constituents are then subject to additional reactions (such as the formation of precipitates), are adsorbed onto sediments, or are taken up in the tissues of organisms (bioconcentrated).

Sulfate is an Indicator of Coal-Mining Activity

Coal-mine drainage can be acidic or alkaline and can seriously degrade both surface- and ground-water supplies. AMD, in which the acidity exceeds alkalinity, typically contains elevated concentrations of sulfate, iron, manganese, aluminum, and other dissolved material. In contrast, neutralized or alkaline mine drainage (NAMD) has an alkalinity that exceeds acidity; however, NAMD can still have elevated concentrations of sulfate, iron, manganese, and other constituents.

Dissolved trace elements are not generally reliable indicators of AMD or NAMD because they may not remain in solution. Sulfate, however, is a reliable indicator of mine drainage because sulfate is highly soluble and chemically stable at the pH levels normally found in natural waters (Hem, 1985).

The U.S. Environmental Protection Agency (USEPA) has established a Secondary Maximum Contaminant Level (SMCL) of 250 mg/L (milligrams per liter) for sulfate. SMCLs are applied to public water supplies and are nonenforceable levels for contaminants that may affect the taste, odor, or appearance of water. High sulfate concentrations in water may cause diarrhea in sensitive populations (U.S. Environmental Protection Agency, 1999a).

The amount of a constituent carried out of a stream system is called the yield. Sulfate yields were, on average, 5 times greater in stream basins where mining has occurred than in unmined basins sampled monthly in 1997–98 (fig. 7). With one exception (Stonycreek River), yields of dissolved iron and dissolved manganese were similar in mined and unmined basins.

The Stonycreek River had the highest sulfate yield of the 11 sampled streams and is considered to be highly degraded by AMD, primarily from abandoned mines.

Table 1. Regional background concentrations of constituents influenced by mine drainage were estimated by using the 90th percentile for each constituent from streams unaffected by mining

[USEPA, U.S. Environmental Protection Agency. mg/L, milligrams per liter; --, not calculated; µg/L, micrograms per liter;]

Selected mining constituents ¹	USEPA Secondary Maximum Contaminant Level	Regional background concentration
Dissolved solids	500 mg/L	--
pH	6.5–8.5	7.0
Sulfate	250 mg/L	20.8 mg/L
Iron	300 µg/L	129 µg/L
Manganese	50 µg/L	81 µg/L
Aluminum	50–200 µg/L	23 µg/L

¹Other coal-mining-related constituents include alkalinity and acidity.

Figure 7. Sulfate is a more stable indicator of mine activity than dissolved iron or manganese.

Currently, efforts are being made to restore the water quality in this river, mainly through the construction of passive treatment systems to treat abandoned-mine discharges inventoried in 1992–95 (Williams and others, 1996). Since 1995, about \$3.5 million has been spent on mine-drainage remediation projects throughout the Stonycreek River Basin, resulting in the removal of iron, aluminum, and acidity from the Stonycreek River at a rate of 111, 133, and 1,192 tons per year, respectively (D. Seibert, Natural Resources Conservation Service, oral commun., 2000). A similar study to identify mine discharges was completed in a Monongahela River tributary, the Cheat River (Williams and others, 1999).

Aquatic Communities are Affected in Streams Receiving Large Amounts of Mine Drainage

Streams receiving mine drainage may range from supporting diverse communities of aquatic life to being lethal to many organisms, depending on a variety of factors. The ecological setting of a stream can affect the types and rates of water-quality changes in response to human influences. Ecoregions and basin size are two factors that relate to differences in aquatic communities. Ecoregions are used to group areas that are ecologically similar and can be expected to have similar aquatic communities. ALMN is divided into six ecoregions (fig. 8), five of which were included in the sampling design in ALMN. Basin size affects species diversity because larger basins tend to have a greater variety of habitats available.

The fish community was sampled at 11 sites in ALMN, 7 of which received mine drainage. A difference in fish abundance and number of fish species was evident between streams in mined basins compared to those in unmined basins. None of the streams sampled had a depressed pH (less than 6.5). In the Central Appalachian Ecoregion, at Stonycreek River, only 2 species (2 individuals) were captured, whereas in Laurel Hill Creek, a similar stream in a nearby unmined area, 16 species (384 individuals) were captured. Where basin sizes were comparable, the presence or absence of coal mining in a basin was evident in some aspects of the fish-community structure (fig. 9).

Few organisms can tolerate even brief periods of acidic or mineral- or silt-laden water. Episodic events or chronic conditions that result in concentrated AMD entering a stream are obvious and result in a nearly complete loss of aquatic species, such as in Stonycreek River. The effects are often more subtle in streams receiving NAMD, where species sensitive to sedimentation, trace-element concentration, or hydrologic changes are affected (Letterman and Mitsch, 1978). In a regional study between ALMN and the Kanawha–New River Basin, 61 sites were sampled for aquatic invertebrates (insects, worms, crustaceans, and mollusks) and water chemistry during a low-flow period in 1998. At sites where sulfate con-

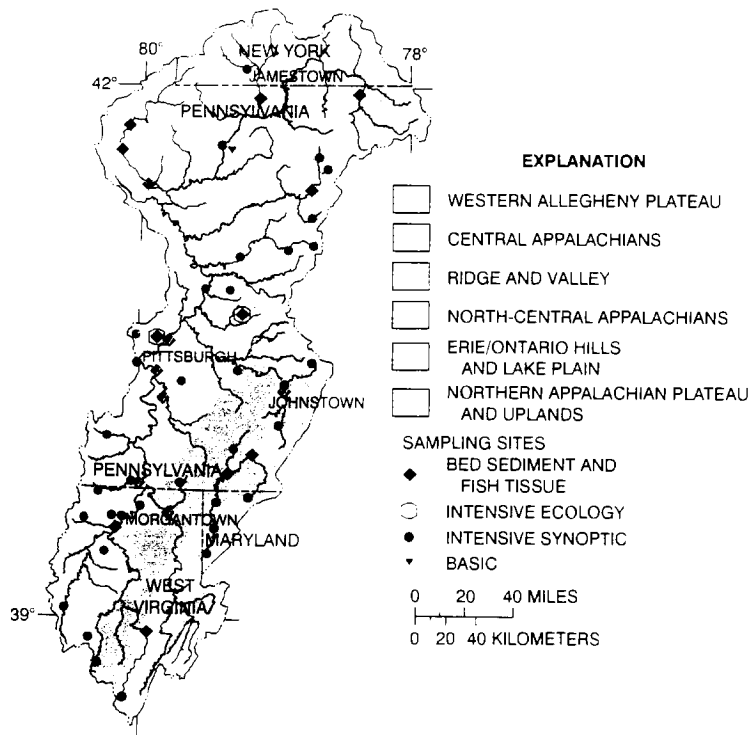

Figure 8. Assessments of the health and condition of aquatic life and habitat focused on four of the six ecoregions represented on this map. Contaminants associated with bed sediment and tissue were analyzed at 19 sites. (Ecoregions from Omernick, 1987)

Figure 9. The number of fish species and the number of individual fish captured per 985-foot stream reach was greater at unmined sites than at mined sites of comparable size.

centrations were greater than the estimated background level. decreasing diversity was noted for three groups of sensitive insect species (mayflies, stoneflies, and caddisflies), although pH was 6.5 or greater at all these sites. (See fig. 23 on page 21.)

INVERTEBRATE INDEX STATUS IS AMONG THE BEST IN THE NATION IN FORESTED SETTINGS

Aquatic life in stream systems where human influence is minimal generally represents a more natural community than in streams strongly influenced by human activity. These sites can be used to define background (reference) conditions that are helpful in interpreting how various land uses change the types and numbers of organisms living downstream. NAWQA examines fish, invertebrate, and algal communities and uses indices based on reference sites as part of assessing water quality. For example, an invertebrate status index (T.F. Cuffney, U.S. Geological Survey, written commun., 2000) averaged 11 invertebrate-community measures (metrics) used to indicate various aspects of the life cycles of the organisms assessed. This index can be used to make relative comparisons between sites sampled by NAWQA.

An ALMN site, East Hickory Creek near Queen, Pa., whose basin is more than 95-percent forested, had the best quality (lowest invertebrate index score) nationally of 140 sites sampled between 1996 and 1998 (Appendix). In contrast, streams in either urban or coal-mine settings ranked among the highest 25 percent of those sampled.

A National Ranking of INVERTEBRATE STATUS in Streams

EXPLANATION
 INVERTEBRATE STATUS INDEX - Higher values suggest a more degraded stream site
 ● Highest 25 percent
 ⊙ Middle 50 percent
 ○ Lowest 25 percent

Ground-Water Quality is Affected Near Mined Areas

During 1996–98, 45 domestic water-supply wells were sampled in ALMN in the high-sulfur coal region of the Appalachian coal fields (Tully, 1996). Water samples were collected from 30 of the 45 wells within about 2,000 feet and hydrologically downgradient (downhill in this area) from a reclaimed surface coal mine. The additional 15 wells are in areas believed to be unmined.

Analysis of ground-water data indicates that surface coal mining continues to affect ground-water quality after all mining and reclamation has ceased. Several constituents related to mine drainage exceeded the USEPA SMCL more frequently in water sampled from wells downgradient from reclaimed surface coal mines than in well water from unmined areas.

Sulfate concentrations exceeded the USEPA SMCL for sulfate (250 mg/L) at 20 percent of domestic wells sampled in mined areas but at no wells sampled in unmined areas. Iron concentrations at wells near mined areas exceeded the SMCL (300 µg/L [micrograms per liter]) in 60 percent of the wells, compared to 20 percent of wells in unmined areas. Similarly, manganese concentrations exceeded the SMCL (50 µg/L) in 70 percent of wells from mined areas compared to 47 percent of wells in unmined areas. Finally, samples from 20 percent of the wells in mined areas exceeded the SMCL for total dissolved solids, whereas samples from only 7 percent of the wells in unmined areas exceeded the SMCL.

Concentrations of mine-related constituents, such as sulfate, iron,

manganese, and dissolved solids can exceed SMCLs for drinking water in unmined areas because of the geologic setting (mostly rocks of Pennsylvanian age that can contain high concentrations of iron and manganese). High concentrations of sulfate in ground water of the Appalachian coal fields, however, usually indicates that coal has been mined nearby or in a location hydrologically upgradient from the sample location. Current regulations do not require treatment of mine-discharge water for sulfate. Discharge water is generally regulated and treated to reduce concentrations of iron and manganese and to maintain pH in the range of 6.5 to 8.5 units.

Concentrations of Trace Elements in Bed Sediment Exceed Aquatic-Life Guidelines

Trace elements typically are present in surface-water systems in small amounts. Local geologic conditions or land-use activities can increase the concentration of some elements to levels that may impair aquatic life or limit water use. Trace elements may be dissolved in water, bound to sediments, or incorporated into the tissues of organisms, depending on the chemical properties of each element. In ALMN, several trace elements in addition to zinc and chromium were detected at high concentrations in bed sediment or tissues (Appendix).

Arsenic is a trace element that is potentially damaging to both human health and aquatic life. Increased arsenic concentrations can result from human activity, such as application of pesticides or the combustion of fossil fuel, or from natural weathering of arsenic-

bearing rock (Ferguson and Gavis, 1972). Arsenic was detected at concentrations above the estimated background concentration of 5.9 µg/g (micrograms per gram) (Canadian Council of Ministers of the Environment, 1995) at all 50 bed-sediment sites sampled between 1996 and 1998 in ALMN. The Probable Effect Level (PEL) for arsenic in bed sediment of 17 µg/g (Canadian Council of Ministers of the Environment, 1995) was exceeded at 12 of 50 sites, where concentrations ranged from 18 to 52 µg/g.

Land use did not appear to be a factor in the arsenic concentrations observed in ALMN, although atmospheric deposition cannot be ruled out. Each of the sites in ALMN where the PEL was exceeded, with the exception of Stonycreek River (a heavily mined basin), were distributed in the northern, once glaciated part of the Allegheny River Basin. Glacial action during the last ice age broke up and moved near-surface rock, exposing this rock to weathering and releasing some arsenic (Welch and others, 1988).

In contrast, concentrations of some other trace elements in ALMN appear to be related to land use. Concentrations of cadmium, copper, chromium, lead, mercury, and zinc each exceeded the PEL aquatic-life guidelines in bed-sediment samples at least once in samples from mined or mixed-land-use sites.

Concentrations of cadmium in whole-fish samples, for which no guidelines exist, are among the highest sampled by NAWQA during 1995–98. Several trace elements (such as nickel) that also have no established guidelines for either bed sediment or tissue are

TRACE ELEMENTS MAY LIMIT AQUATIC LIFE IN URBAN STREAMS AND MINED AREAS

The acidity of some mine drainage may dissolve and subsequently transport large amounts of trace elements from exposed rock. These trace elements, often found naturally in small amounts, can accumulate in streambed sediments. Trace elements, low levels of which are required by organisms, can reach toxic concentrations when concentrated in food, water, or sediments.

Aquatic-life guidelines, used as a reference level, are based on Environment Canada's guideline (Canadian Council of Ministers of the Environment, 1995) and have no regulatory force in the United States. Zinc and chromium were found at all bed-sediment sampling sites in ALMN, and at the 50 sites sampled, the aquatic-life Probable Effects Level (PEL) for zinc (315 µg/g) and chromium (90.0 µg/g) was exceeded at 15 and at 5 sites, respectively (Appendix). Eleven bed-sediment samples from ALMN had zinc concentrations among the highest 10 percent nationally of samples analyzed by NAWQA since 1991. PELs were most often exceeded in areas subjected to industrial or mining land use in ALMN.

Zinc, along with other trace elements that exceed aquatic-life guidelines, may contribute to degradation of aquatic communities in streams. Some sites in ALMN were among the most degraded sites nationally for aquatic invertebrates (Appendix).

elevated in mixed-land-use settings (Appendix).

Water Quality of the Large Rivers of the Allegheny and Monongahela River Basins is Improving

The large rivers sampled in ALMN are important for their envi-

ronmental and esthetic qualities, as well as sources for drinking water. Sections of the upper Allegheny River are designated federally as Scenic Rivers (Pennsylvania Department of Conservation and Natural Resources, 2000). French Creek, a tributary of the Allegheny River, supports several State and

federally protected endangered species (see page 12) and is an important stream nationally for the protection of aquatic species (Masters and others, 1998). Whitewater rafting on the Youghiogheny and Cheat Rivers is a thriving recreational industry.

The water quality in a river that drains large areas integrates water potentially influenced by a broad range of natural and human factors. The industrial and resource extraction land-use history in ALMN previously resulted in poor water quality in some rivers and streams. Early in the 1900s, fish were rarely found in the lower Allegheny and Monongahela Rivers and then only during high flows, when river water was diluted by surface runoff. Crayfish also were rare, and freshwater mussels had been eliminated (Ortmann, 1909). Ortmann described lower reaches of Monongahela River tributaries, the Cheat River and Youghiogheny River, as degraded by mine drainage. As recently as the mid-1960s, fish surveys on the Monongahela River found zero to four fish species (U.S. Army Corps of Engineers, 1976).

The Allegheny River and Monongahela River sites sampled in this study have been sampled comparably under various USGS programs since the early 1970s, permitting a general comparison of water-quality conditions since that time.

A measure of the acidic and basic properties of natural waters is pH. The pH of source water is useful for determining water-treatment

Figure 10. For the two 12-year periods examined, the Allegheny and Monongahela Rivers improved in some water-quality respects (MCL, Maximum Contaminant Level; SMCL, Secondary Maximum Contaminant Level).

options and evaluating the suitability for support of aquatic plants and animals. Natural factors, such as rock types in a basin, can affect pH, as can industrial discharges and mine drainage. As recently as the 1960s, the Monongahela River was occasionally too acidic (low pH) to support a diverse aquatic community (Finni, 1988). Since the early 1970s, the median pH at the NAWQA sampling sites increased from 7.0 in the period 1975 to 1987 to 7.4 in the period 1987 to 1998 in the Allegheny River. During the same periods, the median pH increased from 7.0 to 7.6 in the Monongahela River. Although this represents an overall increase in pH for both sites, about 1 percent of the samples collected from these two sites had pH values that were lower than the minimum aquatic-life water-quality guideline of 6.0 (Pennsylvania Department of Environmental Resources, 1984) during the period 1987 through 1998. For organisms living in these rivers, occasional periods when the pH is either too high or too low can be lethal for a particular species.

trations have decreased by 2 percent in the Allegheny River and by 6 percent in the Monongahela River. Reductions in dissolved solids in the Monongahela River have virtually eliminated the exceedences of the SMCL of 500 mg/L (fig. 10).

Elevated nitrate concentrations can result in increased plant and algal growth (U.S. Geological Survey, 1999a), which can, in turn, alter the taste of water and affect other aquatic life. Nitrate increases can be related to some of the same sources as dissolved solids, including both point-source discharges, such as industrial wastewater discharges and sewage, or nonpoint sources, including atmospheric deposition and agricultural fertilizer use (U.S. Geological Survey, 1999a). In contrast to dissolved solids, however, median nitrate concentrations have increased by 3 percent in the Allegheny River and by 25 percent in the Monongahela River. Nitrate, which contains nitrogen, can be converted to other nitrogen-containing compounds relatively easily. Total nitrogen was not routinely measured in early studies. The increase observed in

The concentration of dissolved solids in a water body can be increased as a result of industrial or municipal wastes, drainage from mines or oil fields, or drainage from agricultural land. Median concentrations of dissolved solids have decreased at the Allegheny and Monongahela River sampling sites over the last 25 years. Dis-

nitrate may be partly the result of changes in the form of nitrogen in the rivers, typically due to sewage-treatment-plant upgrades (U.S. Geological Survey, 1999a).

The general improvement in water quality described above in sections of the Allegheny and Monongahela Rivers has been accompanied by an increase in the number and species diversity of fishes. A sample of the fish community at the Monongahela River site in 1998 contained more than 1,100 individual fish representing 12 species. This included many sport fish such as smallmouth bass and sauger. Species richness was even greater in the Allegheny River, which had 21 species, again including many sport fish as well as species sensitive to pollution, such as redhorse sucker. Significantly, the silver chub, *Macrhybopsis storeriana*, a minnow that had not been seen in these rivers since the late 1800s (Cooper, 1983), was captured in both 1997 and 1998. The recovery of rare species is a further indication of the degree of improvement in water quality in these river segments.

Persistent Pesticides and PCBs were More Prevalent in Fish Tissue than in Sediment

Numerous synthetic organic compounds have been manufactured to fulfill various needs of society. These compounds have a range of stability in the environment. Some break down rapidly, whereas others can be highly stable and persistent. Some stable synthetic organic compounds are no longer in use in the United States.

Organochlorines in this group are commonly soluble in fat or can bond to particles in the water and settle out. Some bioconcentrate in

Grass-roots efforts seek to protect water quality and aquatic life

Many of the water-quality issues receiving national attention arise from landscape-scale activities known as nonpoint sources. Managing nonpoint sources often requires the cooperation of many people living in a river basin.

Watershed groups have been formed by citizens concerned with the conditions in local waterways. Nationally, as well as in ALMN, these groups are increasingly important. Many include partnerships with conservation groups and government agencies.

Many watershed organizations in ALMN are working to improve degraded streams. In contrast, several local groups are actively working to keep their resource in good condition. French Creek is an example of a stream that has maintained high water quality and whose citizens are working to maintain this resource. This creek, and its associated ground water,

supply drinking water to many homes, municipalities, and industries. French Creek also boasts the greatest number and variety of fish, invertebrates, and aquatic plants in ALMN. Many of these species are categorized as endangered by State and Federal governments. Several are found nowhere else in ALMN and at very few other places in the world (see photograph at right). These rare, sensitive species and the high overall species diversity in French Creek are evidence of the high quality of the water and stream habitat in this basin.

Northern riffleshell is a globally endangered species doing well in French Creek and sections of the Allegheny River. Two-thirds of related native North American freshwater mussels are now rare or endangered. These animals are indicators of exceptional stream quality.

fat, reaching higher concentrations in organisms than in the environment. They can accumulate in predators that eat contaminated organisms. In the tissues of animals, these compounds can have a variety of effects including toxicity, reproductive impairment, or cancer. Whole fish from 16 sites in ALMN were analyzed for 28 organochlorine compounds. Streambed sediment was analyzed for 32 compounds at these same 16 sites plus an additional 3 sites (fig. 8). At the sites where both fish and bed sediment were sampled, those compounds detected in both media were present at higher con-

centrations in fish tissue than in the sediment (Appendix).

Although use of PCBs was discontinued in the United States in the 1970s, PCBs were detected in whole-fish tissue samples at 10 of 16 sites in 1997. This mixture of compounds was detected at only 4 of 19 sites in streambed sediment. Those sites at which PCBs were below the detection level in fish tissue were in basins dominated by agriculture or forest. Fish-tissue samples from eight sites with mixed land use had total PCB concentrations above the guideline for protection of fish-eating wildlife (Newell and others, 1987).

DDT and chlordane use has been discontinued in the United States since the 1970s. DDT and its breakdown products were detected in fish at 15 of 16 sites and in sediment at 9 of 19 sites. Only at the Allegheny River at New Kensington, Pa., however, did the concentration of total DDT in fish samples exceed the guideline of 200 mg/kg (micrograms per kilogram) established to protect fish-eating wildlife. Chlordane was detected in 11 of 16 whole-fish samples and in 4 of 19 streambed-sediment samples. The guideline of 500 mg/kg for total chlordane (which also includes breakdown products) for protection of fish-eating wildlife was exceeded in fish samples only at the Monongahela River near Braddock, Pa.

Public-health advisories are in place to restrict consumption or prohibit taking of several fish species from certain sections of the Allegheny and Monongahela Rivers because of PCB and chlordane contamination (Pennsylvania Fish and Boat Commission, 1999). These compounds are relatively stable, are apparently being cycled between aquatic life and bed sediment, and may persist in ALMN for many more years.

Low Concentrations of Numerous Pesticides were Detected in an Agricultural Stream and an Urban Stream

Two basins of similar size were chosen to assess the occurrence and distribution of a broad range of pesticides under different stream-flow conditions. The Deer Creek Basin represented a predominantly residential/urban setting, and the South Branch Plum Creek Basin represented a predominantly agri-

cultural setting (Williams and Clark, 2001).

Of the 84 pesticides and pesticide metabolites (breakdown products) in this analysis, 25 were detected at least once in Deer Creek and 20 were detected at least once in South Branch Plum Creek. Some pesticides show a seasonal pattern in water samples from both streams (fig. 11).

All detectable pesticide concentrations from both streams were less than drinking-water-quality guidelines or standards (table 2). However, the maximum measured concentrations of diazinon in Deer Creek (0.097 $\mu\text{g/L}$) and South Branch Plum Creek (0.094 $\mu\text{g/L}$) exceeded the water-quality guideline to protect aquatic life of 0.08 $\mu\text{g/L}$.

Prometon is the most commonly detected herbicide in surface water and ground water in urban areas

A note on National biological status scores

Although water-quality guidelines for the protection of aquatic life were exceeded for several of the pesticides detected in ALMN, there is no indication that the concentrations have been lethal to the organisms in these streams. National invertebrate and algal scores indicate that these biological communities have not been degraded and are comparable to those at a forested site in ALMN (Appendix). The national fish status score, although indicating that the urban and agricultural setting have better quality fish communities than the forested site, places considerable emphasis on non-native fish species. The forested site is stocked with non-native trout to supplement sport fishing. Abundant non-native fish populations are an indicator of human influence and may point to habitat or water-quality degradation in other situations.

(Capel and others, 1999). It is used as a preemergent herbicide to control vegetation on bare ground around buildings and fences, along rights-of-way, and in conjunction with the application of asphalt. Prometon was detected in 90 percent of the samples collected in Deer Creek. The highest measured concentration was 0.355 $\mu\text{g/L}$ in the first of five storm samples collected on August 25–26, 1998. That concentration was more than 10 times the maximum measured concentration in 1997 but is still well below the drinking-water-quality guideline of 100 $\mu\text{g/L}$. No prometon guidelines have been established for the protection of aquatic life.

The insecticide diazinon is commonly used in homes, gardens,

parks, and commercial areas. Detections of diazinon from samples collected in Deer Creek in 1997 showed no seasonal pattern; however, five of the seven detections were in samples collected shortly after a peak in streamflow due to overland runoff.

The aquatic-life water-quality guideline for carbaryl of 0.2 $\mu\text{g/L}$ was exceeded in four of the five stormflow samples collected in Deer Creek on August 25–26, 1998.

Pesticides are at Low Concentrations when Detected in Ground Water

Ground-water samples from 58 shallow domestic wells throughout ALMN were analyzed for pes-

Figure 11. A distinct seasonal pattern is evident in the concentrations of atrazine, simazine, and metolachlor. The peak concentrations of these three pesticides coincide with herbicide-application periods and increased spring rainfall. (Concentrations below the method detection limit are believed to be reliable detections but with greater than average uncertainty in quantification.)

Table 2. Many pesticides are in widespread use for the control of insects (insecticides) or plants (herbicides). Pesticides may be sold under a variety of names, depending on the manufacturer (Table adapted from U.S. Geological Survey, 1999b) [$\mu\text{g/L}$, micrograms per liter; NA, not available]

Pesticide name	Trade name	Use	Drinking-water-quality guidelines or standards ($\mu\text{g/L}$)	Aquatic-life water-quality guideline ($\mu\text{g/L}$)
Atrazine	AAtrex, Atrex, Atred, Gesaprim	Herbicide	3 ¹	1.8
Diazinon	Basudin, Diazatol, Neocidol, Knox Out	Insecticide	.6	.08
Dieldrin	Panoram D-31, Octalox, Compound 497, Aldrin epoxide	Insecticide	.02	.056
Carbaryl	Carbamine, Denapon, Sevin	Insecticide	700	.2
Metolachlor	Dual, Pennant	Herbicide	70	7.8
Prometon	Pramitol, Princep, Gesagram 50, Ontracic 80	Herbicide	100	NA
Simazine	Princep, Caliber 90, Gesatop, Simazat	Herbicide	4 ¹	10

¹Drinking water-quality standard (Maximum contaminant level).

ticides. One to five pesticide compounds were detected in 34 percent of the samples. Nine different compounds were detected at concentrations ranging from less than 0.001 to 0.17 $\mu\text{g/L}$. All detections were at or below the method-detection limit. No compounds were detected above drinking water-quality guidelines or standards. The five most frequently detected compounds were the agricultural herbicides atrazine, metribuzin, and metolachlor; the insecticide diazinon; and a breakdown product of atrazine, deethylatrazine.

Of the 58 ground-water samples analyzed for pesticides, 30 samples were from wells in valley-fill aquifers and 28 samples were from fractured-rock aquifers (see page 22). Forty percent of the samples from valley-fill aquifers and 29 percent of the samples from fractured-rock aquifers contained at least one pesticide compound. Deethylatrazine was the only pesticide detected in more than 30 percent of all samples in the valley-fill aquifers. No pesticides were detected in more than 22 percent of

sampled wells in the fractured-rock aquifers.

Nine different pesticide compounds were detected in 12 samples from the valley-fill aquifers (fig. 12). The top four detected

compounds in samples from valley-fill aquifers were deethylatrazine, atrazine, metribuzin, and diazinon. Two or more pesticide compounds were detected in 20 percent of the samples in the valley-fill aquifers.

Figure 12. With exception of diazinon, pesticide-detection frequencies in ground water were higher in the valley-fill aquifers than in the fractured-rock aquifers. (Not shown above is the herbicide EPTC detected in a single sample—0.004 $\mu\text{g/L}$.)

PESTICIDES IN THE ALLEGHENY AND MONONGAHELA RIVER BASINS ARE SIMILAR TO THOSE DETECTED NATIONWIDE

The commonly detected pesticides in South Branch Plum Creek, an agricultural basin, and in Deer Creek, an urban basin, were similar to the 15 most commonly detected pesticides in streams in NAWQA studies during 1992–96. The compounds detected in ground water from wells set in both valley-fill aquifers and fractured-rock aquifers are also among those most frequently detected in mixed land-use aquifers nationwide.

*Ground-water samples were not analyzed for the herbicides 2,4-D and Diuron in the Allegheny and Monongahela River Basins.

The most frequently detected mixture of compounds was atrazine (or the metabolite deethylatrazine) and metribuzin, detected in 10 percent of samples from the valley-fill aquifers.

Five different pesticide compounds were detected in the samples from the fractured-rock aquifers (fig. 12). The four most frequently detected compounds in samples from the fractured-rock aquifers were diazinon, deethylatrazine, atrazine, and metribuzin. Two or more pesticide compounds were detected in 14 percent of the samples in the fractured-rock aquifers. The most frequently detected mixture of compounds was metribuzin and diazinon, found in 7 percent of the samples from fractured-rock aquifers.

The higher detection frequency of pesticides in the samples from the valley-fill aquifers is most likely a result of greater vulnerability to pesticide contamination due to permeability of aquifer material and contaminant availability (Lindsey and Bickford, 1999). Both aquifers have similar contaminant-availability ratings; however, the valley-fill aquifers consist of unconsolidated sediments and are more permeable than the fractured-rock aquifers.

Volatile Organic Compounds were Detected at Low Concentrations in an Urban Stream

Volatile organic compounds derived from substances commonly used in residential and urban areas, such as gasoline and cleaning solvents, were detected in 24 of the 25 samples collected from Deer Creek (Pittsburgh metropolitan area) in 1997–98. Of the 87 VOCs

Figure 13. Of 87 VOCs analyzed for, 22 were detected in Deer Creek at Dorseyville, Pa. The 11 most frequently detected VOCs are shown.

analyzed for, 22 VOCs were detected at least once, and 55 percent of those detected were gasoline-related compounds (fig. 13). All measured concentrations of VOCs were well below drinking-water standards and guidelines.

The occurrence of benzene, methylbenzene, methyl *tert*-butyl ether (MTBE), 1,3-1,4-dimethylbenzene, and naphthalene showed

evidence of seasonality in samples collected in 1997. All five compounds were detected in samples collected in February, November, and December, but were absent in samples collected in July, August, and September (fig. 14). Water temperature is a significant factor affecting the concentration and detection of VOCs. VOCs are more likely to be stable and

Figure 14. Volatile organic compounds were detected most often and at highest concentrations in surface-water samples in cool seasons (data from Deer Creek at Dorseyville, Pennsylvania).

detectable in cold water than in warm water. Warm temperatures tend to cause VOCs to be driven into the atmosphere. VOC concentrations in water can increase by a factor of about 3 to 7 when water temperatures decrease from 25°C (Celsius) to 5°C (Lopes and Bender, 1998).

VOCs can accumulate on impervious surfaces and can be flushed into the receiving stream during storms. Data from five storm samples collected in Deer Creek on August 25–26, 1998, showed that the maximum measured concentrations of acetone, carbon disulfide, benzene, 1,2,4-trimethylbenzene, and *p*-isopropyltoluene in a sample were collected as streamflow increased. The lowest concentrations were observed in the last samples collected as the stream receded. The concentration pattern demonstrates a flush-off effect as rains washed VOCs from the land surface to the stream (fig. 15).

Fourteen VOCs detected in a sample collected on December 10, 1997, may have resulted from a flush of accumulated VOCs from impervious surfaces in addition to a low water temperature (5.0°C). Of the 14 VOCs detected, 10 were gasoline-related compounds.

Low Levels of Volatile Organic Compounds were Detected in Most Domestic Wells Sampled

Of the 95 domestic wells throughout ALMN from which samples were collected for VOC analysis, at least one compound was detected in each of 87 samples (92 percent). A total of 28 different compounds were detected overall. Most samples (60 percent) contained two or more VOCs at detect-

Figure 15. At Deer Creek, some VOCs are rapidly transported to streams during storms. These tend to become most concentrated before the floodwaters peak and decline before water returns to prestorm levels.

able levels, and one sample contained seven different VOCs.

All VOC detections were at low concentrations. Twelve VOCs were detected at concentrations at or above 0.1 µg/L, including the four most frequently detected compounds (fig. 16). Of the 28 detected VOCs, drinking-water standards have been established for 20. None

of the VOCs detected exceeded established drinking-water standards or guidelines.

Thirty of the water samples analyzed for VOCs were from wells downgradient from recently reclaimed surface coal mines (mined sites), and 15 of the water samples were from wells in areas underlain by coal but undisturbed

Figure 16. VOCs detected in ALMN ground water at concentrations greater than 0.1 microgram per liter.

by mining (unmined sites). Perhaps as a result of mine machinery use, fuel spills, or adjacent land use, gasoline-related compounds (1,2,4-trimethylbenzene, benzene, methylbenzene, and ethylbenzene) were detected more frequently and at higher concentrations in the samples collected from the mined sites, where these compounds were detected in 29 of 30 samples, compared to 9 detections in 15 samples from unmined sites.

Nitrate is Common in Streams and Ground Water

Nitrate is a nutrient that can affect water used either as a drinking source or as a medium for aquatic life. Nitrate is present naturally in surface water, but elevated concentrations can result in abundant algal growth and toxicity to some aquatic organisms. In well water, nitrate can be a significant health risk at high concentrations. The use of commercial and organic fertilizers and the combustion of fossil fuels has been linked to elevated nitrate concentrations in streams and shallow ground water nationwide (U.S. Geological Survey, 1999a).

In ALMN, 10 stream sites and 95 domestic wells were sampled for nitrate. Samples were collected monthly at the stream sites and once at each well during the period October 1995 through September 1998. Nitrate was detected in all surface-water samples and in 62 percent of ground-water samples. Among wells and streams, only one sample exceeded the USEPA MCL for nitrate in drinking water. The sample was collected from a domestic well in an agricultural setting. The highest median concentration of nitrate in wells and streams was in a stream

Figure 17. Livestock in South Branch Plum Creek, as in many agricultural basins, contribute nitrate to the ecosystem.

in an agricultural setting, South Branch Plum Creek (fig. 17).

The role of land use on the observed nitrate concentrations was investigated by comparison

Why is nitrate important?

Nitrate is the primary form of nitrogen dissolved in streams and ground water. Nitrate forms naturally in soil from transformations of nitrogen, nitrogen-based fertilizers, and manure.

Nitrate is the most widespread contaminant in ground water. Because most ground water eventually discharges to streams, the nitrate in ground water can pose a potential threat to surface-water quality. Surface runoff in areas where commercial fertilizers are used, as well as discharges from wastewater treatment facilities, can also contribute nitrate to streams.

Human ingestion of water with nitrate concentrations in excess of the MCL (10 mg/L as nitrogen) can lead to methemoglobinemia, or "blue-baby syndrome," a sometimes fatal blood disorder in infants.

with a national background concentration for nitrate. The background concentration was estimated from samples collected in undeveloped areas (U.S. Geological Survey, 1999).

Nitrate concentrations in surface-water samples from forested areas in ALMN were less than national background concentration. Among other land uses with potential nitrate sources, concentrations of nitrate often exceeded the background level (figs. 18 and 19).

Activities typical of agriculture and urban/residential land use can lead to an increase in nitrate concentrations. Seasonal fertilizer

applications, animal waste, and sewage are common sources of nitrate. Of the sampled streams in ALMN, 73 percent of samples from a stream draining an agricultural area exceeded background nitrate concentrations. In more populated areas (population density greater than 150 people per square mile), 54 percent of stream samples had nitrate concentrations that exceeded background concentrations.

Overall, streams in basins that integrate various land uses within ALMN had lower concentrations of nutrients than those dominated by either dense population or agri-

Figure 18. Median concentrations of nitrate in streams were higher than those found in ground water.

Figure 19. Streams in agricultural areas had the highest percentage of samples that exceeded national background levels for nitrate (0.6 milligrams per liter in streams and 2.0 milligrams per liter (U.S. Geological Survey, 1999a) in shallow ground water).

culture. Areas with both high population density and significant agricultural acreage exceeded background nitrate concentrations in 49 percent of stream samples.

Ground-water samples analyzed for nitrate were collected from wells in areas of mixed land use. Consequently, no agricultural-urban comparisons could be made for nitrate in ground water.

Radon in Ground Water is Common but Highly Variable

Radon is a radioactive gas that is produced naturally in rocks and soils as an intermediate product in the decay of uranium-238. Radon in ground water originates from nearby soil and rock and is a potential contributing source of radon in indoor air. Exposure to airborne radon has been identified by the U.S. Surgeon General as the second leading cause of lung cancer in the United States. About 20,000 deaths per year in the United States are attributed to airborne radon (U.S. Environmental Protection Agency, 1999b).

Radon concentrations in 56 percent of the 95 ground-water samples analyzed for radon were greater than 300 pCi/L (picocuries per liter), the USEPA proposed standard for drinking water. About 19 percent of the 95 samples exceeded 1,000 pCi/L (fig. 20). Two percent of the 95 samples exceeded the proposed Alternative Maximum Contaminant Level (AMCL) standard of 4,000 pCi/L. To comply with the AMCL, a State or local water utility must develop indoor air radon-reduction programs and reduce radon levels in drinking water to 4,000 pCi/L

Figure 20. Radon concentration in ground water varied considerably within well groupings sampled in the Allegheny and Monongahela River Basins.

(U.S. Environmental Protection Agency, 1999b).

Large variation in radon concentration was found in ground water from the two aquifer systems sampled. Samples from wells in the valley-fill aquifers had a median radon concentration of 665 pCi/L; the median for samples from wells in the fractured-rock aquifers was 350 pCi/L. The higher radon concentrations in water of the valley-fill aquifers may be due to higher uranium content of the valley-fill deposits or may derive from the rock underlying these deposits. Samples from wells downgradient from recently re-claimed surface coal mines had a median radon concentration of 236 pCi/L. By comparison, water samples from wells in areas underlain by coal undisturbed by mining had a median radon concentration of 530 pCi/L. This difference may be due to several factors, such as (1) replacement of high-radon content overburden with lower-radon content backfill or (2) a greater release of radon directly to the air and less

entrapment in ground water after ground disturbance caused by surface mining.

Is radon a risk from your well?

The only way to be sure of radon concentration in ground water from a specific well is to have it tested. The U.S. Surgeon General recommends testing of indoor air radon levels in all homes (and apartments below the third floor). The USEPA-recommended action level for indoor air radon levels is 4 pCi/L. The USEPA recommends testing well water for radon in homes where indoor air levels of radon are high. High concentrations of radon in well water can significantly contribute to airborne levels indoors. Although few of the 95 wells that were tested in ALMN had high concentrations of radon, the results show considerable variability (fig. 20). Ground water from each well should be checked if radon is a concern. If a large part of the indoor radon is from ground-water contribution, the USEPA recommends water treatment to remove radon.

REGIONAL STUDIES: Sulfate concentrations and biological communities in Appalachian coal areas indicate mining-related disturbances despite a general water-quality improvement between 1980 and 1998

In a 1998 study to assess regional water-quality effects of coal mining (Eychaner, 1999), samples representing the Northern Appalachian coal field were collected in the Allegheny and Monongahela River Basins (ALMN), where high-sulfur coal is common and acid mine drainage was historically severe, and samples for the Central Appalachian coal field were collected in the Kanawha-New River Basin (KANA), where acid drainage is uncommon (fig. 21).

Water chemistry in 178 wadeable streams was analyzed once during low streamflow in July and August 1998. Drainage area for most streams was between 4 and 80 mi². Most (170) of these stream sites were also sampled during a 1979–81 study on the effects of coal mining (Britton

and others, 1989), before implementation of Surface Mine and Reclamation Control Act (SMCRA) Regulations began to affect regional water quality. At 61 sites, aquatic invertebrates (insects, worms, crustaceans, and mollusks) also were collected. Ground water was sampled from 58 wells near coal surface mines and 25 wells in unmined areas.

Water-Quality Characteristics Targeted by SMCRA Improved in Streams, but Sulfate and Metals Remain High at Some Sites

Median pH increased and median total iron and total manganese concentrations in streams decreased among mined basins between 1979–81 and 1998 in both coal fields, a reflection that these water-quality characteristics are regulated in mine discharges. Concentrations of sulfate, which is not regulated in mine discharges, exceeded regional background levels at sites downstream from mining (average of about 21 mg/L sulfate in

basins with no history of mining) in more than 70 percent of samples.

The highest sulfate concentrations were measured in basins with the greatest coal production. About one-fourth of all samples exceeded 250 mg/L, the USEPA Secondary Maximum Contaminant Level (SMCL) for drinking water, and all these exceedences were in mined basins (fig. 22). When coal mining ceases within a basin, sulfate concentrations gradually decrease (Sams and Beer, 2000).

Manganese, aluminum, and iron at stream sites in many mined basins also exceeded regional background concentrations (table 1). In the 1998 samples from the northern coal field, median total iron was about equal among mined and unmined basins; but in the central coal field, median total iron among mined basins was lower than among unmined basins. In both coal fields, median total manganese among mined basins was about double that among unmined basins. Exceedences of SMCLs for dissolved iron and manganese were more common in mined basins than in unmined basins, and the aluminum SMCL was exceeded in mined basins only.

Figure 22. Stream water exceeded Secondary Maximum Contaminant Levels at mined sites more often than at unmined sites.

Figure 21. Coal-bearing rocks underlie 55 percent of the area sampled in the Northern and Central Appalachian bituminous coal fields. (Coal-field locations from Tully, 1996)

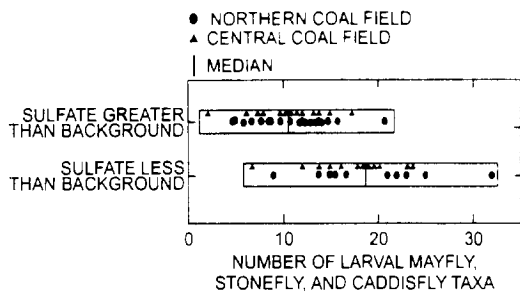

Figure 23. Sulfate concentration in stream water, an indicator of coal production in a basin, was inversely related to the number of mayfly, stonefly, and caddisfly taxa found at water-quality sampling sites.

Figure 24. Sulfate concentrations in ground water generally exceeded regional background levels within about 1,000 feet from surface coal mines.

Invertebrate-Community Impairment Appears Related to Amount of Mining

Invertebrate communities tended to be more impaired in mined basins than in minimally altered basins. Pollution-tolerant species were more likely to be present at mined sites than at unmined sites, whereas pollution-sensitive taxa were few or absent in heavily mined basins. Both an increased sulfate concentration and a decline in some aquatic-insect populations was related to coal production (fig. 23). At sites where sulfate concentrations were above the estimated background level (table 1), the number of taxa of three groups of sensitive insect species (mayflies, stoneflies, and caddisflies) was reduced, although the pH was 6.5 or greater at all these sites.

At the concentrations measured, the sulfate ion is relatively non-toxic to aquatic organisms and may not represent the cause of the decline in mayflies, stoneflies, and caddisflies observed. Sulfate is, however, related to the total coal production from a basin (Sams and Beer, 2000). Invertebrate communities may also have been impaired by other large-scale landscape disturbances—for example, changes

in hydrology, siltation, or trace-metal contamination, all of which can be caused by increased coal production. The communities in basins affected by low to moderate coal production were similar to communities in basins affected by urbanization, agriculture, large construction projects, flow alterations, or wastewater effluents.

Sulfate and Some Metal Concentrations were Higher in Ground Water near Surface Coal Mines

Sulfate concentrations in ground water generally were higher than regional background concentrations in shallow domestic water-supply wells within 1,000 feet of reclaimed surface mines (fig. 24). Water from such wells in the northern coal field contained more sulfate and calcium than did wells in unmined areas in the same region, or at any of the sites in the central coal field. Iron, manganese, aluminum, magnesium, turbidity, and specific conductance also were higher than regional background concentrations within about 2,000 feet of reclaimed surface mines in both coal fields. Concentra-

tions of calcium and magnesium are higher near mined sites because these elements are components of minewater-treatment chemicals and of some of the rocks associated with coal seams. Ground water near reclaimed surface mines exceeded SMCLs for iron, manganese, sulfate, and aluminum more frequently than ground water in unmined areas (fig. 25). Iron and manganese occur naturally in native coal-bearing rocks, sometimes at high concentrations; however, nearly twice as many groundwater samples at mined sites exceeded SMCLs for iron compared to unmined sites. Wells where SMCLs for sulfate and manganese were exceeded were most commonly in the northern coal field.

Figure 25. Ground water exceeded Secondary Maximum Contaminant Levels in mined areas more often than in unmined areas.

STUDY UNIT DESIGN

Stream Chemistry and Ecology

Surface-water assessments included water, bed sediment, and fish tissue chemistry; fish, invertebrate, and algal communities; and physical habitat. Sites were chosen across the study area for spatial coverage and distribution in the major aquatic ecological settings within the Allegheny and Monongahela River Basins (fig. 26).

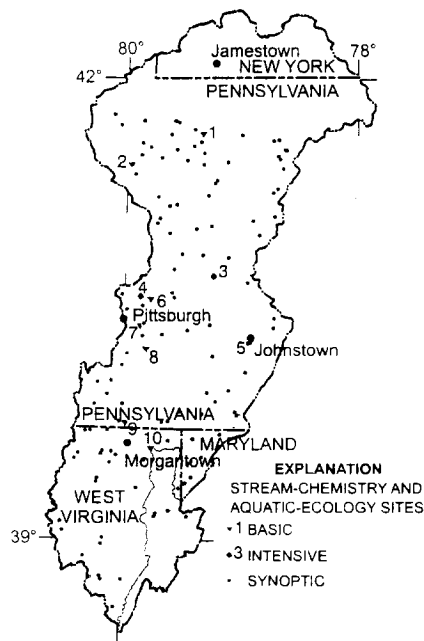

Figure 26. In addition to intensive water-quality sampling at a few sites, one-time sampling at many sites across the study area provided data related to specific land uses. The Cheat River Basin (shaded pink) was similarly sampled.

Basic and intensive sites were sampled monthly for chemistry and annually for ecological condition. One urban site and one agricultural site also were intensively sampled during storms to assess the influence of storm runoff on stream contaminant concentrations. Eighty-nine additional synoptic sites were sampled once to assess the influence of coal mining on water quality across the study area.

Ground-Water Chemistry

Two reconnaissance-type studies were done. The first focused on the fractured-rock aquifers of the coal-bearing Pittsburgh Series rocks of middle and late Pennsylvanian age. The second was set in the coarse- and fine-grained glaciofluvial deposits of the valley-fill aquifers in the northern area of the Allegheny River Basin (fig. 27).

An additional study that focused on mining land use involved sampling of wells that drew water from the fractured-rock aquifers and that

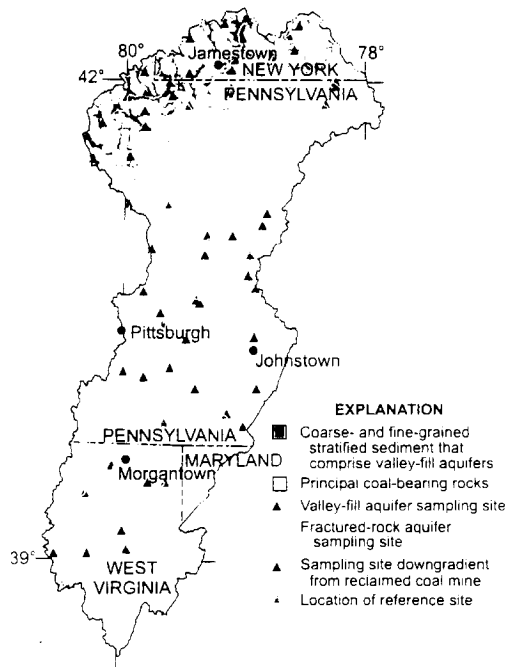

Figure 27. Ground water was sampled from two major aquifer systems, valley-fill aquifers of the northern Allegheny River Basin, and fractured-rock aquifers in the Pittsburgh Series rocks that contain the largest quantities of commercially minable bituminous coal in the ALMN.

were near surface coal mines where mining and reclamation efforts have been completed. The quality of these samples was compared to that of water from 15 wells sampled in unmined areas of the same aquifers.

SUMMARY OF DATA COLLECTION IN THE ALLEGHENY AND MONONGAHELA RIVER BASINS, 1996–98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Basic Sites— General water chemistry	Concentrations, seasonal variation, and annual loads. Data included streamflow, field measurements, major ions, nutrients, organic carbon, suspended sediment, trace elements.	Basic Fixed Sites: Representative of common land-use mixes, as well as basin outflow sites.	8	Monthly: April 1996–Sept. 1998
Intensive sites— Pesticides and VOCs	Concentrations and seasonal variations in pesticides. Data included same constituents as above, plus 83 pesticides (dissolved) and 87 volatile organic compounds (VOCs) (only 1 site).	Basic Fixed Sites with intensive urban or agricultural land use.	2	1997, 1998
Contaminants in bed sediments	Occurrence and distribution of contaminants in bed sediment. Data include trace elements, organochlorine compounds, and volatile organic compounds.	Depositional zones of most stream sites sampled in other components of study.	19	Monthly and more frequently
Contaminants in fish tissue	Occurrence and distribution of contaminants in biota. Data included total PCBs, 30 organochlorine pesticides in whole fish, and 24 trace elements in fish livers.	Most stream sites sampled in other components of study where tissue could be collected.	17	Fish Tissue: Summer 1996 and Summer 1997 (Duplicate taxa at two sites)
Stream Ecology				
Ecological assessments	Macroinvertebrates (benthic invertebrates), fish, algae, aquatic and riparian habitat.	Basic Fixed Sites. Intensive Sites.	8 2	1996–97 (10 sites), 1998 (6 sites) One 3-reach site 1996 and 1997
Synoptic studies	Unmined basin to compare to mined basins. The same data were collected at Basic Sites.	Synoptic Site.	1	Once in 1997
Ground-Water Chemistry				
Aquifer survey— Pittsburgh Series fractured rock	Assess quality across aquifer extent. Data include field measurements, major ions, trace metals, nutrients, Pesticides, VOCs, radon, dissolved organic carbon (DOC).	Existing domestic wells chosen with a statistically random selection process. Well depth range 30 to 250 feet.	30	Once in 1996 (July–August)
Aquifer survey— Glaciofluvial deposits of the valley-fill aquifers	Assess quality across aquifer extent. Data include field measurements, major ions, nutrients, pesticides, VOCs, radon, dissolved organic carbon (DOC).	Existing domestic wells chosen with a statistically random selection process. Well depth range 30 to 250 feet.	30	Once in 1996 (September–October)
Land-use effects— Surface coal mining	Compare ground-water quality near reclaimed surface mines to that in unmined areas. Data include major ions, trace metals, nutrients, VOCs, radon, trace elements, dissolved organic carbon (DOC), chlorofluorocarbons (CFCs).	Existing domestic wells chosen with a statistically random selection process. Well depth range 30 to 250 feet. (Data from 10 fractured-rock sampling sites were re-used as reference data in the Land-use effects study.)	45	Once in 1997 (August–October)
Special Studies				
Low-flow synoptic survey of streams in the Appalachian coal fields	To assess quality of surface water relative to type and age of coal mining in the basins. Standard: Mine-drainage indicators, field measurements. Intensive: same as standard sites, plus: major ions, trace elements, macroinvertebrates, aquatic habitat.	Standard Site network.	89	Standard sites: Once in summer 1998
		Intensive Site network.	32	Intensive sites: Once in summer 1998

GLOSSARY

- Aquifer**—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Background concentration**—A concentration of a substance in a particular environment that is indicative of minimal influence by human (anthropogenic) sources.
- Bed sediment**—The material that temporarily is stationary in the bottom of a stream or other watercourse.
- DDT**—Dichloro-diphenyl-trichloroethane. An organochlorine insecticide no longer registered for use in the United States.
- Ground water**—In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Herbicide**—A chemical or other agent applied for the purpose of killing undesirable plants. See also Pesticide.
- Human health advisory**—Guidance provided by U.S. Environmental Protection Agency, State agencies, or scientific organizations, in the absence of regulatory limits, to describe acceptable contaminant levels in drinking water or edible fish.
- Insecticide**—A substance or mixture of substances intended to destroy or repel insects. See also Pesticides.
- Maximum contaminant level (MCL)**—Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Method detection limit**—The minimum concentration of a substance that can be accurately identified and measured with present laboratory technologies.
- Micrograms per liter ($\mu\text{g/L}$)**—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most stream water and ground water. One thousand micrograms per liter equals 1 milligram per liter.
- Milligrams per liter (mg/L)**—A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most stream water and ground water. One thousand micrograms per liter equals 1 mg/L .
- Organochlorine compound**—Synthetic organic compounds containing chlorine. As generally used, term refers to compounds containing mostly or exclusively carbon, hydrogen, and chlorine. Examples include organochlorine insecticides, polychlorinated biphenyls, and some solvents containing chlorine.
- Pesticide**—A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents, or other "pests."
- pH**—The logarithm of the reciprocal of the hydrogen ion concentration (activity) of a solution; a measure of the acidity (pH less than 7) or alkalinity (pH greater than 7) of a solution; a pH of 7 is neutral.
- Polychlorinated biphenyls (PCBs)**—A mixture of chlorinated derivatives of biphenyl, marketed under the trade name Aroclor with a number designating the chlorine content (such as Aroclor 1260). PCBs were used in transformers and capacitors for insulating purposes and in gas pipeline systems as a lubricant. Further sale for new use was banned by law in 1979.
- Secondary maximum contaminant level (SMCL)**—The maximum contamination level in public water systems that, in the judgment of the U.S. Environmental Protection Agency (USEPA), is required to protect the public welfare. SMCLs are secondary (nonenforceable) drinking water regulations established by the USEPA for contaminants that may adversely affect the odor or appearance of such water.
- Semivolatile organic compound (SVOC)**—Operationally defined as a group of synthetic organic compounds that are solvent-extractable and can be determined by gas chromatography/mass spectrometry. SVOCs include phenols, phthalates, and polycyclic aromatic hydrocarbons (PAHs).
- Suspended sediment**—Particles of rock, sand, soil, and organic detritus carried in suspension in the water column, in contrast to sediment that moves on or near the streambed or rests on the bottom of the stream.
- Trace element**—An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.
- Upgradient**—Of or pertaining to the place(s) from which ground water originated or traveled through before reaching a given point in an aquifer.
- Volatile organic compounds (VOCs)**—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some byproducts of chlorine disinfection.
- Water-quality guidelines**—Specific levels of water quality which, if reached, may adversely affect human health or aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.
- Water-quality standards**—State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.
- Yield**—The mass of material or constituent transported by a river in a specified period of time divided by the drainage area of the river basin.

Coal mining is a difficult land use to quantify but is one that can significantly alter water quality.

APPENDIX—WATER-QUALITY DATA FROM THE ALLEGHENY AND MONONGAHELA RIVER BASINS IN A NATIONAL CONTEXT

For a complete view of Allegheny and Monongahela River Basins data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Allegheny and Monongahela River Basins. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Allegheny and Monongahela River Basins compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, metolachlor concentrations in the Allegheny and Monongahela River Basins urban stream sampled were similar to the national distribution, but the detection frequency was much higher (96 percent compared to 64 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Allegheny and Monongahela River Basins, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- .. Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

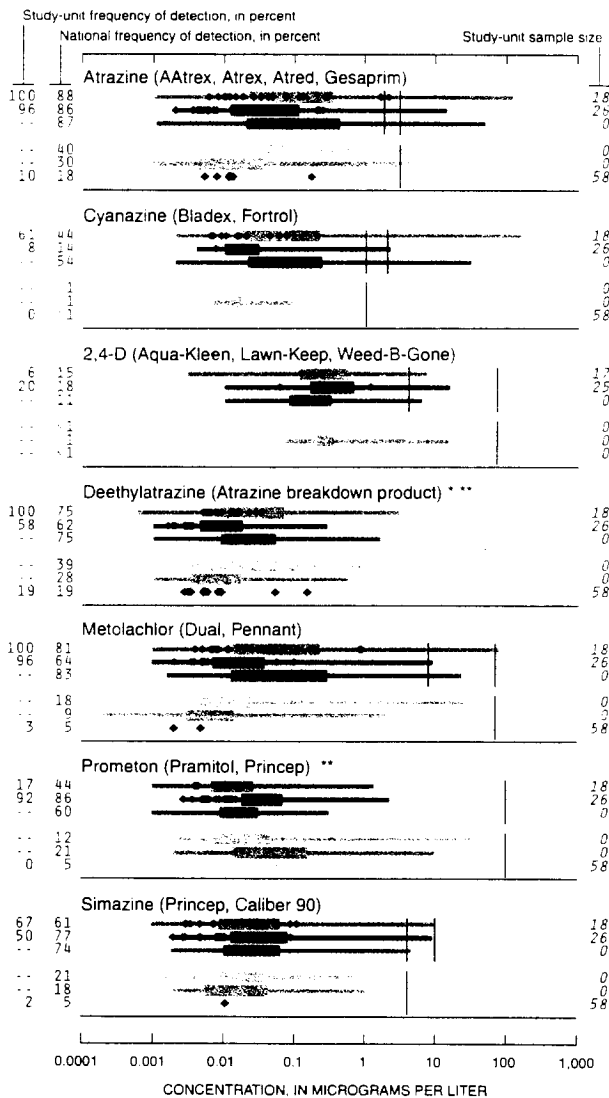

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- : Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- .. No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acetochlor (Harness Plus, Surpass) **
- Acifluorfen (Blazer, Tackle 2S) **
- Alachlor (Lasso, Bronco, Lariat, Bullet) **
- Bentazon (Basagran, Bentazone) **
- Bromoxynil (Buctril, Brominal) *
- DCPA (Dacthal, chlorthal-dimethyl) **
- Dicamba (Banvel, Dianat, Scotts Proturf)
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) **
- Diuron (Crisuron, Karmex, Diurex) **
- EPTC (Eptam, Farmarox, Alirox) **
- Fenuron (Fenulon, Fenidim) **
- MCPA (Rhomene, Rhonox, Chiptox)
- Metribuzin (Lexone, Sencor)
- Napropamide (Devrinol) **
- Neburon (Neburea, Neburyl, Noruben) **
- Pendimethalin (Pre-M, Prowl, Stomp) **
- Propachlor (Ramrod, Satecid) **
- Tebuthiuron (Spike, Tebusan)
- Terbacil (Sinbar) **

Herbicides not detected

Benfluralin (Balan, Benefin, Bonalan) * **
Bromacil (Hyvar X, Urox B, Bromax)
Butylate (Sutan +, Genate Plus, Butilate) **
Chloramben (Amiben, Amilon-WP, Vegiben) **
Clopyralid (Stinger, Lontrel, Transline) * **
2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
Dacthal mono-acid (Dacthal breakdown product) * **
2,6-Diethylaniline (Alachlor breakdown product) * **
Dinoseb (Dinosebe)
Ethalfuralin (Sonalan, Curbit) * **
Fluometuron (Flo-Met, Cotoran) **
Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
MCPB (Thistrol) * **
Molinate (Ordram) * **
Norflurazon (E vital, Predict, Solicam, Zorial) * **
Oryzalin (Surlan, Dirimal) * **
Pebulate (Tillam, PEBC) * **
Picloram (Grazon, Tordon)
Pronamide (Kerb, Propyzamid) **
Propanil (Stam, Stampede, Wham) * **
Propham (Tuberite) **
2,4,5-T **
2,4,5-TP (Silvex, Fenoprop) **
Thiobencarb (Bolero, Saturn, Benthicarb) * **
Triallate (Far-Go, Avadex BW, Tri-allate) *
Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **
Trifluralin (Treflan, Gowan, Tri-4, Trific)

Pesticides in water—Insecticides

Other insecticides detected

Carbaryl (Carbamine, Denapon, Sevin)
Carbofuran (Furadan, Curater, Yaltox)
Chlorpyrifos (Brodan, Dursban, Lorsban)
Fonofos (Dytonate, Capfos, Cudgel, Tycap) **

Insecticides not detected

Aldicarb (Terrik, Ambush, Pounce)
Aldicarb sulfone (Standak, aldoxycarb)
Aldicarb sulfoxide (Aldicarb breakdown product)
p,p'-DDE
Dieldrin (Panoram D-31, Octalox, Compound 497)
Disulfoton (Disyston, Di-Syston) **
Ethoprop (Mocap, Ethoprophos) * **
 α -HCH (alpha-BHC, alpha-lindane) **
 γ -HCH (Lindane, gamma-BHC)
3-Hydroxycarbofuran (Carbofuran breakdown product) * **
Malathion (Malathion)
Methiocarb (Slug-Geta, Grandslam, Mesuroil) * **
Methomyl (Lanox, Lannate, Acinate) **
Methyl parathion (Penncap-M, Folidol-M) **
Oxamyl (Vydate L, Pratt) **
Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
cis-Permethrin (Ambush, Astro, Pounce) * **
Phorate (Thimet, Granutox, Geomet, Rampart) * **
Propargite (Comite, Ornate, Ornate) * **
Propoxur (Baygon, Blattanax, Uden, Proprotax) * **
Terbufos (Conraven, Counter, Piarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

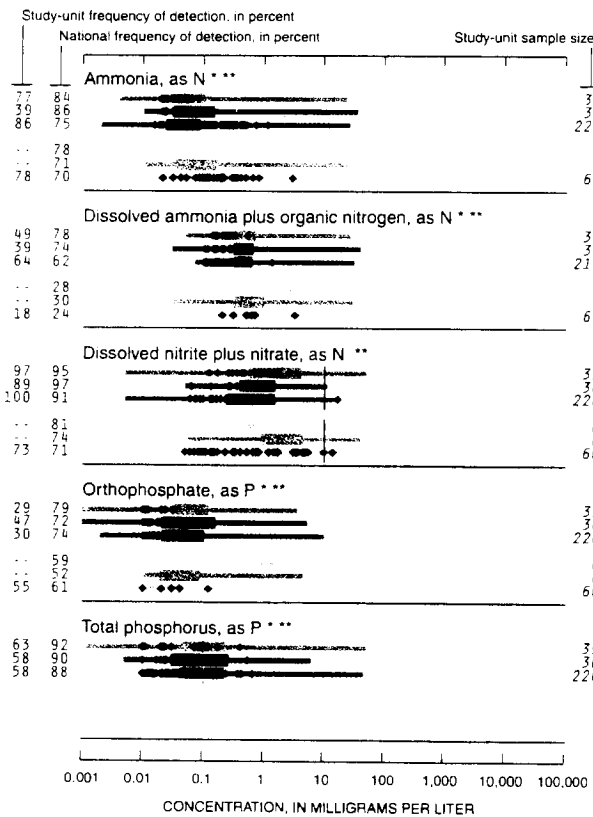

Benzene
Bromodichloromethane (Dichlorobromomethane)
2-Butanone (Methyl ethyl ketone (MEK)) *
sec-Butylbenzene *
Carbon disulfide *
Chlorobenzene (Monochlorobenzene)
Chlorodibromomethane (Dibromochloromethane)
Chloromethane (Methyl chloride)
Dichlorodifluoromethane (CFC 12, Freon 12)
cis-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)
Dichloromethane (Methylene chloride)
1,2-Dimethylbenzene (*o*-Xylene)
1,4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
Ethenylbenzene (Styrene)
Ethylbenzene (Phenylethane)
Iodomethane (Methyl iodide) *
Tetrachloroethene (Perchloroethene)
Tetrachloromethane (Carbon tetrachloride)
Tribromomethane (Bromoform)
1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
1,1,1-Trichloroethane (Methylchloroform)
Trichloroethene (TCE)
Trichloromethane (Chloroform)
1,2,3-Trimethylbenzene (Hemimellitene) *
1,2,4-Trimethylbenzene (Pseudocumene) *

VOCs not detected

tert-Amylmethylether (*tert*-amyl methyl ether (TAME)) *
Bromobenzene (Phenyl bromide) *
Bromochloromethane (Methylene chlorobromide)
Bromoethene (Vinyl bromide) *
Bromomethane (Methyl bromide)
n-Butylbenzene (1-Phenylbutane) *
tert-Butylbenzene *
3-Chloro-1-propene (3-Chloropropene) *
1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
Chloroethane (Ethyl chloride) *
Chloroethene (Vinyl chloride)
1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
1,2-Dibromoethane (Ethylene dibromide, EDB)
Dibromomethane (Methylene dibromide) *
trans-1,4-Dichloro-2-butene ((Z)-1,4-Dichloro-2-butene) *
1,2-Dichlorobenzene (*o*-Dichlorobenzene)
1,3-Dichlorobenzene (*m*-Dichlorobenzene)
1,4-Dichlorobenzene (*p*-Dichlorobenzene)
1,2-Dichloroethane (Ethylene dichloride)
1,1-Dichloroethane (Ethylidene dichloride) *
1,1-Dichloroethene (Vinylidene chloride)
trans-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
1,2-Dichloropropane (Propylene dichloride)
2,2-Dichloropropane *
1,3-Dichloropropane (Trimethylene dichloride) *
trans-1,3-Dichloropropene ((E)-1,3-Dichloropropene)
cis-1,3-Dichloropropene ((Z)-1,3-Dichloropropene)
1,1-Dichloropropene *
Diethyl ether (Ethyl ether) *
Diisopropyl ether (Diisopropylether (DIPE)) *
1,3 & 1,4-Dimethylbenzene (*m*-&*p*-Xylene)
Ethyl methacrylate *
Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *

- 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
- Hexachlorobutadiene
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK)) *
- Isopropylbenzene (Cumene) *
- p-Isopropyltoluene (p-Cymene) *
- Methyl acrylonitrile *
- Methyl-2-methacrylate (Methyl methacrylate) *
- 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
- Methyl-2-propenoate (Methyl acrylate) *
- Methylbenzene (Toluene)
- Naphthalene
- 2-Propanone (Acetone) *
- 2-Propenenitrile (Acrylonitrile)
- n-Propylbenzene (Isocumene) *
- 1,1,2,2-Tetrachloroethane *
- 1,1,1,2-Tetrachloroethane
- 1,2,3,4-Tetramethylbenzene (Phehnitene) *
- 1,2,3,5-Tetramethylbenzene (Isodurene) *
- 1,2,4-Trichlorobenzene
- 1,2,3-Trichlorobenzene *
- 1,1,2-Trichloroethane (Vinyl trichloride)
- Trichlorofluoromethane (CFC 11, Freon 11)
- 1,2,3-Trichloropropane (Allyl trichloride)
- 1,3,5-Trimethylbenzene (Mesitylene) *

Nutrients in water

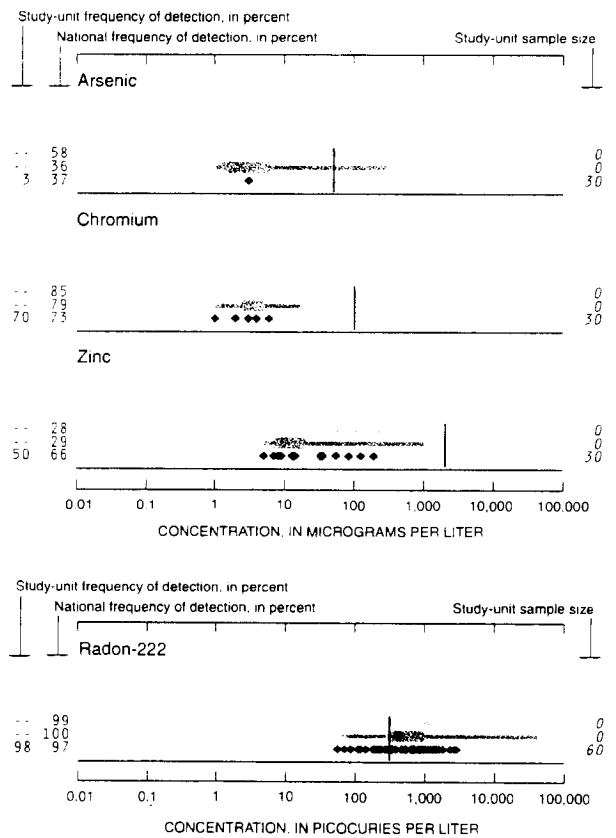

Dissolved solids in water

Trace elements in ground water

Trace-element data are only from the fractured rock aquifer survey. no trace element data were collected from the glacial sediments aquifer

Other trace elements detected

- Lead
- Selenium

Trace elements not detected

- Cadmium
- Uranium

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Allegheny and Monongahela River Basins, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- ** No benchmark for protection of aquatic life

Organochlorines in fish tissue (whole body) and bed sediment

¹ The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

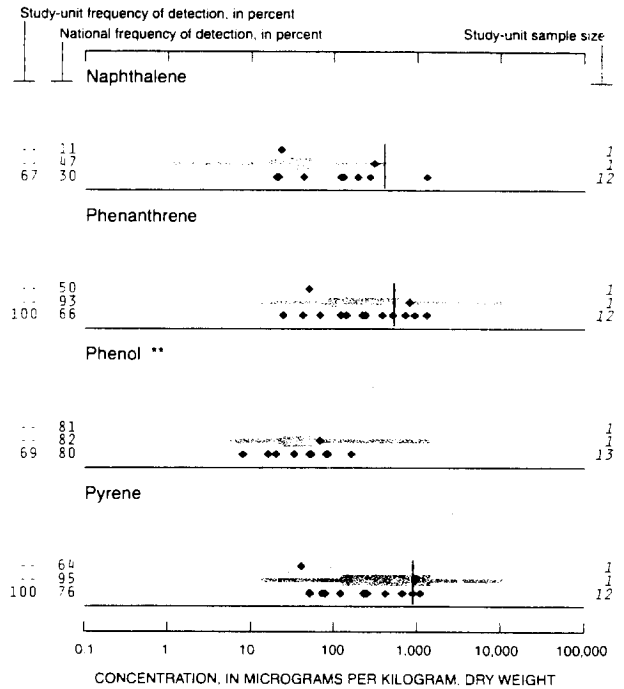

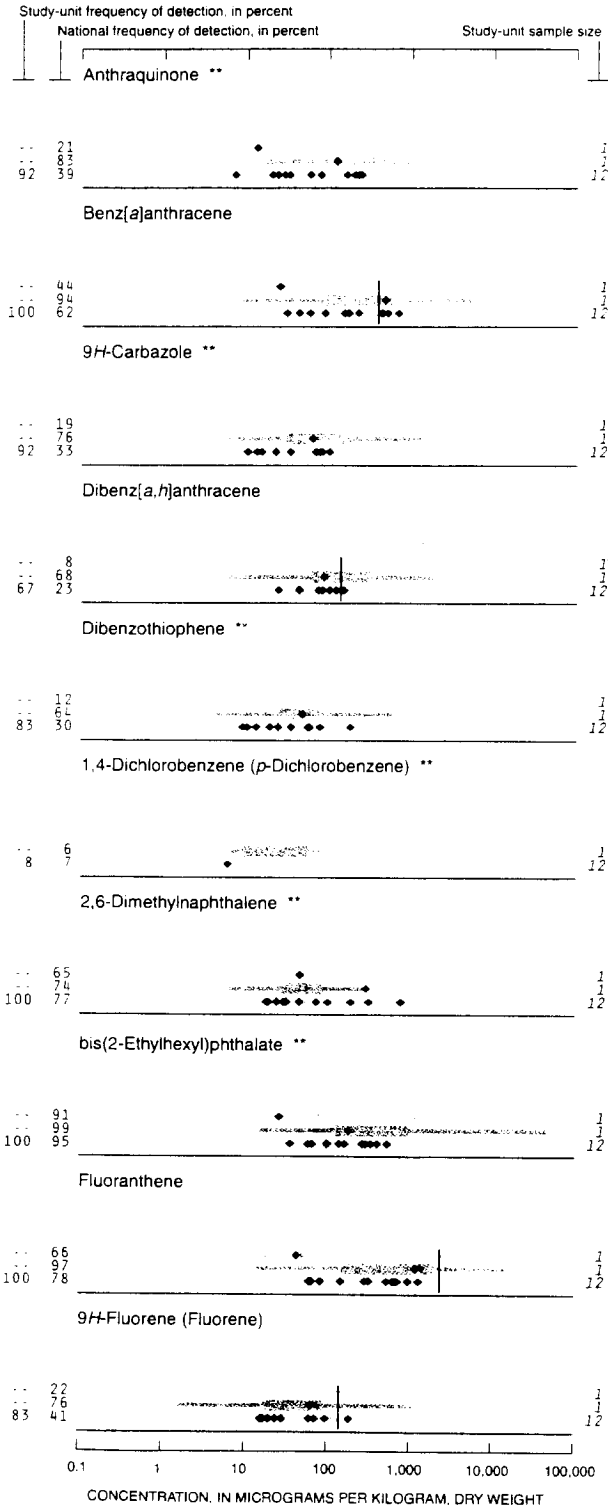

Other organochlorines detected

- o,p'+p,p'*-DDT (sum of *o,p'*-DDT and *p,p'*-DDT) *
- Dieldrin+aldrin (sum of dieldrin and aldrin) **
- Hexachlorobenzene (HCB) **
- o,p'*-Methoxychlor **
- Pentachloroanisole (PCA) * **
- cis*-Permethrin (Ambush, Astro, Pounce) * **
- trans*-Permethrin (Ambush, Astro, Pounce) * **

Organochlorines not detected

- Chloroneb (Chloronebe, Demosan) * **
- DCPA (Dacthal, chlorthal-dimethyl) * **
- Endosulfan I (alpha-Endosulfan, Thiodan) * **
- Endrin (Endrine)
- gamma-HCH (Lindane, gamma-BHC, Gammexane) *
- Total-HCH (sum of alpha-HCH, beta-HCH, gamma-HCH, and delta-HCH) **
- Heptachlor epoxide (Heptachlor breakdown product) *
- Heptachlor+heptachlor epoxide (sum of heptachlor and heptachlor epoxide) **
- Isodrin (Isodrine, Compound 711) * **
- p,p'*-Methoxychlor (Mariate, methoxychlore) * **
- Mirex (Dechlorane) **
- Toxaphene (Camphechlor, Hercules 3956) * **

BIOLOGICAL INDICATORS

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provides a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Lake Erie-Lake Saint Clair Drainages that emerged from an assessment conducted between 1996 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Lake Erie-Lake Saint Clair Drainages assessment. Residents who wish to know more about water quality where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

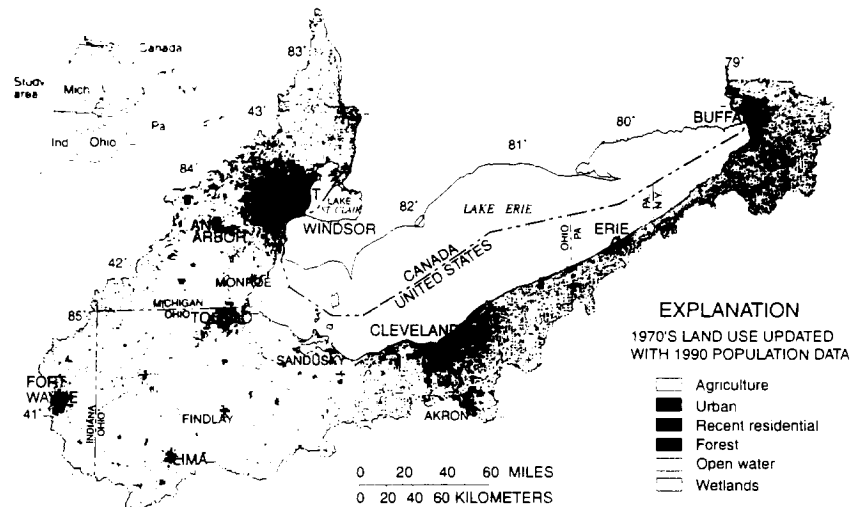

The Lake Erie-Lake Saint Clair Drainages is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Stream and River Highlights

Water quality in the Lake Erie-Lake Saint Clair Drainages is greatly influenced by land use and human activities. A major pathway for contaminant transfer from the land surface to streams is storm runoff from urban and agricultural areas.

As a result of herbicides in runoff, concentrations in streams were in the top 25 percent of streams nationwide and many public-water supplies must treat stream water to reduce herbicide concentrations. As a result of nutrients in runoff, concentrations of total phosphorus and nitrate in some small streams in agricultural areas and in

Land use in the Lake Erie-Lake Saint Clair Drainages was predominantly agricultural and urban. This level of human activity has had substantial effects on water quality in the region.

Indicators of Stream Quality	Small streams		Major rivers	
	Urban	Row crop	Pasture/forest	Mixed
Pesticides ¹				
Total phosphorus ²				
Nitrate ³				
Arsenic ⁴				
Other trace elements ⁴				
Polycyclic aromatic hydrocarbons ⁵				
Polychlorinated biphenyls ⁵				

- Percentage of samples with concentrations **equal to or greater than** a health-related national guideline for drinking water, aquatic life, or above a national goal for preventing excess algal growth (^a Percentage is 1 or less and may not be clearly visible.)
- Percentage of samples with concentrations **less than** a health-related national guideline for drinking water, aquatic life, or below a national goal for preventing excess algal growth (^b Percentage is 1 or less and may not be clearly visible.)
- Percentage of samples with **no detection** (^c Percentage is 1 or less and may not be clearly visible.)

¹ Insecticides, herbicides, and pesticide metabolites, sampled in water.
² Total phosphorus, sampled in water.
³ Nitrate (as nitrogen), sampled in water.
⁴ Arsenic, cadmium, copper, lead, mercury, and zinc, sampled in sediment.
⁵ Industrial chemicals, combustion byproducts, and polychlorinated biphenyls sampled in sediment.

major rivers were in the top 25 percent of streams nationwide. Concentrations of nitrate, although elevated relative to many other streams in the Nation, were infrequently greater than the drinking-water standard of 10 milligrams per liter.

Contamination of the bed sediments of small streams and major rivers by persistent and bioaccumulative contaminants was prevalent. The highest concentrations of PCBs (polychlorinated biphenyls) and mercury were detected in streams draining highly populated urban and mixed land-use areas. Detections of contaminants in fish tissues indicate bioaccumulation; in fact, bioaccumulation of PCBs and DDT in some fish species presents a health risk to fish-eating wildlife.

- The pesticides detected most frequently were among those applied in the greatest quantities to agricultural and mixed land-use areas. The herbicides atrazine, acetochlor, cyanazine, metolachlor, and simazine were detected in 50 to 100 percent of samples. (p. 6)

- Several heavily used herbicides and insecticides were detected in spring and summer at or above a standard for drinking water or a guideline for aquatic life. Elevated pesticide concentrations in streams persisted for 4 to 6 weeks after applications in agricultural and mixed-land-use areas. (p. 8)

- Annual average concentrations of total phosphorus were greater than the U.S. Environmental Protection Agency recommended level for control of nutrient enrichment at 8 of 10 sites sampled in small streams and major rivers draining agricultural and mixed-use land. Streams draining row-crops and mixed-use land are major pathways of phosphorus to Lake Erie. (p. 10)

- Contaminants detected most often in the bed sediments of small streams and major rivers were arsenic, cadmium, copper, lead, mercury, zinc, PCBs, and PAHs (polycyclic aromatic hydrocarbons). The concentrations of arsenic, mercury, PCBs, and PAHs were equal to or greater than sediment guidelines, indicating probable adverse effects on aquatic life, in about 11 to 30 percent of samples. (p. 13)

- The most frequently detected contaminants in fish were highly persistent contaminants—DDT, chlordane, dieldrin, PCBs, and mercury. Except for mercury, use of these compounds in industry and agriculture in the United States was discontinued 15 to 25 years ago. (p. 14)

- Agricultural land use appears to be affecting fish communities in streams draining areas of row-crops. As the amount of row-crops increased relative to forested land, the number of pollution-intolerant fish species decreased. It appears that pollution-intolerant fish can live where agriculture is the primary land use when streams are protected by natural cover. (p. 17)

Major Influences on Surface-Water Quality and Aquatic Biota

- Storm runoff
- Land use and chemical releases
- Bioaccumulative and persistent contaminants

Trends in Surface-Water Quality

Suspended-sediment discharges from the Maumee River Basin decreased by 11.2 percent over the period 1970–98 and corresponded to increased use of conservation tillage to control soil erosion.

Ground Water Highlights

The glacial aquifer is the major source of drinking water in the northwestern part of the study area. In this area, ground-water quality is affected by a combination of human and natural factors. Land use determines which chemicals are used; how readily these chemicals are transported to the ground water is affected by geology.

- In residential areas underlain by sand and gravel, more than 75 percent of ground water recharged since 1953 shows evidence of human activities in the form of nitrate, chloride, or volatile organic compounds (VOCs). Probable sources are (1) septic systems containing human waste and household chemicals, (2) road salt and gasoline residue from paved surfaces, (3) waste from water softeners, or (4) lawn fertilizer. Pesticides were rarely detected. (p. 18)

- In the agricultural study area, which is underlain by till, nitrate and herbicides were detected less frequently than in

most other agricultural areas of the Nation. This observation partially supports the belief that till or tile drains protect the aquifer from contamination. Nevertheless, the ground water is still vulnerable to contamination; almost 60 percent of shallow ground water contained herbicides or elevated concentrations of nitrate. Herbicides were predominantly detected as breakdown products. (p. 20)

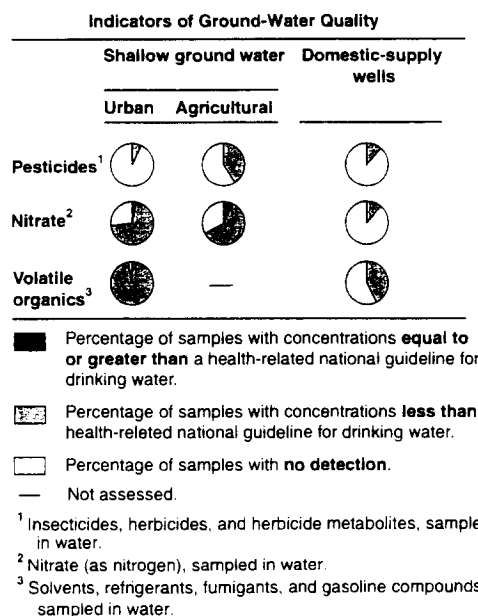

- In residential and agricultural areas, samples from domestic wells met health-related drinking-water standards. However, ground water affected by human activities was detected at depths below 25 feet, the minimum required depth for wells in Ohio and Michigan. (p. 19)

Major Influences on Ground-Water Quality

- Septic systems, roads, and lawns in residential areas
- Herbicides and fertilizer in agricultural areas
- Geology, especially deposits at land surface
- Well depth and ground-water age

Trends in Ground-Water Quality

A significant change in ground-water quality is linked to recent residential development near Detroit. Ground water recharged before 1953 (which predates suburbanization) has concentrations of chemical constituents typical of natural water. In contrast, ground water recharged after 1953 has significantly higher concentrations of constituents derived from human activities.

INTRODUCTION TO THE LAKE ERIE-LAKE SAINT CLAIR DRAINAGES

Major water-quality issues

Streams and aquifers in the Lake Erie-Lake Saint Clair Drainages study area provide water for 10.6 million people. The major water-quality issues in the study area are similar to those facing the rest of the Nation. Natural-resource managers are interested in the effects of urban and agricultural land use on the quality of surface water and ground water, specifically:

- pesticide and nutrient contamination of stream water used for public supply
- nutrient enrichment and sedimentation in streams and subsequent effects on aquatic biota
- impairment of aquatic life from bioaccumulation of organochlorine compounds and mercury
- consumption advisories for certain fish due to bioaccumulation of PCBs and mercury
- degradation of ground water used for domestic supply in areas of new residential development and areas of row-crops

Environmental setting and hydrologic conditions

Lake Erie is the 11th-largest freshwater lake in the world. About two-thirds of the Lake Erie watershed is in the United States, and is referred to as the Lake Erie-Lake Saint Clair Drainages. (For simplicity, this area will be referred to as the "basin.") This 22,300-square-mile area includes sections of Michigan, Indiana, Ohio, Pennsylvania, and New York. The land surface is gently rolling to nearly flat lying. Eight major rivers, all with drainage areas greater than 500 square miles, flow into the system.

Land use

In the Lake Erie-Lake Saint Clair Drainages, about 75 percent of the

land area is in agriculture, 11 percent is urban land, 11 percent is forest, and 3 percent is open water or wetlands. (See land-use map in summary section.)

Corn, soybeans, and wheat are grown predominantly in the western part of the basin (fig. 1). Other agricultural land uses include pasture and forage crops, grown predominantly in the eastern part of the basin (fig. 2). Orchards and vineyards, located mainly along the shores of Lake Erie and in parts of Michigan, is the least widespread type of agricultural land use.

Urban land is an important component of land use in the basin (fig. 3). Detroit and Pontiac, Mich.; Akron, Cleveland, Lima, and Toledo, Ohio; Fort Wayne, Ind.;

Erie, Pa.; and Buffalo, N.Y., were historically significant contributors to industrial America through the production of automobiles, rubber, steel, petroleum, and chemicals. These cities remain important industrial and manufacturing centers. Major urban centers rely on abundant supplies of water for shipping, electric power generation, industry, domestic consumption, and waste assimilation.

Forest and wetlands, once common throughout the basin, have been greatly reduced since the mid-1800s. The greatest percentage of forested land today is in Pennsylvania and New York. Metropolitan parks also support substantial urban forests. Wetlands lie primarily along Lake Erie and Lake Saint

Figure 1. Agriculture is a major industry in the western part of the basin, where corn and soybeans are grown. (Photograph from Natural Resources Conservation Service.)

Figure 2. Pasture and forage crops are found in the eastern part of the basin.

Figure 3. The port of Toledo, Ohio, on the Maumee River exports large amounts of grain from Midwestern farms. Toledo is an industrial center for automobile manufacturing. (Photograph from Ohio Lake Erie Commission.)

Figure 4. Glacial deposits throughout the basin influence the quality and flow of surface water and ground water.

Clair from Detroit, Mich., to Sandusky, Ohio.

Geology

A layer of glacial deposits from 20 to 200 feet thick mantles the entire basin and overlies limestone, sandstone, or shale bedrock. The glacial sediments consist of sand and gravel, till, and fine-grained sediments composed of fine sands, silts, and clay (fig. 4). Sand and gravel are present as discontinuous deposits in river valleys and in the western part of the basin. The most widespread deposit is till, a mixture

of grain sizes. Tills in the Lake Erie-Lake Saint Clair Drainages contain a high content of clay, which slows infiltration of rainfall into the ground.

Water use

More than 10.6 billion gallons of water is used each day in the basin (fig. 5). Cooling during power generation accounts

for 71 percent of the water use. Public and domestic supply account for 17 percent, and industry and mining account for 10 percent of the total use. Normal precipitation is generally adequate for agriculture, so irrigation accounts for less than 1 percent of water use.

Of the more than 1.8 billion gallons per day used for public and domestic supply, about 88 percent is from surface-water sources. Most of the major cities are near Lake Erie and Lake Saint Clair and therefore derive their water from the lakes or their connecting channels (fig. 6). Major rivers are an important source of drinking water for inland cities such as Fort

Figure 5. Water withdrawals in the basin are dominated by thermoelectric power production.

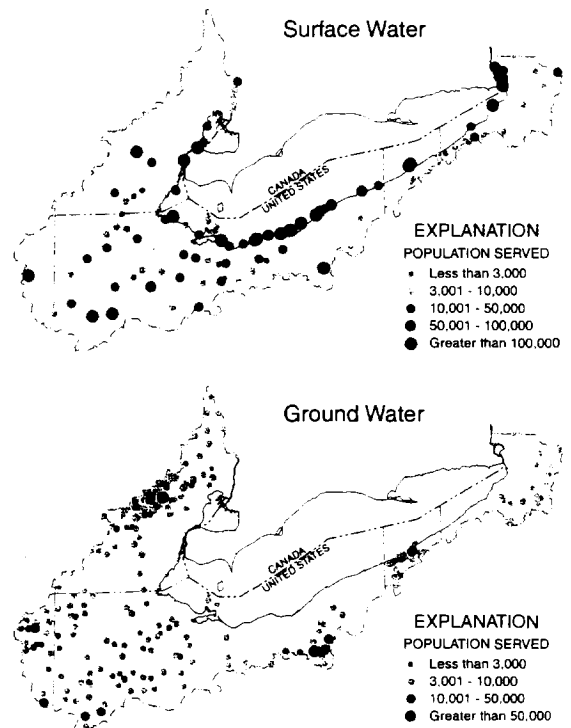

Figure 6. Many public-water supplies with surface-water sources are near Lake Erie or major rivers, whereas public-water supplies with ground-water sources generally are some distance from the lake and major rivers.

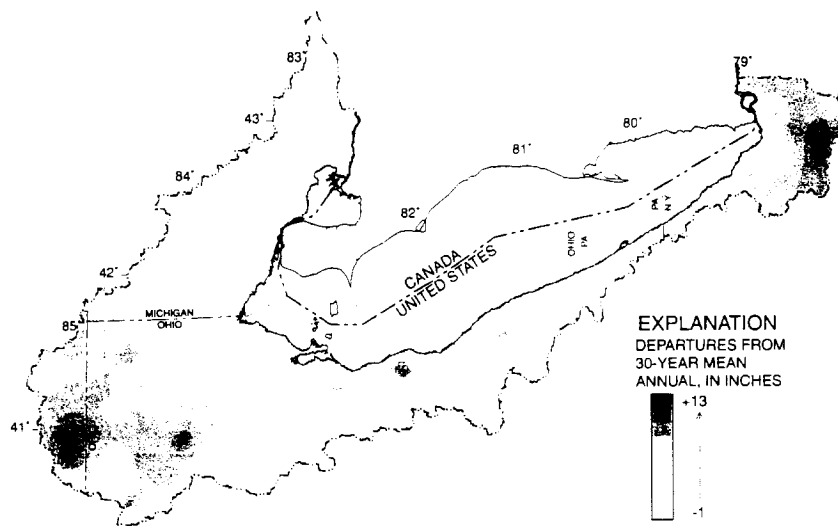

Figure 7. Departures from 30-year mean annual precipitation patterns for water years 1996–98, based on data from 133 weather stations.

Wayne, Ind., and Akron and Lima, Ohio.

About 12 percent of water for human consumption comes from ground water. The cities that use ground water as their major source of drinking water are generally inland (fig. 6). The most productive aquifers are in glacial deposits and limestone and sandstone bedrock.

Hydrologic conditions

Average annual precipitation across the basin ranges from 28 to 47 inches. Precipitation is highest in the northeast because of lake effect, whereby cool, dry air picks up moisture as it travels over warmer lake water and then produces rain or snow as it reaches land. The lowest amounts of precipitation are in the northwestern part of the basin in Michigan. During the study, annual precipitation was 4 to 5 inches above the 30-year mean annual. Some areas received 13 inches of precipitation above the mean, and a few isolated areas

received slightly less than the mean (fig. 7).

The highest streamflows are typically in February, March, and April, as a result of increased precipitation, cold temperatures and little vegetative growth. The lowest streamflows are in August, September, and October (Casey and

others, 1997). During low streamflow, ground water typically contributes most of the flow.

Mean monthly streamflows for the Maumee River at Waterville, Ohio, at the west end of the basin, exceeded the long-term averages by a factor of 2 or more for some months in 1997–98 (fig. 8). Overall, the mean annual streamflow in the Maumee River was 25 percent above average during the sampling period. For Cattaraugus Creek at Gowanda, N.Y., at the east end of the basin, mean monthly streamflow during 1996–98 closely followed the long-term average (fig. 8). In most areas of the basin, higher than average streamflows were observed in water years 1996–98.

Increased streamflow tends to carry higher concentrations of materials associated with land-surface runoff. Low streamflow conditions tend to increase concentrations of materials associated with industrial and municipal discharges or ground water.

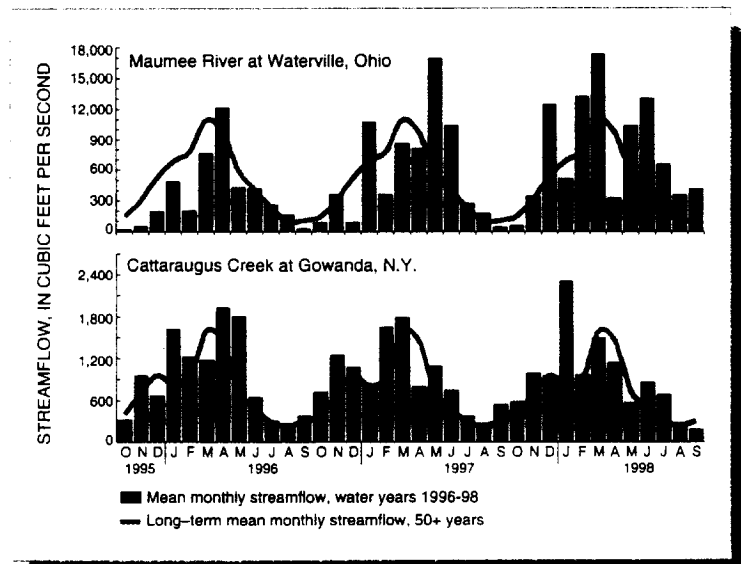

Figure 8. Mean monthly streamflows during water years 1996–98 greatly exceeded long-term averages in some months.

MAJOR FINDINGS

The quality of streams and ground water in the Lake Erie-Lake Saint Clair Drainages is affected by a complex combination of natural factors (precipitation, streamflow, geology) and human factors (land use, chemical use, population density). Specific parts of the basin were targeted for investigation because they have particular combinations of natural and human factors. (See Appendix for details.) A primary factor that was found to influence water quality was land use, and this factor is emphasized throughout the report.

Pesticides were detected in every stream sample

Between March 1996 and February 1998, 305 samples were collected from 10 streams in the basin. Every sample contained at least one pesticide, and most contained mixtures of several pesticides. Some samples contained a mixture of 18 pesticide compounds, which is among the highest number of pesticides detected in a sample nationally.

Figure 9. A total of nearly 8.3 million pounds of pesticides was applied in the agricultural areas of the Lake Erie-Lake Saint Clair Drainages during 1994-95. (Data from Brody and others, 1997.)

More pesticides were detected in large streams than small streams. Overall, 30 different pesticides were detected within the basin. The number of pesticides detected was greater in large

streams and rivers that drain areas of mixed land use (urban and agricultural) than in smaller streams that drain basins dominated by a single land use.

Figure 10. Metolachlor, atrazine, deethylatrazine, cyanazine, and simazine were the most frequently detected herbicides. Diazinon, chlorpyrifos, and carbaryl were the most frequently detected insecticides.

The pesticides most frequently detected in streams were generally those most heavily applied

Pesticide applications to crops in the Lake Erie-Lake Saint Clair Drainages are among the highest nationwide. The five most heavily applied agricultural pesticides—metolachlor, atrazine, cyanazine, acetochlor, and alachlor—were also among the most frequently detected (figs. 9 and 10). Atrazine was detected in every stream-water sample collected during 1996–98 (fig. 10). Metolachlor was detected in 99 percent of samples, and simazine was detected in greater than 80 percent of samples, regardless of land use (fig. 10). Two pesticides that are heavily used in the basin were not analyzed for in this study: (1) glyphosate, an herbicide used in agricultural and urban areas, and (2) endosulfan, an organochlorine insecticide, which was analyzed for in streambed sediment but not in water.

Pesticides detected more frequently in urban than in agricultural areas include the herbicide prometon and the insecticides diazinon and chlorpyrifos (figs. 10 and 11). Chlorpyrifos (Dursban), which was detected in 22 percent of the samples, was recently restricted for residential and commercial use by the U.S. Environmental Protection Agency (USEPA).

Historical-use pesticides are seldom detected in water. Aldrin and DDT are organochlorine insecticides banned in the mid-1970s. Their metabolites (dieldrin and DDE) were each detected in about 1 percent of stream samples. In contrast, total DDT was detected in

nearly 35 percent of all streambed sediment samples (fig. 19, p. 13).

Pesticide metabolites were frequently detected

Little is known about pesticide metabolites (breakdown products) on a watershed level. After application, most pesticides adsorb to soil, infiltrate to ground water, volatilize, or break down to a metabolite (Larson and others, 1999). Deethylatrazine, a metabolite of atrazine, was detected in every sample collected during 1996–98. Additional

triazine and acetanilide herbicides and their metabolites were intensively sampled for at one site, the St. Joseph River near Newville, Ind. Here, the metabolites of triazine compounds, like atrazine, showed the same seasonal pattern and relative concentrations as parent compounds. In contrast, concentrations of the acetanilide parent compounds—alachlor, acetochlor, and metolachlor—were lower than those of their metabolites for most of the year (fig. 12).

Figure 11. The concentration of atrazine was higher in streams draining row-crops, whereas the concentration of diazinon was higher in streams draining urban-land use.

Figure 12. Metabolite concentrations for alachlor, as well as acetochlor and metolachlor (not shown), were greater than parent compounds for much of the year.

No benchmarks for metabolites have been set to protect human health or aquatic life, but some metabolites are believed to be as toxic as parent compounds (Day, 1991). Because metabolites may account for a significant amount of the total pesticides in the environment, they are considered a water-quality concern.

Pesticide concentrations in streams are related to land use, rainfall, runoff, and season

Herbicide concentrations were highest in streams draining row-crops followed by streams draining mixed-use and urban land, and were lowest in streams draining pasture/forested land. Atrazine was detected at the highest concentrations, as high as 85 µg/L (micrograms per liter), in streams draining row crops and at much lower concentrations in streams draining urban land (fig. 11).

Rainfall and runoff affected the concentrations of atrazine in the wet years of 1996–97 compared to the dry year of 1998 in the St. Joseph River near Newville, Ind. (fig. 13). In 1996, streamflow was 330 to 340 percent above average in May and June; in 1997, streamflow was 103 to 129 percent above average in May and June; and in 1998, streamflow was only 36 to 78 percent of the average. The median atrazine concentration detected in the stream was 0.40 µg/L in 1996, 0.45 µg/L in 1997, and 0.14 µg/L in 1998.

Herbicide concentrations in streams are typically highest after application and steadily decrease thereafter. Elevated concentrations of the most heavily used herbicides—metolachlor, atrazine, cyanazine, and ace-

Figure 13. Pesticides such as atrazine show a seasonal trend with streamflow, as shown for the St. Joseph River near Newville, Ind. Differences in the amount and timing of precipitation affect the concentrations, as illustrated by the differences between the wet years of 1996–97 and the dry year of 1998.

tochlor—were detected for 4 to 6 weeks after rainfall and runoff in the spring and early summer (fig. 13, table 1). Pesticides used mostly in urban areas, such as prometon and diazinon, are typically applied in late summer, and this is when the highest concentrations were detected in streams (fig. 11).

Pesticide concentrations in streams have public-health and economic consequences

When concentrations of a contaminant in stream water are greater than a Maximum Contaminant Level (MCL), treatment might be needed to reduce the concentration (Box 1).

The time-weighted average annual concentrations of atrazine were not greater than the drinking-water standard, or MCL, of 3 µg/L at any of the 10

Table 1. Annual and seasonal time-weighted average concentrations of atrazine at 10 stream sites in the Lake Erie-Lake Saint Clair Drainages, 1996–98

Bold indicates concentration is greater than the USEPA's aquatic-life guideline for atrazine of 1.8 micrograms per liter.

¹ Stream is used as a source of drinking water

Box 1—What concentrations of pesticides are considered safe in drinking water?

The USEPA sets drinking-water standards, or Maximum Contaminant Levels (MCLs), and health advisory–lifetime guidelines (HALs) for drinking water, to protect human health. The MCL is the maximum permissible concentration of a contaminant in water delivered to any user of public water systems. MCLs are enforceable standards and are based on an average annual concentration taken from quarterly samples of finished drinking water. HA (Health Advisories) are nonenforceable, risk-based guidelines. Health advisories indicate contaminant exposures below which no short- or long-term adverse human-health effects are expected, based on drinking a specific amount of water for a specific period of time. Risk of illness increases with exposure time and concentration. This report lists only HALs, which are based on a lifetime of 70 years. Standards and guidelines to evaluate the potential adverse effects of pesticides have limitations: (1) Few standards and guidelines have been set for pesticides; of the 88 pesticides analyzed in this study, only 14 MCLs and 38 HALs have been established. (2) Drinking-water standards are based on toxicity tests on a single pesticide and do not evaluate the additive or synergistic effects of multiple pesticides. (3) The standards and guidelines do not address possible effects of pesticides on endocrine systems of humans (Nowell and Resek, 1994; Larson and others, 1999).

stream sites sampled during 1996–98 (table 1). The values from May–July, however, were greater than the MCL at five stream sites (table 1), indicating a need for source-water treatment during that period to remove the pesticides.

Many large water-treatment facilities that withdraw surface water (other than Lake Erie) use activated-carbon filtration during the spring to meet drinking-water standards. In areas of heavy pesticide use, specialized treatment may be necessary year round. For example, the Fort Wayne Water-Filtration Plant uses activated carbon all year. The annual cost of the treatment chemicals at Fort Wayne is approximately \$210,000, about 40 percent of this amount being spent from April to July (Doug Pooler, Fort Wayne Water Filtration Plant, oral commun., 1999). Even with carbon treatment, some treated drinking-water samples tested for atrazine were in excess of the MCL

during 1996–98 (Kelleher, 1999).

Another consequence of heavy pesticide use is the potential effect on aquatic life

Of the 10 streams sampled, 8 had pesticide concentrations, in single samples, in excess of one or more aquatic-life guidelines (fig. 14) (Frey, in press). Concentrations in excess of aquatic-life guidelines were detected for the herbicides atrazine, metolachlor, cyanazine, and metribuzin, and for the insecticides chlorpyrifos, carbaryl, and diazinon. Heavily used compounds—metolachlor, atrazine, cyanazine, and metribuzin—were the compounds with concentrations

Figure 14. The greatest number of concentrations of pesticides affecting aquatic life were detected in streams draining row crops and mixed-use land.

most frequently greater than guidelines. The time-weighted average concentration of atrazine, for example, was in excess of the 1.8- $\mu\text{g/L}$ guideline at 3 of 10 sites annually and at 5 of 10 sites during May–July (table 1).

Box 2—What concentrations of pesticides are considered safe for aquatic life?

Several agencies, including the USEPA, Environment Canada, and the IJC (International Joint Commission), have set guidelines to protect aquatic life. These guidelines are designed to prevent adverse short-term (acute) and long-term (chronic) effects on aquatic life. The aquatic-life guidelines or benchmarks developed by USEPA are based on 4-day average concentrations, are intended to protect 95 percent of the aquatic species, and should not be exceeded more than once in 3 years. The Canadian and IJC aquatic-life guidelines, which are more stringent than those of the USEPA, indicate a single maximum concentration that should never be exceeded. Aquatic-life guidelines have been developed for only 18 pesticides.

Concentrations of nutrients and herbicides in certain streams are among the highest in the Nation

Because the amounts of fertilizers and herbicides applied to agricultural areas are among the highest in the Nation, concentrations of nutrients and herbicides in stream water also are comparatively high at 8 of 10 streams sampled during 1996–98. In eight streams draining agricultural and mixed-use land, average annual concentrations of total phosphorus were in excess of the 0.1-mg/L (milligram per liter) guideline recommended by USEPA to reduce stream eutrophication (fig. 15). In four streams, phosphorus concentrations were in the upper 25 percent of all streams sampled nationwide by NAWQA, as were nitrate concentrations in six streams. In two streams that serve as source waters for public supply, nitrate concentrations in a few samples were detected in excess of the drinking-water standard. Although total phosphorus concentrations appear to be relatively high, the work of other investigators has shown that concentrations of total phosphorus were 40 percent lower in 1995 than in 1976 (Baker and others, 1998). In two of the streams where nutrient concentrations were in the upper 25 percent range on a national basis, average annual concentrations of herbicides were in the upper 25 percent as well. Mixtures of pesticide compounds were found in every stream sample and a total of 30 different pesticides were detected. In one sample, 18 different pesticides were detected. This sample contained more pesticide compounds than 98.5 percent of all the samples collected at 343 sites across the Nation during 1993–98.

Runoff from agricultural land to streams is an important pathway of phosphorus to Lake Erie

In the 1960s, Lake Erie was considered “dead” from the excessive growth and decay of algae and the oxygen-depleting effects of this

decay on the bottom water of the lake (Herdendorf, 1986). By 1971, it was well known that the major sources of phosphorus to the lake were sewage, laundry detergents, and fertilizers. The Great Lakes Water-Quality Agreement (International Joint Commission, 1994) set goals for United States and Canada

to reduce phosphorus inputs to the lake. Actions taken to reduce phosphorus included a limit on the phosphorus content of detergents, a limit of 1.0 mg/L in discharges from sewage-treatment plants, and a total load limit for Lake Erie of 11,000 metric tons per year (International Joint Commission, 1994). Having achieved the point-source reductions over the period 1968–92 (Litke, 1999), the focus shifted to reducing nonpoint sources of phosphorus.

A sustained focus on reducing nonpoint sources of phosphorus to Lake Erie has continued because oxygen depletion in the bottom water in some areas occurs intermittently (Bertram, 1993; Litke, 1999). One reason may be that in years with above-average runoff, annual phosphorus loads to the lake exceed 11,000 metric tons (Dolan, 1993). The excess phosphorus in wet years is thought to come from nonpoint sources (Dolan, 1993).

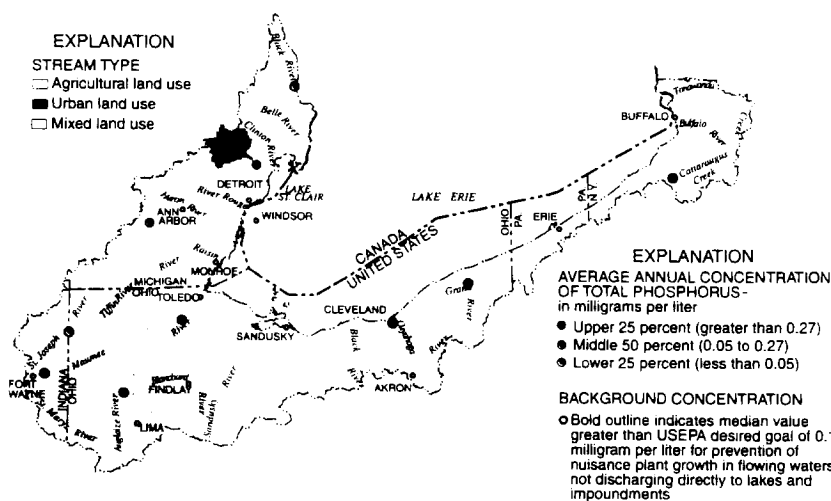

Figure 15. Median concentrations of total phosphorus at 8 of 10 sites in the Lake Erie–Lake Saint Clair Drainages were in excess of 0.1 milligram per liter, the USEPA guideline to control eutrophication in streams.

Fertilizers appear to be the major nonpoint sources of phosphorus to Lake Erie. Greater amounts of phosphorus were applied as fertilizers to each square kilometer of agricultural and mixed-use land than to urban-residential land in 1996–98 (fig. 16). Phosphorus yields, or the amount of phosphorus discharged from a stream per unit area of its basin, ranged from 8.2 to 293 kg/km² (kilograms per square kilometer). The phosphorus yield from only 1 of 10 streams sampled during 1996–98 was in the lower range of yields typical of streams flowing through undeveloped land (Clark and others, 2000). Phosphorus yields in eight streams were similar to or slightly higher than the yields typical of streams flowing through agricultural and mixed-use lands (Gibson and others, 2000).

Phosphorus concentrations were highest in the same streams where yields were highest. Therefore, streams receiving runoff from agricultural and mixed-use lands contributed greater concentrations and amounts of phosphorus to Lake Erie than did streams receiving runoff from urban-residential land

(fig. 16). A conclusion is that agricultural runoff is an important nonpoint source of phosphorus to small streams and major rivers and that major rivers, like the Maumee River, provide a direct pathway to Lake Erie. During 1996–98, the Maumee River contributed an average of 24 percent per year to the 11,000-metric-ton limit.

In the last few years, phosphorus concentrations in Lake Erie appear to be increasing above levels recommended in the Great Lakes Water-Quality Agreement (Scott Painter, Environment Canada, written commun., Oct. 2000). Continued emphasis on managing levels of phosphorus in

Lake Erie appears to be warranted (Box 3).

Figure 16. Unit-area phosphorus inputs to the land surface from fertilizer and manure and unit-area phosphorus outputs from 10 streams in the Lake Erie-Lake Saint Clair Drainages, 1996–98.

Box 3—Recent changes in the food web of Lake Erie—the role of phosphorus and zebra mussels

Concerns about recent declines in some important fish species and the proliferation of zebra mussels, an exotic species, have prompted a renewed interest in the role of phosphorus in Lake Erie. Zebra mussels (shown in the photograph) were introduced into Lake Saint Clair in the mid-1980s and quickly became established in Lake Erie. Because of their filter-feeding behavior, zebra mussels may be affecting fish production in Lake Erie by consuming large amounts of small invertebrates and algae, or plankton, that are the food for small fish, which in turn are the food of larger game fish like yellow perch and walleye. Recent decreases in sport- and commercial-fish harvests, proliferation of zebra mussels, and reductions in phosphorus concentrations in Lake Erie have prompted a renewed interest in how factors such as phosphorus and zebra mussels may be affecting sustainable fish harvests. Adding more phosphorus to the lake to stimulate algal productivity has been suggested, but this could result in increased eutrophication of tributary streams and a return to excessive oxygen depletion in the bottom water of the lake. Furthermore, uncertainties about the response of the lake to phosphorus additions in light of its changing food web have held back plans to apply such a solution. One thing about which everyone can agree is the remarkable ability of exotic species to cause unexpected consequences in ecosystems (U.S. Environmental Protection Agency and Environment Canada, 2000).

Photograph from Ohio Lake Erie Commission.

Decreases in the amounts of suspended sediment carried by rivers correspond to increases in farmers' use of conservation tillage

Cropland in the Maumee River Basin is the largest contributor to soil erosion and sediment in the Maumee River (U.S. Department of Agriculture, 1998), and the river is the largest tributary source of suspended sediments to Lake Erie (Myers and others, 2000). Excessive amounts of sediment discharged from the Maumee River to Lake Erie diminishes the aquatic habitats of fish and other organisms. Maintenance of navigation requires the dredging of approximately 800,000 tons of sediment each year from the Maumee River and Lake Erie at an average annual cost of about \$2.2 million. In response to these problems, the Ohio Lake Erie Commission has set a goal of reducing suspended sediment in Lake Erie tributaries by 67 percent (Ohio Lake Erie Commission, 1998), and the U.S. Army Corps of Engineers has set a

Figure 17. Conservation tillage protects the soil. (Photograph by Steven Davis, Natural Resources Conservation Service).

goal of reducing the amount of sediment dredged from the lower river and its harbor by 15 percent.

Conservation tillage (fig. 17) is a reduced-cultivation method that is being used to decrease soil erosion and thereby the amount of suspended sediment carried by the Maumee River and its tributaries. By maintaining a layer of crop residue from the past year's crop on 30 percent or more of the soil surface, conservation tillage protects the soil from the forces of water erosion. During 1993–98, about 53 percent of all crop fields in the Maumee River Basin and about 50 percent of the crop fields in northwestern Ohio were planted using conservation tillage methods (fig. 18).

Significant decreases in the amounts of suspended sediment carried by the Maumee and Auglaize Rivers over time correspond to increases in conservation tillage. Data from previous studies and new data collected at two sites in the Maumee River Basin during 1996–98 support this conclusion (Myers and others, 2000). An 11.2-percent decrease in

the amount of suspended sediment carried by the Maumee River was detected at Waterville, Ohio, near the mouth (fig. 18), and a 49.8-percent decrease was detected in the amount carried by the Auglaize River near Fort Jennings, Ohio, a tributary stream (Myers and others, 2000). During 1970–98, no trends in streamflow at these two sites were detected. If conditions leading to the downward trends remain the same, then the estimated time necessary to achieve the 15 and 67 percent reduction goals are 30.1 and 205 years, respectively, from the reference condition in 1992.

One reason for the smaller downward trend in the Maumee River compared to that found in its tributary may be related to drainage-basin size. In the large drainage basin of the Maumee River, sediment is deposited in small drainage ditches and streams. These stored sediments are available for resuspension and transport in subsequent storms. This process, as described by Trimble (1975, 1999), creates a lag in the response of rivers to conservation tillage on the land.

Figure 18. Increases in conservation tillage in the Maumee River Basin and elsewhere in northwestern Ohio correspond to decreases in the amount of suspended-sediment carried by the Maumee River at Waterville, Ohio.

Contamination of bed sediments may be causing adverse effects on aquatic life

Bed sediments of small streams and major rivers provide habitat for many aquatic organisms but also serve as a repository for persistent and toxic chemical contaminants that have been released into the environment or that occur naturally. Sediments, once contaminated, can provide a pathway for bioaccumulation. Activities such as dredging of sediments can release contaminants to the surrounding water.

Evidence from laboratory tests shows that contaminated bed sediments can be toxic to aquatic invertebrates (worms, clams, and insect larvae) that are of recreational, commercial, or ecological importance. Contaminated sediments also can affect the food supply required to sustain fish populations (U.S. Environmental Protection Agency, 1997).

Data collected by the U.S. Geological Survey (USGS) and other public-sector agencies at more than 800 locations from 1990 to 1997 were aggregated and analyzed to assess bed-sediment contamination. These data show that **zinc, lead, copper, arsenic, cadmium, mercury, PAHs (polycyclic aromatic hydrocarbons), PCBs (total polychlorinated biphenyls), DDT, and its breakdown products are prevalent in bed sediments, being detected in 30 to 100 percent of samples** (Rheume and others, in press) (fig. 19).

Concentrations of mercury and PCBs (figs. 20 and 21) exceeded Probable Effect Levels (PELs) in 11.8 and 22.4 percent of samples, respectively. PELs are the guide-

Box 4—How are contaminated sediments evaluated?

Effect levels are screening values used to indicate when contaminant concentrations in the bed sediments are likely to be associated with adverse effects on aquatic life. The Threshold Effect Level (TEL) is an estimate of the concentration of a contaminant in bed sediment below which adverse biological effects rarely occur and, if so, only in very sensitive species. The Probable Effect Level (PEL) is an estimate of the concentration of a contaminant in bed sediment above which adverse biological effects frequently occur. These guidelines were developed for the Great Lakes sediments and are used for national assessment in this report. For anthracene and total PAHs, no guideline was available from Smith and others (1996), so guidelines developed by Ingersoll and others (1996) for the Great Lakes were used.

Figure 19. Percentage detection and percentage probability of sample concentrations being greater than a Probable Effect Level in bed sediments of small streams, major rivers, and lakes, Lake Erie-Lake Saint Clair Drainages, 1990–97.

lines established for the protection of aquatic life (Box 4). Contamination of bed sediments with mercury and PCBs was greatest in nearshore areas of Lake Erie, in Lake Saint Clair, and in major rivers that flow through urban areas with industry and populations over 100,000.

Concentrations of arsenic, DDT, and chlordane also exceeded PELs

in the bed sediments of some smaller streams. Samples with detection limits higher than Threshold Effect Levels (TELs) (open circles, figs. 20 and 21) were not useful for assessment purposes. Lower detection limits would have made these data more useful.

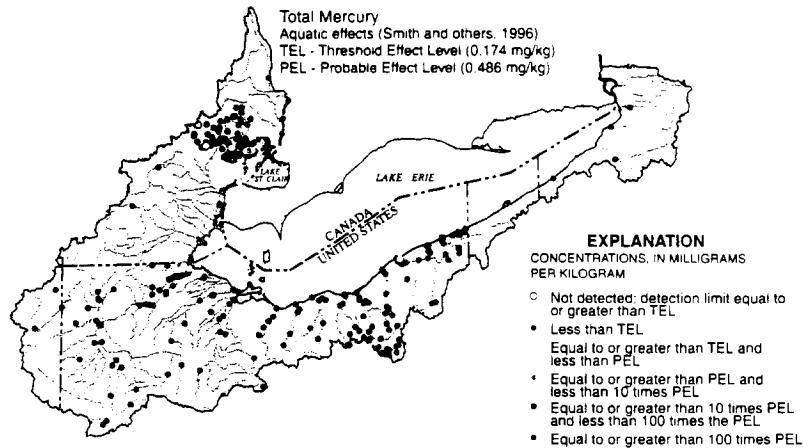

Figure 20. Concentrations of total mercury in recently deposited lakebed and streambed sediments (Data from 1990–97).

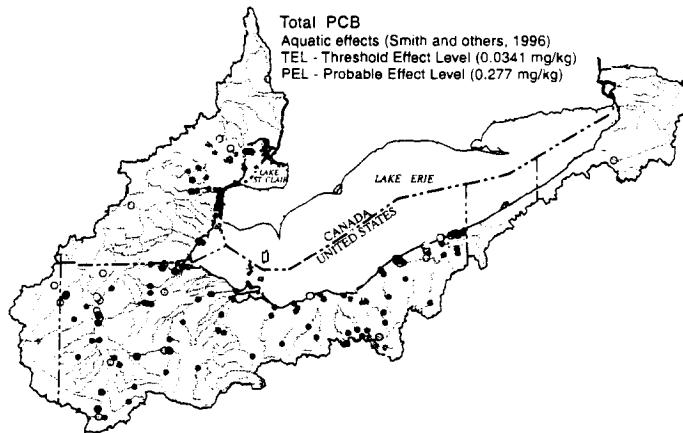

Figure 21. Concentrations of total PCB in recently deposited lakebed and streambed sediments (Data from 1990–97).

Land use and chemical use contribute to contamination of sediments and fish

Most organochlorine pesticides and PCBs have not been manufactured or used in the United States for at least 10–25 years; however, because of their chemical stability (persistence), they were detected in bed sediments and fish collected in 1996–98. Aldrin, DDT, and chlordane were the organochlorine insecticides used in the greatest quantities in the Corn Belt and Great Lakes States in the 1970s. Similarly, historical use of PCBs in industry contributed to their occur-

rence in urban and mixed-use areas.

The highest concentrations of DDT, chlordane, dieldrin, and their breakdown products were detected in bed sediments and fish collected from small streams and major rivers flowing through row-crop, urban, and mixed-use lands. The highest concentrations of PCBs, DDT, and chlordane were detected in bed sediments and fish from streams flowing through urban and mixed-use lands where historical use was greatest. Organochlorine contamination was the lowest in fish and sediments collected from streams in pasture/forest settings.

Unlike organochlorine compounds, mercury has more than 2,000 uses in industry, medicine, agriculture, and commerce. Mercury also is released to the atmosphere as a by-product of coal combustion and waste incineration (Irwin and others, 1997). In 1996–97, mercury was detected in all 15 bed-sediment samples and in all 11 fish-liver samples collected from streams, independent of land-use type. The highest concentrations of mercury, however, were detected in bed sediments and fish collected from small streams and major rivers that flow through urban and mixed-use lands. The magnitude of mercury contamination in bed sediments and fish appears to follow patterns of use in commerce and industry. Mercury was detected in several different fish species that have different feeding habits and that occupy different positions in the food web. Mercury was detected in carp, which are bottom-feeders, in northern hog suckers, which eat insects, and in rock bass, which eat smaller fish (fig. 22).

Figure 22. Total chlordane, total DDT, dieldrin, heptachlor epoxide, mercury, and total PCBs were detected in the tissues of carp, rock bass, and northern hog suckers collected in 1996–97.

Bioaccumulative contaminants in fish may pose a risk to fish-eating wildlife

Where PCBs were detected in fish, they frequently posed a threat to fish-eating wildlife because of their high concentrations. PCBs were found in fish at 8 of 11 sites, and concentrations in fish from 6 sites exceeded the New York State guideline for the protection of fish-eating wildlife (table 2). The maximum concentration of PCBs found in fish was 25 times higher than the guideline set by the New York State Department of Environmental Conservation (NYSDEC) for the protection of fish-eating wildlife (Newell and others, 1987). These fish were collected from the Cuyahoga River at Cleveland, Ohio, a major river that flows through mixed-use land.

DDT was present in fish at 10 of 11 sites but concentrations in fish from only 2 sites exceeded the NYSDEC guideline. The highest concentrations of DDT were in whole fish in streams flowing through urban and mixed-use land—the Clinton River at Sterling Heights, Mich., and the Cuyahoga River at Cleveland, Ohio. Although mercury is a concern, no wildlife consumption guidelines have been established.

Fish-consumption restrictions for humans are based on contaminant concentrations in edible fish fillets, which are typically lower than those in whole fish. The contaminants of most concern in the Lake Erie Basin for human consumption of fish are mercury, PCBs, DDT, chlordane, and dieldrin. These are the same contaminants that are a concern for wildlife consumption (fig. 23). Because of

Table 2. Summary of contaminant concentrations in fish tissue in relation to guidelines for the protection of fish-eating wildlife [$\mu\text{g}/\text{kg}$, micrograms per kilogram; NYSDEC, New York State Department of Environmental Conservation]

Compound found in fish tissue	Number of sites with detections (11 sites sampled)	Maximum detected concentration ($\mu\text{g}/\text{kg}$)	NYSDEC whole-fish guideline for the protection of fish-eating wildlife ($\mu\text{g}/\text{kg}$)	Number of sites with contamination in excess of NYSDEC criteria
Chlordane, total	6	157	500	0
DDT, total	10	450	200	2
Dieldrin	5	32.0	120	0
Heptachlor epoxide	2	10.0	100	0
PCBs, total	8	3,200	130	6

widespread human consumption advisories for fish in the Lake Erie Basin, mercury and PCBs have been identified as critical pollutants and targeted by the USEPA and

Environment Canada for cleanup and elimination (Daher, 1999).

Figure 23. Contaminants can bioaccumulate upward through the food web and may affect the health of human and animal consumers of fish.

Land use appears to affect fish-community composition

Contaminants and nutrients in water and bed sediments appear to affect aquatic life, but human disturbance of physical stream habitat also is thought to be one of the most important causes of declines in certain fish species (Ohio Environmental Protection Agency, 1995). To differentiate the effects on fish of human disturbance from those of contaminants, sites considered to represent good to excellent stream habitat, as rated by the Qualitative Habitat Evaluation Index (QHEI) (Box 5) were selected for assessment of fish. Fish communities were assessed by means of the Index of Biotic Integrity (Box 5).

In 1996–98, stream habitats were rated good to excellent at 11 of 13 sites (fig. 24A), but fish communities were rated good to excellent at only 5 sites (fig. 24B). This may be an indication that the contaminants detected in water and bed sediments

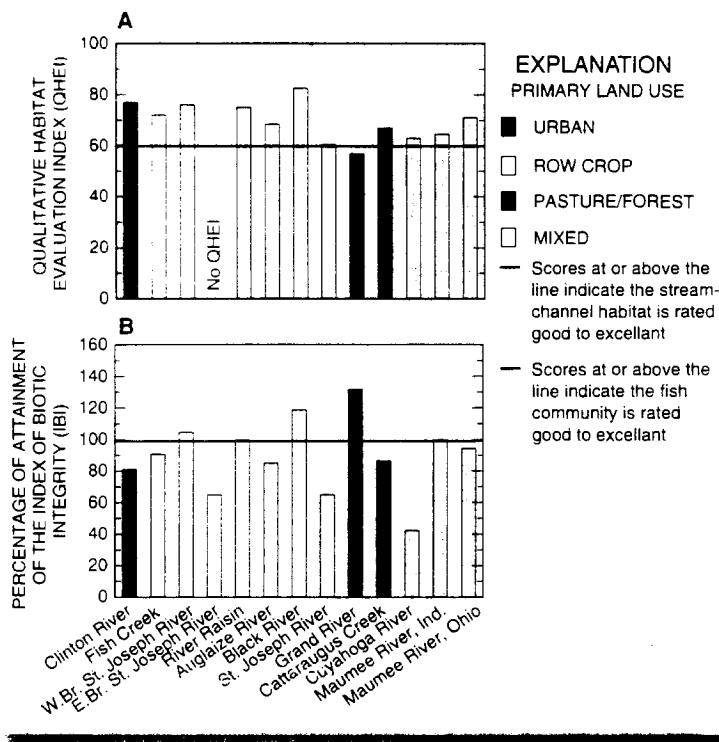

Figure 24. Although most stream sites were rated good to excellent for habitat as measured by the Qualitative Habitat Evaluation Index (A), only five sites were rated good to excellent for fish community composition as measured by the Index of Biotic Integrity (B).

Box 5—Index of Biotic Integrity and Qualitative Habitat Evaluation Index

Aquatic biological communities are sensitive indicators of stream quality. The biological condition of streams is evaluated within water-quality assessment programs by comparing the type, number, and abundance of fish species to those of streams known to be “least impacted” by human activities. The Index of Biotic Integrity (IBI), used by the Ohio Environmental Protection Agency (Ohio Environmental Protection Agency, 1989), also was used in this study to assess fish-community composition. IBI scores are derived by summing 12 individual metric scores from separate factors that describe fish communities. Examples of such metrics are the number of taxa, the number of insect-eating or omnivorous species, the number of pollution-tolerant and pollution-intolerant species, and the relative abundance of fish in each of these categories. Scores for the IBI range from 12 to 60; with ratings of poor, fair, good, and excellent quality assigned to numerical ranges. Higher scores indicate better overall fish-community diversity and abundance. Because the minimum IBI score required for a “good” rating differs somewhat from one ecological region to another, and there are five such regions in this study, each IBI score was reported as a percentage attainment of a “good” rating. A comparison of IBI scores computed independently for the same sites in the same years by the Ohio Environmental Protection Agency and USGS show that results are comparable between the two agencies as long as fish-collection methods are appropriate for the stream size (Covert, in press). A Qualitative Habitat Evaluation Index (QHEI), also developed by the Ohio Environmental Protection Agency (1989), was applied to data collected by USGS at the same stream sites where fish were assessed. The QHEI is composed of seven metrics that describe the physical habitat of streams: width, depth, pools, riffles, grain size of streambed substrates, and vegetation type and width along stream banks. Scores for the QHEI range from 0 to 100, with scores of 60 or better indicating excellent stream-channel habitat.

Figure 25. As the percentage of row-crop land use increased in a stream basin (A) scores for the Index of Biotic Integrity decreased and (B) the number of pollution-intolerant fish decreased.

are affecting fish-community composition.

For example, **agricultural runoff appears to be affecting fish communities in streams draining row crops.** Agricultural practices can heavily stress fish

communities because of runoff of pesticides, nutrients, and sediments that otherwise drain into streams with runoff from the land surface (Sweeney, 1992; Lowrance and others, 1997).

Clear differences can be seen in fish-community composition

among streams draining row-crops that may be related to the relative amount of row crops compared to woodlands and forests. As the amount of row-crops increased, the number of pollution-tolerant fish species in streams also increased (fig. 25B). In contrast, **more pollution-intolerant fish species were found in streams draining areas with lower percentages of row crops and higher percentages of forested land in their basins, especially when the forests were along streams.**

Although only a few sites were examined, **it appears that pollution-intolerant fish can live in streams where agriculture is the primary land use under certain conditions.** This information corroborates the findings of others on the water-quality benefits provided by undisturbed natural stream habitats and wooded riparian areas (figs. 26 and 27).

Clear differences can be seen in fish-community composition

Figure 26. High-quality stream habitat supports a variety of pollution-intolerant fish species along the West Branch of the St. Joseph River.

Figure 27. Poor-quality stream habitat supports pollution-tolerant fish along the East Branch of the St. Joseph River.

Recent residential development has had a widespread effect on ground-water quality

Two studies were done to assess ground-water quality in areas west of Detroit, where recent suburban development overlies sand-and-gravel deposits (Thomas, 2000a). Recent suburban development typically consists of homes on large residential/rural lots or in upper-middle-class subdivisions (fig. 28). Most homes have private wells, septic systems, and water softeners.

Samples of shallow and deep ground water were collected from co-located wells (fig. 29). Shallow ground water was sampled from 30 monitor wells (median depth of 25 feet). Deeper ground water was sampled from 28 domestic wells (median depth of 93 feet). In most places, clay till of varied thickness separates the shallow and deep sand-and-gravel deposits (fig. 29).

Tritium concentrations were used to distinguish ground waters recharged before 1953 (“old waters”) from those recharged after

Figure 28. Much of the recent development west of Detroit in the residential study area consists of low- to medium-density subdivisions. Most homes have private wells, septic systems, and water softeners.

1953 (“young waters”) (Plummer and others, 1993). Water in about one-third of domestic-wells was recharged before 1953, which is prior to widespread residential development in the study area. Old waters show no evidence of human activities. All nitrate concentrations were less than the estimated background value of 2 mg/L (U.S. Geological Survey, 1999), and all

chloride concentrations were less than 25 mg/L, the estimated background concentration based on a historical data set from the same area (Mozola, 1953).

In contrast, more than 75 percent of young waters show evidence of human influence:

- Seventy-six percent of young waters had chloride concentrations greater than background (fig. 30). Probable sources of elevated chloride concentrations are road salt, septic systems, and backwash from water softeners.

- Twenty-six percent of young waters contained nitrate concentrations greater than background (fig. 30). Probable sources of elevated nitrate concentrations in residential areas are septic systems, lawn fertilizer, and pet waste.

- Trace concentrations of VOCs were detected in 29 of the 30 samples from monitor wells. The most frequently detected VOCs were BTEX compounds, which are components of fuels and solvents.

Samples that contained nitrate or VOCs also contained elevated

Figure 29. Ground-water samples were collected from pairs of shallow monitor wells and deeper domestic wells. Sand-and-gravel deposits are at land surface and at varied depths in the subsurface.

Figure 30. In the residential study area, concentrations of nitrate and chloride greater than background concentrations are the result of human activities. Elevated concentrations of chloride were detected far below 25 feet, the minimum well depth required by State regulations.

chloride concentrations. The co-occurrence of these compounds suggests that ground water is affected by a mixture of sources, such as (1) **septic systems** containing domestic waste (nitrate and chloride), water-softener backwash (chloride), and/or household solvents such as drain cleaners (VOCs), (2) infiltration of runoff from **roads** containing road salt (chloride) and fuel residue (VOCs), and/or (3) fertilizer or pet waste (nitrate) from **lawns**.

Pesticides were detected infrequently. Trace concentrations of herbicides were detected in 2 of 30 (7 percent) monitor-well samples. This value is low compared to similar studies in 25 other urban/residential areas, where the median detection frequency of herbicides in shallow ground water was 44 percent (Kolpin, 2000). In the study area, most of the pesticides commonly used on lawns and roadways were analyzed for but were not detected in the shallow ground water.

One monitor-well sample had a nitrate concentration exceeding health-related standards (fig. 30). The sample was from a well too shallow to be used as a source of drinking water, but shallow ground water can migrate to deeper parts of ground-water system or discharge to streams, lakes, and wetlands.

No health-related drinking-water standards were exceeded in samples from domestic wells; however, standards do not exist for all compounds or for mixtures of compounds. Also, all possible constituents were not tested; for example, septic systems can contain bacteria, viruses, or pharmaceuticals.

In Michigan, the minimum depth required for domestic wells is 25 feet. In the study area, the effects of human activities were detected far below this depth (fig. 30). A proposal to increase the required depth for private wells in subdivisions is under consideration by the Michigan Department of Environmental Quality.

Box 6—Chloride/bromide ratios verify that elevated chloride concentrations are due to human activities.

In parts of eastern Michigan, elevated chloride concentrations in shallow ground water have been attributed to upward movement of brine from deep bedrock formations (Mozola, 1953; Long and others, 1988). In the study area, however, Cl/Br ratios indicate that elevated chloride concentrations were not derived from brine, but from halite (rock salt) (Davis and others, 1998). Natural sources of halite are not present in near-surface bedrock or sediments. However, halite is commonly used as road salt, table salt, and as a water-softener additive. The conclusion that elevated chloride concentrations are due to recent human activities is consistent with the observations that (1) chloride concentrations are highest in young, shallow waters, and (2) all old waters have concentrations that are less than background values.

Figure 31. In the agricultural study area, the predominant crops are corn, soybeans, and small grains. (Photograph from Ohio Department of Natural Resources.)

Ground water is vulnerable to contamination in agricultural areas underlain by till

Ground-water quality was assessed in agricultural areas in the northwestern part of the Lake Erie-Lake Saint Clair Drainages (Thomas, 2000b) (fig. 31). In this

Figure 32. In the agricultural study area, clay-rich till occurs at land surface. Shallow tile drains are installed in low spots of farm fields to improve drainage.

region, clay-rich till is at the land surface, and the rate of water infiltration is generally less than in the residential study area, where sand and gravel are at the surface (compare figs. 29 and 32).

Samples of shallow ground water were collected from 30 monitor wells installed in the till at a

median depth of 18 feet. Deeper ground water, from the glacial sand-and-gravel aquifer, was collected from 18 domestic wells with a median depth of 90 feet (fig. 32).

Samples were analyzed for pesticides in the form of parent compounds (the original active ingredient) and metabolites (break-

Figure 33. Pesticides detected in the shallow ground water closely correspond to those most heavily applied in the Lake Erie-Lake Saint Clair Drainages (data from Brody and others, 1997). All are herbicides used on corn and soybeans. Metabolites were detected more frequently, and at higher concentrations, than parent compounds.

down products). **Pesticides were detected in 41 percent of monitor-well samples.** The six compounds detected closely correspond to those most heavily applied in the basin—herbicides used on corn and soybeans (fig. 33). Metabolites were detected three times more frequently, and at higher concentrations, than were parent compounds. Concentrations did not exceed drinking-water standards, but standards do not exist for 9 of the 11 compounds detected. In addition, many samples contained more than one herbicide, and the health effect of mixtures is unknown.

Nitrate concentrations indicative of human influence were detected in 37 percent of monitor-well samples. Probable sources

are nitrogen fertilizers (which are heavily used in the study area), manure, or septic systems. Nitrate concentrations exceeded health-related drinking-water standards in two shallow monitor wells (fig. 34).

Pesticides and nitrate were detected much less frequently in domestic wells than in monitor wells (fig. 34). About 6 percent (1 of 18) of samples from domestic wells contained a trace concentration of a pesticide metabolite, and 6 percent contained a nitrate concentration approximately equal to the background concentration of 2 mg/L.

A common belief is that till protects the ground water from contamination. There appears to

be some truth to this idea because detections of nitrate and herbicides are low relative to other agricultural areas with similarly high application rates. At the same time, this belief is a simplification that may be misleading because ground water is still vulnerable to contamination, especially at shallow depths.

Fifty-nine percent of monitor-well samples showed evidence of human activity—either an herbicide or an elevated nitrate concentration. Moreover, 83 percent of waters from monitor wells were recharged after 1953. These observations indicate that **till does not prevent water at the land surface from moving to the shallow ground water.** In the study area,

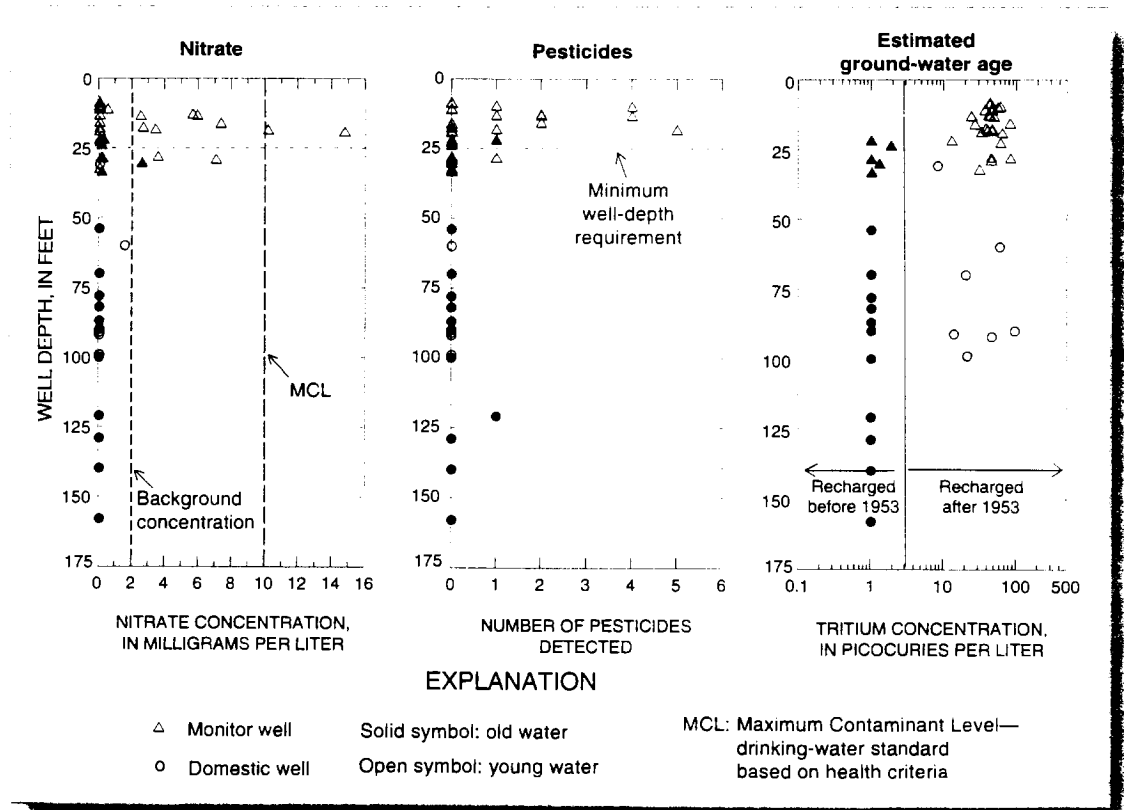

Figure 34. Detections of nitrate or pesticides are relatively infrequent at depths greater than 35 feet; however, deeper ground water is not completely isolated from the land surface because almost half of the waters between depths of 35 and 100 feet were recharged after 1953.

till contains vertical fractures and numerous stringers of sand and gravel that are potential pathways for movement of water from the surface. In areas with similar geology to that in the agricultural study area, active ground-water flow occurs to depths of 35 feet, and sometimes much deeper (Keller and others, 1991).

Similarly, till does not completely prevent water at the land surface from entering the deeper ground water. Eleven percent of domestic-well samples contained either a pesticide or elevated nitrate concentration. Moreover, almost half of the waters from domestic wells between depths of 35 to 100 feet were recharged after 1953 (fig. 34).

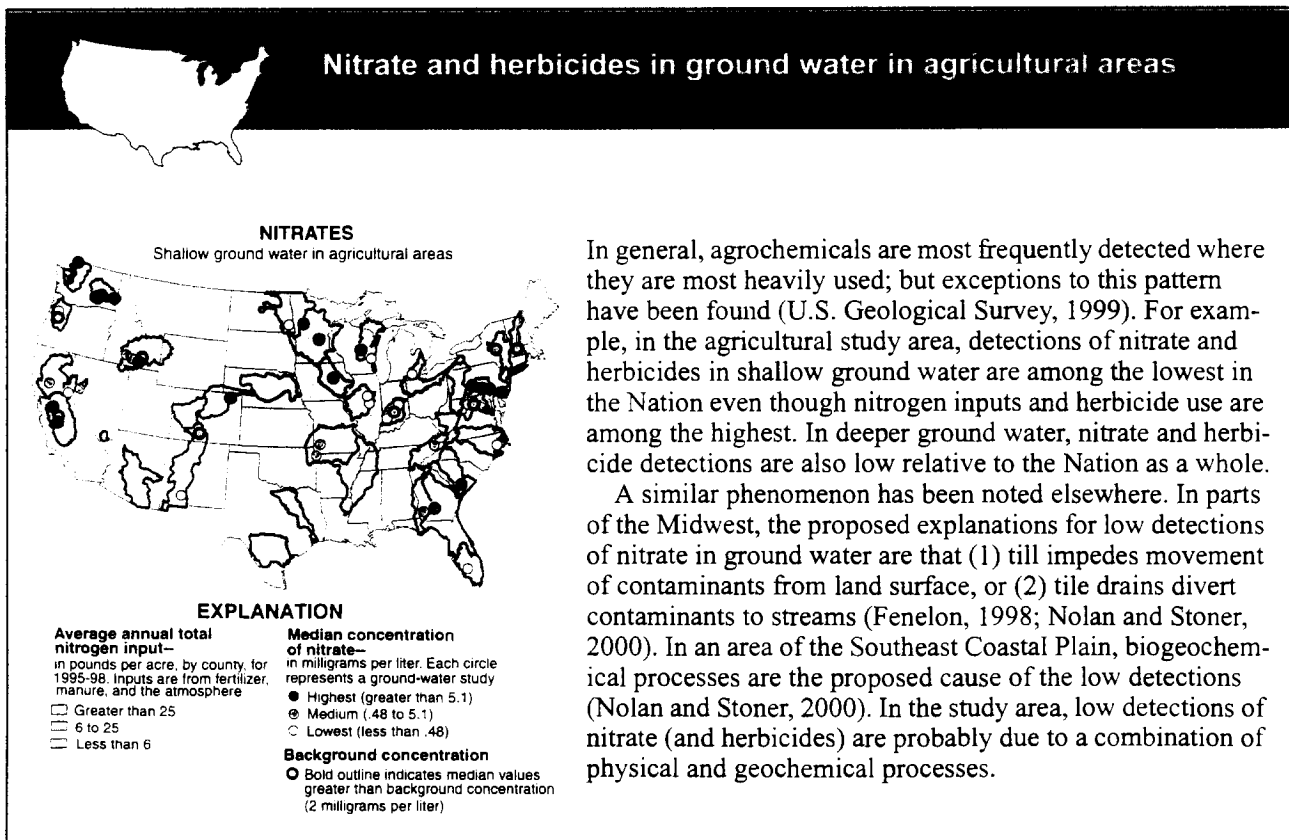

Naturally occurring **geochemical processes** may be partly responsible for the relatively low

detection frequencies of agrochemicals in the ground water. Till and till soils are generally rich in clay and organic matter and therefore are conducive to the sorption or breakdown of pesticides. Most of the pesticides detected were metabolites that had already been partially broken down (fig. 33).

Nitrate also can be transformed in the subsurface. In the presence of organic matter, low dissolved-oxygen concentrations are conducive to denitrification. Ground-water samples from 100 percent of the domestic wells and 50 percent of the monitor wells had dissolved-oxygen concentrations less than 1 mg/L. In addition, the till contains numerous fragments of black shale rich in pyrite, a mineral that can also lead to denitrification (Robertson and others, 1996).

Within the study area, the thickness and composition of the till are variable and not well defined in all locations. Therefore, the degree to which the till protects the ground water—by physical or geochemical means—is probably also variable and difficult to predict.

Low detections of agrochemicals in ground water may be partly due to tile drains, which can divert contaminants from the shallow ground water to streams (Nolan and Stoner, 2000), but tile drains do not completely prevent contaminants from reaching shallow ground water. Nitrate and pesticides were detected in monitor wells 10 to 34 feet deep, whereas tile drains are typically about 3 feet deep. Vertical fractures in the till can provide a direct pathway from the land surface to the water table.

STUDY UNIT DESIGN

Stream Chemistry

A network of 10 stream sites was sampled for various chemical constituents and physical properties from March 1996 through February 1998 (fig. 35, table 3). Sampling was done over a range of stream-flows. Sites were sampled 18–32 times per year; intensive sites were sampled more frequently than basic sites (table 3).

Assessments of contaminants in streambed sediments and fish tissue were made at the 10 fixed streams sites and at one to five

additional sites. Sediment samples were collected and sieved in the field. Whole fish were collected and analyzed for concentrations of organochlorine compounds. Fish livers were analyzed for trace-element concentrations.

Stream Ecology

Sampling was done at least once at 10 sites where water samples were collected. Multiple-year and multiple-reach sampling was done at three sites (table 3). Stream

reaches ranged from 200 to 500 meters in length.

Fish surveys involved electro-fishing and seining. Macroinvertebrates and algae were sampled from natural substrates. Habitats were assessed by identifying and mapping riparian vegetation and measuring geomorphic features of stream channels. Samples of bed and bank materials were collected and analyzed for grain size.

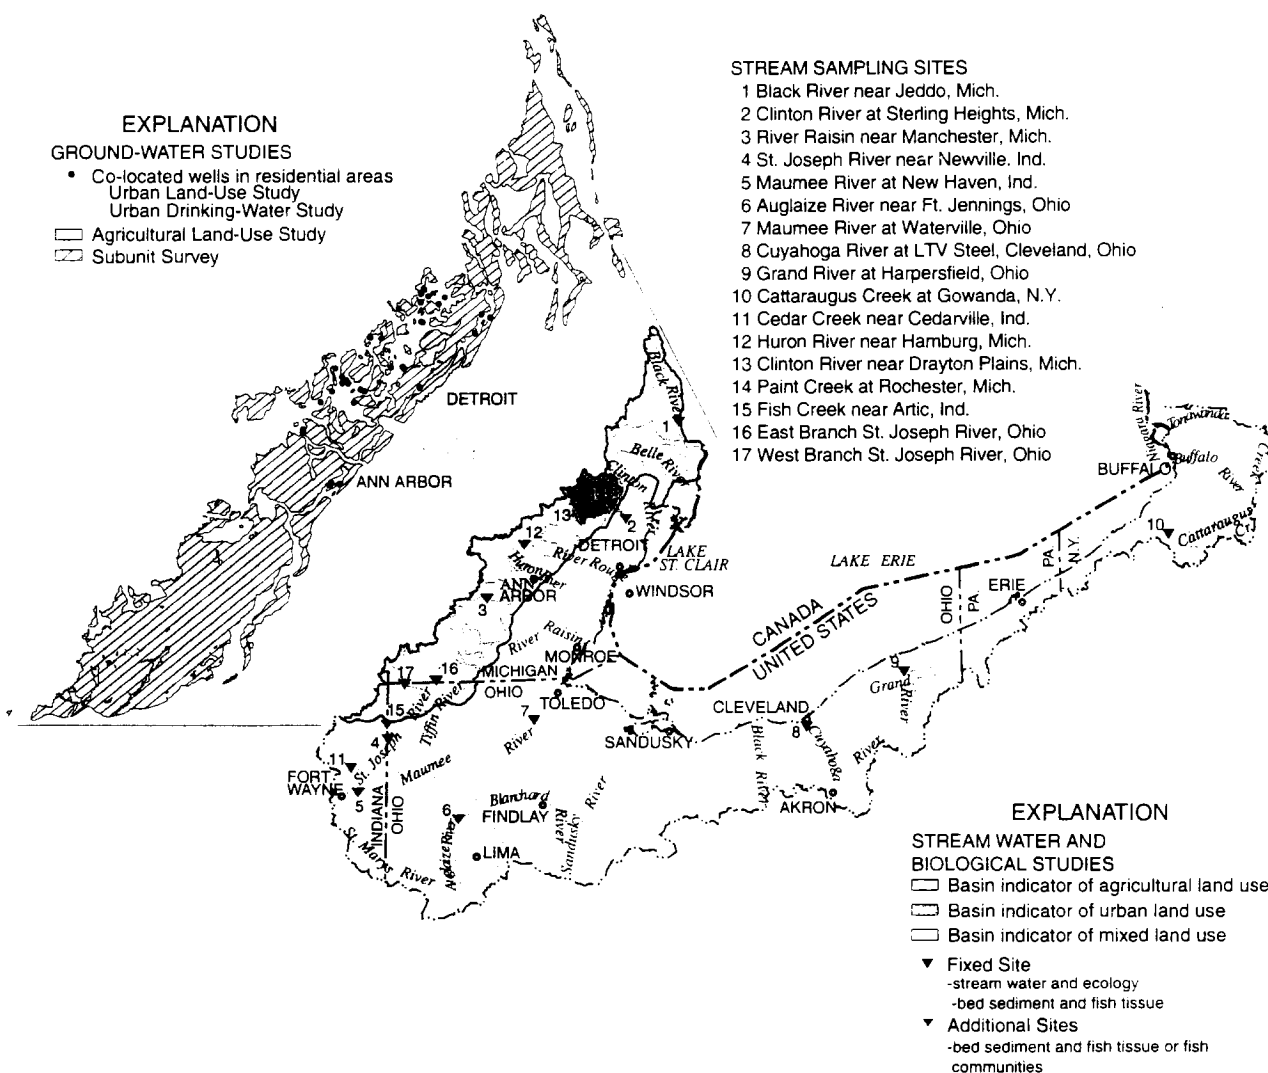

Figure 35. Stream and ground-water sampling sites in the Lake Erie-Lake Saint Clair Drainages, 1996–98.

TABLE 3. SUMMARY OF DATA COLLECTION IN THE LAKE ERIE-LAKE SAINT CLAIR DRAINAGES, 1996-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Contaminants in stream-water—basic sites	Streamflow, pH, specific conductance, temperature and concentrations of nitrogen and phosphorus compounds, major ions, organic carbon, suspended sediment, herbicides, and <i>E. coli</i> were measured to determine occurrence and distribution of contaminants and other constituents	Streams draining areas ranging in size from 132 square miles to 1,230 square miles reflecting agricultural, urban, and mixed land uses.	6	Monthly, plus storms and low flows from March 1996 to February 1998
Contaminants in stream-water—intensive sites	Physical properties and chemical and microbiological constituents mentioned above plus insecticides and VOCs.	Streams draining areas ranging from 310 square miles to 6,330 square miles reflecting agricultural, urban, and mixed land uses.	4	Weekly to monthly, plus storms and low flows from October 1996 to September 1997, bracketed by monthly plus storms from March 1996 to February 1998
Contaminants in streambed sediment	Concentrations as dry weight of trace elements, semivolatile organic compounds, organochlorine compounds, and percent organic content. Determined to assess occurrence and distribution of contaminants.	Shallow depositional zones in a 300-meter reach at all 10 sites sampled for stream-water chemistry and at 5 additional sites	15	One to three times in June–October, 1996–98
Contaminants in fish tissue	Concentrations of trace elements in fish liver and organochlorine compounds, such as PCBs and organochlorine pesticides, in fish tissue were analyzed to determine occurrence and distribution.	Resident fish such as carp, rock bass, and hog suckers at all sites sampled for stream-water chemistry and at one additional site	15	One to three times in June–October, 1996–98
Stream Ecology				
Aquatic biota at stream sites	Community composition of aquatic macroinvertebrates, algae, fish and stream habitat were surveyed to determine effects of water quality on aquatic biota.	Sites co-located with basic and intensive stream-water chemistry sites and at three additional sites	10	One to three times in June–October in 1996–98
Ground-Water Chemistry				
Subunit survey	Water level, pH, specific conductance, temperature and concentrations of nitrogen and phosphorus compounds, major ions, VOCs, organic carbon, insecticides, herbicides, herbicide degradates, radon, and tritium were measured to determine the quality of an aquifer that is an important source of drinking water.	Domestic wells in the northwestern part of the Study Unit. Eighteen of the wells are co-located with monitor wells of the agricultural land-use study.	28	Once, June–August 1998
Agricultural land-use study	Above measurements and compounds (except VOCs and radon) to determine the effects of agricultural land use on shallow ground water.	Monitor wells in agricultural areas in northwestern part of Study Unit.	30	Once, June–August 1998
Urban land-use study	Above compounds (plus VOCs and radon) to determine effects of recent residential development on shallow ground water.	Monitor wells in new residential areas near Detroit, Mich.	30	Once, September–December 1996
Special Study				
Urban drinking-water study	Same as for Subunit survey	Domestic wells co-located with urban land-use wells in new residential areas near Detroit.	28	Once, May–July 1997

Ground-Water Chemistry

Four ground-water studies were done in the northwestern part of the basin (fig. 35), where glacial deposits greater than 100 feet thick serve as the major source of drinking water.

Two of the studies were done on the far outskirts of Detroit, where recent residential developments overlie sand and gravel. An urban

land-use study was done by installing and sampling 30 shallow monitor wells (table 3). A second study involved sampling 28 domestic-supply wells, each of which was co-located with a monitor well.

The agricultural land-use study was done in areas where corn and soybean row crops overlie clay-rich till. Thirty shallow monitor wells were installed in the till and

sampled for a various constituents, including pesticide metabolites.

The subunit survey involved sampling 28 domestic wells that produce water from the glacial aquifer in areas where it is overlain by till. Of the 28 wells, 18 were co-located with monitor wells in the agricultural land-use study area (fig. 35).

GLOSSARY

- Anthropogenic** - A condition or occurrence that is the result of, or is influenced by, human activity.
- Aquifer** - A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Background concentration** - A concentration of a substance in a particular environment that is indicative of minimal influence by human (anthropogenic) sources.
- Base flow** - Sustained, low flow in a stream; ground-water discharge is the source of base flow in most places.
- Bed sediment** - The material that temporarily is stationary in the bottom of a stream or other watercourse.
- Benthic** - Refers to plants or animals that live on the bottom of lakes, streams, or oceans.
- Bioaccumulation** - The biological sequestering of a substance at a higher concentration than that at which it occurs in the surrounding environment or medium. Also, the process whereby a substance enters organisms through the gills, epithelial tissues, dietary, or other sources.
- Biota** - Living organisms.
- Breakdown product** - A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process which may result in a more toxic or a less toxic compound and a more persistent or less persistent compound.
- BTEX** - Benzene, toluene, ethylbenzene, and xylene; volatile organic compounds found in gasoline and solvents.
- Chlordane** - Octachloro-4,7-methanotetrahydroindane. An organochlorine insecticide no longer registered for use in the U.S. Technical chlordane is a mixture in which the primary components are *cis*- and *trans*-chlordane, *cis*- and *trans*-nonachlor, and heptachlor.
- Community** - In ecology, the species that interact in a common area.
- Concentration** - The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as microgram per liter (water sample) or micrograms per kilogram (sediment or tissue sample).
- Denitrification** - A process by which oxidized forms of nitrogen such as nitrate (NO_3^-) are reduced to form nitrites, nitrogen oxides, ammonia, or free nitrogen: commonly brought about by the action of denitrifying bacteria and usually resulting in the escape of nitrogen to the air.
- Detect** - To determine the presence of a compound.
- DDT** - Dichloro-diphenyl-trichloroethane. An organochlorine insecticide no longer registered for use in the United States.
- Dieldrin** - An organochlorine insecticide no longer registered for use in the United States. Also a degradation product of the insecticide aldrin.
- Discharge** - Rate of fluid flow passing a given point at a given moment in time, expressed as volume per unit of time.
- Domestic well** - A private home well, or a well that serves less than 15 households or 25 individuals.
- Endocrine system** - The collection of glands in animals that secrete hormones, which influence growth, gender and sexual maturity.
- Eutrophication** - The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.
- Ground water** - In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Herbicide** - A chemical or other agent applied for the purpose of killing undesirable plants. See also Pesticide.
- Insecticide** - A substance or mixture of substances intended to destroy or repel insects.
- Intolerant organisms** - Organisms that are not adaptable to human alterations to the environment and thus decline in numbers where human alterations occur. See also Tolerant species.
- Invertebrate** - An animal having no backbone or spinal column.
- MCL (Maximum Contaminant Level)** - Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Median** - The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Metabolite** - See breakdown product.
- Monitor well** - A well designed for measuring water levels and testing ground-water quality.
- Nitrate** - An ion consisting of nitrogen and oxygen (NO_3^-). Nitrate is a plant nutrient and is very mobile in soils. In this report, the term "nitrate" is used as shorthand for "nitrate plus nitrite, reported as nitrogen."
- Nutrient** - Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.
- Organochlorine compound** - Synthetic organic compound containing chlorine. As generally used, term refers to compounds containing mostly or exclusively carbon, hydrogen, and chlorine. Examples include organochlorine insecticides, polychlorinated biphenyls, and some solvents containing chlorine.
- Pesticide** - A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests."
- Phosphorus** - A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.
- Polychlorinated biphenyls (PCBs)** - A mixture of chlorinated derivatives of biphenyl, marketed under the trade name Aroclor with a number designating the chlorine

content (such as Aroclor 1260). PCBs were used in transformers and capacitors for insulating purposes and in gas pipeline systems as a lubricant. Further sale for new use was banned by law in 1979.

Polycyclic aromatic hydrocarbon (PAH) - A class of organic compounds with a fused-ring aromatic structure. PAHs result from incomplete combustion of organic carbon (including wood), municipal solid waste, and fossil fuels, as well as from natural or anthropogenic introduction of uncombusted coal and oil. PAHs include benzo[a]pyrene, fluoranthene, and pyrene.

Recharge - Water that infiltrates the ground and reaches the saturated zone.

Runoff - Excess rainwater or snowmelt that is transported to streams by overland flow, tile drains, or ground water.

SMCL (Secondary maximum contaminant level) - Non-enforceable drinking-water standards established by the U.S. Environmental Protection Agency for contaminants that may adversely affect the odor or appearance of drinking water.

Sediment - Particles, derived from rocks or biological materials, that have been transported by a fluid or other natural process, suspended or settled in water.

Semivolatile organic compound (SVOC) - Operationally defined as a group of synthetic organic compounds that are solvent-extractable and can be determined by gas chromatography/mass spectrometry. SVOCs include phenols, phthalates, and polycyclic aromatic hydrocarbons (PAHs).

Streamflow - A type of channel flow, applied to that part of surface runoff in a stream whether or not it is affected by diversion or regulation.

Suspended sediment - Particles of rock, sand, soil, and organic detritus carried in suspension in the water column, in contrast to sediment that moves on or near the streambed.

Taxon (plural taxa) - Any identifiable group of taxonomically related organisms.

Tile drain - A buried perforated pipe designed to remove excess water from soils.

Till - An unsorted glacial deposit characterized by low permeability.

Triazine herbicide - A class of herbicides containing a symmetrical triazine ring (a nitrogen-heterocyclic ring composed of three nitrogens and three carbons in an alternating sequence). Examples include atrazine, propazine, and simazine.

Volatile organic compounds (VOCs) - Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

Water table - The point below the land surface where ground water is first encountered and below which the earth is saturated. Depth to the water table varies widely across the country.

Water year - The continuous 12-month period, October 1 through September 30, in U.S. Geological Survey reports dealing with the surface-water supply. The water year is designated by the calendar year in which it ends and which includes 9 of the 12 months. Thus, the year ending September 30, 1980, is referred to as water year 1980.

APPENDIX—WATER-QUALITY DATA FROM THE LAKE ERIE-LAKE SAINT CLAIR DRAINAGES IN A NATIONAL CONTEXT

For a complete view of Lake Erie-Lake Saint Clair Drainages data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Lake Erie-Lake Saint Clair Drainages. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Lake Erie-Lake Saint Clair Drainages compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, in the Lake Erie-Lake Saint Clair Drainages acetochlor concentrations in agricultural streams were similar to the national distribution, but the detection frequency was much higher (61 percent compared to 33 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Lake Erie-Lake Saint Clair Drainages, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

— Not measured or sample size less than two

12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

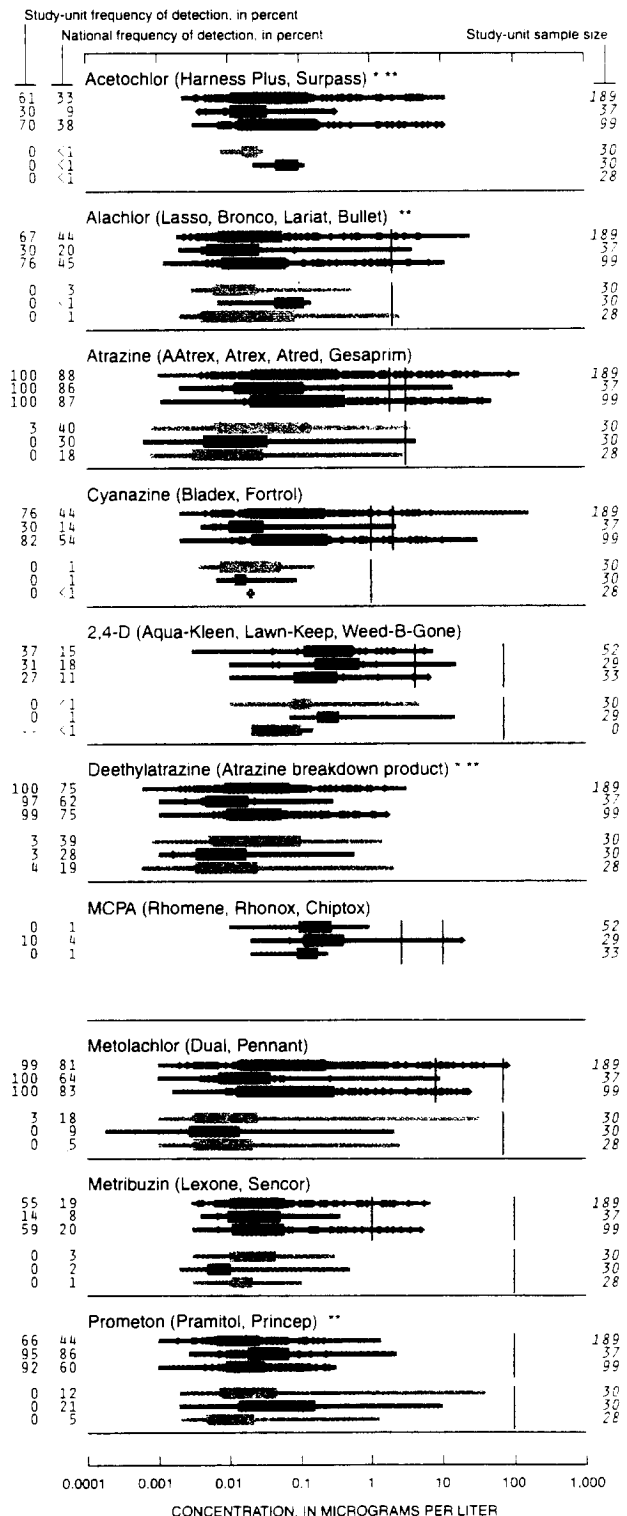

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- * No benchmark for drinking-water quality
- ** No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) ***
- Bentazon (Basagran, Bentazone) **
- Bromoxynil (Buctril, Brominal) *
- Butylate (Sutan +, Genate Plus, Butilate) **
- DCPA (Dacthal, chlorthal-dimethyl) ***
- Dicamba (Banvel, Dianat, Scotts Proturf)
- 2,6-Diethylaniline (Alachlor breakdown product) **
- Diuron (Crisuron, Karmex, Diurex) **
- EPTC (Eptam, Farmarox, Alirox) ***
- Fenuron (Fenulon, Fenidim) **
- Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
- MCPB (Thistrol) **
- Pendimethalin (Pre-M, Prowl, Stomp) **
- Picloram (Grazon, Tordon)
- Propachlor (Ramrod, Satecid) **
- Terbacil (Sinbar) **
- Triclopyr (Garlon, Grandstand, Redeem, Remedy) ***
- Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

- Bromacil (Hyvar X, Urox B, Bromax)
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) ***
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) ***
- Dacthal mono-acid (Dacthal breakdown product) ***
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) ***
- Dinoseb (Dinosebe)
- Ethalfuralin (Sonalan, Curbit) **
- Fluometuron (Flo-Met, Cotoran) **
- Molinate (Ordram) ***
- Napropamide (Devrinol) **
- Neburon (Neburea, Neburyl, Noruben) **
- Norflurazon (Evital, Predict, Solicam, Zorial) **
- Oryzalin (Surflan, Dirimal) ***
- Pebulate (Tillam, PEBC) ***
- Pronamide (Kerb, Propyzamid) **
- Propanil (Stam, Stampede, Wham) **
- Propham (Tuberite) **
- 2,4,5-T **
- 2,4,5-TP (Silvex, Fenoprop) **
- Thiobencarb (Bolero, Saturn, Benthicarb) ***

Pesticides in water—Insecticides

Other insecticides detected

- Carbofuran (Furadan, Curaterr, Yaltox)
- Dieldrin (Panoram D-31, Octalox, Compound 497)
- Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
- alpha-HCH (alpha-BHC, alpha-lindane) **
- Malathion (Malathion)
- Methyl parathion (Penncap-M, Folidol-M) **

Insecticides not detected

- Aldicarb (Temik, Ambush, Pounce)
- Aldicarb sulfone (Standak, aldoxycarb)
- Aldicarb sulfoxide (Aldicarb breakdown product)
- Azinphos-methyl (Guthion, Gusathion M) *
- Disulfoton (Disyston, Di-Syston) **
- Ethoprop (Mocap, Ethoprophos) ***
- gamma-HCH (Lindane, gamma-BHC)
- 3-Hydroxycarbofuran (Carbofuran breakdown product) ***
- Methiocarb (Slug-Geta, Grandslam, Mesuro) ***
- Methomyl (Lanox, Lannate, Acinate) **
- Oxamyl (Vydate L, Pratt) **
- Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
- cis-Permethrin (Ambush, Astro, Pounce) ***
- Phorate (Thimet, Granutox, Geomet, Rampart) ***
- Propargite (Comite, Ornite, Ornamite) ***
- Propoxur (Baygon, Blattanex, Unden, Proprotox) **
- Terbufos (Contraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

- Benzene
- Bromodichloromethane (Dichlorobromomethane)
- 2-Butanone (Methyl ethyl ketone (MEK)) *
- Chlorodibromomethane (Dibromochloromethane)
- 1,4-Dichlorobenzene (*p*-Dichlorobenzene)
- Dichlorodifluoromethane (CFC 12, Freon 12)
- Dichloromethane (Methylene chloride)
- 1,2-Dimethylbenzene (*o*-Xylene)
- 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
- Ethenylbenzene (Styrene)
- Ethylbenzene (Phenylethane)
- Iodomethane (Methyl iodide) *
- 2-Propanone (Acetone) *
- Tetrachloroethene (Perchloroethene)
- 1,1,1-Trichloroethane (Methylchloroform)
- Trichloromethane (Chloroform)
- 1,2,4-Trimethylbenzene (Pseudocumene) *

VOCs not detected

- tert*-Amyl methyl ether (*TAME*) *
- Bromobenzene (Phenyl bromide) *
- Bromochloromethane (Methylene chlorobromide)
- Bromoethene (Vinyl bromide) *
- Bromomethane (Methyl bromide)
- n*-Butylbenzene (1-Phenylbutane) *
- sec*-Butylbenzene *
- tert*-Butylbenzene *
- 3-Chloro-1-propene (3-Chloropropene) *
- 1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
- 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
- Chlorobenzene (Monochlorobenzene)
- Chloroethane (Ethyl chloride) *
- Chloroethene (Vinyl chloride)
- Chloromethane (Methyl chloride)
- 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
- 1,2-Dibromoethane (Ethylene dibromide, EDB)
- Dibromomethane (Methylene dibromide) *
- trans*-1,4-Dichloro-2-butene ((*Z*)-1,4-Dichloro-2-butene) *
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
- 1,3-Dichlorobenzene (*m*-Dichlorobenzene)
- 1,2-Dichloroethane (Ethylene dichloride)
- 1,1-Dichloroethane (Ethylidene dichloride) *
- 1,1-Dichloroethene (Vinylidene chloride)
- trans*-1,2-Dichloroethene ((*E*)-1,2-Dichloroethene)
- cis*-1,2-Dichloroethene ((*Z*)-1,2-Dichloroethene)
- 1,2-Dichloropropane (Propylene dichloride)
- 2,2-Dichloropropane *
- 1,3-Dichloropropane (Trimethylene dichloride) *
- trans*-1,3-Dichloropropane ((*E*)-1,3-Dichloropropane)
- cis*-1,3-Dichloropropane ((*Z*)-1,3-Dichloropropane)
- 1,1-Dichloropropene *
- Diethyl ether (Ethyl ether) *
- Diisopropyl ether (Diisopropylether (DIPE)) *
- Ethyl methacrylate *
- Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
- 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
- Hexachlorobutadiene
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK)) *
- Isopropylbenzene (Cumene) *
- p*-Isopropyltoluene (*p*-Cymene) *
- Methyl acrylonitrile *
- Methyl *tert*-butyl ether (MTBE)
- Methyl-2-methacrylate (Methyl methacrylate) *
- 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *

- Methyl-2-propenoate (Methyl acrylate) *
- Naphthalene
- 2-Propenenitrile (Acrylonitrile)
- n*-Propylbenzene (Isocumene) *
- 1,1,2,2-Tetrachloroethane *
- 1,1,1,2-Tetrachloroethane
- Tetrachloromethane (Carbon tetrachloride)
- 1,2,3,4-Tetramethylbenzene (Phehnitene) *
- 1,2,3,5-Tetramethylbenzene (Isodurene) *
- Tribromomethane (Bromoform)
- 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
- 1,2,4-Trichlorobenzene
- 1,2,3-Trichlorobenzene *
- 1,1,2-Trichloroethane (Vinyl trichloride)
- Trichloroethene (TCE)
- Trichlorofluoromethane (CFC 11, Freon 11)
- 1,2,3-Trichloropropane (Allyl trichloride)
- 1,2,3-Trimethylbenzene (Hemimellitene) *
- 1,3,5-Trimethylbenzene (Mesitylene) *

Trace elements in fish tissue (livers) and bed sediment

BIOLOGICAL INDICATORS

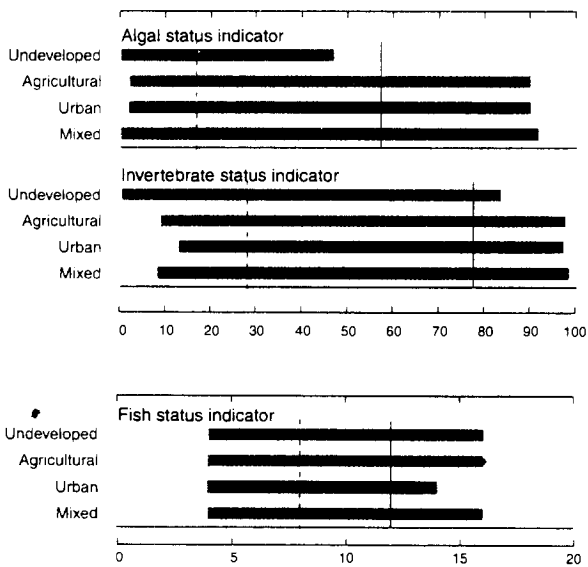

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

Biological indicator value, Lake Erie - Lake Saint Clair Drainages, by land use, 1996-98

APPENDIX—WATER-QUALITY DATA FROM THE KANAWHA-NEW RIVER BASIN IN A NATIONAL CONTEXT	27

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Kanawha–New River Basin that emerged from an assessment conducted between 1996 and 1998 by the U.S. Geological Survey (USGS) National Water–Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings also are explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation’s drinking water, such as by monitoring water from household taps. Rather, NAWQA assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. Comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of instream habitats as elements of a complete water-quality assessment.

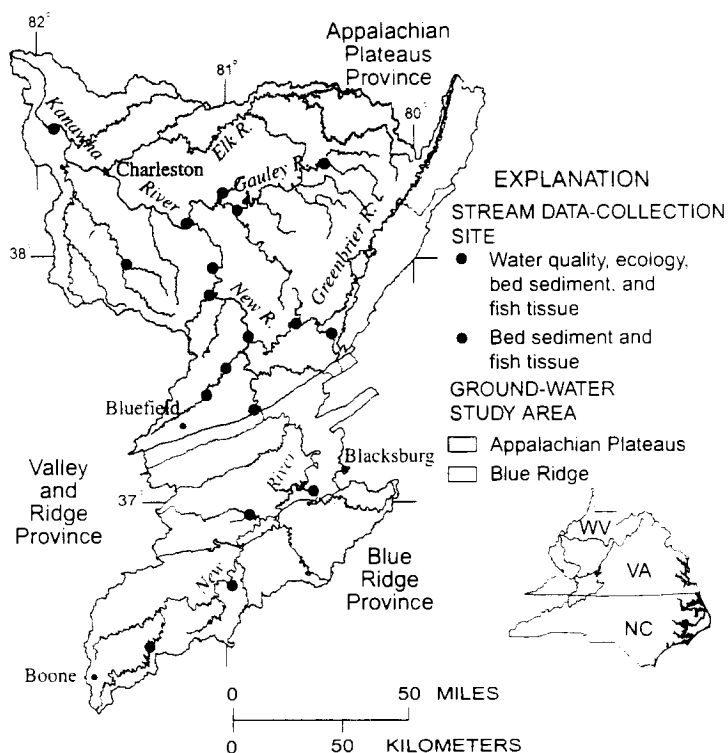

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during this water-quality assessment. Residents of West Virginia, Virginia, and North Carolina who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM of the USGS seeks to improve scientific and public understanding of water quality in the Nation’s major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Kanawha–New River Basin is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

The Kanawha–New River Basin is generally mountainous, forested, humid, and rural. Agriculture is concentrated in the southern half of the basin; major products are cattle and hay. Seven percent of all coal mined in the United States is produced from the Appalachian Plateaus Physiographic Province within the basin.

Stream and River Highlights

The generally low population and intensity of agriculture and urban land uses throughout the Kanawha–New River Basin are reflected in low concentrations of nutrients and pesticides in streams and rivers.

Streams in the coal region of the Appalachian Plateaus Physiographic Province generally improved between about 1980 and 1998 with respect to pH, total iron, total manganese, and sedimentation. These improvements were among the regulatory goals of the Surface Mining Control and Reclamation Act of 1977 (SMCRA). Other unregulated factors, however, show the effects of continued mining. Mine drainage in the basin is rarely acidic but has high concentrations of sulfate, which decrease slowly after mining ends. Stream-bottom sedimentation in mined basins remains greater than in undisturbed basins.

- Streams draining basins that have been mined since 1980 show increased dissolved sulfate, decreased median bed-sediment particle size, and impaired benthic-invertebrate communities compared to streams not mined since 1980. (p. 5–11)

- In all basins studied where more than 100,000 tons of coal per square mile have been mined, the stream benthic-invertebrate community is impaired in comparison to rural parts of the basin where less than 10,000 tons of coal per square mile have been mined since 1980. Some basins in which the benthic-invertebrate community is impaired, however, were not heavily mined. Benthic invertebrates are sensitive indicators of many types of disturbance and respond to impairment of either stream chemistry or physical habitat. (p. 7–8)

- Effects on stream benthic-invertebrate communities caused by coal mining were of similar magnitude to the effects caused by urban development and agriculture elsewhere in the Nation. (p. 11)

- Kanawha Falls is the upstream limit for the range of several fish species. Non-native fish continue to expand their range in tributaries of the New and Gauley Rivers. (p. 12–14)

- *Escherichia coli* (*E. coli*) bacteria concentrations exceeded the national guideline for public swimming areas in 26 percent of samples from major rivers and in 43 percent of samples from tributary streams, but no outbreak of waterborne disease was reported during 1991–98. Inadequate sewage treatment and manure management contribute to elevated *E. coli* concentrations. (p. 14–15)

- Volatile organic compounds (VOCs) continue to be detected in the Kanawha River downstream from the Charleston metropolitan area. (p. 16)

- Nickel, chromium, zinc, and certain toxic organic compounds were found in bed sediment in concentrations that could harm aquatic life. Elevated concentrations of cadmium, mercury, nickel, selenium, and zinc were measured in fish tissue at some sites. (p. 12)

Major Influences on Streams and Rivers

- Coal mining
- Improper disposal of human and animal wastes
- Past industrial activities

Ground-Water Highlights

Ground water in the Appalachian Plateaus and Blue Ridge Physiographic Provinces moves mostly in a network of narrow fractures within a few hundred feet of the land surface, and drains toward the nearest stream. Wells normally tap only a few of the many local fractures. The ridgetops bound each local aquifer, which generally are affected only by local contaminant sources. In small areas of the basin where caves and solution cavities in limestone bedrock are common, wells can have high yields but are susceptible to contamination from fecal bacteria, pesticides, and other toxic chemicals.

- Radon concentrations in the Blue Ridge were among the highest in the Nation. Almost 90 percent of wells sampled there exceeded the proposed U. S. Environmental Protection Agency (USEPA) primary drinking-water standard of 300 picocuries per liter (pCi/L). One-third of these wells contained more than 4,000 pCi/L, the proposed alternate drinking-water standard. Radon is a radioactive gas that forms during the decay of natural uranium. (p. 18–19)

- Modern well construction can prevent fecal bacteria from reaching drinking water in most areas of the basin. Bacteria were frequently detected only at older wells. (p. 19)
- Potentially explosive concentrations of methane were found in water at 7 percent of wells in the coal region of the Appalachian Plateaus. (p. 17)
- Nutrients, pesticides, and VOCs were detected in low concentrations throughout the basin. In the Blue Ridge, however, water from more than 50 percent of wells contained pesticides, an indication that the ground water is vulnerable to contamination. (p. 19)
- In the Appalachian Plateaus, iron and manganese concentrations exceeded USEPA drinking-water guidelines in at least 40 percent of the wells and in about 70 percent of wells near reclaimed surface coal mines. Elevated sulfate concentration and slightly acidic water were more common at wells within 1,000 feet of reclaimed mines than elsewhere. (p. 10 and 17)

Major Influences on Ground Water

- Composition of soils and bedrock
- Improper disposal of human and animal wastes
- Current and past mining practices
- Pesticide usage and other toxic chemical releases

INTRODUCTION TO THE KANAWHA–NEW RIVER BASIN

Population and Human Activities

The Kanawha River and its major tributary, the New River, drain 12,223 mi² in North Carolina, Virginia, and West Virginia (Messinger and Hughes, 2000). Most of the total basin population of 870,000 (1990 data) live in rural areas, and industrial and residential areas cover less than 5 percent of the total area in the basin (fig. 1). Only about 30 percent of the population live in towns larger than 10,000 people, including the 25 percent who live in the Charleston, W. Va.,

metropolitan area. The total population has not changed substantially since the 1950s, mostly because of emigration from rural parts of the basin to urban centers in the Midwest and the South.

The only major industrial area in the basin is along the terrace of the Kanawha River, within about 20 miles of Charleston (fig. 2). Chemical industry practices that profoundly polluted the Kanawha River during the 1950s and 1960s have changed, and discharge of pollutants to streams has greatly decreased, although

bed sediment and fish remain contaminated with dioxin and other industrial chemicals (Henry, 1981; Kanetsky, 1988; West Virginia Division of Environmental Protection, 2000).

In the Kanawha–New River Basin, most coal is mined in the Appalachian Plateaus in West Virginia (McColloch, 1998). About 7 percent of the coal mined in the United States comes from the Kanawha–New River Basin (Fedorko and Blake, 1998; Messinger and Hughes, 2000). Most coal mined in the basin has a low sulfur content. Coal production has increased since passage of the Clean Air Act amendments of 1990, which mandated a reduction of sulfate emissions to decrease acid precipitation.

Physiography

The streams and rivers of the basin drain areas in three physiographic provinces: the Blue Ridge (17 percent), the Valley and Ridge (23 percent), and the Appalachian Plateaus (60 percent). In the Appalachian Plateaus, little of the land is flat, and most flat land is in the flood plains and terraces of streams.

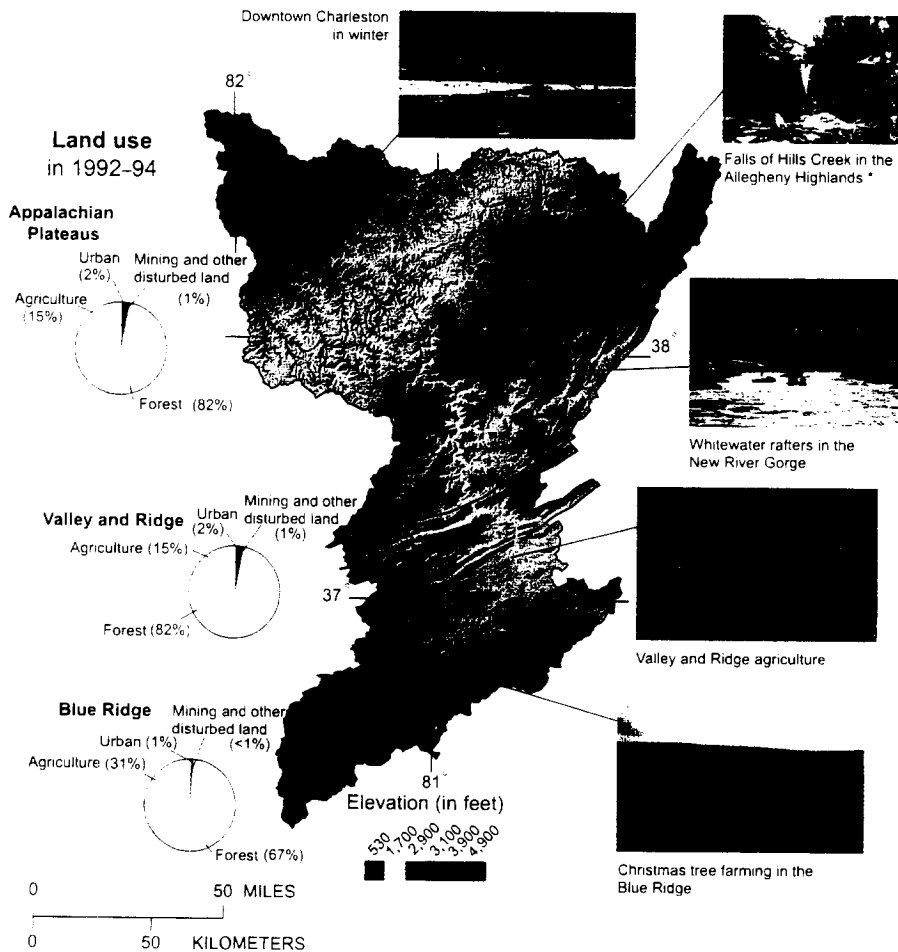

Figure 1. In the mountainous Kanawha–New River Basin, elevation ranges from over 4,000 feet in the Allegheny Highlands of the Appalachian Plateaus Province and the Blue Ridge Province to about 560 feet at the mouth of the river at Point Pleasant, W. Va. Forest accounted for 81 percent of the land cover in 1993 (Multi-Resolution Land Characteristics Interagency Consortium, 1997). Logging is a major industry throughout the basin. The entire basin was logged by the early 20th century, and no undisturbed areas remain (Clarkson, 1964). Coal mining is prevalent in the Appalachian Plateaus. The Blue Ridge Province contains proportionally more agricultural land than the Appalachian Plateaus and Valley and Ridge Provinces. Cattle, hay, and corn grown as cattle feed are the primary agricultural products (National Agriculture Statistics Service, 1999). Physiographic provinces from Fenneman, 1938.

* Photograph by Julie Archer, and used by permission.

Figure 2. Coal and motor fuel commonly are transported by barge on the Kanawha River, downstream from Kanawha Falls.

The Valley and Ridge is characterized by strongly folded ridges separated by relatively flat, broad valleys. These two regions are underlain by sedimentary rocks. The Blue Ridge is characterized by igneous and metamorphic rocks that have been folded and faulted.

Water Use

In 1995, 61 percent of the basin's population depended on surface-water supplies for domestic needs (Solley and others, 1998). Thirty percent relied on domestic water wells. The remaining nine percent used public-supply water wells. In 1995, total withdrawal of water was about 1,130 Mgal/d (million gallons per day); total consumptive use was about 118 Mgal/d.

Hydrologic Conditions and Features

With some exceptions, mean streamflow during the study was within about 10 percent of long-term mean flows at most gaging stations (see records from a representative station in fig. 3). Major flooding occurred throughout the Appalachian Plateaus in January 1996, seven months before sampling began, and streamflow at several gaging stations within the Kanawha–New River Basin exceeded the 100-year flood flow (Ward and others, 1997). A thunderstorm in June 1998 caused flooding in the northwestern part of the basin where flow on a few small streams exceeded the 100-year recurrence interval (Ward and others, 1999). With the exception of these floods, no other flows exceeded the 10-year recurrence

interval. No streams in the basin were in drought conditions during the study.

Streamflow varies most through the year in the western Appalachian Plateaus, and it varies least through the year in the Blue Ridge. On average, streamflow throughout the basin is greatest in February and March and least in September through October. Maximum streamflow does not coincide with maximum precipitation because summer vegetation uses a large fraction of the precipitation.

The river system in the Kanawha–New River Basin is regulated by four major flood-control dams, three navigation dams, and several smaller dams. The two largest dams are on the Gauley River (Summersville Dam) and Elk River (Sutton Dam). The other two major dams are on the New River. The navigable reach of the Kanawha River is in backwater caused by the navigation dams. In this reach, stream depth is greater and velocity is less than in the undammed reaches of the major rivers. All pools behind dams in the basin collect sediment. Dams are also major barriers to fish movement.

Figure 3. After a major flood in January 1996, streamflow from Williams River at Dyer, W. Va., and precipitation from Richwood, W. Va., were normal throughout the study period. The long-term average annual streamflow at Williams River at Dyer, W. Va. is 336 cubic feet per second. Long-term average precipitation at the Richwood, W. Va. location is 48 inches per year.

MAJOR FINDINGS

Persistent Changes in Water Chemistry and Aquatic Biology are Evident in Coal-Mined Areas

About 7 percent of all coal mined in the Nation comes from an area of 5,000 mi² in the Appalachian Plateaus part of the Kanawha–New River Basin. Production of the mostly low-sulfur coal nearly doubled from 1980 to 1998 as mining technology advanced, individual mines became larger, and employment decreased. Total production is about 90 million tons per year. A coal seam 1 foot thick and 1 mile square weighs about 1 million tons.

Most drainage basins within the coal region have been mined repeatedly as technology has advanced and economics have changed. Only three unmined basins greater than 10 mi² in the coal mining region were identified in this study. Among mined basins, cumulative coal production of less than 10,000 ton/mi² of coal during 1980–95 is low. Cumulative production in many basins ranged from 100,000 to 1,000,000 ton/mi².

Most water that drains from coal mines in the Kanawha–New River Basin is naturally neutral or alkaline rather than acidic. When iron pyrite in coal and adjacent rocks is exposed to air and water during mining, a series of chemical reactions produce dissolved iron and sulfuric acid (Rose and Cravotta, 1998). Natural or applied limestone, lye, or anhydrous ammonia can neutralize the acid (Skousen and others, 1998), but sulfate ions dissolved in water generally remain as evidence of the reactions. Sulfate concentrations in streams decrease slowly after mining ends (Sams and Beer, 2000).

Since 1981, Total Iron and Manganese have Decreased in Stream Basins where Coal Mining has Continued, but Sulfate has Increased

During low flow in July 1998, water samples from 57 wadeable streams (drainage area less than 1 to 128 mi²) were analyzed once. Samples were collected from streams in the region of the Appalachian Plateaus where coal has been mined. At least three analyses were available for 51 of the sites for 1979–81, before the Surface Mining Control and Reclamation Act (SMCRA) affected regional water quality (Ehlke and others, 1982). Each 1998 analysis was compared to the one earlier analysis with the closest corresponding stream-flow. Results were interpreted with respect to cumulative mining history and other land uses in each basin.

Median concentrations of total iron and total manganese were lower in 1998 than during 1979–81 in 33 basins that had been mined both before and after SMCRA, but sulfate concentration and specific conductance were higher (table 1). In 1998, median total manganese, specific conductance, sulfate, and pH were higher in 37 basins mined since 1980 than in 20 basins unmined since then; median total iron was lower in the mined basins, possibly reflecting aggressive treatment of permitted discharges.

Table 1. Medians of regulated constituents improved between 1979–81 and 1998 in 33 mined basins

[µg/L, micrograms per liter; µS/cm, microsiemens per centimeter; mg/L, milligrams per liter]

Regulated Constituents	Median value	
	1979–81	1998
pH (standard units)	7.1	7.5
Total iron (µg/L)	455	150
Total manganese (µg/L)	150	78
Unregulated Constituents		
Specific conductance (µS/cm)	360	446
Sulfate (mg/L)	91	150

At the time the SMCRA and subsequent regulations were established, acidification and subsequent increase in metal concentrations, but not sulfate concentration, were known to degrade stream quality. Regulations,

Figure 4. Sites with a low concentration of sulfate drained basins with little recent coal production. Sites with a high concentration of sulfate drained basins with a wide range of recent coal production.

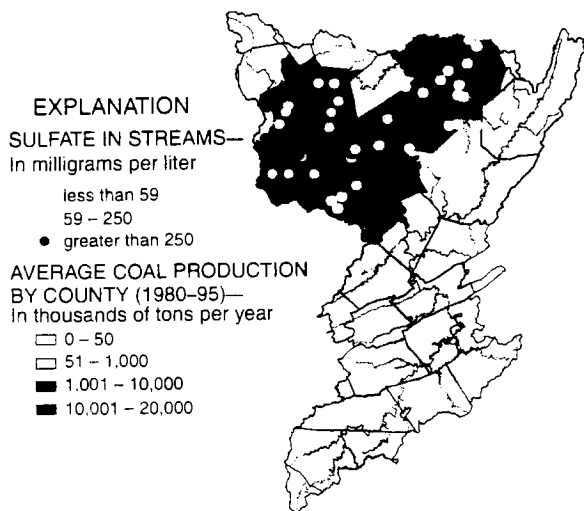

Figure 5. Sulfate concentration in wadeable streams was highest in counties with the highest coal production.

therefore, were targeted at decreasing mining-related acidification and concentrations of iron and manganese, but were not designed to decrease sulfate concentrations. Sulfate concentrations less than 59 mg/L (milligrams per liter; study median) were measured only from basins where less than 142,000 ton/mi² of coal were produced during 1980–95 (figs. 4 and 5). In contrast, manganese concentrations less than 32 µg/L (micrograms per liter; study median) were measured at several heavily mined basins (fig. 6).

Sulfate concentration in streams draining mined areas does not correlate strongly with coal production because sulfate production depends on local geology, mining practice, and possibly results from activities in addition to mining. Sulfate concentration is higher than background, however, in basins with the greatest coal production. Background sulfate concentration was less than 25 mg/L in 16 of 20 basins not mined since 1980. In contrast, sulfate concentration was greater than 250 mg/L in 8 of 15 mined basins drained by streams tributary to the Coal River. The USEPA guideline for sulfate in drinking water is 250 mg/L.

For two years, water chemistry was analyzed monthly and at high flow at two streams in heavily mined basins, and at one stream where no coal had been mined since 1980. At the mined sites, sulfate, several other ions, and specific conductance decreased as streamflow increased; at the unmined site, major-ion concentrations were low at all flows (fig. 7). Dissolved iron and manganese concentrations were virtually unrelated to flow at all three sites. At both Peters Creek near

Figure 6. Concentrations of manganese in about half of the streams draining heavily mined basins were less than the study median.

Lockwood and Clear Fork at Whitesville, specific conductance was correlated with sulfate concentration, and correlations were nearly as strong between specific conductance and dissolved calcium, magnesium, sodium, and chloride. The same patterns were found in data for the sites before the implementation of the SMCRA.

Streamflow, water temperature, pH, and specific conductance were measured hourly at the two mined sites during the same two years. In the Coal River Basin at Clear Fork, sulfate concentration (estimated from the hourly specific conductance) exceeded the

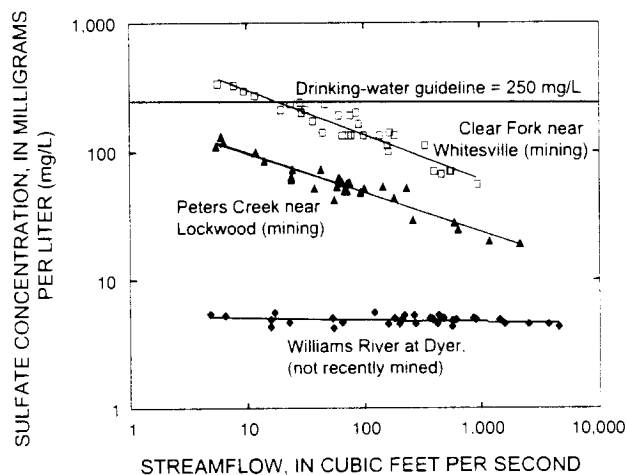

Figure 7. The concentration of sulfate, like other major ions, decreased with flow at two heavily mined sites but was consistently low at a site with no recent mining (Clear Fork $R^2 = 0.90$, Peters Cr $R^2 = 0.91$, Williams River $R^2 = 0.11$).

250-mg/L guideline about 25 percent of the time. Sulfate concentrations across a range of flow at Clear Fork were at least 10 percent greater in 1998 than in 1979–81.

Coal-mining methods in the Kanawha–New River Basin

In the Kanawha–New River Basin, half of the coal comes from underground mines and half from surface mines. Surface subsidence is expected above longwall mines, which remove about 90 percent of a coal seam, but is less common above room-and-pillar mines that may remove only 60 percent. Surface mines, both smaller contour mines and larger mountaintop mines, can remove 100 percent of a series of seams. Surface-mine operators working in steep-slope areas cannot simply replace all waste-rock material within the boundaries of the mine sites, because broken rock takes more space than consolidated rock. The excess is placed in valleys as fill material where the land is flat enough to provide a stable foundation, but the valley fills greatly affect the stream environment (U.S. Environmental Protection Agency, 2000).

Stream Benthic-Invertebrate Communities are Impaired at Mined Sites

In all streams sampled that drain areas where large quantities of coal have been mined, the benthic-invertebrate community is impaired in comparison to rural parts of the study area where little or no coal has been mined since 1980 (fig. 8). Some streams in which

Figure 8. Only sites with little recent coal production had healthy invertebrate communities as measured by low (favorable) scores on the Modified Hilsenhoff Biotic Index, although not all impaired sites were in areas of high coal production.

Figure 9. Invertebrates that are intolerant of fine sediment were present at unmined sites and sites with little coal production since 1980. (Photograph by * Jennifer Hiebert, University of Alberta; ** D.B. Chambers, USGS; *** Arturo Elosegi, North American Benthological Society. All photos reproduced with permission)

the community is impaired drained areas that were not heavily mined.

Invertebrate communities were sampled from riffles at 29 wadeable streams in areas of the Appalachian Plateaus where coal is or has been mined (Chambers and Messinger, 2001). The sites were separated into two groups by statistical comparison of species composition and abundance. Each group contained communities that were similar. The communities that included several insect taxa known for intolerance of fine sediment were identified as the less impaired group of sites. These taxa include *Epeorus* mayflies and *Dolophilodes* and *Rhyacophila* caddisflies (fig. 9). *Epeorus* is a genus of relatively large mayflies that cling to the bottom of large, loosely embedded rocks. Fine sediment can fill the openings in the stream bottom where they live. Caddisflies in the genus *Dolophilodes* spin finely meshed nets that can be clogged with silt. *Rhyacophila* are mobile predators typically found in clean, cool-water streams. These intolerant taxa were not present in the invertebrate communities at sites identified as poorer. In addition, scores from the MHBI (Modified Hilsenhoff Biotic Index; see glossary) and proportions of pollution-tolerant taxa from the midge family were significantly greater at the more impaired group of sites. The MHBI and other biological metrics are mathematical summaries of characteristics that change predictably in response to environmental stress. They are used to measure ecological health of a system (Karr and Chu, 1999).

Benthic invertebrates are good indicators of overall stream-water quality

Benthic invertebrates are sensitive indicators of many types of stream disturbance (Barbour and others, 1999). Because most have a life span of about a year and many remain in the same short section of stream during most of their lives, they are particularly well suited for assessments of short-term, local disturbances within a watershed. Fish, however, often move throughout a stream system, enabling them to seek refuge from such disturbances. An impaired invertebrate community is more than a disruption in the aquatic food web—it indicates that stream chemistry and (or) physical habitat are impaired. Stream-chemistry data provide useful information about the stream's quality only for the time of sampling, but benthic-invertebrate communities can show the effects of short-term disturbances that can easily be missed when stream-quality assessments rely only on chemical measurements.

Differences in land use, stream habitat, and stream chemistry between the groups of sites suggest possible causes for the different invertebrate communities. The less impaired group of sites drained basins that were unmined, or where less than 10,000 ton/mi² were mined during 1980–95. Most basins in the more impaired group of sites had been mined within the last 20 years by both surface and underground methods; most contained abandoned mines that pre-dated SMCRA and produced 100,000 to 1,000,000 ton/mi² of coal. Some of the basins in the more impaired group, however, had not been mined since 1980. Coal production during 1980–95 is not an ideal indicator of the environmental disturbance caused by coal mining, but it related better to environmental measurements than did production over a shorter interval, number of abandoned mines, or mine discharge permits (Chambers and Messinger, 2001).

At the more impaired sites, the proportion of total land area as strip mines, quarries, disturbed land, or gravel pits was significantly greater than at the less impaired sites. In addition, sulfate concentration, specific conductance, and alkalinity of stream water were all higher. Stream pH did not differ significantly between the two groups; pH is regulated in mine discharges.

Two basins that were not mined since 1980 contained valley fills similar to those constructed at large surface mines. The invertebrate community in Mill

Creek near Hopewell, W. Va., which drains an area with few relatively small fills, grouped with the less impaired sites. Davis Creek at Trace Creek, W. Va., drains several large fills at a shopping center and was in the poorer group.

Instream habitat structure also differed significantly between the two groups. Sites from the less impaired group had less sand and silt in the stream bottom. Smaller median sediment size correlated with decreased number of taxa of mayflies, stoneflies, and caddisflies (EPT taxa) and an increased (more impaired) score on the Modified Hilsenhoff Biotic Index (fig. 10; $r^2 = 0.46$ and 0.43 , respectively). Among the sites sampled, correlations between invertebrate metrics and coal production (or factors relating to coal mining) were weak, largely because some streams were impaired by other land uses. Erosion and sediment deposition in basins with active mines have decreased overall because of controls required under SMCRA, but temporal comparisons are not possible. Sedimentation in 1998 remained generally greater, however, at sites in basins with coal production since 1980 than in unmined basins.

The invertebrate-community degradation represented the cumulative effects of mining before and after SMCRA, deep mining and surface mining, mines in and out of compliance with applicable regulations, and all other nonmining disturbances in the basins. Impaired sites from this region ranked near the middle of an index that ranked NAWQA sites representing different land uses throughout the United States. (See discussion of effects on invertebrate communities nationally, p. 11). Logging and ongoing construction probably contribute to sedimentation, but their extent in each basin could not be quantified. Logging may contribute more sediment per disturbed volume of soil than mining.

Figure 10. Invertebrate-community metrics show generally better conditions (lower MHBI) at sites with coarser streambeds and lower sulfate concentrations, although correlations are weak.

Regional study: Sulfate concentrations and biological communities in Appalachian coal fields indicated mining-related disturbances despite a general water-quality improvement between 1980 and 1998

In a 1998 study to assess regional water-quality effects of coal mining (Eychaner, 1999), samples representing the Northern Appalachian coal field were collected in the Allegheny and Monongahela River Basins (ALMN), where high-sulfur coal is common and acid mine drainage was historically severe, and samples for the Central Appalachian coal field were collected in the Kanawha–New River Basin (KANA), where acid drainage is uncommon (fig. 11).

Water chemistry in 178 Wadeable streams was analyzed once during low flow, in July and August 1998. Drainage area for most streams was between 4 and 80 mi². Most (170) of these sites were also part of a study on the effects of coal mining that was conducted during 1979–81 (Herb and others, 1981a, 1981b; 1983; Ehlike and others, 1982), before regional water quality was affected by implementation of regulations from the Surface Mining Control and Reclamation Act (SMCRA). At 61 sites, aquatic invertebrates (insects, worms, crustaceans, and mollusks) also were collected. Ground water was sampled from 58 wells near coal surface mines and 25 wells in unmined areas. Wells sampled downgradient from reclaimed surface coal mines reflect the local effects of mining.

Concentrations of Regulated Constituents Improved in Stream Base Flow From About 1980 to 1998

During low-flow conditions, sulfate in more than 70 percent of samples from streams downstream from coal mines in both coal regions exceeded the regional background concentration. Background was calculated as about 21 mg/L sulfate from data for basins with no

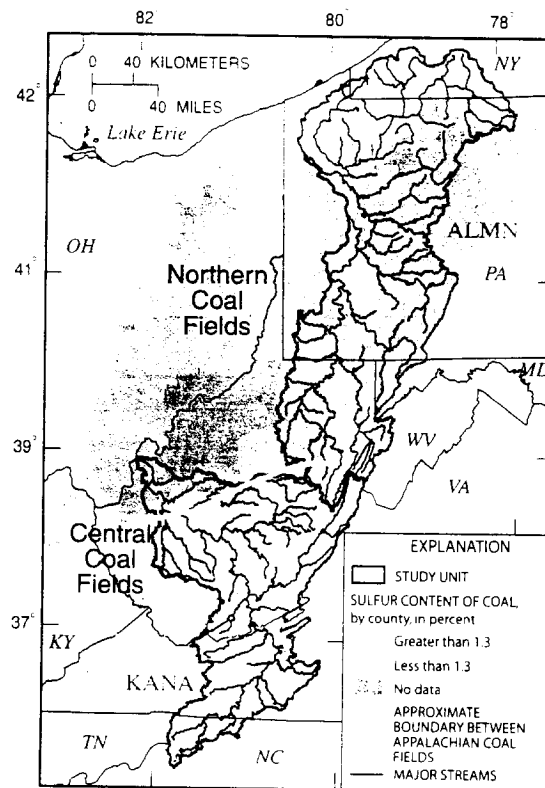

Figure 11. Coal seams in the Appalachian coal region vary in sulfur content, and the fields are identified primarily on the basis of this difference (Tully, 1996). The Kanawha–New River Basin contains mostly lower sulfur coal, while the Allegheny and Monongahela River Basins contain mostly higher sulfur coal.

history of coal mining. The highest concentrations were measured in basins with the greatest coal production. One-fourth of all samples exceeded 250 mg/L, the USEPA drinking-water guideline.

Total iron, total manganese, and total aluminum also exceeded regional background concentrations (129, 81, and 23 µg/L, respectively) in many streams in mined basins. The median concentrations of total iron in the northern coal region were about equal between mined and unmined basins, but in the central region, concentrations of median total iron among mined basins were lower than among unmined basins. In both regions, median concentrations of total manganese among mined basins were about double that among unmined basins.

Median pH increased, and median concentrations of total iron and total manganese

decreased among mined basins between 1979–81 and 1998 in both regions, reflecting that regulations restricting these constituents in mine drainage are effective. Even so, stream sites downstream from mines more commonly exceeded drinking-water guidelines for sulfate, iron, manganese, and aluminum concentrations than streams in unmined basins (fig. 12).

Figure 12. Stream water more often exceeded drinking-water guidelines at mined sites than at unmined sites.

Figure 13. Sulfate concentration in stream water was inversely related to the number of mayfly, stonefly, and caddisfly taxa found at water-quality sampling sites.

Aquatic Benthic Invertebrate Communities are Impaired in Mined Basins

Aquatic invertebrate communities tended to be more impaired where there was more coal mining, when compared to basins where there was little coal mining. Pollution-tolerant species are more likely to be present at mined sites than at unmined sites, whereas pollution-sensitive taxa were fewer in number or non-existent in heavily mined basins. Increasing coal production correlated with both an increased concentration of sulfate and a decline in some aquatic insect populations (fig. 13). Of the 61 sites where aquatic invertebrates were collected, those sites with sulfate concentrations higher than the estimated background concentration had the lower diversity of three groups of sensitive insect species (mayflies, stoneflies, and caddisflies), even though the pH of the water at all sites was greater than 6.5.

At the concentrations measured, the sulfate ion is relatively non-toxic to aquatic organisms and may not represent the cause of the decline observed in mayflies and stoneflies. Sulfate concentration was, however, positively correlated with the total coal production from a basin (Sams and Beer, 2000). Other landscape disturbances associated with coal mining—changes in streamflow, siltation, or trace metal contamination—could affect the invertebrate community. Negative effects on communities caused by mining were of similar magnitude to the effects

Figure 15. Ground-water samples more often exceeded drinking-water guidelines in mined areas than in unmined areas.

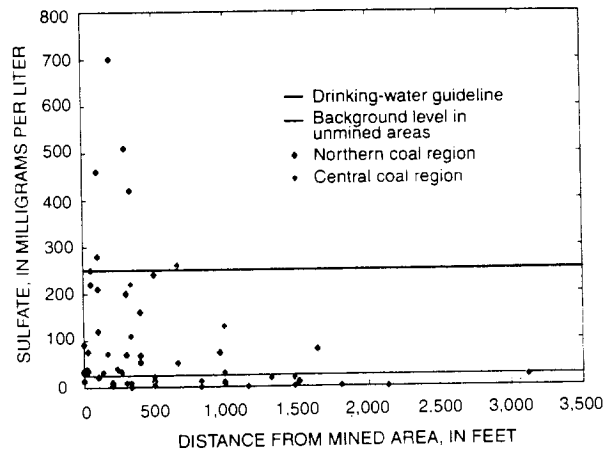

Figure 14. Sulfate concentrations in ground water are greater within 1,000 feet of reclaimed surface coal mines and in the northern coal region than at greater distance and in the central coal region.

of urban development, agriculture, large construction projects, flow alterations, or wastewater effluent.

Sulfate, Iron, and Manganese Concentrations were Elevated in Wells Near Reclaimed Surface Mines

At mined sites in both coal regions, pH was lower and sulfate concentration was greater at mined sites than at unmined sites. Sulfate concentrations in ground water were higher than background concentrations in shallow wells within 1,000 feet of reclaimed surface mines (fig. 14). Samples from wells in the northern coal region contained more sulfate than wells at unmined sites in the same region, or at any of the sites in the central coal region. Iron, manganese, and aluminum were higher than background concentrations within about 2,000 feet of reclaimed surface mines (1,800, 640, and 11 $\mu\text{g/L}$, respectively).

Water from most wells, except at unmined sites in the northern coal region, exceeded guidelines for iron and manganese, which make the water unpleasant to drink (fig. 15). The concentrations in both regions were higher near reclaimed mines than at unmined sites.

Effects of mining on invertebrate communities were of similar magnitude to the effects caused by urban development and agriculture nationally

Invertebrate communities at two coal mining stream sites ranked near the middle of more than 600 NAWQA sites sampled nationwide during 1991–98. These sites had index scores better than national median scores for urban sites, about the same as national median scores for agricultural sites, and worse than national median scores for undeveloped sites. The community at a forested and undeveloped site in the Appalachian Plateaus was within the best 10 percent of NAWQA sites nationally and within the best 25 percent of undeveloped sites.

Nationally, invertebrate communities at heavily agricultural sites were commonly highly impaired. In the Kanawha–New River Basin, agriculture is usually of low intensity and centers on pasturing small herds of cattle and growing cattle feed. Invertebrate communities at two agricultural sites, one in the Appalachian Plateaus and one in the Blue Ridge Physiographic Province, were within the best 10 percent of all sites nationally.

Sites in undeveloped and agricultural basins in the Kanawha–New River Basin rank among the best sites nationally in the National Invertebrate Community Status Index. More impaired sites in the Kanawha–New River Basin rank about the same or better than most sites that represent developed land uses nationally. (Low scores correspond to diverse invertebrate communities.)

Some Contaminants are Widespread and Present at Potentially Harmful Concentrations in Streambed Sediment and Fish Tissue

Ten Polycyclic Aromatic Hydrocarbons were Found in Streambed Sediments in Concentrations that may Harm Aquatic Life

Forty samples of streambed sediment from 36 sites in the Kanawha–New River Basin were analyzed for polycyclic aromatic hydrocarbons (PAHs) during 1996–98. PAHs are components of wood smoke, diesel exhaust, soot, petroleum, and coal. Their toxicity varies, and some are carcinogenic to humans and other animals. Of the 12 PAHs for which guidelines were available, 10 were detected at concentrations exceeding the Probable Effect Level (PEL; see information box on sediment-quality guidelines), and all were detected at concentrations exceeding the Threshold Effect Level (TEL).

High concentrations of PAHs were present in each physiographic setting in the basin except for the Blue Ridge, although the only high concentrations in the Valley and Ridge/Appalachian Plateaus transition zone were in basins where coal has been mined. The highest

Sediment Quality Guidelines

NAWQA's bed-sediment sampling protocol (Shelton and Capel, 1994) is designed to maximize the chance of detecting contaminants that have been transported in a stream during the previous 1–3 years. The data from this study were compared to final Canadian Sediment Quality Guidelines (SQGs) rather than the preliminary USEPA guidelines. SQGs have been issued by Environment Canada for 8 trace elements and 12 PAHs (Canadian Council of Ministers of the Environment, 1999). At concentrations below a Threshold Effect Level (TEL), contaminants are rarely expected to have a toxic effect on aquatic life. At concentrations above a Probable Effect Level (PEL), toxic effects are expected frequently. Concentrations of substances that exceed SQGs may imply, but not prove, that organisms in the streams of interest are at risk from those substances.

PAH concentrations measured in this study were in the Appalachian Plateaus. Some of the highest PAH concentrations were measured at some of the most heavily mined sites in the basin, although the correlation between coal production and streambed PAH con-

centration was weak ($r^2 = 0.52$, among 20 wadeable stream sites within the coal region). Coal samples from several commonly mined seams in West Virginia were between 20 and 85 percent PAH by mass (W.H. Orem, U.S. Geological Survey, written commun., July 2000). Coal particles are common in sediment from many streams in the coal fields. The PAHs from the coal particles, however, may not be bioavailable (Chapman and others, 1996). Unlike other NAWQA study areas, no correlation was found between most other land uses and PAH concentration.

Four Trace Elements were Present in Streambed Sediment in Concentrations That May Harm Aquatic Life

A total of 53 bed-sediment samples from 47 sites in the Kanawha–New River Basin were analyzed for trace elements during 1996–98. All eight of the trace elements for which criteria were available were found at some sites in concentrations exceeding their Threshold Effect Level (fig. 16; see information box on sediment-quality guidelines). Nickel, chromium, zinc, and lead were detected at concentrations exceeding their Probable Effect Level. Nickel concentrations exceeded the Probable Effect Level most frequently (in 47 of the 53 samples), based on the 1995 Sediment Quality Guidelines; a final SQG was not issued for nickel at the time that other SQGs were finalized.

Trace-element concentrations also were determined in livers of common carp or rock bass in 27 samples from 18 sites in 1996 and 1997. Some samples contained concentrations of arsenic, cadmium, lead, mercury, nickel, selenium, and zinc that were among the highest 25 percent of more than 900 NAWQA samples nationwide (1991–98). Concentrations of cadmium, mercury, nickel, selenium, and zinc in fish-tissue samples from the Kanawha–New River Basin ranked among the highest 10 percent of all NAWQA samples; six samples contained cadmium concentrations ranking among the highest 10 percent of all NAWQA samples, and five samples contained selenium concentrations ranking among the highest 10 percent of all NAWQA samples. One fish-tissue sample, from Kanawha River at Winfield, contained cadmium at a concentration ranking in the highest 1 percent of all samples in the

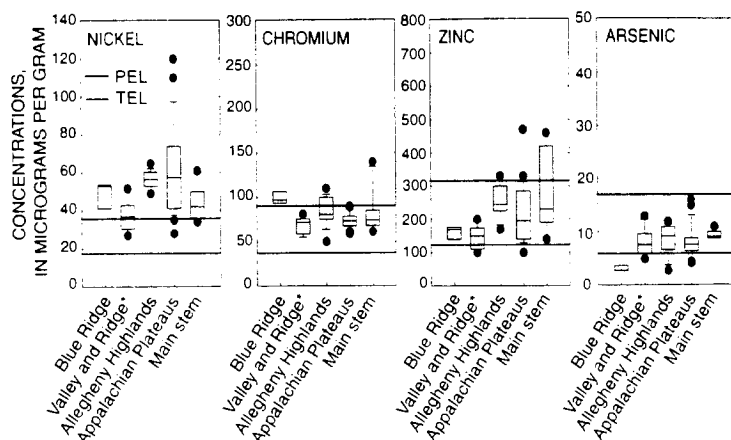

Figure 16. Some trace element concentrations in stream-bed sediment exceeded Environment Canada's effects-based criteria at several sites in the basin. Probable effects levels (PEL) are those concentrations at which harmful effects to aquatic life are thought to be likely, and were exceeded most frequently in the Allegheny Highlands and other Appalachian Plateaus streams. Threshold effects levels (TEL) were exceeded at all sites by nickel and chromium. *Valley and Ridge sites include transition zones between provinces.

Nation. Determining the human health or ecological significance of these concentrations is problematic, because tissue samples were collected from many different species and because fish-liver tissue is not normally eaten by humans.

Fish Communities Differ Considerably Throughout the Basin, but Non-native Species Continue to Expand Their Range

Fish communities in the Kanawha–New River Basin are complex and vary widely among streams of different size, physiographic setting, and land use. Individual species are distributed in patches, particularly upstream from Kanawha Falls (Jenkins and Burkhead, 1994). This patchy distribution can confound comparisons among streams (Strange, 1999). The quality of the regional fish community is generally good, although the national NAWQA fish index seems to underrate that quality because it does not consider the patchy distribution.

Non-native Fish Continue to Expand Their Range in Tributaries of the New and Gauley Rivers

Three fish species were collected for the first time at often-sampled sites in tributaries of the New and Gauley Rivers (Cincotta and others, 1999). Margined madtoms, a popular bait species, were collected for the

first time from Second Creek near the village of Second Creek. Margined madtoms are native to some parts of the New River and some of its tributaries, but they had never before been collected from the Greenbrier River Subbasin. Telescope shiners (fig. 17), natives of the Tennessee River Basin, have been collected in the New River since 1958, and they continue to expand their range. Telescope shiners were collected from another often-sampled site, Williams River at Dyer, in the Gauley River Subbasin; this was their first collection upstream from Summersville Dam, a large impoundment. Telescope shiners also were collected for the first time from two Meadow River tributaries, also in the Gauley River Subbasin. Least brook lamprey were collected for the first time from Williams River at Dyer, their second collection from the Gauley River Subbasin. Populations of all these species were well established, and the ongoing expansion of their ranges suggests that all were relatively recent bait-bucket introductions to the New River system. Two of these reaches, and all of these streams, had been thoroughly sampled in the late 1970s (Hocutt and others, 1978, 1979).

Figure 17. Example of a telescope shiner (*Notropis telescopus*), a non-native species in the Kanawha–New River Basin. (Photograph from Jenkins and Burkhead, 1994; used by permission from the Virginia Department of Game and Inland Fisheries)

Other fish collected for the first time in the basin were in tributaries of the Coal River. The new species in Coal River distribution records were from large tributaries where few or no surveys had been made since the 1930s. Mottled sculpin, bluebreast darter, river carpsucker, blacknose dace, and longnose dace all were collected for the first time from Clear Fork near Whitesville or Spruce Laurel Fork at Clothier, major tributaries to the Big or Little Coal Rivers, respectively. Several of these records represented the most upstream collections in their respective forks of the Coal River, although all had been collected from the Coal River Subbasin. These new-species records most likely represent undersampling of streams that have often been

overlooked by investigators rather than new range expansions.

In some regions of the United States, the highest proportion of non-native fish are typically present in the most impaired streams (Maret, 1997; Waite and Carpenter, 2000). In these regions, unimpaired streams are typically cold-water streams with complex physical habitat and low nutrient concentrations. In impaired streams where agricultural and urban land uses are common, stream temperature and nutrient concentrations are high and physical habitat is degraded. Many non-native fish tolerate these conditions better than many native species do, enabling the non-natives to displace the natives. No such relation was found in the Kanawha–New River Basin, where sedimentation and increased dissolved solids have impaired streams, but where temperature and nutrient concentrations have remained low (Messinger and Chambers, 2001, in press). The proportion of introduced fish in the New River system was high, even though other measures did not indicate impairment.

Fish Species Common Throughout the Ohio River Basin are Not Native Upstream from Kanawha Falls

The New River system, which fisheries biologists consider to include the Gauley River and its tributaries, supports a different collection of fish species than the downstream Kanawha River system, which is part of the larger Ohio River system (Jenkins and Burkhead, 1994). Kanawha Falls (see front cover), a 24-foot waterfall 2 miles downstream from the confluence of the New and Gauley Rivers, is the boundary between the New River and Kanawha River systems. This waterfall has been a barrier to upstream fish movement since glaciers affected streams more than 1 million years ago. The New River system lacks native species diversity, and it has unfilled ecological niches. It has only 46 native fishes and the lowest ratio of native fishes to drainage area of any river system in the Eastern United States.

The lack of native-species diversity allowed other species to develop in the New River system, which has the largest proportion of endemic species (found nowhere else in the world) in eastern North America (8 of 46). Introduced fish species have prospered in the New River system: Jenkins and Burkhead (1994) cite the New River system as having the largest number and proportion (42 of 89) of introduced freshwater species

of all major eastern and central North American drainages.

Although many species have been introduced and become naturalized throughout the 19th and 20th centuries, the New River fish fauna remain susceptible to invasion. In contrast, 118 fish species are reported from the Kanawha River system downstream from Kanawha Falls (Stauffer and others, 1995); none of these fish species are endemic to the Kanawha River system, and only 15 are considered possible, probable, or known introductions.

Fish Communities are Controlled By a Variety of Environmental Factors in the Kanawha–New River Basin

In testing the possible effects of coal mining on fish communities, results were less definitive than for benthic invertebrates (p. 8–9). No common fish metrics (Karr and Chu, 1999; Barbour and others, 1999) correlated closely with mining intensity or its surrogate, sulfate concentration. The study included sites both upstream and downstream from Kanawha Falls, and differences in many metrics between the two groups mask differences among land-use categories (Messinger and Chambers, 2001, in press). However, fish were collected at only 13 wadeable sites in the coal region, which did not represent a full gradient of mining intensity.

High Concentrations of Fecal Bacteria Remain in Streams if Sources are Close

Concentrations of *Escherichia coli* (*E. coli*) exceeded the national guideline for public swimming areas in 26 percent of samples from major rivers in the Kanawha–New River Basin and in 43 percent of samples from tributary streams (fig. 18); however, no outbreak of water-borne disease was reported from the basin during 1991–98 (Barwick and others, 2000). Bacteria concentration

in stream water varies widely, reflecting the changing balance between bacterial sources and many factors that help or hinder bacteria transport. Because of the wide variability, comparisons between streams based on only a few samples can be misleading; a few generalizations, however, can be made.

First, streams contain more bacteria if the sources are close to the stream and the sampling site. Among large rivers, median concentrations of *E. coli* were lowest in the New River Gorge at Thurmond, in a reach distant from any large city (fig. 18). Concentrations were highest in the Kanawha River downstream from the Charleston metropolitan area at Winfield. In the two tributary basins with the highest median concentrations, most homes are clustered close to the streams because the land slopes steeply elsewhere. In contrast, four tributary streams in basins with more moderate slopes, where bacteria sources are more dispersed, had median *E. coli* concentrations less than half as high. Regardless of slope, direct contamination of a stream by sewage or manure can produce extremely high concentrations, as Gillies and others (1998) observed in the Greenbrier River.

Second, bacteria concentrations exceeding guidelines are much more common when streamflow is greater than average, so streams generally contain more bacteria in winter than in summer (fig. 19). *E. coli* concentrations exceeded guidelines in less than one-third of summer samples from moderate-slope tributaries and less than one-fifth from large rivers. In the three

Figure 18. *E. coli* bacteria concentrations in streams vary widely.

Figure 19. Guidelines for *E. coli* are exceeded more often in winter than in summer for most streams.

tributary basins with steeper slope, however, concentrations were higher in summer than winter.

Finally, streams contain more bacteria if the bacteria sources are large. Williams River, the tributary basin with the lowest median concentration of *E. coli* (fig. 18) is home to only 5 people per square mile, compared to the average of 71 people per square mile throughout the entire Kanawha–New River Basin. For twice the population density, median *E. coli* was about 300 percent higher among steep-slope tributaries. Among the moderate-slope basins, however, including the Blue-stone River Basin with 201 people per square mile, median *E. coli* was only about 10 percent higher for twice the population density. Neither the estimated number of cattle nor the percentage of agricultural land use in the tributary basins showed a relation to the median bacteria concentrations.

Facts about *E. coli*

Escherichia coli (*E. coli*) is a bacterium that grows in the intestines of people, other mammals, and birds. Most strains of *E. coli* do not cause disease, but they do indicate water contamination by feces, which could contain other disease-causing organisms. The national guideline for public swimming areas is less than 235 *E. coli* colonies per 100 milliliters of water (col/100 mL) in any single sample (U.S. Environmental Protection Agency, 1986). That level is intended to allow no more than 8 gastrointestinal illnesses per 1,000 swimmers. For waters infrequently used for full-body-contact recreation, the guideline is 576 col/100 mL.

Nutrient and Organic-Chemical Concentrations in Surface Water are Low in Most of the Basin

Nutrients were Detected at Low Concentrations in Streams of the Kanawha–New River Basin

Mean concentrations of nutrients in the Kanawha–New River Basin were at or below national background levels. Most concentrations, however, exceed those measured at a stream-water-monitoring site at Williams River, which drains mostly National forest. The highest mean nitrate concentration measured was 1.5 mg/L. Flow-weighted mean ammonia concentrations ranged from less than 0.02 to 0.04 mg/L. Mean total phosphorus concentration was less than 0.1 mg/L at nine sites; the maximum was 0.15 mg/L. Nitrate and phosphorus are typically increased by agricultural or urban land uses, and certain nutrients, such as ammonia, can accumulate from natural sources.

Differences in nutrient concentrations were found among sites because of differences in land use/land cover, and physiography. Generally, basins with more agriculture produced more mean total nitrogen than did forested basins. The lowest mean total nitrogen concentration in streams, 0.71 mg/L was that for mostly forested tributary basins in the Appalachian Plateaus produced (fig. 20). The lowest mean concentration in the basin, or background concentration, was 0.45 mg/L, at Williams River. Tributary streams with basins mostly or wholly within the Valley and Ridge Physiographic Province had the highest mean total nitrogen, 1.04 mg/L. One stream in the Blue Ridge had a mean total nitrogen concentration of 0.94 mg/L. The mean total nitrogen concentration was not substantially different between large rivers and smaller tributaries (0.83 and 0.90 mg/L respectively).

Four sites, draining forest mixed with agriculture or coal mining, ranked among the best sites in the Nation in a national Algal Status Index. This index measures the proportion of algal samples that belong to species that are tolerant of high nutrient concentrations and siltation.

Pesticides were Detected at Low Concentrations in Surface Water

Pesticides were sampled for 9 to 25 times at four sites in 1997. Two sites were on main-stem, large streams. The other two sites on tributary streams drained basins with more than 30 percent agricultural

Figure 20. Because much of the Kanawha–New River Basin is forested, surface water and ground water contain low concentrations of nutrients and few pesticides.

land and some urban land. (See Study Unit Design, p. 20). Time of sampling covered the seasonal spectrum of both climate and pesticide application. The pesticides detected at all sites are routinely detected at agricultural sites across the Nation.

Surface-water samples in the Kanawha–New River Basin contained only a few pesticides at low levels. In all, 23 of 83 pesticides analyzed for were detected (Ward and others, 1998). All pesticide detections were less than 1 $\mu\text{g/L}$; concentrations detected did not exceed USEPA drinking-water standards or aquatic-life criteria. The most commonly detected pesticides were atrazine, deethylatrazine (a breakdown product of atrazine), metolachlor, prometon, simazine, and tebuthiuron. Atrazine, deethylatrazine, metolachlor and simazine were detected in more than 90 percent of samples.

Dioxin is a particularly toxic contaminant in certain herbicides formerly manufactured near Charleston and is a known contaminant in the lower Kanawha River, but it was not analyzed for this study. Dioxin in the lower Kanawha River is the target of ongoing regulatory investigations by USEPA and other agencies.

Many VOCs Detected in the Lower Kanawha River

Numerous volatile organic compounds (VOCs) have been detected routinely at low concentrations in the Kanawha River downstream from the Charleston metropolitan area (Tennant and others, 1992). In this study, more than 20 VOCs were detected, at concentrations ranging from 0.015 to 0.3 $\mu\text{g/L}$, in each of two samples collected in late 1997 from the Kanawha River at Winfield. Each sample was analyzed for 85 compounds (Ward and others, 1998). The compounds detected at

Winfield, downstream from Charleston, included chloroform, motor fuel and aromatic compounds such as benzene, and industrial compounds such as ethers. In contrast, only a single compound was detected in one of two samples collected from the Kanawha River upstream at Kanawha Falls.

During 1987–96, one or more of 21 VOCs were detected in 50 percent of all daily samples collected for the Ohio River Valley Water Sanitation Commission (ORSANCO) from an industrial water intake at St. Albans, downstream from Charleston (Lundgren and Lopes, 1999). Benzene and toluene were the two most frequently detected compounds, and a maximum of 11 compounds was detected in a single sample. Median concentrations ranged from 0.1 to 2.3 $\mu\text{g/L}$. Gasoline spills or leaks of as little as 10 gallons per day that reach the river could produce the concentrations measured at St. Albans.

Radon Concentrations and Bacterial Contamination are the Principal Ground-Water-Quality Concerns

Physiographic Province, Geology, Well Construction, and Land Use Affect the Quality of Water from Domestic Wells

Ground water from private wells provides domestic supply for 30 percent of the people in the Kanawha–New River Basin. High concentrations of radon are a concern in the Blue Ridge (p. 18), and private wells can be contaminated by fecal bacteria throughout the basin (p. 19), but the occurrence of other contaminants differs among the physiographic provinces.

APPALACHIAN PLATEAUS PHYSIOGRAPHIC PROVINCE

In the layered sedimentary rocks of the Appalachian Plateaus, ground water moves mostly in a network of narrow fractures within a few hundred feet of the land surface (Wyrick and Borchers, 1981; Harlow and LeCain, 1993). Individual fractures typically connect to only a few others, and a well normally taps only a few of the many fractures nearby. Recharge comes from rain and melting snow. Ground water flows generally toward the nearest stream, forming local aquifers bounded by the ridgetops. Contamination of a local aquifer and its stream is most likely to come from local sources.

Water samples were collected from 30 newer domestic wells or similar-capacity public-supply wells throughout the Appalachian Plateaus (Sheets and Kozar, 2000) and from 28 generally older domestic wells close to surface coal mines where reclamation was completed between 1986 and 1996. Wells near active mines were not sampled. Most of the wells were between 40 and 200 feet deep, and most water levels were between 10 and 90 feet below land surface.

Concentrations of iron and manganese exceeded USEPA drinking-water guidelines in 40 and 57 percent, respectively, of the wells throughout the Appalachian Plateaus and in about 70 percent of wells near reclaimed mines. Water that exceeds these guidelines is unpleasant to drink and can stain laundry and plumbing fixtures, but it is not a health hazard.

Potentially hazardous concentrations of methane, an odorless component of natural gas that is often associated with coal seams, were detected in water at 7 percent of the wells. At concentrations greater than about 10 mg/L, methane can bubble out of water pumped from a well. If enough gas collects in a confined space, an explosion is possible. In the West Virginia coal fields, any well water that bubbles is a potential methane explosion hazard.

Other chemical analyses of ground water samples collected as part of this study showed the following water-quality characteristics and conditions. Water from 61 percent of the wells near reclaimed mines was slightly acidic (pH less than 6.5) and could leach lead or copper from water pipes in homes. Only 23 percent of other Appalachian Plateaus wells produced acidic water. Radon exceeded the proposed USEPA standard at half the wells throughout the Appalachian Plateaus (p. 18). Water from half the wells exceeded 20 mg/L of sodium, the upper limit that USEPA suggests for peo-

ple on a sodium-restricted diet. Arsenic in water from 7 percent of the wells exceeded the 10- $\mu\text{g/L}$ standard set in January 2001, but none exceeded the previous 50- $\mu\text{g/L}$ standard. Concentrations of radon, sodium, and arsenic were lower in wells near reclaimed mines than in wells remote from reclaimed mines. Home water-treatment techniques can remove lead, copper, sodium, and arsenic from drinking water.

BLUE RIDGE PHYSIOGRAPHIC PROVINCE

In the igneous and metamorphic bedrock of the Blue Ridge, as in the Appalachian Plateaus, ground water moves in a network of shallow fractures. Local aquifers generally drain toward the nearest stream (Coble and others, 1985).

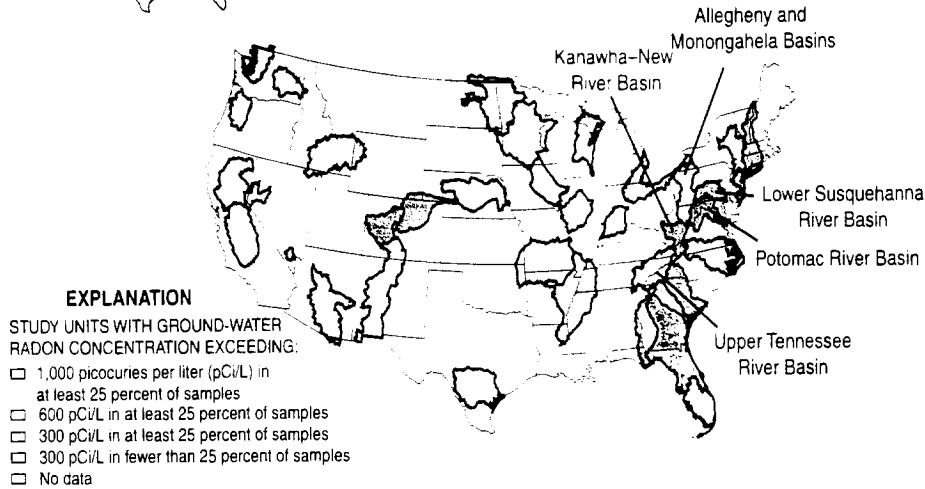

Water samples were collected from 30 newer domestic wells or similar low-capacity public-supply wells throughout the Blue Ridge. Most of the wells were between 100 and 350 feet deep, and most water levels were between 10 and 70 feet below land surface.

Ground water in the Blue Ridge is susceptible to contamination. Chlorofluorocarbon concentrations showed that the water in 89 percent of the wells had been recharged within the previous 20 years, indicating that contaminants could be transmitted readily into the fractured rock aquifers (Kozar and others, 2001).

Chemical analyses of ground water samples collected as part of this study indicated that concentrations of radon were among the highest in the Nation (p. 18); iron and manganese concentrations exceeded guidelines at only 17 percent of the wells; sodium exceeded 20 mg/L at 3 percent of the wells; and arsenic did not exceed 1 $\mu\text{g/L}$ at any of the sites. Pesticides were detected at 57 percent of the wells. The presence of the common agricultural herbicide atrazine in ground water, even in low concentrations, shows that potential contaminants could move quickly from the land surface into the drinking-water aquifer.

Valley and Ridge Physiographic Province ground-water conditions can be inferred from studies in similar settings in the Potomac River Basin, which was one of the 1991 NAWQA study units. See Lindsey and Ator, 1996 and Ator and others, 1998 for more details.

Radon concentrations in ground water were among the highest in the Nation

Radon is a radioactive gas that forms during the decay of natural uranium. Igneous and metamorphic rocks, like those in the Blue Ridge, commonly contain more uranium than other rock types. Radon in the air in homes is the second leading cause of lung cancer; and radon causes 2–3 percent of all cancer deaths in the United States. Homes can be designed or remodeled to

remove radon from both drinking water and interior air. The only way to determine if an individual well or home exceeds standards, however, is to have the water or air tested. Information on radon testing and removal is available at <http://www.epa.gov/safewater/radon/qa1.html> and other Web sites.

Radon concentration exceeds 1,000 pCi/L (picocuries per liter) in at least 25 percent of ground-water samples collected in many areas of the Eastern United States. In the Kanawha–New River Basin, 30 percent of samples exceeded 1,000 pCi/L (Appendix, p. 27), making the basin comparable to the Potomac and Lower Susquehanna River Basins to the northeast. Within the basin, however, radon in two-thirds of samples from wells in the Blue Ridge exceeded 1,000 pCi/L, but only in 10 percent of samples from the Appalachian Plateaus. The northern part of the basin, therefore, is more comparable to the adjacent Allegheny and Monongahela Rivers and Upper Tennessee River Basins.

Ground-water Radon Concentrations were Highest in the Blue Ridge

Radon concentrations were greater than 300 pCi/L, the proposed drinking-water standard (U.S. Environmental Protection Agency, 1999), in 87 percent of wells sampled in the Blue Ridge (fig. 21). The maximum concentration detected was 30,900 pCi/L (Kozar and Sheets, 1997). Of the 30 wells sampled, 10 contained concentrations of radon greater than 4,000 pCi/L, the alternate standard USEPA has proposed for regions where action is taken to decrease airborne radon. As water is used in a home, radon in the water can lead to an increase in radon in the air, which is the major exposure path for people.

Radon concentrations exceeded 300 pCi/L at 50 percent of wells sampled throughout the Appalachian Plateaus. The maximum in any sample was 2,500 pCi/L (fig. 21). The area is underlain primarily by sandstone, shale, coal, and limestone sedimentary rocks, in which uranium is less common than in igneous and metamorphic rocks.

At 28 wells downgradient from recently reclaimed surface coal mines, the median radon concentration was just 115 pCi/L, and the maximum was 450 pCi/L.

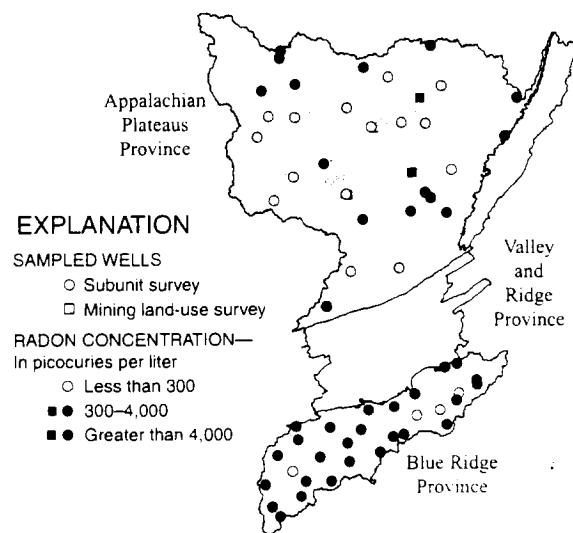

Figure 21. Radon concentrations vary greatly among physiographic provinces.

In comparison, at 15 wells in the same geologic units but not near mines, the median concentration was 200 pCi/L.

Modern Well Construction Can Prevent Fecal Bacteria from Reaching Drinking Water in Most Areas

Escherichia coli (*E. coli*) and the broader fecal coliform group of bacteria indicate the possible presence of disease-causing organisms. Standards for public drinking-water supplies do not permit the presence of any of these bacteria at detectable levels. Septic systems or livestock near a well are the probable sources of bacteria throughout the basin. Proper well construction can prevent bacteria from reaching the well water in some settings, and drinking water can be disinfected with chemicals or ultraviolet light.

Water from wells less than 25 years old in the Appalachian Plateaus and Blue Ridge was generally free from fecal bacteria (table 2). The sampled wells were generally in good condition, with a section of solid pipe at the top of the well sealed with concrete into the soil and rock (Sheets and Kozar, 1997). A residential septic system typically was nearby, but no heavy livestock use was within several hundred yards. Bacteria were found, however, at one fourth of the wells in a second study in the Appalachian Plateaus, which included some older wells and some without seals. Near these wells, there also may have been bacteria sources other than a septic system.

Table 2. *E. coli* or other fecal coliform bacteria were detected in few modern wells

Setting	Percentage of wells where bacteria were detected
Appalachian Plateaus:	
Newer wells	3
Older wells	26
Blue Ridge (newer wells only)	0

Most wells in limestone aquifers in the basin, including the Valley and Ridge, are at risk of contamination by bacteria (Boyer and Pasquarell, 1999), even if septic systems or livestock wastes are not nearby (Mathes, 2000), because ground water moves rapidly through solution channels in the rock. The wide valleys that typically overlie limestone aquifers are heavily used for livestock and agriculture.

Volatile Organic Compounds and Pesticides in Ground Water were Found in Low Concentrations

Both volatile organic compounds (VOCs) and pesticides were detected at low concentrations in the ground water of the Kanawha–New River Basin (Appendix, p. 27). Thirteen percent of samples (9 of 60) contained VOC concentrations greater than 0.1 µg/L. Of the seven detected VOCs, however, only three have established drinking-water standards. None of the VOCs identified in samples exceeded these standards. Pesticides were found above a detection limit of 0.001 µg/L in 32 percent of samples (19 of 60). Of the 12 detected pesticides, 4 have established drinking-water standards, none of which was exceeded.

Pesticides were detected in 17 of 30 wells sampled in the Blue Ridge, where 30 percent of the land was being used for agriculture in 1993. The most commonly detected pesticides, at one-third of the wells, were atrazine and its breakdown product deethylatrazine. The maximum concentration of all pesticides detected in a single sample was 0.14 µg/L. Two other pesticides, *p,p'*-DDE and simazine, were present in more than 10 percent of samples at a maximum concentration of 0.025 µg/L in this province. In the largely non agricultural Appalachian Plateaus, however, pesticides were detected only at two wells.

Nutrient Concentrations in Ground Water were At or Below National Background Levels

Nutrients were prevalent at relatively low concentrations in ground water of the Kanawha–New River Basin. Nitrate concentration in 1 of 88 wells sampled in this study exceeded the USEPA drinking-water standard of 10 mg/L (as nitrogen). Most ground water contained less nitrate than does precipitation in the basin. Concentrations of other nutrients measured were at or below national background levels. These findings are consistent with national findings on nutrients in the ground water of forested areas, and the Kanawha–New River Basin is about 80 percent forested.

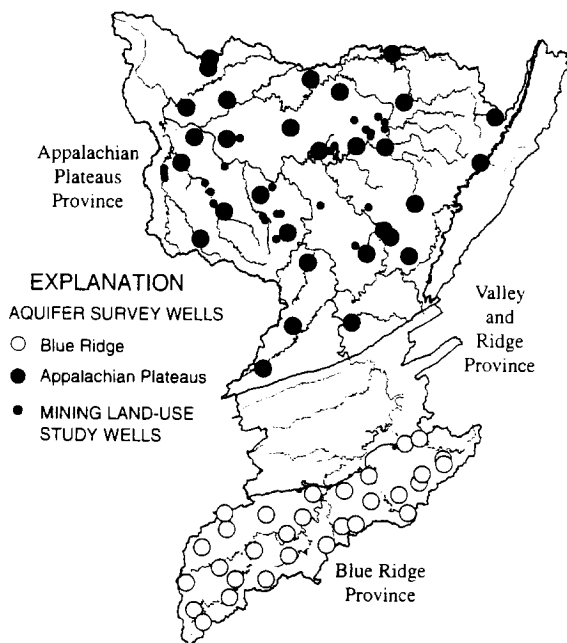

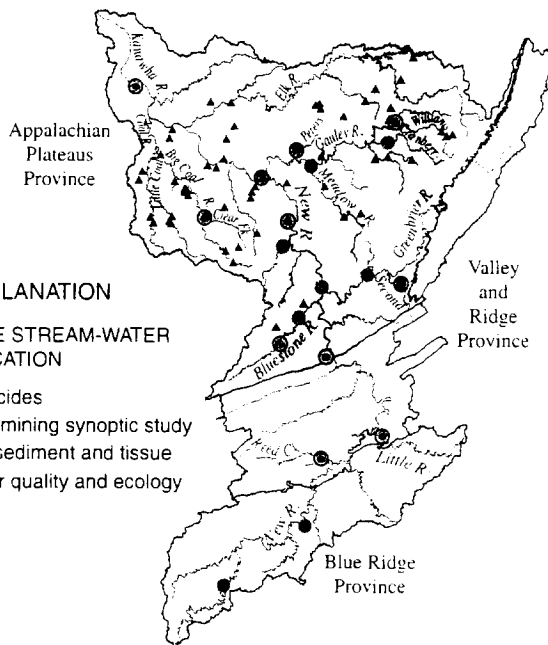

In the water of Appalachian Plateaus wells, the relatively high median ammonia concentration for a forested region—0.16 mg/L— is probably a result of mineralization of organic material. In contrast, ground water in the Blue Ridge, where a greater percentage of land is used for agriculture, had ground water with a higher median nitrate concentration (0.42 mg/L) and a higher median dissolved-oxygen concentration (5.1 mg/L).

STUDY UNIT DESIGN

Studies in the Kanawha–New River Basin were designed to describe the general quality of water and the aquatic ecosystem and to relate these conditions to natural and human influences (Gilliom and others, 1995). The design focused on the principal environmental settings—combinations of geohydrology, physiography, and land use—throughout the basin. The studies supplement assessment work by State agencies (Virginia Department of Environmental Quality, 1998; North Carolina Department of Environment and Natural Resources, 1999; West Virginia Division of Environmental Protection, 2000).

Stream Chemistry and Ecology

The sampling network was designed to characterize the effects of land use on stream quality at various scales. Water chemistry, fish and invertebrate communities, habitat, and bed-sediment and fish-tissue chemistry were used as indicators of stream quality. Fixed Sites were chosen on large rivers at the boundary between the Valley and Ridge and Appalachian Plateaus Physiographic Provinces, downstream from the Greenbrier and Gauley Rivers, and near the mouth of the Kanawha River. Fixed Sites also were chosen on tributaries to represent the effects of agriculture, coal mining, forest, and a relatively large human population in an otherwise rural setting.

Ground-Water Quality

The ground-water network was designed to broadly characterize the resource. Little previous information was available in the aquifer-survey areas. Aquifer surveys examined more constituents than any previous study and included a random component in site selection that allows estimates to be made for the whole population of similar wells. The land-use study targeted current effects of mining reclamation standards that have developed since around 1980.

Study component (Type of site)	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
STREAM CHEMISTRY AND ECOLOGY				
Fixed sites— General quality of the water column	Concentration, seasonal variability, and load of major ions, common metals, nutrients, bacteria, organic carbon, dissolved oxygen, suspended sediment, pH, specific conductance, and temperature. Continuous streamflow monitoring.	Large rivers with mixed land use, draining 3,700 to 11,800 square miles at sites located between major tributaries or at boundaries of regional environmental settings. Tributary streams draining 40 to 300 square miles in basins with predominant land uses of agriculture, coal mining, forest, and rural residential.		Monthly plus storms: about 30 samples during October 1996 through September 1998.
Fixed sites— Dissolved pesticides	Concentration and seasonal variability of 86 organic compounds in addition to the general water-column constituents listed above.	One large river downstream from the Valley and Ridge Physiographic Province and one near the mouth of the Kanawha River. Tributary streams with extensive agricultural land use.		Semimonthly to monthly: 14 or 15 samples in 1997. Weekly to monthly, during 1997: 9 or 25 samples.
Fixed sites— General stream ecology and habitat	Fish, benthic invertebrate, and algae communities were sampled and physical habitat was described to determine the presence and community structure of aquatic species.	Fixed sites where general water-column samples were collected.	11	Once, in 1997; three reaches sampled at each of three tributary sites in 1998.
Contaminants in fish tissue	To determine the presence of potentially toxic compounds in food chains that can include humans. Data included 22 elements and 28 organic compounds. Samples were a composite of at least five fish from one species, usually rock bass or common carp.	Fixed sites where general water-column samples were collected, plus contrasting settings in three large basins with mixed land use and five tributaries.	19	1 or 2 samples per site and species, during 1996 or 1997: 27 total samples.
Contaminants in bed sediment	To determine the presence of potentially toxic compounds attached to sediments accessible to aquatic life. Data included 44 elements and more than 100 organic compounds.	Same as sites for contaminants in fish. Composite samples were collected from depositional zones, where fine-grained sediments transported within the past year settle out of the water.	19	One or 2 samples during 1996 or 1997: 21 total samples.
Synoptic sites— Coal mining	To assess the present effects of coal mining in Appalachian Plateaus streams and the change in stream chemistry since about 1980. Data included discharge, alkalinity, acidity, pH, specific conductance, sulfate, chloride, and dissolved and total iron, manganese, and aluminum. Coordinated with a similar study in the Allegheny-Monongahela study unit. Benthic invertebrate community, physical habitat, contaminants in bed sediment, and other major ions in addition to constituents listed above. Fish community, in addition to constituents listed above.	Streams draining 0.2 to 128 square miles in areas of known mining history, including unmined basins. Most of the sites were sampled for water-column chemistry during 1979-81. A subset of sites described above, draining 8.8 to 128 mi ² . A subset of benthic invertebrate sites.	19, including unmined sites	One sample during low flow, July 1998.
GROUND-WATER				
Aquifer Surveys— Blue Ridge and Appalachian Plateaus	General water quality, to determine the occurrence and distribution of contaminants. Data included major ions, nutrients, bacteria, organic carbon, 19 trace elements, 47 pesticides, 86 volatile organic compounds, dissolved oxygen, turbidity, pH, specific conductance, and temperature. Samples from the Blue Ridge were analyzed for an additional 39 pesticides.	Domestic and public supply wells 25 years old and younger, and in good condition.	60	Once in 1997.
Land-use effects, reclaimed surface coal mines	General water quality, to determine effects of present reclamation requirements. Data included the constituents from aquifer surveys, without pesticides or volatile organic compounds. Coordinated with a similar study in the Allegheny-Monongahela Study Unit.	Domestic wells within 3,100 feet downgradient from a fully reclaimed surface coal mine. Reclamation was complete between 2 and 12 years before sampling. None of the sites were near "mountaintop removal" mines. Included both old and new wells.	28, compared to 10 unmined aquifer survey sites.	Once in 1998.

GLOSSARY

- Aquatic-life criteria**—Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms.
- Aquifer**— A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Background concentration**— A concentration of a substance in a particular environment that is indicative of minimal influence by human (anthropogenic) sources.
- Bed sediment**— The material that temporarily is stationary in the bottom of a stream or other watercourse.
- Benthic**— Of, related to, or occurring on the bottom of a water body.
- Community**— In ecology, the species that interact in a common area.
- Constituent**— A chemical or biological substance in water, sediment, or biota that can be measured by an analytical method.
- Criterion**— A standard rule or test on which a judgment or decision can be based. Plural, **Criteria**.
- Cubic foot per second (ft³/s, or cfs)**— Rate of water discharge representing a volume of 1 cubic foot passing a given point during 1 second, equivalent to approximately 7.48 gallons per second, or 448.8 gallons per minute, or 0.02832 cubic meter per second.
- Detection limit**— The minimum concentration of a substance that can be identified, measured, and reported within 99 percent confidence that the analyte concentration is greater than zero; determined from analysis of a sample in a given matrix containing the analyte.
- Dissolved constituent**— Operationally defined as a constituent that passes through a 0.45-micrometer filter.
- Dissolved solids**— Amount of minerals, such as salt, that are dissolved in water; amount of dissolved solids is an indicator of salinity or hardness.
- Downgradient**— At or toward a location farther from the source of ground-water flow.
- Drainage basin**— The portion of the surface of the Earth that contributes water to a stream through overland runoff, including tributaries and impoundments.
- Drinking-water standard or guideline**— A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contaminate levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.
- Escherichia coli***—A common species of intestinal or fecal bacteria.
- Fecal bacteria**— Microscopic single-celled organisms (primarily fecal coliforms and fecal streptococci) found in the wastes of warm-blooded animals. Their presence in water is used to assess the sanitary quality of water for body-contact recreation or for consumption. Their presence indicates contamination by the wastes of warm-blooded animals and the possible presence of pathogenic (disease producing) organisms.
- Intolerant organisms**— Organisms that are not adaptable to human alterations to the environment and thus decline in numbers where human alterations occur. See also Tolerant species.
- Major ions**—Constituents commonly present in concentrations exceeding 1.0 milligram per liter. Dissolved cations generally are calcium, magnesium, sodium, and potassium; the major anions are sulfate, chloride, fluoride, nitrate, and those contributing to alkalinity, most generally bicarbonate and carbonate.
- Maximum contaminant level (MCL)**— Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Micrograms per liter (µg/L)**— A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most streamwater and ground water. One thousand micrograms per liter equals 1 milligram per liter.
- Milligrams per liter (mg/L)**— A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most streamwater and ground water.
- Minimum reporting level (MRL)**— The smallest measured concentration of a constituent that may be reliably reported using a given analytical method. In many cases, the MRL is used when documentation for the detection limit is not available.
- Modified Hilsenhoff Biotic Index (MHBI)**— The Hilsenhoff Biotic Index (HBI) is a benthic invertebrate community index developed by W.L. Hilsenhoff. The HBI is determined by assigning a pollution tolerance value for each family of benthic invertebrates, then computing the average tolerance for a sample. In a modification of the HBI developed by R.W. Bode and M.A. Novak, pollution tolerance values are assigned by genus, which provides greater resolution in the average tolerance.
- Nutrient**— In aquatic systems, a substance that contributes to algal growth. Nutrients of concern include nitrogen and phosphorus compounds, but not elemental nitrogen.
- Picocurie (pCi)**— One trillionth (10^{12}) of the amount of radioactivity represented by a curie (Ci). A curie is the amount of radioactivity that yields 3.7×10^{10} radioactive disintegrations per second (dps). A picocurie yields 2.22 disintegrations per minute (dpm), or 0.037 dps.

Polycyclic aromatic hydrocarbon (PAH)— A class of organic compounds with a fused-ring (aromatic) structure. PAHs result from incomplete combustion of organic carbon (including wood), municipal solid waste, and fossil fuels, as well as from natural or anthropogenic introduction of uncombusted coal and oil. PAHs include benzo(a)pyrene, fluoranthene, and pyrene.

Recharge— Water that infiltrates the ground and reaches the saturated zone.

Secondary maximum contaminant level (SMCL)— The maximum contamination level in public water systems that, in the judgment of the U.S. Environmental Protection Agency (USEPA), is required to protect the public welfare. SMCLs are secondary (nonenforceable) drinking water regulations established by the USEPA for contaminants that may adversely affect the odor or appearance of such water.

Sediment— Particles, derived from rocks or biological materials, that have been transported by a fluid or other natural process, suspended or settled in water.

Specific conductance— A measure of the ability of a liquid to conduct an electrical current.

Suspended (as used in tables of chemical analyses)— The amount (concentration) of undissolved material in a water-sediment mixture. It is associated with the material retained on a 0.45-micrometer filter.

Suspended sediment— Particles of rock, sand, soil, and organic detritus carried in suspension in the water column, in contrast to sediment that moves on or near the streambed.

Taxon— Any identifiable group of taxonomically related organisms, such as a species or family. Plural, **Taxa**.

Tolerant species— Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.

Trace element— An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.

Upgradient— At or toward a location nearer to the source of ground-water flow.

Volatile organic compounds (VOCs)— Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

Water-quality standards— State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.

Watershed— See Drainage basin.

APPENDIX—WATER-QUALITY DATA FROM THE KANAWHA–NEW RIVER BASIN IN A NATIONAL CONTEXT

For a complete view of Kanawha–New River Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbcctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Kanawha–New River Basin. Selected results for this basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Kanawha–New River Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, simazine concentrations in Kanawha–New River Basin agricultural streams were similar to the national distribution, but the detection frequency was much higher (94 percent compared to 61 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Kanawha–New River Basin, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

.. Not measured or sample size less than two

12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- .. No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

Acetochlor (Harness Plus, Surpass) **
 Alachlor (Lasso, Bronco, Lariat, Bullet) **
 Bentfluralin (Balan, Benefin, Bonalan) **
 Cyanazine (Bladex, Fortrol)
 DCPA (Dacthal, chlorthal-dimethyl) **
 2,6-Diethylaniline (Alachlor breakdown product) **
 Dinoseb (Dinosebe)
 Diuron (Crisuron, Karmex, Diurex) **
 EPTC (Eptam, Farmarox, Alirox) **
 Fenuron (Fenulon, Fenidim) **
 Molinate (Ordram) **
 Napropamide (Devrinol) **
 Oryzalin (Surflan, Dirimal) **
 Prometon (Pramitol, Princep) **
 Triallate (Far-Go, Avadex BW, Tri-allate) *
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) **
 Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

Acifluorfen (Blazer, Tackle 2S) **
 Bentazon (Basagran, Bentazone) **
 Bromacil (Hyvar X, Urox B, Bromax)
 Bromoxynil (Buctril, Brominal) *
 Butylate (Sutan +, Genate Plus, Butilate) **
 Chloramben (Amiben, Amilon-WP, Vegiben) **
 Clopyralid (Stinger, Lontrel, Transline) **
 2,4-D (Aqua-Kleen, Lawn-Keep, Weed-B-Gone)
 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) **
 Dacthal mono-acid (Dacthal breakdown product) **
 Dicamba (Banvel, Dianat, Scotts Proturf)
 Dichlorprop (2,4-DP, Seritox 50, Lentemul) **
 Ethalfurailin (Sonalan, Curbit) **

Fluometuron (Flo-Met, Cotoran) **
 Linuron (Lorox, Linex, Sarclax, Linurex) ***
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Metribuzin (Lexone, Sencor)
 Neburon (Neburea, Neburyl, Noruben) ***
 Norflurazon (Evitai, Predict, Solicam, Zorial) ***
 Pebulate (Tillam, PEBC) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **

BIOLOGICAL INDICATORS

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Upper Tennessee River Basin that emerged from an assessment conducted between 1994 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

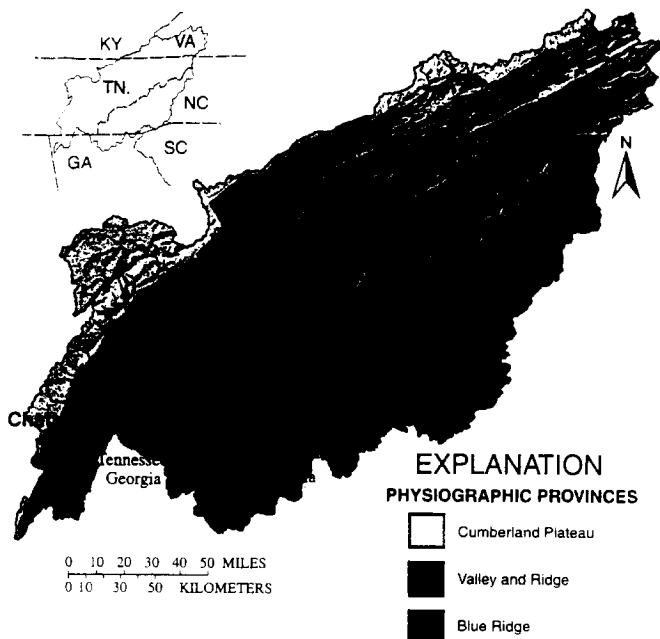

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Upper Tennessee River Basin assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Upper Tennessee River Basin Study Unit is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

The Upper Tennessee River Basin encompasses about 21,390 square miles and includes parts of four States: Tennessee, North Carolina, Virginia, and Georgia. Three major physiographic provinces are represented in the basin: the Cumberland Plateau, Valley and Ridge, and Blue Ridge Provinces. Most of the 2.4 million people residing in the basin live in the four metropolitan areas of Knoxville and Chattanooga, Tennessee; Asheville, North Carolina; and the Tri-Cities area of Tennessee and Virginia.

Surface-Water Highlights

The Upper Tennessee River Basin is characterized by an abundance of surface water that usually meets existing guidelines for drinking-water supply, recreation, and the protection of aquatic life. Bacteria levels, however, frequently exceed State standards for contact recreation both in agricultural and urban areas. In addition, mixtures of pesticides were detected at 67 of the 74 stream sites sampled. No pesticide concentrations exceeded drinking-water standards, but standards have not been determined for 11 of the 31 compounds detected.

- Bacteria levels frequently exceeded State standards in agricultural streams and streams in urban areas. Runoff from pasture land and direct livestock access to streams contribute to elevated bacterial counts in agricultural streams. Aging wastewater infrastructures are the most likely cause of elevated bacteria counts in urban streams.
- Inputs from urban and agricultural land uses have increased nutrient levels in streams. Yields of total nitrogen in streams are correlated to agricultural inputs, such as animal waste and fertilizer applications, whereas yields of total phosphorus are correlated with wastewater discharges. Tributary reservoirs serve as effective sinks for both nitrogen and phosphorus species in the basin.

- Herbicides and herbicide degradates were detected in 98 percent of the 428 total stream-water samples collected but at levels within drinking-water standards and aquatic-life guidelines. Insecticides used on agricultural fields, gardens, and lawns were detected infrequently (less than 12 percent of samples) and were at levels within drinking-water standards. Concentrations exceeding aquatic-life guidelines were observed, however, for carbaryl, diazinon, and lindane.
- Contamination from previous industrial and mining activities persists in parts of the basin resulting in fish-consumption advisories for PCB's (polychlorinated biphenyls), dioxin, and mercury in certain reservoirs and stream reaches. SVOC (semivolatile organic compounds) sediment concentrations exceeding aquatic-life guidelines were detected in some stream reaches draining coal mining areas.
- The Upper Tennessee River Basin is widely known for its aquatic diversity of fish and mussel species. While mussel populations are recovering in some parts of the basin, overall diversity is slowly declining.
- Releases and spills resulting in fish and mussel kills have occurred in many parts of the basin and pose a threat to isolated and endangered populations of aquatic species.

Selected Indicators of Stream-Water Quality

	Small Streams			Major Rivers
	Mixed Land Use	Agricultural	Forest	Mixed Land Use
Pesticides ¹	●	●	●	●
Phosphorus ²	●	●	●	●
Trace elements ³	●	●	●	●

Volatile organic compounds ⁵	—	●	—	—
Bacteria	●	●	●	●
Semivolatile organic compounds ⁶	●	●	●	●

● Percentage of samples with concentrations equal to or greater than a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or below a national goal for preventing excess algal growth

● Percentage of samples with concentrations less than a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or below a national goal for preventing excess algal growth

— Percentage of samples with no detection (^a Percentage is 1 or less and may not be clearly visible)

— Not assessed

¹ Insecticides, herbicides, and pesticide metabolites, sampled in water.

² Total phosphorus, sampled in water.

³ Arsenic, mercury, and metals, sampled in sediment.

⁴ Organochlorine compounds including DDT and PCBs, sampled in sediment.

⁵ Solvents, refrigerants, fumigants, and gasoline compounds, sampled in sediment.

⁶ Miscellaneous industrial chemicals and combustion by-products, sampled in sediment.

Trends in Stream-Water Quality

Because of water-treatment improvements, nitrogen and phosphorus levels for most of the streams in the Upper Tennessee River Basin remained unchanged or decreased from 1970 to 1993. Nitrogen concentrations, however, increased significantly for many streams in the Blue Ridge physiographic province because of nonurban residential development and aquaculture.

Trends in other water-quality constituents are difficult to assess because of changes in data-collection methods over time and an overall lack of data. Persistent organochlorine compounds such as DDE, a breakdown product of DDT, which was discontinued in 1973, and chlordane, which was discontinued in 1988, are still detected in fish tissues and bottom sediments in various parts of the basin.

Major Influences on Surface Waters

- Runoff from agricultural and urban areas
- Effluent from wastewater-treatment facilities
- Persistent sediment contamination
- Episodic spills and toxic releases

Ground-Water Highlights

Although ground-water use accounts for a little more than 3 percent of the total water use in the basin, over one-third of the population relies upon ground-water sources for drinking water. In the Upper Tennessee River Basin, ground-water studies focused on the carbonate rock formations of the Valley and Ridge physiographic province, which compose the most prolific aquifers in the basin and are the most susceptible to contamination. These aquifers typically provide water that meets all Federal and State drinking-water standards with the exceptions of nitrate and bacteria. Nitrate concentrations in domestic wells and springs used as drinking-water sources were within drinking-water standards and guidelines. Levels of nitrate exceeding drinking-water standards were detected only in shallow agricultural monitoring wells. Numerous pesticides and volatile organic compounds were detected in wells and springs, but none exceeded drinking-water standards.

- Bacteria levels exceeding finished drinking-water standards were detected in 11 of 30 wells used for untreated domestic drinking-water supply and in all 35 springs sampled. Bacteria levels in two springs exceeded State standards for recreation. Seventeen of the springs sampled are used for untreated drinking-water supplies.
- Nitrate was present in all domestic wells and springs but usually in concentrations well within the Federal drinking-water standard. Five of 30 monitoring wells that were installed adjacent to burley tobacco fields contained nitrate concentrations exceeding the drinking-water standard.

- Pesticides were detected in 40 percent of the agricultural wells, 43 percent of domestic water-supply wells, and 69 percent of the springs in relatively low concentrations. No pesticide concentrations exceeded drinking-water standards; however, 5 of the 18 compounds detected currently do not have standards. The most frequently detected pesticides were atrazine and metalaxyl (tobacco-specific) in the agricultural wells and atrazine, tebutiuron, and prometon in domestic wells and springs.
- Volatile organic compounds were detected in 86 percent of the springs and 67 percent of the domestic wells sampled. Trichloromethane was the most frequently detected compound of the 28 volatile organic compounds that were detected; but carbon disulfide, propanone, and methylbenzene generally were detected in the highest concentrations. None of the volatile organic compounds exceeded drinking-water standards or guidelines, but only 12 of the 28 currently have standards.

Major Influences on Ground Water

- Agricultural and urban land uses
- Permeability of soils and aquifer materials
- Bedrock fracture patterns and karst features

Selected Indicators of Ground-Water Quality

	Agricultural Shallow Ground Water	Domestic Supply Wells	Springs
Pesticides ¹			
Nitrate ²			
Radon ³

⁴ Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water.

INTRODUCTION TO THE UPPER TENNESSEE RIVER BASIN

The Upper Tennessee River Basin Study Unit encompasses about 21,390 square miles and includes the entire drainage area of the Tennessee River and its tributaries upstream from the USGS gaging station at Chattanooga, Tennessee. The study area includes parts of four States: Tennessee (11,500 square miles), North Carolina (5,480 square miles), Virginia (3,130 square miles), and Georgia (1,280 square miles). In 1990, the total population of the study area was about 2.4 million, of which about 1.6 million resided in the four metropolitan statistical areas of Chattanooga and Knoxville, Tennessee; Asheville, North Carolina; and the Tri-Cities area of Kingsport and Johnson City, Tennessee, and Bristol, Tennessee and Virginia.

Parts of three physiographic provinces—the Cumberland Plateau, Valley and Ridge, and Blue Ridge Provinces—compose the Upper Tennessee River Basin. Altitudes range from 621 feet above sea level at Chattanooga to 6,684 feet at Mount Mitchell, which is

just northeast of Asheville, North Carolina, and is the highest point in the Eastern United States. The Study Unit contains some of the most rugged terrain in the Eastern United States, including the Great Smoky Mountains range. The crest of the Smoky Mountains exceeds 5,000 feet for 34 miles along the Tennessee-North Carolina State line, has 16 peaks that exceed 6,000 feet, and is the most massive mountain range east of the Mississippi River.

The region generally has a temperate climate; temperatures and annual precipitation totals largely are dependent on land-surface elevations. Average annual temperatures in the area generally decrease by about 3 degrees Fahrenheit for every 1,000-foot increase in elevation. Average annual precipitation ranges from about 40 inches in some low-lying, sheltered areas in the Valley and Ridge province to more than 90 inches at elevations over 6,000 feet. Precipitation generally is distributed evenly throughout the year with no distinct dry and wet seasons.⁽¹⁾

Forests cover more than 67 percent of the Study Unit (fig. 1) and five National Forests—Jefferson, Pisgah, Cherokee, Nantahala, and Chattahoochee National Forests—wholly or partially lie within the basin. Agricultural land, predominantly pasture, is the second most common land use and accounts for more than 26 percent of the study area. Row crops account for only about 2.6 percent of the study area. Most of the agricultural land is located in the stream valleys and gently rolling parts of the Valley and Ridge physiographic province. The crests of steep ridges and more rugged areas of the basin remain forested. Less than 4.5 percent of the basin is developed. Row crops and developed areas, however, generally affect water-quality conditions much more than their small percentages would indicate.

Forest is the predominant land use in the Upper Tennessee River Basin.

Pasture is the predominant agricultural land use in the Upper Tennessee Basin.

Row crops account for only 2.6 percent of the Upper Tennessee River Basin.

Urban and industrial land uses have greater water-quality effects than their land-use percentages might indicate.

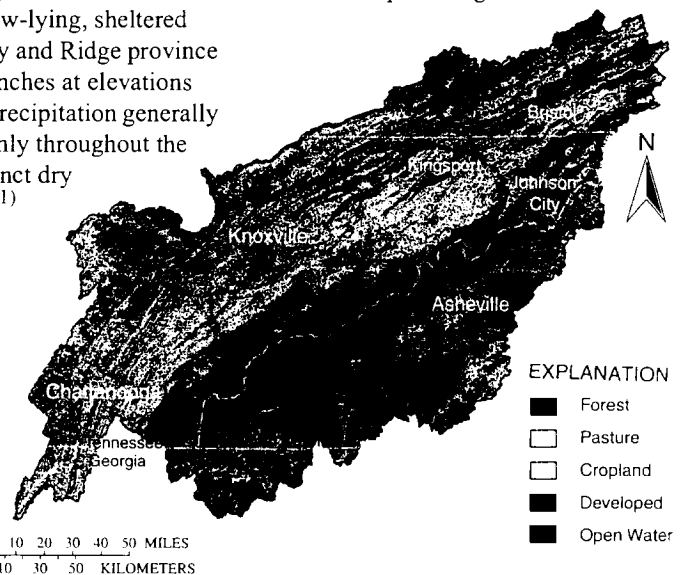

Figure 1. Water-quality conditions in the Upper Tennessee River Basin are influenced by land uses.

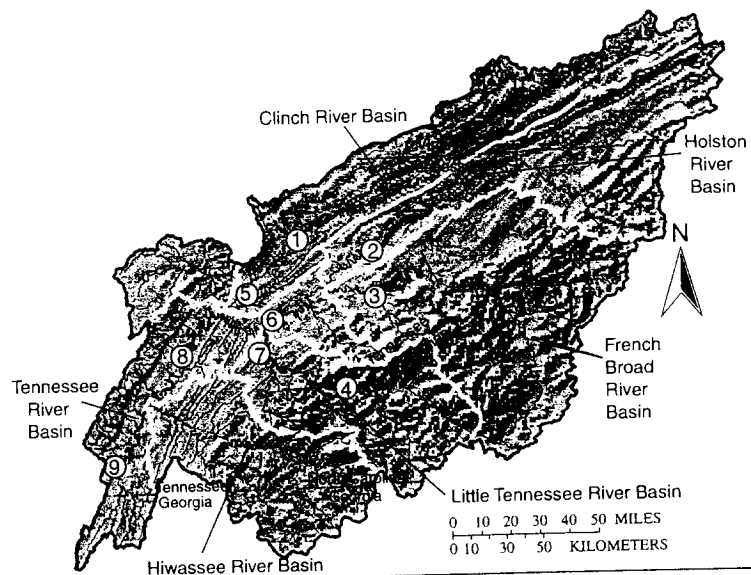

Surface-Water Features

The most prominent surface-water features of the Upper Tennessee River Basin are the tributary and main-stem reservoirs constructed and maintained by the Tennessee Valley Authority (TVA) and sometimes referred to as the "Great Lakes of the South." Four main-stem reservoirs are primarily flow-through systems that provide power generation and maintain navigational depths but provide little flood storage. These four reservoirs have a combined capacity of about 3.1 million acre-feet. Seventeen tributary reservoirs provide flood storage and power generation. These tributary reservoirs have a combined storage capacity of some 10 million acre-feet. An additional 17 privately owned and operated reservoirs also are located in the study area and have a combined storage capacity of about 0.6 million acre-feet.⁽²⁾

Five major tributaries (fig. 2) account for about 86 percent of the annual mean discharge of 35,450 cubic feet per second at the Tennessee River at Chattanooga and over 87 percent of the total area of the upper Tennessee River Basin. The Clinch (4,413 square miles), Holston (3,776 square miles), French Broad (5,124 square miles), Little Tennessee (2,627 square miles), and Hiwassee (2,700 square miles) Rivers each exhibit distinctive climatic and runoff characteristics. Average annual precipitation in these river basins ranges from about 45 inches in the Holston River Basin to almost 60 inches in the Little Tennessee River Basin, which receives the highest rainfall in the continental United States outside of the Puget Sound area of

Large reservoirs are the most prominent surface water features of the Upper Tennessee Basin.

Reservoir number	Reservoir name	Reservoir type	Surface area, in acres	Total capacity, in acre-feet
1	Norris	Tributary storage	34,200	969,000
2	Cherokee	Tributary storage	30,300	580,300
3	Douglas	Tributary storage	30,400	631,200
4	Fontana	Tributary storage	10,640	476,900
5	Melton Hill	Flow-through	5,960	16,100
6	Fort Loudon	Flow through	14,600	120,000
7	Tellico	Flow through	15,860	63,800
8	Watts Bar	Flow through	39,000	191,000
9	Chickamauga	Flow through	35,000	175,000

Figure 2. Two types of major reservoirs are on five major tributaries of the Upper Tennessee River.

Washington State.⁽³⁾ Average annual runoff totals have similar variations and range from about 18 inches in the Holston River Basin to more than 34 inches in the Little Tennessee River Basin.⁽⁴⁾

Water Use

In 1995, withdrawals of surface and ground water in the Upper Tennessee River Basin totaled about 4.8 billion gallons per day. Surface-water withdrawals for once-through cooling at thermoelectric plants accounted for about 3.5 billion gallons per day, or 73 percent of this total. Other uses (fig. 3) were commercial and industrial, 702 million gallons per day; public and domestic supply, 394 million gallons per day; agricultural, 203.3 million gallons per day; and mining, 10.4 million gallons per day, all of which were predominantly surface-water withdrawals.⁽⁵⁾ A total of 897 facilities were permitted to discharge wastewater in 1995 to area streams.

Total ground-water withdrawals in the basin for 1995 were about 138 million gallons per day and accounted for about 10.5 percent of the total non-thermoelectric water use in the basin. About 77 percent of the ground-water withdrawals were for public and domestic supply for over one-third of the basin's population.

Figure 3. Nonthermoelectric water use in the Upper Tennessee River Basin, 1995. (Thermoelectric water use accounted for 73 percent of the total water use.)

Hydrologic Conditions

Understanding hydrologic variations over time is necessary for assessing water-quality conditions as well as for providing a context with which to evaluate trends. Overall, rainfall during the data-collection period was about 10 percent greater than the long-term mean values. Most of the excess rainfall occurred in the northern part of the basin, as the Knoxville and Tri-Cities weather stations both recorded about 4 inches per year more than their long-term averages of 46.7 and 41.3 inches, respectively. During this same period, rainfall at Chattanooga averaged only about 1 inch per year more than the long-term average of 53.3 inches.⁽⁶⁾

Although precipitation usually is distributed relatively evenly throughout the year in the Upper Tennessee River Basin with no pronounced dry or wet seasons, two relatively dry periods occurred in the late summer and fall of 1997 and 1998. These periods are reflected in the rainfall departures in figure 4 and streamflow discharges in figure 5.

Ground-Water Resources

Ground water in the Upper Tennessee River Basin occurs almost exclusively in unconfined water-table conditions with no regional flow systems. Ground-water flow systems usually are less than 10 square miles in areal extent and are largely controlled by the bedrock geology (fig. 6) and thickness of overlying regolith.

The Cumberland Plateau is characterized by hard, relatively impermeable sandstone of Pennsylvanian age generally overlain by thin soils. Well yields generally range from 5 to 50 gallons per minute from fractures, faults, and bedding-plane openings. Over much of the province, however, reliable ground-water supplies are not obtainable. Similarly, the Blue Ridge physiographic province is characterized by fractured crystalline igneous and metamorphic rock of low porosity and little storage capacity.

Figure 4. Departures from mean monthly rainfall at three stations in the Upper Tennessee River Basin reflect hydrologic conditions during the 1996-98 study period. (Data from National Weather Service, Morristown, Tenn.)

Figure 5. Mean monthly discharge for the Clinch and Nolichucky Rivers reflect the abnormally dry summers of 1997 and 1998.

Well yields depend upon interception of water-bearing fracture systems and usually range from 10 to 25 gallons of water per minute where available.

The Valley and Ridge physiographic province is underlain by folded and extensively faulted limestone, dolomite, shale, and sandstones that occur in long subparallel belts trending southwest to northeast. The principal water-bearing units are the carbonate-based dolomites and limestones, which provide water for many cities and industries. Yields generally range from

5 to 200 gallons per minute, but wells penetrating extensive solution features may yield as much as 2,000 gallons per minute.⁽⁷⁾ Solution features, such as caves and sinkholes with their inherent permeability, make the Valley and Ridge carbonate aquifers the most susceptible in the basin to contamination.

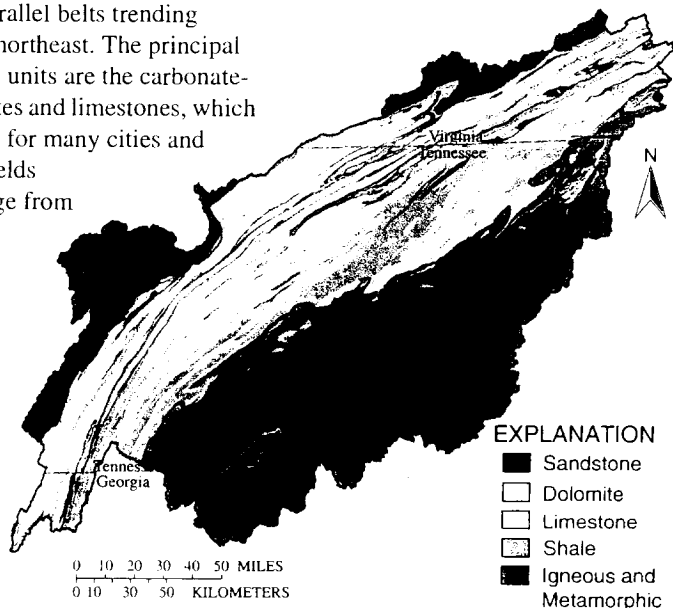

Figure 6. Ground-water availability is a function of surface geology in the Upper Tennessee River Basin.

Biological Diversity

The Upper Tennessee River Basin is noted nationally for its diversity of freshwater fishes and mussels. The basin provides habitat for 174 species of fish, including 25 species that are non-native.

Of the 149 fish species native to the Upper Tennessee River, 29 are found only in the Tennessee and adjacent Cumberland River Basins, and 15 are found only in the Upper Tennessee River. Fifteen fish species in the basin are federally listed as endangered or threatened and 50 species are listed under management categories used by the four States.

Most of the fish diversity in the basin is concentrated in the Valley and Ridge physiographic province, which includes 141 of the 149 native Upper Tennessee species, most notably in the Upper Clinch and lower Holston River Basins (fig. 7). The Clinch River alone is home to 126 Upper Tennessee River native species, 12 of which are federally protected and 41 of which are State listed. Four previously recorded fish species are no longer found in the Clinch River, the largest number of eliminated fish species for any Upper Tennessee drainage.

The Upper Tennessee River also includes one of the most diverse freshwater mussel fauna in the world with 85 different species having historically been recorded. Twenty-five of these species are no longer found in the basin, mostly because of habitat destruction associated with reservoir

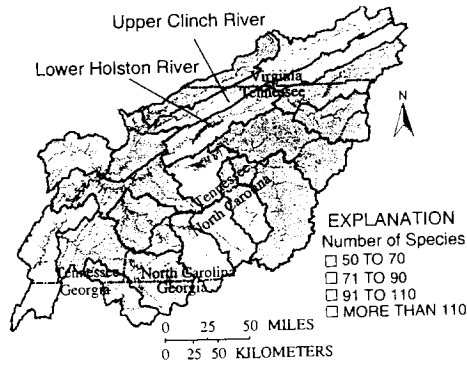

Figure 7. Fish diversity is highest in the Lower Holston and Upper Clinch River systems.

impoundment, and 11 are now believed to be extinct. Of the 60 freshwater mussel species now found in the Upper Tennessee River Basin, 30 species are under Federal protection and 52 species are listed by the States.

As with fishes, most of the freshwater mussel diversity is associated with the Valley and Ridge physiographic province, especially the Clinch River system (fig. 8). The Clinch River is now home to about 52 species of a previously recorded total of 79. Of the current total, 28 are federally listed and 38 are listed by the States.

Home to more than 300 globally rare species, the Upper Clinch River system, which includes the Powell River, has attracted attention from a number of environmental organizations including the designation as one of the "Last Great Places" by the Nature Conservancy. The Clinch River system also is considered to be one of the more biologically threatened river systems in the country (fig. 9). Of the 178 freshwater fish and mussel species presently inhabiting the Clinch River Basin, more than one-fourth are considered to be at-risk.⁽⁸⁾

Study Unit Design Focuses on Land Use.

Chemical and biological samples were collected from selected rivers and streams draining different land-use areas to assess overall quality as well as the effects of specific land uses. The study focused on agricultural land use and unregulated streams in the Valley and Ridge physiographic province. At Basic Fixed Sites, water samples were collected monthly and during storms to assess runoff conditions. Synoptic sites were sampled only once during periods of average flow.

Springs, domestic wells, and specifically installed agricultural monitoring wells were sampled to assess overall ground-water quality in the basin. Ground-water studies focused on the dolomite and limestone areas of the Valley and Ridge province, which provide the best aquifers and are the most susceptible areas in the basin to ground-water contamination. (See Study Unit Design, page 23, for details.)

MAJOR FINDINGS

Bacteria in the Upper Tennessee River Basin

Fecal indicator bacteria are the most frequent and widespread water-quality standard exceedances involving potential adverse effects to human health in the Upper Tennessee River Basin. The indicator bacteria themselves usually are harmless and easy to detect, but they are indicators of the presence of fecal material and have been shown to be associated with some waterborne disease-causing organisms. The presence of indicator bacteria, however, cannot be considered direct proof of any threat to human health, and research is underway to find better indicators.

Bacterial Counts Frequently Exceed Standards

The State of Tennessee's current water-quality standards are based on a total fecal coliform level of 200 colonies per 100 milliliters of water, as a mean value.⁽⁹⁾ This value is commonly exceeded in agricultural and urban streams in the Upper Tennessee River Basin (fig. 10). In agricultural areas, livestock waste is the most likely bacterial source both from allowing livestock direct access to streams and runoff from animal-waste areas. Bacterial counts generally increase during higher streamflows associated with runoff events in the agricultural areas (fig. 11).

Deteriorated and leaky sewage systems, faulty sewage treatment plants, urban runoff, and combined sewer overflow systems are among the

Livestock are a major contributor to fecal coliform levels in area streams.

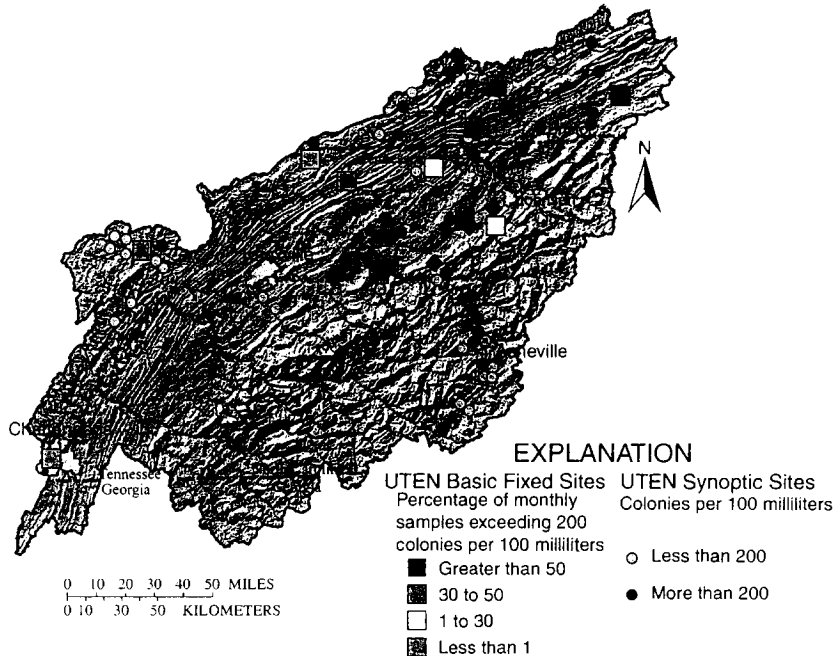

Figure 10. Fecal coliform bacteria frequently exceed standards in Upper Tennessee River (UTEN) streams.

sources of bacterial contamination in many urban streams. For example, all of the urban streams draining the central Knoxville, Tennessee, area regularly exceed bacterial standards⁽¹⁰⁾ because of widespread leakage from very old and deteriorating sewer systems in the older parts of the city. Replacement in 1998 of an obsolete combined sewer overflow system for one city neighborhood, however, has improved conditions for that neighborhood and adjacent parts of Fort Loudon Reservoir. These conditions highlight the continuing need for infrastructure improvements, especially in older urban areas.

Figure 11. Fecal coliform counts vary with streamflow at Big Limestone Creek in Tennessee.

In Upper Tennessee River Basin urban areas, deteriorated sewerage systems and combined sewer overflows produce elevated fecal coliform levels.

Bacteria Frequently Are Detected in Domestic Wells and Springs

A common misconception is that untreated ground water from wells and springs generally is safe for consumption because percolation through the soil removes most contaminants. While the soil can act as a natural filter, this does not guarantee the absence of contaminants. In fact, about half of the waterborne-disease outbreaks in the United States since 1900 have involved contaminated ground water.⁽¹¹⁾

Ground-water systems such as the carbonate systems of the Upper Tennessee River Basin are particularly susceptible to contamination from surface sources. Ground-water flow paths in these systems usually are shallow, principally involving the upper 10 to 20 feet of highly fractured and heavily weathered rock. In addition, the common presence of bedrock outcrops, areas of thin overburden, and karst features such as sinkholes provide direct avenues for aquifer contamination (fig. 12). Other potential sources for bacterial contamination include faulty or poorly placed septic systems and poor well construction or sanitation practices.

For finished drinking water, the detection of as few as 4 coliform bacteria colonies per 100 milliliters (col/100 mL) or the detection of 1 col/100 mL of fecal coliform bacteria, or *E. coli*, warrants concern for human health.⁽¹²⁾ Of 30 domestic wells used as sources for untreated drinking water, 11 (37 percent) exceeded the total coliform drinking-water standard and 9 (30 percent)

Figure 12. Upper Tennessee ground-water flow systems can be affected by a number of potential contamination sources such as sinkholes, outcrops of bedrock, and areas with thin overburden. (Not to scale)

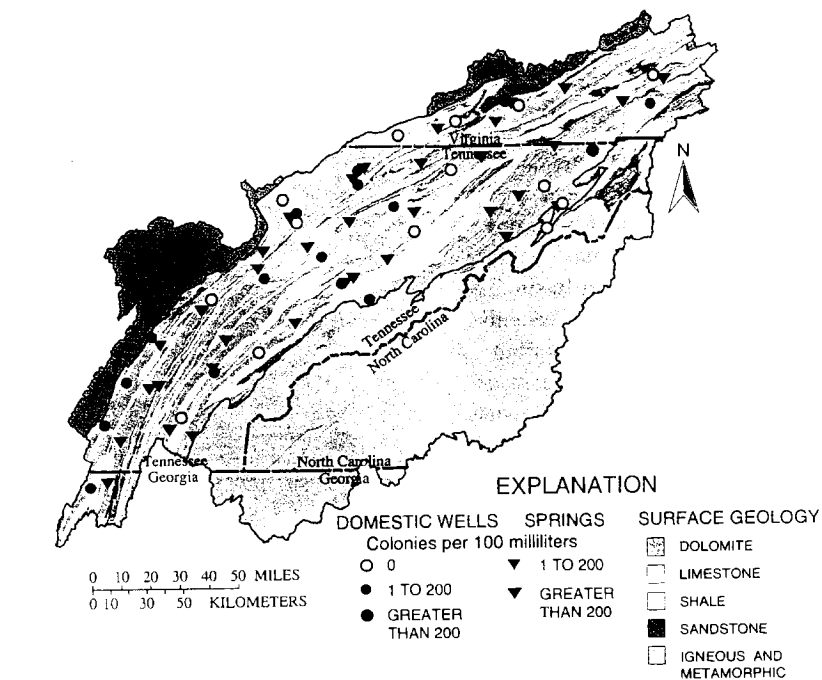

Figure 13. Coliform bacteria are often detected in Upper Tennessee River Basin ground water.

the *E. coli* drinking-water standard (fig. 13). The highest *E. coli* value detected was 1,600 col/100 mL.

Total coliform values for 35 springs sampled in the Upper Tennessee River Basin ranged from 10 to 1,900 col/100 mL and *E. coli* ranged from 0 to 660 col/100 mL. All of the springs tested exceeded drinking-water standards for total coliform bacteria, and 95 percent of the springs exceeded the *E. coli* standard. Two springs exceeded the *E. coli* body-contact standard of 126 col/100 mL. Sixteen of the 35 springs are used as domestic water supplies and others are used for filling water containers by the roadside with what usually is believed to be "clean mountain spring water."

Most of the rural population in the Upper Tennessee River Basin depend on shallow domestic wells for water supply.

Although much of the public perceives them as clean sources of drinking water, springs are very susceptible to contamination.

Nutrients in the Upper Tennessee River Basin

Nutrients are nitrogen and phosphorus compounds that are essential for plant growth. When found at elevated concentrations, however, nutrients can degrade water quality. The enrichment of a water body with nutrients, called eutrophication, can result in dense, rapidly multiplying growths, or blooms, of algal species and other nuisance aquatic plants. These can clog water intake pipes and filters and interfere with recreational activities, such as fishing, swimming, and boating. Subsequent decay of algal blooms can overload water bodies with oxidizable debris and result in foul odors, bad taste, and reduced dissolved oxygen levels, which are harmful to other aquatic life.⁽¹³⁾

Nutrients in the Upper Tennessee River Basin originate from point and nonpoint sources. Point sources are typically piped discharges from wastewater-treatment facilities and large urban and industrial stormwater systems. Nonpoint sources include stormwater runoff from urban and agricultural areas. In the Upper Tennessee River Basin, applications of synthetic fertilizers and manure are major sources.

Nutrient Loadings and Yields Vary among Upper Tennessee River Subbasins

Nutrient loadings in the Upper Tennessee River subbasins are primarily influenced by land use and streamflow conditions. Loads were estimated by using a constituent transport model and multiple regression to relate streamflow to the concentration of a water-quality constituent to derive loads.⁽¹⁴⁾ Twenty-three stations with adequate streamflow and chemical records were used for nitrogen calculations and 20 for total phosphorus.

The highest yields in the study area for both nutrient species were detected in the French Broad River Basin, particularly the upstream portion that includes Asheville, North Carolina (figs. 14 and 15). The French Broad River, as a whole, accounted for about 40 percent of the 138,000 pounds per day (lb/d) average annual total nitrogen load⁽¹⁵⁾ and about 25 percent of the 13,500 lb/d average annual total phosphorus load,⁽¹⁶⁾ leaving the basin at Chattanooga, Tennessee. The Holston River Basin added another 22 percent of the total nitrogen load but only 8 percent of the total phosphorus load.

A combination of agricultural and urban runoff is probably responsible for conditions in the French Broad River. In addition, the French Broad River and its tributaries have a history of water-quality problems associated with industrial point-source discharges. These basins also had the highest yields and loadings in the Upper Tennessee River Basin for total ammonia and organic forms of nitrogen.

Nutrient loadings and yields generally were lowest in those basins with relatively low percentages of agricultural land use and at sites directly downstream from tributary reservoirs. The fate of nutrients in the reservoirs depends on the physical characteristics of the reservoir (volume, surface area, depth, and hydraulic retention time) and its trophic state.⁽¹⁷⁾ The tributary reservoirs in the Upper Tennessee River Basin commonly function as sinks for nutrient species by providing a favorable environment for nitrogen transformation and by efficiently trapping both dissolved and sediment-bound phosphorus. Outflow loads of total phosphorus below Norris Lake on the Clinch River, for example, were 37 percent of the inflow load from the Clinch and Powell River Basins. Load estimates for the Holston River upstream and downstream from

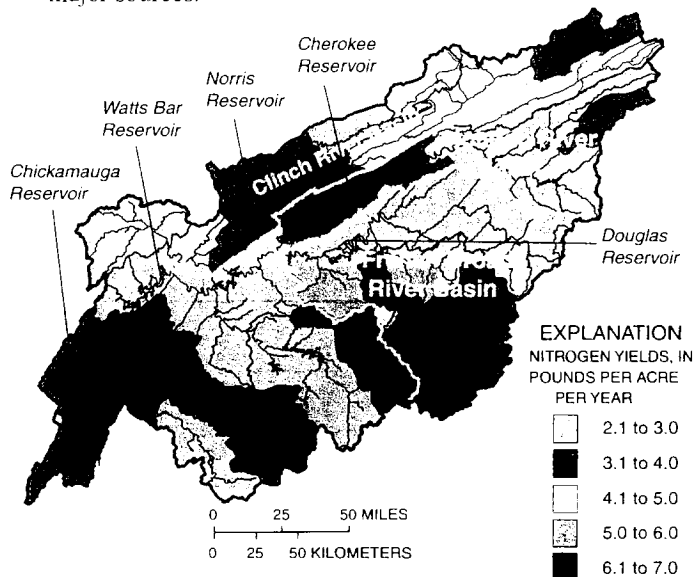

Figure 14. Mean annual total nitrogen yields between 1973 and 1993 were highest in the upper French Broad and upper Clinch River Basins.

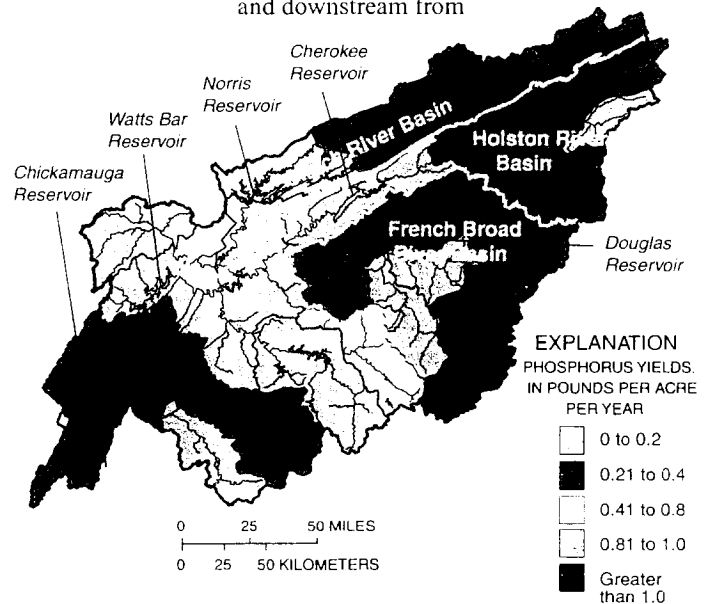

Figure 15. Mean annual total phosphorus yields between 1973 and 1993 were highest in the upper French Broad River Basin.

Cherokee Reservoir similarly indicate that the reservoir traps about 46 percent of the incoming load of total phosphorus. In contrast, less trapping occurs in the main-stem reservoirs, which are predominantly flow-through systems with limited storage capacity and relatively short residence times. Outflow phosphorus loads downstream from Chickamauga and Watts Bar Reservoirs significantly exceeded the inflow loads from upstream drainages. The increased loads can be attributed to low rates of trapping as well as additional input from ungaged areas adjacent to the reservoirs.⁽¹⁶⁾

Nutrient Concentrations and Yields Vary with Land Use

The relation between total nitrogen concentrations and land-use percentages was investigated for 87 sites in the Upper Tennessee River Basin and was found to be statistically significant. Stations in forested watersheds had the lowest concentrations of total nitrogen, whereas stations in agricultural areas had the highest. Concentrations of nitrogen in urban and mixed land-use areas were significantly greater than forested watersheds but were somewhat less than nitrogen concentrations in agricultural watersheds. Total nitrogen concentrations tended to increase with increased development whether agricultural or urban (fig. 16).⁽¹⁵⁾

Nitrogen sources also were investigated by using regression analysis between annual basin yields and total annual inputs from fertilizer, animal waste, wastewater discharges, and atmospheric deposition. For total nitrogen, basin yields significantly and positively correlated with agricultural inputs but only weakly correlated with wastewater discharges and atmospheric inputs. This tends to identify agricultural land use as the major contributor to annual instream nitrogen yields.⁽¹⁸⁾

The relation between total phosphorus concentrations and land-use percentages also were investigated for 83

Figure 16. Median total nitrogen concentrations can be related to (A) agricultural, and (B) urban land uses.

Figure 17. Median total phosphorus concentrations can be related to (A) agricultural and (B) urban land uses.

sites in the Upper Tennessee River Basin. Although the relation was not quite as clear as with nitrogen, statistically significant increases in total phosphorus concentrations also accompanied increased development whether urban or agricultural (fig. 17). As with total nitrogen, the lowest phosphorus concentrations were detected at sites in predominantly forested watersheds, whereas sites in urban and agricultural areas had the highest phosphorus concentrations.⁽¹⁶⁾

Phosphorus sources also were investigated by using calculated basin yields and total annual inputs from fertilizer,

Agricultural land uses appear to account for most of the total nitrogen loads to area streams.

animal waste, wastewater discharges, and the atmosphere. Phosphorus yields were found to strongly correlate with wastewater discharges but not with the agriculturally related input categories. This suggests that wastewater discharges may account for most of the total phosphorus load in basin streams (J.F. Connell, U.S. Geological Survey, written comun., October 20, 2000). Agriculturally applied phosphorus may be assimilated quickly by area soils thereby reaching area streams slowly if at all.

Wastewater discharges appear to account for most of the total phosphorus in Upper Tennessee River Basin streams.

Nutrient Concentrations in Upper Tennessee River Basin Surface Waters Generally Are Lower Than National Median Concentrations

Although nutrient concentrations and loadings are a concern in parts of the Upper Tennessee River Basin, concentrations generally are low for most area subbasins when compared with national averages. Mean total nitrogen concentrations exceeded or equaled the national median values only for three agricultural sites: Big Limestone Creek (83 percent agricultural), Copper Creek (51 percent agricultural), and the Nolichucky River (39 percent agricultural). Similar results

were obtained for total phosphorus at Big Limestone Creek and the Nolichucky River, but the French Broad River flowing into Tennessee from North Carolina also exceeded the national median value. Although relatively low, mean total phosphorus concentrations at most sites exceeded the U.S. Environmental Protection Agency (USEPA) goal of 0.05 mg/L total phosphorus for surface water entering reservoirs.

Total nitrogen exceeded the national median value only at the two intensively sampled agricultural sites.

Total phosphorus exceeded the national mean in two heavily agricultural drainages and also in the French Broad River below the Asheville, N.C., urban area.

Nitrogen Species Changed by Wastewater Treatment

Prior to the widespread implementation of wastewater treatment, nitrogen loadings for most Upper Tennessee River Basin streams primarily consisted of reduced species such as ammonia and various organic forms. These nitrogen species generally are undesirable in surface water because of associated color changes and decreases in dissolved oxygen levels. In addition, under certain conditions, ammonia nitrogen can be highly toxic to aquatic life. Wastewater-treatment facilities convert these undesirable forms to the oxidized species, nitrite and nitrate.

At the Tennessee River at Chattanooga, Tennessee, as with most major streams in the Upper Tennessee River Basin, the ratio of reduced to oxidized nitrogen species began to change in the late 1970s (fig. 18), corresponding to

Figure 18. The predominant nitrogen species changed at the Tennessee River at Chattanooga, Tennessee, between 1970 and 1998.

the implementation of wastewater-treatment facilities. By about 1983, the oxidized nitrogen species, nitrate and nitrite, became the predominant forms of nitrogen discharged from the basin, a trend which has continued to the present.

Loading Trends Increase in Parts of the Upper Tennessee Basin

Trend analyses for 56 stations using the seasonal Kendall statistical analysis test indicated significant increases in total nitrogen at seven sites in the Upper Tennessee River Basin and significant decreases at eight sites (fig. 19). Sites showing decreases were all on relatively major streams (average drainage area, 2,600 square miles) or below major impoundments. Of the seven sites showing increases, six are in the Blue Ridge physiographic province and six drain basins with forests accounting for more than 75 percent of the total land use. The exception is Beaver Creek, which drains the Bristol, Tennessee and Virginia, urban area in the Valley and Ridge Province. The average area of basins showing nitrogen increases was only 276 square miles.⁽¹⁵⁾

Of the seven sites showing increases, five are in the Blue Ridge in North Carolina—two sites on the French Broad River and one each on the Little Tennessee River and tributaries to the Hiwassee and Pigeon Rivers. Much of this area is undergoing nonurban residential development in the form of vacation homes. Nitrogen loads are probably increased by the sewage and fertilizer use associated with this development.

Nonurban residential development in the Blue Ridge Mountains is most likely the largest contributor to increasing total nitrogen concentrations.

Similar trend analyses for 42 sites to detect changes in total phosphorus concentrations yielded only one site with significant increases (fig. 20). West Chickamauga Creek, which drains a major industrial and urban setting, showed high concentrations for the entire period of record. Most (33) sites showed no trend, and eight sites

showed significant decreases. These sites are dominated for the most part by pasture and forest; however, three sites are downstream from major wastewater discharges.⁽¹⁶⁾ For sites in these more urbanized basins, improvements in wastewater-treatment processes are clearly responsible for the downward phosphorus trends.

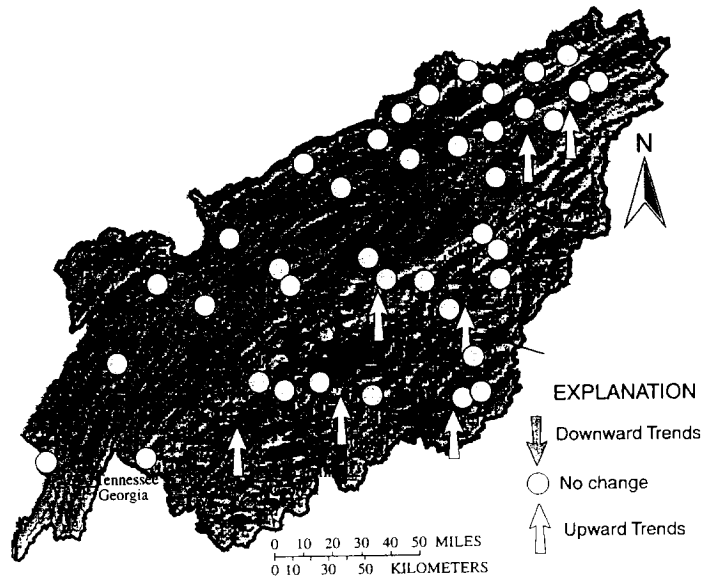

Figure 19. Total nitrogen increased in parts of the Upper Tennessee River Basin between 1970 and 1993.

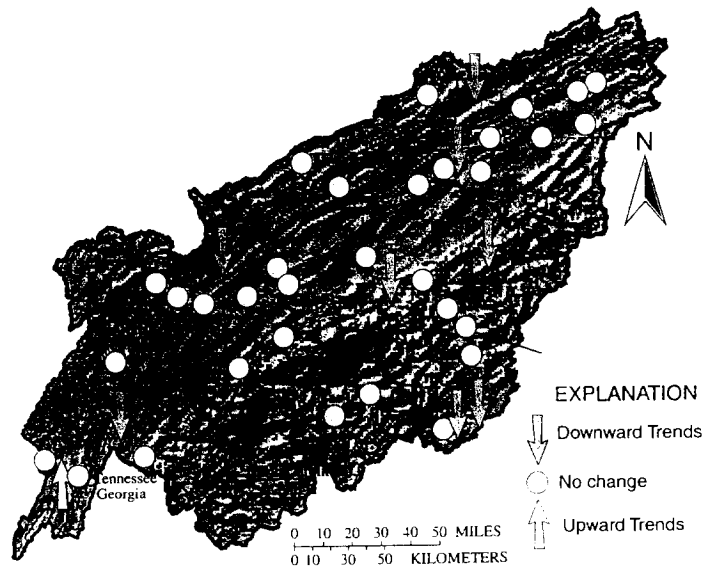

Figure 20. Total phosphorus decreased or remained unchanged in the Upper Tennessee River Basin between 1970 and 1993.

Nutrient Concentrations Generally Are Low in Upper Tennessee River Basin Ground Water

All of the nutrients measured in the Upper Tennessee River Basin ground water were relatively low, as is usually typical of ground water. Most nutrient species are retained by soil particles or organic matter, taken up by plants, or utilized by soil bacteria and never enter the ground-water flow system. Exceptions are the nitrate and ammonia forms of nitrogen; however, only nitrate has a drinking-water standard, which is 10 mg/L. Drinking water containing nitrate concentrations higher than the standard can cause methemoglobinemia, a life-threatening illness in infants.

Nitrate was present in all wells and springs sampled in the Upper Tennessee River Basin but usually at concentrations of 3 mg/L or less. This included all of the 30 domestic wells used for drinking-water supply that were sampled and the 35 springs sampled across the basin. The median nitrate concentration for domestic wells was 0.59 mg/L, slightly more than the 25th percentile value nationally; the median nitrate concentration for springs was 1.16 mg/L, which was significantly lower than the national 50th percentile. The higher concentrations detected in springs most likely reflect the predominance of relatively short ground-water flow paths associated with localized recharge and runoff. No nitrate concentrations in excess of the 10-mg/L standard were detected in any domestic wells or springs.

Nitrate concentrations in excess of the 10 mg/L standard were detected in 5 of the 30 wells installed during the study period to monitor shallow ground-water quality under and adjacent to tobacco fields. Tobacco is the main cash crop in the Upper Tennessee River Basin and is usually grown in small but intensively fertilized and cultivated plots. In general, fertilizer applications for tobacco cultivation are much greater than for any other row-type crop raised in the Upper Tennessee River Basin.

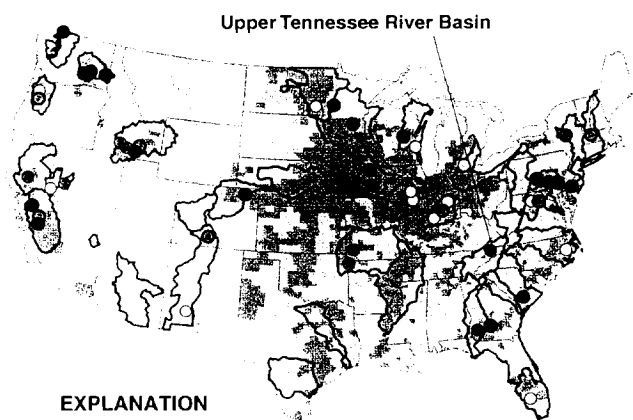

The median nitrate concentration in the shallow agricultural monitoring wells, however, was 0.68 mg/L—only slightly more than the median concentration for domestic wells and the national 25th percentile. Among the concentrations found nationally for agricultural and urban land uses, this value falls in the lower end of the medium range as shown in the accompanying figure.

The results indicate that nitrate contamination of extensive areas of ground water in the Upper Tennessee River Basin is very unlikely. High nitrate concentrations relative to the 10 mg/L drinking-water standard were detected only in shallow ground water directly under heavily fertilized tobacco plots. Tobacco fields typically

cover only about 2 acres and are widely scattered across the study area. The potential for nitrate contamination of drinking-water sources is, therefore, very low outside of the immediate vicinity of tobacco fields.

Median ground-water nitrate concentrations in the Upper Tennessee River Basin were significantly lower than the national median

EXPLANATION

Median concentration of nitrate— in milligrams per liter. Each circle represents a ground-water study

- Highest (greater than 5.1)
- Medium (0.48 to 5.1)
- Lowest (less than 0.48)

Background concentration

- Bold outline indicates median values greater than background concentration (2 milligrams per liter)

Average annual total nitrogen input— in pounds per acre, by county, for 1995-98. Inputs are from fertilizer, manure, and the atmosphere

- Greater than 25 pounds per acre
- 6 to 25 pounds per acre
- Less than 6 pounds per acre

Median nitrate concentrations in shallow ground water beneath agricultural land use in the Upper Tennessee River Basin were in the medium range on a national basis.

Pesticides in the Upper Tennessee River Basin

Pesticides are widely used in the Upper Tennessee River Basin to control insects, fungi, weeds, and other undesirable organisms. These compounds vary in their toxicity, persistence in the environment, and transport characteristics. Use of some of the more persistent organochlorine compounds, such as DDT, chlordane, dieldrin, and aldrin has been discontinued in the United States, but their residues are still detected in the environment. Although pesticides usually are applied to specific areas and directed at specific organisms, these compounds often become widely distributed and pose hazards to nontarget organisms. Of 18 sites sampled for organochlorine residues in bottom material and biota in the Upper Tennessee River Basin, chlordane was detected at three sites and dieldrin and DDT-related residues at two sites.

Pesticides were Frequently Detected in Surface Water

Pesticide use in the Upper Tennessee River Basin is primarily for agricultural purposes. Herbicides, including atrazine and its degradation product, deethylatrazine, had some of the highest application rates and were also among the most frequently detected pesticides in the basin. Herbicides were detected in 98 percent of the 428 surface-water samples collected; atrazine was found in 91 percent and deethyl-

atrazine in 86 percent. Metolachlor and simazine were detected in 62 and 40 percent, respectively. Tebuthiuron and prometon, which are used most commonly in noncrop areas, were also among the most frequently detected herbicides (in 58 and 31 percent of the samples collected, respectively). The most frequently detected insecticides were diazinon (12 percent), carbaryl (10 percent), and chlorpyrifos (10 percent), all of which are used on a variety of crops to control pests.

Detection frequencies for 27 pesticides detected at 3 intensively sampled agricultural sites in the Upper Tennessee River Basin (fig. 21) generally illustrate the results obtained at all 13 Basic Fixed Sites from which surface-water samples were collected. Overall, a total of 32 pesticides were detected. Chlorothalonil, alpha-BHC, and terbacil each were detected once and ethoprop was detected twice.

Some differences among the three sites are notable and probably reflect different agricultural practices and hydrologic conditions. For example, at the Nolichucky River site, compounds generally not found at other sites such as cyanazine, alachlor, DCPA, metribuzin, bromacil, and diazinon, were detected. Molinate, trifluralin, and p,p'-DDE were detected only at the Copper Creek site, which also had a significantly higher frequency of detection for tebuthiuron. Pesticide detection frequencies at Big Limestone Creek and the Nolichucky River were, as expected, similar for several compounds

Pesticides are widely used in the Upper Tennessee Basin for control of insects, fungi, weeds, and other undesirable organisms.

including metolachlor, simazine, prometon, and napropamide. Big Limestone Creek is a tributary to the Nolichucky River, and both drain the same general agriculturally dominated area. The Big Limestone Creek drainage basin, however, contains more dairy operations than other parts of the Nolichucky drainage basin, which may account for some of the differences between the two sites.

Table 1. Major pesticides used in the Upper Tennessee River Basin, listed in order of estimated total pounds of active ingredient applied annually (1991-94) ⁽¹⁸⁾

Insecticides	Herbicides	Fungicides			
Oil	256,000	Atrazine	116,000	Methyl bromide..	423,000
Acephate	80,700	2-4-D	55,600	1-3-D	342,000
Chlorpyrifos.....	71,500	Metolachlor	46,300	Captan.....	108,000
Carbaryl	27,200	Alachlor	40,900	Ziram	69,500
Fenamiphos.....	17,200	Pebulate	31,400	Sulfur	58,700
Carbofuran.....	17,000	Pendimethalin	25,200	Chloropicrin	45,100
Formetanate.....	16,300	Butylate	24,800	Mancozeb	40,400
Azinphos-methyl..	14,400	Simazine.....	23,800	Metalaxyl	28,100
Phosmet.....	9,420	Glyphosate.....	16,100	Manab	21,500

Figure 21. Pesticide detections at three agriculturally dominated sites followed similar patterns.

Mixtures of Pesticides Are Common

Pesticides were seldom detected alone in surface-water samples and usually occurred as mixtures of several compounds. Generally, the effects of pesticide mixtures on biota or humans are not included in water-quality criteria, which are most commonly based on single-species, single-chemical toxicity tests conducted under laboratory conditions. As a result, potential adverse effects on biota may be underestimated.

Of the 163 samples collected at the three intensive sites, only 2 samples at Copper Creek contained only one detectable pesticide compound, and only 5 total samples contained only two compounds (fig. 22). Among the intensively sampled sites, samples from the Nolichucky River at Lowlands, Tennessee, generally contained more detectable pesticide compounds than samples from the other sites, but usually at lower concentrations. This reflects the larger drainage area of the Nolichucky River (1,687 square miles) as compared to the drainage areas of the other intensive sites (79 and 106 square miles for Big Limestone and Copper Creeks, respectively). Similarly, more pesticides also were detected in sam-

Figure 22. Pesticides usually were detected as mixtures of different compounds.

ples from Big Limestone Creek, which has a larger percentage of agricultural land use and a greater variety of crops than the Copper Creek Basin in Virginia.

Peak Pesticide Concentrations Are Seasonal

Pesticide concentrations were found to be seasonal and closely related to land use. The highest concentrations occurred in the more heavily agricultural basins in late spring and early summer, coinciding with crop applications. Results of weekly sampling results at the three intensively sampled agricultural sites illustrate the seasonality and short-lived nature of the peak concentrations in streams draining agricultural areas (fig. 23). Peak concentrations coincided with the first substantial runoff event following agricultural applications in May 1996, after which concentrations declined relatively rapidly to near-background levels. Less frequent sampling would have made it less likely to

have noted the existence of the peaks. Because these streams are "flashy" in that peak discharges come and go very quickly, it is possible that even higher concentrations can occur for short periods of time. Seasonality also was evident at sites not characterized or directly influenced by intense agricultural activities. Atrazine and metolachlor concentrations at Clear Creek at Lilly Bridge, a predominantly forested watershed and part of the Obed National Wild and Scenic River watershed, also showed a distinct seasonality but with much lower concentrations (fig. 24). The seasonal pattern at this site is more gradual, suggesting atmospheric input more than runoff from agricultural activity.

Figure 23. Atrazine concentrations were seasonal in the Upper Tennessee River Basin intensively sampled sites, March 1996 - April 1997.

Figure 24. Atrazine and metolachlor concentrations were seasonal in monthly samples at Clear Creek at Lilly Bridge, March 1997 - September 1998.

Pesticide Concentrations Usually Meet Guidelines

Although most of the water samples collected contained detectable concentrations of one or more pesticides, no concentrations exceeded any drinking-water standards or guidelines. Only 20 of the 31 pesticides detected, however, have established guidelines. Of the 15 compounds that have aquatic-life guidelines, four were detected at concentrations higher than the guidelines. Carbaryl concentrations in excess of the 0.20- $\mu\text{g}/\text{L}$ (micrograms per liter) aquatic-life criterion⁽¹⁹⁾ were found in four samples—two each from the Guest River near Millers Yard, Virginia, and the Nolichucky River at Lowlands, Tennessee (fig. 25). Lindane, an organochlorine used primarily for the protection of tobacco transplants, was above the 0.01- $\mu\text{g}/\text{L}$ criterion in three samples from three different sites, two of which were in the same subbasin - Little Limestone Creek and the Nolichucky River at Lowlands, Tennessee.

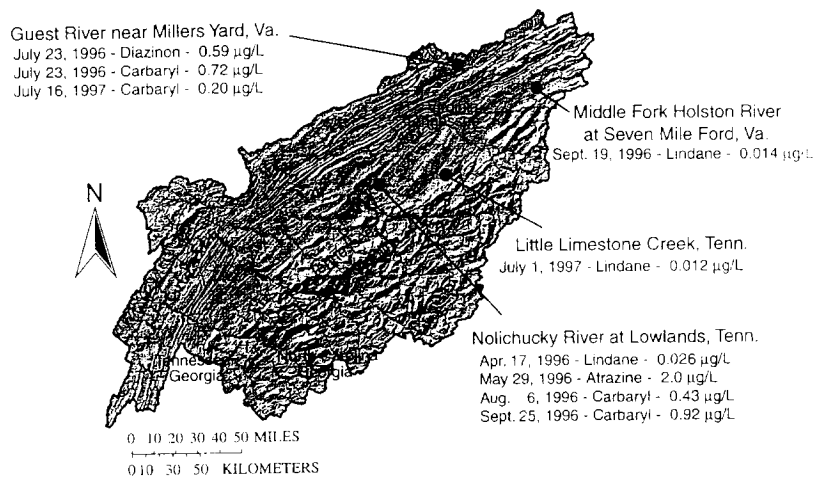

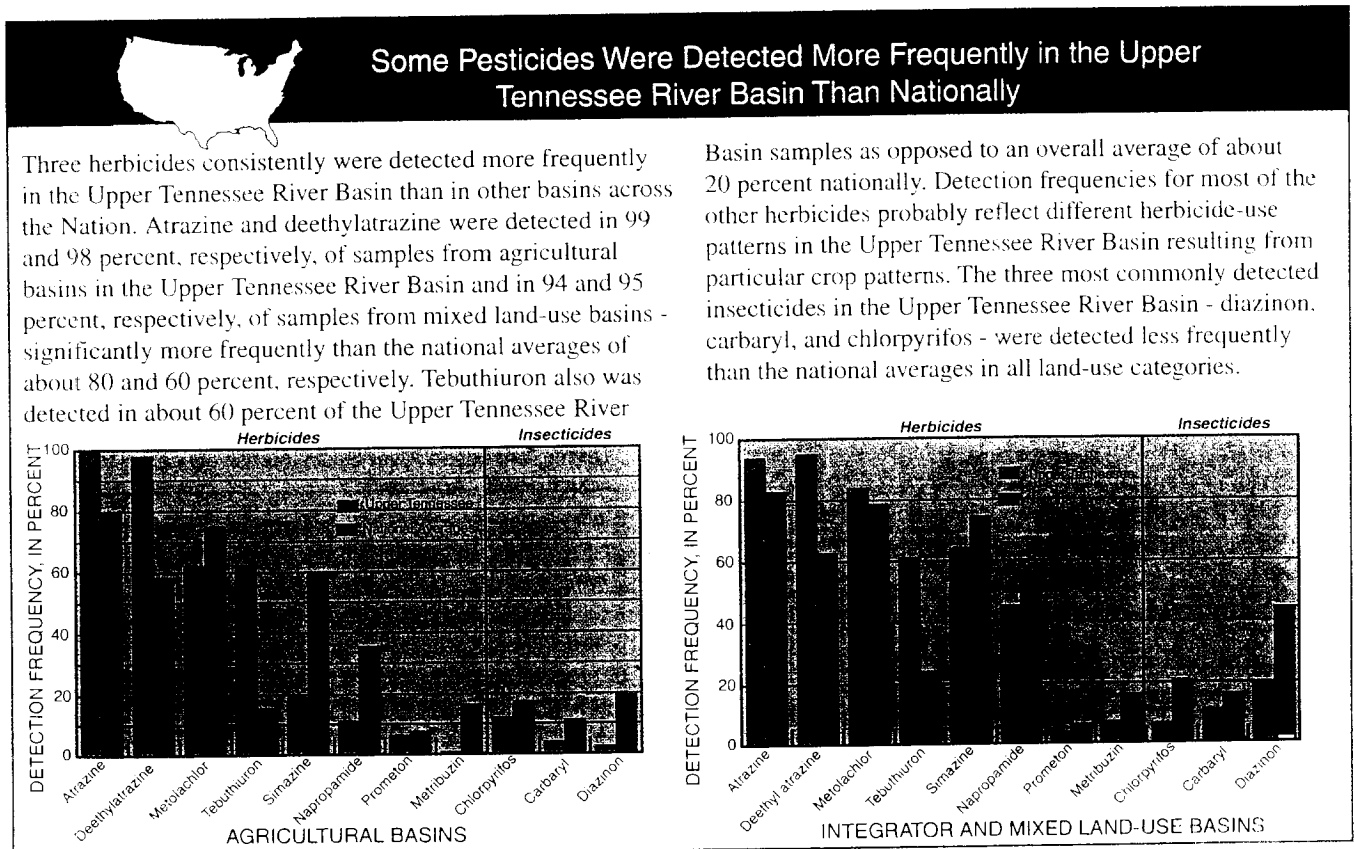

Figure 25. Pesticide concentrations, in micrograms per liter ($\mu\text{g}/\text{L}$), infrequently exceeded aquatic-life criteria in the Upper Tennessee River Basin, 1996-98.

An atrazine concentration higher than the 0.18- $\mu\text{g}/\text{L}$ criterion⁽²⁰⁾ also was detected in one sample taken at the Nolichucky River at Lowlands, Tennessee, in May 1996. This was the only criterion exceedance noted for any herbicide even though herbicides were detected much more frequently than the other

pesticide types. One sample collected at the Guest River near Millers Yard, Virginia, contained a diazinon concentration that was not only greater than the aquatic-life guideline of 0.08 $\mu\text{g}/\text{L}$ but approached the USEPA lifetime health advisory level of 0.60 $\mu\text{g}/\text{L}$ for drinking water.

Pesticides Were Detected at Low Levels in Ground Water

Pesticides were detected in Upper Tennessee River Basin ground-water samples more often than not, but generally at concentrations less than 0.01 µg/L. Pesticide concentrations in ground water did not exceed any drinking-water standards or guidelines. Usually, however, pesticides occur in mixtures for which criteria are not available. In addition, 5 of the 11 pesticides detected have no established guidelines or criteria.

Pesticides were detected in springs significantly more often and in more pesticide detections per sample than in other ground-water sources sampled (fig. 26). This probably reflects the greater vulnerability of springs to surface contamination either from the immediate area or karst features in the carbonate bedrocks. More frequent detections also may reflect the larger drainage areas from which springs capture ground water as opposed to wells. Of the 35 springs sampled, 24 (69 percent) contained detectable pesticide concentrations, and 12 (34 percent) contained detectable quantities of three or more different compounds. Detection frequencies in agricultural and domestic wells, by contrast, were significantly lower and similar to one another; 12 of 30 (40 percent) agricultural wells and 13 of 30 (43 percent) domestic wells contained detectable pesticide concentrations. Of these detections, only three (10 percent) samples from agricultural wells had detections of three or more pesticides. Eight (27 percent) domestic wells, however, had detections of three or more compounds.

Pesticides were detected more frequently in Upper Tennessee River Basin springs than in other sources of ground water.

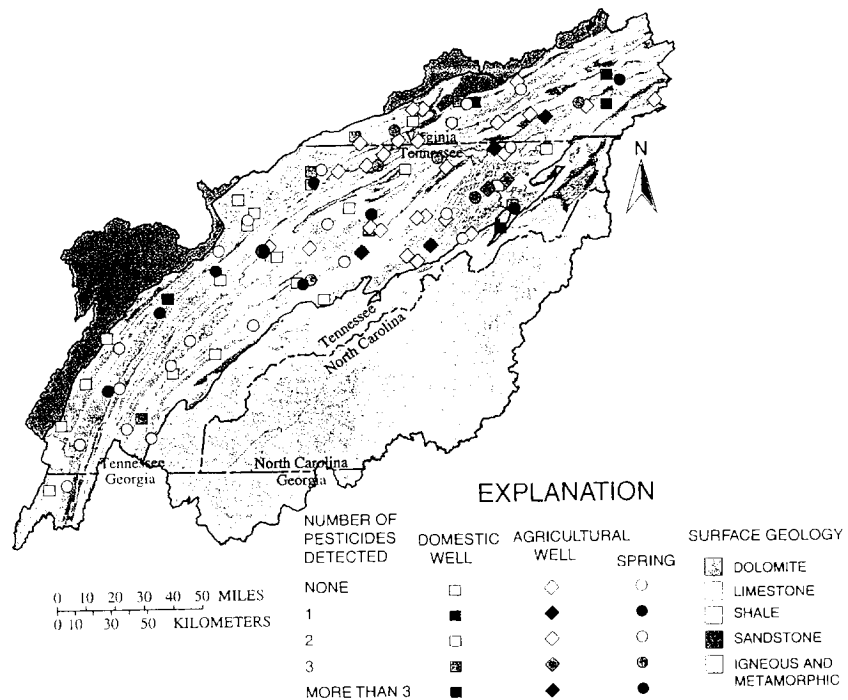

Figure 26. Pesticides were detected at low concentrations in Upper Tennessee River Basin ground water.

Atrazine and its degradation product, deethylatrazine, were the pesticides most commonly detected in all ground-water samples but were detected twice as frequently in springs as in other ground-water sources (fig. 27). Tebuthiuron, the third most frequently detected pesticide, also was detected more than twice as frequently in springs as in domestic wells. The different pesticide mixtures typical of the agricultural wells sampled reflect the focus on tobacco in this phase of the study. In general, a different suite of pesticides are used for tobacco than for most other crops. For example, atrazine and other broadleaf herbicides are toxic to tobacco.

Figure 27. Pesticides were detected more frequently in springs than in wells in the Upper Tennessee River Basin.

Volatile Organic Compounds Were Frequently Detected in Ground Water

Ground-water samples were collected from 30 domestic wells and 35 springs tapping carbonate strata in the Upper Tennessee River Basin. Volatile organic compounds (VOCs) were detected in most of the ground-water samples (fig. 28) but generally at very low concentrations—often in orders of magnitude below the established reporting limit. Twenty-eight different VOCs were detected during sampling, 12 of which have drinking-water standards. No measured concentrations, however, exceeded these standards.

VOCs were detected more frequently in springs (86 percent) than in domestic wells (67 percent) and generally at slightly higher concentrations. Of the 20 samples with one or more concentrations greater than 0.1 µg/L, 14 were taken from springs and only 6 from wells. Similarly, of the 28 compounds detected, 22 were detected in spring samples and only 18 were detected in domestic wells.

The most frequently detected VOCs were trichloromethane (51 percent), chloromethane (28 percent), styrene (23 percent), tetrachloroethane (18 percent), carbon disulfide (11 percent), and trichloroethene (9 percent). The remaining 22 compounds were detected in three or fewer samples (less than 5 percent).

Other than the greater detection frequencies for spring samples, no areal or other occurrence patterns could be found. As is the case nationally, the source for many of the most common VOCs detected in ground water, such as trichloromethane, is unclear. The greater occurrence of detections in springs as well as the widespread but random pattern of occurrence suggests the possibility of atmospheric origins, but no definite source can be identified at present.

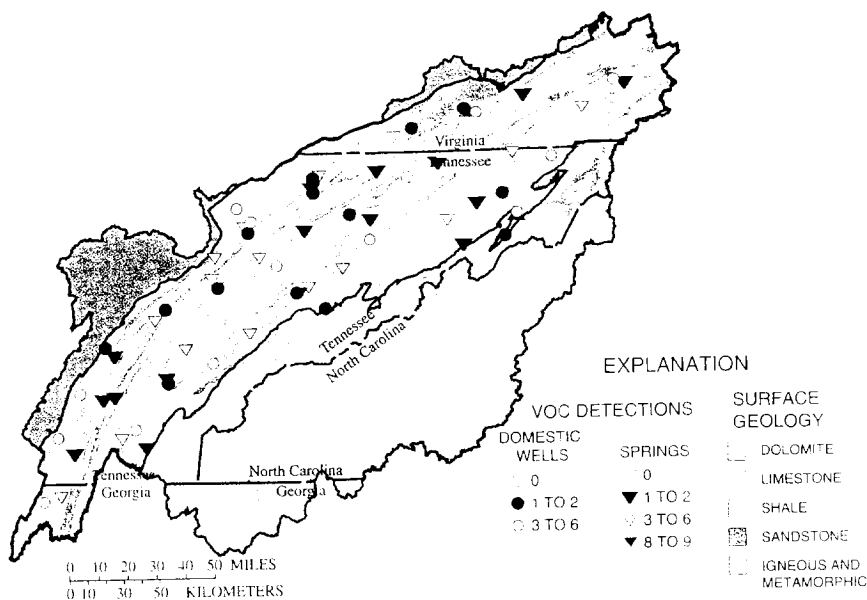

Figure 28. Volatile organic compounds (VOCs) are often detected in Upper Tennessee River Basin ground water.

Upper Tennessee River Basin and National VOC Detection Frequencies Are Similar

Detection frequencies in Upper Tennessee River Basin wells for the 10 most commonly detected VOCs nationally were similar to national detection frequencies found for ambient ground water in all land-use settings. All compounds were assessed at a common detection level of 0.1 mg/L. Trichloromethane was the most

commonly detected compound nationally as well as in the Upper Tennessee River Basin but typically was detected at concentrations far below drinking-water standards. The results are consistent with the mixed urban and rural land uses surrounding most Upper Tennessee River Basin ground-water sites.

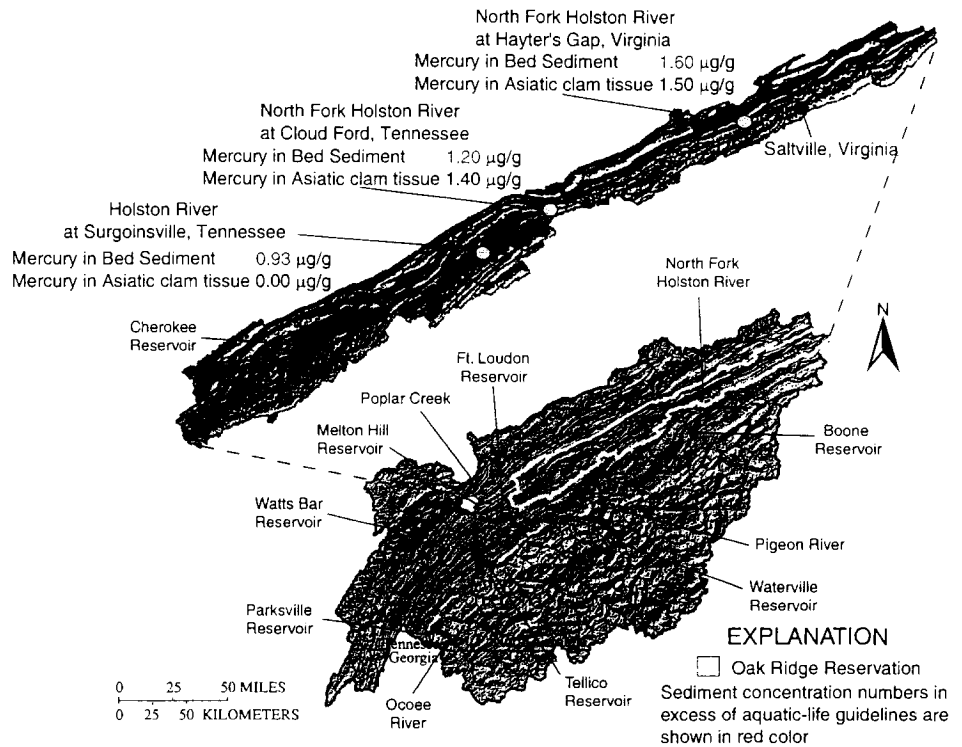

Upper Tennessee River Basin detection frequencies were similar to national results for the 10 most commonly detected VOCs nationally. (Assessment level of 0.1 microgram per liter)

Water-Quality Influences of Industry and Mining

Industrial and mining activities prior to the passage of the Clean Water Act in 1972 have left a legacy of contaminated sediment that continues to affect water quality in parts of the Upper Tennessee River Basin. The most widespread contaminants are PCBs (polychlorinated biphenyls) and mercury, mostly from industrial activities dating from 1950 to 1972. Sources for some of the other contaminants, however, such as those affecting the Pigeon and Ocoee Rivers date back as far as 1908 and 1843, respectively.

Mercury in the North Fork Holston River is a result of the operation of a chlor-alkali plant on the banks of the river from 1950 through 1971. An estimated 75 pounds of mercury per day were discharged either directly to the river or into unlined holding ponds along the riverbank.⁽²¹⁾ Although soils at the site have been remediated, the site continues to discharge mercury.⁽²²⁾ Bed-sediment and tissue samples taken from the Holston River system (fig. 29) were the only samples taken during the study that were above the Canadian guideline for aquatic-life protection (0.486 micrograms per gram total mercury). Although tissue samples in the main-stem Holston River site at Surgoinsville were free of mercury, the bed-sediment results suggest that mercury may be migrating farther downstream than previously thought and may eventually reach Cherokee Reservoir.

Mercury is also a major contaminant in the drainages downstream from the Department of Energy's 35,585-acre Oak Ridge Reservation (ORR), such as East Fork Poplar Creek, the White Oak Creek watershed, and the lower Clinch River - Watts Bar Reservoir. The ORR, established in 1942 as part of the Manhattan Project to develop the atomic bomb, encompasses three major facilities — X-10, originally for weapons research but now Oak Ridge National Laboratory (ORNL); Y-12, for the fabrication of nuclear weapons compo-

Location	Contaminant	Source	Comment
N. Fk. Holston River	Mercury	Industrial point source	Fish consumption advisory
Boone Reservoir	PCBs, Chlordane	Not identified	Fish consumption advisory

Ft. Loudon Reservoir	PCBs	Industrial point source	Fish consumption advisory
Tellico Reservoir	PCBs	Not identified	Fish consumption advisory
Parksville Reservoir	Metals	Abandoned mining area	None
Ocoee River	Metals	Abandoned mining area	None

Figure 29. Mercury, in micrograms per gram, and organic contaminants persist in bed sediments and biological tissues in parts of the Upper Tennessee River Basin.

nents; and K-25, for uranium enrichment by gaseous diffusion. As a result of these operations, about 527 sites covering approximately 15 percent of the total ORR area have been identified as contaminated with metals, including mercury, radionuclides, a variety of VOCs, and nitrates.⁽²³⁾

Most of the contamination has remained confined within the ORR, which was added in its entirety to USEPA's National Priorities List in 1989. A number of contaminants, most notably mercury, PCBs, and cesium-137, however, have migrated to downstream areas. The State of Tennessee has posted a fish-consumption advisory for ORR drainages as well as Watts

Bar Reservoir as a result of bioaccumulation of mercury and PCBs in some fish species.

A 1983 inventory estimated that about 2 million pounds (1,088 metric tons) of mercury was 'lost' from operations related to thermonuclear bomb development on the ORR.⁽²⁴⁾ Most of this mercury is believed to have volatilized into the atmosphere, but much remains within ORR facilities and in Watts Bar Reservoir sediments. Analyses of sediment cores indicate that the highest discharges of mercury and cesium-137 occurred during the 1950s, and that about 76 metric tons of mercury has accumulated in Watts Bar sediments. About 91 percent of the 335

curies of cesium-137 released from the ORR have also been retained by the lake sediments. The concentrations detected are not believed to pose an imminent human health risk, especially if the deep sediments are not disturbed.⁽²⁵⁾

Mining of the massive sulfide deposits in the Copper Basin along the Ocoee River began in 1843. Copper was the primary metal extracted, but iron, sulfur, zinc, and small amounts of gold and silver also were produced. Before 1900, Copper Basin was the largest metal-mining district in the Southeast. The last mine was closed in 1987.⁽²⁶⁾

High concentrations of sulfur dioxide produced by smelting operations devastated the surrounding environment, resulting in a "moonscape" of about 25 square miles. Erosion of the area resulted in high sediment and associated metal loads to area streams. Although thousands of acres have been revegetated and the landscape is being slowly transformed back to forest, relatively high metal concentrations remain in the upper reaches of Parksville Reservoir and the Ocoee River.

Discharge of essentially untreated paper-mill effluent to the Pigeon River began in early 1908 and continued until plant improvements were instituted in the 1990s. Dioxins were first detected in fish samples from the river in 1988 (dioxin detection methods were not available until 1985) and became an immediate priority with respect to human health effects.⁽²⁷⁾ Dioxins have not been detected in recent samples, including bed-sediment and tissue samples taken during the Upper Tennessee NAWQA study. The State of Tennessee, however, continues a precautionary fish-consumption advisory for the Tennessee portion of the river.

Even though discussions regarding the Pigeon River continue between the States of Tennessee and North Carolina, all parties agree that conditions have improved significantly. Once nearly devoid of aquatic life, benthic invertebrate and fish populations in the

Tennessee portion of the Pigeon River are showing signs of recovery. Water-ville Lake, however, still retains tons of contaminated sediments deposited since the dam became operational in 1930, and these sediments remain a potential source of dioxin and other contaminants.

Polycyclic aromatic hydrocarbons (PAHs) commonly are detected as pollutants in soils and sediments, occur naturally in crude oil and coal, and also can result from the incomplete combustion of fossil fuels and forest fires.⁽²⁸⁾ In the upper Clinch River Basin, PAH concentrations reflect the presence of coal fines from upstream mining activities.

Twenty-nine PAHs were found in upper Clinch River bed-sediment samples and, with only a few exceptions, were not detected in the 12 samples taken from other parts of the Upper Tennessee Basin. Although PAHs are known to be toxic to fish, mussels, and aquatic insects, sediment-quality guidelines for the protection of aquatic life have been established for only 12 of the compounds detected. Of these, only two compounds – naphthalene and phenanthrene – exceeded their respec-

tive Canadian probable-effect levels of 391 µg/kg (micrograms per kilogram) and 515 µg/kg (fig. 30). The probable-effect levels define concentrations above which adverse effects are expected. A third compound, benzo(a)anthracene, occurred in concentrations very near its guideline of 385 µg/kg, and a number of compounds lacking guidelines were found at concentrations of 1,000 µg/kg or greater.

The highest concentrations generally follow the results for naphthalene and phenanthrene and occurred in the major river sites nearest, on a relative basis, to upstream mining activities. For example, concentrations at the Powell River and Pendleton Island sites exceeded those found at the Clinch River near Tazewell, which is farther removed from active mining in terms of river miles. Higher gradients and water velocities in the tributaries to the major streams prevent the accumulation of fine-grained sediment and coal fines. The main river channels, however, contain large pools and backwater areas where fine-grained material and associated constituents are deposited.

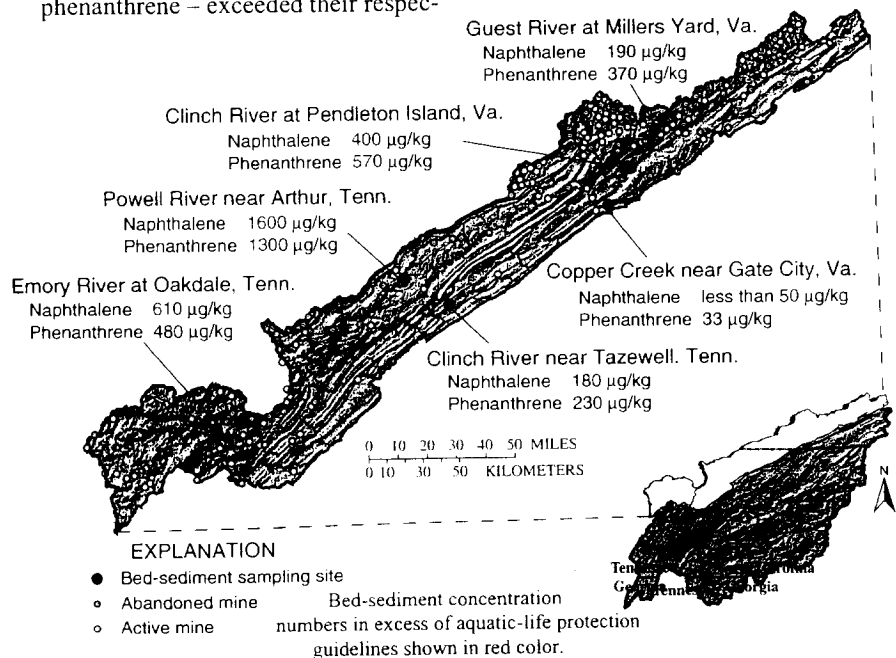

Figure 30. Relatively high polycyclic aromatic hydrocarbon (PAH) concentrations, in micrograms per kilogram, are common in bed sediments in the upper Clinch River Basin.

Freshwater Mussels in the Clinch and Powell Rivers

Freshwater mussel species diversity has been slowly declining in the Clinch and Powell Rivers of Tennessee and Virginia over the past 100 years. The numbers of mussel species found in these rivers are shown in figure 31 for selected periods of time and illustrate the long-term trend in loss of species diversity. The numbers do not precisely show numbers of species lost but reflect difficulties in finding specimens as species decline and, in some cases, difficulty with basin access. For example, prior to 1915, the upper parts of the river basins were inaccessible and remained unsurveyed.

Although some forms were lost, survey results from 1963 to 1971 indicate that the fauna survived TVA impoundment largely intact. Mussel declines became apparent, however, in the mid-1970's, and by that time many previously common mussel species had become rare, extirpated, or extinct.

Figure 31. Freshwater mussel species diversity in the Clinch and Powell Rivers, Tennessee and Virginia, 1899-1999.

The greatest declines in mussel abundance occurred during the record drought from 1983 to 1988 (fig. 32). Since that time, the Clinch River in Tennessee has shown remarkable recovery, both in mussel densities and species numbers. The Virginia parts of the Clinch and the Powell Rivers, however, have recovered to only a little more than half the densities recorded in 1979, mostly reflecting recovery of the three most abundant species. Most of the rare and more sensitive species continue to decline in the Powell River and in the Virginia part of the Clinch River.⁽²⁹⁾

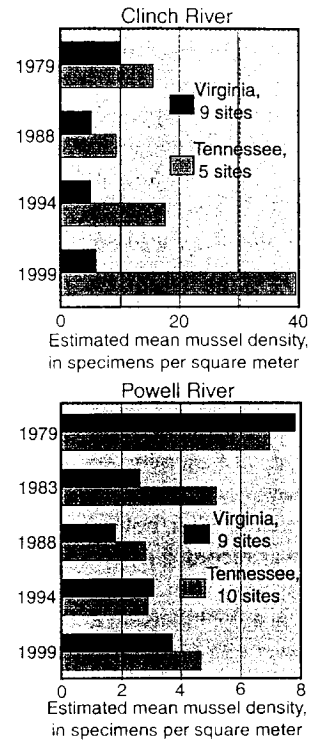

Figure 32. Estimated mean densities of freshwater mussel specimens in the Clinch and Powell Rivers, Tennessee and Virginia, 1979-99.⁽²⁹⁾

Upper Tennessee River Biological Communities in a National Context

Three biological indicators, which typically respond to changes in stream degradation, illustrate the relation of Upper Tennessee River Basin sites to the overall range of NAWQA sites nationwide. For all indicators, higher values suggest a more degraded stream site.

Algal status focuses on the changes in the percentage of certain algae in response to increasing siltation. Within the Upper Tennessee River Basin, the only sites in the highest 25 percent nationally are Big Limestone Creek, which drains predominantly agricultural land use, and the Pigeon River, which has been heavily affected by industrial wastes.

Invertebrate status is the average of 11 invertebrate (primarily insects, worms, crayfish, clams) metrics that summarize changes in richness, tolerance, trophic conditions, and dominance commonly associated with water-quality degradation. Among the Upper Tennessee River Basin sites, the two that rank highest on the index are the Pigeon and French Broad Rivers. The Pigeon River is recovering from decades of receiving industrial wastes. The French Broad River is principally affected by urban development in the Asheville, North Carolina, area and agriculture in the lower part of the basin.

Fish status is the sum of scores of four fish metrics (percentage of tolerant, omnivorous, non-native individuals, and percentage of individuals with external anomalies) that tend to increase in association with water-quality degradation. The Holston River at Surgoinsville, Tennessee, which ranked highest on this index, is characterized by relatively high concentrations of mercury and copper in bed sediments, probably derived from upstream industrial activities.

EXPLANATION

- 25th percentile of sites in 16 NAWQA Study Units, 1994 - 98.
- 75th percentile of sites in 16 NAWQA Study Units, 1994 - 98.
- ◆ Biological status assessed at a site

Toxic Spills and Releases

The NAWQA Program, like most water-quality assessments, is designed to gather information on general water-quality conditions and analyze problems that tend to be chronic as opposed to episodic. Even though the NAWQA Program provides for sampling during storm events in order to achieve a more complete "picture" of water-quality conditions, detection of every instance of water contamination is clearly beyond the program's defined scope. In general, this is true of every other ongoing State or Federal water-quality assessment.

In late May 1996, however, a toxic release was recorded at the Big Limestone Creek site (fig. 33, number 8) that resulted in a fishkill over several miles in the lower end of the stream. The apparent cause was excessive ammonia concentrations that were traced to agricultural activities upstream. If not for the sampling activity being conducted at the site, the kill most likely would have gone unreported. Given the relatively remote nature of many biologically diverse stream reaches in the Upper Tennessee River Basin, it is possible that many similar episodes go unreported as well.

The number of relatively rare and threatened aquatic species in the Upper Tennessee River Basin make accidental spills and releases a particular concern in parts of the basin. Habitat modifications resulting from human activities, such as impoundments and pollution, have restricted the greatest numbers and variety of aquatic fauna to only a few tributaries.⁽³²⁾ In addition, impoundments have effectively separated once contiguous biological communities into smaller, more vulnerable sub-units.

The upper Clinch and Powell watersheds are home to the most diverse fish and mussel fauna in the Upper Tennessee River Basin. These two subbasins are effectively separated from biological interaction, however, by Norris Lake and are very vulnerable to coal-

Number and Date of incident	Site name	Spill source	Contaminant

Figure 33. Contaminant releases have resulted in fish and mussel kills in the Upper Tennessee River Basin, 1995-99. (30, 31)

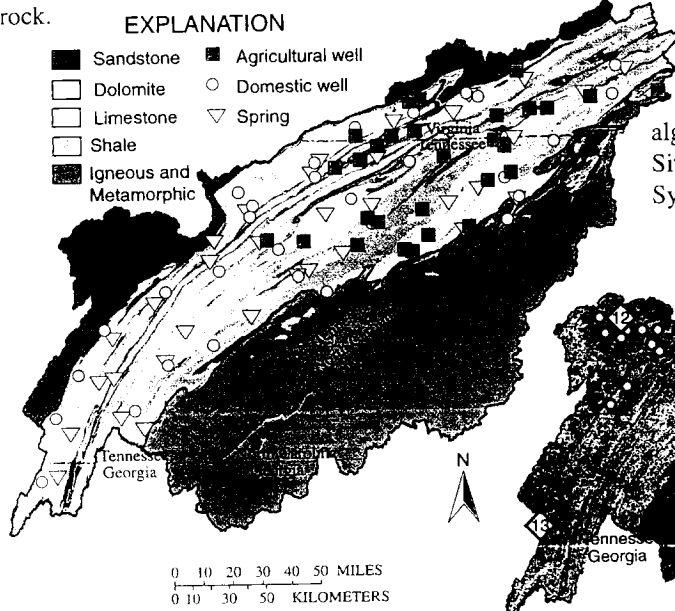

fine spills from numerous active and abandoned mining sites in their headwaters. At least five coal-fine spills occurred during the 1995-99 study period (G. Heffinger, U.S. Fish and Wildlife Service, written commun., April 17, 2000).

Mussel species generally are of the greatest concern because of their lack of mobility and the longer times typi-

cally required for populations to recover. For example, data collected in 1971 following a very large 1967 fly-ash spill in the Clinch River found that fish and aquatic insects were reestablished relatively quickly. Mussels, however, have yet to recolonize the 9- to 10-mile reach directly downstream from the spill site.⁽³³⁾

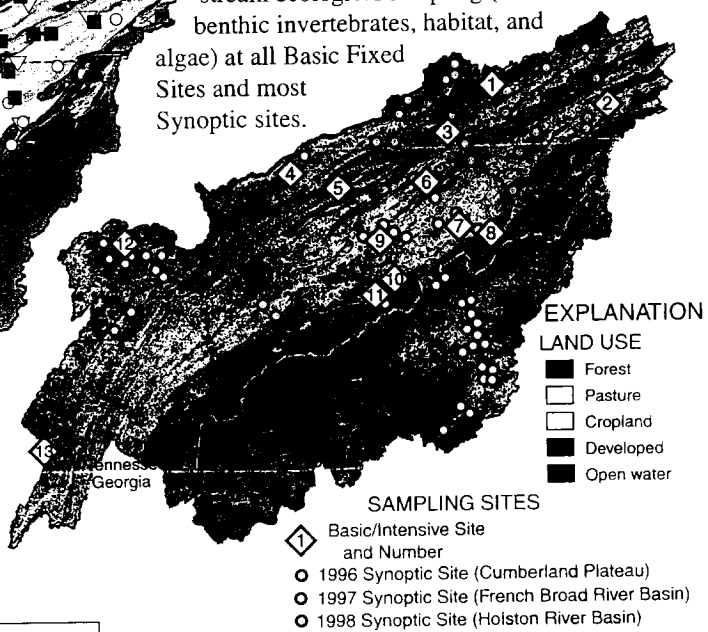

STUDY UNIT DESIGN

Study designs for both ground-water and surface-water components focused principally on the Valley and Ridge province. The Valley and Ridge is home to the majority of the Study Unit population and is the most highly developed in terms of agriculture and urban land uses. Ground-water studies focused on the carbonate-based dolomites and limestones of the Valley and Ridge. These geologic units form the most prolific aquifers in the Upper Tennessee River Basin and also are the most susceptible to contamination because of their associated karst and solution features. Ground-water resources are very limited in the Blue Ridge and Cumberland Plateau provinces because of the relatively impermeable nature of the bedrock and the low water-storage capacity of the thin soils that overlie the bedrock.

Surface-water studies focused on the unregulated portions of the Upper Tennessee River Basin principally in the Valley and Ridge province, which contains the most intense agricultural activity in the basin. Thirteen basic fixed stream-sampling sites were operated during the study to monitor water-quality conditions with time in various parts of the basin. Data-collection sites were selected to cover the major subbasins of the Upper Tennessee River and to encompass the major land uses. An additional 61 sites were sampled during the study as part of three synoptic networks designed to better describe areal water-quality variations of the subbasins. In keeping with the NAWQA multiple lines of evidence approach to describe water-quality conditions,⁽³⁴⁾ data-collection activities included water-column chemistry

at all sites, bed-sediment and Asiatic clam tissue samples at Basic Fixed Sites, and stream ecological sampling (fish communities, benthic invertebrates, habitat, and algae) at all Basic Fixed Sites and most Synoptic sites.

SUMMARY OF DATA COLLECTION IN THE UPPER TENNESSEE RIVER BASIN, 1994–98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Bottom-sediment survey	Sediment in depositional zones was sampled for pesticides, other synthetic organic compounds, and trace elements to determine the presence of potentially toxic compounds. Water-quality samples also were taken at each site, including major ions, nutrients, organic carbon, pesticides, bacteria, and suspended sediment.	Selected rivers and streams.	15	Once (1995, 1996, 1998)
Water-chemistry sites	Water-chemistry data, including major ions, nutrients, organic carbon, pesticides, bacteria, and suspended sediment, were used to describe concentrations and loads.	Sampling occurred near selected continuous streamflow sites.	13	Variable (1996–98)
Storm sampling program	Water-chemistry data, including major ions, nutrients, organic carbon, pesticides, bacteria, and suspended sediment, were used to describe concentrations and loads.	Samples were taken at water-chemistry sites during high-flow conditions.	variable	Variable (1996–98)
Nutrient/pesticide synoptic studies	Water-chemistry data, including major ions, nutrients, organic carbon, pesticides, bacteria, and suspended sediment, were used to describe concentrations of selected constituents.	Surface-water sampling sites in the Cumberland Plateau, French Broad River Basin, and the Valley and Ridge were selected to describe conditions across the Study Unit.	64	Variable (1996, 1997, 1998)
Intensive pesticide sampling	Pesticides, major ions, organic carbon, suspended sediment, bacteria, and nutrients were analyzed to determine seasonal variations in concentrations and loads.	Water-chemistry sites located in intensive agricultural basins or mixed land-use basins.	3	Biweekly (March–Nov., 1996)
Stream Ecology				
Contaminants in Asiatic clams	Asiatic clams were sampled for pesticides, other synthetic organic compounds, and trace elements to determine the presence of potentially toxic compounds.	Selected rivers and streams.	15	Once (1995, 1996, 1998)
Aquatic biology	Biological communities and stream habitat were assessed and fish, macroinvertebrates, and algae were quantitatively sampled.	Biological communities and habitat at basic fixed water-chemistry sites, and biological communities at synoptic sites.	13 fixed sites, 63 synoptic sites	Once (1995–98)
Spring synoptic study	Macroinvertebrates were qualitatively sampled.	Spring sites.	35	Once (Aug.–Nov., 1997)
Ground-Water Chemistry				
Agricultural land-use survey	Water-chemistry data, including major ions, nutrients, organic carbon, pesticides, and radionuclides, were analyzed to determine the effects of timely tobacco production on shallow ground-water quality.	Shallow 2-inch monitoring wells were installed adjacent to tobacco fields in the Valley and Ridge in northeastern Tennessee and southwestern Virginia.	30	Once (June and July, 1997)
Shallow spring survey	Water-chemistry data, including major ions, nutrients, organic carbon, pesticides, bacteria, and radionuclides, were analyzed to determine the quality of ground water.	Randomly selected springs in the Valley and Ridge.	35 springs	Once (Aug.–Nov., 1997)
Shallow well survey	Water-chemistry data, including major ions, nutrients, organic carbon, pesticides, bacteria, and radionuclides, were analyzed to determine the quality of ground water.	Randomly selected wells in the Valley and Ridge.	20 wells	Once (Aug.–Nov., 1997)

Aquatic-life criteria—Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms.

Aquifer—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.

Basic Fixed Sites—Sites on streams at which streamflow is measured and samples are collected for temperature, salinity, suspended sediment, major ions and metals, nutrients, and organic carbon to assess the broad-scale spatial and temporal character and transport of inorganic constituents of stream water in relation to hydrologic conditions and environmental settings.

Bed sediment—The material that temporarily is stationary in the bottom of a stream or other watercourse.

Bed sediment and tissue studies—Assessment of concentrations and distributions of trace elements and hydrophobic organic contaminants in streambed sediment and tissues of aquatic organisms to identify potential sources and to assess spatial distribution.

Benthic invertebrates—Insects, mollusks, crustaceans, worms, and other organisms without a backbone that live in, on, or near the bottom of lakes, streams, or oceans.

Constituent—A chemical or biological substance in water, sediment, or biota that can be measured by an analytical method.

Contamination—Degradation of water quality compared to original or natural conditions and due to human activity.

Cubic foot per second (ft³/s, or cfs)—Rate of water discharge representing a volume of 1 cubic foot passing a given point during 1 second, equivalent to approximately 7.48 gallons per second or 448.8 gallons per minute or 0.02832 cubic meter per second.

Degradation products—Compounds resulting from transformation of an organic substance through chemical, photochemical, and/or biochemical reactions.

Detection limit—The minimum concentration of a substance that can be identified, measured, and reported with 99 percent confidence that the analyte concentration is greater than zero; determined from analysis of a sample in a given matrix containing the analyte.

Discharge—Rate of fluid flow passing a given point at a given moment in time, expressed as volume per unit of time.

Drainage area—The drainage area of a stream at a specified location is that area, measured in a horizontal plane, which is enclosed by a drainage divide.

Drinking-water standard or guideline—A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.

Indicator sites—Stream sampling sites located at outlets of drainage basins with relatively homogeneous land use and physiographic conditions; most indicator-site basins have drainage areas ranging from 20 to 200 square miles.

Integrator or Mixed-use site—Stream sampling site located at an outlet of a drainage basin that contains multiple environmental settings. Most integrator sites are on major streams with relatively large drainage areas.

Intensive Fixed Sites—Basic Fixed Sites with increased sampling frequency during selected seasonal periods and analysis of dissolved pesticides for 1 year. Most NAWQA Study Units have one to two integrator Intensive Fixed Sites and one to four indicator Intensive Fixed Sites.

Karst—A type of topography that results from dissolution and collapse of carbonate rocks such as limestone and dolomite, and characterized by closed depressions or sinkholes, caves, and underground drainage.

Load—General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.

Main stem—The principal course of a river or a stream.

Metamorphic rock—Rock that has formed in the solid state in response to pronounced changes of temperature, pressure, and chemical environment.

Micrograms per liter (µg/L)—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most stream water and ground water. One thousand micrograms per liter equals 1 mg/L.

Milligrams per liter (mg/L)—A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most stream water and ground water.

Nonpoint source—A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs from plants and trees are types of nonpoint source pollution.

Point source—A source at a discrete location such as a discharge pipe, drainage ditch, tunnel, well, concentrated livestock operation, or floating craft.

Synoptic sites—Sites sampled during a short-term investigation of specific water-quality conditions during selected seasonal or hydrologic conditions to provide improved spatial resolution for critical water-quality conditions.

Tributary—A river or stream flowing into a larger river, stream, or lake.

Volatile organic compounds (VOCs)—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

Water-quality standards—State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.

Water table—The point below the land surface where ground water is first encountered and below which the earth is saturated. Depth to the water table varies widely across the country.

Yield—The mass of material or constituent transported by a river in a specified period of time divided by the drainage area of the river basin.

APPENDIX—WATER-QUALITY DATA FROM THE UPPER TENNESSEE RIVER BASIN IN A NATIONAL CONTEXT

For a complete view of Upper Tennessee River Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Upper Tennessee River Basin. Selected results for this Basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Upper Tennessee River Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, tebuthiuron concentrations in Upper Tennessee River Basin major aquifers were similar to the national distribution, but the detection frequency was much higher (31 percent compared to 3 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Upper Tennessee River Basin, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- ** No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acetochlor (Harness Plus, Surpass) **
- Alachlor (Lasso, Bronco, Lariat, Bullet) **
- Bromacil (Hyvar X, Urox B, Bromax)
- Cyanazine (Bladex, Fortrol)
- DCPA (Dacthal, chlorthal-dimethyl) **
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) **
- Diuron (Crisuron, Karmex, Diurex) **
- Metribuzin (Lexone, Sencor)
- Molinate (Ordram) ***
- Napropamide (Devrinol) **
- Pendimethalin (Pre-M, Prowl, Stomp) **
- Prometon (Pramitol, Princep) **
- 2,4,5-T **
- 2,4,5-TP (Silvex, Fenoprop) **
- Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) **
- Bentazon (Basagran, Bentazone) **
- Bromoxynil (Buctril, Brominal) *
- Butylate (Sutan +, Genate Plus, Butilate) **
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) ***
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) ***
- Dacthal mono-acid (Dacthal breakdown product) ***

Dicamba (Banvel, Dianat, Scotts Proturf)
 2,6-Diethylaniline (Alachlor breakdown product) * **
 Dinoseb (Dinosebe)
 EPTC (Eptam, Farmarox, Alirox) * **
 Ethalfuralin (Sonalan, Curbit) * **
 Fenuron (Fenuion, Fenidim) * **
 Fluometuron (Flo-Met, Cotoran) **
 Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Norflurazon (E vital, Predict, Solicam, Zorial) * **
 Oryzalin (Surflan, Dirimal) * **
 Pebulate (Tillam, PEBC) * **
 Picloram (Grazon, Tordon)
 Pronamide (Kerb, Propyzamid) **
 Propachlor (Ramrod, Satecid) **
 Propanil (Stam, Stampede, Wham) * **
 Propham (Tuberite) **
 Terbacil (Sinbar) **
 Thiobencarb (Bolero, Saturn, Benthiocarb) * **
 Triallate (Far-Go, Avadex BW, Tri-allate) *
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **

Pesticides in water—Insecticides

Other insecticides detected

Carbofuran (Furadan, Curater, Yaltox)
 Chlorpyrifos (Brodan, Dursban, Lorsban)
 Diazinon (Basudin, Diazatol, Neocidol, Knox Out)
 Malathion (Malathion)

Insecticides not detected

Aldicarb (Temik, Ambush, Pounce)
 Aldicarb sulfone (Standak, aldoxycarb)
 Aldicarb sulfoxide (Aldicarb breakdown product)
 Azinphos-methyl (Guthion, Gusathion M) *
 Dieldrin (Panoram D-31, Octalox, Compound 497)
 Disulfoton (Disyston, Di-Syston) **
 Ethoprop (Mocap, Ethoprophos) * **
 Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
 Methiocarb (Slug-Geta, Grandslam, Mesuroil) * **
 Methomyl (Lanox, Lannate, Acinate) **
 Methyl parathion (Pennacp-M, Folidol-M) **
 Oxamyl (Vydate L, Pratt) **
 Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
 cis-Permethrin (Ambush, Astro, Pounce) * **
 Phorate (Thimet, Granutox, Geomet, Rampart) * **
 Propargite (Comite, Omite, Ornamate) * **
 Propoxur (Baygon, Blattanex, Unden, Proprotox) * **
 Terbufos (Contraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

tert-Amylmeylether (tert-amyl methyl ether (TAME)) *
 Benzene
 Bromodichloromethane (Dichlorobromomethane)
 2-Butanone (Methyl ethyl ketone (MEK)) *
 n-Butylbenzene (1-Phenylbutane) *
 Carbon disulfide *
 Chlorobenzene (Monochlorobenzene)
 Chloroethane (Ethyl chloride) *
 1,3-Dichlorobenzene (m-Dichlorobenzene)
 1,4-Dichlorobenzene (p-Dichlorobenzene)
 Dichlorodifluoromethane (CFC 12, Freon 12)
 1,1-Dichloroethane (Ethylidene dichloride) *
 1,1-Dichloroethene (Vinylidene chloride)
 cis-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)
 Diethyl ether (Ethyl ether) *
 Diisopropyl ether (Diisopropylether (DIPE)) *
 1,2-Dimethylbenzene (o-Xylene)
 1,3 & 1,4-Dimethylbenzene (m-&p-Xylene)
 Ethenylbenzene (Styrene)
 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
 Ethylbenzene (Phenylethane)
 Iodomethane (Methyl iodide) *
 Isopropylbenzene (Cumene) *
 p-Isopropyltoluene (p-Cymene) *
 Methylbenzene (Toluene)
 2-Propanone (Acetone) *
 n-Propylbenzene (Isocumene) *
 Tetrachloroethene (Perchloroethene)
 1,2,3,4-Tetramethylbenzene (Prehnitene) *
 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
 1,1,1-Trichloroethane (Methylchloroform)
 Trichloroethene (TCE)
 1,2,3-Trimethylbenzene (Hemimellitene) *
 1,2,4-Trimethylbenzene (Pseudocumene) *
 1,3,5-Trimethylbenzene (Mesitylene) *

VOCs not detected

Bromobenzene (Phenyl bromide) *
 Bromochloromethane (Methylene chlorobromide)
 Bromoethene (Vinyl bromide) *
 Bromomethane (Methyl bromide)
 sec-Butylbenzene *
 tert-Butylbenzene *
 3-Chloro-1-propene (3-Chloropropene) *
 1-Chloro-2-methylbenzene (o-Chlorotoluene)
 1-Chloro-4-methylbenzene (p-Chlorotoluene)
 Chlorodibromomethane (Dibromochloromethane)
 Chloroethene (Vinyl chloride)
 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
 1,2-Dibromoethane (Ethylene dibromide, EDB)

- Dibromomethane (Methylene dibromide) *
- trans*-1,4-Dichloro-2-butene ((Z)-1,4-Dichloro-2-butene) *
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
- 1,2-Dichloroethane (Ethylene dichloride)
- trans*-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
- Dichloromethane (Methylene chloride)
- 1,2-Dichloropropane (Propylene dichloride)
- 2,2-Dichloropropane *
- 1,3-Dichloropropane (Trimethylene dichloride) *
- trans*-1,3-Dichloropropene ((E)-1,3-Dichloropropene)
- cis*-1,3-Dichloropropene ((Z)-1,3-Dichloropropene)
- 1,1-Dichloropropene *
- 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
- Ethyl methacrylate *
- Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
- Hexachlorobutadiene
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK)) *
- Methyl acrylonitrile *
- Methyl-2-methacrylate (Methyl methacrylate) *
- 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
- Methyl-2-propenoate (Methyl acrylate) *
- Naphthalene
- 2-Propenenitrile (Acrylonitrile)
- 1,1,2,2-Tetrachloroethane *
- 1,1,1,2-Tetrachloroethane
- Tetrachloromethane (Carbon tetrachloride)
- 1,2,3,5-Tetramethylbenzene (Isodurene) *
- Tribromomethane (Bromoform)
- 1,2,4-Trichlorobenzene
- 1,2,3-Trichlorobenzene *
- 1,1,2-Trichloroethane (Vinyl trichloride)
- Trichlorofluoromethane (CFC 11, Freon 11)
- 1,2,3-Trichloropropane (Allyl trichloride)

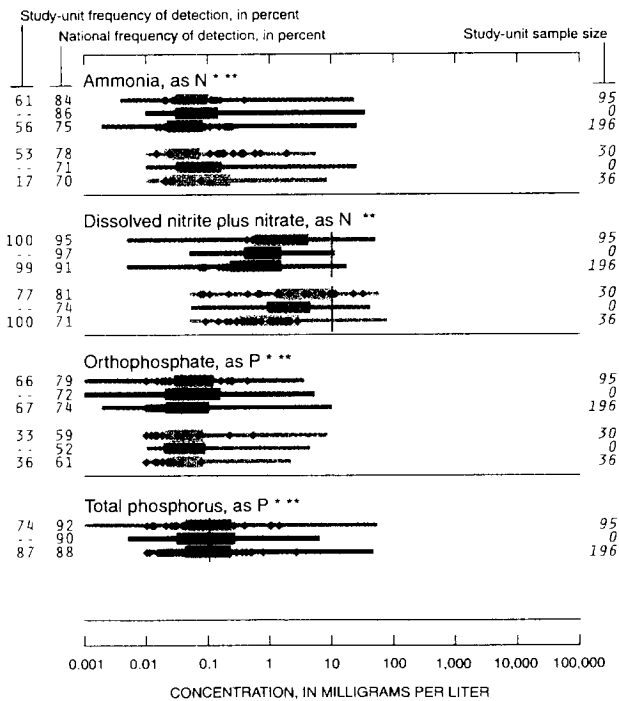

Dissolved solids in water

Trace elements in ground water

Nutrients in water

Other nutrients detected

Dissolved ammonia plus organic nitrogen as N ***

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Upper Tennessee River Basin, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- ** No benchmark for protection of aquatic life

Organochlorines in fish tissue (whole body) and bed sediment

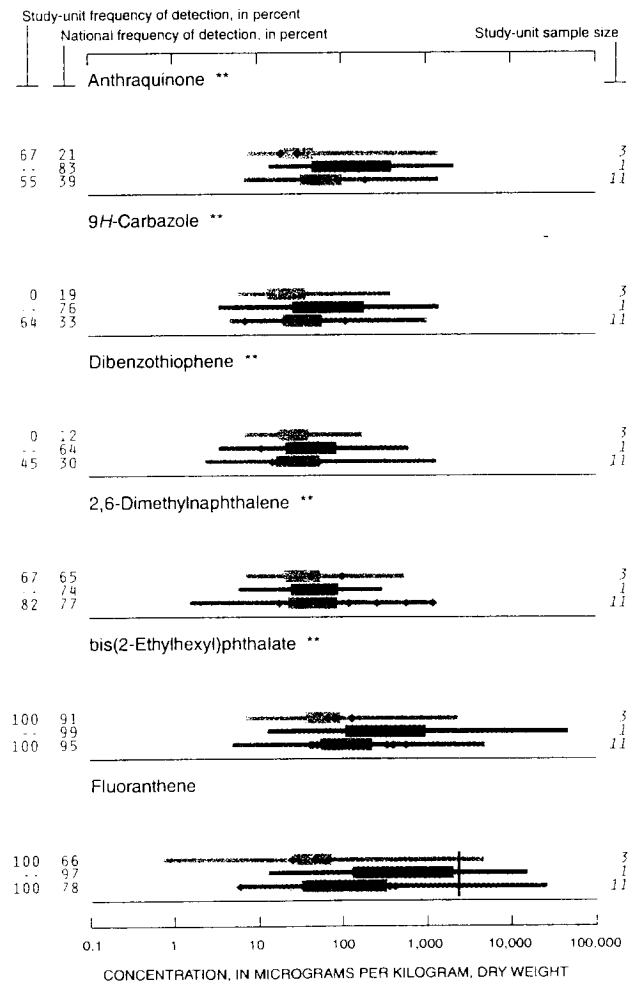

Other organochlorines detected

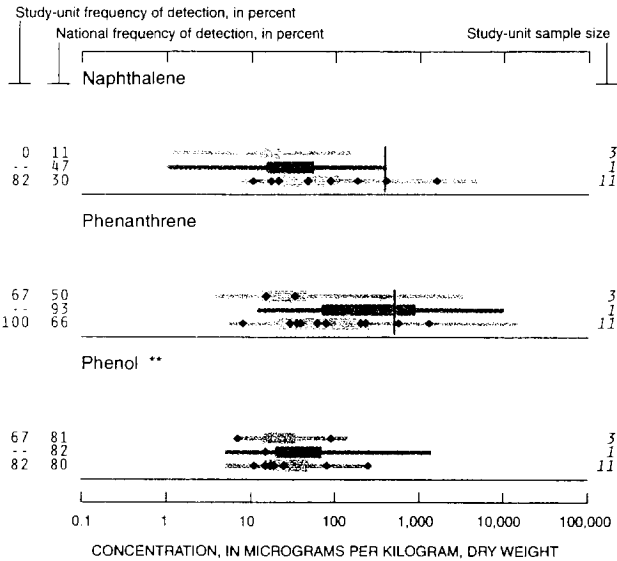

- o,p'*+*p,p'*-DDD (sum of *o,p'*-DDD and *p,p'*-DDD) *
- p,p'*-DDE * **
- o,p'*+*p,p'*-DDE (sum of *o,p'*-DDE and *p,p'*-DDE) *
- o,p'*+*p,p'*-DDT (sum of *o,p'*-DDT and *p,p'*-DDT) *

Organochlorines not detected

- Chloroneb (Chloronebe, Demosan) * **
- DCPA (Dacthal, chlorthal-dimethyl) * **
- Endosulfan I (alpha-Endosulfan, Thiodan) * **
- Endrin (Endrine)
- gamma-HCH (Lindane, gamma-BHC, Gammexane) *
- Heptachlor epoxide (Heptachlor breakdown product) *
- Heptachlor+heptachlor epoxide (sum of heptachlor and heptachlor epoxide) **
- Hexachlorobenzene (HCB) **
- Isodrin (Isodrine, Compound 711) * **
- p,p'*-Methoxychlor (Marlate, methoxychlore) * **
- o,p'*-Methoxychlor * **
- Mirex (Dechlorane) **
- Total PCB
- Pentachloroanisole (PCA) * **
- cis*-Permethrin (Ambush, Astro, Pounce) * **
- trans*-Permethrin (Ambush, Astro, Pounce) * **
- Toxaphene (Camphechlor, Hercules 3956) * **

Semivolatile organic compounds (SVOCs) in bed sediment

Other SVOCs detected

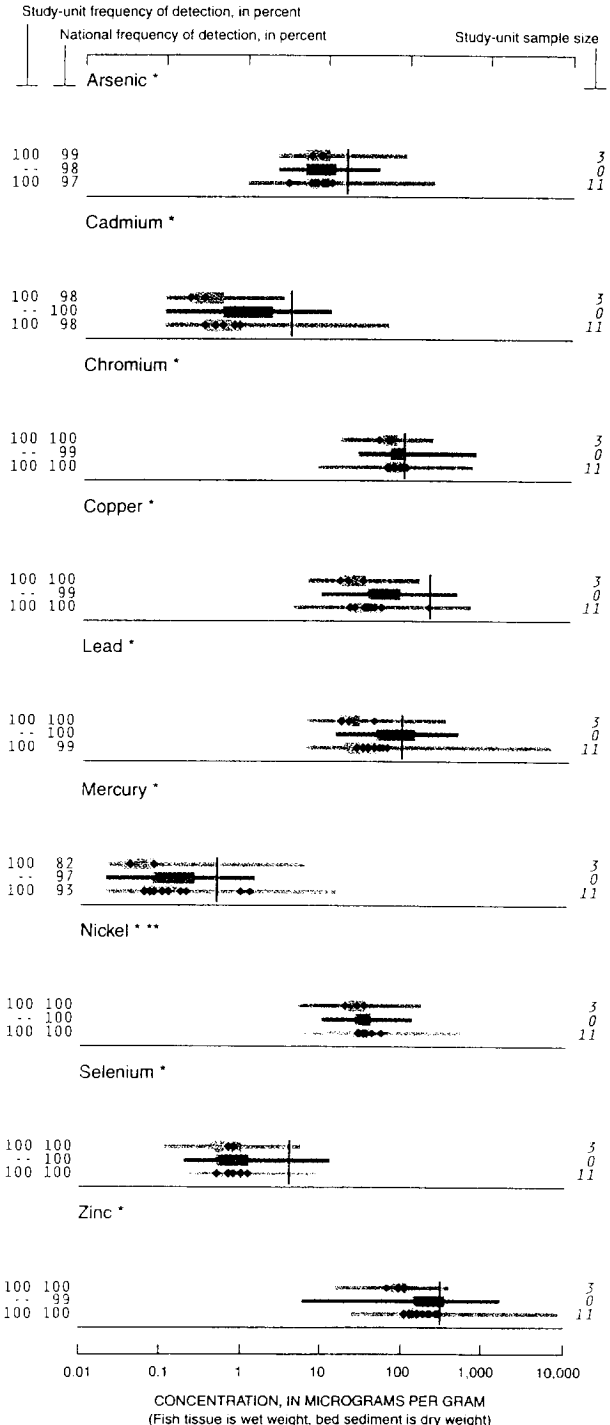

- Acenaphthene
- Acenaphthylene
- Acridine **
- C8-Alkylphenol **
- Anthracene
- Benz[a]anthracene
- Benzo[a]pyrene
- Benzo[b]fluoranthene **
- Benzo[ghi]perylene **
- Benzo[k]fluoranthene **
- 2,2-Biquinoline **
- Butylbenzylphthalate **
- Chrysene
- p-Cresol **
- Di-n-butylphthalate **
- Di-n-octylphthalate **
- Dibenz[a,h]anthracene
- Diethylphthalate **
- 1,2-Dimethylnaphthalene **
- 1,6-Dimethylnaphthalene **
- Dimethylphthalate **
- 2-Ethynaphthalene **
- 9H-Fluorene (Fluorene)
- Indeno[1,2,3-cd]pyrene **
- Isophorone **
- Isoquinoline **
- 1-Methyl-9H-fluorene **
- 2-Methylantracene **
- 4,5-Methylenephenanthrene **
- 1-Methylphenanthrene **
- 1-Methylpyrene **
- Phenanthridine **
- Pyrene
- Quinoline **
- 2,3,6-Trimethylnaphthalene **

SVOCs not detected

- Azobenzene **
- Benzo[c]cinnoline **
- 4-Bromophenyl-phenylether **
- 4-Chloro-3-methylphenol **
- bis(2-Chloroethoxy)methane **
- bis(2-Chloroethyl)ether **
- 2-Chloronaphthalene **
- 2-Chlorophenol **
- 4-Chlorophenyl-phenylether **
- 1,2-Dichlorobenzene (o-Dichlorobenzene) **
- 1,3-Dichlorobenzene (m-Dichlorobenzene) **
- 1,4-Dichlorobenzene (p-Dichlorobenzene) **
- 3,5-Dimethylphenol **
- 2,4-Dinitrotoluene **

- Nitrobenzene **
- N-Nitrosodi-n-propylamine **
- N-Nitrosodiphenylamine **
- Pentachloronitrobenzene **
- 1,2,4-Trichlorobenzene **

Trace elements in fish tissue (livers) and bed sediment

BIOLOGICAL INDICATORS

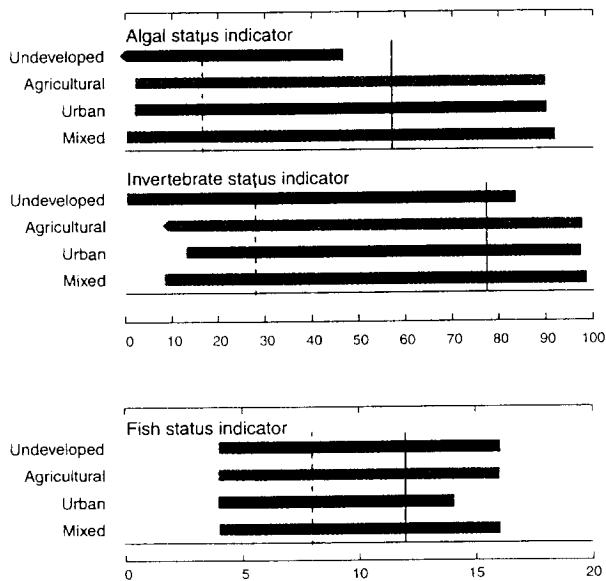

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation

Biological indicator value, Upper Tennessee River Basin, by land use, 1995-98

- ◆ Biological status assessed at a site

Errata Sheet

U.S. Geological Survey Circular 1206

Subsequent to publication of U.S. Geological Survey Circular 1206, "Water Quality in the Santee River Basin and Coastal Drainages, North and South Carolina, 1995-98," errors were found on pages 15 and 20.

On page 15, the unit of measurement used in figure 15 to express the median concentration of trace elements in bed sediment and tissue should have been micrograms per gram, rather than micrograms per kilogram. A correct figure 15 is below.

On page 20, the label on the left side of the top graph of figure 18 for the unit of measurement used to express the median concentration of atrazine erroneously included ammonia. The label for the unit of measurement used to express the median concentration of ammonia should have been on the right side of the top graph. A correct figure 18 is below.

We apologize for any inconvenience these errors may have caused.

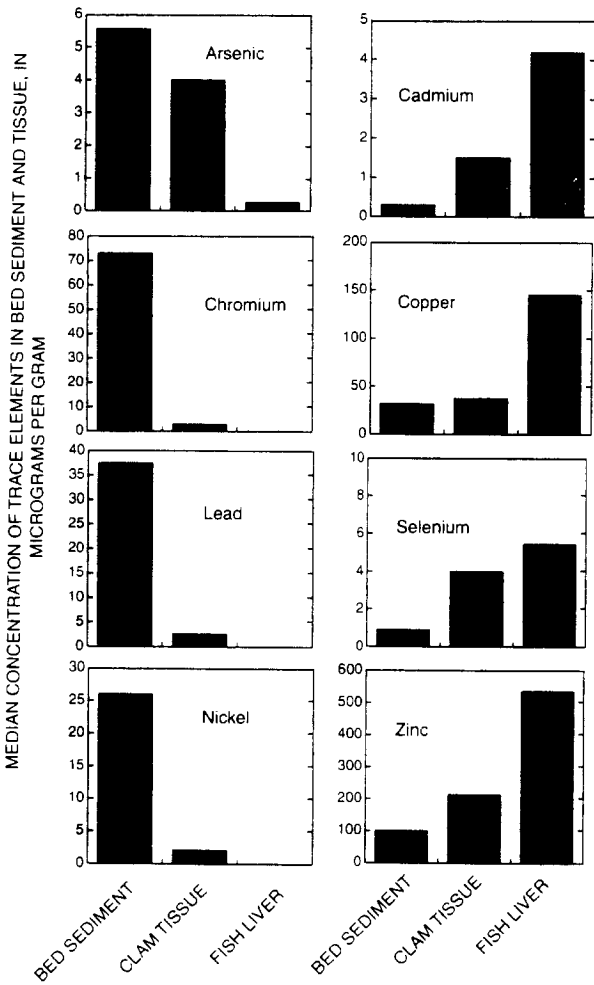

Figure 15. Cadmium, copper, selenium, and zinc were detected at higher concentrations in clam and fish tissue than in sediment, suggesting that they accumulate in the tissues. Conversely, arsenic, chromium, lead, and nickel were detected in lower concentrations in tissues than in sediment, indicating that these metals do not accumulate in the tissues.

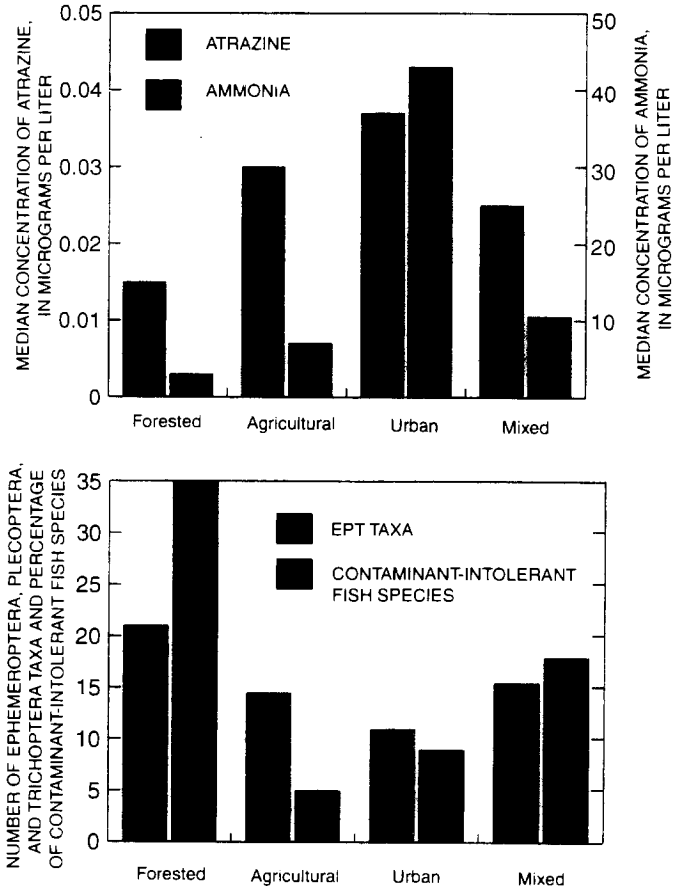

Figure 18. Compared to forested sites, urban and agricultural sites have higher concentrations of atrazine and ammonia as well as lower numbers of fish and invertebrates that are intolerant of contamination.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Santee River Basin and coastal drainages that emerged from an assessment conducted between 1995 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Santee River Basin and coastal drainages assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

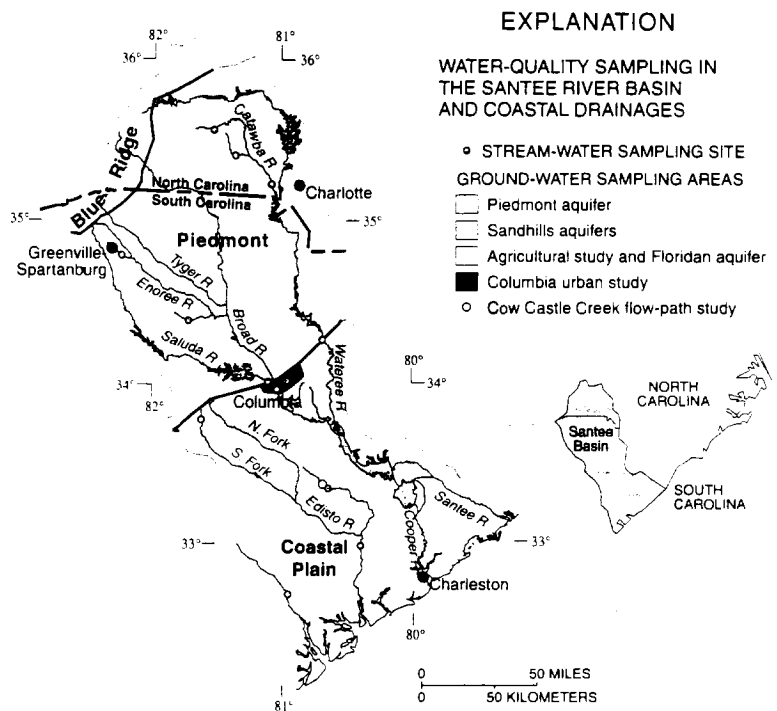

The Santee River Basin and coastal drainages is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Stream and River Highlights

Surface water sampled in the Santee River Basin and coastal drainages generally meets existing Federal and State guidelines for drinking-water quality and protection of aquatic life. However, urban and agricultural land uses have affected water quality, as indicated by elevated concentrations of bacteria, pesticides, and nutrients in basins dominated by these land uses.

- The herbicides atrazine, simazine, and tebuthiuron were detected in almost every stream in the Santee Basin, including those in forested areas, at levels below aquatic-life and drinking-water guidelines. Four insecticides—malathion, diazinon, chlorpyrifos, and parathion—exceeded aquatic-life guidelines. No pesticides exceeded drinking-water standards, though 7 of the 30 compounds detected do not have drinking-water standards and 13 do not have aquatic guidelines. Pesticide concentrations had seasonal patterns,

Percentage of samples with concentrations equal to or greater than a health-related national guideline for drinking water, aquatic life, or contact recreation; or above a national goal for preventing excess algal growth

Percentage of samples with concentrations less than a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or below a national goal for preventing excess algal growth

Percentage of samples with no detection

Not assessed ~ Insufficient data

¹ Insecticides, herbicides, and pesticide metabolites, sampled in water.
² Total phosphorus and nitrate (as nitrogen), sampled in water.
³ Arsenic, mercury, and metals, sampled in sediment.
⁴ Organochlorine compounds including DDT and PCB's, sampled in sediment.
⁵ Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water.
⁶ Fecal coliform bacteria, sampled in water.
⁷ Miscellaneous industrial chemicals and combustion by-products, sampled in sediment.

The Santee River Basin and coastal drainages (the "Santee Basin") is an approximately 24,000-square-mile area in North and South Carolina that encompasses the Blue Ridge Mountains, the Piedmont, and the Coastal Plain (Fenneman, 1946). Most of the 3.5 million people in the Santee Basin live in urban areas. Eighty-six percent of the water used in homes and for industry is treated surface water withdrawn from rivers or reservoirs. Ground water is the main water source for rural households.

with the highest concentrations measured in the spring following application.

- Nitrate concentrations did not exceed drinking-water standards in any streams sampled. Average total phosphorus concentrations in four streams were above the U.S. Environmental Protection Agency (USEPA) recommended goal to prevent nuisance aquatic growth. The South Fork Catawba River had an average total phosphorus concentration that was four times higher than the USEPA goal and is a significant source of phosphorus to downstream lakes. Wastewater discharge and agricultural runoff are major sources of nitrogen and phosphorus.
- Trace metals were detected frequently in bed sediment and tissue, mostly at concentrations within aquatic-life guidelines. Arsenic, chromium, and lead exceeded guidelines in a few samples. Although concentrations were not high in sediment samples, data suggest that mercury is accumulating in fish and clams in concentrations that are harmful to humans or animals that eat them. Sampling by State agencies has

resulted in fish-consumption advisories for mercury in 49 rivers and reservoirs in South Carolina.

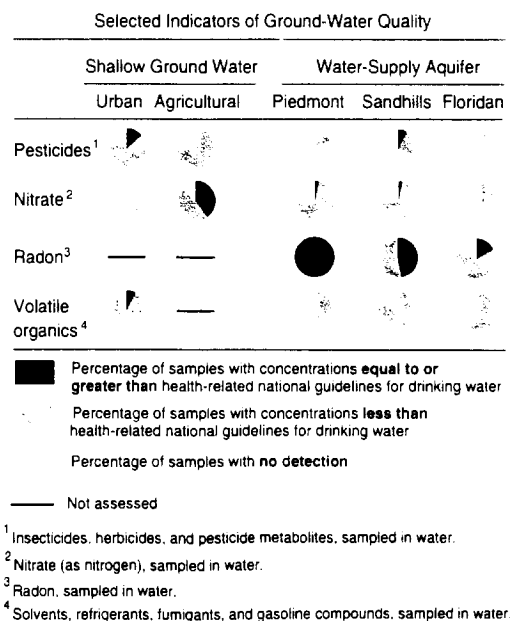

- Organochlorine pesticides were detected frequently in bed sediment and tissue. Most of these compounds have been discontinued for use for many years but continue to be detected because they are persistent in the environment. A derivative of DDT was detected at concentrations exceeding aquatic-life standards in sediment at three agricultural sites.
- Volatile organic compounds (VOCs) known to occur in the aquifer adjacent to Gills Creek, an urban stream in Columbia, S.C., were frequently detected in the creek as well. Although no existing Federal or State drinking-water standards or aquatic guidelines were exceeded, this finding is consistent with the important influence of ground-water quality on stream-water quality.
- Bacteria levels frequently exceeded South Carolina standards for contact recreation in streams in forested, urban, and agricultural areas. Standards were exceeded more frequently in small streams than in large rivers.
- Biological communities in urban and agricultural streams had fewer species of fish and invertebrates that can tolerate contamination than forested and mixed land-use streams. This suggests that contaminants resulting from these land uses affect the natural communities that live in these areas, although factors such as habitat alteration can cause similar changes in biological communities.

Ground-Water Highlights

Ground water in the Santee Basin generally meets existing Federal and State standards for drinking water except with respect to nitrate, which failed to meet the drinking-water standard in almost one-half of the shallow monitoring wells sampled in agricultural areas, and radon, which did not meet proposed standards in about one-half the drinking-water wells sampled basinwide. Pesticides were detected frequently in urban, agricultural, and drinking-water supply wells, but only two samples exceeded drinking-water standards. Many wells contained low concentrations of numerous synthetic chemicals related to industry, household use, and motor vehicles, and a few of these chemicals were at levels above drinking-water standards.

- Pesticides were detected in 17 of 90 wells sampled in drinking-water supply aquifers. Of the 34 detected, only 2 pesticides exceeded drinking-water standards, but 11 of the detected pesticides do not have standards. Most wells in agricultural and urban areas contained at least one pesticide, but only two wells in urban areas had concentrations that exceeded drinking-water standards.

- Nitrate is the only nutrient that was detected in significant concentrations in ground water, and it exceeded drinking-water standards in almost one-half of the shallow monitoring wells in agricultural areas. Although this finding indicates significant contamination of shallow ground water, most drinking-water wells are located in deeper aquifers. Nitrate in the Piedmont and Sandhills aquifers was elevated above natural concentrations but exceeded standards in only two wells. The Floridan aquifer, which is protected for the most part by confining units in the study area, had relatively low concentrations of nitrate.
- Radon, a naturally occurring radioactive gas, was detected in almost all wells sampled in drinking-water aquifers. Over one-half of the wells had concentrations that exceeded proposed Federal drinking-water standards. Most of the wells with radon concentrations that exceeded the proposed standard are located in the Piedmont aquifer.
- VOCs were detected in 27 of 30 monitoring wells in an urban setting. Most compounds were detected at extremely low levels; however, the concentrations of trichloroethylene, a solvent, and methyl *tert*-butyl ether, a gasoline additive, were above a drinking-water standard and an advisory level, respectively, in one well each. Thirteen of the 35 compounds detected do not have drinking-water standards. VOCs in drinking-water supply aquifers were detected throughout the Santee Basin, but no concentrations exceeded drinking-water standards.

INTRODUCTION TO THE SANTEE RIVER BASIN AND COASTAL DRAINAGES

The Santee River Basin and coastal drainages includes about 24,000 square miles in North and South Carolina. The Santee River has the second largest drainage area in the Eastern United States, and its basin makes up 70 percent of the study area. The basins of the Cooper, Edisto, and numerous smaller rivers make up the remainder of the study area. Throughout this report, the study area, including these smaller river basins, will be collectively referred to as the "Santee Basin."

Physiography and Water Quality

The rugged mountains of the Blue Ridge physiographic province are sparsely populated. Land-use effects on water quality are minimal because the area is largely undeveloped. Consequently, the Blue Ridge has more pristine water quality and intact stream ecosystems than other parts of the study area.

The rolling hills and abundant water resources of the Piedmont have attracted industrial development and human population growth. Many of the areas experiencing urban growth are in the Piedmont, near the headwaters of rivers that supply drinking water and also receive treated waste water. Since flows in these headwater streams are smaller than they are farther along the stream courses, they have a limited capacity to assimilate large quantities of wastewater and nonpoint-source inputs from the urban areas.

The flat-lying topography and fertile soils of the Coastal Plain are ideal for agricultural use. Development for shipping, industry, and tourism is mostly limited to land within a few miles of the coast.

Most of the Coastal Plain is characterized by slow-moving, low-gradient streams that commonly are bordered by extensive swamps (Smock and Gilinsky, 1992). The combination of slow-moving water and large quantities of organic matter in the swamps results in a characteristically dark-colored water called "blackwater." Under natural conditions, blackwater streams have low pH and contain low concentrations of dissolved oxygen. These conditions can make the stream particularly susceptible to water-quality degradation by the contribution of oxygen-consuming chemicals in wastewater discharge or nonpoint contamination.

Land Use and Water Quality

The Santee Basin has a rapidly growing population of about 3.5 million people. Most of the people live in the urban areas of Charlotte, N.C., and Greenville-Spartanburg, Columbia, and Charleston, S.C. (fig. 1). The most common types of urban development are commercial and residential.

As urban areas develop, increased use of pesticides and fertilizers on lawns and landscaped areas can lead to increased concentrations of these chemicals in ground and surface waters. Commercial and residential use of solvents and fuel products can result in their introduction to ground and

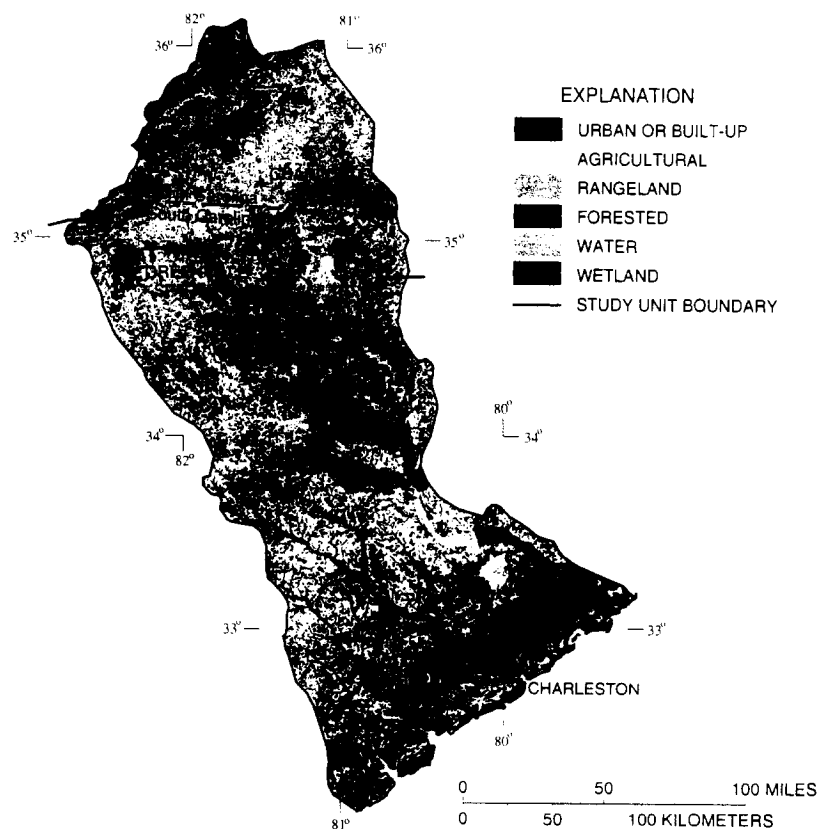

Figure 1. Land use in the Santee Basin includes about 60 percent forested, 30 percent agricultural, and 6 percent urban lands.

surface water through accidental spills or leaking storage tanks. Bacteria and nutrients can enter water through leaking sewer lines, malfunctioning septic tanks, and from runoff of pet and waterfowl wastes. Although thoroughly regulated, discharges from wastewater treatment plants increase as population grows, increasing the loading of nutrients to streams.

Agriculture is an important economic activity throughout the Santee Basin. Row crop agriculture is most common in the Coastal Plain, where corn, soybeans, and cotton are the most common crops (South Carolina Agricultural Statistics Service, 1999). Pasture for hay and for grazing cattle is typical of agricultural land in the Piedmont. These agricultural activities can result in elevated nutrient and pesticide levels in streams and ground water from runoff or infiltration of manure, fertilizer, or pesticides.

Most of the land in the Santee Basin is forested. Forests range from largely unaltered hardwoods in the Blue Ridge and mixed pine and hardwood stands in the Piedmont to intensively managed pine plantations and forested wetlands in the Piedmont and Coastal Plain. Trees are commercially harvested in all of these areas, producing various levels of soil disturbance, erosion, and increased sediment loads in the streams.

Climate Conditions and Water Quality

The major climatic factors affecting water quality are seasonal and areal distributions of precipitation. The amount of rainfall affects water quality because areas with higher rainfall generally have greater runoff and more infiltration to ground water. However,

increased flows also can help to dilute concentrations of chemicals in ground water and surface water. The distribution of rainfall in the Santee Basin is fairly uniform except for very high precipitation in the Blue Ridge (South Carolina Water Resources Commission, 1983; fig. 2).

Seasonal variability of rainfall also is important. Generally the highest concentrations of pesticides in streams occur when rainfall immediately follows pesticide applications. Rainfall is highest in spring and summer, typically when agricultural and residential lawn pesticides are applied.

Rainfall also is important because it contains nutrients and metals that contribute to concentrations of these compounds in surface water. Atmospheric deposition accounts for the majority of ammonia and nitrate nitrogen in streams (Maluk and others, 1998). A study also has suggested that mercury contamination in the Santee Basin results from atmospheric deposition (Krabbenhoft and others, 1999).

Figure 2. Precipitation affects water quality by producing runoff to streams and infiltration to aquifers.

Water Use

Most of the 7 billion gallons of water used each day in the Santee Basin is surface water (fig. 3). About 85 percent of this water is used in the production of electricity, and the remainder is used for public water supplies, commercial and industrial uses, irrigation of crops, and watering livestock.

Ground water accounts for only about 14 percent of total water use but is a very important resource. Private domestic wells are the only

Figure 3. Most water used in the Santee Basin is supplied by surface water. Ground water is important because it is the major source of domestic water supply in rural areas. Relative size of pie charts represents relative percentage water use.

viable sources of water in areas not served by public water supplies

Flow Regulation, Impoundments, and Surface-Water Quality

The regulation of flow in the Santee Basin has altered the historical seasonal flow patterns in the rivers. High peak flows and extreme low flows downstream from major reservoirs generally are less common than they were prior to construction of the reservoirs. The alteration of flow primarily affects the physical habitat of the rivers and also can affect stream temperature. Populations of aquatic organisms are altered due to changed conditions in the streams downstream from reservoirs. For example, cold water discharged from the bottom of Lake Murray makes it possible for trout to survive nearly 100 miles beyond their normal range.

Reservoirs are especially affected by stream chemistry because they trap sediment and the phosphorus that attaches to the sediment. This trapping process can cause lakes to become eutrophic, or

nutrient enriched, and cause algal blooms. Occasionally, fishkills result when the artificially large algal population dies and the dissolved oxygen, which is necessary for fish survival, is consumed during the decaying process. Of 11 major lakes in the study area, 9 contained areas with "excessive nutrients, extremely high productivity" and were "susceptible to nuisance macrophyte growth and algal blooms" (Stecker and Crocker, 1991).

Aquifer Characteristics and Ground-Water Quality

Shallow ground water (generally less than 50 feet below land surface) is vulnerable to contamination in much of the Santee Basin. Fertilizers, pesticides, and spills or leaks of chemicals at or near the land surface can move rapidly to the water table. Areas with sandy soils are particularly susceptible to contamination because these coarse-grained soils allow rapid transport and provide little opportunity for filtration or degradation of contaminants.

Sandy soils typically are present in parts of the Coastal Plain and to a lesser degree in the Piedmont.

Deep aquifers also can be susceptible to contamination, depending on their degree of connection to the surface. The Piedmont, Sandhills, and Floridan aquifers supply most of the ground water in the Santee Basin (fig. 4). Ground water in the Piedmont aquifer occurs in fractures or cracks in the hard crystalline bedrock. In most areas, the bedrock is overlain by clay soils of variable thickness. Sandhills aquifers are unconfined; that is, they have no clay layer above them to inhibit the downward movement of contaminants to the aquifer. The Floridan aquifer is confined toward the coast but is unconfined farther inland. Of the three aquifers, the Sandhills aquifer is the most susceptible to contamination because of its sandy soils and lack of confinement. The Floridan aquifer, near the coast, is the least susceptible because it is confined.

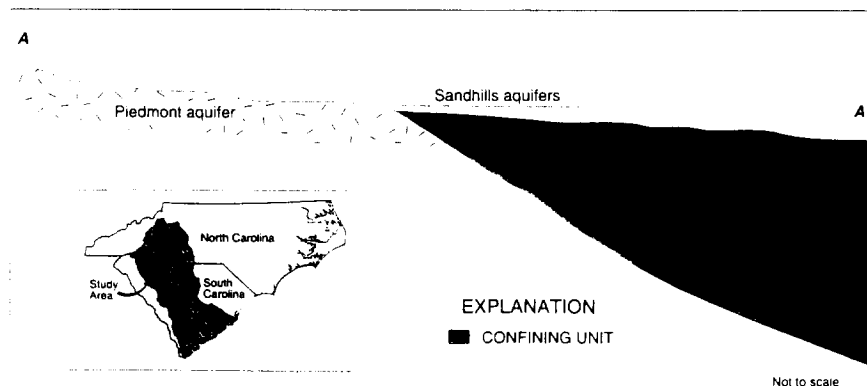

Figure 4. Aquifers sampled in the Santee Basin include the surficial, Piedmont, Sandhills, and Floridan aquifers (modified from Aucott and others, 1987). The Black Creek, Middendorf, and Cape Fear aquifers are not used much in the study area because of the cost of drilling deep wells and poor water quality.

MAJOR FINDINGS

Pesticides Commonly Were Detected in Santee Basin Streams

Thirty pesticides, including 22 herbicides and 8 insecticides, were detected in streams in the Santee Basin (Maluk and Kelley, 1998). Of the 161 surface-water samples collected, 141 contained at least one pesticide. At least one pesticide was detected at all of the sites, including forested sites that have little influence from humans.

Although detections were frequent, concentrations tended to be low, with no herbicides and only four insecticides and one metabolite exceeding aquatic-life criteria. None of the pesticide concentrations exceeded drinking-water standards. Thirteen of the 30 pesticides detected do not have aquatic criteria and 7 do not have drinking-water standards (U.S. Environmental Protection Agency, 1996).

Herbicides were the most commonly detected pesticides in streams. Atrazine, an herbicide used on corn as well as turfgrasses and golf courses, was detected at the most sites, occurring at 11 of the 13 sampling sites. Other frequently detected herbicides were simazine, metolachlor, and prometon. Tebuthiuron, an herbicide that generally is used to control weeds on highway and railroad rights-of-way, also was detected frequently.

Insecticides were detected much less frequently than herbicides, accounting for less than one-third of the pesticides detected. Most insecticides detected are used on agricultural and ornamental crops, lawns, livestock, and in homes and gardens. Those most commonly detected included chlorpyrifos, diazinon, malathion, and carbaryl.

Insecticides were detected most frequently in urban streams, such as Gills Creek in Columbia, S.C.

Urban Streams Contain More Pesticides than Other Streams

Pesticides were detected more frequently in urban streams than in agricultural streams (fig. 5). The most commonly detected herbicides—simazine, prometon, atrazine, and tebuthiuron—were detected nearly twice as frequently in water samples collected at urban sites than at agricultural sites. Conversely, some herbicides such as metolachlor and alachlor were detected almost exclusively at agricultural sites.

Insecticides were detected about four times more frequently at urban stream sites than at agricultural stream sites, and aquatic-life criteria were exceeded in nine samples collected at urban sites and in three samples collected at agricultural sites. The insecticide diazinon was detected only in urban streams, whereas chlorpyrifos was detected frequently in both urban and agricultural streams. This agrees with national findings in which insecticides were detected more frequently in urban than in

Figure 5. Pesticides, particularly insecticides, were detected more frequently in urban streams than in agricultural streams.

agricultural streams (U.S. Geological Survey, 1999).

These findings indicate that while agricultural activities contribute pesticides to surface water, concentrations are rarely high enough to affect aquatic life. The consequences of urban and suburban use of pesticides is much more significant, with concentrations of insecticides frequently at levels that can affect aquatic life.

Pesticides Showed Seasonal Patterns in Streams

Some herbicides showed patterns of occurrence that can be related to seasonal applications and weather patterns. At Gills Creek, an urban stream, concentrations of herbicides, such as atrazine, simazine, and tebuthiuron, peaked in the spring following application and gradually decreased over the summer (fig. 6). Atrazine and simazine followed a similar pattern at Cow Castle Creek, an agricultural stream, with the addition of a second peak in early fall. The highest concentrations at all sites

were observed during storms that followed applications.

Understanding these patterns of occurrence is important because sampling programs need to be designed so that critical periods of high pesticide concentrations are monitored. This information also can be used by environmental managers to assess risk associated with agricultural chemical use.

Few Pesticides Were Detected in Drinking-Water Supply Aquifers

Of the 90 drinking-water, industrial, and irrigation supply wells sampled in the Floridan, Piedmont, and Sandhills aquifers, 17 had detectable concentrations of pesticides; of those, only two wells had pesticide concentrations that exceeded USEPA drinking-water standards (U.S. Environmental Protection Agency, 1996). Eleven of the 34 pesticides detected in drinking-water supply aquifers did not have water-quality standards.

The Sandhills aquifers are more susceptible to contamination than

Figure 6. Herbicide concentrations generally peaked following spring applications in Gills Creek, an urban stream.

the other aquifers, as is illustrated by the larger number of pesticides detected and the higher detection frequency in the Sandhills aquifers than in the Piedmont and Floridan aquifers (fig. 7). In addition, the two wells that had pesticide concentrations exceeding USEPA drinking-water standards were located in the Sandhills aquifers. Drinking water obtained from the Piedmont and Floridan aquifers is probably unlikely to contain pesticides at harmful levels; however, the high rate of detection and large number of pesticides detected in the Sandhills aquifers are a cause for concern.

Ground-water samples are pumped directly into a mobile laboratory for processing samples and conducting field analyses.

Figure 7. The large number of pesticides detected in the Sandhills aquifers illustrates its relatively high susceptibility to contamination.

The differences in the rate and number of detections in the aquifers may be related to differences in aquifer properties. The Sandhills are largely composed of layers of coarse and fine sand with various quantities of clay. No continuous confining unit or soil layer overlies the aquifer to impede the movement of contaminants into ground water. At the other extreme, the Floridan aquifer has an overlying clay confining layer that impedes vertical movement of contaminants throughout much of its extent (Aucott and others, 1987). The Piedmont aquifer has an overlying layer of weathered bedrock that contains abundant clay. The thickness of this unit is highly variable, but generally it impedes rapid vertical movement of contaminants from land surface to ground water.

Pesticides Were Common in Shallow Ground Water in Urban and Agricultural Areas

Pesticides were detected in 24 of 30 shallow wells in urban areas and in 22 of 30 wells in agricultural areas (Reuber, 1999). Dieldrin concentrations exceeded drinking-water standards in four urban wells; however, the wells sampled were installed for monitoring purposes only and are not drinking-water supply wells. Dieldrin also exceeded aquatic-life standards in these four urban wells, and tebutiuron concentrations exceeded aquatic-life standards in one agricultural well. Generally, ground-water concentrations are not compared to aquatic-life standards; however, these concentrations can be of concern because shallow ground water can discharge to streams, elevating the pesticide concentrations in surface water.

Pesticides were detected in ground water in urban areas about twice as frequently as in agricultural areas (fig. 8). Some pesticides detected in urban and agricultural ground water were the same, although insecticides were detected more frequently in urban ground water. This was similar to national NAWQA findings. The insecticide most frequently detected at urban sites was dieldrin. Although its agricultural use was canceled in the mid-1970s, dieldrin (and aldrin, which breaks down to dieldrin) was used for termite control until the mid-1980s and is a persistent compound (Barbash and Resek, 1996). Dieldrin was also the most commonly detected pesticide in urban ground water nationally (U.S. Geological Survey, 1999).

Shallow wells for the urban ground-water study were installed by the U.S. Geological Survey with assistance from the South Carolina Geological Survey.

Figure 8. Pesticides were detected more frequently at urban ground-water sites than at agricultural sites.

Organochlorine Pesticides Were Detected in Bed Sediment and Tissues

Fourteen pesticides were detected in streambed-sediment samples, and 21 of 24 sites sampled had at least one detectable pesticide. All of the pesticides detected in sediment were organochlorine insecticides, such as chlordane, dieldrin, mirex, and DDT and its derivatives. Many of these compounds had their agricultural uses cancelled more than 20 years ago, yet they still appear in sediment samples. The reason for this is because the compounds are persistent, or are highly resistant to chemical breakdown.

Of the compounds detected, only DDE, a breakdown product of DDT, exceeded guidelines for the protection of aquatic life. The guidelines were exceeded at three sites, all of which are in basins with a high percentage of agricultural land. In addition, DDT concentrations were only slightly below the aquatic guidelines at several sites. Comparisons of land use to concentrations of organochlorine pesticides generally did not show strong relations, primarily because these insecticides were used in both urban and agricultural settings (fig. 9). The only prominent rela-

Figure 9. Bed sediment in forested settings has significantly lower total organochlorine pesticide concentrations than bed sediment in other land-use settings.

tion is the uniformly low levels of these pesticides detected at forested sites where these chemicals were less likely to be used.

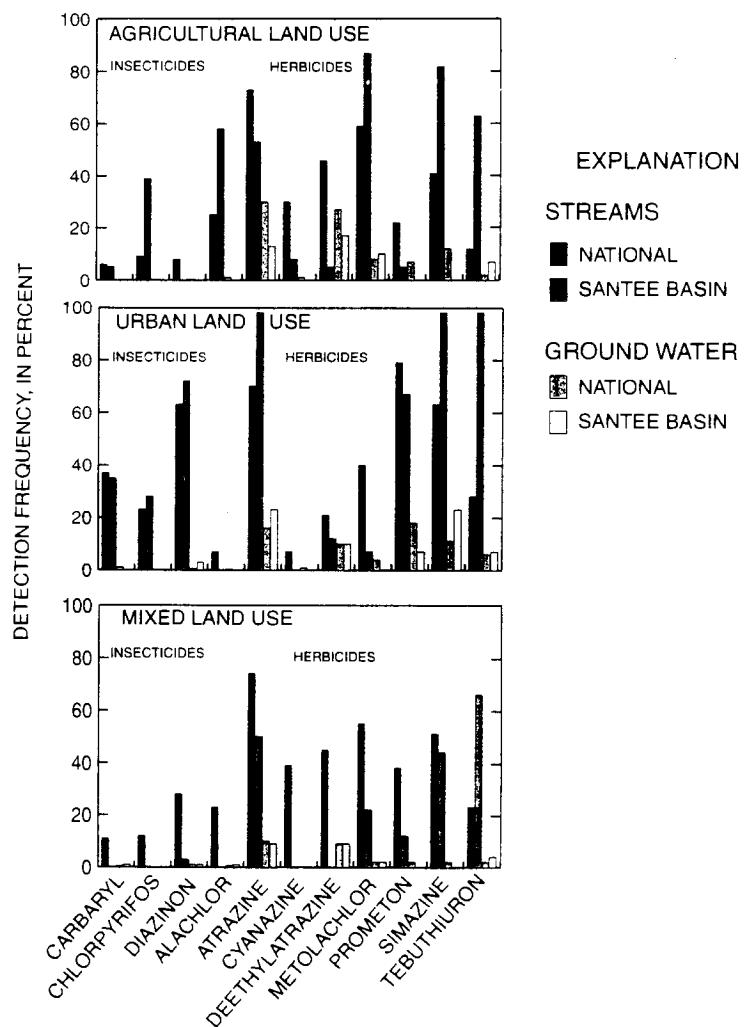

The same pesticides detected in sediments were also in clam and fish tissues. Concentrations measured were generally much higher in tissue than in sediment; however, a direct comparison of these concentrations may not be valid because of potential differences in exposure rates of sediment and fish, differences in uptake by sediment organic carbon and tissue, and partitioning in fish tissue.

Organochlorine pesticides, such as DDT, can be found in streambed sediment and can accumulate in tissues of fish, such as this carp.

SANTEE BASIN PESTICIDE FINDINGS WERE SIMILAR TO NATIONAL FINDINGS

The most common pesticides detected in the Santee Basin included atrazine, simazine, tebutiuron, prometon, and metolachlor. These pesticides were among the top 11 pesticides detected nationally. Consistent with national findings, herbicides were the most common type of pesticide detected in streams and aquifers in agricultural areas in the Santee Basin, whereas insecticides were more prevalent in urban areas. Overall, streams and aquifers that integrate different land uses had lower concentrations of pesticides than those that are dominated by either agricultural or urban land uses. Detections of pesticides in mixed land-use streams in the Santee Basin overall were much less frequent than national detections. The most striking differences between national and Santee Basin findings are the more frequent detections of alachlor, diazinon, and metolachlor in agricultural streams, simazine in agricultural and urban streams, and tebutiuron in all land-use settings in the Santee Basin. The greater detection frequency does not appear to result from higher use of these compounds in the Santee Basin.

Phosphorus Concentrations in Streams Frequently Exceeded USEPA Goals

Nutrients measured in streams in the Santee Basin, such as ammonia, nitrite, nitrate, phosphate, and orthophosphate, were elevated above background concentrations in areas affected by agricultural and urban runoff. Of these nutrients, the only one governed by a drinking-water standard is nitrite-plus-nitrate nitrogen (hereinafter referred to as nitrate) because it is the only nutrient that directly affects human health. None of the surface-water samples had concentrations of nitrate that were above the drinking-water standard of 10 milligrams per liter (mg/L) (U.S. Environmental Protection Agency, 1996).

Phosphorus concentrations were above the USEPA goal in several rivers in the Santee Basin. For example, the flow-weighted mean annual concentration of total phosphorus in the South Fork Catawba River is about four times higher than the USEPA goal for streams entering a reservoir (U.S. Environmental Protection Agency, 1986) (fig. 10). This is important because many of the reservoirs in the Santee Basin are eutrophic; that is, they have high levels of nutrients that can result in excessive growth of algae (Stecker and Crocker, 1991). Much of the phosphorus and nitrogen that feeds the algae is carried into the reservoirs by major rivers. The South Fork Catawba River flows into Lake Wylie directly downstream of the sampling site and is the only stream sampled that enters directly into a reservoir.

The USEPA also has a goal of 0.1 mg/L total phosphorus for

streams that do not directly discharge to reservoirs (U.S. Environmental Protection Agency, 1986). The purpose of this goal is to prevent excessive plant growth in streams. Indian Creek, N.C., Congaree River, and Brushy Creek do not meet this goal based on mean annual concentrations (fig. 10). Only two of the streams sampled did not have at least one sample above the goal. These were Jacob Fork River and McTier Creek, both of which drain forested watersheds. The remaining streams had percentages of individual samples that exceeded the goal, ranging from 4 to 96 percent.

An analysis of nutrient data collected by State monitoring agencies during 1973–93 (Maluk and others, 1998) showed that all but 3 of 90 stream and lake sites exceeded the applicable phosphorus goal at least once, and 23 sites had median concentrations that exceeded the goal.

The Congaree River is one of several rivers in the Santee Basin that exceeded the U.S. Environmental Protection Agency goal for phosphorus.

Although 34 of the 90 sites showed decreasing trends in phosphorus concentrations, 53 showed no trend, and 3 had increasing trends.

Agricultural Runoff and Industrial Discharges are Sources of Nutrients in Surface Water

For all the streams in the study unit, except in the South Fork Catawba River, there is a strong relation between orthophosphate

Figure 10. Three streams in the Santee Basin frequently exceeded the U.S. Environmental Protection Agency goal for phosphorus in surface waters not entering reservoirs, and one exceeded the goal for waters entering reservoirs.

(the predominant form of dissolved phosphorus in streams) concentrations and the percentage of agricultural land in the basins sampled (fig. 11). This relation most likely results from the runoff of phosphate-containing chemical fertilizer and manure from agricultural lands. The relation generally is not influenced by municipal waste-water discharges because phosphate-containing detergents have been banned for domestic use in the Santee Basin since the late 1990s (Litke, 1999).

The South Fork Catawba River has much higher concentrations of orthophosphate than would be predicted from the amount of agricultural land in the basin (fig. 11). This may result from a lack of a phosphorus ban on industrial users. The South Fork Catawba River Basin contains a large concentration of industries that use phosphate detergents, which are a potential source for the high orthophosphate levels in the South Fork Catawba River (Lindsey and Lewis, 1994).

Water-Supply Aquifers Rarely Exceeded Drinking-Water Standards for Nitrate

With the exception of nitrate, most nutrient concentrations in ground water in the Santee Basin were low. This is fairly typical of ground water in which most forms of nitrogen and phosphorus are negligible (Nolan and Stoner, 2000).

Nitrate concentrations exceeded the USEPA (1996) drinking-water standard of 10 mg/L in 14 of the 150 wells sampled. Drinking water containing concentrations of nitrate above the standard can result in methemoglobinemia, a life-threatening illness. All but two of the

Figure 11. The concentration of orthophosphate in streams is directly related to the percentage of agricultural land in the stream basin except for the South Fork Catawba River.

wells that exceeded the standard were located in the shallow aquifer beneath agricultural land in the Coastal Plain. In fact, wells in the agricultural land-use study had the highest concentrations of nitrate overall, with concentrations up to 23 mg/L and a median concentration about double the national NAWQA median for agricultural land use (fig. 12). Although the shallow aquifer generally is not used for drinking-water supplies, the potential for movement of nitrate-enriched water to deeper aquifers used for water supply is a cause for concern. Wells beneath urban land had lower median con-

centrations of nitrate than wells in agricultural lands and were lower than the national NAWQA median for urban land use.

Nitrate concentrations measured in the three drinking-water supply aquifers sampled in the Santee Basin were variable. The Piedmont had the highest nitrate concentrations, followed by the Sandhills and Floridan aquifers (fig. 13). Only two wells exceeded the drinking-water standard for nitrate, one each in the Piedmont and Sandhills aquifers. With the exception of these two wells, most concentrations measured were well within the standard. One of the wells with a concentration above the standard was an irrigation well located in the middle of a corn and soybean field; the other was adjacent to a golf course. These results suggest that most wells in these three aquifers are safe from high levels of nitrate, but some concern is justified for wells located near areas with high fertilizer use.

The higher nitrate concentrations in the Piedmont and Sandhills aquifers are related to the lack of con-

Figure 12. Nitrate concentrations in shallow ground water in agricultural areas were higher than those in urban areas and in major aquifers.

Figure 13. The Piedmont and Sandhills aquifers had higher median nitrate concentrations than the Floridan aquifer.

finement for these aquifers, which readily allows the downward movement of surficial contaminants. Water in these aquifers often has high dissolved oxygen concentrations, which prevents denitrification (the removal of nitrate by conversion to nitrogen gas). By comparison, the Floridan aquifer has the lowest nitrate concentrations because it is confined, meaning little water moves vertically into the aquifer, and it has little dissolved oxygen, a condition which can promote denitrification.

Nitrate in Ground Water Can Affect Nitrate Concentrations in Streams

Local conditions can strongly affect the nitrogen concentrations in ground water and how much nitrate discharges from ground water to surface water. A study of the transport of nitrate in ground water was conducted at an agricultural site adjacent to Cow Castle Creek, S.C. (fig. 14). At this site, ground water beneath a corn field had concentrations of nitrate more than 28 mg/L, nearly three times the drinking-water standard. Along the ground-water flow path, nitrate concentrations decreased to less than 5 mg/L.

Directly below the streambed, nitrate concentrations were above 4 mg/L. However, as ground water moves upward to the stream, it passes through an organic-rich zone containing little dissolved oxygen. Denitrification occurring in this zone results in water with a nitrate concentration of only 0.4 mg/L.

Denitrification may not always be effective in removing nitrate at

all locations where ground water discharges to Cow Castle Creek. This is evidenced by the high concentrations of nitrate measured in Cow Castle Creek during low flow when most streamflow is attributed to ground-water discharge.

Water levels were measured simultaneously in Cow Castle Creek and at multiple depths in the aquifer below the creek. Under most streamflow conditions, water from the aquifer was moving upward into the creek.

Figure 14. Concentrations of nitrate are reduced through denitrification as ground water flows to Cow Castle Creek. Typical wells used for water supply in this area are greater than 100 feet deep. Nitrate concentrations at that depth generally are not above drinking-water standards.

PHOSPHORUS CONCENTRATIONS IN THE SANTEE BASIN WERE IN THE MIDDLE RANGE OF NATIONAL RESULTS

Six of the 12 streams sampled in the Santee Basin had average concentrations of total phosphorus that were within the medium concentration range of all streams sampled in the NAWQA Program. The exceptions were an agricultural area drained by Indian Creek in North Carolina, which ranked high nationally, and two mixed land-use streams, which were in the lowest category for phosphorus. Nationally, higher concentrations of phosphorus corresponded to areas of the Midwest that also had high inputs of phosphorus from fertilizer and manure that were applied to agricultural lands. Phosphorus inputs from agriculture in the Santee Basin were typically in the low to middle range. The two mixed land-use sites that had the lowest phosphorus concentrations compared to national results were located on the Saluda and Edisto Rivers. The Saluda River site is located downstream from a major reservoir that traps much of the phosphorus carried into the system. The Edisto River is located in the Coastal Plain and mostly drains forested and agricultural lands. Extensive wetlands border the Edisto River and may act as local traps for phosphorus attached to sediment.

EXPLANATION

AVERAGE ANNUAL CONCENTRATION OF TOTAL PHOSPHORUS--IN MILLIGRAMS PER LITER

- Highest (greater than 0.27)
- Medium (0.05 to 0.27)
- Lowest (less than 0.05)

BACKGROUND CONCENTRATIONS

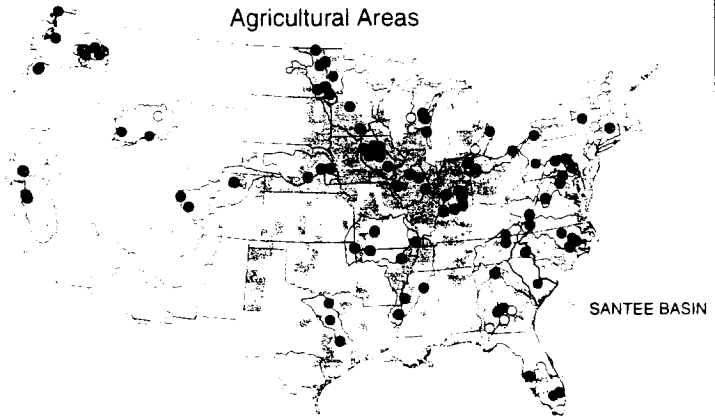

- Bold outline indicates median values greater than USEPA desired goal of 0.1 milligrams per liter for prevention of nuisance plant growth in flowing waters not discharging directly to lakes and impoundments

AVERAGE ANNUAL TOTAL PHOSPHORUS INPUT--IN POUNDS PER ACRE, BY COUNTY, FOR 1995-98. INPUTS ARE FROM FERTILIZER AND MANURE

- ▢ Less than 2 pounds per acre

TOTAL PHOSPHORUS IN STREAMS

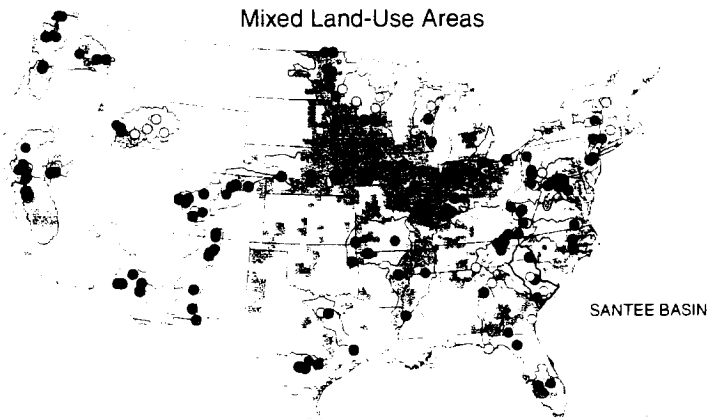

Agricultural Areas

Urban Areas

Mixed Land-Use Areas

Bed Sediment Had Low Concentrations of Trace Elements

Trace elements in bed sediment were detected frequently but mostly at concentrations below those expected to affect aquatic life (Canadian Council of Ministers of the Environment, 1995). Arsenic and lead exceeded aquatic standards in one sample each, and chromium exceeded standards in four samples. The samples with elevated chromium concentrations were not associated with any particular land use; however, most of these samples were collected at sites in the Piedmont. This suggests that the elevated concentrations may be naturally occurring as a result of geologic conditions in the Piedmont.

Regional differences in bed sediment trace-metal concentrations were observed in the study area. In general, a decrease in the bed-sediment concentrations of arsenic, chromium, copper, nickel, and zinc occurs from the Blue Ridge southward across the Piedmont to the Coastal Plain. In the same direction, an increase in the bed-sediment concentrations of lead, mercury, and selenium occurs. These differences are likely a result of geologic differences among the areas (Abrahamsen, 1999).

A comparison of land use with bed sediment trace-element concentrations indicates that lead is significantly higher in sediment from urban streams than in sediment from forested streams. Neither agricultural nor mixed land-use streams had significantly higher concentrations of lead than forested streams (Abrahamsen, 1999).

MERCURY CONTAMINATION POTENTIAL IN SANTEE BASIN WAS HIGHEST IN NATION

Mercury is a widespread and extremely toxic contaminant that affects the Nation's aquatic ecosystems. Approximately 80 percent of the fish consumption advisories in the Nation were issued as a result of contamination by mercury (U.S. Environmental Protection Agency, 1998). Methylmercury is the form of mercury that is easily accumulated in the tissues of organisms. As part of the NAWQA Program, a nationwide investigation of methylmercury in water, sediment, and fish tissues was conducted (Krabbenhoft and others, 1999). Analysis of samples collected in the Santee Basin indicated that they had the greatest methylation efficiency (the ratio of methylmercury to total mercury) in the Nation. In other words, conditions at the sites sampled in the Santee Basin are such that a relatively small amount of elemental mercury in water can result in high concentrations of methylmercury being available for accumulation in fish tissue. The types of sites sampled were primarily blackwater streams, which typically have large amounts of dissolved organic carbon and low dissolved oxygen concentrations. The bacteria that convert elemental mercury to methylmercury thrive under these conditions. Many of the streams that are covered by State fish-consumption advisories are blackwater streams.

NAWQA STUDY AREAS SAMPLED FOR THE NATIONAL PILOT STUDY OF MERCURY CONTAMINATION

Trace Elements Accumulated in Clam Tissue and Fish Livers

Trace metals are naturally occurring and were detected in all fish liver and clam tissue samples collected. Nine trace elements (arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, and zinc) have been classified as priority pollutants because they are toxic to aquatic organisms in low concentrations (Code of Federal Regulations, 1996). Of these nine metals, concentrations of cadmium, copper, selenium, and zinc were higher in clams and fish liver tissue than those measured in sediment. Carp liver tissue contained significantly higher concentrations of these metals than those in clams and bed sediment, indicating that the metals accumulate in fish livers. Concentrations of arsenic, chromium, lead, and nickel were significantly lower in tissues than in sediment, suggesting that these metals do not accumulate in tissues (fig. 15). Concentrations of mercury were higher in clam tissue than in sediment and fish livers. Although data suggest that some metals accumulate in tissues, most metals do not have criteria for assessing risk to human health or aquatic wildlife associated with fish consumption.

Concentrations of mercury in clams and fish liver tissue from the Edisto River were 24 and 8 times greater, respectively, than the South Carolina action level for issuance of a fish-consumption advisory. Data collected in the NAWQA Program cannot be used to assess potential risk to human health because fish livers were used for analyses, whereas fish filets are needed to assess human-

health risk. Consumption advisories generally are not applied to clams because few humans consume them. The South Carolina Department of Health and Environmental Control (2000) has issued fish-consumption advisories

because of high levels of mercury in 49 rivers and reservoirs in the Santee Basin, including the Edisto River.

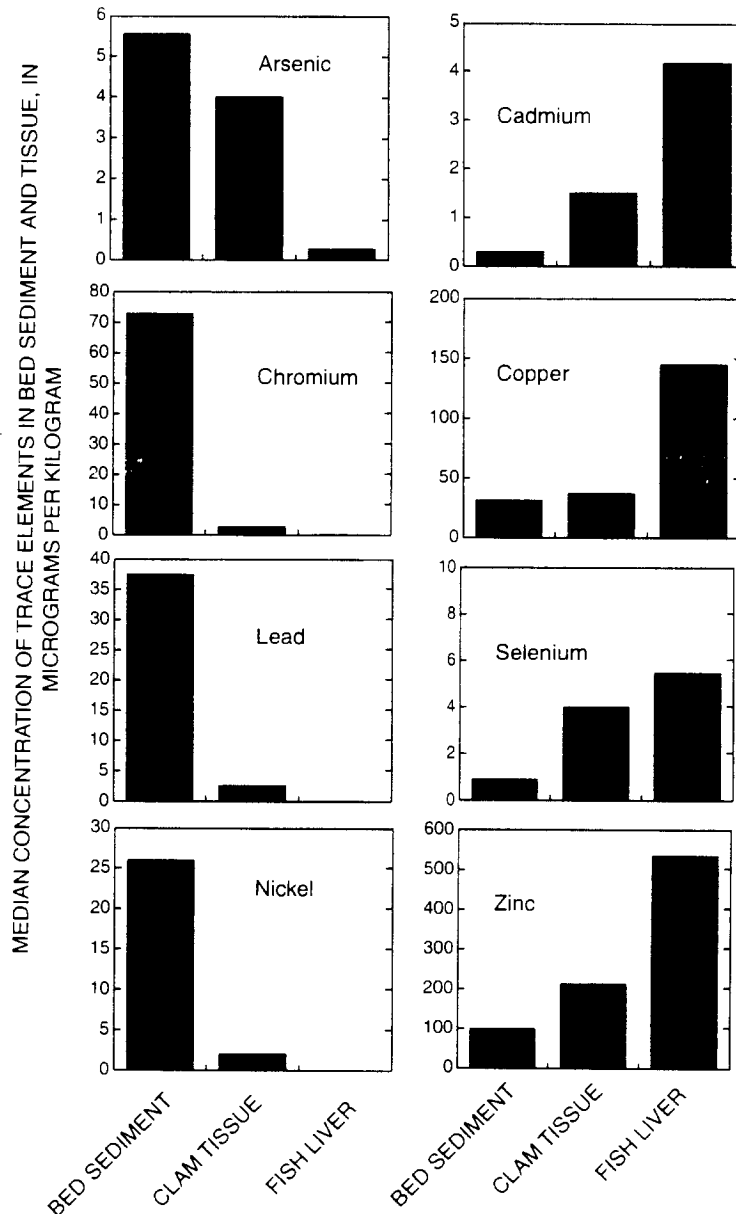

Figure 15. Cadmium, copper, selenium, and zinc were detected at higher concentrations in clam and fish tissue than in sediment, suggesting that they accumulate in the tissues. Conversely, arsenic, chromium, lead, and nickel were detected in lower concentrations in tissues than in sediment, indicating that these metals do not accumulate in the tissues.

Radon Exceeded Proposed Standards in Many Wells

Ninety-six percent of the 90 wells sampled in drinking-water supply aquifers of the Santee Basin contained measurable quantities of radon, a colorless, odorless gas that can cause cancer in humans. The gas results from the radioactive decay of uranium in rocks and soil and can enter homes directly from the soil or in drinking water supplied by wells. Radon is a health risk through direct inhalation of the gas and from drinking water contaminated with radon.

Of the 90 wells sampled, radon exceeded the USEPA's (1999) proposed maximum contaminant level (MCL) of 300 picocuries per liter (pCi/L) in 100, 47, and 17 percent of the wells in the Piedmont, Sandhills, and Floridan aquifers, respectively (fig. 16). For wells not meeting the MCL, the USEPA has proposed an Alternative Maximum Contaminant Level (AMCL) of 4,000 pCi/L. To comply with the

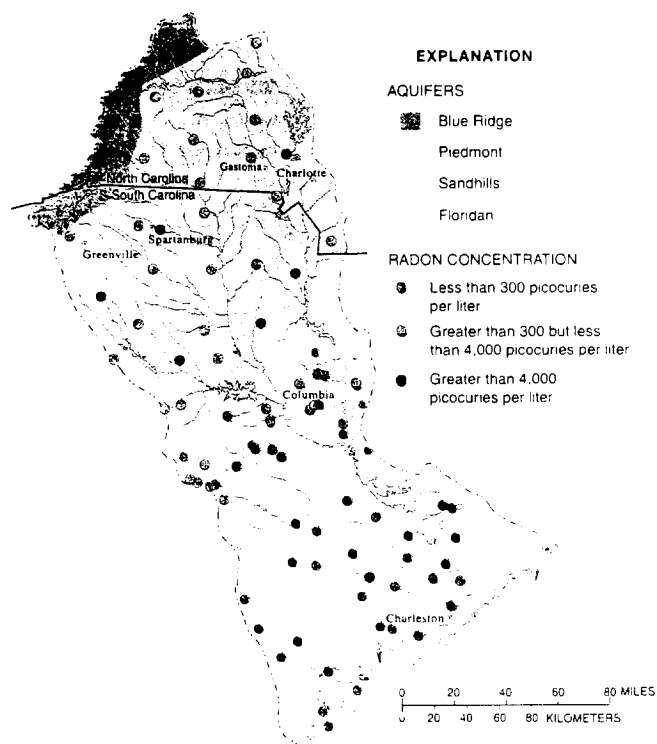

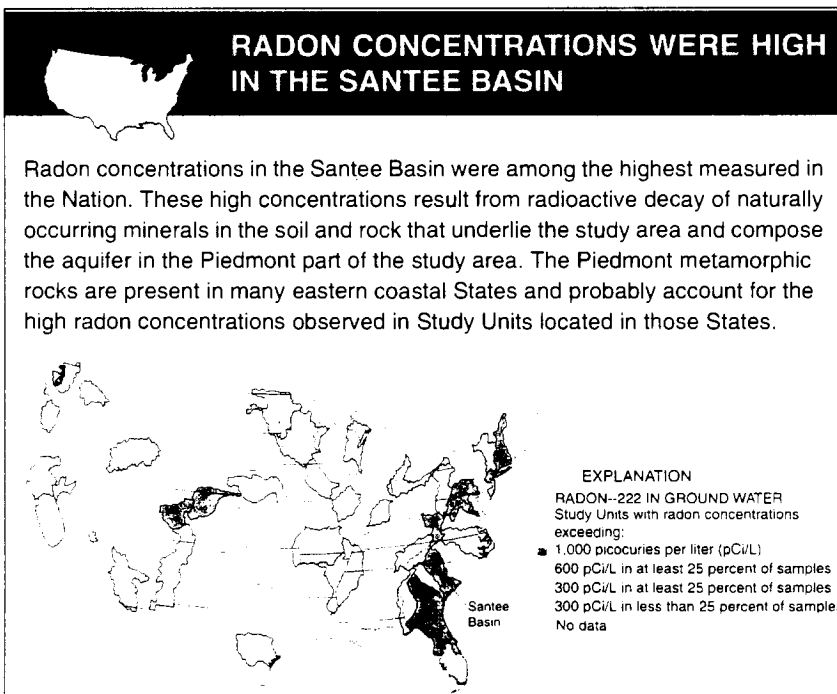

Figure 16. Radon concentrations were highest in the Piedmont and Sandhills aquifers, resulting from naturally high levels of uranium in near-surface rocks and sediment.

AMCL, the State or local water utility must develop indoor air radon-reduction programs and reduce radon levels in drinking water to 4,000 pCi/L. Of the wells that were sampled in the Piedmont, Sandhills, and Floridan aquifers, 20 percent, zero percent, and less than 1 percent, respectively, exceeded the proposed AMCL.

Wells in the Piedmont had much higher concentrations of radon, on average, than wells sampled in the Sandhills and Floridan aquifers (fig. 16). This results from the greater relative abundance of minerals containing uranium in the metamorphic rocks that compose the Piedmont aquifer. The same bedrock underlies the Sandhills and Floridan aquifers, but generally at depths ranging from several hundred to several thousand feet.

Volatile Organic Compounds Were Common in Urban Ground Water

All but 3 of 30 monitoring wells installed in commercial and residential areas of Columbia, S.C., contained a variety of volatile organic compounds (VOCs), a group of chemicals that includes gasoline additives, solvents, and disinfection by-products (Reuber, 1999). Thirty-five such compounds were detected. Most wells contained three or more VOCs, and one well contained 15 different VOCs.

Most of the VOC detections were at extremely low levels. The five VOCs detected with the highest concentrations were methyl *tert*-butyl ether (MTBE), trichloroethene (TCE), acetone, *tert*-amyl methyl ether (TAME), and trichloromethane. Of the 35 detected VOCs, 21 have established drinking-water standards; of these, only TCE exceeded the standard. Currently there is no standard for MTBE, but the MTBE concentra-

tion in one well exceeded a drinking-water advisory.

Some of the most frequently detected compounds included trichloromethane, chloromethane, and bromodichloromethane. These compounds can result from the chlorination of drinking water and can enter ground water by infiltration from irrigation systems or from leaky water-supply lines. Other VOCs that were detected were solvents, such as TCE, tetrachloroethene, and acetone. These compounds have commercial and industrial uses as degreasers and dry-cleaning solvents, but they are often used in households for similar purposes. The gasoline additives MTBE and TAME and the gasoline component benzene also were detected in Columbia's ground water. These compounds can enter ground water from leaking gasoline storage tanks, spills, and potentially through atmospheric deposition (Lopes, 1998).

The diffuse, nonpoint nature of sources of VOCs in ground water

makes it difficult to attribute detected compounds to particular homes or businesses, posing a problem for scientists who seek to establish the relative importance of these sources and for regulators who seek to educate the public or control the release of toxic substances.

Volatile Organic Compounds in Streams Can Result from Ground-Water Discharge and Urban Runoff

Ten VOCs were detected in seven monthly stream-water samples that were collected from Gills Creek, an urban stream in the Columbia metropolitan area. MTBE, chloromethane, methylbenzene, chlorobenzene, and acetone were detected most frequently. None of the VOCs detected in Gills Creek were at concentrations exceeding drinking-water or aquatic-life standards. Six of the VOCs detected do not have standards.

VOCs have many sources, including contaminated precipitation, surface-water runoff, and ground-water discharge. Though the sources are diffuse and hard to measure directly, inferences can be made about the likely sources. For example, samples collected in Gills Creek while the water level was rising during a rainstorm indicate that as streamflow increased, the concentration of acetone increased. This suggests that the source of acetone in the samples was from contaminated precipitation or stormwater runoff (Lopes and others, 2000). If the acetone resulted from continuously discharging ground water, the concentration would be expected to decrease as dilution by rainfall and runoff increased.

Shallow ground water in the Columbia, S.C., metropolitan area contains a variety of volatile organic compounds, but mostly at low concentrations.

Stormwater samples for volatile organic compounds were collected by using special samplers developed for the NAWQA Program.

During the summer of 1996, 20 different VOCs were detected at low concentrations in individual samples collected at 16 surface-water sites scattered throughout the Gills Creek Basin. The compounds detected in the highest concentrations included MTBE, 1,1-dichloroethene, trichloroethene, methylbenzene, and 1,2-dibromo-3-chloropropane—all solvents except for MTBE, which is a gasoline additive. Fifteen of the compounds detected in surface water also were present in the Columbia ground-water samples. This result is not surprising because the samples were collected during low streamflow conditions when the ground-water contribution to Gills Creek is greatest; consequently, VOCs from contaminated ground water most likely would be detected in stream samples.

Drinking-Water Aquifers Had Low Concentrations of Volatile Organic Compounds

Of the 90 wells sampled in the Piedmont, Sandhills, and Floridan aquifers, 62 contained detectable concentrations of VOCs. All of the 28 compounds detected met USEPA drinking-water standards; however, 19 of the compounds did not have standards. The VOCs measured had widely ranging detection limits, making comparisons among compounds and aquifers difficult. A subset of the compounds having detection limits of 0.05 microgram per liter ($\mu\text{g/L}$) or lower was used to make comparisons. This comparison shows that

about twice as many wells in the Sandhills aquifers contain VOCs as those in the Floridan and Piedmont aquifers. The more frequent occurrence of VOCs in the Sandhills aquifers probably relates to their greater susceptibility to contamination.

Data on VOCs in drinking-water aquifers indicate that although these compounds are widespread, concentrations are sufficiently low that human health is not immediately at risk. However, the fact that detections were so frequent suggests that aquifers are susceptible to contamination and should be carefully monitored.

Ground water affects the quality of surface water

Presently, surface water is used for most public water supplies in the Columbia metropolitan area. However, the quality of these supplies is largely controlled by ground-water quality, especially during summer months. In areas of the basin with sandy soils, such as the Sandhills, flow in streams is contributed mostly by discharge from ground water. Discharging ground water transports contaminants, including VOCs, that can result in water-quality problems in streams and lakes. Consequently, the health of aquatic organisms and surface-water drinking supplies can be affected by the chemical quality of shallow ground water discharged to streams and reservoirs. Several streams in the metropolitan area, including Penn Branch and Jackson Creek, have high concentrations of nutrients and pesticides that evidence suggests result from ground-water discharge (Maluk, 1999).

Urban and Agricultural Streams Had High Concentrations of Bacteria

Thirteen of 17 streams sampled for fecal coliform bacteria had at least one sample that exceeded the South Carolina single-sample standard of 400 colonies per 100 milliliters (col/100 mL; South Carolina Department of Health and Environmental Control, 1992). This standard was implemented to reduce the risk of gastrointestinal disorders that are associated with recreational contact with water containing elevated levels of bacteria. All concentrations measured in this report were compared to South Carolina standards for consistency; North Carolina does not recognize a single-sample standard.

Urban and agricultural streams had more concentrations of bacteria that exceeded standards than forested and mixed land-use streams (fig. 17). Several creeks repeatedly had high concentrations of bacteria. For example, one of the urban streams sampled, Brushy Creek, exceeded the standard in 60 percent of the samples collected.

The highest bacterial concentrations measured were at agricultural sites, such as Cow Castle Creek and Indian Creek, N.C., which had concentrations of 21,600 and 12,000 col/100 mL, respectively. The highest concentrations observed in urban streams were much lower—around 2,000 col/100 mL. Forested streams generally had the lowest peak concentrations, ranging from about 500 to 1,000 col/100 mL. Samples were collected under all flow conditions, and higher concentrations as well as standard exceedances tended to occur at higher streamflows.

Stream Size is Important

All of the regularly monitored small streams exceeded the South Carolina single-sample standard for bacteria. Most large rivers did not exceed the standard during the period sampled, including the Wateree, Saluda, Congaree, and Edisto Rivers. The median bacterial concentrations in streams with drainage areas larger than 100 square miles (mi²) were significantly lower than those in streams with drainage areas less than 100

Bacterial cultures were prepared and counted in a mobile field laboratory and in the USGS South Carolina District laboratory.

mi². Because major rivers and small streams have similar sources of bacteria, the most likely reason for the differences in bacterial levels is dilution by the larger flows in the major rivers.

Sources of Bacteria

A comparison of bacterial concentrations to the physical and chemical parameters of the water indicate that surface-water runoff accounts for much of the elevated fecal coliform concentrations (Wilhelm and Maluk, 1998). Bacterial concentrations increased as streamflow, organic nitrogen, organic carbon, phosphorus, and suspended-sediment concentrations increased. Because increases in these parameters usually result from surface-water runoff, the implication is that the increase in bacteria also resulted from runoff.

In agricultural areas, bacteria in runoff may result from applications of manure to fields and from animal holding and feeding areas. Urban sources include runoff from lawns containing pet wastes, leaking or failed septic tanks and sewer lines, and municipal or industrial discharges. Bacterial contamination in forested areas most likely results from fecal contamination by wildlife.

Figure 17. Urban and agricultural streams had more concentrations of bacteria that exceeded South Carolina State standards than forested and mixed land-use streams.

Biological Communities Reflected Land-Use Differences

Biological communities that inhabit streams in Santee Basin agricultural and urban areas were indicative of degraded water quality compared to those that inhabit streams that drain forested areas. Fish that have a low tolerance for contamination make up a smaller percentage of the fish community at agricultural and urban sites than at forested sites (fig. 18). This can result because fish such as darters and shiners that are sensitive to contaminants do not thrive at degraded sites. Other species such as catfish, redbreast sunfish, and some minnows that are relatively unaffected by contaminants will take the place of the more sensitive fish.

Urban and agricultural streams also had lower numbers of invertebrate species that are intolerant of contaminants than forested and mixed land-use streams. This is evidenced by the lower numbers of Ephemeroptera, Plecoptera, and Trichoptera (EPT) taxa, a group of aquatic insects that are relatively intolerant of contamination, at urban and agricultural sites. The USEPA (Plafkin and others, 1989)

Over 85 fish species were identified during ecological sampling in the Santee Basin.

Figure 18. Compared to forested sites, urban and agricultural sites have higher concentrations of atrazine and ammonia as well as lower numbers of fish and invertebrates that are intolerant of contamination.

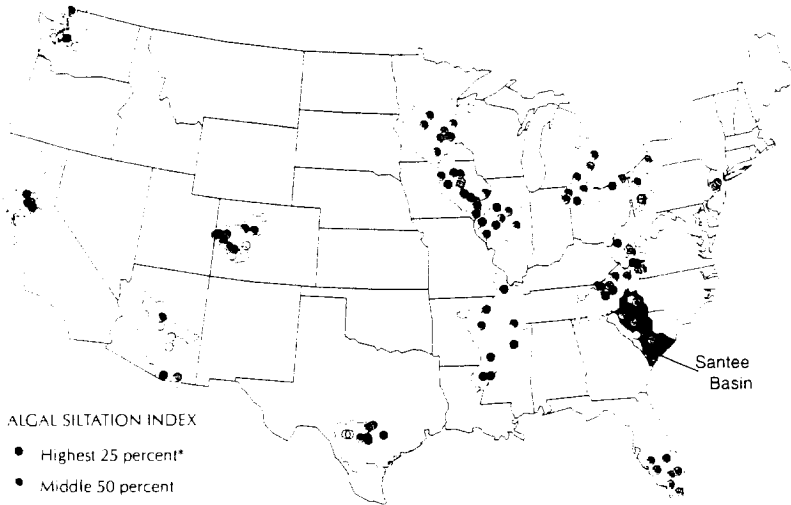

uses the presence or absence of EPT taxa as an indicator of aquatic community health.

Water-quality constituents and contaminant-intolerant species are related (fig. 18). Median concentrations of ammonia, a nutrient associated with wastewater discharges, and atrazine, an agricultural and turfgrass herbicide, are highest at urban and agricultural sites, corresponding to low numbers of contaminant-intolerant fish and invertebrate species. This suggests that these water-quality constituents have an effect on the aquatic community; however, other factors, primarily those associated with

aquatic habitats, can affect aquatic community health in ways that are similar to those that result from changes in water quality. In addition, sample sites were located in several different physiographic provinces, including the Blue Ridge, Piedmont, and Coastal Plain. Differences in species distributions and habitat in these different settings can make comparisons difficult to interpret. Most likely, a combination of water quality and habitat disturbance associated with agricultural and urban land uses results in the observed differences in biological communities.

SANTEE BASIN STREAMS WERE IN THE MIDDLE OF NATIONAL BIOLOGICAL RANKINGS

ALGAL SILTATION INDEX

- Highest 25 percent*
- Middle 50 percent
- ◌ Lowest 25 percent

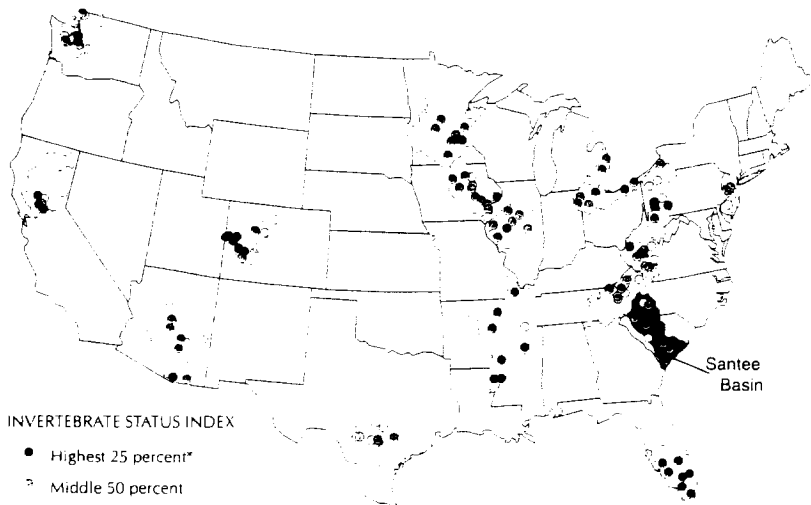

*Higher values suggest a more degraded stream site

Algal Siltation Index

Algal data collected in each of the NAWQA Study Units were combined and compared to show differences in the percentage of species that are able to avoid burial by sediment (Bahls and others, 1992). High percentages of these mobile algae are indicative of siltation of benthic habitats. Two sites in the Santee Basin were in the highest 25-percent category. One of these sites is the Edisto River, a blackwater river that has low light penetration. The high ranking at this site may result from low-light conditions that favor mobile algal species. Other variables that can lower light levels in streams can affect this index, including turbidity and forest canopy closure.

Invertebrate Status Index

A multimetric index was developed to compare invertebrate populations nationally. The index is an average of 11 metrics that summarize changes in richness, tolerance, trophic condition, and dominance associated with water-quality degradation. Only one site in the Santee Basin, an urban stream, was placed in the highest 25-percent category. The remaining Santee Basin sites were in the middle category, except for Jacob Fork River and McTier Creek, which were in the lowest category. Both of these sites represent the least degraded water quality in the study area and were located in areas with the least effects of human activity. Nationally, urban and agricultural sites tended to have the most degraded invertebrate communities according to this index.

INVERTEBRATE STATUS INDEX

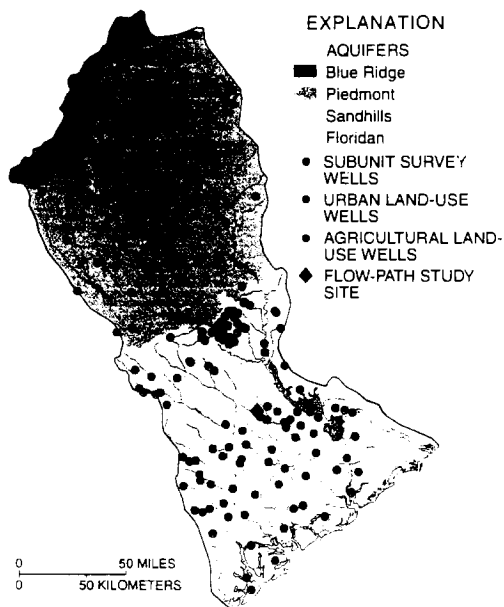

- Highest 25 percent*

- ◌ Lowest 25 percent

*Higher values suggest a more degraded stream site

STUDY UNIT DESIGN

STREAM CHEMISTRY AND BIOLOGY

Fixed sites were sampled to examine differences in streamwater quality due to the environmental setting, a combination of land use, geology, physiography, and climate. Intensive fixed sites were a subset of fixed sites that were sampled more frequently to determine the occurrence and seasonal variability of pesticides. Aquatic community structure, including algae, fish, and macroinvertebrates, was studied at each fixed site to quantify the effects of water quality on stream biota. Synoptic studies focused on low streamflow conditions in an urban setting in Gills Creek, S.C., and a mixed land-use setting in the South Fork Catawba River Basin, N.C. Streambed sediments and fish and clam tissues were sampled to determine the occurrence and distribution of trace elements and organic compounds.

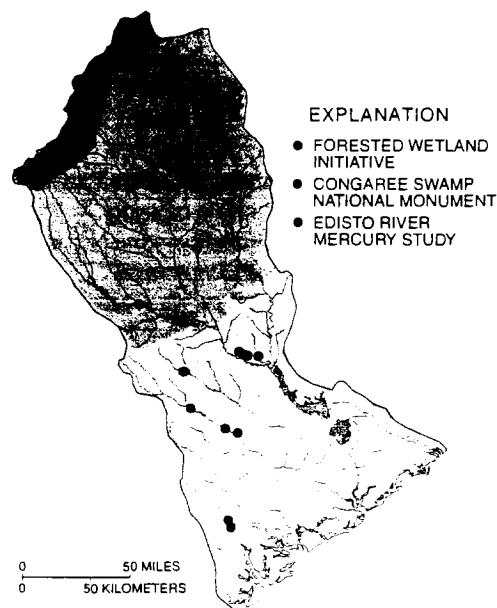

GROUND-WATER CHEMISTRY

Subunit surveys were conducted in three drinking-water supply aquifers to assess overall water quality. Land-use studies in urban and agricultural settings evaluated the effects of these land uses on shallow ground water. An agricultural flow-path study examined the transport and fate of nutrients and pesticides in shallow ground water.

SPECIAL STUDIES

The effects of a forested wetland on nutrient concentrations in stream water were studied as part of the Forested Wetland Initiative, a joint research project with the U.S. Forest Service. Baseline data on water quality and aquatic communities were collected in cooperation with the National Park Service at Congaree Swamp National Monument (Maluk and Abrahamsen, 1999). A study to determine the accumulation of mercury in fish tissues was conducted in the Edisto River Basin.

SUMMARY OF DATA COLLECTION IN THE SANTEE RIVER BASIN AND COASTAL DRAINAGES, 1995-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry and Biology				
Fixed sites	Streamflow was measured continuously and samples were collected monthly for major ions, nutrients, organic carbon, suspended sediment, bacteria, pesticides, and physical properties to describe concentration, seasonal variability, and loads.	Streams draining basins ranging in size from 14 to 7,850 square miles and representing forested, agricultural, urban, and mixed land uses.	13	Monthly, plus 3-6 storms (October 1995-September 1997) Pesticides (February, May, August 1996)
Intensive fixed sites	In addition to the above constituents, samples were analyzed for dissolved pesticides to describe concentration and seasonal variability.	A subset of fixed sites draining agricultural, urban, and mixed land uses.	3	Weekly during growing season (February 1996-October 1997)
Urban synoptic study	Streamflow, major ions, nutrients, organic carbon, suspended sediment, bacteria, pesticides, volatile organic compounds, and physical properties were determined under low-flow conditions to describe concentrations and spatial distributions.	Urban streams draining basins ranging in size from 0.5 to 59.4 square miles.	16	September 1996
South Fork Catawba River synoptic study	Streamflow, major ions, nutrients, organic carbon, suspended sediment, bacteria, and physical properties were determined under low-flow conditions to describe concentrations and spatial distributions.	Mixed land use streams draining basins ranging in size from 5 to 350 square miles.	20	October 1997
Streambed sediments	Streambed sediments were analyzed for trace elements and hydrophobic pesticides and other organic compounds to determine occurrence and spatial distribution.	Sediment depositional zones at all fixed sites and other selected sites.	20	Summer 1995
Aquatic biota	Clams and fish livers were analyzed for trace metals, and clams and whole fish were analyzed for organic compounds to determine occurrence and spatial distribution.	All fixed sites and other selected sites.	20	Summers 1995, 1996
Fixed site reach assessment	Fish, benthic invertebrates, algae, and aquatic and riparian habitats were sampled and described to assess aquatic biological community structure in different land uses and associated habitats.	Stream reaches located at or near fixed sites. Sites represent the variety of land uses, geology, and physiography within the Santee Basin	13	Once in 1996 or 1997; Multiyear sites, once during 1996-98
Ground-Water Chemistry				
Study unit survey	Major ions, nutrients, pesticides, volatile organic compounds, dissolved organic carbon, trace metals, radon and physical parameters analyzed in three major drinking-water aquifers to determine ground-water quality.	Randomly chosen existing public supply, private domestic, irrigation, and industrial supply wells in the Piedmont, Sandhills, and Floridan aquifers.	90 (30 per aquifer)	Sandhills—Summer 1996 Floridan—Spring 1999 Piedmont—Fall 2000
Urban land-use study	Major ions, nutrients, pesticides, volatile organic compounds, dissolved organic carbon, and physical parameters analyzed in shallow ground water in the Columbia, South Carolina, metropolitan area.	Wells installed at randomly chosen commercial/residential land-use areas.	30	Summer 1996
Agricultural land-use study	Major ions, nutrients, pesticides, dissolved organic carbon, and physical parameters analyzed in shallow ground water in row-crop agricultural lands of the lower Coastal Plain.	Wells installed at randomly chosen row-crop land-use areas.	30	Summer 1997
Flow-path study	Major ions, nutrients, pesticides, dissolved organic carbon, and physical parameters analyzed to determine fate and transport of pesticides and nutrients in an agricultural setting.	Multidepth wells installed along a ground-water flow path in the lower Coastal Plain.	34	November 1997; April and August 1998
Special Studies				
Forested Wetland Initiative	Major ions, nutrients, and organic carbon analyzed upstream and downstream from a forested wetland to compare changes in concentrations.	Coosawhatchie River in the lower Coastal Plain.	2	Approximately quarterly, 1996-97
Congaree Swamp National Monument	Streamflow, major ions, nutrients, organic carbon, suspended sediment, bacteria, pesticides, and physical properties to describe concentrations and seasonal variability. Fish, benthic invertebrates, algae, and aquatic habitat described to assess aquatic biological community structure.	Streams draining basins ranging in size from 32 to 70 square miles with agricultural, urban, and forested land uses that drain into Congaree Swamp.	4	Quarterly 1996-98
Edisto mercury study	Sediment, stream water, aquatic insects, and vegetation, and whole fish analyzed for elemental and methyl mercury to examine bioaccumulation of mercury.	Blackwater streams in the Edisto River Basin and a reference site in the Piedmont	5	Once in 1998

GLOSSARY

- Ammonia**—A compound of nitrogen and hydrogen (NH_3) that is a common by-product of animal waste. Ammonia readily converts to nitrate in soils and streams.
- Aquatic-life criteria**—Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms.
- Aquifer**—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Atmospheric deposition**—The transfer of substances from the air to the surface of the Earth, either in wet form (rain, fog, snow, dew, frost, hail) or in dry form (gases, aerosols, particles).
- Bedrock**—General term for consolidated (solid) rock that underlies soils or other unconsolidated material.
- Bed sediment**—The material that temporarily is stationary in the bottom of a stream or other watercourse.
- Concentration**—The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as microgram per liter (water sample) or micrograms per kilogram (sediment or tissue sample).
- Confined aquifer (artesian aquifer)**—An aquifer that is completely filled with water under pressure and that is overlain by material that restricts the movement of water.
- Confining layer**—A layer of sediment or lithologic unit of low permeability that bounds an aquifer.
- Contamination**—Degradation of water quality compared to original or natural conditions due to human activity.
- Degradation products**—Compounds resulting from transformation of an organic substance through chemical, photochemical, and/or biochemical reactions.
- Denitrification**—A process by which oxidized forms of nitrogen such as nitrate (NO_3^-) are reduced to form nitrites, nitrogen oxides, ammonia, or free nitrogen; commonly brought about by the action of denitrifying bacteria and usually resulting in the escape of nitrogen to the air.
- Detect**—To determine the presence of a compound.
- DDT**—Dichloro-diphenyl-trichloroethane. An organochlorine insecticide no longer registered for use in the United States.
- Drainage area**—The drainage area of a stream at a specified location is that area, measured in a horizontal plane, which is enclosed by a drainage divide.
- Drinking-water standard or guideline**—A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.
- Eutrophication**—The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.
- Fecal bacteria**—Microscopic single-celled organisms (primarily fecal coliforms and fecal streptococci) found in the wastes of warm-blooded animals. Their presence in water is used to assess the sanitary quality of water for body-contact recreation or for consumption. Their presence indicates contamination by the wastes of warm-blooded animals and the possible presence of pathogenic (disease producing) organisms.
- Flow path**—An underground route for ground-water movement, extending from a recharge (intake) zone to a discharge (output) zone such as a shallow stream.
- Ground water**—In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Herbicide**—A chemical or other agent applied for the purpose of killing undesirable plants. See also Pesticide.
- Insecticide**—A substance or mixture of substances intended to destroy or repel insects.
- Intolerant organisms**—Organisms that are not adaptable to human alterations to the environment and thus decline in numbers where human alterations occur.
- Invertebrate**—An animal having no backbone or spinal column.
- Major ions**—Constituents commonly present in concentrations exceeding 1.0 milligram per liter. Dissolved cations generally are calcium, magnesium, sodium, and potassium; the major anions are sulfate, chloride, fluoride, nitrate, and those contributing to alkalinity, most generally assumed to be bicarbonate and carbonate.
- Maximum contaminant level (MCL)**—Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Median**—The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Metamorphic rock**—Rock that has formed in the solid state in response to pronounced changes of temperature, pressure, and chemical environment.
- Method detection limit**—The minimum concentration of a substance that can be accurately identified and measured with present laboratory technologies.
- Micrograms per liter ($\mu\text{g/L}$)**—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most streamwater and ground water. One thousand micrograms per liter equals 1 mg/L.
- Milligrams per liter (mg/L)**—A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most streamwater and ground water. One thousand micrograms per liter equals 1 mg/L.
- Minimum reporting level (MRL)**—The smallest measured concentration of a constituent that may be reliably reported using a given analytical method. In many cases, the MRL is used when documentation for the method detection limit is not available.
- Monitoring well**—A well designed for measuring water levels and testing ground-water quality.
- Nitrate**—An ion consisting of nitrogen and oxygen (NO_3^-). Nitrate is a plant nutrient and is very mobile in soils.
- Nutrient**—Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.
- Pesticide**—A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests."
- Phosphorus**—A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.
- Study Unit**—A major hydrologic system of the United States in which NAWQA studies are focused. Study Units are geographically defined by a combination of ground- and surface-water features and generally encompass more than 4,000 square miles of land area.
- Trace element**—An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.
- Unconfined aquifer**—An aquifer whose upper surface is a water table; an aquifer containing unconfined ground water.
- Volatile organic compounds (VOCs)**—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.
- Water table**—The point below the land surface where ground water is first encountered and below which the earth is saturated. Depth to the water table varies widely across the country.

APPENDIX—WATER-QUALITY DATA FROM THE SANTEE RIVER BASIN AND COASTAL DRAINAGES IN A NATIONAL CONTEXT

For a complete view of Santee River Basin and coastal drainages data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Santee River Basin and coastal drainages. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Santee River Basin and coastal drainages compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, tebuthiuron concentrations in Santee River Basin and coastal drainages agricultural streams were similar to the national distribution, but the detection frequency was much higher (66 percent compared to 22 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Santee River Basin and coastal drainages, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

◆◆ Not measured or sample size less than two

12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- ◆◆ No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) * **
- Bentazon (Basagran, Bentazone) **
- Bromacil (Hyvar X, Urox B, Bromax)
- Butylate (Sutan +, Genate Plus, Butilate) **

Cyanazine (Bladex, Fortrol)
 DCPA (Dacthal, chlorthal-dimethyl) * **
 2,6-Diethylaniline (Alachlor breakdown product) * **
 Diuron (Crisuron, Karmex, Diurex) **
 EPTC (Eptam, Farmarox, Alirox) * **
 Ethalfuralin (Sonalan, Curbit) * **
 Fenuron (Fenuon, Fenidim) * **
 Fluometuron (Flo-Met, Cotoran) **
 Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
 Metribuzin (Lexone, Sencor)
 Molinate (Ordran) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Norflurazon (Evital, Predict, Solicam, Zorial) * **
 Oryzalin (Surflan, Dirimal) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **
 Pronamide (Kerb, Propyzamid) **
 Propham (Tuberite) **
 Terbacil (Sinbar) **
 Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

Acetochlor (Harness Plus, Surpass) * **
 Bromoxynil (Buctril, Brominal) *
 Chloramben (Amiben, Amilon-WP, Vegiben) **
 Clopyralid (Stinger, Lontrel, Transline) * **
 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
 Dacthal mono-acid (Dacthal breakdown product) * **
 Dicamba (Banvel, Dianat, Scotts Proturf)
 Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Napropamide (Devrinol) * **
 Pebulate (Tillam, PEBC) * **
 Picloram (Grazon, Tordon)
 Propachlor (Ramrod, Satecid) **
 Propanil (Stam, Stampede, Wham) * **
 2,4,5-T **
 2,4,5-TP (Silvex, Fenoprop) **
 Thiobencarb (Bolero, Saturn, Benthicarb) * **
 Triallate (Far-Go, Avadex BW, Tri-allate) *
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **

Pesticides in water—Insecticides

Other insecticides detected

Aldicarb (Temik, Ambush, Pounce)
 Aldicarb sulfone (Standak, aldoxycarb)
 Carbofuran (Furadan, Curaterr, Yaltox)
 Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
 Methiocarb (Slug-Geta, Grandslam, Mesuro) * **
 Methomyl (Lanox, Lannate, Acinate) **
 Oxamyl (Vydate L, Pratt) **
 cis-Permethrin (Ambush, Astro, Pounce) * **
 Propoxur (Baygon, Blattanex, Uden, Proprotox) * **

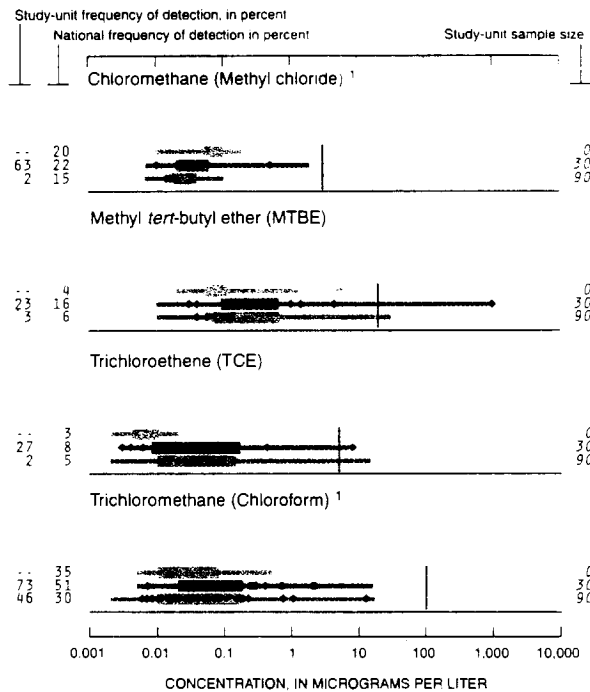

Insecticides not detected

Azinphos-methyl (Guthion, Gusathion M) *
 Disulfoton (Disyston, Di-Syston) **
 Ethoprop (Mocap, Ethoprophos) * **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 gamma-HCH (Lindane, gamma-BHC)
 Methyl parathion (Penncap-M, Folidol-M) **
 Phorate (Thimet, Granutox, Geomet, Rampart) * **
 Propargite (Comite, Omite, Ornamite) * **
 Terbufos (Conraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

¹ Many of the samples in this study were diluted prior to laboratory analysis and therefore the actual detection frequency may be larger than the value listed.

Other VOCs detected

- tert*-Amyl methyl ether (*tert*-amyl methyl ether (TAME)) *
- Benzene
- Bromodichloromethane (Dichlorobromomethane)
- Bromomethane (Methyl bromide)
- 2-Butanone (Methyl ethyl ketone (MEK)) *
- sec*-Butylbenzene *
- tert*-Butylbenzene *
- Chlorobenzene (Monochlorobenzene)
- Chlorodibromomethane (Dibromochloromethane)
- Chloroethane (Ethyl chloride) *
- Chloroethene (Vinyl chloride)
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
- 1,3-Dichlorobenzene (*m*-Dichlorobenzene)
- 1,4-Dichlorobenzene (*p*-Dichlorobenzene)
- Dichlorodifluoromethane (CFC 12, Freon 12)
- 1,2-Dichloroethane (Ethylene dichloride)
- 1,1-Dichloroethane (Ethylidene dichloride) *
- 1,1-Dichloroethene (Vinylidene chloride)
- trans*-1,2-Dichloroethene ((*E*)-1,2-Dichloroethene)
- cis*-1,2-Dichloroethene ((*Z*)-1,2-Dichloroethene)
- Dichloromethane (Methylene chloride)
- 1,2-Dichloropropane (Propylene dichloride)
- Diethyl ether (Ethyl ether) *
- 1,2-Dimethylbenzene (*o*-Xylene)
- 1,3 & 1,4-Dimethylbenzene (*m*-&*p*-Xylene)
- 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
- Ethylbenzene (Phenylethane)
- Iodomethane (Methyl iodide) *
- Isopropylbenzene (Cumene) *
- p*-Isopropyltoluene (*p*-Cymene) *
- Methylbenzene (Toluene)
- 2-Propanone (Acetone) *
- 1,1,2,2-Tetrachloroethane *
- Tetrachloroethene (Perchloroethene)
- Tetrachloromethane (Carbon tetrachloride)
- 1,2,3,5-Tetramethylbenzene (Isodurene) *
- Tribromomethane (Bromoform)

- 1,1,1-Trichloroethane (Methylchloroform)
- Trichlorofluoromethane (CFC 11, Freon 11)

VOCs not detected

- Bromobenzene (Phenyl bromide) *
- Bromochloromethane (Methylene chlorobromide)
- Bromoethene (Vinyl bromide) *
- n*-Butylbenzene (1-Phenylbutane) *
- 3-Chloro-1-propene (3-Chloropropene) *
- 1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
- 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
- 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
- 1,2-Dibromoethane (Ethylene dibromide, EDB)
- Dibromomethane (Methylene dibromide) *
- trans*-1,4-Dichloro-2-butene ((*Z*)-1,4-Dichloro-2-butene) *
- 2,2-Dichloropropane *
- 1,3-Dichloropropane (Trimethylene dichloride) *
- trans*-1,3-Dichloropropene ((*E*)-1,3-Dichloropropene)
- cis*-1,3-Dichloropropene ((*Z*)-1,3-Dichloropropene)
- 1,1-Dichloropropene *
- Diisopropyl ether (Diisopropylether (DIPE)) *
- Ethenylbenzene (Styrene)
- Ethyl methacrylate *
- Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
- 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
- Hexachlorobutadiene
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK)) *
- Methyl acrylonitrile *
- Methyl-2-methacrylate (Methyl methacrylate) *
- 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
- Methyl-2-propenoate (Methyl acrylate) *
- Naphthalene
- 2-Propenenitrile (Acrylonitrile)
- n*-Propylbenzene (Isocumene) *
- 1,1,1,2-Tetrachloroethane
- 1,2,3,4-Tetramethylbenzene (Prenhitene) *
- 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
- 1,2,4-Trichlorobenzene
- 1,2,3-Trichlorobenzene *
- 1,1,2-Trichloroethane (Vinyl trichloride)
- 1,2,3-Trichloropropane (Allyl trichloride)
- 1,2,3-Trimethylbenzene (Hemimellitene) *
- 1,2,4-Trimethylbenzene (Pseudocumene) *
- 1,3,5-Trimethylbenzene (Mesitylene) *

Uranium

Trace elements not detected

Cadmium

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Santee River Basin and coastal drainages, 1995-98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

- ◆ Detected concentration in Study Unit
- 56 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 22 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991-98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- No benchmark for protection of aquatic life

Organochlorines in fish tissue (whole body) and bed sediment

² The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

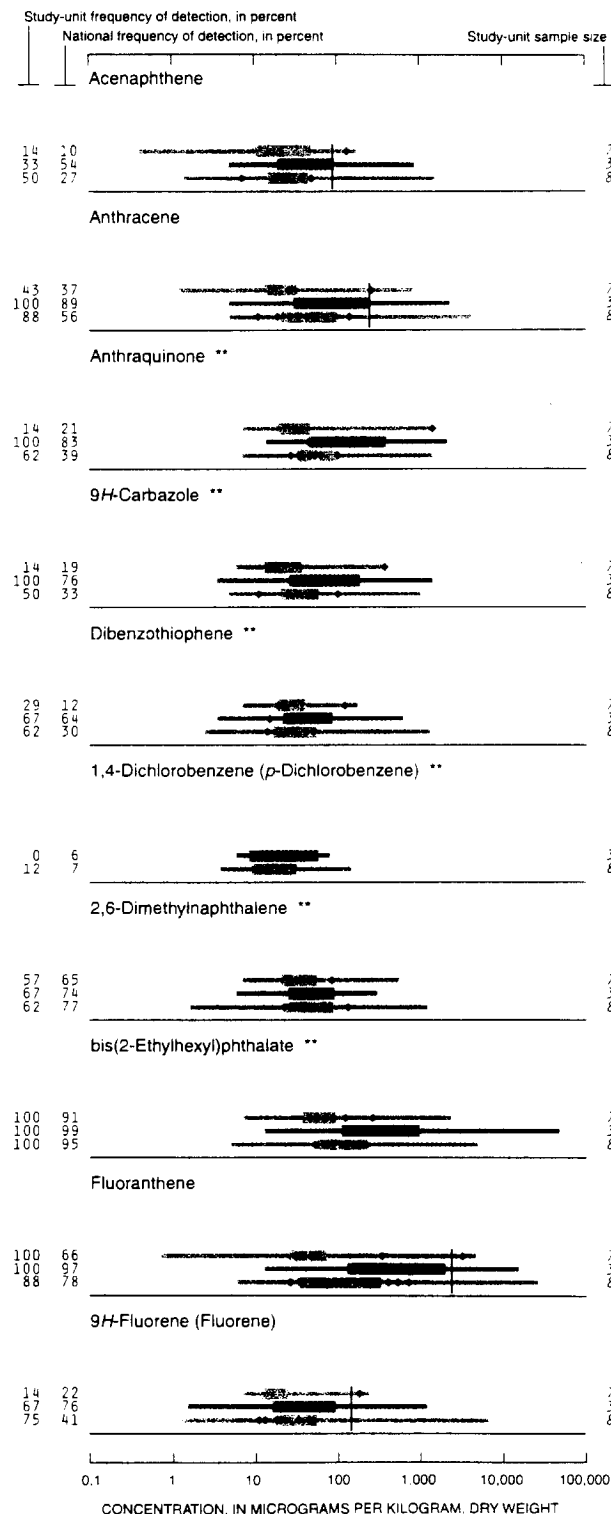

Other organochlorines detected

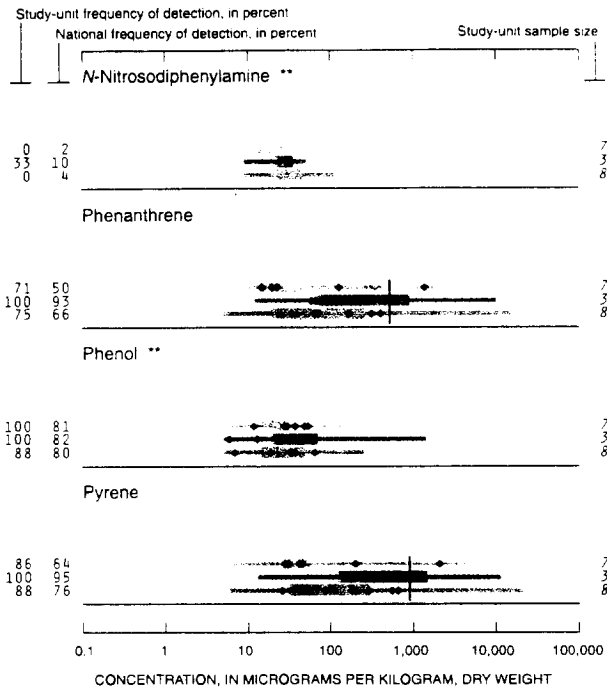

- DCPA (Dacthal, chlorthal-dimethyl) * **
- o,p'*+*p,p'*-DDT (sum of *o,p'*-DDT and *p,p'*-DDT) *
- Heptachlor epoxide (Heptachlor breakdown product) *
- Hexachlorobenzene (HCB) **
- Mirex (Dechlorane) **

Organochlorines not detected

- Chloroneb (Chloronebe, Demosan) * **
- Endosulfan I (alpha-Endosulfan, Thiodan) * **
- Endrin (Endrine)
- gamma-HCH (Lindane, gamma-BHC, Gammexane) *
- Total-HCH (sum of alpha-HCH, beta-HCH, gamma-HCH, and delta-HCH) **
- Isodrin (Isodrine, Compound 711) * **
- p,p'*-Methoxychlor (Mariate, methoxychlor) * **
- o,p'*-Methoxychlor * **
- cis*-Permethrin (Ambush, Astro, Pounce) * **
- trans*-Permethrin (Ambush, Astro, Pounce) * **
- Toxaphene (Camphechlor, Hercules 3956) * **

Semivolatile organic compounds (SVOCs) in bed sediment

Other SVOCs detected

- Acenaphthylene
- Acridine **
- Benzo[a]anthracene
- Benzo[a]pyrene
- Benzo[b]fluoranthene **
- Benzo[ghi]perylene **
- Benzo[k]fluoranthene **
- Butylbenzylphthalate **
- Chrysene
- p-Cresol **
- Di-n-butylphthalate **
- Di-n-octylphthalate **
- Dibenz[a,h]anthracene
- Diethylphthalate **
- 1,2-Dimethylnaphthalene **
- 1,6-Dimethylnaphthalene **
- Dimethylphthalate **
- 2-Ethyl-naphthalene **
- Indeno[1,2,3-cd]pyrene **
- Isoquinoline **
- 1-Methyl-9H-fluorene **
- 2-Methylanthracene **
- 4,5-Methylenepheneanthrene **
- 1-Methylphenanthrene **
- 1-Methylpyrene **
- Naphthalene
- Phenanthridine **
- Quinoline **
- 2,3,6-Trimethylnaphthalene **

SVOCs not detected

- C8-Alkylphenol **
- Azobenzene **
- Benzo[c]cinnoline **
- 2,2-Biquinoline **
- 4-Bromophenyl-phenylether **
- 4-Chloro-3-methylphenol **
- bis(2-Chloroethoxy)methane **
- 2-Chloronaphthalene **
- 2-Chlorophenol **

- 4-Chlorophenyl-phenylether **
- 1,2-Dichlorobenzene (o-Dichlorobenzene) **
- 1,3-Dichlorobenzene (m-Dichlorobenzene) **
- 3,5-Dimethylphenol **
- 2,4-Dinitrotoluene **
- Isophorone **
- Nitrobenzene **
- N-Nitrosodi-n-propylamine **
- Pentachloronitrobenzene **
- 1,2,4-Trichlorobenzene **

Trace elements in fish tissue (livers) and bed sediment

BIOLOGICAL INDICATORS

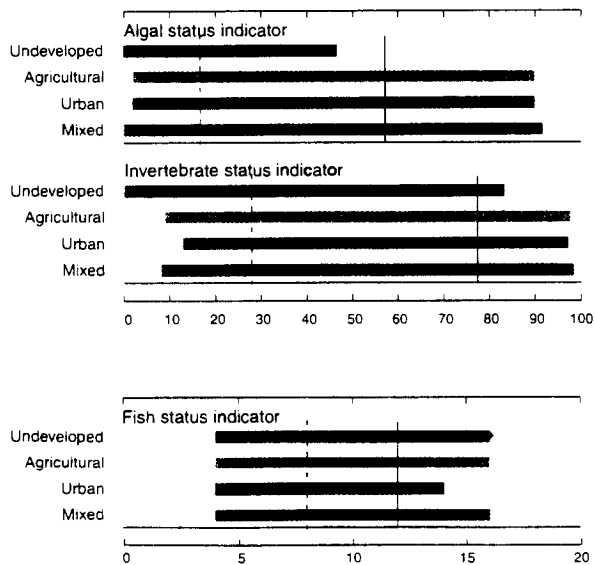

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation

Dear Sir or Madam:

We are pleased to enclose "Water Quality in Southern Florida, 1996-98," a publication from the U.S. Geological Survey Circular series which addresses water-quality issues of regional and national concern. This series is designed to present results on surface- and ground-water in major river basins across the Nation. The report presents significant findings on multiple nutrients and pesticides in surface and ground water from agricultural and urban areas. The conditions in south Florida were documented during 1996-98 for the Southern Florida study of the National Water Quality Assessment Program (NAWQA). Results indicate that the Everglades ecosystem has been altered by human activities.

We hope that the report will be useful to you and provide new insights on existing water-resource conditions in south Florida. If you or your organization would like additional copies of the report, or if you would like to discuss a particular aspect of the report or the NAWQA Program, please contact Ben McPherson, Chief of the Southern Florida NAWQA Program, by telephone at (813) 884-9336, by mail at U.S. Geological Survey, 4710 Eisenhower Blvd., Suite B-5, Tampa, FL, 33634, or by e-mail at bmcphers@usgs.gov.

We also encourage you to visit the NAWQA home page on the World Wide Web (<http://water.usgs.gov/nawqa>) to take advantage of other NAWQA products, including other publications, data sets, and maps of chemical use and occurrence. The site not only provides direct access to our national studies, but also to our individual assessments in more than 50 major river basins and aquifer systems across the Nation.

Thank you for your continued commitment to our Nation's water-resource needs.

Sincerely yours,

Carl R. Goodwin
USGS State Representative, Florida

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the southern Florida area studied by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program between 1996 and 1998. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings also are explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Southern Florida assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The southern Florida area is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Surface-Water Highlights

The environment in southern Florida is being degraded by human activities. Native biota have been reduced greatly in abundance and diversity by drainage, development, alteration of water flows, degradation of water quality, and by continuing invasions of exotic species. The Everglades ecosystem, which is adapted to water that has an extremely low phosphorus concentration, is being altered by agricultural activities that produce high levels of phosphorus in water. Nutrient loading in the major rivers is contributing to over-enrichment of Lake Okeechobee and estuaries such as Charlotte Harbor. Mercury has accumulated in Everglades game fish, and consumption of the fish poses a potential human health risk. Mercury has accumulated

in the Everglades food web because natural conditions and human influences enhance methylation of mercury to its organic form and because high atmospheric mercury deposition rates (among the highest in the Nation) sustain mercury methylation.

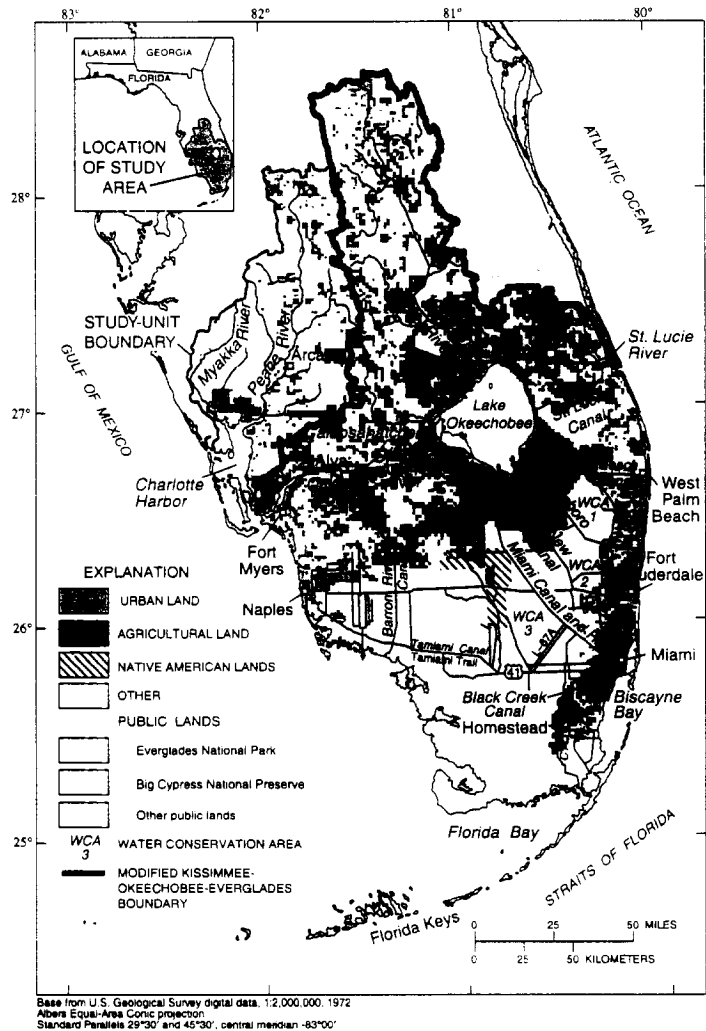

Federal and State agencies and environmental groups agree that parts of southern Florida should be restored to predevelopment conditions. Restoration will require massive changes in the water-management system to restore pre-development drainage patterns, improve water quality, and protect native biota.

Major findings on water quality and biology from this study:

- Concentrations of total phosphorus (TP) at the Southern Florida (SOFL) National Water-Quality Assessment (NAWQA) Program sites were above Everglades background levels and exceeded the U.S. Environmental Protection Agency's (USEPA) Everglades water-quality standard of 0.01 milligram per liter (mg/L). A major source of the high TP is fertilizer from agriculture.
- Concentrations of dissolved organic carbon (DOC) in southern Florida water were relatively high compared with those in other waters of the Nation. High DOC concentrations provide food for bacteria to grow, reduce light penetration in the water, and enhance transport and cycling of pesticides and trace elements such as mercury.
- Pesticides were detected in almost all SOFL samples. Most concentrations were below aquatic-life criteria; however, the criteria do not address potential effects of mixtures of

pesticides and their degradation products, which were common in the samples.

- Organochlorine pesticides, such as DDT and its degradation products, are still prevalent in bottom sediment and fish tissue at the SOFL sites, even though most uses of these compounds have been discontinued in recent decades. The mobilization of these pesticides by the reflooding of Everglades farm lands could lead to food-web contamination.
- Of 21 NAWQA basins nationwide, the Everglades has the second highest ratio of methylmercury to mercury in sediment. This enrichment in methylmercury enhances mercury uptake by the biota.
- The frequency of external anomalies (lesions, ulcers, and tumors) on fish collected at two SOFL agricultural canal sites was in the top 25 percent of

Urban, agricultural, Native American, public lands and other important features in the Southern Florida NAWQA Study Unit (McPherson and Halley, 1996).

144 NAWQA sites sampled nationwide. Anomalies can be indications that fish are stressed by contamination.

- Exotic animals and plants are a threat to native biota. Ten of the 54 exotic fish species established in the region were collected at the SOFL sites. Several herbicides used to control exotic plants were detected in surface water.

Major Influences on Surface Water and Ecology

- Drainage modifications and wetland destruction.
- Runoff from agricultural and urban areas.
- High concentrations of DOC and its effects on the transport of mercury and the attenuation of light.
- Deliberate or accidental release of exotic species.

Ground-Water Highlights

In much of the SOFL region, ground water in the surficial aquifers, such as the Biscayne aquifer, is of good quality and usually meets Federal and State drinking-water quality standards. Contaminants are usually in low concentrations, presumably because of rapid flushing and recharge as a result of high annual rainfall (about 55 inches) and shallow aquifers and porous limestone that allow the easy interchange of surface and ground water. However, because of the shallow aquifers and porous limestone, ground water is vulnerable to surface contamination and to saltwater intrusion.

Major findings on ground-water quality from this study include the following:

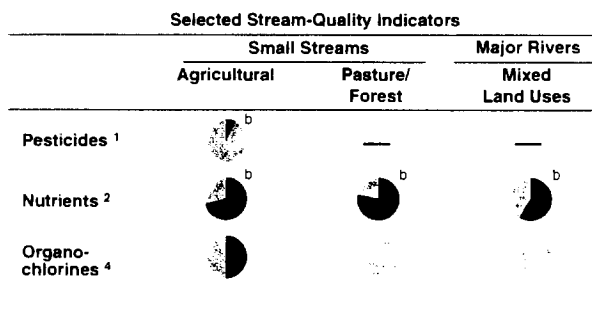

- Nitrate concentrations were below the drinking-water standard (10 mg/L) in 108 SOFL wells

(Biscayne and other surficial aquifers), except for two shallow wells in the unnamed surficial aquifer of the citrus area.

- Pesticides were detected in more than 85 percent of the SOFL wells and beneath every type of land use studied, but no concentrations exceeded any USEPA or State of Florida drinking-water standard.
- Pesticides detected in shallow ground water were associated with specific land uses. For example, the herbicides bromacil and norflurazon were detected almost exclusively in citrus areas. Metolachlor and simazine were common in mixed agricultural areas near the southern Everglades.
- Volatile organic carbon compounds (VOCs) commonly were detected in water from shallow and deep wells in the Biscayne aquifer. Concentrations of one industrial VOC, vinyl chloride, exceeded the USEPA maximum contaminant level (MCL) of 2 micrograms per liter ($\mu\text{g/L}$) for drinking water in two samples.
- Radon-222 radioactivity exceeded the proposed MCL (300 picocuries per liter (pCi/L)) in the majority of samples from the Biscayne aquifer, including untreated water from the public-supply wells.

Major Influences on Ground Water

- Porous, shallow limestone aquifers overlain by thin layers of sandy, permeable soils.
- Water-management practices involving canals, pumps, gates, locks, and saltwater-control structures.
- Agricultural and urban land-use practices and aquatic-weed control.

Percentage of samples with concentrations **equal to or greater than** a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or above a national goal for preventing excess algal growth (^a Percentage is 1 or less and may not be clearly visible)

Percentage of samples with concentrations **less than** a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or below a national goal for preventing excess algal growth

Percentage of samples with **no detection** (^b Percentage is 1 or less and may not be clearly visible)

Not assessed

¹ Insecticides, herbicides, and pesticide metabolites, sampled in water.

² Total phosphorus (TP) sampled in water. Aquatic-life guidelines based on USEPA Everglades standard of 0.01 mg/L TP for small Everglades streams and on USEPA national goal of 0.1 mg/L TP for major rivers.

³ Nitrate (as nitrogen), sampled in water.

⁴ Organochlorine compounds including DDT and PCBs, sampled in fish tissue.

⁵ Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water.

INTRODUCTION TO THE SOUTHERN FLORIDA NAWQA STUDY UNIT

The Everglades are remarkable for the quantity of the water there, which continually bubbles and ebbs clear as crystal. —Alonso Sotomayor, 1513, p. 11. Nov., Dec. 1911.

Both these grand rivers (Miami and Neuse) possess a gaily beautiful clear water, also the Florida (fringed on either side by the wild swamps of hammocks, pine and palmetto) forming the eastern scenery of the South. —W. MacGonigal, 1842, p. 10. National Geographic Magazine, Vol. 10, p. 10.

In the mid-1800s southern Florida was a lush, subtropical wilderness of pine forest, hardwood hammocks, swamps, marshes, estuaries, and bays. Wetlands dominated the landscape. The region contained one of the largest wetlands in the continental United States, the Everglades, which was part of a larger watershed—the Kissimmee-Okeechobee-Everglades—which extended more than half the length of the Florida peninsula (fig. 1). Wetlands of the Everglades, Big Cypress Swamp, and Mangrove and Coastal Glades stretched continuously across much of the southern part of the peninsula south of Lake Okeechobee (fig. 1). To the north, much of the Flatwoods physiographic province also was wetlands; upland habitats were primarily on the narrow Lake Wales and Atlantic Coastal Ridges.

Freshwater in the Everglades and other wetlands generally moved as

sheetflow in marshes, sloughs, and cypress strands. Numerous small streams and rivers near the coast, such as the Miami River, drained into mangrove forests and tidal waters and provided the freshwater that sustained the highly productive and abundant coastal fisheries around the southern end of the peninsula (McIvor and others, 1994).

The wetlands of southern Florida made much of the region inhospitable for human habitation. Settlers and developers in the late 1800s and early 1900s began to drain the wetlands for commercial and safety

reasons. Loss of lives as a result of hurricane flooding in the 1920s accelerated drainage projects. Today, many of the region's original wetlands have been drained. Water in the region is now intensively managed, with more than 1,400 miles of primary canals and more

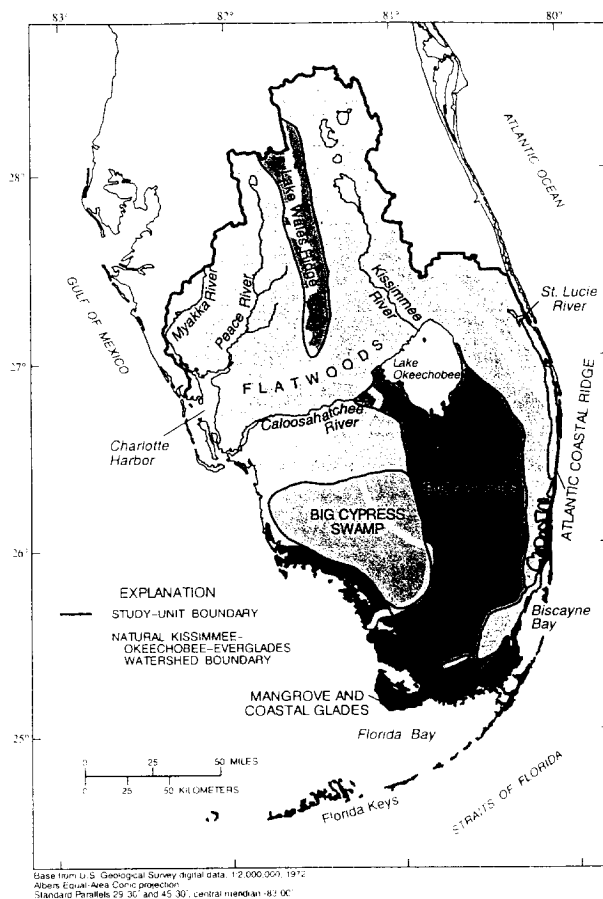

Figure 1. Physiographic provinces of southern Florida. (Modified from Davis, 1943; Parker and others, 1955.)

The Southern Florida (SOFL) National Water-Quality Assessment study encompasses about 19,500 square miles. It is part of a regional ecosystem that includes coastal waters between Charlotte Harbor on the Gulf of Mexico and the St. Lucie River on the Atlantic Ocean and the lands that drain into these waters. The elevation in the study area ranges from about 300 feet above sea level to sea level along the coast. It includes a large and rapidly growing urban population (about 5 million people) along the Atlantic coast and a less rapidly growing population (over a million people) along the gulf coast, areas of intense agricultural development around Lake Okeechobee and along the southeastern edge of the Everglades, and vast regions of wetlands, including the Everglades National Park (ENP), Big Cypress National Preserve, and other parks, preserves, and conservation areas that are mostly in public ownership. Ground water from the shallow, highly porous Biscayne aquifer is the source of most of the drinking water for the densely populated southeast coast.

Complex canal system in northern Everglades.

Northern Big Cypress Swamp.

than 100 water-control structures. The larger rivers, such as the Kissimmee and Caloosahatchee Rivers, have been canalized and controlled to enhance their ability to move water. About half the Everglades have been lost to drainage and development since the early 1900s; the remaining Everglades, included in the Everglades National Park (ENP), conservation areas, and the Loxahatchee National Wildlife Refuge, are protected from physical destruction, but it has been degraded by altered quantity, quality, and timing of freshwater inflows.

Drainage and development of wetlands have adversely affected water quality and ecology throughout southern Florida. Water

pumped into canals from agricultural lands commonly has high concentrations of nutrients and pesticides. The high nutrient concentrations and loads entering Lake Okeechobee and the Everglades from farms and cattle lands have degraded water quality. Phosphorus concentrations in Lake Okeechobee have increased two and one-half times since the 1970s, and massive algal blooms have become more frequent and persistent. The increased nutrient loading to the Everglades is stressing native vegetative communities. Sawgrass, which is adapted to a low-nutrient environment, is being replaced by cattails in parts of the northern Everglades where nutrient loading has been excessive. Drainage and development also has resulted in loss of peat soils, contamination by pesticides, saltwater intrusion into aquifers near the coast, mercury buildup in the biota, fragmentation of landscape, loss of wetland functions, widespread invasion by exotic species, increased algal blooming, seagrass die-off, and declines in fishing resources in coastal waters.

An abundant and uncontaminated supply of freshwater was a primary environmental characteristic of southern Florida in predevelopment times. Increased human population and activity have brought not only increased need for water but also a decrease in water supply and deterioration in water quality. These changes in the hydrologic system, wrought by growth and development, are thought to be the major causes of the substantial declines in the health of the remaining natural ecosystem.

A consensus has begun to emerge among environmental groups and Federal and State agencies that southern Florida, and particularly the Everglades, should be restored to the extent possible to the predevelopment ecosystem. A first and primary step in this undertaking is the restoration of predevelopment hydrologic conditions to the remaining natural system. Plans are to change the manmade water-conveyance system and restore the natural hydrologic cycle of the predevelopment Everglades as a means of contributing to overall ecosystem restoration.

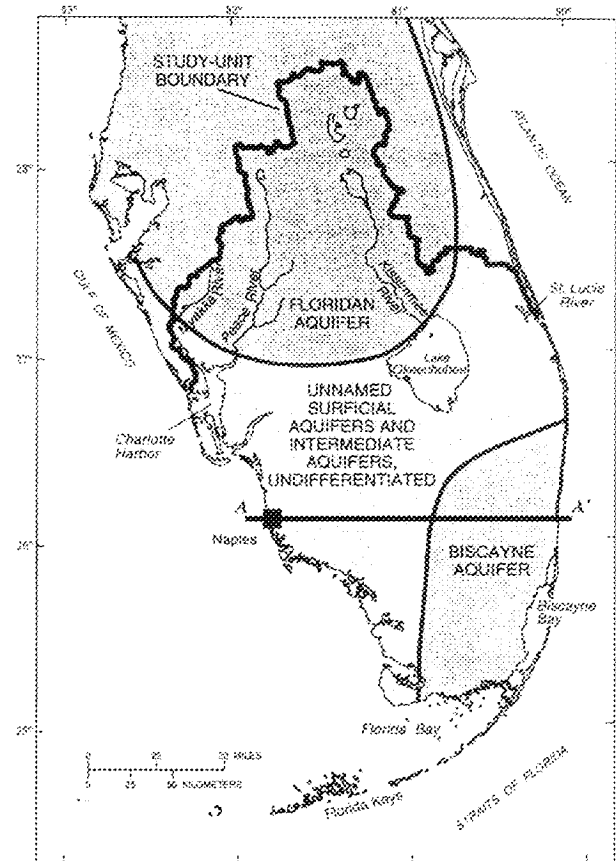

Aquifers and Water Use

Southern Florida, which is underlain by shallow marine carbonate sediments to depths of 20,000 feet, contains three major aquifer systems: the Floridan, the intermediate, and the surficial aquifer systems (figs. 2a,b). The confined Floridan aquifer system is the principal source of water for human use in the northern part of the south Florida area, but water from this aquifer is too mineralized for most uses in the southern part of the area. The semiconfining layers of the intermediate aquifer system, which overlies the Floridan, serves as the confining unit for the Floridan aquifer, a source of freshwater for public supply along the east coast. The surficial aquifer system includes the highly permeable Biscayne aquifer, which is the principal source of potable water for the more than 5 million people in southeastern Florida. The Biscayne aquifer has been designated as a sole source drinking water supply by the USFPA.

Most of the potable water supply in southern Florida is withdrawn from shallow aquifers, generally from wells less than 250 feet deep. Ground water supplied 94 percent of 2.2 million gallons per day (MGD) of the water used by most of the 1.8 million people in the SDF. South Florida 1990 Water Use Report (in 1991, 2,735 MGD) (USFPA, 1991). The USFPA also provides water for agricultural irrigation. Richard J. Marzullo, USFPA, "Groundwater Resources of Southern Florida," 1990.

Figure 2a. The three main aquifer systems of southern Florida.

Figure 2b. Generalized subsurface section A-A' showing aquifers of southern Florida (Klein and others, 1975).

Rainfall

Annual rainfall in southern Florida ranges from about 40 to 65 inches. The east coast usually receives the greatest amount of rainfall, whereas the Florida Keys

and areas near Lake Okeechobee and Charlotte Harbor usually receive the least. More than half the rainfall occurs from June through September and is associated with thunderstorms and tropical cyclones. Rainfall during the

remainder of the year usually is the result of large frontal systems and is broadly distributed rather than localized. April and May typically have the least rainfall. Annual and seasonal rainfalls vary from year to year (fig. 3).

Figure 3. Annual rainfall was above average during the 1996-98 sampling period. (Data from the National Oceanic and Atmospheric Administration's National Climate Center.)

HOW IS THE SOUTHERN FLORIDA NAWQA DIFFERENT FROM OTHER NAWQA STUDY UNITS?

- Drainage basins are poorly defined.
- Surface and ground water are closely connected.
- Sheetflow is common through the "River of Grass" and other wetlands.
- Surface-water flow in canals and rivers is highly managed and regulated.
- Organic soils (peats) are abundant, but much has been lost to oxidation.
- The farming season is in winter.
- Coastal meteorological effects often dominate.
- Tropical storms are common.
- Nutrient concentrations are naturally low in the Everglades and other pristine wetlands.
- Dissolved organic carbon concentrations are high.
- Water color is dark in some rivers and wetlands.
- There are extensive subtropical wetlands and public lands, including four national parks, preserves, or refuges.
- Many exotic species thrive in the subtropical climate.

MAJOR FINDINGS

Nutrient enrichment is prevalent in surface water

Water quality has been degraded in large parts of southern Florida by human activities that result in high nutrient concentrations and over-enrichment. Nutrient concentrations at the SOFL NAWQA sites are elevated when compared with Everglades background concentrations (see box below). The high nutrient concentrations, primarily from agricultural runoff, have contributed to overenrichment of surface water, including Lake Okeechobee, estuaries such as Charlotte Harbor, and the northern Everglades. The high phosphorus concentrations in agricultural runoff entering the northern Everglades are a significant cause of ecosystem degradation.

The USEPA recently (May 26, 1999) approved a new water-quality standard of 0.01 mg/L or less for phosphorus in the Miccosukee Federal Indian reservation lands of the Everglades. The State of Florida is reviewing additional scientific information and plans to adopt a numerical phosphorus standard for other parts of the Everglades.

Figure 4. Concentrations of total phosphorus (TP) at SOFL NAWQA sites during 1996–98 frequently exceeded the USEPA recommended goal of 0.1 mg/L and Everglades standard of 0.01 mg/L. Concentrations of TP at Everglades National Park reference sites were near or below 0.01 mg/L.

NUTRIENT CONCENTRATIONS VARY WIDELY IN SOUTHERN FLORIDA AND THE NATION

Concentrations of nutrients in surface water at the SOFL sites vary widely compared with national NAWQA median concentrations. Generally, the high nutrient concentrations in southern Florida are at canal and river sites north of the Tamiami Trail and are associated with agricultural activities. Concentrations of phosphorus in surface water of the more pristine Everglades (south of the Tamiami Trail) are more than an order of magnitude lower than national background concentrations. The Everglades ecosystem is adapted to water that has extremely low phosphorus concentrations and is being adversely affected by agricultural runoff with high concentrations of phosphorus. Concentrations of phosphorus in southern Florida are highest in the Peace River (fig. 4) and are well above national median concentrations. The high concentrations in the Peace River are associated with natural sources (phosphatic deposits) as well as mining and agricultural activities in the basin.

Concentrations of nutrients in shallow ground water at SOFL wells generally are lower than or comparable with the national background concentrations. Median con-

centrations of nitrate in the southern Florida wells are one-fourth the national background concentration and median concentrations of orthophosphate are comparable to the national background concentration. Concentrations of nutrients at the SOFL sites are plotted against corresponding national nutrient ranges for different land uses in Appendix A.

Nutrient concentrations of the national NAWQA and the SOFL NAWQA study areas, national background, and Everglades background sites in mg/L [SW, surface water; GW, shallow ground water; <, less than; --, no data]

Total phosphorus (SW)	0.12	0.006–0.79	0.1	<0.004
Total nitrogen (SW)	1.3	0.7–2.6	1.0	1.1
Nitrite plus nitrate (SW)	0.71	0.006–0.59	0.6	0.005
Ammonia (SW)	0.046	0.017–0.25	0.1	<0.015
Ammonia (GW)	0.02	0.24–0.438	--	--
Nitrite plus nitrate (GW)	1.85	<0.05–0.44	2.0	--
Orthophosphate (GW)	0.11	0.013–0.028	0.02	--

⁴Everglades National Park, site P-34, medians; data from South Florida Water Management District (1992).

Ground-water sampling, eastern Everglades C-111 agricultural basin.

All routinely sampled SOFL sites (BFS sites, see Glossary) had phosphorus concentrations that exceeded the USEPA Everglades standard of 0.01 mg/L, but the two southern sites, Canal C-111 and Tamiami Canal at bridge 105, had median concentrations near the 0.01-mg/L Everglades standard (fig. 4). The ENP reference sites had median phosphorus concentrations below 0.01 mg/L and are characteristic of pristine Everglades water.

Seasonal changes in total phosphorus concentrations often are related to changes in water levels

Figure 5. Total phosphorus concentrations increased as discharge and water levels declined at Tamiami Canal at Bridge 105, Big Cypress National Preserve.

and flows. Generally, concentrations were below 0.02 milligram per liter (mg/L) at the Big Cypress Swamp reference site (Br 105) during 1996–98, but increased to more than 0.10 mg/L as water flows and levels declined during the dry season (fig. 5). The increase in phosphorus concentrations occurs when fish, wading birds, and other aquatic organisms congregate in ponded waters and their wastes contribute nutrients to the remaining inundated areas. The relatively greater ground-water contributions to surface water during the dry season also may increase nutrient concentrations. The background marsh sites in the ENP had very low concentrations of phosphorus (less than 0.01 mg/L) throughout the

1996–98 sampling period, and effects of seasonal low water levels on nutrients were not evident.

The dominant source of phosphorus loading in southern Florida is fertilizer (fig. 6). Manure and atmospheric sources are also important in some subbasins. Annual phosphorus loads estimated for selected canals and rivers were highest in the Peace River and lowest in the eastern Big Cypress Swamp. Much more phosphorus has been transported seaward from the northern Everglades and Okeechobee basins by the Caloosahatchee River, St. Lucie Canal, and major canals of Palm Beach County than is transported seaward in the southern Everglades (Haag and others, 1996).

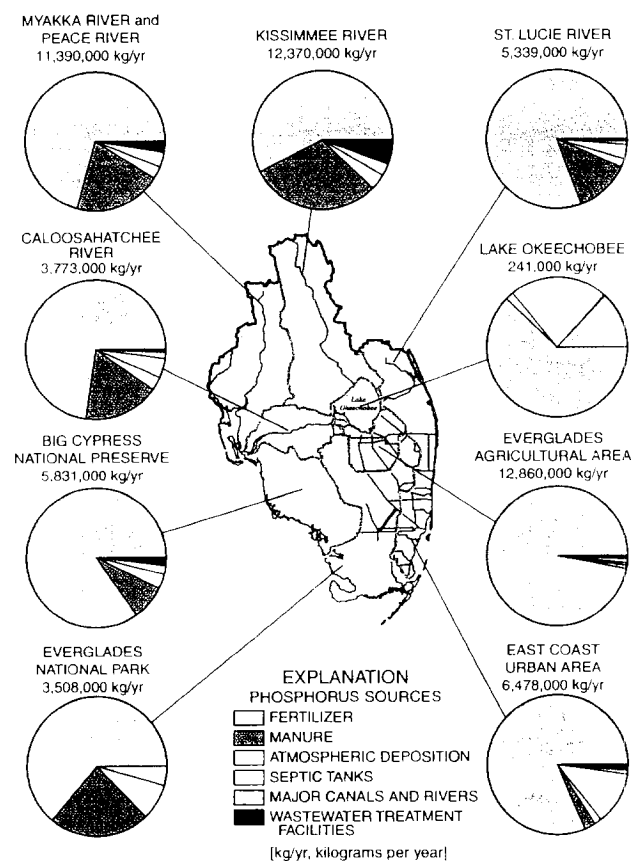

Figure 6. Estimated phosphorus loading from point and nonpoint sources in surface-water basins in southern Florida (Haag and others, 1996).

Nutrient concentrations in ground water are highly variable

High nitrate concentrations (greater than 10 mg/L) in drinking water can cause a life-threatening illness in infants known as "blue-baby syndrome." Nitrate concentrations in ground water were low (commonly not detected) in most of the 108 wells sampled in the SOFL Study Unit, but a few occasionally were elevated. In areas with agricultural land use. Wells located in or near the mixed-agricultural land-use area (including public-supply wells) tended to yield water with detectable concentrations of nitrate, but no nitrate concentrations exceeded the drinking-water standard of 10 mg/L. More than half of the wells located in citrus groves yielded water with no detectable nitrate concentrations, but two wells had nitrate concentrations above the drinking-water standard. With a few exceptions, shallow Biscayne aquifer wells in the urban land-use area contained water with relatively low concentrations of nitrate.

Ammonia concentrations in ground water in the SOFL Study Unit were relatively high compared with concentrations in other NAWQA Study Units across the Nation. The median ammonia concentration (0.396 mg/L) in the

SOFL citrus land-use survey was the highest of 47 NAWQA agricultural surveys nationwide. Median concentrations of ammonia in the SOFL urban and study-unit survey (public water supply) ranked second and fifth highest, respectively, in these categories nationally.

Dissolved phosphorus concentrations in SOFL wells ranged from 0.001 to 0.79 mg/L; most land-use areas had median concentrations less than 0.01 mg/L (table 1). Concentrations above 0.05 mg/L occurred in some wells in all land-use and public-supply surveys, but highest concentrations generally were in the deeper public-supply wells of the Biscayne aquifer and in the citrus land-use area. The source of the relatively high concentrations of phosphorus in ground water may be fertilizers or naturally occurring phosphatic materials associated with silt and clays.

Dissolved organic carbon concentrations are commonly high

Dissolved organic carbon (DOC) originates from natural sources, such as living and decaying plants, and from human sources. DOC represents about half the dissolved organic matter (DOM) in natural waters (Hem, 1985). In southern Florida, DOC concentrations commonly are high compared with

other natural waters in the Nation and may constitute, as DOM, a significant fraction of the dissolved solids (table 2).

Concentrations of DOC ranged from 4.8 to 52.0 mg/L at the SOFL surface-water sites, and from 0.6 to 80 mg/L at the ground-water sites (table 4). The highest DOC concentrations (median of 34.0 mg/L) occurred at Hillsboro Canal at S-6 in the northern Everglades down-gradient from the Everglades Agricultural Area, which has highly organic muck soils that are thought to be a source of DOC. In contrast, the Big Cypress Swamp reference site at Tamiami Trail Bridge 105 had the lowest concentrations (median of 9.5 mg/L) of the routinely sampled sites. This site is characterized by natural swamp vegetation and thin carbonate soils and rock. Concentrations of DOC at sites along the Tamiami Trail (1996-97) ranged from 4.8 to 26.9 mg/L (table 2), and tended to be low in the central and eastern Big Cypress Swamp and higher in the western Big Cypress and to the east in the Everglades (Miller and others, 1999).

The amount of DOC in water is significant. It can (1) contribute to water color, which absorbs sunlight and reduces the amount of light available for use by submerged aquatic plants and phytoplankton,

Table 1. Dissolved phosphorus concentrations varied widely in shallow wells in southern Florida during 1997-98. (Different detection levels were reported for different survey types during the period)

(2) serve as a source of carbon for bacterial growth; (3) form complexes with trace elements, such as mercury, and make them more soluble and mobile in water (Reddy and others, 1999); (4) reduce bio-availability of nonionic organic compounds through sorption, entrapment, or sequestering the compounds (Nowell and others, 1999, p. 296); (5) increase the solubilities of relatively insoluble compounds, such as p,p'-DDT, PCBs, and lindane (Chiou and others, 1986); and (6) react with chemicals used to disinfect public water supplies and produce undesirable by-products, such as chloroform and other trihalomethanes.

Naturally occurring dissolved organic matter (DOM) causes the tea-colored water in many of Florida's rivers and swamps. Water color can have significant ecological effects by decreasing available light in the water column and reducing algal and aquatic plant productivity and growth. In the Peace River and upper Charlotte Harbor, for example, color can contribute up to about half of the total light attenuation in the water column, and this high attenuation limits algal phytoplankton and seagrass growth (McPherson and Miller, 1987). The range in color for southern Florida water, including the NAWQA sites, is shown in table 3.

that may have harmful effects on human health.

Pesticides are present in most surface-water samples

Pesticides are widely used in southern Florida to control insects, fungi, weeds, and other undesirable organisms. These compounds vary in their toxicity, persistence, and transport. Some of the more persistent pesticides, such as DDT, chlor-dane, dieldrin, and aldrin, have been discontinued for use in Florida, but their residues persist in the environment. Although pesticides usually are applied to specific areas and directed at specific organisms, these compounds often become widely

Pesticide application in vegetable farming area.

distributed and pose potential hazards to nontarget organisms.

Intensive pesticide sampling (up to weekly sampling) was conducted at three SOFL sites (IFS sites, see Glossary) that represented three different agricultural land uses — mixed vegetable crops (C-111 basin), sugarcane (S-6), and citrus (U.S. Sugar). Pesticides were detected in all but one sample from the three intensive-sampling sites during 1996-98. The most frequently detected pesticides included those with highest annual application rates, such as the herbicides atrazine, bromacil, simazine, 2,4-D, and diuron. Atrazine, the most frequently detected pesticide overall, was detected in about 90 percent of all samples. The other most frequently detected pesticides overall were metachlor, simazine, tebuthiuron, norflurazon, bromacil, and diuron.

PESTICIDE DETECTIONS VARY WITH LAND USE IN SOUTHERN FLORIDA AND THE NATION

Different patterns of pesticide detections were evident in surface and ground water of the different land-use areas of southern Florida. For example, norflurazon and bromacil frequently were detected in citrus land-use areas but seldom detected in other agricultural and urban areas. Detections of prometon and fenuron were relatively high in the public-supply wells of the Biscayne aquifer but were much lower in other areas. Many of the same pesticides were detected in surface and ground water nationwide, but a few such as alachlor, cyanazine, and carbofuran were mostly absent in southern Florida. The most commonly detected pesticides, such as atrazine, simazine, and metolachlor, were more common in surface water than in ground water in both southern Florida and the Nation. Concentrations of selected herbicides at SOFL sites are plotted against corresponding national herbicide ranges for different land uses in Appendix A.

Concentrations of pesticides in water were seasonal and related to land use. Concentrations of atrazine peaked at all three sites in late winter and spring (fig. 7). Concentrations were highest at the S-6 site, where some samples had atrazine concentrations that exceeded the Canadian aquatic-life criterion of 2 µg/L and the USEPA MCL of 3 µg/L. Concentrations at the other two sites were significantly lower, with maximum values less than 1 µg/L.

A pesticide of particular concern, endosulfan, was detected mainly at the Canal C-111 site (fig. 8). Endosulfan was detected by the South Florida Water Management

Figure 7. Concentrations of atrazine at the Intensive Fixed Sites, August 1996–December 1998, showing similar seasonal occurrence patterns but different concentrations.

Figure 8. Concentrations of endosulfan at Canal C-111 at S-177, August 1996-September 1998.

Residential land near Fort Lauderdale.

District (SFWMD) over a number of years in the C-111 basin at levels considered to be a threat to aquatic life in the basin and in nearby Florida Bay (Miles and Pfeuffer, 1997). During the intensive sampling period of the SOFL study (1996-98), endosulfan concentrations were 0.05 $\mu\text{g/L}$ or less (fig. 8), which is just below the Florida Department of Environmental Protection criterion (0.056 mg/L) for Class III (recreation, propagation and maintenance of a healthy, well-balanced population of fish and wildlife) freshwater. Detections of endosulfan were frequent in 1996 but became less frequent in the following 2 years, as the use of this pesticide was discouraged and an alternate, imidacloprid, was introduced.

Mixtures of pesticides were common in samples from SOFL and other national NAWQA sites

The NAWQA Program uses Federal drinking-water standards and guidelines to assess the quality of drinking water in potential surface- or ground-water sources prior to treatment and distribution. This complements many ongoing Federal, State, and local monitoring programs that assess drinking water after treatment and distribution.

(see figure on page 13). The effects of pesticide mixtures on biota or humans are not included in criteria, which are based on the results of single-species, single-chemical toxicity tests conducted in the laboratory. As a result, analyses of individual pesticides may underestimate potential adverse effects of contaminants on biota (Nowell and others, 1999).

Regional patterns of pesticides, VOCs, and trace elements are evident in ground water

Pesticides were detected in ground water from more than 85 percent of the 108 SOFL wells and beneath every type of land use studied. No pesticide concentration

exceeded USEPA or State of Florida drinking-water standards or health advisories.

VOCs commonly were detected in water from shallow, residential land-use wells and deeper public-supply (study-unit survey) wells in the Biscayne aquifer (fig. 9). Vinyl chloride, trichloroethylene, *tetra*-chloroethylene, *cis*-1,2-dichloroethylene, and methyl *tert*-butyl ether (MTBE) were detected more commonly in the older residential and industrial areas and in public-supply wells near mixed agricultural lands. Toluene, *p*-isopropyltoluene, and 1,2,4-trimethyl-benzene commonly were detected in the newer residential areas and in public-supply wells near mixed agricultural lands. Two samples from public-supply wells in more industrial-

Figure 9. Percentages of common volatile organic carbons (VOCs) detected in water from shallow urban (residential) and agricultural wells and from deeper public-supply wells (see Study Unit Design on page 22 for locations).

ized areas had vinyl chloride concentrations (4.68 and 3.18 µg/L) slightly above the USEPA MCL of 2 µg/L.

Urban and agricultural activities are sources of trace-element contamination in ground water. Arsenic and copper are used as fungicides in citrus groves. Arsenic (in the herbicide monosodium meth-ane arsonate) is used in turf-grass maintenance on golf courses, and concentrations of arsenic in shallow ground water are sometimes elevated (Swancar, 1996).

Arsenic has been implicated as causing several cancers. Because of this health concern, the USEPA is considering lowering the MCL for arsenic from 50 to about 5 µg/L. Concentrations of arsenic in shallow ground water exceeded 5 µg/L in some of the urban and citrus land-use SOFL wells. Concentrations of copper in the SOFL ground-water samples reached 19 µg/L, which is well below the drinking-water MCL of 1,300 µg/L.

Uranium and radon-222, two naturally occurring radioactive

elements that are potential carcinogens, exceeded drinking-water standards in some shallow ground water in the SOFL Study Unit.

Uranium exceeded the MCL in 5 of 116 samples. Radon-222, a gaseous radionuclide that, when released to the air and inhaled is a significant cause of lung cancer, exceeded the proposed MCL of 300 picocuries per liter (pCi/L) in more than 75 percent of the samples from the Biscayne aquifer.

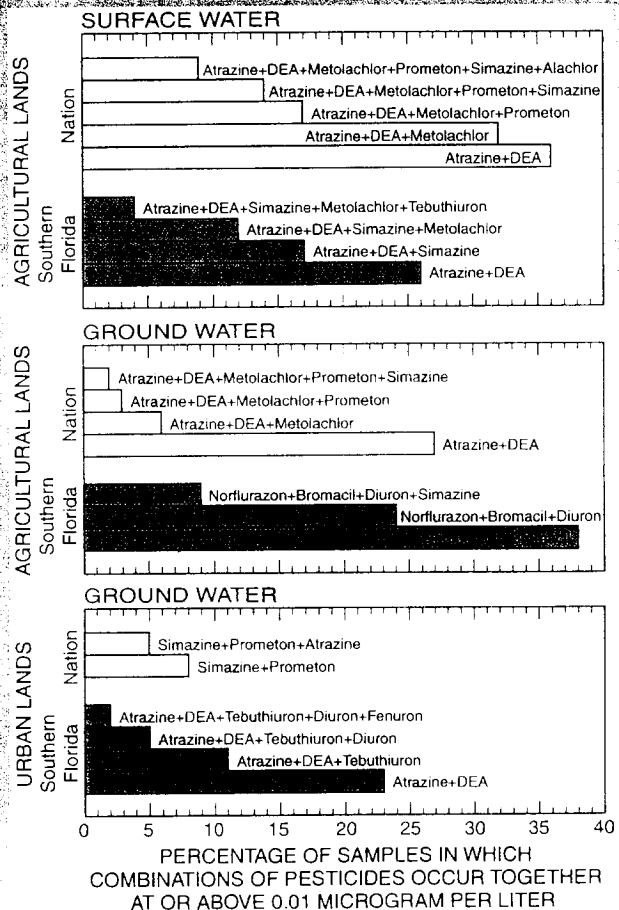

WHAT COMBINATIONS OF PESTICIDES OCCUR MOST FREQUENTLY IN SOUTHERN FLORIDA AND THE NATION?

The composition of the most common pesticide mixtures in surface water of agricultural areas in the SOFL Study Unit is similar to, but generally lower than, that of mixtures in agricultural areas nationwide. Atrazine, deethylatrazine (DEA), simazine, and metolachlor are found together most frequently in both southern Florida and the Nation.

Ground water in the SOFL Study Unit, however, has a different composition of pesticide mixtures than is found in ground water in other areas of the Nation. Norflurazon and bromacil were found together most frequently as mixtures in the SOFL Study Unit; these pesticides commonly are used on citrus crops.

The composition of the most common pesticide mixtures in ground water in urban areas in the SOFL Study Unit also differs from that throughout the rest of the Nation: the most common pesticides in mixtures were atrazine and DEA in the SOFL Study Unit compared with simazine and prometon nationwide. The atrazine and DEA in shallow ground water of the southern Florida urban study area may originate from local residential lawn herbicide applications or may be transported from nearby agricultural lands, either through the atmosphere or in canals. Canals that drain agricultural lands recharge shallow ground water in this urban area.

DEA is deethylatrazine. National data from U.S. Geological Survey, 1999.

Transport of Herbicides and their Breakdown Products

To evaluate the geochemical transport of herbicides, water and bed-sediment samples were collected in May 1997 and February 1998 from six SOFL sites (fig. 10) representing different land uses. The samples were analyzed after the methods of Thurman and others (1990) and Meyer and others (1993) for a suite of herbicides and breakdown products. Low levels (0.05 to 2.5 $\mu\text{g/L}$) of one or more herbicides were detected in water at all sites, including atrazine at every site. Other herbicides detected include ametryn, prometryn, and metolachlor at the sugarcane site, simazine and metolachlor at a mixed-agricultural (vegetable) site, and ametryn, simazine, and terbutryn at a citrus site. Atrazine (at trace levels) and ametryn (exceeding 40 micrograms per kilogram ($\mu\text{g/kg}$)) were detected in the sediment samples from the sugarcane site (S-6) in both years. The only other herbicides detected in sediments were trace levels of ametryn and alachlor at the mixed-agricultural (vegetable) site (Canal C-111). A breakdown product of alachlor, 2,6-diethylaniline, was detected in water at the same site. At the sugarcane site, S-6, the ratio of sediment-to-water concentration for ametryn was 240 (1997) and 580 (1998) and was zero for atrazine both years, which indicates that ametryn is transported primarily in sediment and atrazine is transported primarily in water.

The ratio of the concentration of deethylatrazine to the parent herbicide atrazine (DAR) has been used as an indicator of herbicide transport and surface- and ground-water interaction in the Midwestern States. Generally, a ratio greater than 1.0 indicates slow unsaturated zone transport and ground-water contributions to surface water (Adams and Thurman, 1991; Thurman and others, 1991; 1992). An elevated ratio also can be caused by photodecomposition of atrazine to deethylatrazine during atmospheric transport of herbicides (Goolsby and others, 1997). A ratio less than 0.1 indicates rapid overland-flow transport to surface water shortly after herbicide application. In southern Florida, DAR values were less than 0.1 at the sugarcane site (S-6), suggesting rapid transport of the herbicide into canal water shortly after herbicide application. The DAR at three other sites was between 0.1 and 1.0, which suggests post-application runoff. The DAR value of 1.0 at the background site (Br-105) presumably is from low-level atmospheric transport and photodecomposition because this site is remote from any farm runoff or ground-water sources of atrazine. The higher values above 1.0 at the citrus site (U.S. Sugar) and Canal C-111 at S-178 could indicate ground-water contributions (as in the Midwest) or more rapid photodegradation of atrazine in southern Florida because of higher temperatures, stronger sunlight, or greater soil organic carbon content and soil moisture than in the Midwest.

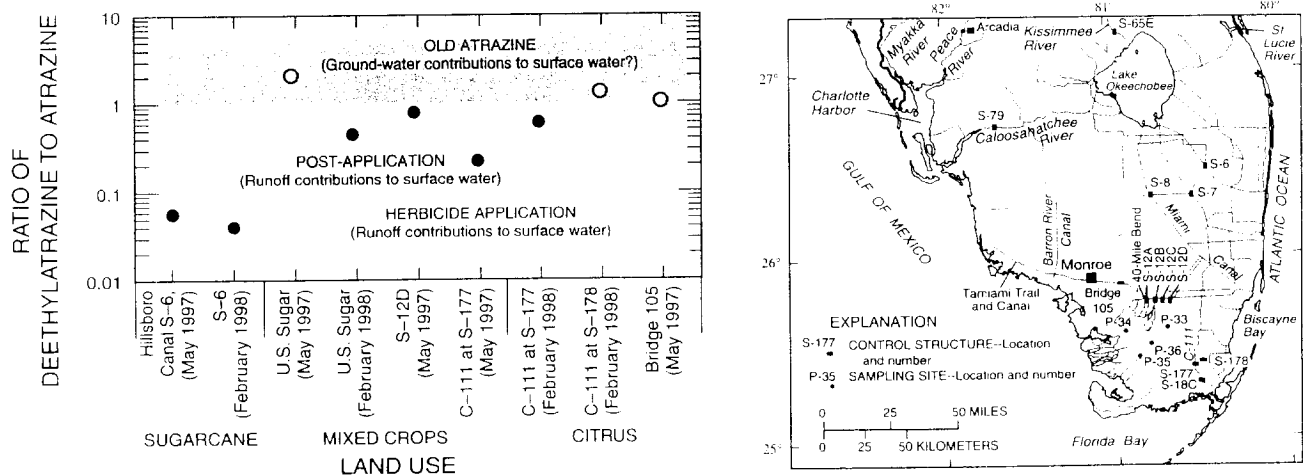

Figure 10. Ratio of deethylatrazine to atrazine (DAR) in surface water at selected sites, 1997–98 (M.T. Meyer, U.S. Geological Survey, written commun., 1998).

Pesticides, PCBs, other organics, and trace elements have accumulated in bottom sediment and fish

Many pesticides, other trace organic compounds, and trace elements are hydrophobic; that is, in aquatic environments they tend to be associated with sediment particles and biological tissues rather than dissolved in water. For this reason, sampling bottom sediment and fish is an effective way to assess the occurrence of these contaminants in the aquatic environment.

The most frequently detected pesticides in bottom sediment at the SOFL sites during 1996–98 were DDT and its breakdown products DDE and DDD, ranging from 2.4 to 670 micrograms per kilogram ($\mu\text{g}/\text{kg}$). DDE exceeded the Canadian sediment quality guidelines probable effects level (PEL) of $6.75 \mu\text{g}/\text{kg}$ (Environment Canada, 1999) at four of the seven fixed sites, including the Hillsboro Canal at S-6 ($308 \mu\text{g}/\text{kg}$) and the Kissimmee River at S-65E ($670 \mu\text{g}/\text{kg}$). More than 40 organic compounds were detected in bed-sediment from the Hillsboro Canal at S-6, including ametryn, chlordane, DDT compounds, dieldrin,

Row crops, C-111 basin, southern Florida.

endosulfan, and other semivolatile organic compounds, including polycyclic aromatic hydrocarbons (PAHs).

The most frequently detected pesticides in fish at 15 SOFL sites also were DDT and its breakdown products. Largemouth bass and (or) Florida gar were collected at each site, and one or more samples (5–8 whole fish) were analyzed for pesticides. DDT compounds were detected in 25 of the 27 composited fish samples. Concentrations of total DDT ranged from less than 5 to $1,170 \mu\text{g}/\text{kg}$ in Florida gar and from less than 5 to $610 \mu\text{g}/\text{kg}$ in largemouth bass. The most commonly detected and abundant DDT product was *p,p'*-DDE. Total DDT concentrations exceeded the $200 \mu\text{g}/\text{kg}$ guidelines (Newell and others, 1987) for the protection of fish-eating wildlife in 4 of 27 fish samples. Highest concentrations of total DDT were in canals of the northern Everglades near agricultural lands. For comparison, during 1970–73 concentrations of total DDT in 49 composite fish samples from 12 sites in southern Florida ranged from 6 to $800 \mu\text{g}/\text{kg}$. In 1978, total DDT concentrations in 23 fish samples ranged from 3 to $1,650 \mu\text{g}/\text{kg}$ (Haag and McPherson, 1997).

Fish sampling in Big Cypress Swamp as part of the southern Florida NAWQA study.

Other organochlorine compounds and PCBs detected in the composite whole-fish samples collected during 1995–96 include polychlorinated biphenyls (PCBs) and the pesticides dieldrin, mirex, and various compounds of chlordane (*cis*-chlordane, *oxy*-chlordane, *trans*-chlordane, *trans*-nonachlor, and *cis*-nonachlor). Maximum concentrations of pesticides occurred primarily in fish collected in Hillsboro Canal at S-6. PCBs were detected in three separate fish samples; the maximum concentration ($140 \mu\text{g}/\text{kg}$) was in fish collected from Black Creek Canal. Dieldrin and toxaphene were two other pesticides commonly detected in composite fish samples from the Everglades in the early 1970s. Concentrations of dieldrin in largemouth bass were as high as $130 \mu\text{g}/\text{kg}$, and concentrations of toxaphene were as high as $5,000 \mu\text{g}/\text{kg}$. In 1995, dieldrin concentrations ranged from less than 5 to $18 \mu\text{g}/\text{kg}$, and 5 of 27 fish samples had detectable dieldrin. Toxaphene was not detected in fish collected during 1995–96, but the analytical method was not very sensitive for toxaphene (only levels greater than $200 \mu\text{g}/\text{kg}$ could be detected).

The types and amounts of pesticides used in Florida have changed over the years because of new technology, land use, and State and Federal regulations. One of the most frequently detected herbicides in bed sediment in southern Florida, ametryn, is used in relatively small amounts on sugarcane crops (6 tons per year [tons/y]) (Miles and Pfeuffer, 1997). By far, the greatest frequency of insecticide detection was the organochlorine insecticides, such as DDD, DDE, DDT, dieldrin, and heptachlor. DDT was banned for most uses in the Nation in 1973. These insecticides also are the most frequently detected pesticides in bottom sediments (Shahane, 1994). Although most organochlorine pesticides such as DDT and chlordane are no longer sold in the United States, they persist in the environment and continue to pose potential threats to wildlife and humans. Persistent organochlorine pesticides were detected beginning in the late 1960s and early 1970s (Kolipinski and Higer, 1969; McPherson, 1973) in bottom sediment and fish that are a part of the food chain in the Everglades. Reflooding of farm lands for Everglades restoration potentially could lead to mobilization of persistent organochlorine pesticides and foodweb contamination, as occurred in Lake Apoka just north of the study area. Many organochlorine pesticides and PCBs also have been linked to hormone disruption and reproductive problems in aquatic animals (Colborn and others, 1993).

Polynuclear aromatic hydrocarbons (PAHs) are contaminants in soils and sediments and originate from such sources as crude oil and tar and from forest fires and incom-

plete combustion of fossil fuels. Bottom-sediment samples were collected at 10 sites in a survey of the Barron River Canal in 1998 to evaluate the occurrence of PAHs and other semivolatile organic compounds in the vicinity of the Big Cypress National Preserve (Miller and McPherson, U.S. Geological Survey, in press). PAHs normalized to organic carbon had patterns of distribution that indicated sources to be roads, vehicles, or an old creosote wood-treatment facility. Concentrations of phthalate esters and the trace elements arsenic, cadmium, and zinc in the Barron River Canal appear to have a nonpoint source and to be influenced by local bed-sediment properties, such as sediment particle size and organic content. At some Barron River Canal sites, lead, copper, and zinc, normalized to aluminum, exceeded background levels and may be enriched by human activities. Trace elements in bottom-sediment samples from the Barron River Canal sites did not exceed the Canadian PEL for freshwater sediment.

Mercury is a contaminant in the Southern Florida Study Unit

Game fish in the Everglades have concentrations of mercury that exceed recommended levels (1.5 micrograms per gram, $\mu\text{g/g}$) for human consumption (Ware and others, 1990; fig. 11). The maximum concentrations of mercury found in edible portions of largemouth bass (4.4 $\mu\text{g/g}$) collected from the Everglades exceeded mercury concentrations in game

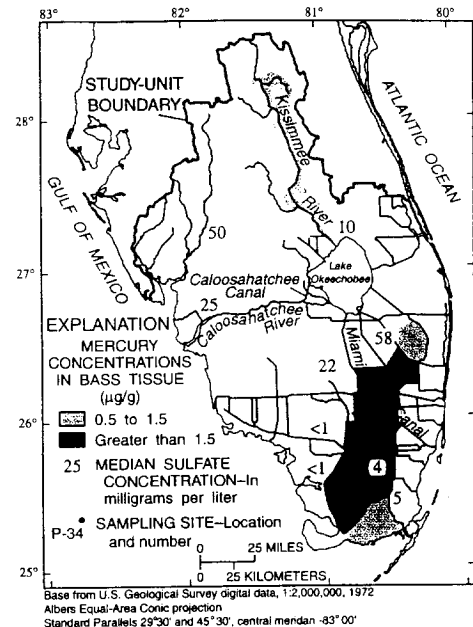

Figure 11. Mercury concentrations in largemouth bass tissue equaled or exceeded 0.5 $\mu\text{g/g}$ in an area in southern Florida. (Lambou and others, 1991). Median sulfate concentrations at SOFL sites, P-33 and P-34, in mg/L, 1996-98 (P-site data from South Florida Water Management District).

fish from all other parts of the State (Stober and others, 1995). The NAWQA Program specifies that trace elements (including mercury) be determined for fish livers. Thus, the data are not directly comparable to data from studies analyzing fish filets (the edible portion of the fish). Mercury concentrations in composite samples of largemouth bass livers from the SOFL sites ranged from 0.4 $\mu\text{g/g}$ in Black Creek Canal to 42 $\mu\text{g/g}$ in Miami Canal at S-8. Mercury concentrations in Florida gar livers ranged from 2.1 $\mu\text{g/g}$ in the Caloosahatchee River at Alva to 190 $\mu\text{g/g}$ in the Miami Canal at S-8. Largemouth bass and gar are top predators; on average, mercury concentrations in gar livers were about four times higher than mercury concentrations in largemouth bass livers.

Figure 12. High concentrations of mercury in Everglades fish, birds, and other organisms is a result of food web bioaccumulation of methylmercury, which originates primarily at the sediment and periphyton-water interface (modified from Krabbenhoft, 1996).

The high concentrations of mercury in fish result from food-web bioaccumulation of methylmercury, the most biologically available form of mercury in the environment (fig. 12). Buildup in the Everglades food web begins with high rates of bacterial mercury methylation at the sediment-water interface and subsequent transport of methylmercury from this interface into the water column. The Everglades region had one of the highest methylmercury to mercury ratios in sediment of the 21 NAWQA basins sampled in 1998 (Krabbenhoft and others, 1999a).

Mercury methylation rates in the Everglades are affected by complex physical-chemical-biological processes that vary widely from day to night, from season to season, and along spatial gradients. Two of the most important controls on mercury methylation are availability of sulfur and bacterial cycling of sulfur. Sulfur inputs to the Everglades have increased over background levels during the 20th century as a result of runoff containing agricul-

tural fertilizers. Large inputs of sulfur in parts of the northern Everglades have stimulated sulfate reduction that would normally favor methylation, but very high levels of sulfide in the eutrophic areas have an inhibitory effect on methylation rates. Lower levels of sulfur contamination in the central Everglades (fig. 11) have increased sulfate reduction and mercury methylation without the inhibitory effects of excess sulfide on methylation rates (Benoit and others, 1999; Orem and others, 1999, p. 79). Concentrations of mercury are higher in fish and other organisms in the more remote and low-nutrient waters of the central and southern Everglades than in the high-nutrient waters of the northern Everglades (Cleckner and others, 1998; Gilmour and others, 1998; Hurley and others, 1998).

Degradation of methylmercury also is a dynamic process that varies from day to night and spatially across the Everglades. Microbial demethylation rates in the sediments do not show strong spatial patterns, whereas photo-

demethylation rates in the water column do show a strong north to south upward trend, ranging from 2 to 15 percent per day, as a result of decreasing DOM in the water column from north to south and the resulting increase in light penetration in the south (Krabbenhoft and others, 1999b).

Atmospheric sources supply mercury that sustains methylation and food-web biomagnification in the Everglades. The southern Florida area has one of the highest atmospheric mercury deposition rates (25 micrograms per square meter per year, $\mu\text{g}/\text{m}^2/\text{y}$) in the United States (Krabbenhoft and others, 1999a). Atmospheric inputs have local sources, such as medical, municipal, and industrial incinerators, landfills, power plants, and other urban activities, and global sources. Local sources are considered by most investigators to be primarily responsible for the relatively high atmospheric mercury inputs in southern Florida.

Biological communities are influenced by water quality

The distribution of fish, invertebrates, and algae within a river or canal is influenced by natural conditions and human activities that affect water quality and available habitat. Generally, a diverse aquatic community composed of a variety of species and dominated by no single species or group of species is an indicator of favorable biotic conditions and an absence of contaminants and other environmental stresses. Although human activities have caused significant changes in many southern Florida freshwater habitats, it is important to understand how unique natural conditions in southern Florida influence the composition of aquatic communities there.

Sixty-three species of fish in 26 families were collected in the seven canals and rivers sampled in the SOFL Study Unit during 1996–98. The fish community included 43 native species and 10 exotic or non-native species. Additionally, 10 species of marine fish that periodically inhabit portions of canals and rivers in southern Florida also were collected. The chemical composition of freshwater in southern

Florida, in particular the concentrations of sodium, chloride, and calcium, facilitates the invasion and occasional establishment of fishes with broad salinity tolerance (Loftus and Kushlan, 1987). No fish species listed as threatened or endangered in the United States or Florida were collected in southern Florida during the NAWQA study.

Florida rivers have smaller drainage basins and fewer fish species than rivers in the adjacent Southeastern United States (Swift and others, 1986). Natural conditions, in this case the repeated rise and fall of sea level over geologic time, have reduced the number of freshwater fish species in the Florida peninsula. The present fish community represents the most recent reinvasion following sea-level withdrawal (Bass, 1990). The most important natural factors limiting the diversity of the fish community are unsuitability of habitat and climate for temperate species (Loftus and Kushlan, 1987).

The rivers in southern Florida have very low gradients, typically only a few inches per mile (McPherson and Halley, 1996), as well as slow current velocities, high water temperatures, and low

dissolved-oxygen concentrations. Fish and invertebrate communities are characterized by species that prefer these conditions and by the absence of related species that are found only in cool, swiftly flowing, well-oxygenated streams. The number of fish species collected at SOFL sites, or the species richness of the community, tended to increase with increasing mean annual dissolved-oxygen concentrations. Some game-fish species, such as bass, were absent at sites with the lowest dissolved-oxygen concentrations. One entire group of invertebrates (Plecoptera: stoneflies), which prefer cool running waters, usually are not found anywhere in the waters of southern Florida. Diptera (true flies) was the dominant insect group at all sites (fig. 13). Many of the Diptera were species in the family Chironomidae (midges), which are adapted to aquatic environments with sandy substrates and very low dissolved-oxygen concentrations, such as those prevalent in southern Florida surface waters. Species in this family are also tolerant of nutrient enrichment and contaminants.

Figure 13. Diptera (true flies) dominated the insect community at the Southern Florida National Water-Quality Assessment Study Unit Sites, 1996–98.

In the canals and some of the rivers of southern Florida, habitat alteration is significant. The canal channels are rectangular in cross-section, and they have been channelized and are routinely dredged to facilitate navigation and the movement of water. There are few areas of shallow water (littoral zone) to provide sufficient light for attached algae (periphyton) and suitable spawning areas for fish. Moreover, aquatic vegetation is periodically removed for water-management purposes, further reducing habitat for small fish and invertebrates that serve as food for fish. The species richness of fish and the total numbers of fish collected generally were lowest in the canals of southern Florida in basins with agricultural land use (fig. 14). The canals and channelized rivers have little suitable habitat of any kind for many aquatic insects that prefer hard substrate, such as caddisflies (Trichoptera) and some mayflies (Ephemeroptera); snags (woody debris) are scarce because bankside vegetation is usually cleared, and hard surfaces, such as rock, are limited to porous limestone outcroppings.

Fish can be categorized on the basis of their ability to tolerate a range of environmental conditions. There were no intolerant fish species collected in any of the canals in southern Florida (fig. 14). The presence of intolerant species in the Peace River during the SOFL study, as well as in earlier studies (Champeau, 1990), indicates favorable biotic conditions. The Peace River is unique among the rivers sampled in southern Florida because it has not been

channelized, and the main channel is connected to the flood plain during periods of high water. The flood plain provides a refuge for fish during high flow, perhaps enhancing survival and reproduction. Also, periodic flooding results in input of particulate organic matter and dissolved organic carbon from the flood plain, which increases the productivity of the river and increases its ability to support a diverse fish community.

The environmental conditions in the Peace River also supported a diverse aquatic insect community compared to most other SOFL sites (fig. 13). For example, the Peace River had the highest mean dissolved-oxygen concentration of any southern Florida site. Hard substrates, such as the woody snags preferred by many aquatic insects, were abundant. Seasonal input of leaf debris (particulate organic matter) from the flood plain provides a valuable food source for many aquatic invertebrates. In contrast, Hillsboro Canal, a relatively degraded SOFL site, had insects from a number of different groups, but few of the pollution-

sensitive insects, including caddisflies, were present.

In many parts of the United States, the abundance of a group of invertebrate taxa referred to as the EPT taxa (Ephemeroptera, Plecoptera, Trichoptera) is used to assess the biotic condition of streams and rivers. Species in these insect groups generally thrive in conditions of flowing water, moderate to high dissolved oxygen, and low suspended sediment and are intolerant of contaminants and habitat disturbance. The relative abundance of EPT taxa compared to the more tolerant Diptera taxa can be used to assess and compare sites. However, this metric must be used with caution because Plecoptera usually are not found in southern Florida. The Peace River had the highest EPT/Diptera ratio compared to the other SOFL sites. The Peace River also supported a diverse algae community with the greatest species richness (220 species) of all the SOFL sites. Total phosphorus and nitrogen concentrations were high in the Peace River compared to other SOFL sites because of natural conditions and human activities. The avail-

ability of these essential nutrients, combined with an unmodified habitat and more shallow-water areas, may contribute to a more diverse algal community.

The Tamiami Canal is unique among the SOFL canal sites because land within its basin is mostly undeveloped, limiting the input of contaminants. However, the environmental conditions are stressful because the shallow canal has almost no flow, the water is warm, and dissolved-oxygen concentra-

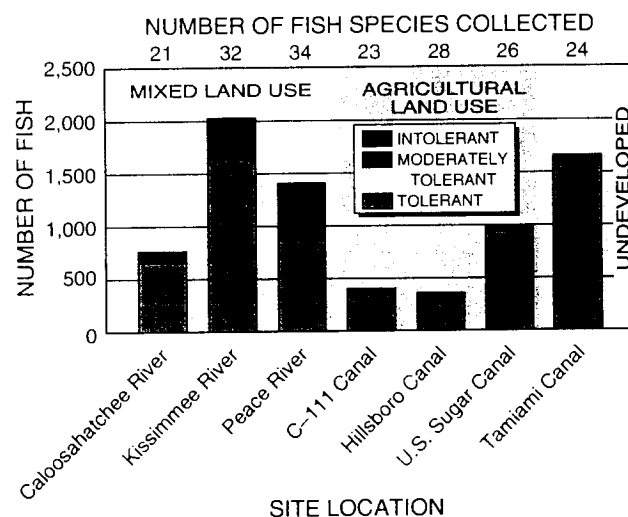

Figure 14. Environmentally tolerant fish are common in southern Florida canals and rivers.

tions typically are very low. Nutrient concentrations were among the lowest of the SOFL sites. The insect community was dominated by Diptera, although some Trichoptera that are adapted to still or slow-flowing conditions were collected. Bluegreen algae were relatively abundant. The fish community showed little similarity to any of the other sites and was

characterized by an abundance of minnows and Florida gar. The Tamiami Canal had the smallest proportion (5 percent) of fish with external anomalies. External anomalies, such as eroded fins, lesions, ulcers, tumors, and external parasites, can be an indication that fish are stressed by environmental conditions or contaminants. The highest

percentages of fish with external anomalies were from the Hillsboro (32 percent) and C-111 Canals (22 percent). Anomalies at these two sites were primarily external parasites, eroded fins, and anatomical deformities. These two sites were in the top 25 percent of 144 NAWQA sites sampled nationwide.

SOUTHERN FLORIDA AQUATIC COMMUNITIES IN A NATIONAL CONTEXT

Algae Siltation Index

Algae collected at the seven southern Florida NAWQA sites were compared to algae at 140 national NAWQA sites by using the Siltation Index (Bahls and others, 1992). This index is the relative abundance of the motile diatoms *Navicula*, *Nitzschia*, *Cylindrotheca*, and *Surirella* in a diatom count. These diatoms are able to move through silt particles, and because they are able to avoid being buried, they are considered more tolerant of sedimentation than other diatoms. The values for this index are higher for streams in agricultural basins. Based on the relative abundance of these diatoms, the undeveloped Southern Florida site (Tamiami Trail Canal) falls into the less degraded stream category, whereas the agricultural sites are between the 25th and 50th percentile, and two of the three major river sites in the mixed land-use category are near or above the 75th percentile. See pages 18–20 for how algae communities compare at sites within the SOFL Study Unit.

Invertebrate Community Status Index (ICSI)

Invertebrate communities at the seven southern Florida NAWQA sites were compared to invertebrate communities at NAWQA sites nationwide by using a multimetric index. The index combines 11 metrics, including ones that assess taxa richness and diversity, taxa richness of mayflies, stoneflies, and caddisflies, and various measures of environmental tolerance. Using the ICSI, all seven of the Southern Florida sites ranked above the 75th percentile, indicating that they are among the most degraded sites in the Nation. Use of the ICSI in southern Florida must be approached with caution because background environmental conditions prevalent at all sites, including slow water velocities and low dissolved-oxygen concentrations, probably contribute to the high index values and may obscure differences in invertebrate communities because of other factors, such as land use or changes in habitat. The dominance of Diptera (true flies), insects that are tolerant of degraded environmental conditions, and low diversity of insects overall contribute to the high ICSI scores for Southern Florida. See pages 18–20 for how insect communities compare at sites within the SOFL Study Unit.

Fish Status Index

To facilitate comparisons, fish collected at NAWQA sites across the Nation were classified based on four fish metrics (percentage of tolerant, omnivorous, non-native individuals, and percentage of individuals with external anomalies). Nationwide, higher values suggest a more degraded stream site. Six of the SOFL sites, including the reference site, ranked in the highest 25th percentile category for the Nation. Environmental conditions mentioned above for invertebrates also may contribute to stress in the fish community at sites including the reference site. This environmental stress can lead to dominance of tolerant fish, favorable conditions for exotic species, and increased external anomalies at some sites in the SOFL Study Unit, leading to higher values compared with other sites nationwide. See pages 18–20 for a discussion of how fish communities compare at sites within the SOFL Study Unit.

Exotic species are a threat to native biota

Exotic or non-native species of fish, as well as other animals and plants, represent a major threat to native biota in southern Florida. Exotic fish compete with native species for food and habitat. Exotic plants crowd out native species and can form dense monocultures that alter habitat for birds, fish, and other native biota. Ten exotic fish species were collected at the SOFL sites during 1996–98 (fig. 15). Cichlids were the most numerous and widespread exotic species, including the black acara, Mayan cichlid, peacock cichlid, blue tilapia, spotted tilapia, and the oscar. The other exotic species collected (pike killifish, grass carp, walking catfish, and sailfin catfish) were all rare and found at only one or two sites each. Fifty-four exotic fish species have been recorded in southern Florida, and the total statewide exceeded 125 species by 1998 (Fuller and others, 1999). Nearly all the exotic fish species were originally imported for the aquarium trade and either escaped from fish farms or were released by individuals with home aquariums. Exotic fish usually are most abun-

dant in streams that have been altered by human activity (Moyle, 1986). Generally, the canal sites in southern Florida had more exotic species than the major rivers. The number of species of exotic fish at SOFL sites ranked in the top one-third of NAWQA sites nationwide.

The swamp eel (*Monopterus albus*), recently introduced from Southeast Asia, is a potentially dangerous invader. The swamp eel can breathe air for extended periods of time, enabling it to inhabit stagnant water and even live out of water. This characteristic also enhances its ability to disperse widely. It is a voracious general predator, making it a threat to native fishes, amphibians, and aquatic invertebrates. The swamp eel was not collected at any of the SOFL sites during 1996–98. However, this species has affected regional water-management practices. Selected water-control structures in the vicinity of established populations are not being opened to prevent or at least retard dispersal, particularly into waters of ENP.

In addition to fish, other exotic species are of great concern in Florida. At least 25 percent of all plant species in the State are exotic

Figure 15. Exotic fish species were collected at all SOFL sites, 1996–98.

(Langeland, 1998). Melaleuca, a wetland tree, covers almost 400,000 acres in the State and is particularly troublesome in the Water Conservation Areas (Laroche, 1994). Brazilian pepper, a wetland shrub, has infested more than 100,000 acres in the ENP (Ferriter, 1997). Hydrilla, water hyacinth, water milfoil, and water lettuce are the most abundant exotic aquatic plant species infesting canals throughout southern Florida. Efforts to control or eradicate exotic plant species involve the use of mechanical, chemical, and biological control methods. Numerous herbicides are applied, including 2,4-D, copper sulfate, diquat, endothall, fluridone, glyphosate, imazapyr, triclopyr, and others. At least two of these compounds (2,4-D and triclopyr) have been detected in surface water at the SOFL sites.

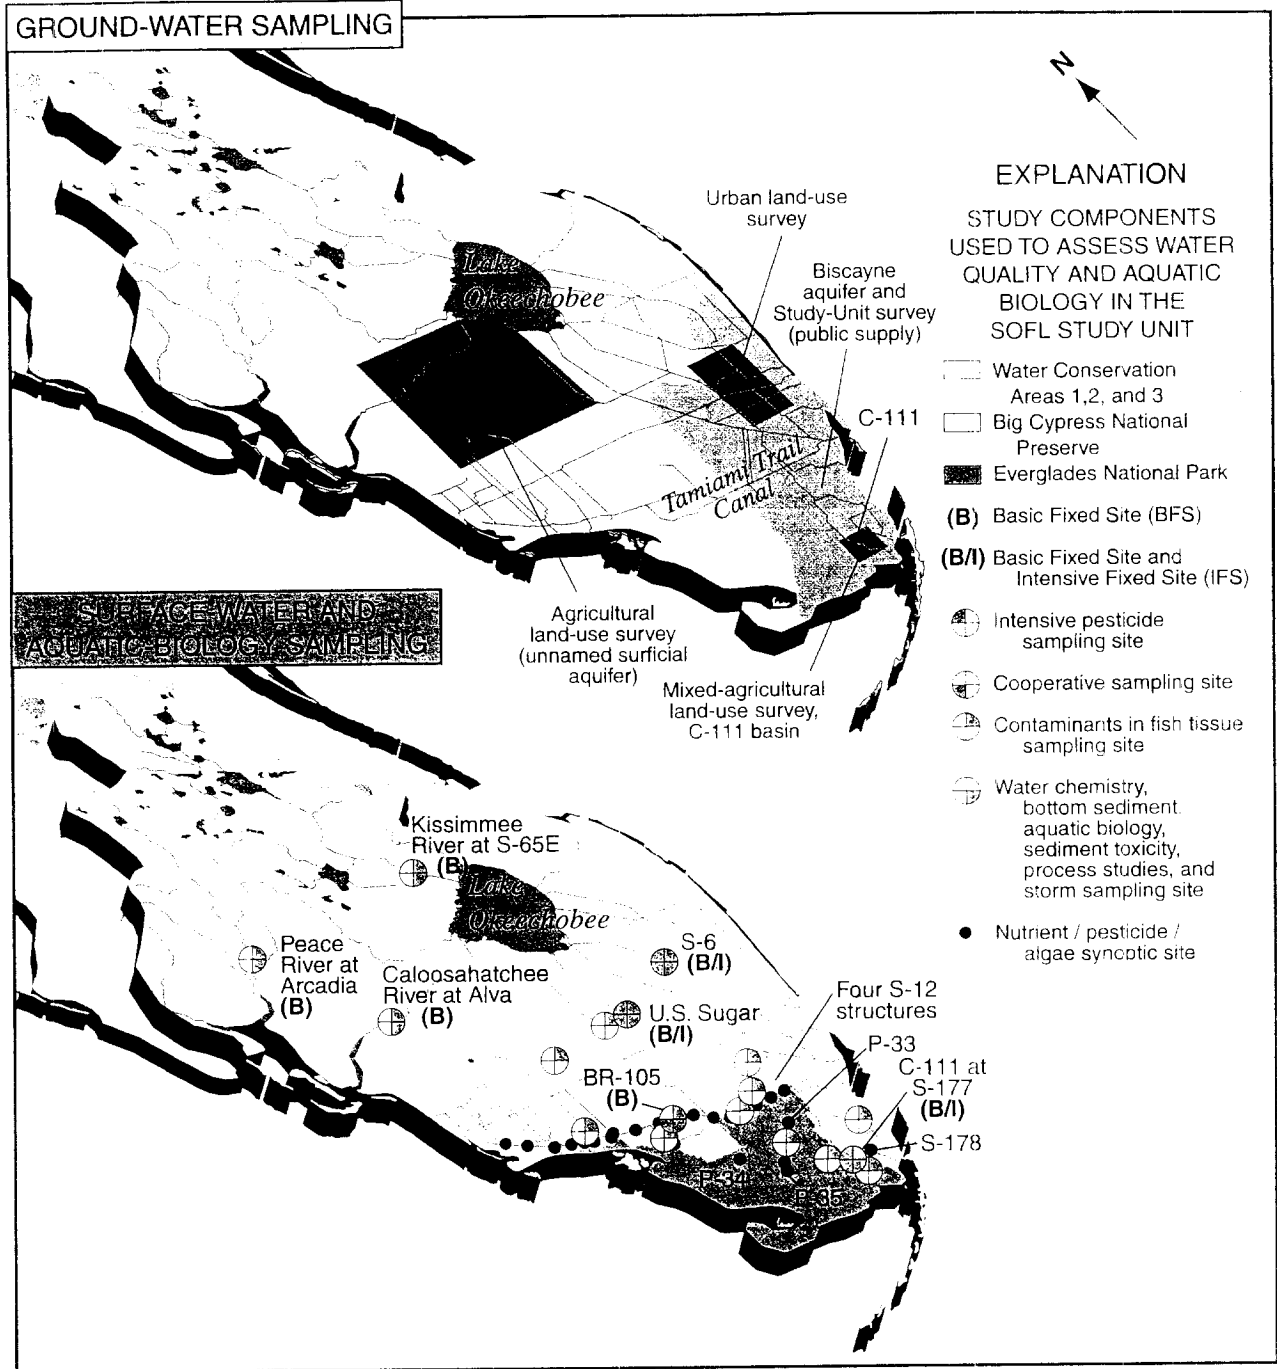

The exotic sailfin catfish, *Pterygoplichthys disjunctivus*, is a South American invader.

The Asian swamp eel, *Monopterus albus*, continues to spread.

STUDY UNIT DESIGN

Study component (Type of site)	Objectives	Brief description and water-quality parameters	Number of sites	Sampling frequency during water year	Historical data available
SURFACE WATER					
Bottom-sediment survey (BFS)	Determine presence of potentially toxic compounds in sediment at selected sites	Sample the depositional zone for pesticides, other synthetic organic compounds, and trace elements at water-chemistry sites	7	1 (1996)	some
Water-chemistry sites (BFS)	Describe concentrations and loads of major ions and nutrients at selected sites	Sample near-continuous streamflow sites for major ions, nutrients, organic carbon, and suspended sediment	7	2-6 in 1996 12-31 in 1997 12 in 1998	data at some sites
Cooperative sampling program (BFS)	Assess the influence of sampling method and location on water-quality data	Sample water-chemistry sites on the same day as the SFWMD using both USGS methods and SFWMD methods	5	2-6 in 1996 12-31 in 1997 12 in 1998	none
Storm sampling (BFS)	Assess effects of runoff during high-flow conditions on surface-water quality	Sample water-chemistry sites during high-flow conditions for major ions, nutrients, organic carbon, and suspended sediment	variable	variable (1997 and 1998)	some
Nutrient/pesticide synoptic studies	Determine the concentration of nutrients and pesticides across southern end of Study Unit during high and low flow	Sample sites along the Tamiami Trail Canal during low flow (June) and high flow (August) for major ions, mercury, nutrients, organic carbon, and pesticides	30	3 (Aug. 1996, June and August 1997)	limited
Process studies	Describe processes controlling the degradation and biological availability of pesticides	Deploy and collect semipermeable membrane devices at selected sites. Collect water and bottom-sediment samples	variable	4 (1997-98)	undetermined
Intensive pesticide sampling (IFS)	Determine seasonal variation in the occurrence and concentrations of nutrients and pesticides at water-chemistry sites	Sample water-chemistry sites that are located in specified agricultural land-use areas (citrus, sugarcane, and vegetables) for nutrients and pesticides	3	2 in 1996; weekly/biweekly in 1997; monthly in 1998	some
GROUND WATER					
Urban land-use survey	Describe water quality in a residential and light commercial land-use area in a shallow aquifer susceptible to contamination	Sample monitoring wells for major ions, nutrients, organic carbon, pesticides, radionuclides, trace elements, and volatile organic compounds (VOCs)	38 wells	1 (1997)	some
Ground-water and surface-water synoptic survey	Determine which water-quality constituents are transported through shallow ground water into surface water in an agricultural land-use area	Sample shallow wells and surface-water sites for major ions, nutrients, pesticides, and VOCs before and during a surface-water release in a canal that drains agricultural land	7 wells; 9 surface-water sites	1-5 (1997)	none
Agricultural land-use survey	Describe the effects of citrus land use on water quality in a shallow aquifer.	Sample new wells for major ions, nutrients, pesticides, radionuclides, and trace elements	30 wells	1 (1998)	some
Study-unit survey (public supply)	Describe overall water quality in the Biscayne aquifer, which is used for drinking-water supply	Sample existing wells for major ions, nutrients, organic carbon, pesticides, radionuclides, trace elements, and VOCs	30 wells	1 (1998)	some
AQUATIC BIOLOGY					
Contaminants in fish tissue	Determine the presence of contaminants that can accumulate in fish tissue	Collect largemouth bass and Florida gar at a large number of sites. Sample composites of whole fish for organic compounds and fish livers for trace elements	15	1 (1996)	limited
Sediment toxicity testing	Evaluate potential toxicity of bed sediment at the water-chemistry sites	Collect bed-sediment samples and evaluate their potential toxicity by using ASTM methods and <i>Hyallela azteca</i>	7	1 (1996)	none
Aquatic biology	Assess biological communities and stream habitat at the Basic Fixed Sites	Quantitatively sample fish, macroinvertebrates, and algae near water-chemistry sites. Quantitatively describe stream habitat for these organisms	7	3 (1 per year during 1996-98)	limited
Algae synoptic studies	Determine the influence of nutrients on the algal community along a nutrient gradient in the southern part of the basin	Collect algae using artificial substrate samplers at sites across the Tamiami Trail Canal	10-13	3 (June, August, November, 1997)	none

GLOSSARY

- Aquatic-life criteria** - Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms.
- Aquifer** - A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Basic Fixed Sites (BFS)** - Sites on streams or canals at which streamflow is measured and samples are routinely collected for temperature, salinity, major ions, nutrients, and organic carbon. Samples may also be periodically collected for contaminants in bottom sediment, biota, storm effects, or other constituents.
- Breakdown products** - Compounds resulting from transformation of an organic substance through chemical, photochemical, and/or biochemical reactions.
- DDT** - Dichloro-diphenyl-trichloroethane. An organochlorine insecticide no longer registered for use in the United States. DDT degradation products include DDE and DDD.
- Drinking-water standard or guideline** - A threshold concentration in a public drinking-water supply, designed to protect human health.
- Ecosystem** - The interacting populations of plants, animals, and microorganisms occupying an area, plus their physical environment.
- Intensive Fixed Sites (IFS)** - Basic Fixed Sites with increased sampling frequency during selected seasonal periods and analysis of dissolved pesticides for 1 year.
- Load** - General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.
- Maximum contaminant level (MCL)** - Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Methylation** - The addition of a methyl group ($-CH_3$) to a molecule or atom through a chemical reaction.
- Micrograms per liter ($\mu\text{g/L}$)** - A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most stream water and ground water.
- Nutrient** - Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.
- Organochlorine insecticide** - A class of organic insecticides containing a high percentage of chlorine. Includes dichlorodiphenylethanes (such as DDT), chlorinated cyclo-dienes (such as chlordane), and chlorinated benzenes (such as lindane).
- Periphyton** - Organisms that grow on underwater surfaces; periphyton include algae, bacteria, fungi, protozoa, and other organisms.
- Pesticide** - A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests."
- Phosphorus** - A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.
- Phthalates** - A class of organic compounds containing phthalic acid esters [$C_6H_4(COOR)_2$] and derivatives. Used as plasticizers in plastics. Also used in many other products (such as detergents, cosmetics) and industrial processes (such as defoaming agents during paper and paperboard manufacture, and dielectrics in capacitors).
- Polychlorinated biphenyls (PCBs)** - A mixture of chlorinated derivatives of biphenyl, marketed under the trade name Aroclor with a number designating the chlorine content (such as Aroclor 1260). PCBs were used in transformers and capacitors for insulating purposes and in gas pipeline systems as a lubricant. Further sale for new use was banned by law in 1979.
- Polycyclic aromatic hydrocarbon (PAH)** - A class of organic compounds with a fused-ring aromatic structure. PAHs result from incomplete combustion of organic carbon (including wood), municipal solid waste, and fossil fuels, as well as from natural or anthropogenic introduction of uncombusted coal and oil. PAHs include benzo(a)pyrene, fluoranthene, and pyrene.
- Recharge** - Water that infiltrates the ground and reaches the saturated zone.
- Reference site** - A sampling site selected for its relatively undisturbed conditions.
- Trace element** - An element found in only minor amounts (concentrations less than 1.0 mg/L) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.
- Volatile organic compounds (VOCs)** - Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.
- Water-quality criteria** - Specific levels of water quality which, if reached, are expected to render a body of water unsuitable for its designated use.
- Water-quality standards** - State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.
- Water year** - The 12-month period October 1 through September 30, designated by the calendar year in which it ends.

APPENDIX—WATER-QUALITY DATA FROM SOUTHERN FLORIDA IN A NATIONAL CONTEXT

For a complete view of Southern Florida data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbcx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in Southern Florida. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in Southern Florida compare to results from across the Nation, and how conditions compare among the several land uses. Graphs show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, norflurazon concentrations in Southern Florida ground water in agricultural areas were similar to the national distribution, but the detection frequency was much higher (72 percent compared to 2 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Southern Florida, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

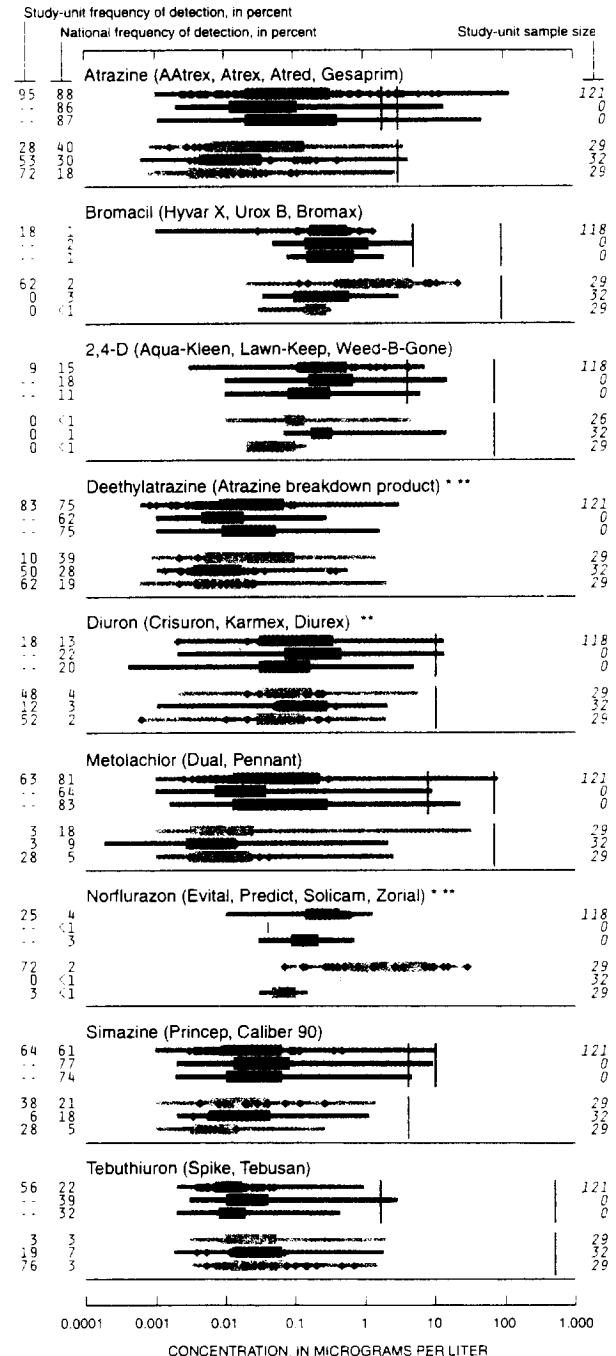

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Alachlor (Lasso, Bronco, Lariat, Bullet) **
- Benfluralin (Balan, Benefin, Bonalan) ***
- Bentazon (Basagran, Bentazone) **
- Butylate (Sutan +, Genate Plus, Butylate) **
- Cyanazine (Bladex, Fortrol)

DCPA (Dacthal, chlorthal-dimethyl) * **
 Dicamba (Barvel, Dianat, Scotts Proturf)
 2,6-Diethylaniline (Alachlor breakdown product) * **
 EPTC (Eptam, Farmarox, Alirox) * **
 Fenuron (Fenulon, Fenidim) * **
 Linuron (Lorox, Linex, Sarclax, Linurex, Afalon) *
 Metribuzin (Lexone, Sencor)
 Napropamide (Devrinol) * **
 Prometon (Pramitol, Princep) **
 Pronamide (Kerb, Propyzamid) **
 Propanil (Stam, Stampede, Wham) * **
 Terbacil (Sinbar) **
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **

Herbicides not detected

Acetochlor (Harness Plus, Surpass) * **
 Acifluorfen (Blazer, Tackle 2S) **
 Bromoxynil (Buctril, Brominal) *
 Chloramben (Amiben, Amilon-WP, Vegiben) **
 Clopyralid (Stinger, Lontrel, Transline) * **
 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
 Dacthal mono-acid (Dacthal breakdown product) * **
 Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
 Dinoseb (Dinosebe)
 Ethalfurailin (Sonalan, Curbit) * **
 Fluometuron (Flo-Met, Cotoran) **
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Molinate (Ordram) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Oryzalin (Surflan, Dirimal) * **
 Pebulate (Tillam, PEBC) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **
 Picloram (Grazon, Tordon)
 Propachlor (Ramrod, Satecid) **
 Prophanil (Tuberite) **
 2,4,5-T **
 2,4,5-TP (Silvex, Fenoprop) **
 Thiobencarb (Bolero, Saturn, Benthiocarb) * **
 Triallate (Far-Go, Avadex BW, Tri-allate) *
 Trifluralin (Treflan, Gowan, Tri-4, Trific)

Azinphos-methyl (Guthion, Gusathion M) *
 Diazinon (Basudin, Diazatol, Neocidol, Knox Out)
 Disulfoton (Disyston, Di-Syston) **
 Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 gamma-HCH (Lindane, gamma-BHC)
 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
 Methiocarb (Slug-Geta, Grandslam, Mesurol) * **
 Oxamyli (Vydate L, Pratt) **
 Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
 cis-Permethrin (Ambush, Astro, Pounce) * **
 Phorate (Thimet, Granutox, Geomet, Rampart) * **
 Propargite (Comite, Omite, Ornamite) * **
 Terbufos (Contraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

¹ Many of the samples in this study were diluted prior to laboratory analysis and therefore the actual detection frequency may be larger than the value listed.

Pesticides in water—Insecticides

Other insecticides detected

Carbofuran (Furadan, Curaterr, Yaltox)
 Chlorpyrifos (Brodan, Dursban, Lorsban)
 Dieldrin (Panoram D-31, Octalox, Compound 497)
 Ethoprop (Mocap, Ethoprophos) * **
 Malathion (Malathion)
 Methomyl (Lanox, Lannate, Acinate) **
 Methyl parathion (Pennacp-M, Folidol-M) **
 Propoxur (Baygon, Blattanex, Unden, Propotox) * **

Insecticides not detected

Aldicarb (Temik, Ambush, Pounce)
 Aldicarb sulfone (Standak, aldoxycarb)
 Aldicarb sulfoxide (Aldicarb breakdown product)

Other VOCs detected

tert-Amylmethylether (tert-amyl methyl ether (TAME)) *
 Benzene
 Bromochloromethane (Methylene chlorobromide)
 Bromodichloromethane (Dichlorobromomethane)
 2-Butanone (Methyl ethyl ketone (MEK)) *
 Carbon disulfide *
 1-Chloro-2-methylbenzene (o-Chlorotoluene)
 Chlorobenzene (Monochlorobenzene)
 Chlorodibromomethane (Dibromochloromethane)
 Chloromethane (Methyl chloride)
 Dibromomethane (Methylene dibromide) *
 1,3-Dichlorobenzene (m-Dichlorobenzene)
 1,4-Dichlorobenzene (p-Dichlorobenzene)
 Dichlorodifluoromethane (CFC 12, Freon 12)
 1,1-Dichloroethane (Ethylidene dichloride) *
 1,1-Dichloroethene (Vinylidene chloride)
 trans-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
 cis-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)
 Dichloromethane (Methylene chloride)
 1,2-Dichloropropane (Propylene dichloride)
 Diethyl ether (Ethyl ether) *
 1,2-Dimethylbenzene (o-Xylene)
 1,3 & 1,4-Dimethylbenzene (m-&p -Xylene)
 1,4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
 Ethylbenzene (Phenylethane)
 p-Isopropyltoluene (p-Cymene) *
 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
 Methylbenzene (Toluene)
 Naphthalene
 2-Propanone (Acetone) *
 Tetrachloroethene (Perchloroethene)
 Tribromomethane (Bromofom)
 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
 Trichloroethene (TCE)
 Trichloromethane (Chlorofom)
 1,2,4-Trimethylbenzene (Pseudocumene) *

VOCs not detected

- Bromobenzene (Phenyl bromide) *
- Bromoethene (Vinyl bromide) *
- Bromomethane (Methyl bromide)
- n*-Butylbenzene (1-Phenylbutane) *
- sec*-Butylbenzene *
- tert*-Butylbenzene *
- 3-Chloro-1-propene (3-Chloropropene) *
- 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
- Chloroethane (Ethyl chloride) *
- 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
- 1,2-Dibromoethane (Ethylene dibromide, EDB)
- trans*-1,4-Dichloro-2-butene ((*Z*)-1,4-Dichloro-2-butene) *
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
- 1,2-Dichloroethane (Ethylene dichloride)
- 2,2-Dichloropropane *
- 1,3-Dichloropropane (Trimethylene dichloride) *
- trans*-1,3-Dichloropropene ((*E*)-1,3-Dichloropropene)
- cis*-1,3-Dichloropropene ((*Z*)-1,3-Dichloropropene)
- 1,1-Dichloropropene *
- Diisopropyl ether (Diisopropylether (DIPE)) *
- Ethenylbenzene (Styrene)
- Ethyl methacrylate *
- Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
- 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
- Hexachlorobutadiene
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK)) *
- Iodomethane (Methyl iodide) *
- Isopropylbenzene (Cumene) *
- Methyl acrylonitrile *
- Methyl-2-methacrylate (Methyl methacrylate) *
- Methyl-2-propenoate (Methyl acrylate) *
- 2-Propenenitrile (Acrylonitrile)
- n*-Propylbenzene (Isocumene) *
- 1,1,2,2-Tetrachloroethane *
- 1,1,1,2-Tetrachloroethane
- Tetrachloromethane (Carbon tetrachloride)
- 1,2,3,4-Tetramethylbenzene (Prehnitene) *
- 1,2,3,5-Tetramethylbenzene (Isodurene) *
- 1,2,4-Trichlorobenzene
- 1,2,3-Trichlorobenzene *
- 1,1,1-Trichloroethane (Methylchloroform)
- 1,1,2-Trichloroethane (Vinyl trichloride)
- Trichlorofluoromethane (CFC 11, Freon 11)
- 1,2,3-Trichloropropane (Allyl trichloride)
- 1,2,3-Trimethylbenzene (Hemimellitene) *
- 1,3,5-Trimethylbenzene (Mesitylene) *

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Southern Florida, 1996-98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

-- Not measured or sample size less than two

12 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991-98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and state agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- ** No benchmark for protection of aquatic life

Organochlorines in fish tissue (whole body) and bed sediment

² The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

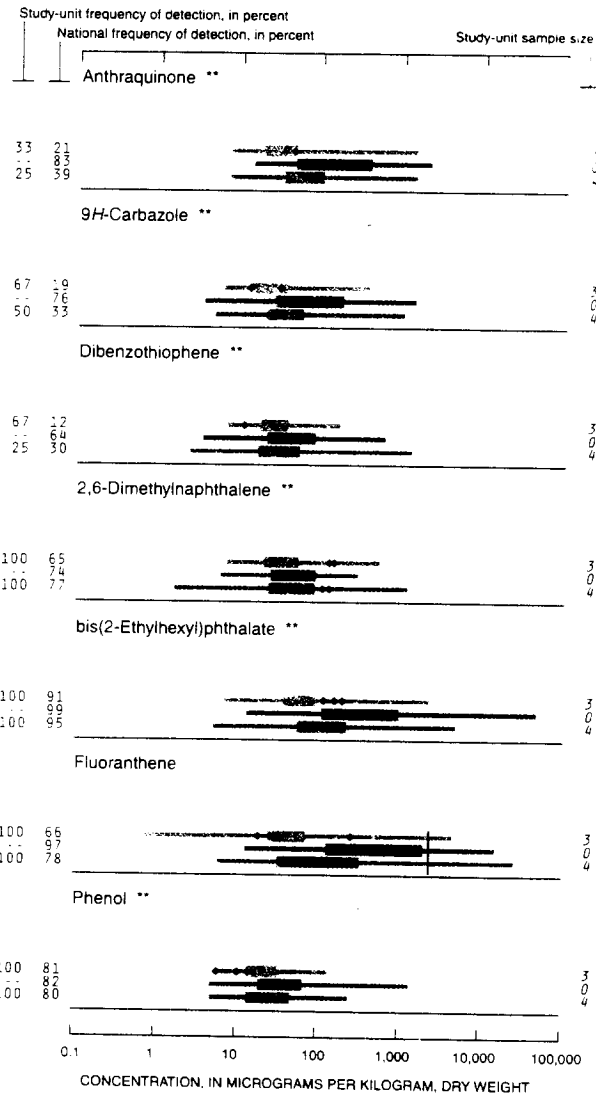

Other organochlorines detected

Dieldrin+aldrin (sum of dieldrin and aldrin) **
Endosulfan I (alpha-Endosulfan, Thiodan) ***
Mirex (Dechlorane) **

Organochlorines not detected

Chloroneb (Chloronebe, Demosan) ***
DCPA (Dacthal, chlorthal-dimethyl) ***
Endrin (Endrine)
gamma-HCH (Lindane, gamma-BHC, Gammexane) *
total-HCH (sum of alpha-HCH, beta-HCH, gamma-HCH, and delta-HCH) **
Heptachlor epoxide (Heptachlor breakdown product) *
Heptachlor+heptachlor epoxide (sum of heptachlor and heptachlor epoxide) **
Hexachlorobenzene (HCB) **
Isodrin (Isodrine, Compound 711) ***
p,p'-Methoxychlor (Mariate, methoxychlore) ***
o,p'-Methoxychlor ***
Pentachloroanisole (PCA) ***
cis-Permethrin (Ambush, Astro, Pounce) ***
trans-Permethrin (Ambush, Astro, Pounce) ***
Toxaphene (Camphechlor, Hercules 3956) ***

Semivolatile organic compounds (SVOCs) in bed sediment

Other SVOCs detected

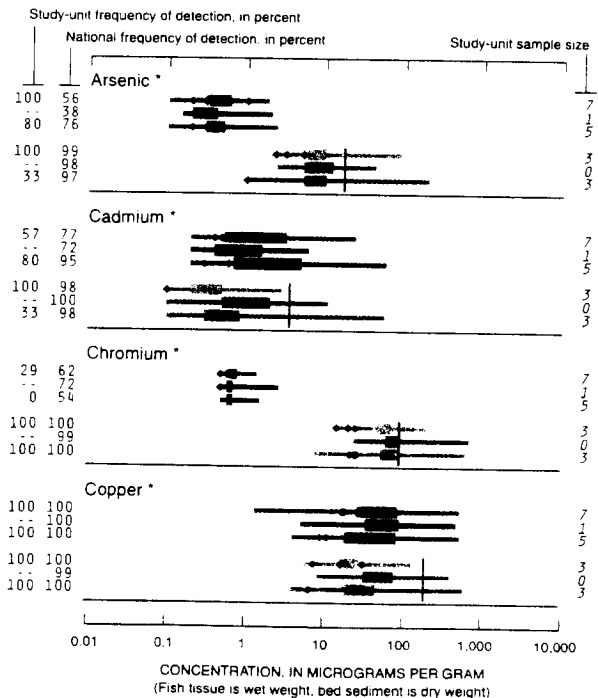

Acenaphthene
 Acenaphthylene
 Acridine **
 Anthracene
 Benz[*a*]anthracene
 Benzo[*a*]pyrene
 Benzo[*b*]fluoranthene **
 Benzo[*ghi*]perylene **
 Benzo[*k*]fluoranthene **

 Isophorone **
 Isoquinoline **
 Nitrobenzene **
N-Nitrosodi-*n*-propylamine **
N-Nitrosodiphenylamine **
 Pentachloronitrobenzene **
 Quinoline **
 1,2,4-Trichlorobenzene **

Trace elements in fish tissue (livers) and bed sediment

BIOLOGICAL INDICATORS

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

Biological indicator value, Southern Florida, by land use, 1996-98

- ◆ Biological status assessed at a site

National ranges of biological indicators, in 16 NAWQA Study Units, 1994-98

- Streams in undeveloped areas
- Streams in agricultural areas
- Streams in urban areas
- Streams in mixed-land-use areas
- 75th percentile
- - - 25th percentile

A COORDINATED EFFORT

Coordination among agencies and organizations is an integral part of the NAWQA Program. We thank the following agencies and organizations who contributed data used in this report or participated in the Study Unit liaison committee.

Federal Organizations

National Park Service
National Oceanic and Atmospheric Administration
U.S. Army Corps of Engineers
U.S. Department of Agriculture
U.S. Environmental Protection Agency
U.S. Fish and Wildlife Service
National Marine Fisheries Service

State Agencies

Florida Marine Research Institute
Florida Department of Agriculture and Consumer Services
Florida Department of Environmental Protection
Florida Game and Freshwater Fish Commission
Florida Geological Survey
Florida Park Service
South Florida Water Management District
Southwest Florida Water Management District

Private Organizations

Nature Conservancy

Native American

Miccosukee Tribe of Indians of Florida
Seminole Tribe of Florida

Universities

University of Miami
University of Florida
Florida International University

Local Agencies

City of Naples
Metropolitan Dade County
Palm Beach County
Broward County
Collier County

Special thanks to U.S. Geological Survey employees for their contributions:

Bruce Bernard, lead technician for SOFL, John Byrnes, Mark Zucker for data collection. Becky Deckard, Teresa Embry, Pat Mixson, and Ron Spencer for production of the report, including editing, layout, and illustrations. Michael Meyers for his contribution on pesticide degradation.

Appreciation also is extended to those individuals and agencies that reviewed this report: Edward Oaksford, U.S. Geological Survey, Michael Thurman, U.S. Geological Survey, Richard Pfeuffer, South Florida Water Management District.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Mississippi Embayment that emerged from an assessment conducted between 1995 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Mississippi Embayment assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

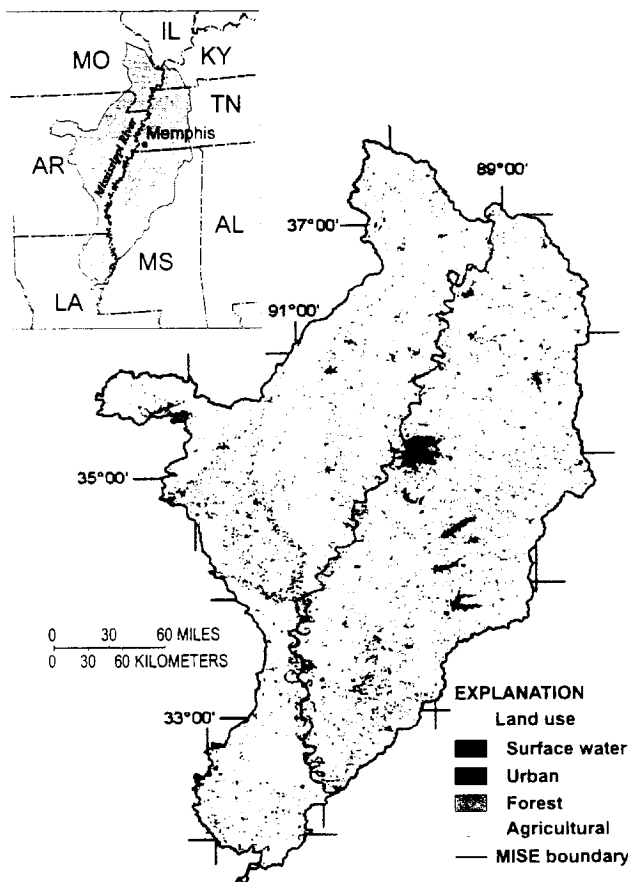

The Mississippi Embayment is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Stream and River Highlights

The climate, rainfall, soil type, and surficial geology of the Mississippi Embayment (MISE) Study Unit strongly influence land use in the basin and subsequently influence water quality. About 62 percent of the Study Unit is used for agriculture. In areas of intensive row-crop production, as much as 90 percent of the land is used for agriculture. This influence from agricultural land use, with additional contributions from urban areas, has resulted in streams that often have high turbidities, mixtures of pesticides, and degraded riparian habitat. Biological communities in the streams commonly are stressed. However, human activities on the Earth's surface seem to have a limited effect on the ground-water resources, which supply the vast majority of the region's drinking water.

- Herbicides frequently were detected in streams draining agricultural or mixed land-use basins; insecticides were detected less often. Pesticides in over 60 percent of samples collected from these streams exceeded aquatic-life guidelines. Insecticides frequently were detected in samples from the urban stream; diazinon and chlorpyrifos were detected in every sample, usually in concentrations above aquatic-life guidelines.
- Nitrogen concentrations in the MISE generally were in the middle range of the national data, whereas total phosphorus concentrations were in the 67th to 93d percentile. The phosphorus concentrations in the Study Unit probably were related to many factors, such as rainfall amounts, soils, and artificial drainage of agricultural fields. No sample exceeded the guidelines and standards for nitrate or ammonia, but most exceeded the U.S. Environmental Protection Agency's (USEPA) goal of 0.1 mg/L (milligram per liter) of phosphorus for the prevention of plant nuisances in streams.
- Although the sale of the organochlorine insecticide DDT was discontinued in 1972, DDT and metabolites (chemicals resulting from the breakdown of DDT) were widespread within the MISE. DDT, or one of its metabolites, was found in every fish tissue sample collected and was found in 67 percent of the streambed-sediment samples. Detectable levels of a metabolite of DDT were measured in 14 percent of surface-water samples.
- Although volatile and semivolatile organic compounds often were detected in urban stream water and in bed sediment, they were rarely at levels of concern.
- Aquatic organisms present in the MISE streams were typical of those found in impacted or degraded streams. Fish

The Mississippi Embayment (MISE) Study Unit is an approximately 49,800-square-mile area in the six States of Arkansas, Kentucky, Louisiana, Mississippi, Missouri, and Tennessee. Land use in the MISE is principally agricultural. Approximately 62 percent of the study area is agricultural, 33 percent is forested, and 5 percent represents other land uses. The land use in some of the smaller drainage basins sampled is greater than 90 percent agricultural.

communities in most of the streams were dominated by fish tolerant of poor water quality conditions. The aquatic insects and algal communities generally were tolerant of turbid, silty conditions.

- Methyl parathion, a metabolite of DDT, and several other pesticides were detected in air and rain samples collected in an agricultural area and in the urban area of Jackson, Mississippi.

Major Influences on Streams and Rivers

- Runoff from agricultural and urban areas
- Drainage modifications and channelization of streams
- Modification or elimination of riparian habitat

Selected Stream-Quality Indicators

	Small Streams			Major Rivers
	Urban	Agricultural	Undeveloped	Mixed Land Uses
Pesticides ¹			—	
Total phosphorus ²			—	
Nitrate ³			—	
Trace elements ⁴	—		—	
Organo-chlorines ⁵	—		—	
Volatile organics ⁶		—	—	—
Semivolatile organics ⁷	—		—	

Percentage of samples with concentrations **equal to or greater than** a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or above a national goal for preventing excess algal growth

Percentage of samples with concentrations **less than** a health-related national guideline for drinking water, aquatic life or water-contact recreation; or below a national goal for preventing excess algal growth

— Not assessed

¹ Insecticides, herbicides, and pesticide metabolites, sampled in water.

² Total phosphorus, sampled in water.

³ Nitrate (as nitrogen), sampled in water.

⁴ Arsenic, mercury, and metals sampled in sediment.

⁵ DDT and PCBs sampled in fish tissue.

⁶ Solvents, refrigerants, fumigants, and gasoline compounds sampled in water.

⁷ By-products of fossil-fuel combustion; components of coal and crude oil sampled in sediment.

Ground-Water Highlights

Ground-water quality in the Mississippi Embayment Study Unit generally is very good. Ground water in the deep Tertiary aquifers, which supply most of the region's drinking water, generally is isolated from surface activities by thick "confining layers" of clays. Surface activities influence ground water where shallow deposits cover the hills in the eastern part of the Study Unit and in the Memphis shallow aquifers more than in the deeper aquifers. The abundant ground water in the alluvial aquifer of the Mississippi River valley is near the land surface but is covered by dense clays.

- Pesticides, such as atrazine, simazine, and metolachlor, were detected most frequently in the ground water in the shallow deposits that cover the hills in the eastern part of the Study Unit and in ground water underlying urban areas.

Bentazon, molinate, and fluometuron were the pesticides most frequently detected in the alluvial aquifer. Atrazine and dieldrin were detected one time each in shallow urban wells at levels above the drinking-water standards and guidelines.

- Nutrient concentrations in the ground water in the MISE generally were low. All nitrate concentrations were below the USEPA drinking-water standard of 10 mg/L.
- Radon is naturally occurring and was detected in almost every well sampled. Concentrations above the USEPA-proposed drinking water standard of 300 picocuries per liter were found in water from only 16 of 109 wells. These levels are low, relative to levels detected in other NAWQA Study Units.
- Volatile organic compounds (VOCs) were detected in ground water throughout the Study Unit; however, concentrations were well within drinking-water standards. The most frequently detected VOCs were 1,2,4-trimethylbenzene and carbon disulfide.

Major Influences on Ground Water

- Ground water is commonly protected from surface activities by thick, regional clay layers.

INTRODUCTION TO THE MISSISSIPPI EMBAYMENT

In 1821, while painting a peregrine falcon, John James Audubon described the Yazoo River, the largest river wholly contained within the Mississippi Embayment Study Unit, as “a beautiful stream of transparent water, covered by thousands of geese and ducks and filled with fish” (Smith, 1954). Since that time, the bottomland hardwood forests that covered the Mississippi River Alluvial Plain have been cleared for agricultural use of the rich alluvial soils for the production of cotton, soybeans, rice, and corn. This clearing of the land has exposed the fine alluvial soils to erosion. Over time, the clays, along with nutrients and agricultural chemicals sorbed to the clay surfaces, were washed into the rivers and streams, thus greatly changing the water quality of the area.

Physiography and Ecoregions

Within the Mississippi Embayment (MISE) Study Unit, the surficial geology is the underlying controlling factor for the physiography, land use, biological communities, and water quality of the area. Therefore, the areas defined as physiographic regions (Fenneman, 1938) strongly correspond to

Much of the Mississippi Embayment Study Unit was bottomland hardwood forests and wetlands well into the 20th century.

FIG. 1. Peregrine Falcon (Kinglet's Hawk)

John James Audubon's painting of the peregrine falcon that he worked on while visiting the Yazoo River area in 1821. (Reprinted courtesy of the National Audubon Society.)

the related ecoregions defined by Omernik in 1987 (fig. 1).

About 57 percent of the MISE Study Unit lies within the Mississippi Alluvial Plain physiographic province and ecoregion. This area has been dominated by the flow and flooding of the Mississippi River during the past 2 million years or more. The Mississippi Alluvial Plain is an area of little topographic relief with an average slope of about 0.5 foot per mile toward the Gulf of Mexico. One of the distinct features of the alluvial plain is the formation of natural levees along the banks of the rivers, and the associated backswamp deposits that are dominated by dense alluvial clays and historically have supported extensive wetland areas. These clays have created low permeability soils, which limit the ability of rainwater to infiltrate the ground surface and may cause runoff from agricultural fields to rapidly enter rivers and streams. These clays also seem to limit the susceptibility of the ground water to surface activities in intense agricultural areas.

Thirty-five percent of the remainder of the Study Unit lies in

the Gulf Coastal Plains physiographic province, which includes the area identified as the Mississippi Valley Loess Plains and Southeastern Plains ecoregions (fig. 1). The Gulf Coastal Plains are separated from the eastern edge of the Mississippi Alluvial Plain by the Loess Hills, which extend most of the length of the Study Unit. These hills are made of wind-blown silts, rise a few hundred feet above the Mississippi Alluvial Plain, and average about 15 miles in width. The remaining part of the Gulf Coastal Plains uplands and Southeastern Plains ecoregion generally is rolling to hilly with low to moderate topographic relief. The soils are composed, in part, of silts and are more permeable than the alluvial clays; there are indications that this allows for the downward infiltration of precipitation. This may partly protect the streams and rivers from compounds carried in runoff but may make the ground water slightly more susceptible to surface contamination. These coarser soils on steeper slopes are more erodible than alluvial soils, and large amounts of soil from the Gulf Coastal Plains uplands have

eroded into the Mississippi Alluvial Plain.

In the west, the Study Unit abuts small areas of the Ozark Highlands. Limited sampling was done in these areas during this project.

The land surface generally slopes toward the Mississippi River from both the eastern and western sides of the Study Unit and to the south toward the Gulf of Mexico. Thus, nearly all of the activities in this Study Unit that influence water quality ultimately influence the water quality of the Mississippi River and the Gulf of Mexico.

Geology

The Mississippi Alluvial Plain is in the northern part of the Missis-

issippi Embayment, a geologic structural trough in which the underlying crust of the Earth forms a deep valley. Large rivers, such as the Mississippi, Arkansas, and Ohio Rivers, have flowed through this region, carved the surface, and deposited clay, silt, sand, and gravel, collectively called alluvium. During the past 2 million years, up to 300 feet of alluvium has filled this valley. The alluvium can be grouped into three major units: the Pleistocene Prairie Complex, Pleistocene valley trains, and the Holocene alluvium (see fig. 7 for map; Autin and others, 1991; Saucier, 1994).

The Prairie Complex is older than the Pleistocene valley trains and the Holocene alluvium. Sauc-

ier (1994) suggested that the Prairie Complex was deposited between about 120,000 years ago and the time of the greatest extent of the last glacier, about 18,000 years ago. The Pleistocene valley trains were mostly deposited during two time periods, between about 60,000 and 25,000 years ago and during the waning phase of the latest glacial period between 18,000 and 10,000 years ago. Glacial outwash (melting) flowing from north to south provided enough energy to cause a braided stream depositional environment to form in the Lower Mississippi River Valley during this time. By about 9,000 years ago, the rate of glacial outwash in the Lower Mississippi River Valley declined, and valley train deposi-

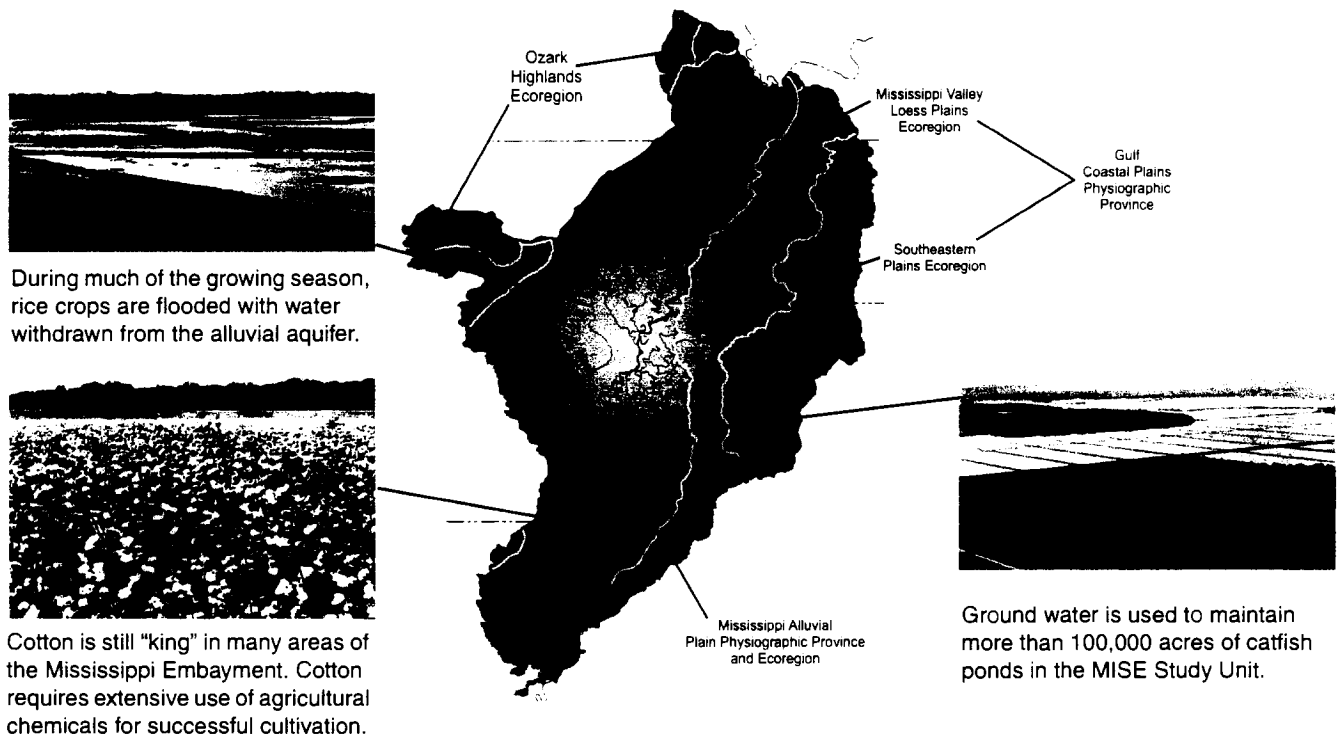

Figure 1. Boundaries for Fenneman's (1938) physiographic regions are very similar to Omernik's Level III ecoregions (1987), at least in part because the surficial geology is a controlling factor in the MISE Study Unit. The only major metropolitan area in the Study Unit is Memphis, Tennessee. The area has many rivers, as well as several large river systems, including the Yazoo and St. Francis Rivers and parts of the White and Arkansas Rivers. Major crops include soybeans, cotton, rice, and corn. Catfish farms are a major component of the landscape as well as a principal user of ground water.

tion ceased. The braided stream depositional process of the Pleistocene epoch was replaced by the lower energy meander stream depositional process of the Holocene epoch near major rivers, such as the Mississippi and Arkansas Rivers. (See fig. 2 for more explanation.) Autin and others (1991) reported that the depositional transition from Pleistocene valley trains (braided streams) to Holocene alluvium (meander streams) started near Baton Rouge, Louisiana, around 12,000 years ago and migrated northward to near Cairo, Illinois, by 9,000 years ago.

The Pleistocene valley train deposits generally have a coarser grain size than the Holocene alluvium. Also, water well drillers' logs indicate that the clay and silt layer near the surface is thicker in the Holocene alluvium, whereas the underlying sand and gravel layer (alluvial aquifer) is thicker in the Pleistocene valley train deposits.

Hydrogeology

Two principal aquifer systems provide drinking-water supplies in the Mississippi Embayment—the Tertiary and the alluvial aquifers (fig. 3).

Tertiary Aquifers

The geologic groups associated with the deep Tertiary aquifers are the Midway, Wilcox, Claiborne, and the Jackson groups. The deep Tertiary aquifers sampled in this study are thick sand deposits within the Wilcox and Claiborne groups. The names of the aquifers, from youngest to oldest, include the Cockfield, Sparta, Winona-Tallahatta, Memphis, Meridian-upper Wilcox, and Wilcox.

Figure 2. Although the photograph on the left was recently taken of a stream in the Western United States, its braided condition is representative of what streams in the Mississippi Valley may have looked like during the Pleistocene geologic period. These high-energy systems allow sand and gravel carried by the stream to be deposited in the flood plain. The photograph on the right depicts a classic meandering stream. Streams like this are low-energy systems and primarily deposit clay, silt, and fine sand in the flood plains adjacent to the streams. This depositional pattern is present today and has been the dominant form of deposition in the Lower Mississippi River Valley during the last 9,000 to 12,000 years. These differences in depositional environments appear to influence the chemistry of the ground water, the bioaccumulation of pesticides, and biological communities.

The natural regional flow of ground water in the Mississippi Embayment in the Tertiary aquifers is from the outcrop areas in the upper Gulf Coastal Plain, laterally along the aquifers toward the embayment axis, and then upward through overlying confining units and aquifers to the surface of the Mississippi Alluvial Plain (Grubb, 1986; Ackerman, 1989). Pumping

in the deep Tertiary aquifers has caused recharge rates to increase in the outcrop and production areas of the aquifer (Williamson and others, 1990).

Alluvial Aquifers

The Mississippi River confining unit is composed of the upper silt and clay of the Quaternary allu-

Figure 3. Generalized geohydrologic section of the Mississippi River alluvial aquifer and underlying Tertiary aquifers (from Arthur, 1994).

Figure 4. This hydrograph is representative of streams in the Mississippi Alluvial Plain. Often streams in this Study Unit flood rapidly, remain at high levels for long periods, and have very low streamflows in the fall. During the years of this project, 1996 was drier than usual, and 1997 and 1998 were wetter than usual.

vium, whereas the Mississippi River alluvial aquifer is composed of the lower sand and gravel of the Quaternary alluvium (Boswell and others, 1968; Ackerman, 1989). Overlying silt and clay of the confining unit impedes recharge into the alluvial aquifer. Confining unit thickness generally ranges from 10 to 50 feet and generally increases from north to south within the MISE Study Unit. The thickness of the alluvial aquifer ranges from 60 to 140 feet. Wells screened in the alluvial aquifer typically yield between 1,000 and 2,000 gallons per minute (Whitfield, 1975). Prior to development, ground-water flow is believed to have been generally from the older adjacent and underlying aquifers toward the alluvial aquifer (Williamson and others, 1990).

Climate

Climate in the MISE Study Unit varies from humid, temperate in the northern part to humid, subtropical in the southern part. This warm climate results in a long growing season and few killing

frosts, which influences the types of crops that can be grown and the amount of pesticides that generally are applied. Mean annual precipitation ranges from about 48 inches per year in the northern part of the Study Unit to 56 inches per year in the southern part. Precipitation generally is greatest in April and least in October but is distributed fairly evenly throughout the year. This causes minor drought conditions to occur frequently during the

summer, when the evapotranspiration rate is higher than the precipitation rate. These conditions also result in streams which flood rapidly, remain at high levels for long periods of time, and have low flows in the fall (fig. 4).

Water Use

In general, about three times as much ground water is used compared to surface water in the MISE Study Unit (fig. 5). During the summer months, both ground and surface water are used for irrigating crops. Most (in excess of 7 billion gallons per day) of the irrigation water is withdrawn from the alluvial aquifer. This aquifer is also used for domestic drinking water, aquaculture (primarily for catfish ponds), power production, and other commercial and industrial needs. Ground water, primarily from the Tertiary aquifers, is used for public supply. The principal use of surface water is for power production where it is used for cooling water for electric power generation. The second largest use of surface water is for irrigation.

Figure 5. Ground-water use in the Mississippi Embayment (MISE) Study Unit is dominated by irrigation usage. Surface water is also used for irrigation, but more is used for cooling water for electrical power production.

MAJOR FINDINGS

Nutrient Contributions to the Mississippi River System

Although nitrogen and phosphorus, as well as silica and other nutrients, are natural and important parts of a healthy ecosystem, severe water-quality problems can arise if an ecosystem becomes enriched, or overloaded, with nutrients. In recent years, scientists have become aware of a large area of low dissolved oxygen that develops off the coast of Louisiana and Texas each summer. The extent and duration of this area of low dissolved oxygen has been related to the amount of nutrients, especially nitrogen, and freshwater flowing from the Mississippi River into the Gulf of Mexico (Goolsby and others, 1999). The proximity of the MISE Study Unit to the Gulf and the use of nitrogen fertilizer in the agricultural areas of the Study Unit, especially the Yazoo River Basin, have led to speculation that the surface waters of the Study Unit may be contributing a disproportionate amount of nitrogen and phosphorus to the Mississippi River and ultimately to the Gulf of Mexico.

In the MISE Study Unit investigations have shown that concentrations of nutrients (except total phosphorus) are higher in the Mississippi River at Vicksburg, Mississippi than near the mouth of the Yazoo River (table 1). The annual load of nitrogen and phosphorus from the Yazoo River for the 1996–97 calendar years, while significant, was only a small percentage of the load carried by the Mississippi River (Coupe, 1998).

Water-Quality Standards

Concentrations of nitrogen and phosphorus were measured from weekly to at least monthly at nine

The Yazoo River, the river with the largest drainage area wholly contained in the Mississippi Embayment Study Unit, enters the Mississippi River just north of these bridges at Vicksburg, Mississippi.

stream-sampling sites in the MISE Study Unit. Nitrate concentrations never exceeded the drinking-water standard of 10 mg/L in any sample, and ammonia concentrations did not exceed aquatic-life guidelines. However, the USEPA goal of 0.1 mg/L or less total phosphorus for streams not entering reservoirs was exceeded in every sample from the urban stream and in more than 50 percent of the samples from five streams located in the Mississippi Alluvial Plain. Samples from the

streams located in the Gulf Plains exceeded the recommended goal of 0.1 mg/L or less total phosphorus in less than 50 percent of the samples.

Comparison of Nitrogen and Phosphorus in Streams in the Mississippi River Basin

The yield of nitrogen (mass per unit area), from streams in the MISE Study Unit during 1995–96 was compared to the average yield during 1980–96 from streams in

Table 1. Concentrations of nutrients near the mouth of the Yazoo River compared to the Mississippi River at Vicksburg, Mississippi.

[Concentrations are in milligrams per liter]

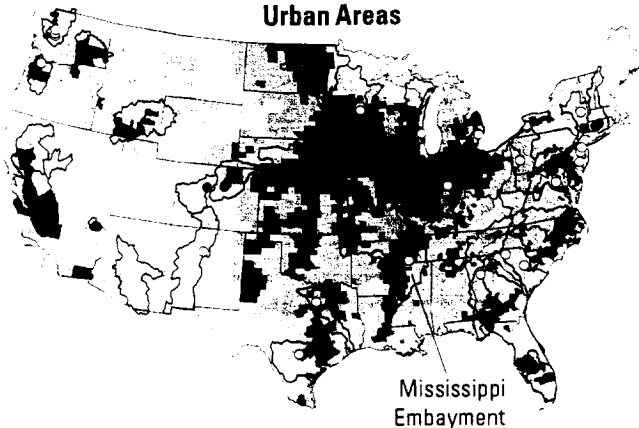

Constituent	Site	Year	Maximum	Minimum	Mean
Total nitrogen	Yazoo River	1996–97	3.3	0.57	1.3

	Mississippi River	1984–93	0.13	0.02	0.058

National Comparison of Total Nitrogen in Streams

TOTAL NITROGEN IN STREAMS

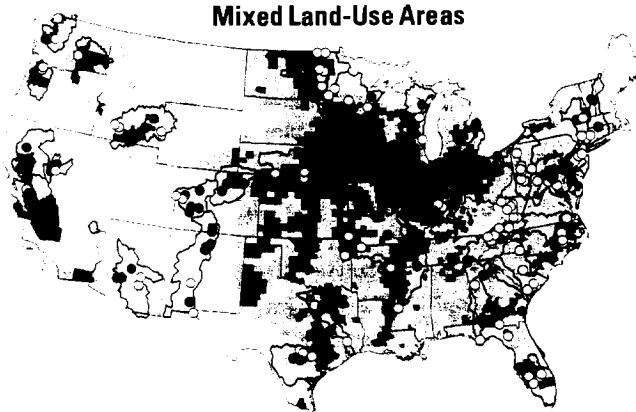

Urban Areas

Nitrogen is a natural and important component of a healthy stream; however, too much nitrogen can lead to degraded stream-water quality, affecting both the aquatic ecosystem and its use as a recreational or drinking-water source for humans. The sources of nitrogen in surface water are many and include atmospheric deposition, municipal and industrial wastewater, and fixation of nitrogen from the atmosphere by plants and some species of algae.

By far, the biggest source of nitrogen in an agricultural setting, such as the Mississippi Embayment (MISE) Study Unit, is from the application of fertilizer to crops. For most of the Study Unit, the average annual total nitrogen input from fertilizer, manure, and the atmosphere combined is greater than 25 pounds per acre. Most of the agriculturally productive Midwest receives the same amount.

Mixed Land-Use Areas

The average annual concentration of total nitrogen from agricultural and mixed land-use streams in the MISE Study Unit is in the medium range, whereas nationally, most streams that drain areas with greater than 25 pounds per acre of nitrogen input are in the high range. The lower concentrations of total nitrogen in the MISE Study Unit may be due to the milder climate that increases microbial activity in the winter and to the increased uptake of nitrogen by vegetation during the longer growing season.

Nationally, the average annual total nitrogen concentrations in urban streams, including the one urban site in the Mississippi Embayment Study Unit, tend to fall into the "medium" classification.

Agricultural Areas

EXPLANATION

Average annual concentration of total nitrogen —
in milligrams per liter

- Highest (greater than 2.9)
- Medium (0.64 to 2.9)
- Lowest (less than 0.64)

Average annual total nitrogen input —
in pounds per acre, by county, for 1995–98.
Inputs are from fertilizer, manure, and the atmosphere

- Greater than 25 pounds per acre
- 6 to 25 pounds per acre
- Less than 6 pounds per acre

the Mississippi River Basin. These data indicate that the yield of nitrogen from the MISE Study Unit was less than the average yield from streams in intensive agricultural areas of the Midwest, but more than from streams in the drier West or in the less agricultural Upper Mississippi River Basin. The flow-weighted mean total nitrogen concentrations for streams in the MISE Study Unit were generally in the 50th to 60th percentile for all data collected in the national NAWQA Program (372 stream sites). The exception was the mean nitrogen concentration at the smallest mixed land-use site which was near the 20th percentile, nationally.

The yields of total phosphorus generally were higher in the MISE Study Unit than from most other areas in the Mississippi River Basin, and the percentile ranking of

the flow-weighted mean total phosphorus concentration generally was quite high (67th to 93d). Again, the exception was the smallest mixed land-use site, where the mean total phosphorus concentration was near the 40th percentile. These high phosphorus yields were somewhat unexpected, as the soils in the MISE Study Unit, while fertile, do not contain excessive amounts of phosphorus. Also, phosphorus is used less as a fertilizer in the MISE Study Unit than in many parts of the Midwest (Battaglin and Goolsby, 1995), and due to the rural nature of the MISE, there are few significant point sources. One hypothesis for the high yields and concentrations of phosphorus in the MISE involves a combination of factors, such as soils, rainfall, and agricultural drainage. The sediment in the rivers of the MISE Study

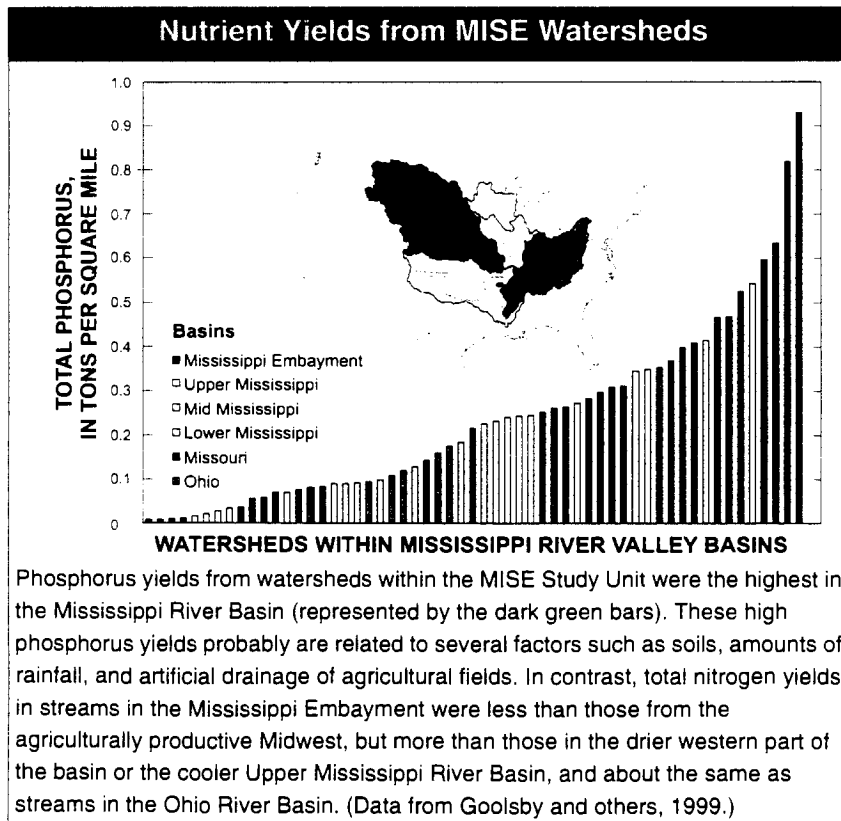

Unit is composed of fine, clay-sized particles to which phosphorus can sorb. Heavy rainfalls in the Study Unit increase the potential for erosion and the movement of these fine clay-sized particles from agricultural fields into the streams. Additionally, because of the large amount of rain, the tight clays that decrease infiltration of water, and the relatively flat terrain, much of the Study Unit has artificial drainage to expedite the movement of water. Most of this artificial drainage is surface drainage, which has been shown to decrease nitrate concentrations but to increase total phosphorus concentrations.

The Effects of Land Use and Geology on Nutrient Concentrations and Yields

Generally, total nitrogen and phosphorus concentrations and yields were higher in streams with predominantly agricultural land use in the Mississippi Alluvial Plain, but the highest nutrient concentrations and yields were from the urban stream. However, one stream located in the Gulf Plains in an area with no urban land use and only a moderate amount of agricultural land use had comparatively high total nitrogen and phosphorus yields. The high yields in this stream are reflective of the steep topography of the area and channelization of the stream for flood-control purposes.

More details on nutrients in the Yazoo River can be found in the report: Coupe, R.H., 1998, Concentrations and loads of nitrogen and phosphorus in the Yazoo River, northwestern Mississippi, 1996-97: U.S. Geological Survey Water-Resources Investigations Report 98-4219, 17 p.

The report also can be downloaded at: <http://ms.water.usgs.gov/misenawqa/>

Pesticides Commonly Found in Mississippi Embayment Surface Water

The occurrence and temporal distribution of more than 80 pesticides and pesticide metabolites were determined at five stream-sampling sites from 1996 to 1998 in the MISE Study Unit. More than 230 stream samples were collected and analyzed. The five rivers sampled included three rivers with small, primarily agricultural watersheds; one river with a small, urban watershed; and one large river (the Yazoo River) with mixed land use (row-crop agriculture, forest, pasture, and a small amount of urban). Pesticides, usually herbicides, frequently were detected in water samples from all five rivers sampled. Aquatic-life guidelines were frequently exceeded in the urban stream and occasionally exceeded in all of the rivers sampled in the MISE Study Unit.

Agricultural Streams

The pesticides detected in the rivers that drain the agricultural watersheds in the MISE Study Unit

Water samples are filtered and processed in a mobile laboratory immediately after sample collection.

showed distinct seasonal patterns that corresponded to the type of crops grown in the basin and the use of pesticides on those crops. For instance, the highest concentration of the pre-emergent herbicide atrazine frequently was found early in the growing season (April-May) corresponding to its application prior to the planting of corn and grain sorghum (fig. 6). The highest concentrations of herbicides that are used on other crops (cotton and

rice) with later planting dates, or herbicides that are used after the crop has emerged from the ground, such as fluometuron and molinate, were detected later in the growing season (June–July). The concentrations of most of these herbicides were well below any acute toxicity; however, the long-term effects of chronic exposure to low levels of multiple herbicides are not well known.

Figure 6. Herbicides in agricultural streams in the Mississippi Embayment Study Unit had higher concentrations, showed clear seasonal patterns, and contained different compounds than herbicides in urban streams. The urban stream samples were dominated by simazine, a turf grass herbicide. Concentrations of herbicides in the urban stream remained fairly constant throughout the year, whereas agricultural sites had concentrations that peaked in the spring shortly after application. Agricultural sites also were dominated by different herbicides (in this case atrazine).

Urban Stream

The type, amounts, and timing of the occurrence of pesticides in the stream draining an urban watershed are much different from those in the agricultural streams (fig. 6). The herbicides most frequently occurring in the urban stream such as atrazine, 2,4-D, simazine, and prometon, are those used in lawn care and in the maintenance of rights-of-way. The urban stream was also the only stream with frequent occurrences of insecticides: chlorpyrifos and diazinon were detected in every urban stream sample collected and exceeded the aquatic-life guidelines in 12 of 25 and 24 of 25 samples, respectively.

Many pesticides are applied by aircraft in the Study Unit.

DDT Metabolites in Surface Water

Although DDT strongly sorbs to sediments rather than readily dissolving in water, detectable levels of DDE, a metabolite of DDT, were found in 14 percent of the filtered stream-water samples analyzed.

More details on pesticides in streams in the MISE can be found in the report: Coupe, R.H., 2000. Occurrence of pesticides in five rivers of the Mississippi Embayment Study Unit, 1996–98: U.S. Geological Survey Water-Resources Investigations Report 99–4159, 69 p.

The report also can be downloaded at: <http://ms.water.usgs.gov/misenawqa/>

Tertiary Aquifers Have High-Quality Drinking Water

During the spring of 1996, water samples were collected from 30 public-supply wells in the deep Tertiary aquifers in the MISE Study Unit. The most significant finding from this part of the study is that all of the samples analyzed from these public-supply wells met all existing drinking-water standards and guidelines. Concentrations of most of the constituents measured that could adversely affect water quality, including nutrients, pesticides, radon, and volatile organic compounds, were below drinking-water standards and guidelines.

The Deep Tertiary Aquifers

The deep Tertiary aquifers underlie about 80 percent of the MISE Study Unit. Much of the population in this part of the country depends on these aquifers for drinking water. Wells sampled

Ground-water samples commonly were collected from municipal drinking-water facilities, such as the one pictured above.

range in depth from 208 to 1,460 feet below the ground surface.

Sample Results

Water from wells in the deep Tertiary aquifers had low nutrient concentrations. The highest nutrient concentration measured in a sample was 3.8 mg/L of nitrite plus nitrate nitrogen, which is less than half the drinking-water guideline of 10 mg/L. Pesticides were detected in water from only one of the wells. Water from the shallowest well sampled had a 0.16- $\mu\text{g/L}$ (microgram per liter) concentration of the herbicide bromacil and a 0.004- $\mu\text{g/L}$ concentration of deethylatrazine, a metabolite of the herbicide atrazine. Volatile organic compounds (VOCs) are compounds that have a high vapor pressure relative to their water solubility and include such things as components of gasoline and organic solvents. VOCs were detected frequently in the MISE, but concentrations were far below drinking-water guidelines. Samples from 26 of the 30 public-supply wells had at least one VOC detection. The VOCs most commonly detected were methyl-ethylketone and 1,2,4-trimethylbenzene, detected in 23 and 7 percent of the wells, respectively. Nutrients, pesticides, and VOCs generally enter the ground water from surface contamination; however, public-supply wells were generally deep enough to avoid elevated levels of these compounds.

Radon in water from the public-supply wells ranged from 54 to 270 picocuries per liter; none exceeded guidelines. Radon levels found in the ground water in the MISE were the second lowest of the 16 Study Units sampled during 1996–98.

Ground-water sample preparation occurred inside plastic enclosures in order to minimize sample contamination from chemicals in the atmosphere.

Few Pesticides Detected in Memphis Shallow Aquifers

In addition to the Tertiary aquifers, 32 shallow monitoring wells (not public-supply, drinking-water wells) were sampled in the shallow aquifers near Memphis, Tennessee. Results were similar to those from the deep Tertiary aquifer study except that pesticides were more frequently detected and radon concentrations were higher. An atrazine concentration of 3.14 $\mu\text{g/L}$ was measured in one well, which narrowly exceeded the drinking-water guideline of 3.0 $\mu\text{g/L}$, and dieldrin was measured above the drinking-water guideline of 0.02 $\mu\text{g/L}$ in another well.

More details on ground-water quality in the deep Tertiary aquifers can be found in the report:

Gonthier, G.J., 2000, Water quality in the deep Tertiary aquifers of the Mississippi Embayment, 1996: U.S. Geological Survey Water-Resources Investigations Report 99-4131, 91 p.

Water-Quality Differences in Geological Subunits of the Alluvial Aquifer

Previous researchers have studied the alluvial aquifer as a single Quaternary feature (Grubb, 1986; Ackerman, 1989). However, during this NAWQA investigation, the results of the water-chemistry studies were examined by dividing the area into different major geologic units, two of which are the Pleistocene valley trains and the Holocene alluvium (Saucier, 1994). The data collected suggest that the differences in the geology influence the chemical makeup of the

ground water in the alluvial aquifer.

The Alluvial Aquifer

The alluvial aquifer is a large, underground, water-bearing layer of sand and gravel in the Lower Mississippi River Valley (fig. 7). Water use from the alluvial aquifer is enormous; pumpage from the aquifer is about 7 billion gallons per day (Mesko and others, 1990). Most of the water pumped from the alluvial aquifer is used to irrigate crops or to maintain aquaculture, but the ground water also is used for public supply and industry.

Many of the water samples collected from the alluvial aquifer were taken from irrigation wells in agricultural areas.

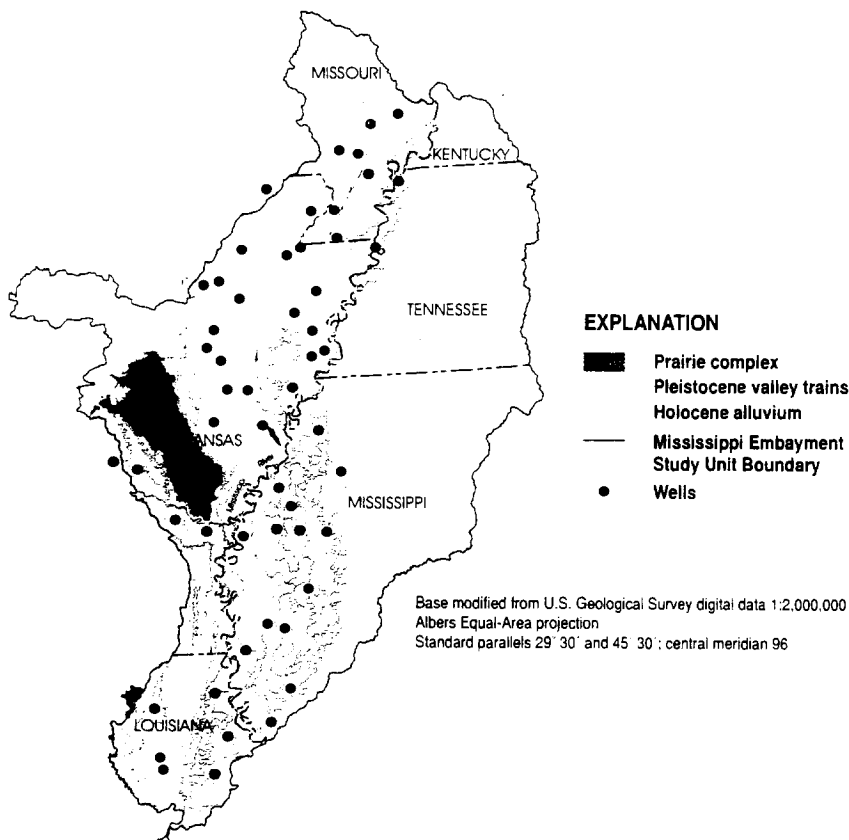

Figure 7. The colored part of this map depicts the areal extent of the three main geologic subunits of the alluvial aquifer and the location of the 54 wells that were sampled as part of this study. Statistically significant differences exist in the nutrient, carbon, and metal chemistry of the water sampled in wells located in the Pleistocene valley trains as compared to the Holocene alluvium, demonstrating the effect of geology on other components of the environment.

Water-Chemistry Analysis Results

Twenty-nine wells in the Pleistocene valley trains and 25 wells in the Holocene alluvium were sampled during the summer of 1998. At least one pesticide was detected in water from 19 of the 54 wells, but none of the concentrations were above drinking-water standards or guidelines. The most frequently detected pesticide was bentazon, an herbicide used to control weeds in soybean fields. Other pesticides detected in the alluvial aquifer in very low concentrations were molinate, fluometuron, 2,4-D, fenuron, atrazine, deethylatrazine, metolachlor, propanil, and *p,p'* DDE. At least one VOC was detected in water from 25 of 46 wells; 1,2,4-trimethylbenzene was detected most frequently. However, all of the VOC concentrations were well below drinking-water standards or guidelines.

Pleistocene Valley Trains and the Holocene Alluvium

The two subunits of the alluvial aquifer, the Pleistocene valley trains and the Holocene alluvium, have different lithological charac-

teristics. The Pleistocene valley trains generally have coarser grain sizes than the Holocene alluvium, whereas the Holocene alluvium has a thicker clay and silt surficial unit. These characteristics indicate that ground-water flow may be more active in the Pleistocene valley trains.

Results of the ground-water chemistry showed that sulfate, pH, tritium, chloride, and radon-222 were present in higher concentrations in water from wells in the Pleistocene valley trains, whereas dissolved organic carbon, iron, ammonia, fluoride, potassium, bicarbonate, magnesium, radium-226, barium, calcium, chromium, and dissolved solids were present in higher concentrations in water from wells in the Holocene alluvium.

Examples of some of these differences are shown in figure 8. Water in the Holocene alluvium tends to be older than water in the Pleistocene valley trains; that is, it has been underground longer. This increases possible contact with buried organics, resulting in less dissolved oxygen, which could influence concentrations of other chemical constituents.

Arsenic Concentrations

Arsenic, a compound that has been implicated in causing several cancers, was found at concentrations that exceeded current drinking-water guidelines in water from only one irrigation well that pumped water from the alluvial aquifer. However, concentrations at several other wells were high

enough to justify additional testing if proposals to lower the standards are promulgated.

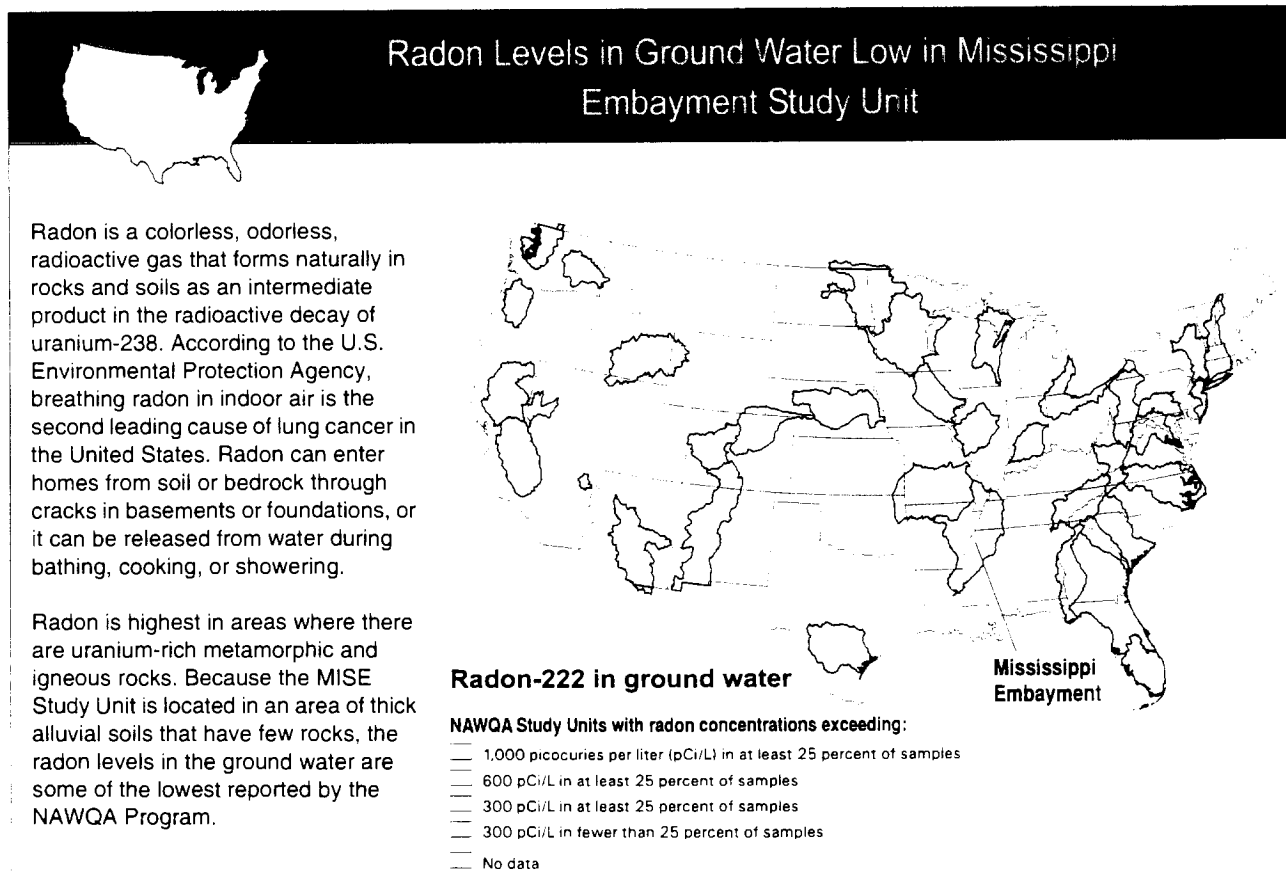

Figure 8. This graph shows some of the differences in chemistry in water from the Pleistocene valley trains and from the Holocene alluvium for a few selected constituents. Water from the wells in the Holocene deposits tended to be older and had lower oxygen levels. Low dissolved-oxygen concentrations in ground water may be associated with the presence of ammonia, dissolved organic carbon, and iron.

Aquatic Communities Show Environmental Stress

A combination of natural and anthropogenic (human-related) factors results in stream conditions that stress aquatic communities in the Mississippi Embayment Study Unit. The streams have naturally low gradients that result in sluggish flows and slow rates of reaeration (the ability of oxygen to enter the water). Also, the streams, in their natural conditions, have an abundance of streamside vegetation and swamps, resulting in an abundance of organic material in the water. This organic material is a good source of food for invertebrates (aquatic insects, crayfish, and freshwater shrimp) that inhabit the streams, but decay of the organic material and seasonally high water temperatures contribute to low dissolved-oxygen concentrations. The combination of low flow, high organic concentrations, and high temperatures results in a natural environment in which the organisms are often stressed by low dissolved-oxygen concentrations.

These natural conditions are coupled with many anthropogenic conditions in the area. These include stream channelization, which can eliminate riparian vegetation and degrade stream habitat; agricultural runoff into streams, which adds sediments, pesticides, and fertilizers to the aquatic environment; and the decline in the base flow of the streams due to ground-water withdrawal, which reduces the quantity of water available for organisms. This combination of natural and anthropogenic conditions affects each of the major biotic communities differently.

Algae

As a result of the dominant agricultural land use, fine alluvial soils, and limited vegetation in streamside or riparian areas, most of the streams in the MISE Study Unit are very turbid. Turbidity refers to the reduced clarity of surface water due to particles (usually sediment) suspended in the water. Many of the streams within the MISE also have moderately high phosphorus levels, which encourage algal growth. However, the algal growth in the streams is often more limited by the inability of light to penetrate the turbid waters, than by lack of nutrients. One indication of this can be seen in the Algal Siltation Index on page 17. This index uses the relative abundance of diatom species, which are able to move

and avoid being buried under large amounts of sediment, as an indication of stream-water quality. Levels of this index are high in agricultural areas of the MISE and moderate in mixed land-use areas.

Aquatic Invertebrates

Aquatic invertebrates in the MISE are influenced by habitat quantity and quality as well as by water chemistry. Often, the loss of stream and riparian habitat in the MISE is associated with stream channelization, where streams have been cleared, ditched, and straightened to facilitate the movement of floodwaters. These activities also result in the loss of microhabitats that are essential to aquatic invertebrates for food sources and refuge. Lower numbers of invertebrate taxa were found at sites that had

Streams in the Mississippi Embayment Study Unit have small changes in elevation from their headwaters to the mouth of the stream. This makes them very slow moving and generally contributes to low oxygen concentrations in the streams. The natural streams commonly have swamps adjacent to them, resulting in water stained with organics, ample habitat, and difficult sampling conditions, as shown above. The many channelized streams in the area (see upper left photograph) have commonly lost all of their riparian vegetation, and the streams have little habitat for aquatic organisms.

Some of the samples for both algae and invertebrates were collected by scraping organisms off submerged sticks in the streams. These sticks are commonly some of the best remaining habitats in many streams and rivers in the Mississippi Embayment Study Unit.

lower habitat quality (fig. 9). Other factors, including turbidity, low dissolved-oxygen concentrations, and the introduction of contaminants to the water, also affect invertebrate communities.

When compared to samples collected in other NAWQA Study Units across the United States (p. 17), invertebrate communities in MISE agricultural areas have low numbers of species and high proportions of tolerant organisms.

Fish

The condition of the fish communities in the MISE Study Unit was related to both water quality

Figure 9. The number of invertebrate taxa increased as the quality of the invertebrate habitat increased in MISE streams.

A prime habitat for invertebrates in the Mississippi Embayment Study Unit is this "undercut bank" where insects and other organisms hide in the roots and sticks. This habitat is removed or disturbed by channelization of streams and rivers or other habitat alterations.

and land-use activities. The best quality fish communities occurred where instream variables such as turbidity, total ammonia, the average number of herbicides detected, and total DDT in fish tissue were lowest. As shown in figure 10, the number of bass, an important game fish in the MISE, was highest at the sites where the turbidity was lowest. The condition of the fish communities also was correlated to landscape-level variables such as insecticide application rates and soil permeability.

When compared to fish communities collected at NAWQA Study Units across the Nation (p. 17), the MISE had more fish that are omnivores (that is, fish that eat whatever is available and therefore are more tolerant than fish that have more restrictive diets) and more fish that are considered tolerant of poor water-quality conditions. However, there were fewer anomalies

(sores, parasites and other abnormalities on the fish) and non-native fish found in the MISE than in other locations. This resulted in an overall national fish ranking of MISE agricultural streams slightly below the midpoint between the most degraded and least degraded streams in the NAWQA Program, whereas mixed land-use streams ranged from good to less than average.

Figure 10. The number of bass collected at a stream site was highest in those streams where the turbidity was the lowest.

Comparison of Mississippi Embayment Aquatic Communities to National Results

Algal Siltation Index

Algae collected at the 8 MISE basic fixed ecology sites were compared to algae at 140 other NAWQA sites by use of the Siltation Index (Bahls and others, 1992). This index is the relative abundance of motile diatoms, the species *Navicula*, *Nitzschia*, *Cylindrotheca*, and *Surirella* in a diatom count. These diatoms are able to move through silt particles and are associated with fine sediments. Because they are able to avoid being buried, they are considered more tolerant of sedimentation than other diatoms. Generally, this index tends to be higher for streams in agricultural basins. Relative to this index, all of the MISE agricultural sites fall into the most-degraded category for streams along with one of the mixed land-use sites, whereas the other two sites fall into the middle 50 percent.

A National Ranking of ALGAL STATUS in Streams

- Highest 25 percent*
 - Middle 50 percent
 - Lowest 25 percent
- * Higher values suggest a more degraded stream site

Invertebrate Community Status Index

To compare the invertebrate communities at MISE ecological basic fixed sites to national sites, a multimetric index called the Invertebrate Community Status Index was developed. The index combines 11 metrics, including ones that address taxa richness and diversity, richness of mayflies, stoneflies, and caddisflies, and tolerance metrics. Relative to this index, MISE agricultural streams are all ranked within the 25-percent most-degraded category for streams, whereas the mixed land-use streams have one site that falls into each category. Across the United States, both agricultural and urban sites tend to fall into the more degraded category.

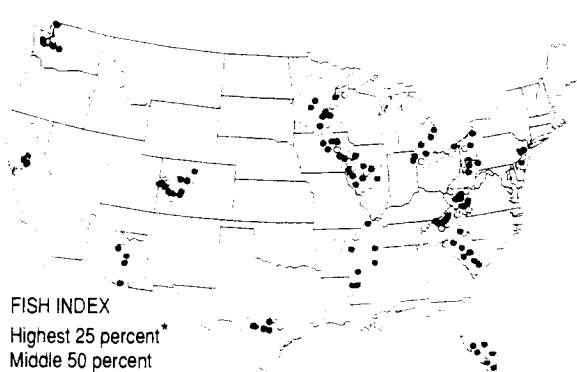

Fish Community Index

Similar in concept to the invertebrates, a multimetric fish index was developed to facilitate the comparison of fish communities across the United States. This index included four metrics: the percentage of tolerant individuals, the percentage of omnivorous individuals, the percentage of non-native individuals, and the percentage of individuals with anomalies. In all four metrics, a high percentage of individuals with the characteristic is typical of degraded sites. Agricultural sites in the MISE Study Unit generally fell at the boundary between the most-degraded category and the middle 50 percent (four sites are represented by the symbol at the 60-percent point). The mixed land-use sites ranged from the least-degraded category to the highly degraded category.

A National Ranking of FISH STATUS in Streams

- Highest 25 percent*
 - Middle 50 percent
 - Lowest 25 percent
- * Higher values suggest a more degraded stream site

Organochlorine Pesticides Persist in Fish Tissue

During the 1950s and 1960s, organochlorine pesticides were heavily used in the MISE Study Unit to control insects, particularly those associated with the cultivation of cotton. One of the most widely used organochlorine insecticides was DDT. In 1972, the sale of DDT was discontinued, and the use of most of the persistent organochlorine pesticides was discontinued during the 1970s. Nearly 30 years later, however, DDT or its metabolites were detected in fish tissue from all 41 sites sampled in the Study Unit. Thirty of these sites have total DDT levels in excess of the 0.2-mg/kg (milligram per kilogram) or 200 µg/kg (micrograms per kilogram) criterion set by the State of New York for the protection of fish-eating wildlife (Newell and others, 1987).

Although somewhat less prevalent and at lower concentrations, other organochlorine compounds also were detected in fish, including chlordane (at 33 percent of the sites), dieldrin (79 percent), heptachlor (7 percent), mirex (29 percent), and toxaphene (56 percent).

Most of the rivers in the MISE Study Unit were too deep to wade, so boat-mounted electroshocking equipment was used to collect fish (usually common carp) for tissue analysis.

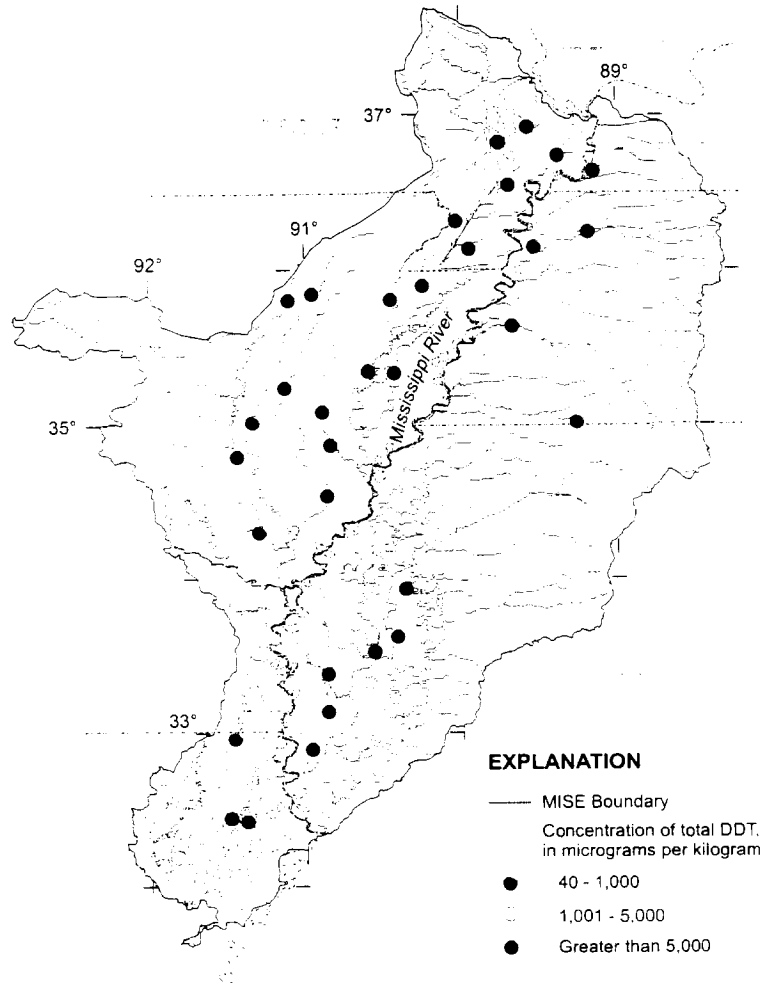

Figure 11. The concentrations of organochlorine pesticides were measured in fish tissue collected at 41 sites in the MISE Study Unit. Total DDT, an insecticide that has not been sold in the United States since 1972, was detected at all sites and occurs in concentrations that are of possible human health concern at some sites.

Of the 506 sites sampled thus far in the National Water-Quality Assessment Program, the highest concentrations of total DDT and toxaphene were found in fish collected in the Mississippi Embayment Study Unit (see pages 33 and 34 in Appendix A).

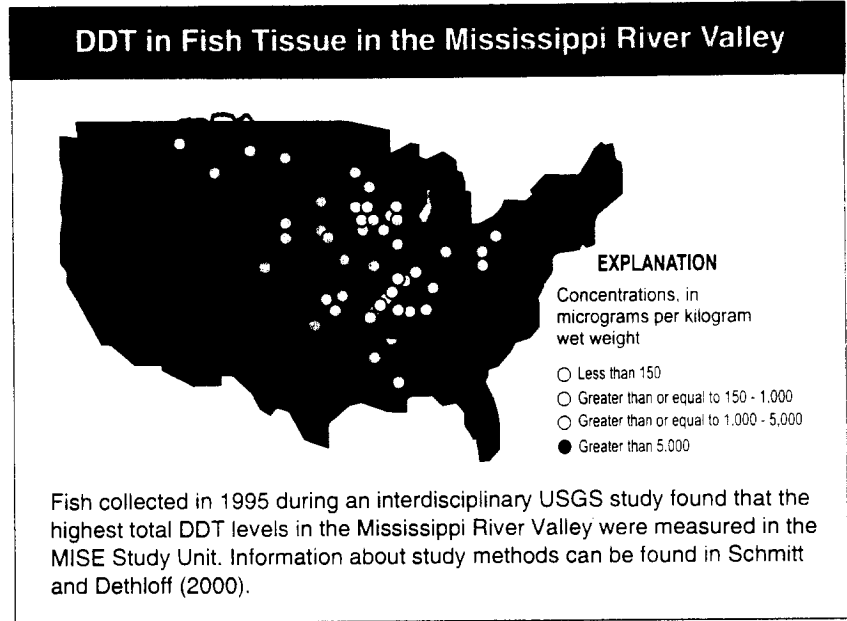

Distribution of Concentrations of DDT Within the Mississippi Embayment Study Unit

Although DDT was detected in fish tissue at every sampling site,

tissue samples from sites in the southern part of the Study Unit (fig. 11) had much higher concentrations of total DDT. On a national scale, Nowell and others, (1999) presented a positive correlation between median total DDT concentrations in whole fish and agricultural use of DDT in 1966. In the MISE, however, there seem to be additional factors influencing the persistence of DDT in fish tissue. Fish tissue data were compared to dozens of land-use and water-chemistry variables. Good correla-

tions can be made between total DDT concentrations and dissolved ammonia, nitrate, total phosphorus, and turbidity. The correlations with land-use variables, such as the percentage of the basin in agricultural production or the percentage of the basin in which cotton is grown, are much weaker, suggesting that factors in addition to land use and pesticide use are contributing to the distribution of DDT.

A relation exists between the concentrations of DDT in fish tissue and the geology of the area. Total DDT concentrations are much higher at sites in the Holocene alluvium than in the Pleistocene valley trains (fig. 12). The soils and geologic deposits in the Holocene alluvium are largely composed of dense clays that may cause agricultural runoff from these areas to enter the streams directly rather than infiltrate through the soils. Also, DDT tends to sorb onto clay particles and may be carried into streams attached to

these particles. Once in the stream, the cohesive nature of clay tends to prevent the material from moving downstream. These combined mechanisms may cause greater amounts of DDT to be in streams and available to organisms in Holocene areas than in streams in the Pleistocene valley trains.

Total DDT concentrations were detected in streambed sediments at all 15 sites measured. However, the concentrations in the sediments were many times lower than those in fish tissue.

Human Health Considerations

Because the NAWQA sampling was designed to measure the occurrence and distribution of compounds in the environment rather than address human health issues, whole fish (usually common carp) rather than fish fillets or other edible fish parts were analyzed for organochlorine compounds. However, the high concentrations of organochlorines that were detected at some of the sites in the MISE Study Unit suggest the need for further investigation. In the years since the sale of DDT and toxaphene has been discontinued, concerns have been raised about not only the toxicity of the pesticides but also the carcinogenic nature of organochlorine compounds.

Figure 12. The concentration of total DDT in fish tissue is higher at Holocene alluvium sampling sites than at sites in the Pleistocene valley trains. The mean concentration for the Holocene sites is 2,895 micrograms per kilogram, while the mean concentration for the Pleistocene sites is 522 micrograms per kilogram.

Pesticides in Air and Rain Samples from Agricultural and Urban Sites

During the 1995 growing season, weekly air and rain samples were collected from two sites in Mississippi and analyzed for 49 pesticides and pesticide metabolites. The two sites represented an agricultural area and an urban area. Every air and rain sample had detectable levels of multiple pesticides; the pesticides detected and the frequency of detection varied between the two sites and were related to the types of pesticides used nearby. However, long-range transport appears to have an effect, as some pesticides that are not registered for use in an urban setting were found in air and rain samples at the urban site. These findings demonstrate that small amounts of pesticides can be transported through the atmosphere and deposited into aquatic and terrestrial ecosystems at a substantial distance from their point of use.

Pesticides in the Air

Pesticides can enter the atmosphere through volatilization, wind

erosion of soil particles to which pesticides are attached, and direct spraying into the atmosphere during pesticide application.

Seasonal distribution of pesticides at the agricultural site is related to local application times of individual compounds. At the start of the study in April, the herbicides pendimethalin and trifluralin were the pesticides found in the highest concentrations in the air. In May, the two pesticides with the highest measured concentrations were the herbicides propanil and thiobencarb, which typically are used on rice. By August, the insecticide methyl parathion was detected in the highest concentration of any of the pesticides in the air at the agricultural site.

In contrast, diazinon was detected in the highest concentration in the air at the urban site. Chlorpyrifos also was detected frequently, and carbaryl, methyl parathion, and trifluralin were found less often. Although most of these compounds are used commonly in residential settings for such purposes as termite control, methyl parathion is used only for insect control in agricultural settings, thus

The yellow polyurethane foam plug was used to collect pesticides distributed into the gas phase of the atmosphere.

suggesting the long distance atmospheric transport of this compound.

Pesticides in the Rain

Once in the atmosphere, pesticides can be degraded, transported, and (or) redeposited. Deposition can be either wet, as with rain or snow, or dry, as with gaseous sorption and particle fallout.

The urban atmospheric sampling site on the left is in a residential area in southern Jackson, Mississippi, a metropolitan area of about 400,000 people. The site is more than 10 miles from the nearest agricultural field. The agricultural site on the right is located in the center of a catfish pond complex in Sharkey County, Mississippi. This site was selected to measure pesticides in the atmosphere in an area with minimal influence of direct application of pesticides to nearby fields. The nearest agricultural field is about one-half mile away, and the major crops grown in this area are soybeans, cotton, corn, and rice.

Figure 13. Pesticide concentrations in rainfall samples collected at an agricultural site in Mississippi during the 1995 growing season. In the spring, atrazine and propanil were detected in higher concentrations, but by summer the dominant pesticide measured was methyl parathion.

The concentrations of selected pesticides detected in rainfall samples from the agricultural site are shown in figure 13. The pesticides detected in the highest concentrations during the early part of the growing season were the herbicides atrazine, used on corn and grain sorghum, and propanil, used mainly on rice. Later in the growing season, the pesticide found in the highest concentrations was the insecticide methyl parathion.

The pesticides detected in rainfall samples from the urban site— atrazine, carbaryl, methyl parathion, and propanil—were similar to those found at the agricultural site, but the concentrations were much lower. Because methyl parathion and propanil do not have legal urban uses, it is assumed that these pesticides were transported in the atmosphere from their application areas. Methyl parathion and propanil are the first and sixth most heavily used agricultural pesticides in Mississippi.

Metabolites of DDT in the Air

In order to fully understand the fate, transport, and environmental effects of a pesticide, major metabolites of the pesticide commonly are included in the sampling program. One of the major metabolites of the organochlorine insecticide DDT is *p,p'*-DDE. In 1971, Stanley and others (1971) detected *p,p'*-DDE in the air at an agricultural site near Stoneville, Miss. (about 60 miles north of the Sharkey County site) in concentrations ranging from 2.6 to 7.1 ng/m³ (nanograms per cubic meter). Twenty-four years later, the range of *p,p'*-DDE in air samples from the agricultural site ranged from 0.13 to 1.1 ng/m³, lower than reported by Stanley and others (1971) but still significant considering that there is no current use of DDT in the area. These results indicate that a persistent metabolite of *p,p'*-DDT was still measurable in the air more than two decades after the sale of DDT was discontinued in the United States.

DDT Metabolites in the Air Across Mid-America

The air concentrations of *p,p'*-DDE, a metabolite of DDT, were determined at paired urban and agricultural sites in Mississippi, Iowa, and Minnesota (Foreman and others, 2000). The agricultural site in Mississippi and the urban site in Iowa had detectable levels of *p,p'*-DDE in every sample. Approximately 10 to 30 percent of the samples collected at the other sites had detectable levels of *p,p'*-DDE. It is likely that these concentrations of *p,p'*-DDE are from past local use of DDT. However, DDT is still being used in other parts of the world, and it is possible that some proportion of this *p,p'*-DDE originated elsewhere and was transported in the atmosphere.

More details on pesticides in the atmosphere can be found in the paper: Coupe, R.H., Manning, M.A., Foreman, W.T., Goolsby, D.A., and Majewski, M.S., 2000, Occurrence of pesticides in urban and agricultural areas of Mississippi, April–September 1995: *Science of the Total Environment*, v. 248, no. 2–3, p. 227.

The paper also can be downloaded at: <http://ms.water.usgs.gov/misenawqa/>

Integration of Biological, Geological, and Chemical Data Improves Understanding of Aquatic Systems

One of the most significant advances in the aquatic sciences during the last century is the growing understanding that aquatic systems, such as lakes and rivers, are profoundly influenced by the biological, chemical, and physical aspects of the drainage basin in which the water body is located (Wetzel, 1983). Although the conceptual framework for these ideas is decades old, scientists are still developing the technologies and accumulating the data bases necessary to more fully understand the relations between a body of water, the biotic components within it, and the chemical and physical influences of the drainage basin.

In the NAWQA Program, researchers often collect biological, geological, and chemical information from the same stream sites and analyze land use from the corresponding drainage basins. This information presents an opportunity to examine biogeochemical relations within the watersheds. This interdisciplinary approach has yielded at least three broad findings in the MISE Study Unit. Three findings, which need to be examined in more detail to guide scientific understanding and management in this region, are: (1) DDT and its metabolites remain detectable in many parts of the environment; (2) numerous interrelations exist between the biological, geological, and chemical components of the MISE Study Unit; and (3) evidence exists that the geology of the Study Unit exerts an influence

on many aspects of the environment.

DDT and Its Metabolites Are Present Throughout the Environment

Nearly 30 years after the sale of DDT was discontinued, the pesticide and its metabolites were detected in all parts of the MISE Study Unit environment. While residual total DDT is found throughout the world, the concentrations in the MISE are among the highest in the United States. (See water, fish tissue, and bed sediment sections of the national comparison tables on pages 31, 33, and 34 for a comparison of MISE results to other NAWQA Study Units in the United States.) A metabolite of DDT, DDE persists in various concentrations in many different parts of the MISE environment, including the air, water, streambed sediment, and fish tissue, generating interesting questions about its transport, accumulation, and persistence.

Biological and Chemical Relations

The MISE Study Unit has numerous complex interrelations among stream biology, basin geology, stream chemistry and land use. Some of these interrelations are illustrated by a variety of linear relations among biological, geological, and chemical components of 36 stream sites and their drainage basins in the MISE Study Unit (fig. 14). Figures 14A and 14C illustrate how differences in stream chemistry can affect biological communities in the stream. Figure 14A shows that the number of insectivore fish taxa decreases as total ammonia increases, whereas figure 14C

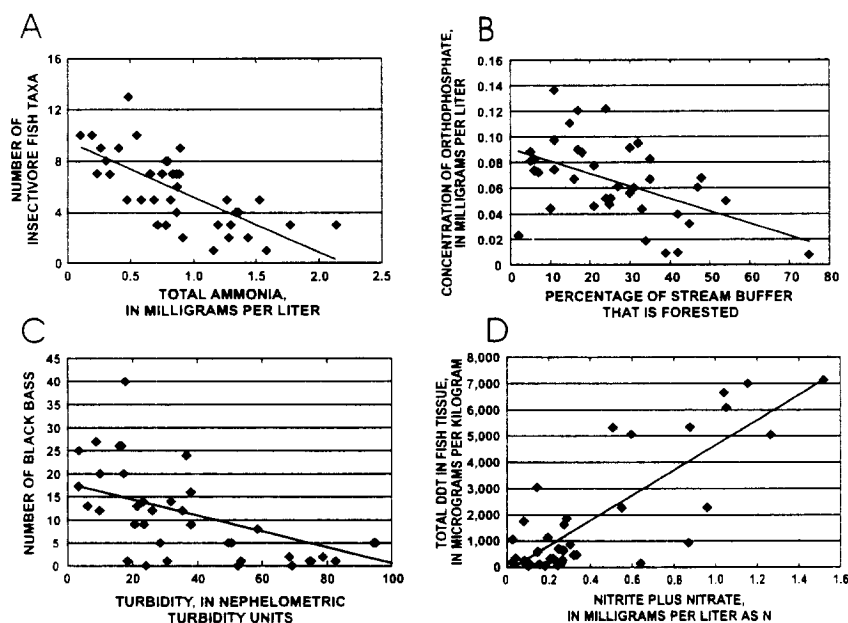

Figure 14. There are numerous interrelations among stream biology, basin geology, stream chemistry, and land use in the Mississippi Embayment Study Unit. The lines in these graphs represent linear relations between some of the variables.

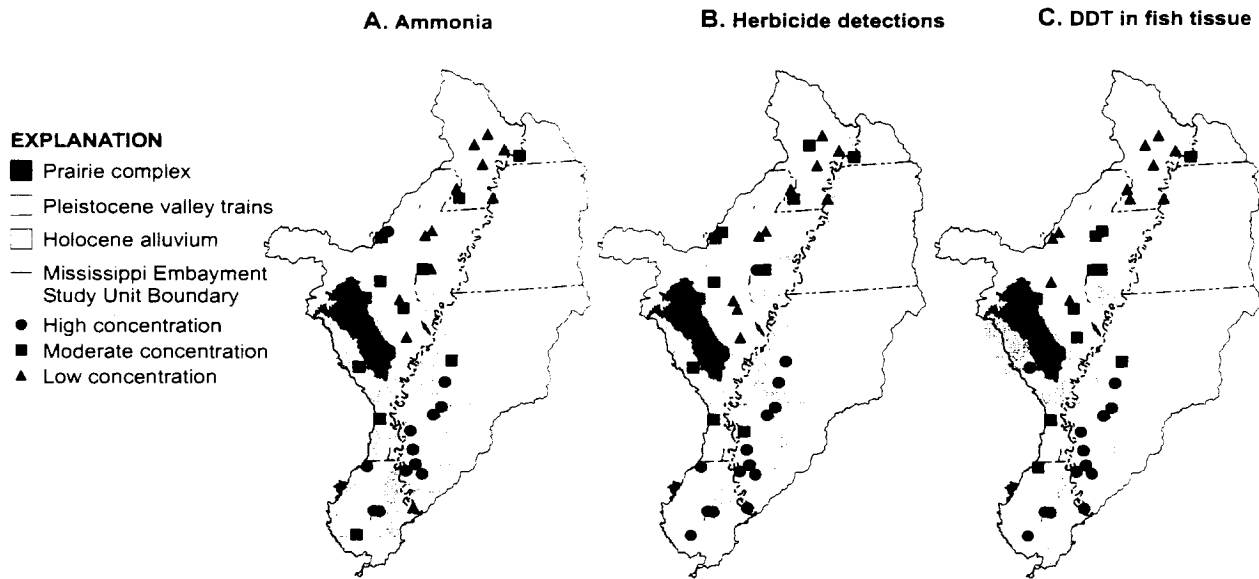

Figure 15. Several variables in the MISE Study Unit vary spatially and correspond generally to the Quaternary geology of the Mississippi Alluvial Plain. Soils formed from the Holocene alluvium tend to be dense, thick clays, whereas the Pleistocene features tend to have soils that have more silts and sands. These soils influence permeability and runoff, which in turn, appear to affect the amount and persistence of agricultural chemicals in the streams.

shows that the number of black bass decreases as turbidity increases. Figures 14B and 14D show how factors in the drainage area, but not in the stream, can influence the stream. Figure 14B shows that as the percentage of forested stream buffer (the area within 60 meters of the streams) increases, concentrations of orthophosphate in the stream decrease, indicating the value of vegetated stream buffers in minimizing the amount of runoff entering streams and rivers. Finally, figure 14D illustrates that as the concentration of dissolved nitrite plus nitrate increases, the amount of total DDT in fish tissue increases, suggesting that conditions that facilitate agricultural runoff affect nutrient levels in the streams and the long-term bioaccumulation of organochlorine pesticides in fish tissue.

The sum of these various relations shows the complexity of the system, underscores the need for

multidisciplinary studies in order to thoroughly understand the Mississippi Embayment Study Unit, and discourages simplistic, one-dimensional management solutions.

Geology Influences Many Variables

Within the Mississippi Embayment Study Unit, the geology of the land surface appears to exert an overarching influence on many components of the environment. The dense, tight clays of the Holocene alluvium dictate the types of crops grown and cause high runoff potential in the area. These factors help to determine the types of agricultural chemicals that are applied and the amounts of these chemicals that are transported into rivers and streams. Once in the streams, the clays tend to cause chemicals sorbed to sediments to remain locally in the bed sediment rather than to be washed downstream. Sites where high concentrations of ammonia were found are

clustered in the Holocene alluvium (fig. 15A), whereas similar clusters occurred for the number of herbicides detected in the water (fig. 15B) and the amount of total DDT found in fish tissue (fig. 15C). In turn, many biological metrics were lower at sites located in the Holocene alluvium, and differences in ground-water chemistry were detected (pages 13 and 14).

This information reaffirms that a better understanding of the underlying geology of the Earth itself is needed to fully understand the effects of human activities on the environment.

Carp used for tissue analysis.

STUDY UNIT DESIGN

Stream Chemistry

The stream-chemistry network was designed to measure the effects of land use (primarily cropland) on stream quality and to integrate the effects of multiple land uses and hydrogeologic settings on water quality. Data from the Basic Fixed Sites were used to examine differences in water quality from one basin to another. Data from Intensive Fixed Sites, which were sampled more often, were used to examine seasonal changes in stream quality and to calculate fluxes from the basin. Also, detailed data on pesticides dissolved in the water were collected at intensive sites. A synoptic study was conducted to measure a selected set of constituents at 38 sites in the Study Unit in order to better understand spatial differences among the basins and to compare water chemistry to biological and landscape parameters.

- EXPLANATION**

 - Bed Sediment and Tissue Sites

Stream Ecology

Ecological assessments were done annually at the basic and intensive stream-chemistry sites. The objective of these studies was to investigate biological, chemical, and physical data as multiple lines of evidence to assess water quality. Some of the assessments examined multiple reaches of a stream to determine spatial variations in the community structure of the aquatic organisms. Synoptic studies were designed to examine spatial variability in biological communities in the Study Unit and to relate this variability to stream chemistry and landscape variables. Early in the project, bed sediment and fish tissue were sampled at a subset of sites; later in the project, fish tissue was sampled for organochlorine concentrations at all of the synoptic sites.

Ground-Water Chemistry

Three surveys examined the effects of land use on ground water in different aquifer settings. The deep Tertiary aquifers are the deepest aquifers studied and the ones that provide drinking water to the greatest number of people in the Study Unit. The Memphis shallow aquifer survey was designed to assess the ground-water quality in commercial and residential areas. The alluvial aquifer survey examined ground-water quality from a shallow aquifer that is heavily used for agriculture.

- Deep Tertiary Aquifers
 - Memphis Shallow Aquifer
 - Alluvial Aquifer

SUMMARY OF DATA COLLECTION IN THE MISSISSIPPI EMBAYMENT STUDY UNIT, 1995-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Basic Fixed Sites	Continuous streamflow, nutrients, major ions, organic carbon, suspended sediment, and physical parameters were measured to describe concentrations and seasonal variations.	Sites were selected to represent the range of ecoregions, physiographic regions, and land uses present in the Study Unit.	9	Samples were collected monthly February 1996 - January 1998.
Intensive Fixed Sites	In addition to the above list of data collected at the Basic Fixed Sites, information on 82 dissolved pesticides was collected to determine concentrations, seasonal variations, and loads. Volatile organic compounds also were measured at the urban site.	Three of the sites were located at streams that drained intensive agricultural areas but were dominated by different crop types. One site was a large river site with mixed land use. The remaining site was located in a rapidly growing urban area.	5	Sampling frequency ranged from biweekly during the growing season to weekly throughout the remainder of the period February 1996 - January 1998.
Synoptic Sites—Water Chemistry	Nutrients, pesticides, and physical properties were measured to broaden the spatial coverage of water-quality information in the Study Unit.	Synoptic sites were selected in an effort to sample streams that drained all major crop types grown in the Study Unit.	38	Samples were collected once during May, July, and August 1997.
Stream Ecology				
Ecological Assessment Sites	Fish, macroinvertebrate, algae, and habitat data were collected to examine relations among the biological community and water chemistry, land use, and physical components of the landscape and drainage basin.	Sites were selected to represent the range of ecoregions, physiographic regions, and land uses present in the Study Unit.	8	Samples were collected once during low-flow conditions in the summers of 1996-98; at two sites, three reaches were sampled in 1996.
Synoptic Sites—Ecology	Fish, macroinvertebrate, habitat, and streamflow data were collected once at a larger number of sites to develop a better understanding of the spatial aspects of aquatic communities in the Study Unit.	Synoptic sites were selected in an effort to sample streams that drained all major crop types grown in the Study Unit.	38	Samples were collected July-September 1997 for macroinvertebrates; July-September 1998 for fish.
Contaminants in Bed Sediments	Total PCB's, organochlorine pesticides, semivolatile organic compounds, and trace elements were measured in order to determine the occurrence and distribution of contaminants in stream sediments.	Sites were selected to represent the range of ecoregions, physiographic regions, and land uses present in the Study Unit.	15	Samples were collected during August and September 1995.
Contaminants in Fish Tissue	Organochlorine pesticides were measured in whole fish, and trace elements were measured in fish liver.	Sites were selected in an effort to sample streams that drained all major crop types grown in the Study Unit.	41 (pesticides) 15 (trace elements)	Samples were collected during late summer low-flow conditions in 1995-98.
Ground-Water Chemistry				
Deep Tertiary Aquifers	Nutrients, major ions, pesticides, volatile organic compounds, radioisotopes, stable isotopes, and physical parameters were measured to determine overall water quality in a deep aquifer used for drinking water.	Public-supply wells screened in the deep Tertiary aquifers (Claiborne and Wilcox Groups) were sampled.	30	Samples were collected once during April and May 1996.
Memphis Shallow Aquifers	Nutrients, major ions, trace elements, pesticides, volatile organic compounds, radioisotopes, stable isotopes, and physical parameters were measured to determine overall water quality in shallow aquifers in a rapidly developing urban area.	Twenty-four monitoring wells screened in the shallow water-table aquifer and eight monitoring wells screened in the upper part of the Memphis aquifer were sampled.	32	Samples were collected once during April and May 1997.
Alluvial Aquifer	Nutrients, major ions, trace elements, pesticides, volatile organic compounds, radioisotopes, stable isotopes, and physical parameters were measured to determine overall water quality in an aquifer largely used for agricultural irrigation, but also for public supply and industry.	Twenty-five irrigation wells screened in the Holocene alluvium and 29 irrigation wells screened in the Pleistocene valley trains were sampled.	54	Samples were collected once during the summer of 1998.
Special Studies				
Pesticides in the Atmosphere	Pesticides were measured in the air and in the rain.	Two sites were sampled—one in an agricultural area in Sharkey County, Miss., and one in an urban area in Jackson, Miss.	2	Samples were collected April-September 1995.
Pesticides in Fish Tissue in the Mississippi River	Organochlorine pesticides in whole fish (common carp) were measured to determine if pesticides leaving the Yazoo River Basin could be detected in fish in the Mississippi River.	Four sites were selected within an area 100 miles upstream and another four sites were selected 100 miles downstream from the confluence of the Yazoo River and the Mississippi River.	8	Samples were collected once during November 1997.

GLOSSARY

- Algae** - Chlorophyll-bearing nonvascular, primarily aquatic species that have no true roots, stems, or leaves; most algae are microscopic, but some species can be as large as vascular plants.
- Alluvial aquifer** - A water-bearing deposit of unconsolidated material (sand and gravel) left behind by a river or other flowing water.
- Alluvium** - Deposits of clay, silt, sand, gravel or other particulate rock material left by a river in a streambed, on a flood plain, delta, or at the base of a mountain.
- Aquatic-life criteria** - Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms. See also Water-quality guidelines, Water-quality criteria, and Freshwater chronic criteria.
- Aquifer** - A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Atmospheric deposition** - The transfer of substances from the air to the surface of the Earth, either in wet form (rain, fog, snow, dew, frost, hail) or in dry form (gases, aerosols, particles).
- Basic Fixed Sites** - Sites on streams at which streamflow is measured and samples are collected for temperature, salinity, suspended sediment, major ions and metals, nutrients, and organic carbon to assess the broad-scale spatial and temporal character and transport of inorganic constituents of streamwater in relation to hydrologic conditions and environmental settings.
- Bed sediment** - The material that temporarily is stationary in the bottom of a stream or other watercourse.
- Bioaccumulation** - The biological sequestering of a substance at a higher concentration than that at which it occurs in the surrounding environment or medium. Also, the process whereby a substance enters organisms through the gills, epithelia tissues, dietary, or other sources.
- Biota** - Living organisms.
- Channelization** - Modification of a stream, typically by straightening the channel, to provide more uniform flow; often done for flood control or for improved agricultural drainage or irrigation.
- Community** - In ecology, the species that interact in a common area.
- Concentration** - The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as microgram per liter (water sample) or microgram per kilogram (sediment or tissue sample).
- Criterion** - A standard rule or test on which a judgment or decision can be based.
- Degradation products** - Compounds resulting from transformation of an organic substance through chemical, photochemical, and/or biochemical reactions.
- Detection limit** - The minimum concentration of a substance that can be identified, measured, and reported within 99 percent confidence that the analyte concentration is greater than zero; determined from analysis of a sample in a given matrix containing the analyte.
- DDT** - Dichloro-diphenyl-trichloroethane. An organochlorine insecticide no longer registered for use in the United States.
- Dissolved solids** - Amount of minerals, such as salt, that are dissolved in water; amount of dissolved solids is an indicator of salinity or hardness.
- Drainage area** - The drainage area of a stream at a specified location is that area, measured in a horizontal plane, which is enclosed by a drainage divide.
- Drinking-water standard or guideline** - A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.
- Ecosystem** - The interacting populations of plants, animals, and microorganisms occupying an area, plus their physical environment.
- Eutrophication** - The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.
- Fixed Sites** - NAWQA's most comprehensive monitoring sites. See also Basic Fixed Sites and Intensive Fixed Sites.
- Ground water** - In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Habitat** - The part of the physical environment where plants and animals live.
- Herbicide** - A chemical or other agent applied for the purpose of killing undesirable plants. See also Pesticide.
- Holocene** - A subdivision of geologic time which began at the end of the Pleistocene (approximately 9,000 to 11,000 years ago) and extends to the present.
- Human health advisory** - Guidance provided by U.S. Environmental Protection Agency, State agencies or scientific organizations, in the absence of regulatory limits, to describe acceptable contaminant levels in drinking water or edible fish.
- Intensive Fixed Sites** - Basic Fixed Sites with increased sampling frequency during selected seasonal periods and analysis of dissolved pesticides for 1 year. Most NAWQA Study Units have one to two integrator Intensive Fixed Sites and one to four indicator Intensive Fixed Sites.
- Load** - General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.
- Loess** - Homogeneous, fine-grained sediment made up primarily of silt and clay, and deposited over a wide area (probably by wind).
- Maximum contaminant level (MCL)** - Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Median** - The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Metabolite** - A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process which may result in a more toxic or a less toxic compound and a more persistent or less persistent compound.
- Method detection limit** - The minimum concentration of a substance that can be accurately identified and measured with present laboratory technologies.

- Micrograms per liter ($\mu\text{g/L}$)** - A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most streamwater and ground water. One thousand micrograms per liter equals 1 mg/L.
- Minimum reporting level (MRL)** - The smallest measured concentration of a constituent that may be reliably reported using a given analytical method. In many cases, the MRL is used when documentation for the method detection limit is not available.
- Nitrate** - An ion consisting of nitrogen and oxygen (NO_3^-). Nitrate is a plant nutrient and is very mobile in soils.
- Nonpoint source** - A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs from plants and trees are types of nonpoint source pollution.
- Nutrient** - Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.
- Organochlorine insecticide** - A class of organic insecticides containing a high percentage of chlorine. Includes dichlorodiphenylethanes (such as DDT), chlorinated cyclodienes (such as chlordane), and chlorinated benzenes (such as lindane). Most organochlorine insecticides were banned because of their carcinogenicity, tendency to bioaccumulate, and toxicity to wildlife.
- Periphyton** - Organisms that grow on underwater surfaces; periphyton include algae, bacteria, fungi, protozoa, and other organisms.
- Phosphorus** - A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.
- Physiography** - A description of the surface features of the Earth, with an emphasis on the origin of landforms.
- Pleistocene** - A subdivision of geologic time which began about 2 million years ago and ended at the beginning of the Holocene epoch, approximately 9,000 to 11,000 years ago.
- Quaternary** - A subdivision of geologic time which began about 2 million years ago and extends to the present. The Quaternary period is further divided into two epochs, the Pleistocene and the Holocene.
- Recharge** - Water that infiltrates the ground and reaches the saturated zone.
- Sediment quality guideline** - Threshold concentration above which there is a high probability of adverse effects on aquatic life from sediment contamination, determined using modified USEPA (1996) procedures.
- Semivolatile organic compound (SVOC)** - Operationally defined as a group of synthetic organic compounds that are solvent-extractable and can be determined by gas chromatography/mass spectrometry. SVOCs include phenols, phthalates, and polycyclic aromatic hydrocarbons (PAHs).
- Species diversity** - An ecological concept that incorporates both the number of species in a particular sampling area and the evenness with which individuals are distributed among the various species.
- Species (taxa) richness** - The number of species (taxa) present in a defined area or sampling unit.
- Stream reach** - A continuous part of a stream between two specified points.
- Study Unit** - A major hydrologic system of the United States in which NAWQA studies are focused. Study Units are geographically defined by a combination of ground- and surface-water features and generally encompass more than 4,000 square miles of land area.
- Study-Unit Survey** - Broad assessment of the water-quality conditions of the major aquifer systems of each Study Unit. The Study-Unit Survey relies primarily on sampling existing wells and, wherever possible, on existing data collected by other agencies and programs. Typically, 20 to 30 wells are sampled in each of three to five aquifer subunits.
- Synoptic sites** - Sites sampled during a short-term investigation of specific water-quality conditions during selected seasonal or hydrologic conditions to provide improved spatial resolution for critical water-quality conditions.
- Taxon (plural taxa)** - Any identifiable group of taxonomically related organisms.
- Total DDT** - The sum of DDT and its metabolites (breakdown products), including DDD and DDE.
- Trace element** - An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.
- Triazine herbicide** - A class of herbicides containing a symmetrical triazine ring (a nitrogen-heterocyclic ring composed of three nitrogens and three carbons in an alternating sequence). Examples include atrazine, propazine, and simazine.
- Turbidity** - Reduced clarity of surface water because of suspended particles, usually sediment.
- Volatile organic compounds (VOCs)** - Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.
- Water-quality criteria** - Specific levels of water quality which, if reached, are expected to render a body of water unsuitable for its designated use. Commonly refers to water-quality criteria established by the U.S. Environmental Protection Agency. Water-quality criteria are based on specific levels of pollutants that would make the water harmful if used for drinking, swimming, farming, fish production, or industrial processes.
- Water-quality guidelines** - Specific levels of water quality which, if reached, may adversely affect human health or aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.
- Water-quality standards** - State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.
- Water year** - The continuous 12-month period, October 1 through September 30, in U.S. Geological Survey reports dealing with the surface-water supply. The water year is designated by the calendar year in which it ends and which includes 9 of the 12 months. Thus, the year ending September 30, 1980, is referred to as the water year 1980.
- Wetlands** - Ecosystems whose soil is saturated for long periods seasonally or continuously, including marshes, swamps, and ephemeral ponds.

APPENDIX—WATER-QUALITY DATA FROM THE MISSISSIPPI EMBAYMENT IN A NATIONAL CONTEXT

For a complete view of Mississippi Embayment data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Mississippi Embayment. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Mississippi Embayment compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, fluometuron concentrations in Mississippi Embayment agricultural streams were similar to the national distribution, but the detection frequency was much higher (63 percent compared to 8 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Mississippi Embayment, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- .. Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- .. No benchmark for protection of aquatic life

Pesticides in water—Herbicides

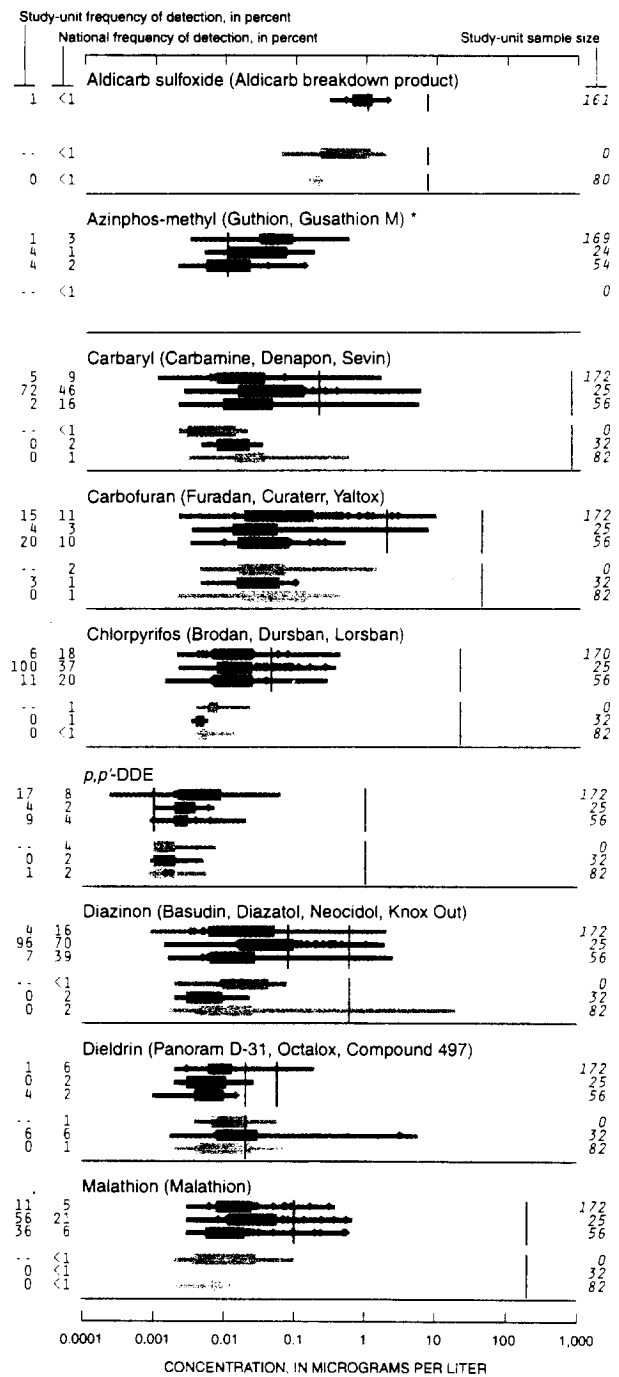

Other herbicides detected

- Acetochlor (Harness Plus, Surpass) ***
- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) ***
- Bentazon (Basagran, Bentazone) **
- Bromacil (Hyvar X, Urox B, Bromax)
- Bromoxynil (Buctril, Brominal) *
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) ***
- DCPA (Dacthal, chlorthal-dimethyl) ***
- Dacthal mono-acid (Dacthal breakdown product) ***
- Dicamba (Banvel, Dianat, Scotts Proturf)
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) ***
- Dinoseb (Dinosebe)
- EPTC (Eptam, Farmarox, Alirox) ***
- Fenuron (Fenulon, Fenidim) ***
- Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
- MCPA (Rhomene, Rhonox, Chiptox)
- Napropamide (Devrinol) ***
- Neburon (Neburea, Neburyl, Noruben) ***
- Norflurazon (Evitall, Predict, Solicam, Zorial) ***
- Pebulate (Tillam, PEBC) ***
- Picloram (Grazon, Tordon)
- Pronamide (Kerb, Propyzamid) **
- Propachlor (Ramrod, Satecid) **
- Propanil (Stam, Stampede, Wham) ***
- Tebuthiuron (Spike, Tebusan)
- Terbacil (Sinbar) **
- Thiobencarb (Bolero, Saturn, Benthicarb) ***
- Triclopyr (Garlon, Grandstand, Redeem, Remedy) ***
- Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

- Butylate (Sutan +, Genate Plus, Butilate) **
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) ***
- 2,6-Diethylaniline (Alachlor breakdown product) ***
- Ethalfuralin (Sonalan, Curbit) ***
- MCPB (Thistrol) ***
- Oryzalin (Surflan, Dirimal) **
- Propham (Tuberite) **
- 2,4,5-T **
- 2,4,5-TP (Silvex, Fenoprop) **
- OTrallate (Far-Go, Avadex BW, Tri-allate) *

Pesticides in water—Insecticides

Other insecticides detected

- Disulfoton (Disyston, Di-Syston) **
- Methomyl (Lanox, Lannate, Acinate) **
- Methyl parathion (Penncap-M, Folidol-M) **
- Propargite (Comite, Omite, Ornamite) ***

Insecticides not detected

- Aldicarb (Temik, Ambush, Pounce)
- Aldicarb sulfone (Standak, aldoxycarb)
- Ethoprop (Mocap, Ethoprophos) ***

Fonofos (Dyfonate, Capfos, Cudgel Tyca) **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 gamma-HCH (Lindane, gamma-BHC)
 3-Hydroxycarbofuran (Carbofuran breakdown product) ***
 Methiocarb (Slug-Geta, Grandslam, Mesuro) **
 Oxamyl (Vydate L, Pratt) **
 Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
 cis-Permethrin (Ambush, Astro, Pounce) ***
 Phorate (Thimet, Granutox, Geomet, Rampart) **
 Propoxur (Baygon, Blattanex, Uden, Proprox) ***
 Terbufos (Contraven, Counter, Pilarfox) **

1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
 1,2-Dibromoethane (Ethylene dibromide, EDB)
 Dibromomethane (Methylene dibromide) *
 trans-1,4-Dichloro-2-butene ((Z)-1,4-Dichloro-2-butene) *
 1,2-Dichlorobenzene (o-Dichlorobenzene)
 1,3-Dichlorobenzene (m-Dichlorobenzene)
 1,2-Dichloropropane (Propylene dichloride)
 2,2-Dichloropropane *
 1,3-Dichloropropane (Trimethylene dichloride) *

BIOLOGICAL INDICATORS

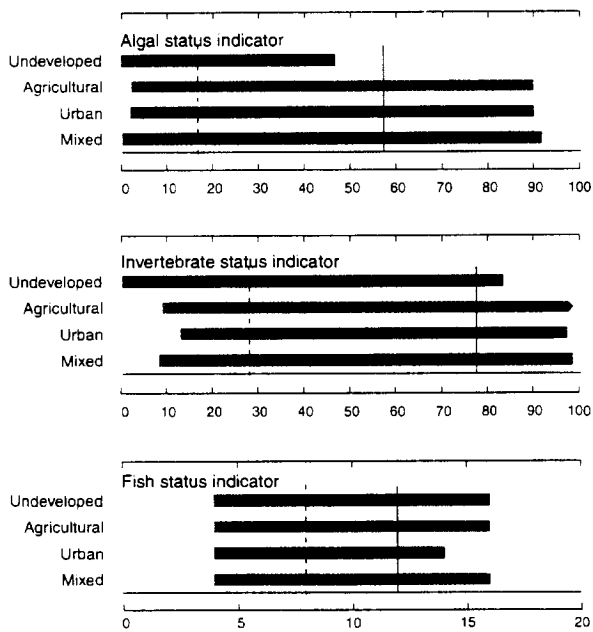

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation

APPENDIX—WATER QUALITY FROM THE LOWER ILLINOIS RIVER BASIN IN A NATIONAL CONTEXT	30

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the lower Illinois River Basin that emerged from an assessment conducted between 1995 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the lower Illinois River Basin assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA program.

The lower Illinois River Basin is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Stream and river highlights

During the past century, agricultural runoff, channel and drainage modifications, urbanization, and other activities have altered water quality, aquatic biological communities, and aquatic habitat in the lower Illinois River Basin. The water quality of large rivers, such as the Illinois and Sangamon Rivers, was more likely to meet drinking-water standards than water quality of small streams during 1995–98. In spring, concentrations of nitrate—especially in small streams—exceeded the Maximum Contaminant Level (MCL) of 10 mg/L (milligrams per liter) for drinking water. Some of these streams replenish drinking-water reservoirs. In samples collected during runoff from spring and early summer storms, concentrations of herbicides and a few insecticides exceeded drinking-water standards or guidelines, or guidelines to protect aquatic life. In a few samples from small streams, concentrations of commonly used agricultural pesticides were among the highest nationally. Although most concentrations were low with respect to existing drinking-water standards or guidelines, criteria for the protection of human health or wildlife have not been established for more than one-half of the chemicals detected.

- Nitrogen and phosphorus concentrations were among the highest in the Nation. The highest concentrations in the basin were found in small streams in agricultural areas. The MCL for nitrate was exceeded in 15 percent of samples from all streams and rivers. The concentration of total phosphorus in most samples (79 percent) from all streams and rivers exceeded the 0.1-mg/L guideline recommended by U.S. Environmental Protection Agency (USEPA) to prevent excess algal growth in streams. (See pages 6–8.)
- Nitrate concentrations in the Illinois River at the inflow to the basin (Ottawa) and outflow from the basin (Valley City) were similar; however, approximately twice the amount of nitrogen was transported out of the basin (124,000 tons per year) as was transported into the basin (66,000 tons per year). (See page 6.)
- During August 1997, concentrations of nitrate in streams were lower in the basin than in other NAWQA study-area streams of the upper Midwest. Algal communities may have incorporated much of the instream nitrogen, resulting in lower nitrate concentrations in the water during late summer. (See pages 7–10.)
- Three herbicides commonly used by farmers to protect corn and soybean crops—atrazine, metolachlor, and cyanazine—were detected in every sample collected during 1995–98. During periods of spring runoff, these herbicides exceeded drinking-water standards or guidelines or aquatic-life guidelines. Another herbicide, acetochlor, was detected in most samples (81 percent). (See pages 12–17.)
- Pesticide breakdown products were detected much more frequently than the parent compound, and generally

The lower Illinois River Basin occupies approximately 18,000 square miles in central and west-central Illinois. The basin lies almost entirely within the Till Plains physiographic section. The glacial materials account for the flat prairie landscape and the thick, rich soils. The three physiographic subsections influence water quality indirectly by influencing the type and intensity of agricultural activities. [1]

at higher concentrations and for a longer period of time after application. (See pages 16–17.)

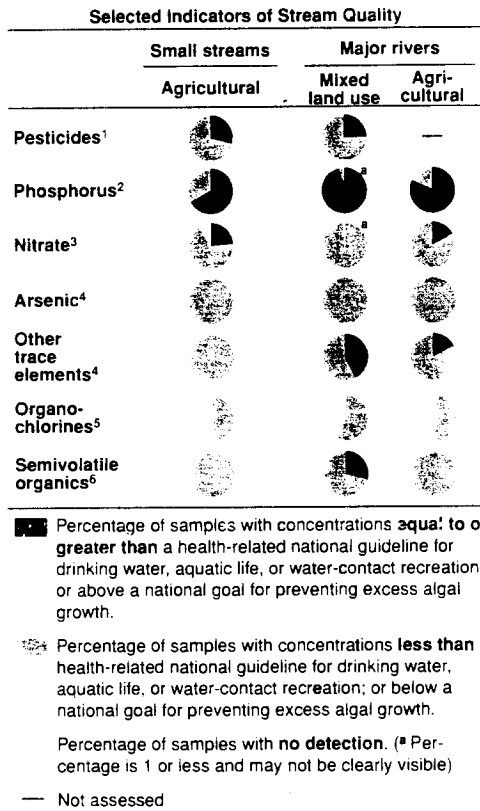

- Organochlorine compounds (including insecticides no longer used) were detected in fish tissue and sediment, and polycyclic aromatic hydrocarbons were detected in sediments at levels of concern. (See pages 17–22.)
- The biological communities of streams in the basin comprised many organisms that are tolerant of poor water quality; however, some high-velocity streams had fairly diverse invertebrate communities. (See pages 20–21.)

Trends in stream-water quality

For decades, fertilizers and many pesticides have been applied to crops and land. The persistence of pesticides and breakdown products in the soil, water, and sediment within a watershed is not well understood. Concentrations of the herbicides alachlor and cyanazine, however, decreased from the 1991–92 period to the 1996–98 period in the Illinois River because of reduced application rates since the early 1990s. (See page 16.)

Major influences on streams and rivers

- Subsurface (tile) drainage from agricultural areas
- Agricultural and urban land-surface runoff
- Drainage modification to streams and channels

Ground-water highlights

In contrast to the water quality of streams and rivers in the basin and the quality of ground water in other areas across the Nation, agricultural chemicals in ground-water samples from shallow monitoring wells (generally less than 100 feet deep) and drinking-water wells only rarely exceeded the nitrate MCL. Except for radon and nitrate, shallow ground water in the lower Illinois River Basin generally met drinking-water standards or guidelines. Except for radon and arsenic, the water quality in the Mahomet aquifer (greater than 200 feet deep) meets all drinking-water standards or guidelines.

- Major corn and soybean herbicides were not as frequently detected in ground-water samples as they were in stream-water samples. No ground-water sample exceeded

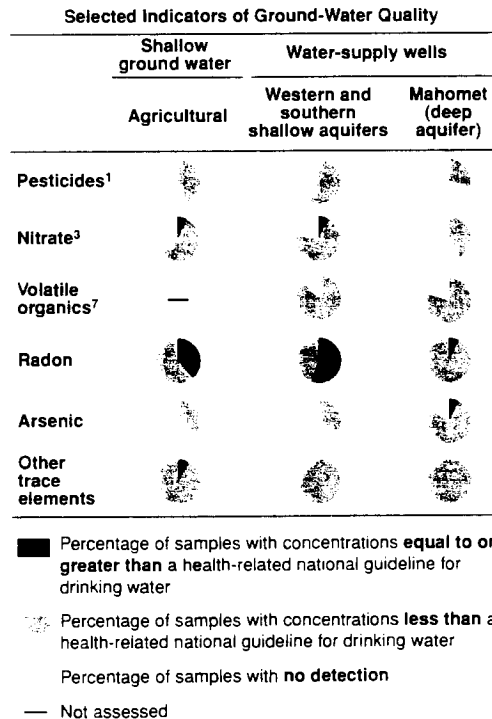

¹ Insecticides, herbicides, and pesticide breakdown products, sampled in water.
² Total phosphorus, sampled in water.
³ Nitrate (as nitrogen), sampled in water.
⁴ Arsenic, mercury, and trace metals, sampled in sediment.
⁵ Organochlorine compounds including DDT and PCBs, sampled in sediment.
⁶ Miscellaneous industrial chemicals and combustion by-products, sampled in sediment.
⁷ Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water.

drinking-water standards or guidelines for pesticides. (See page 17.)

- Naturally occurring arsenic exceeded the current MCL of 50 µg/L (micrograms per liter) in 2 of 30 wells sampled in the Mahomet aquifer, a major drinking-water source. If the MCL is lowered to 5 µg/L, as proposed by the USEPA, samples from 60 percent (18 of 30) of the domestic (private household) and public-supply (publicly owned wells generally serving a community) wells sampled would probably exceed the lower standard. (See page 22.)
- Geologic materials underlying the basin indicate that it is an area of potentially high radon concentrations in ground water. In about one-half of the samples of shallow ground water, radon exceeded the proposed MCL of 300 pCi/L (picocuries per liter). Only 2 of 30 samples from the Mahomet aquifer exceeded the proposed radon MCL. (See pages 23–24.)
- Volatile organic compounds (VOCs) were detected in samples from 83 percent of shallow domestic and public-supply wells, but no samples exceeded drinking-water standards or guidelines. VOCs were detected in 80 percent of samples from the Mahomet aquifer but at concentrations near the method detection limit and well below drinking-water standards and guidelines. (See page 24.)

Major influences on ground water

- Agricultural and urban land uses
- Permeability of soil and aquifers
- Minerals in geological materials

INTRODUCTION TO THE LOWER ILLINOIS RIVER BASIN

The lower Illinois River Basin (the basin) encompasses 18,000 mi² (square miles) of central and west-central Illinois between the upper end at Ottawa and the confluence of the Illinois River with the Mississippi River near Grafton. The basin includes all of 22 counties and parts of 19 counties.

As of 1990, 1.3 million people lived in the basin. More than 50 percent of the population lived in the counties of Macon, McLean, Peoria, Sangamon, and Tazewell. The four most populated cities are Peoria, Springfield, Decatur, and Bloomington. The basin population decreased by 7 percent from 1980 to 1990 [2].

Land use

Agriculture is the predominant land use—typically corn and soybean row crops. Agriculture accounts for 88 percent of the overall land area, whereas forests account for 7 percent and urban areas account for about 2 percent (fig. 1). The remaining land use, about 3 percent, is mostly grassland, wetland, or water.

The small-stream basins that were sampled during 1995–98 have even higher percentages of land devoted to farming; for example, the Panther Creek Basin is 99 percent agricultural land (fig. 2). The lower Illinois River Basin has some of the most highly productive and intensively cultivated farmland in the world. As a result, application rates of farm-related chemicals are among the highest in the country in support of corn and soybean production. Runoff from these vast, flat farm areas carries relatively high concentrations of nutrients and pesticides into the

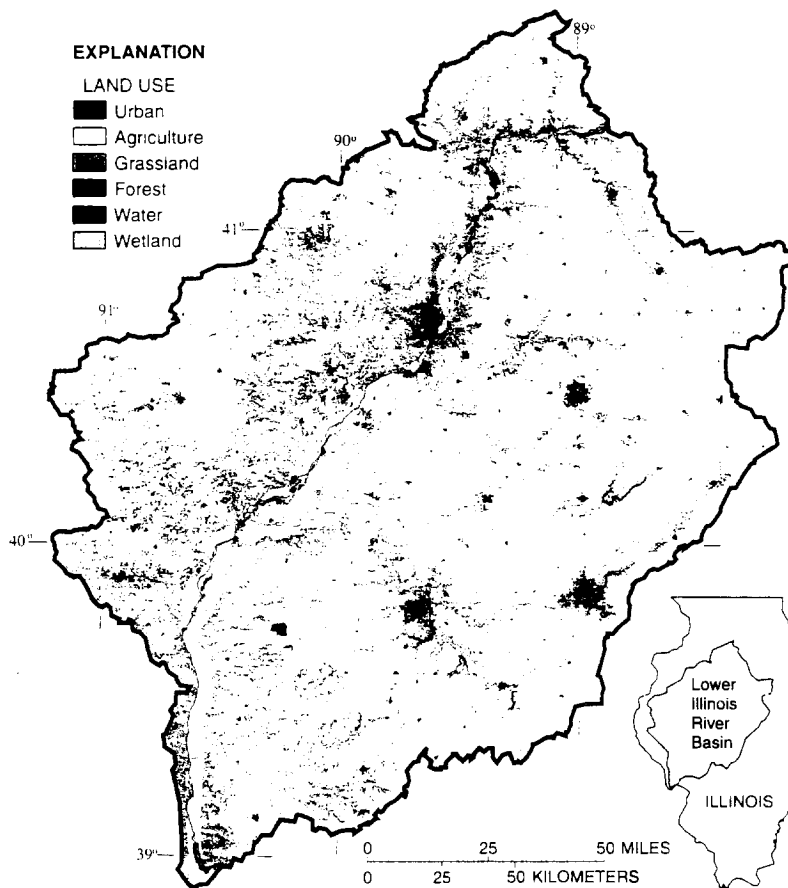

Figure 1. Land use in the lower Illinois River Basin is predominantly agriculture. Farming is most intensive in the part east of the Illinois River. Streambanks generally are steeper west of the Illinois River and are more forested than streambanks east of the river.

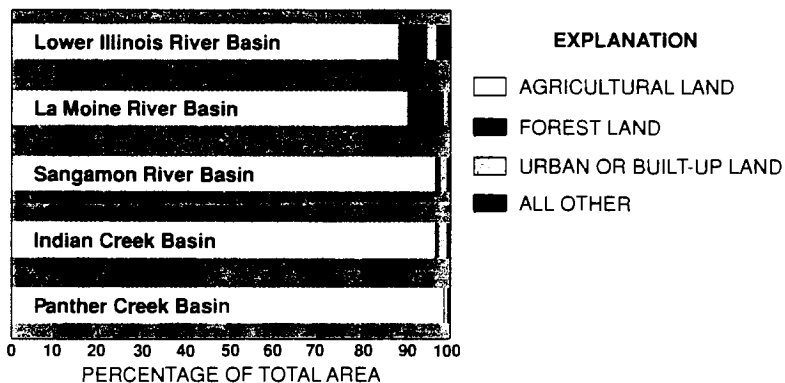

Figure 2. Proportion of land devoted to agriculture varies only slightly among basins—from 88 percent in the entire lower Illinois River Basin to 99 percent in the Panther Creek Basin.

small streams and major rivers of the basin.

Animal farming is also a significant industry in the basin [2], and runoff from manure spreading is a contributor to some of the highest levels of nitrate and total nitrogen found in the rivers and streams of the United States.

Study design in relation to land use

Chemical and biological samples were collected from a range of river and stream sizes in different landscape types and from shallow aquifers. A deep aquifer (Mahomet aquifer) was sampled to assess the overall water quality. A group of the shallow large-bore wells used for domestic (private household) supply was sampled, as well as other shallow domestic wells, to assess overall water quality and determine the occurrence of human-induced contaminants and the extent of land-use effects on recently recharged ground water.

Figure 4. Hydrologic conditions during the data-collection period were near normal. Some relatively dry periods resulted in below-normal flow, and several wet periods resulted in above-normal flow on the Illinois River at Valley City.

Water use

In the lower Illinois River Basin, 48 percent of the public- or municipal-supply water is drawn from ground-water sources and 52 percent from surface-water sources (fig. 3). All private-supply

water, usually for domestic use, is from ground water. Rural residents (about 25 percent of the population) generally are self-supplied from ground water [2]. In most of the western and southern parts of the basin, homeowners rely on cisterns or large-diameter dug or bored wells [3]. These large-diameter wells are highly susceptible to contamination from surface-water runoff and shallow ground water.

Irrigation, which is confined to sandy soils near the center of the basin, is entirely supplied by ground water.

Hydrologic conditions during the study period

Rainfall generally was near normal during the data-collection period (fig. 4). Typically, the largest rainstorms are during April to July. The generally normal rainfall had exceptions: in particular, water year 1997 (October 1996–September 1997) was slightly drier than

Figure 3. Water withdrawals in the lower Illinois River Basin are dominated by thermoelectric withdrawals (cooling water for power generation). Drinking water is supplied roughly equally from surface-water reservoirs and ground-water supplies.

Figure 5. Ground-water conditions were near normal during 1989–98, including the data-collection period. In 1993, the observation-well water level shows the effect of the significant 1993 flood on the shallow ground water. (Data from K. Hlinka, Illinois State Water Survey, and National Weather Service.)

normal, and spring 1996 had fewer storms than normal.

Ground-water levels reflected the near-normal rainfall conditions, particularly in the southern part of the basin (fig. 5). Shallow ground water typically is recharged in late winter and early spring, then the level falls during the summer growing season. Water level in a representative well is shown in figure 5, along with 10 years of annual rainfall data collected near Peoria, which lies near the center of the basin.

The lower Illinois River

The Illinois River is a navigable waterway that connects the Mississippi River to Chicago and the Great Lakes. Barges carrying grain and other commodities are a significant influence on suspended sediment and water quality. The mean annual flow of the Illinois River increases from about 12,600 ft³/s (cubic feet per second) at Ottawa to 22,600 ft³/s at Valley City [2]. Five major tributaries—Vermilion River, Spoon River, Mackinaw River, La Moine River, and Sangamon River—and many smaller streams join the Illinois River (fig. 6). Flow gaging and sampling of the outflow from the basin is done at Valley City because the water level of the Mississippi River, at times, affects the flow of the Illinois River downstream from Valley City.

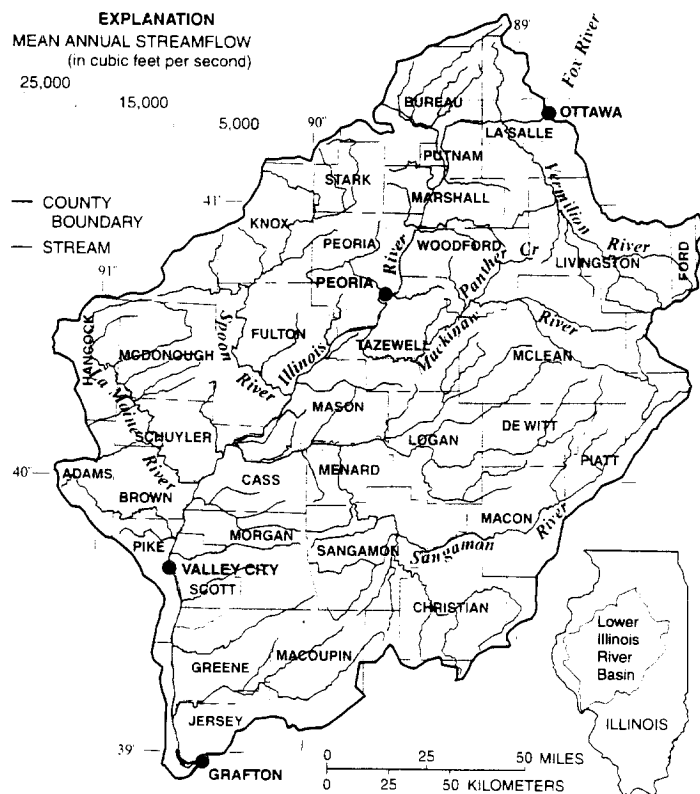

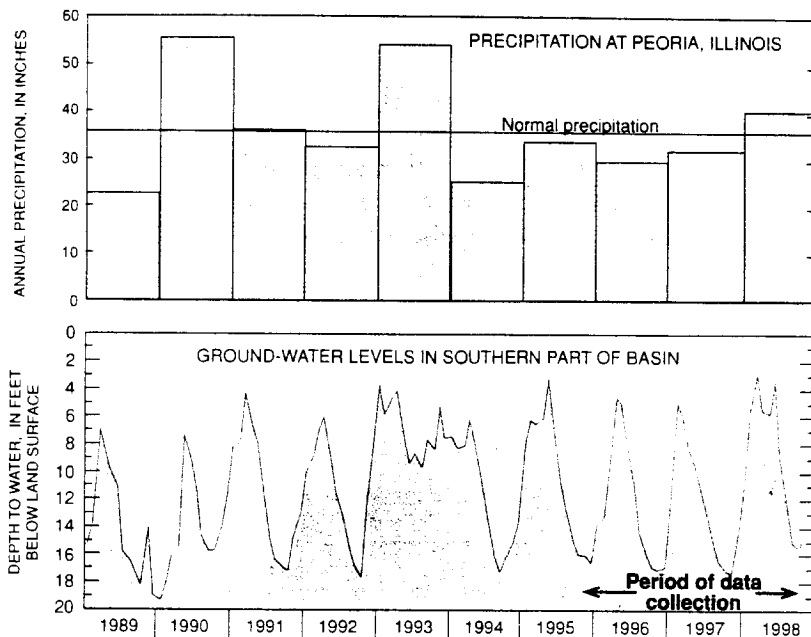

Figure 6. The lower Illinois River has five major tributaries. The inflow to the basin is at Ottawa, Ill., where the Fox River joins the Illinois River. Where the Illinois River leaves the basin and enters the Mississippi River near Grafton, Ill., the outflow is almost double that of the inflow.

MAJOR FINDINGS

Nutrient concentrations in streams and rivers are a major concern

Agriculture is the most important activity in the lower Illinois River Basin from an economic and water-quality perspective (fig. 7). Application rates of nitrogen and phosphorus in synthetic fertilizer and manure are among the highest in the Nation. The high application rates of agrichemicals in the basin were reflected by the kinds and amounts of contaminants found in streams, rivers, and ground water. Nevertheless, contaminants associated with urban or industrial activities also were detected in some streams, rivers, and wells.

Figure 7. Farming and related businesses are major activities in the lower Illinois River Basin. Agriculture has a significant effect on water quality and wildlife habitat. (Photograph by David J. Fazio, USGS.)

Flow-weighted concentrations of nitrate (nitrate as nitrogen) were generally highest in small streams in intensive agricultural areas and east of the Illinois River (fig. 8). The lowest flow-weighted mean concentration of nitrate was for the Illinois River at Valley City—the outflow from the basin. Concentrations of nutrients were similar at the basin inflow (Illinois River at Ottawa) and the basin outflow (Illinois River at Valley City). Urban sources, primarily wastewater effluent, however, were major contributors at the inflow [4], whereas agriculture provided most of the nutrient contribution to the water resources within the basin.

The nitrate load (amount of nitrate in water that moves past a location on the river) measured at the outflow from the basin, 124,000 ton/yr (tons per year), was nearly twice the load measured at the inflow, 66,000 ton/yr (fig. 9). Flow-weighted mean concentrations of nitrate are similar between the two Illinois River locations; therefore, the difference in loads is

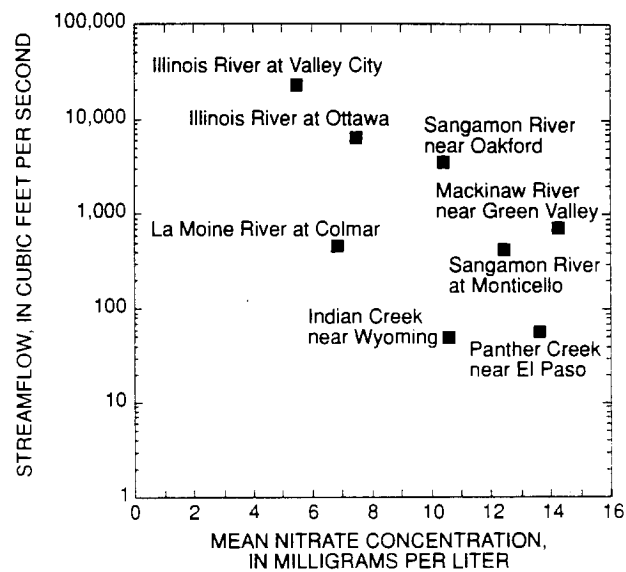

Figure 8. Mean nitrate concentrations generally are lowest in the Illinois River. Nitrate concentrations in the three largest rivers show a downward trend with increasing streamflow from the Sangamon River near Oakford to the Illinois River at Ottawa and to the Illinois River at Valley City. The La Moine River, which is the only river or stream sampled that lies entirely within the Galesburg Plain physiographic subsection, does not fit the general trend. The nitrate concentrations are flow-weighted means.

directly related to the difference in streamflow (fig. 6). The lower Illinois River Basin contributes roughly the same amount of nutrients to the Mississippi River as does the upper Illinois River Basin, which includes the

Figure 9. About twice as much nitrate and total phosphorus leaves the lower Illinois River as enters it. The loads for the upper Illinois River Basin—the basin upstream from Ottawa—are about one-half of the respective loads for the lower Illinois River Basin.

What Was Assessed?

The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, NAWQA assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. Comparisons made in this report to drinking-water standards and guidelines are made only in the context of the available untreated resource.

Chicago urban area and rural areas in Illinois, Indiana, and Wisconsin.

The annual nitrogen yield (amount of nitrogen in water that flows out of the watershed divided by the area of the watershed) measured at the river and stream locations ranged from 4.6 to 12 (ton/mi²)/yr (tons per square mile per year), the smallest yields being measured in the largest river and the largest yields measured in the smallest streams. The overall yield for the basin (Illinois River at Valley City) was 4.6 (ton/mi²)/yr during 1995–98.

Substantial differences among nutrient concentrations in small agricultural basins and the lower nutrient concentrations in large rivers indicate that hydrological and biochemical processes reduce the nitrate concentration as nitrate moves through the basin and into the Mississippi River. Instantaneous concentrations of nutrients varied with season: nitrate concentrations were highest during the winter and spring and lowest in the late summer and fall.

Sites on the largest rivers—the Illinois River at Ottawa and Valley City and the Sangamon River near Oakford—had the highest flow-weighted mean concentrations of

total organic nitrogen, ammonia nitrogen, and phosphorus; the latter two are indicators of urban wastewater effluent [4]. The Sangamon River near Oakford had the highest flow-weighted mean concentration of total organic nitrogen, ammonia nitrogen, and phosphorus. Samples from middle-sized La Moine River at Colmar generally had higher flow-weighted mean concentrations of most nutrients compared with samples from the Sangamon River at Monticello, which also is middle sized but is at the eastern edge of the basin. Flow-weighted mean concentrations of nitrate in samples from the Sangamon River at Monticello, however, were greater than those in samples from the La Moine River at Colmar. Panther Creek near El Paso, a small-basin site, generally had higher concentrations of most nutrients than did Indian Creek near Wyoming, another small-basin site.

Stream and river samples often exceeded the nitrate drinking-water standard and phosphorus guideline

Flow-weighted mean concentrations of nitrate for five of the eight sample locations in the basin, including two locations on the Sangamon River (used for public water supplies), were higher than the Maximum Contaminant Level (MCL) of 10 mg/L nitrate as nitrogen established for drinking water.

The concentration of total phosphorus in most samples (80 percent) from all streams and rivers exceeded the 0.1 mg/L guideline recommended by USEPA to prevent eutrophication in streams. Samples from Indian Creek near Wyoming had the highest concentrations of total phos-

Streamflow-Weighted Concentrations

Drinking-water standards are generally based on the yearly average of samples collected quarterly. This is a legal definition of yearly average concentrations. Truly representative “average” water-quality conditions of a stream would require daily samples for some streams because of the variability in the concentration and in streamflow from day to day—especially over a period of storm runoff. During a storm, the levels of contaminants in a stream can vary 10 times or more from beginning to end. A method is needed to address this variability and “weigh” the concentrations found in individual “point” samples from a stream. A process is used to estimate the daily load or amount of a chemical that flows past a point. The daily loads are summed and then divided by the amount of streamflow to get an average for the period of interest. This flow weighting produces a more accurate mean concentration of a specific chemical for a period such as a year or, as for this report, for the 2–3 year period when samples were collected.

phorus, and samples from Panther Creek near El Paso had the smallest. Indian Creek near Wyoming is downstream from a small wastewater-treatment plant, which is likely the reason for the higher total phosphorus at this site.

Nitrate concentrations were lower than in other areas of the Corn Belt during late summer

During August 1997, concentrations of dissolved nitrate and total nitrogen were found to be lower in streams and rivers of the lower Illinois River Basin than in some other areas of the Midwest. A synoptic study was done at 70 sites with drainage areas between 100

and 1,000 mi² in Illinois, Iowa, and Minnesota in August 1997, when streamflow had approximately reached the annual minimum [5]. Median concentrations of dissolved nitrate in streams generally increased northwestward, from Illinois (0.52 mg/L) to Iowa (1.5 mg/L) to Minnesota (3.5 mg/L). No significant relations between nitrate concentrations and streambank characteristics or soil permeability were identified. Streams that have formed on windblown glacial materials, however, generally had lower concentrations than streams formed on glacial till (unsorted material left behind by continental glaciers). The windblown materials typically have slightly higher permeability than the glacial till and are more likely to allow rainwater to infiltrate rather than run off to streams.

In Illinois, rainfall and thus runoff to streams was low before and during synoptic sampling; therefore, most streamflow was derived from ground-water seepage. Thus the low nutrient concentrations in ground water in the basin—much lower than those in streams and rivers—are a major reason why low nitrate concentrations were detected in the streams during August 1997 in the basin.

Differences in moisture conditions and precipitation during the 3-month period before the August sampling (wettest in Minnesota and driest in Illinois) probably also contributed to the differences in concentrations across the three-State region. The percentages of total nitrogen present as organic nitrogen and ammonia were higher in Illinois than in other parts of the study area. Nitrogen incorporation in algae also was a factor in the distribution of dissolved nitrate. Algal communities, particularly phytoplankton, were more stable and productive in Illinois than in other parts of the three-State synoptic study, and much of the nitrogen in the aquatic system was incorporated into these plant communities in the basin.

Nitrate concentrations differed upstream and downstream from water-supply reservoirs

Dissolved nitrate concentrations in samples from the Sangamon River (at Monticello) were found to be more variable upstream from several water-supply reservoirs than downstream from the reservoirs (fig. 10). From April through June, nitrate concentrations were frequently above the MCL of 10 mg/L (highest concentration, 17 mg/L) in the Sangamon River at Monticello, 29 mi upstream from Lake Decatur, the drinking-water source for the city of Decatur.

Figure 10. Nitrate concentration in the Sangamon River is affected by reservoirs and other factors. Monticello lies upstream from several water-supply reservoirs and the cities of Springfield and Decatur. Oakford lies downstream from the reservoirs. The reservoirs are for water supply, and during spring they are replenished by river water that exceeds the drinking-water standard for nitrate. Water leaving the reservoirs usually does not exceed the nitrate standard and has less variability in nitrate concentrations.

The city of Decatur often must treat water for nitrate above the MCL during spring and early summer or mix the high-nitrate surface water with ground water to lower the nitrate concentration. Nitrate concentrations also were highest in the spring in the Sangamon River near Oakford, which is downstream from Lake Decatur and other water-supply reservoirs used by the city of Springfield. Concentrations in samples from the Sangamon River near Oakford, however, seldom exceeded the nitrate MCL.

Conversely, concentrations of nitrate usually were less than 1 mg/L in the Sangamon River at Monticello from August through November, but typically remained higher than 1 mg/L at the Oakford site during the same period. Data from Scribner and others [6] indicate that nitrate concentrations of reservoirs in corn- and soybean-producing areas of the Midwest have nutrient concentrations and patterns similar to those in the Sangamon River near Oakford.

Algal index indicates comparatively poor water quality in Corn Belt

Small streams in the Corn Belt have both poorer water quality, as indicated by the algal status index, and higher nitrate concentrations than small streams in other parts of the Nation. The algal status index reflects a greater relative abundance of benthic algal species that are considered tolerant of poor water-quality conditions, including high nutrient concentrations.

The lower Illinois River Basin lies within the eastern one-half of the Corn Belt.

Results for this study are from data collected in 16 NAWQA Study Units from 1996 to 1998.

Algae grow on virtually all stream surfaces receiving light. Algal communities are the foundation of the food web of many streams, serving as a food source for invertebrates and fish.

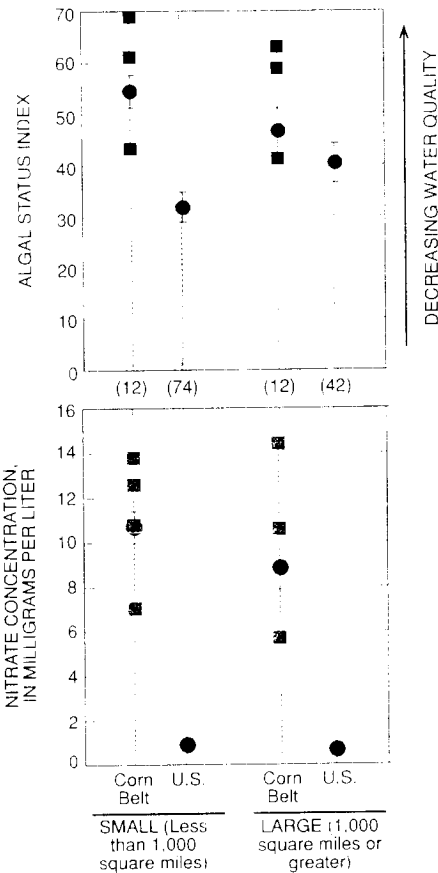

Nuisance algal growth can result from excess nutrients and can lead to large variations in dissolved oxygen concentrations.

In large streams, flow-weighted mean concentrations of nitrate were also higher in the Corn Belt than in the rest of the Nation, but the algal status index was not significantly higher. The dynamics of the algal community change with stream size, and the importance of phytoplankton (floating algae) increases as streams get larger. The algal status index does not reflect the composition of the phytoplankton community, and this may explain the differences observed between small and large streams.

Chemical, physical, and biological factors all influence the algal community and local stream conditions. The algal status index at individual lower Illinois River Basin streams was similar to that at other streams in the Corn Belt.

Excess nutrients often cause algal blooms that can be seen in streams and rivers in the basin. Algae reduce the amount of nutrients that remain in the water by converting nutrients into algal biomass. (Photograph by Paul J. Terrio, USGS.)

GEOGRAPHIC REGION AND STREAM BASIN SIZE EXPLANATION

- Algal index mean for Corn Belt or U.S. (●) Two standard errors of the mean
 - Nitrate mean for Corn Belt or U.S. (●) Two standard errors of the mean
 - Algal index for samples from lower Illinois River Basin streams or rivers
 - ▣ Nitrate mean for samples from lower Illinois River Basin streams or rivers
- Numbers in parentheses are samples in each group

Algal status index values and nitrate concentrations for the lower Illinois River Basin, and for Study Units in the Corn Belt, are higher than mean values for Study Units in the Nation.

Riparian buffer zones influence the quality of midwestern streams and rivers

Despite similar land use throughout the Corn Belt region of the Midwest, streams flowing through cropland differ considerably in their ecological characteristics, in part because of differences in riparian buffer zones (see text boxes). This conclusion is based on an investigation of 70 streams and rivers within three NAWQA Study Units in the upper Midwest during August 1997 (figure at right) [5; 7]. Specifically, increases in tree cover in buffer zones were associated with aquatic biological communities indicative of good stream quality, reduced nuisance algal growths, and maintenance of sufficient dissolved oxygen concentrations to support diverse communities of aquatic organisms. For example, the number of aquatic insects indicative of good stream quality tended to increase with increases in percentage of tree cover, especially in sites where streamflow and dissolved oxygen conditions were favorable. Fish communities, sampled at 24 sites in the UMIS Study Unit, also indicated better overall conditions in streams with wooded riparian zones than those with more open canopy [8].

The influence of riparian buffer zones on the quality of 70 midwestern streams and rivers was evaluated in the Upper Mississippi River (UMIS), Eastern Iowa (EIWA), and lower Illinois River Basins (LIRB).

Streams with less tree cover, and thus less shading, contained relatively large growths of phytoplankton (algae suspended in the water) at levels considered indicative of eutrophication [9].

Organic enrichment resulting from excessive algal production in some midwestern streams may reduce dissolved oxygen concentrations and be detrimental to other requirements of aquatic organisms.

Shading from tree cover in riparian buffer zones may influence nutrient concentrations indirectly by reducing the growth of phytoplankton. In streams where phytoplankton were abundant (often where buffer zones were thin or lacking), dissolved nitrate concentrations were significantly lower (figure below) [9]. The lower nutrient concentrations may result from uptake by the abundant phytoplankton. Thus, assessments of eutrophication would benefit from consideration of biological communities and the riparian zone, rather than being based solely on nutrient concentrations in the water.

Dissolved nutrient concentrations decreased in eutrophic streams with excessive algal productivity. Rates of nutrient uptake by the algae can exceed rates at which nutrients are transported by streams during low-flow conditions.

Digital images derived from USGS topographic maps were used to estimate the percentage of trees in a riparian buffer zone (a 100-meter width on each side of the stream) for 2- to 3-mile segments upstream from each sampling site, supplemented by vegetation surveys at the sampling site [5].

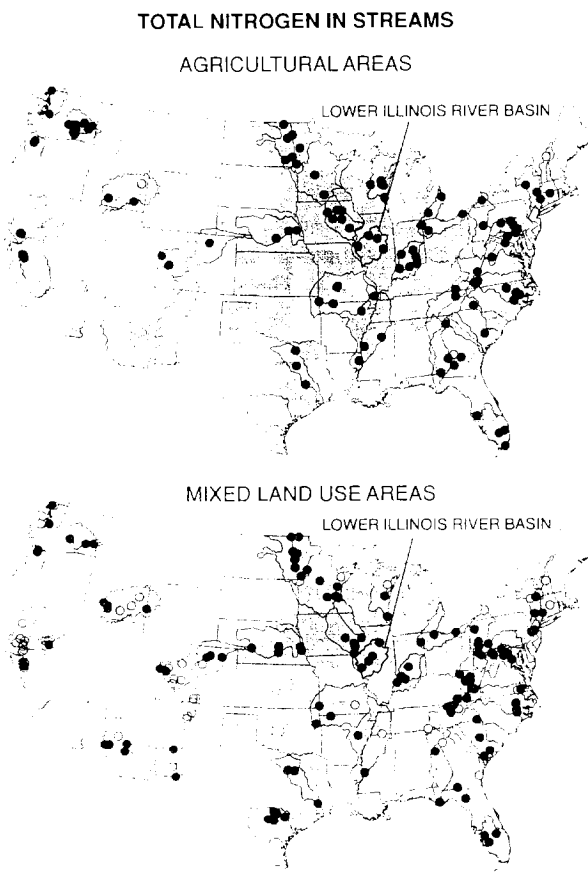

Resource agencies, including the U.S. Department of Agriculture, encourage maintenance of strips of trees or grass between cropland and streams as a best management practice. These "riparian buffer zones" are thought to intercept runoff of sediment and chemicals from fields, promote bank stability, and provide shading and habitat for aquatic life [10]. Riparian buffer zones should be considered along with other important factors that affect chemical and biological indicators of stream quality, such as soil drainage properties and stream hydrology [7].

Nutrient concentrations were among the highest in the Nation

Concentrations, loads, and yields of nutrients in the lower Illinois River Basin were among the highest in the Nation. When compared with data from NAWQA studies nationwide, nitrate concentrations in the lower Illinois River Basin were in the highest 10 percent at every sampling location, and total phosphorus concentrations were in the highest 25 percent at seven of the eight locations.

Soybeans, which are a major crop in the lower Illinois River Basin, are important for nutrient management and the nitrogen balance of agricultural watersheds. The roots of soybeans harbor bacteria that fix nitrogen from the atmosphere into the soil in a form that can be used by the plant, and by other crops the following year. (Photograph by Kelly L. Warner, USGS.)

Of the 10 largest rivers monitored by NAWQA, greater than 20,000 cfs mean daily streamflow, the lower Illinois River Basin site at Valley City had the highest flow-weighted mean nitrate and total nitrogen concentrations (see Streamflow-Weighted Concentrations). The concentrations were greater than twice the concentrations of both nitrate and total nitrogen of the next highest ranked location—Mississippi River at Hastings, Minnesota—and of a comparable size river location—Mississippi River at Red Wing, Minnesota.

Goolsby, Battaglin, and others [11, 12] concluded that the basin is one of the areas of highest nitrogen yield (amount of nitrogen runoff into streams per unit area) contributing to the Mississippi River. Alexander and others [13] estimated that 50 percent to greater than 90 percent of the nitrogen exported from much of the basin is transported to the Gulf of Mexico, where excess nutrients help create hypoxia—oxygen concentrations below the level required by most aquatic life in the Gulf. The Illinois River contributes from 15 to 20 percent of the total nitrogen that goes into the Gulf of Mexico from the Mississippi River [14, 12].

Roughly between 61,000 and 124,000 tons of nitrogen is transported annually from the lower Illinois River Basin to the Gulf of Mexico. More than one-half of the excess nitrogen entering the Gulf from the Mississippi River basin thought to come from the upper Mississippi basin—basin that is an upstream from St. Louis, Missouri. The Illinois River joins the Mississippi River just north of St. Louis.

Nitrate concentrations in some shallow wells exceeded the drinking-water standard

The 117-well network sampled in the basin consisted of 57 shallow monitoring wells installed for the study (fig. 11) and 60 water-supply wells of various types. Although the concentrations of nitrate in none of the 30 samples from the deep Mahomet aquifer exceeded the MCL (all concentrations were below 0.10 mg/L), nitrate concentrations in the shallow wells exceeded the MCL in 7 percent (6 of 87) of the shallow-well samples. Concentrations above the MCL ranged from 11 to 77 mg/L. All exceedances of the nitrate MCL were in samples from wells less than 50 feet deep.

Figure 11. Study-Unit staff installed 57 wells to sample recently recharged ground water. Assistance and geological expertise was provided by the Illinois State Geological Survey. (Photograph by William S. Morrow, Jr., USGS.)

An important reason for fewer detections and much lower concentrations of nitrate and other agrichemicals in ground water is artificial drainage (where present) and the geological materials from which the soils developed. Most farmland in Illinois is artificially drained by ditches and subsurface drains (tile drains) because of the poor natural drainage of the soils

and their parent materials (fig. 12). Artificial drainage short circuits infiltrating water to streams through the subsurface drains rather than allowing the water to move downward to the water table or to deeper aquifers [15]. Subsurface drainage also decreases the amount of potential runoff across land surface to streams because the soil is less saturated and ponding is less likely [15]. Another factor that helps prevent agrichemicals from reaching wells is that the fine-grained materials may be conducive to rapid breakdown of many of the chemicals.

One-half of the shallow wells installed for monitoring recently recharged ground water (28 of 57) were installed in the geological materials overlying the Mahomet aquifer. The shallow ground water in this area has a high potential for eventually recharging the underlying Mahomet aquifer [2]. Sampling results from these wells indicate the Mahomet aquifer is fairly well protected from contamination at land surface.

Some pesticides were always detected in streams and rivers

Herbicides are applied during spring planting to virtually all corn and soybean crops in the basin. Insecticides are applied during the summer to about 10 to 30 percent of the corn crop, depending on weather conditions. Approximately 6,000 to 6,700 tons of agricultural pesticides were applied annually in the lower Illinois River Basin during 1996–98 (data from [16–18]).

Atrazine, which is commonly applied to corn in the basin, and its breakdown products (hydroxyatrazine, deisopropylatrazine, and

Figure 12. Subsurface drainage allows water with high concentrations of agrichemicals to be transported directly to ditches and streams. The outlet pipe from a subsurface drain at center of photograph is draining into the stream. (Photograph by Kelly L. Warner, USGS.)

deethylatrazine) were the most frequently detected pesticide and related compounds in streams throughout the basin and shallow ground water beneath cropland. Atrazine was detected in every stream sample collected from the basin, even during winter. Prometon, which is not used in appreciable amounts on cropland but commonly is applied for weed control in rights-of-way in the basin, was detected frequently in streams (93 percent of samples) and infrequently in shallow ground water (7 percent of samples).

In samples collected at Illinois River at Valley City (basin outflow), 40 pesticides or pesticide breakdown products were detected. Atrazine and metolachlor were always present, and cyanazine was detected in 97 percent of the samples.

Because the method detection limit varies widely from one pesticide or related compound to another, a common reporting level is used to compare detections of the pesticides and compounds on an equal basis. In figure 13, the frequency of detection of pesticides in stream and river samples and ground-water samples is shown

at a common reporting level of 0.05 µg/L. Of the pesticides detected in 1 percent or more of samples, those shown in figure 13, only 2,4-D had a higher method detection limit than 0.05 µg/L; therefore the detection frequency of 2,4-D may be underestimated in figure 13. Even at the common reporting level, atrazine was detected in almost all stream and river samples.

Pesticide concentrations in streams periodically exceeded drinking-water standards

Concentrations of atrazine and cyanazine in some individual samples exceeded USEPA drinking-water standards or guidelines. Annual average concentrations of each compound in streams and rivers, however, were below their respective MCL (atrazine: 3 µg/L) or lifetime health advisory level (HAL) (cyanazine: 1 µg/L). Carbofuran, diazinon, chlorpyrifos, and carbaryl were the only insecticides detected. Diazinon concentration exceeded the Great Lakes water-quality objective (0.08 µg/L) [19] in one sample at Illinois River at Valley City during August 1998.

Some pesticide concentrations that exceeded human health standards or guidelines also were potentially toxic to aquatic life. For example, an atrazine concentration of 110 µg/L in a single sample from the La Moine River at Colmar (fig. 14) exceeded not only the USEPA MCL (3 µg/L) but also the Canadian guideline for the protection of freshwater aquatic life (1.8 µg/L) [20]. In samples from the Illinois River at Ottawa and at Valley City and the Sangamon River at Oakford, all exceedances of the cyanazine HAL and the

Figure 13. Many commonly applied pesticides were frequently detected in streams and rivers in the lower Illinois River Basin. Detections in ground water were far fewer, and some of the pesticides frequently detected in surface water (such as cyanazine, acetochlor, and alachlor) were not detected in shallow ground water at or above the common reporting level of 0.05 micrograms per liter.

metolachlor aquatic-life guideline (7.8 µg/L) were concurrent with an exceedance of the atrazine MCL. In contrast, diazinon concentrations twice exceeded the Great Lakes water-quality objective and one chlorpyrifos concentration exceeded the aquatic-life guideline (0.041 µg/L) independent of all other pesticide exceedances.

In samples from the La Moine River at Colmar and the Sangamon River at Monticello, for every pesticide other than atrazine, concentrations exceeded a drinking-water standard or guideline concurrent with an atrazine MCL exceedance. The lone exception was cyanazine, which exceeded the HAL independent of all other standard or guideline exceedances.

Currently (2000), drinking-water standards or guidelines and aquatic life guidelines have been established only for individual pesticides. Furthermore, USEPA drinking-water MCLs or HALs are established for only 25 of the 40 pesticides detected in the lower Illinois River Basin. Pesticides, however, commonly are found in mixtures of as many as 21 compounds in surface water (fig. 15). Although most samples of shallow ground water contained relatively few detectable concentrations of pesticides compared to samples from streams and rivers, two or more pesticides were detected

in all samples where any of pesticides were detected at all. The health effects of such combinations of pesticides in drinking water, even in low concentrations, are not well understood.

Pesticide concentrations in streams have a seasonal pattern

Herbicide concentrations in stream and river samples are highest in late spring to early summer (fig. 16), and insecticide concentrations typically peak in midsummer. The highest pesticide concentrations typically occur during the first one or two periods of storm runoff after pesticide application. During seasonal peaks, concentrations of pesticides in samples of stream water exceeded drinking-water standards or guidelines or aquatic-life guidelines. For example, for about 6 weeks after herbicide application in the spring, concentrations of atrazine at Illinois River at Valley City were greater than the MCL of 3 µg/L. The annual mean atrazine concentration in the Illinois River at Valley City for 1996 through 1998, however, never exceeded the MCL. Peak concentrations of the insecticides diazinon and chlorpyrifos were measured during July or August of 1997 or 1998.

Figure 14. During late spring and early summer, many pesticides exceeded drinking-water standards or guidelines or aquatic-life guidelines. The graph shows concentrations of selected pesticides in the La Moine River at Colmar during part of 1997. (Registration limit for acetochlor is from [21]; ALC, Aquatic-Life Criterion from [20]; HAL, Health Advisory Level.)

Figure 15. Most samples from streams and rivers contained multiple pesticides and related compounds. Five or more compounds were detected in more than 90 percent of samples. The maximum number of compounds detected at or above the method detection limit in one sample was 21.

Insecticides are often applied later in the growing season than herbicides.

Many factors affect the presence and concentration of pesticides in streams

The presence and concentration of pesticides in streams in the lower Illinois River Basin are influenced

Figure 16. Pesticide concentrations vary seasonally. The sum of pesticide concentrations in samples peaks in late spring during runoff from rainstorms. Often, runoff from spring rains supplies reservoirs on some rivers and streams with a substantial amount of the water storage for the remainder of the year. Monthly mean totals are for all locations sampled for pesticides during October 1996–September 1998.

by land use and agricultural practices (fig. 17) such as pesticide application rate, drainage of crop land, and cropping methods. Natural factors, such as the size of the streams, type of terrain, and soil characteristics, also are important determinants. In addition, the distribution of individual pesticides in streams throughout a watershed depends on the physical and chemical properties of the pesticides that are in use—properties such as sorption (the ability of a pesticide to stick to soil particles), transformation (the ease with which a pesticide breaks down in the environment), and volatilization (the tendency of a pesticide to become gaseous and rise into the atmosphere).

Concentrations of agricultural chemicals generally reflect application rates

The most heavily applied pesticides (more than 1 million pounds of active ingredient per year;

Figure 17. Pesticides are used to protect crops and increase production. Pesticides are often sprayed directly on the plants in the field. Other pesticides are incorporated into the soil, partly to limit the amount of chemical that leaves the field. (Photograph by Kelly L. Warner, USGS.)

acetochlor, atrazine, cyanazine, and metolachlor) were generally the most frequently detected in streams and shallow aquifers. Herbicides such as alachlor and simazine, which are no longer applied as heavily as in previous decades, still are detected at relatively high rates. Bentazon is not applied as heavily as other herbicides, yet it is frequently detected in stream and well samples (fig. 18).

Pesticide concentrations in water also were commonly related to drainage of water over and through agricultural soils, pesticide uptake by plants and microbes, and attachment to soil particles. Pesticide and nutrient persistence and regional differences in soils, geology, and climate govern the distribution of

Figure 18. Detection rates in streams are mainly affected by the amount of pesticide applied in the basin. Detection rates in ground water, even for those pesticides that are heavily applied, are much lower.

these water-quality indicators in the lower Illinois River Basin.

The relatively infrequent detection of metolachlor in well samples may be related to the following factors:

1. Metolachlor is applied after weeds sprout and emerge, and it is taken up by plants and is converted to other compounds.
2. Soil microbes effectively degrade metolachlor.
3. Soils retain metolachlor instead of allowing it to run off or seep downward to ground water.

Stream size affects pesticide concentrations

In the lower Illinois River Basin, pesticide concentrations in small streams typically range from the highest to the lowest observed concentrations, whereas concentrations in large rivers are moderate and less variable. For example, during the period when most pesticides are washed into streams (May through July), the maximum concentration of atrazine measured in the Sangamon River at Monticello was about twice as high as that measured in the Illinois River. The highest concentrations of several pesticides, including atrazine (110 µg/L; May 1997), acetochlor (12 µg/L; May 1998), cyanazine (16 µg/L; May 1997), and 2,4-D (7.3 µg/L; May 1998) were detected in samples from the La Moine River at Colmar. In contrast,

in months other than May or June, 70 percent (35 of 50) of samples from Sangamon River at Monticello had total pesticide concentrations that were less than 1 µg/L, as compared with 79 percent (26 of 33) of the samples from Illinois River at Valley City. Samples for analysis of pesticides were not collected from the smallest streams monitored.

Concentrations of alachlor and cyanazine in the Illinois River decreased

Application rates of cyanazine decreased during the 1996–98 sampling period in anticipation of its use being eliminated in 2003. Alachlor use has declined since the early 1990s—in fact, no use of alachlor was reported for 1998 in the basin. The use of alachlor, by voluntary agreement [21], is decreasing as acetochlor replaces it (fig. 19).

Cyanazine was detected in 97 percent of the river and stream samples and alachlor was detected in 74 percent of the samples during 1996–98. A comparison of mean monthly concentrations of those detections, however, shows a different story. During 1991–92, samples that were comparable to those collected as part of this NAWQA study were collected from the Illinois River at Valley City. The mean monthly concentrations for the two periods, separated by about 4–5 years or longer, indicate that concentrations of alachlor and cyanazine have substantially decreased (fig. 20).

Figure 19. Use of herbicides on corn and soybeans in Illinois changed during 1988–97. Use of three common herbicides has declined from their peak use, but the use of acetochlor has increased substantially. (Data from [22].)

Figure 20. Monthly mean concentrations of cyanazine and alachlor declined substantially in water samples collected from the Illinois River at Valley City.

Pesticide breakdown products were detected more frequently than the parent compound

In stream and river samples (fig. 21) and ground-water samples (fig. 22), pesticide breakdown products, such as metolachlor ethanesulfonic acid (a breakdown product of metolachlor) and deethylatrazine (a breakdown product of atrazine) were detected more frequently at higher concentrations than their respective parent compounds. The toxicity of most of these breakdown products generally is unknown. Also unknown is the combined effect of parent compounds and the breakdown products. Drinking-water standards or guidelines or aquatic-life guidelines have been established for only a few pesticide breakdown products.

Most of the residue of metolachlor detected in ground water consisted of breakdown products (fig. 22). Metolachlor was frequently detected in streams and rivers. Because primarily breakdown products of metolachlor were found in ground water, metolachlor must break down before it can reach ground water.

Figure 21. Breakdown products of common herbicides account for most of the analyzed herbicide residue in river water. Long after the parent compound drops below detection, breakdown products can still be detected. Earlier in the spring, acetochlor concentrations peaked at 9 micrograms per liter at this location, Sangamon River at Monticello. (ESA, ethanesulfonic acid)

Pesticides were not frequently detected in ground water

Pesticides are much less common in ground water than in streams. Six compounds, all herbicides (atrazine, metolachlor, prometon, bentazon, cyanazine, and dicamba), were detected in monitoring and water-supply wells. No insecticides were detected in ground-water samples. Only four of these pesticides were detected more than once. The maximum number of pesticides detected in a single well sample was four. Concentrations of all pesticides detected were very low (less than 0.44 µg/L). In ground-water samples, no pesticide came close to exceeding an existing drinking-water standard or guideline.

Insecticides discontinued in the 1970s were still detected in fish and sediment

Several organochlorine compounds (dieldrin, heptachlor epoxide, chlordane, and DDT) were commonly detected in fish tissue. Fish samples usually comprised 8 specimens of common carp, but at several locations

Standards for water, biota, and sediment quality

The USEPA [23–25] is responsible for setting drinking-water standards and guidelines to protect human health. Maximum Contaminant Level (MCL) is the maximum allowable concentration of a contaminant in water delivered to any user of public water systems. MCLs are enforceable standards based on an average annual concentration taken from four quarterly samples of finished drinking water. Health Advisory Level (HAL) is a nonenforceable, risk-based guideline. HALs indicate contaminant exposures below which no short- or long-term human-health effects are expected, based on drinking a specific amount of water for a specific period of time. Risk of illness increases with exposure time and concentration. Of 88 pesticides analyzed for in water, 14 have MCLs and 38 have HALs.

Guidelines to protect aquatic life have been set by several agencies including the USEPA, Environment Canada [26, 20], and the International Joint Commission (IJC) [19]. The aquatic-life guidelines developed by USEPA are based on 4-day average concentrations, are intended to protect 95 percent of the aquatic species, and should not be exceeded more than once in 3 years. The Canadian and IJC aquatic-life guidelines, which are more stringent than those of the USEPA, indicate a single maximum concentration that should never be exceeded. Aquatic-life guidelines have been established for only 18 pesticides.

Probable Effect Levels (PELs), are used to indicate contaminant concentrations in freshwater sediment associated with adverse effects on aquatic life for the Great Lakes region. The PEL is an estimate of the concentration above which adverse biological effects frequently occur [19, 27]. PELs are established for 18 of the 43 organochlorine and semivolatile organic compounds and 8 of 29 trace elements analyzed for this study.

Figure 22. Breakdown products account for most of the residue of metolachlor in ground water. In these 10 shallow wells, metolachlor or its residue was detected. Metolachlor never exceeded the HAL (70 µg/L) in well samples; no drinking-water standards or guidelines have been established for the breakdown products.

white suckers were collected. These compounds are insecticides or insecticide breakdown products. Most of the organochlorine insecticides are no longer used because their registration was canceled by USEPA in the 1970s. Dieldrin, which was applied to corn and around buildings against termites, is a transformation product of aldrin, another insecticide that was applied to corn before use was discontinued during the early 1970s [28].

Dieldrin was detected in every tissue sample and one-third of the bed-sediment samples collected

in the lower Illinois River Basin (table 1). The highest dieldrin concentration in fish tissue in the NAWQA Program across the Nation was detected in fish from the Sangamon River. Every concentration detected in the basin was in the highest 10 percent of the national NAWQA results. Aquatic-life guidelines were exceeded in 30 percent of the samples.

Heptachlor epoxide is a breakdown product of the insecticide heptachlor. The highest heptachlor epoxide concentration in fish tissue in the NAWQA Program nationally was detected in the La Moine River.

Heptachlor epoxide was detected throughout the basin but at only one location in the Illinois River. The concentration of heptachlor epoxide in all fish tissue samples from the lower Illinois River Basin in which the compound was detected exceeded the concentration in more than 95 percent of all NAWQA samples. Heptachlor epoxide was not detected in any bed-sediment samples.

Chlordane was found in every tissue sample and in two bed-sediment samples. No concentrations exceeded applicable guidelines. Total chlordane, as defined for this report, is the sum of five individual components of technical chlordane [28]. Among NAWQA studies nationwide, the highest concentration of oxychlordane (a breakdown product of chlordane) in fish tissue was found in fish from the Sangamon River at Monticello.

DDT was once a widely used insecticide in agricultural and urban areas of the United States. Legal use of DDT ended in 1972. Adverse effects of DDT on fish and wildlife include growth impairment, reproductive failure, and inhibition of thyroid activity, and recent studies have shown DDT to be disruptive of reproductive cycles in animals [28].

Breakdown products of DDT were detected in every fish-tissue sample and in almost one-half the bed-sediment samples. The highest total DDT concentrations in the basin in fish tissue and sediment were in samples from Illinois River locations. Concentrations in fish tissue also were high at two Sangamon River locations (in Monticello and downstream from Springfield) compared to national NAWQA data. In bed sediment, excluding

Table 1. Summary of total chlordane, total DDT, dieldrin, heptachlor epoxide, DDD, DDE, and total PCB concentrations in fish tissue (carp or white suckers) and bed sediment. The detections are compared to guidelines for the protection of fish-eating wildlife. DDD and DDE are breakdown products of DDT

□ AQUATIC-LIFE GUIDELINES

□ Bold outline indicates exceedance by one or more herbicides. Number is percentage of samples that exceeded a guideline within 3-year period.

National results from river and stream sampling reflect results found for pesticides in the Lower Illinois River Basin [29]. Atrazine and metolachlor were the most frequently detected herbicides nationally and in the basin. Roundup and simazine were the next most frequent detections in the Nation, whereas cyanazine, prometon, and alachlor were the next most frequent detections in the basin. Roundup has no listed agricultural use and is mainly applied to lawns and roadsides.

The frequent detection of these herbicides in streams and rivers is due, at least in part, to the high level of application to crops and land areas. However, the major differences between the national and basin herbicide use patterns is that the frequency of detections and detection concentrations were generally higher in the basin. Basin agriculture, especially corn and soybean production, has the highest rates of chemical applications

in the United States. Comparing only watersheds that are primarily agricultural, the results of the basin are similar to those from the rest of the Nation in frequency of detection.

For ground water, national and Lower Illinois River Basin pesticide sampling results also are similar. Nationally, detections of pesticides are less frequent and the concentrations are lower in wells than in streams. However, the detections of pesticides in ground water in the basin are even less frequent than in well samples for other agricultural areas in the United States. Most of the Lower Illinois River Basin is underlain by glacially derived material that is poorly drained. Subsurface drainage diverts water to streams rather than allowing it to move downward (p. 12). The fine-grained, glacially derived material is conducive to rapid breakdown of many of the pesticides. These factors help prevent pesticides from reaching wells, thereby keeping the concentrations lower than those found in ground water in other parts of the Nation.

□ DRINKING-WATER STANDARDS OR GUIDELINES

□ Bold outline indicates exceedance by one or more herbicides. Number is percentage of wells that exceeded a standard or guideline.

Illinois River locations, DDT breakdown products were detected only in a small stream in Decatur.

Other organochlorine compounds are persistent in sediments and fish

Polychlorinated biphenyls (PCBs) are a mixture of organochlorine compounds used in industrial processes. Even though production and use of PCBs was banned in the United States in 1979, PCBs commonly are found in fish and sediments because large amounts were produced, they degrade slowly, and they are transported in the atmosphere [28]. PCBs were detected in 75 percent of the fish-tissue samples in the basin, and these detections were geographically widespread. All detections in the basin exceeded the water-quality guidelines for the protection of fish-eating wildlife developed by the New York State Department of Environmental Conservation [27]. The highest PCB concentrations in fish tissue were in samples from Illinois River locations, with concentrations decreasing with increasing downstream distance from Chicago. PCBs were detected at only one location in the bed sediment.

In sufficiently high concentrations, most organochlorine compounds can be toxic to fish and other animals. These compounds bioaccumulate in animal tissue and may result in tumors, hormonal and behavioral problems, immune- and respiratory-system suppression, and abnormal development. Available evidence indicates that concentrations of these compounds have decreased over time and may be leveling off nationally [30, 28].

Common stream animals indicate poor water-quality conditions

Degradation of streams and habitat is caused by more than just chemical contamination. Biological community measures are used to assess water quality because the living components of stream ecosystems reflect the physical, chemical, and biological attributes of a stream. Measures of the algal, benthic-macroinvertebrate (fig. 23), and fish communities in streams each respond to different aspects of water quality over differing time periods and geographic areas.

Algal, benthic macroinvertebrate, and fish indices (table 2)

Figure 23. Freshwater mussels are relatively long-lived animals that are indicators of long-term water quality. These mussels were from the North Fork Vermilion River in central Illinois. Mussels bury themselves in the bottom where they filter organic matter from the water. During the twentieth century, freshwater mussel populations declined drastically in the lower Illinois River Basin. (Photograph by David J. Fazio, USGS.)

¹ Represents 140 sites in the NAWQA national network that have algal, invertebrate, and fish data.

were used to assess water quality as part of the NAWQA Program [32]. The higher the index, the more degraded the stream conditions. (See Appendix.) The algal status index reflects the relative abundance of benthic algal species that are considered tolerant of poor water-quality conditions, including high nutrient concentrations. In some regions, this index correlates with transport and deposition of silt.

Eleven community characteristics were used in the invertebrate community status index to assess water quality. The fish status indicator is the sum of scores of four fish-population characteristics (percent tolerant species, percent omnivorous fish, percent non-native fish, and individuals with external anomalies) that increase in concert with water-quality degradation (fig. 24).

In relation to the rest of the Nation, the invertebrate status index in the lower Illinois River Basin was intermediate at all sites except one (table 2). Macroinvertebrate communities of streams in

Figure 24. Longnose gar from the Sangamon River in central Illinois. In the basin, the Longnose gar is the most common gar found in small rivers. Many fish were collected, measured, and released to determine the health of the fish communities in the streams and rivers sampled. (Photograph by David J. Fazio, USGS.)

Figure 25. Basin streams with fast current had the most diverse macroinvertebrate communities. (Photograph by David J. Fazio, USGS.)

the basin are dominated by many species that are widely distributed, most of which are tolerant of the effects of excess nutrients. Excessive quantities of nutrients in runoff to streams can be harmful to intolerant species by stimulating algal growth that may

decrease dissolved-oxygen concentrations at night. The highest proportions of sensitive macroinvertebrate species were in streams with comparatively swift currents because increased water velocity can increase rates of stream aeration and thus maintain higher dissolved-oxygen concentrations (fig. 25).

Algae index values were either high or intermediate in relation to the entire Nation. The algal status index indicates that general algal conditions (as an indicator of water quality) in the Corn Belt are poor relative to the rest of the country. (See pages 9–10.)

One of the lowest fish-index scores in the country (indicating a healthy fish community) was at Panther Creek near El Paso. This small, shaded stream held a variety of habitats and a diverse fish population. All the biological index scores were high (degraded community) for the Sangamon River near Oakford. Little habitat diversity was found at this site, and concentrations of nutrients were high.

Highest concentrations of polycyclic aromatic hydrocarbons were in bed sediment near urban areas

Polycyclic aromatic hydrocarbons (PAHs) were detected in concentrations at or above a common reporting level of 50 µg/kg in as much as 50 percent of the bed-sediment samples (fig. 26). PAHs are by-products of combustion; sources include fires, manufacturing, power generation, and vehicle emissions. With sufficient exposure, many PAHs are carcinogenic, causing tumors in fish and other animals, and many PAHs are toxic to some organisms [33]. In the basin, the highest PAH concentrations were in the bed sediment of the Illinois River at locations upstream from Peoria. The highest PAH concentrations at other sites in the basin were near urban areas: specifically, in

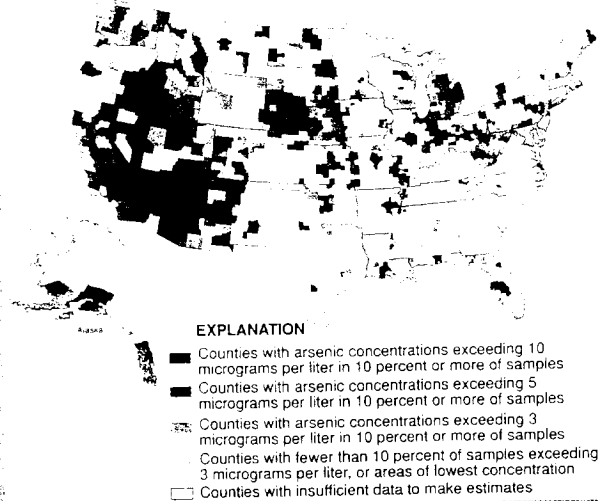

Figure 26. Four polycyclic aromatic hydrocarbons (PAHs) were detected at concentrations that may be detrimental to wildlife that live in bed sediments. Many PAHs are prevalent in sediments of the basin. Shown are percent detections at or above 50 micrograms per kilogram in bed-sediment samples and percent detections that exceed Canadian guidelines for protection of aquatic life [26]. [*], no guideline available; PEL, Probable Effect Level]

Arsenic in ground water is a national concern

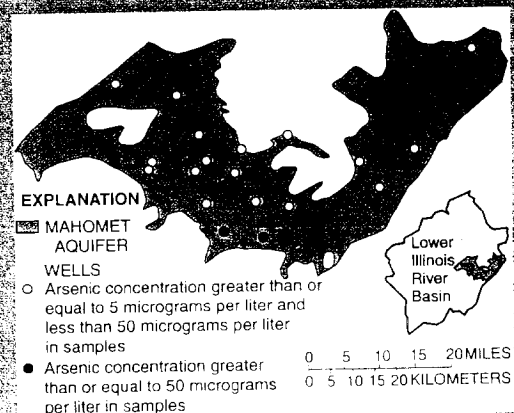

Arsenic is a naturally occurring trace element in natural waters. With sufficient exposure, arsenic can cause skin, lung, bladder, liver, and kidney cancer in humans [34, 21]. It also has been reported to impair development and hearing; to adversely affect the vascular, gastrointestinal, and nervous systems; and to be associated with diabetes. The current (2000) arsenic MCL applies to the sum of all arsenic forms in finished drinking water. The USEPA has proposed a new MCL of 5 µg/L.

Areas in the Western United States and upper Midwest have relatively high arsenic concentrations in ground water. In Illinois, the dark areas on the map generally indicate the counties

overlying the Mahomet aquifer, where water from about 7 percent of wells sampled (2 of 30) exceeded the current MCL (50 µg/L) and 60 percent would exceed the lower MCL. Only few concentrations of arsenic above 5 µg/L and none above 50 µg/L in shallow wells (less than 100 feet deep) were found at wells in the western and southern shallow aquifers and other areas in the lower Illinois River Basin.

Nationally, water from 1 percent of wells sampled exceeded the current MCL [35], and only 16 percent would exceed the proposed new standard in Illinois, if they do not treat the water for arsenic. In Illinois, people who draw water from the Mahomet aquifer have greater risk of drinking arsenic in water than ground-water users in the rest of the United States.

a small stream in the city of Decatur, in the Vermilion River near its confluence with the Illinois River (downstream from Streator and Pontiac), and in the Sangamon River downstream from Springfield. Four detections of PAH compounds exceeded the Canadian interim freshwater sediment-quality guidelines for the protection of aquatic life [26].

Arsenic exceeded the drinking-water standard in the Mahomet aquifer

The Mahomet aquifer is overlain by more than 100 feet of clay-rich glacial material. Contamination of this aquifer by human activities is minimal [31]. Although arsenic resulting from human activities can contaminate water, high concentrations of arsenic in the Mahomet aquifer are from natural sources. Arsenic concentrations in parts of the Mahomet aquifer

exceeded the USEPA current MCL of 50 µg/L. In 1999, the National Academy of Science [34] concluded that this current standard does not sufficiently protect public health. The USEPA has proposed lowering the MCL to 5 µg/L. If the arsenic MCL were lowered to 5 µg/L, then water from more than 60 percent of the wells sampled (18 of 30) would exceed the new level.

Within the lower Illinois River Basin, the percentage of private-well samples with concentrations of arsenic above 50 µg/L was approximately the same as that of samples from public-supply wells. Statewide data from the Illinois Environmental Protection Agency [31], however, indicate the percentage of concentrations above 5 µg/L was different between the public wells and private wells statewide.

ILLINOIS RIVER: A history of degradation and recovery

In Illinois, 7 percent of the fish species have disappeared since about 1900, and many more species are in decline [36]. Smith [37] listed eight conditions responsible for the loss of many fish populations in Illinois streams. Some of these conditions can be found in the basin: siltation; drainage of natural lakes, swamps, and prairie marshes; desiccation during drought; species interactions, including competition from non-native fish; industrial, domestic, and agricultural pollution other than siltation; dams and reservoirs; and increased water temperature.

One of the most notable effects of human activity on stream life occurred between 1900 and 1920 in the Illinois River downstream from Chicago, after the Chicago Sanitary and Shipping Canal opened. The biological repercussions of industrial and domestic wastes being diverted to the Illinois River peaked in about 1920, when plants, benthic organisms, and fish practically were eliminated from the Illinois River downstream from Chicago to a point downstream from Peoria [38]. Since the 1920s, water quality in this reach of the Illinois River has gradually improved because of the improved wastewater-treatment practices upstream. Monitoring by the Illinois Natural History Survey (INHS) has documented partial recovery of fish communities. Between 1957 and 1992,

common carp and goldfish dominated fish communities in the main stem of the upper Illinois River. **By 1993, however, native species had returned to the main stem, and the relative abundance of common carp and goldfish had declined significantly** [39]. In contrast, fish life in the bottomland lakes along the lower Illinois River has not increased to the degree anticipated from improvement in dissolved-oxygen conditions [40, 41].

Compared to urban areas upstream from the basin, streams in predominantly agricultural areas generally have higher biotic integrity and more diverse fish communities that commonly include various intolerant fish species [42, 43, and 37].

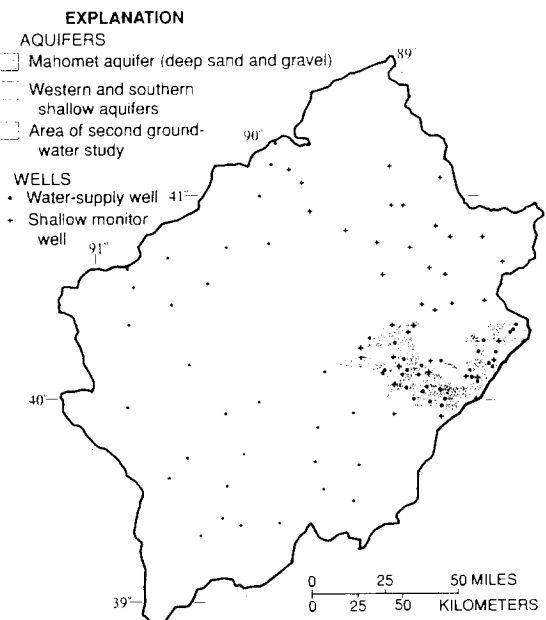

The Illinois River historically was an important wildlife resource. It is gradually recovering that status.

Radon exceeded the proposed drinking-water standard in almost one-half of shallow wells

The bedrock underlying the glacial materials in the lower Illinois River Basin and especially the glacial material itself contain a high concentration of the source elements that decay into radon. As a result, the potential for high concentrations of radon in ground water and soil gas in the basin is greater than the national average (W.S. Morrow, Jr., U.S. Geological Survey, written commun., 2000).

Radon was detected in all 30 water samples from the Mahomet aquifer (fig. 27). Concentrations of radon ranged from 110 to 730 picocuries per liter (pCi/L), and the mean concentration was 190 pCi/L.

Figure 27. Ground-water studies encompassed most of the area of the lower Illinois River Basin. Two studies of water-supply wells and two studies of shallow, recently recharged ground water were completed. The first set of shallow monitor wells was drilled in the material overlying the Mahomet aquifer.

The samples from the Mahomet aquifer, however, had the lowest average radon concentrations of the four groups of study wells. (See pages 25–26.) Concentrations in 7 percent of Mahomet aquifer samples (2 of 30) exceeded the proposed USEPA radon MCL of 300 pCi/L. No sample concentrations exceeded the USEPA-proposed Alternative Maximum Contaminant Level (AMCL) for radon of 4,000 pCi/L. The MCL is proposed for drinking water where there is no other indoor-air radon-mitigation strategy. The AMCL is proposed for drinking water where a multimedia indoor-air mitigation strategy is used to reduce radon exposure.

Radon concentration was higher in samples from the 57 shallow monitoring wells and the 30 water-supply wells in the western and southern shallow aquifers than in the Mahomet aquifer. In the samples from the western and southern shallow aquifers, 55 percent (16 of 29) exceeded the proposed MCL, but none exceeded the proposed higher AMCL. Radon was highest in the samples from shallow monitoring wells in the glacial materials overlying the Mahomet aquifer (fig. 27). In the shallow monitoring wells, 38 percent (22 of 57) of the samples exceeded the radon MCL, although no sample exceeded the AMCL.

Volatile organic compounds were detected in ground water at low concentrations

Samples were collected from 60 private and public water-supply wells in the basin to determine the extent

of contamination by volatile organic compounds (VOCs); 30 of the wells were in the Mahomet aquifer and the other 30 were in the western and southern shallow aquifers. Detections were similar in samples from wells in the western and southern shallow aquifers (83 percent) and in the Mahomet aquifer (80 percent). One sample from a well in the area of western and southern shallow aquifers contained 0.57 µg/L of methyl *tert*-butyl ether (MTBE)—well below the HAL for MTBE of 20 µg/L. The concentration of VOCs in almost all of the samples was at or near the method detection limit and was usually 10 to 100 times lower than applicable standards or guidelines for drinking water. The source of these VOCs—especially those in the Mahomet aquifer, which is largely protected from atmospheric or land-use contamination—is uncertain.

Fish and sediment in the Illinois River have high concentrations of trace elements

The Canadian interim freshwater sediment-quality guidelines for the protection of aquatic life [26] were exceeded at four locations for various trace elements. Three of these locations were on the Illinois River close to Chicago. In the Illinois River, bed-sediment concentrations of seven metals (chromium, copper, lead, mercury, nickel, selenium, and zinc) were highest near Ottawa and decreased downstream [44] (fig. 28).

In many samples of fish tissue collected in the lower Illinois River Basin, cadmium concentrations were high compared to those in all samples analyzed in the rest of the Nation. (See Appendix.) Concentrations of trace elements were examined in carp liver collected at 17 locations in the basin. The highest cadmium concentration in carp liver from across the Nation (52 milligrams per kilogram dry weight) was detected in the Vermilion River near its confluence with the Illinois River. Concentrations of cadmium in 10 carp-liver samples from the basin were in the upper one-third of the concentrations in all carp-liver samples collected in the Nation. Of those 10 samples, 6 were collected from the Illinois River main stem. Fitzpatrick and others [45] found cadmium at higher than background concentrations in sediment or biota at urban and agricultural locations in the upper Illinois River Basin. Long-term chronic exposure to cadmium can cause kidney and bone damage in humans. Mining and activities related to mining are the main sources of cadmium in the environment from human activities, but other sources include waste incineration, sewage sludge, fertilizers, batteries, tires, and many industrial processes [23].

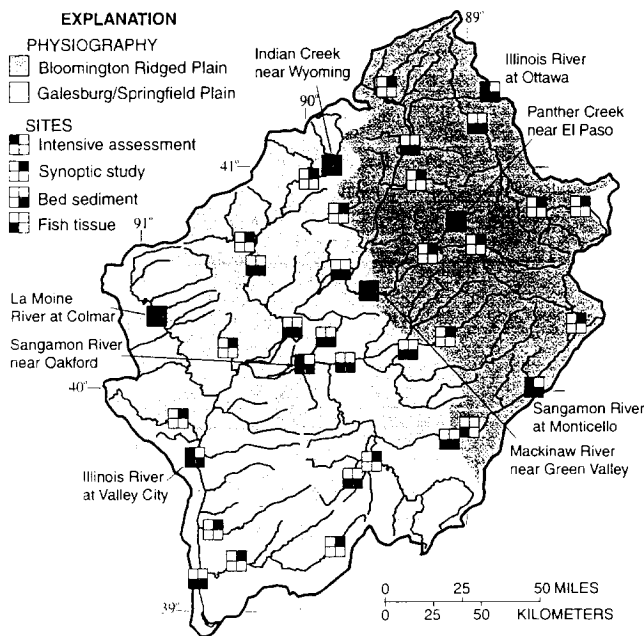

Figure 28. Concentrations of three metals in bed sediments decreased in the Illinois River from Ottawa, Ill., to Kingston Mines, Ill. The concentrations of metals were highest near the confluence of the Fox River and the Illinois River at Ottawa.

STUDY UNIT DESIGN

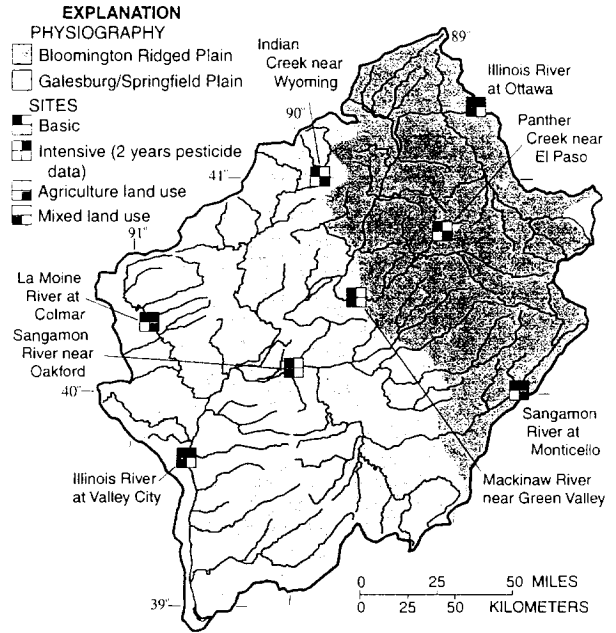

Stream chemistry

The main objective of the stream-chemistry component of the study was to assess the relation between agricultural land use and basin size and chemical constituents of surface water. Stream and river sampling locations were distributed among subbasins and on the Illinois River. Sampling locations included Basic and Intensive Fixed Sites—sampled at regular intervals for a period of 2 to 3 years—and Synoptic Sites that were sampled during a 2-week period in August 1997.

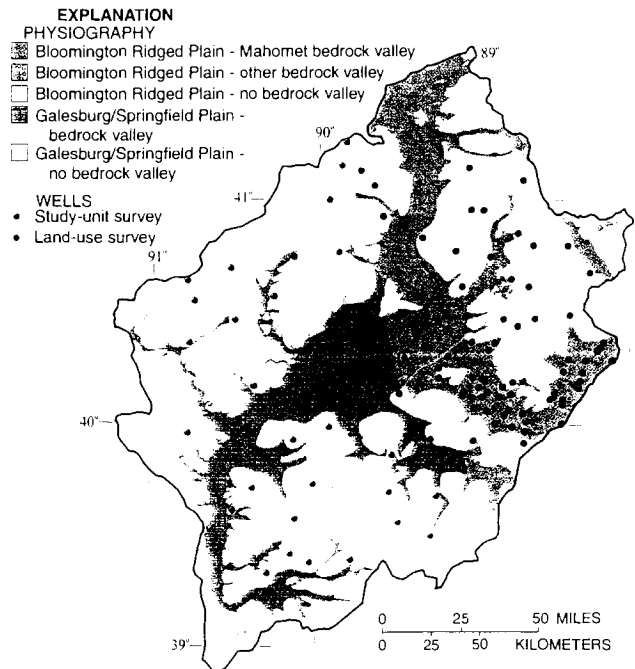

Ground-water chemistry

One objective of the ground-water chemistry component of the study was to determine whether chemical constituents of ground water were related to agricultural land uses (land-use surveys). Another objective in two surveys of domestic (household) and public-supply (municipal) wells (Study-Unit surveys) was to assess the overall water quality in selected drinking-water-source aquifers (Mahomet aquifer and the western and southern shallow aquifers) and to determine whether they are affected by land-use practices. The full extent of the Mahomet aquifer (in the Mahomet bedrock valley) is not shown. Results for the Mahomet aquifer are representative only for that part shown.

Stream ecology

The main objective of the ecology component of the study was to assess surface-water quality by integrating the physical, chemical, and biological factors. Ecology Sites were distributed at the basic fixed sites and at smaller subbasins that are all predominantly agricultural land. Sites were classified as either intensive or synoptic on the basis of the level and schedule of sampling effort.

Summary of data collection in the lower Illinois River Basin, 1995-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Basic Sites—general water quality	Concentrations, seasonal variation, and annual loads. Data included streamflow, nutrients, major ions, organic carbon, suspended sediment, water temperature, specific conductance, alkalinity, pH, and dissolved oxygen.	Basic Fixed Sites: representative of common land uses, as well as major tributary and basin outflow sites.	8	Monthly plus storms; 2 years
Intensive Sites—pesticides	Concentrations and seasonal variations in pesticides and breakdown products. Data included 75 pesticides and 13 breakdown products of the most heavily applied herbicides.	Subset of Basic Sites: Two watersheds with greater than 90 percent row-crop agriculture and the basin inflow and outflow sites.	4	Weekly to monthly Jan. 1996–June 1998
Synoptic Sites—water chemistry and pesticides	Spatial distribution of nutrients, pesticides, and pesticide breakdown products. Data included nutrients and 24 pesticides and pesticide breakdown products.	Basic Sites Additional sites	4 17	Once in August 1997 during minimum flow
Contaminants in bed sediments	Occurrence and distribution of contaminants in bed sediment. Data included total PCBs, 32 organochlorine pesticides, 63 semivolatile organic compounds, and 44 trace elements.	Depositional zones of Basic Fixed Sites and some additional sites.	21	Once; June–October in 1996–97
Contaminants in fish	Occurrence and distribution of contaminants in biota. Data included total PCBs, 30 organochlorine pesticides in whole fish, and trace elements in fish livers.	Most stream sites also sampled for bed sediments.	20	Once; June–October in 1996–97
Stream Ecology				
Intensive assessments	Relations among biological communities and water chemistry, physical habitat, and land use. Includes spatial relations, along with spatial variation. Data included algae, invertebrates, fish communities, and physical habitat.	Basic Fixed Sites	8	1 reach, 1 year (1996) 1 reach, 3 years (1996–98) 3 reaches, 1 year (1996 or 1997)
Synoptic studies	Better spatial assessment. Data collected were same as above.	Synoptic Sites	21	Once in August 1997
Ground-Water Chemistry				
Aquifer survey—domestic and public supply wells	Occurrence and distribution of chemicals in domestic and public supply wells. Data included major ions, nutrients, 75 pesticides, 13 pesticide breakdown products, 73 volatile organic compounds, dissolved organic carbon, trace elements, and radon.	Domestic and public supply wells across the subunit aquifers	56	Once in November in 1997
Resample selected aquifer survey wells	Confirmation of low-level or questionable detections of pesticides, breakdown products, and age-dating chemicals.	A subset of the wells above	10	Once in 1998
Resample selected aquifer survey wells	Confirmation of high-level detections of arsenic and to determine the chemical nature of the dissolved arsenic. Data included major ions and selected dissolved metals in addition to two chemical forms of arsenic.	A subset of wells from the deep aquifer survey with arsenic that exceeded the drinking water standard.	10	Once in 1997
Land-use effects—corn and soybean row crops	Describe the effects of agricultural land use on shallow ground water in the area underlain by most recent glacial geologic material. Data included major ions, nutrients, 75 pesticides, 13 pesticide breakdown products, dissolved organic carbon, trace elements, and radon.	Very shallow monitoring wells installed for this study	56	Once in 1997

GLOSSARY

- Algae**—Chlorophyll-bearing nonvascular, primarily aquatic species that have no true roots, stems, or leaves; most algae are microscopic, but some species can be as large as vascular plants.
- Aquifer**—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Bed sediment**—The material that temporarily is stationary in the bottom of a stream or other watercourse.
- Benthic**—Refers to plants or animals that live on the bottom of lakes, streams, or oceans.
- Breakdown product**—A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process that may result in a more toxic or a less toxic compound and a more persistent or less persistent compound.
- Concentration**—The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as microgram per liter (water sample) or micrograms per kilogram (sediment or tissue sample).
- Cubic foot per second (ft³/s, or cfs)**—Rate of water discharge representing a volume of 1 cubic foot passing a given point during 1 second, equivalent to approximately 7.48 gallons per second or 448.8 gallons per minute or 0.02832 cubic meter per second.
- Ground water**—In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Habitat**—The part of the physical environment where plants and animals live.
- Herbicide**—A chemical or other agent applied for the purpose of killing undesirable plants. See also Pesticide.
- Insecticide**—A substance or mixture of substances intended to destroy or repel insects. See also Pesticide.
- Intolerant species**—Those species that are not adaptable to human alterations to the environment and thus decline in numbers where human alterations occur. See also Tolerant species.
- Invertebrate**—An animal having no backbone or spinal column.
- Load**—General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.
- Mean**—The average of a set of observations, unless otherwise specified.
- Median**—The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Method detection limit**—The minimum concentration of a substance that can be accurately identified and measured with present laboratory technologies.
- Micrograms per liter (µg/L)**—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most stream water and ground water. One thousand micrograms per liter equals 1 milligram per liter.
- Milligrams per liter (mg/L)**—A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most stream water and ground water. One thousand micrograms per liter equals 1 milligram per liter.
- Nitrate**—An ion consisting of nitrogen and oxygen (NO₃⁻). Nitrate is a plant nutrient and is very mobile in soils.
- Organochlorine compound**—Synthetic organic compounds containing chlorine. As generally used, this term refers to compounds containing mostly or exclusively carbon, hydrogen, and chlorine. Examples include organochlorine insecticides, polychlorinated biphenyls, and some solvents containing chlorine.
- Periphyton**—Organisms that grow on underwater surfaces; periphyton include algae, bacteria, fungi, protozoa, and other organisms.
- Pesticide**—A chemical applied to crops, rights-of-way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests."
- Phosphorus**—A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.
- Phytoplankton**—See Plankton.
- Picocurie (pCi)**—One trillionth (10⁻¹²) of the amount of radioactivity represented by a curie (Ci). A curie is the amount of radioactivity that yields 3.7 × 10¹⁰ radioactive disintegrations per second (dps). A picocurie yields 2.22 disintegrations per minute (dpm) or 0.037 dps.
- Plankton**—Floating or weakly swimming organisms at the mercy of the waves and currents. Animals of the group are called zooplankton, and the plants are called phytoplankton.
- Point source**—A source at a discrete location such as a discharge pipe, drainage ditch, tunnel, well, concentrated livestock operation, or floating craft.
- Relative abundance**—The number of organisms of a particular kind present in a sample relative to the total number of organisms in the sample.
- Riparian**—Areas adjacent to rivers and streams often with a high density, diversity, and productivity of plant and animal species relative to nearby uplands.
- Semivolatile organic compound (SVOC)**—Operationally defined as a group of synthetic organic compounds that are solvent-extractable and can be determined by gas chromatography/mass spectrometry. SVOCs include phenols, phthalates, and polycyclic aromatic hydrocarbons (PAHs).
- Sorption**—General term for the interaction (binding or association) of a solute ion or molecule with a solid.
- Subsurface drain**—A shallow drain installed in an irrigated field to intercept the rising ground-water level and maintain the water table at an acceptable depth below the land surface.
- Tolerant species**—Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.
- Trace element**—An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.
- Volatile organic compounds (VOCs)**—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.
- Yield**—The mass of material or constituent transported by a river in a specified period of time divided by the drainage area of the river basin.

APPENDIX—WATER-QUALITY DATA FROM THE LOWER ILLINOIS RIVER BASIN IN A NATIONAL CONTEXT

For a complete view of lower Illinois River Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the lower Illinois River Basin. Selected results for this basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the lower Illinois River Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, acetochlor concentrations in lower Illinois River Basin agricultural streams were similar to the national distribution, but the detection frequency was much higher (83 percent compared to 33 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, lower Illinois River Basin, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

— Not measured or sample size less than two

12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- Drinking-water quality (applies to ground water and surface water)
- Protection of aquatic life (applies to surface water only)
- Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) * **
- Bromoxynil (Buctril, Brominal) *
- Butylate (Sutan +, Genate Plus, Butilate) **
- DCPA (Dacthal, chlorthal-dimethyl) * **
- Dacthal mono-acid (Dacthal breakdown product) * **
- Dicamba (Banvel, Dianat, Scotts Proturf)
- 2,6-Diethylaniline (Alachlor breakdown product) * **
- Diuron (Crisuron, Karmex, Diurex) **
- EPTC (Eptam, Farmarox, Alirox) * **
- Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
- MCPA (Rhomene, Rhonox, Chiptox)
- Metribuzin (Lexone, Sencor)
- Molinate (Ordram) * **
- Pendimethalin (Pre-M, Prowl, Stomp) * **
- Propachlor (Ramrod, Satecid) **
- Terbacil (Sinbar) **
- Triallate (Far-Go, Avadex BW, Tri-allate) *
- Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **
- Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

- Bromacil (Hyvar X, Urox B, Bromax)
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) * **
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
- Dinoseb (Dinosebe)
- Ethalfuralin (Sonalan, Curbit) * **
- Fenuron (Fenulon, Fenidim) * **
- Fluometuron (Flo-Met, Cotoran) **
- MCPB (Thistrol) * **
- Napropamide (Devrinol) * **
- Neburon (Neburea, Neburyl, Noruben) * **
- Norflurazon (E vital, Predict, Solicam, Zorial) * **
- Oryzalin (Surflan, Dirimal) * **
- Pebulate (Tillam, PEBC) * **
- Picloram (Grazon, Tordon)
- Pronamide (Kerb, Propyzamid) **
- Propanil (Stam, Stampede, Wham) * **
- Propham (Tuberite) **
- 2,4,5-T **
- 2,4,5-TP (Silvex, Fenoprop) **
- Thiobencarb (Bolero, Saturn, Benthiocarb) * **

Pesticides in water—Insecticides

Other insecticides detected

- Carbaryl (Carbamine, Denapon, Sevin)
- Carbofuran (Furadan, Curaterr, Yaltox)
- Dieldrin (Panoram D-31, Octalox, Compound 497)
- Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
- Malathion (Malathion)
- Methyl parathion (Pencap-M, Folidol-M) **
- Oxamyl (Vydate L, Pratt) **
- Propargite (Comite, Omite, Ornamate) * **
- Terbufos (Contraven, Counter, Pilarfox) **

Insecticides not detected

- Aldicarb (Temik, Ambush, Pounce)
- Aldicarb sulfone (Standak, aldoxycarb)
- Aldicarb sulfoxide (Aldicarb breakdown product)
- Azinphos-methyl (Guthion, Gusathion M) *
- Disulfoton (Disyston, Di-Syston) **
- Ethoprop (Mocap, Ethoprophos) * **
- alpha-HCH (alpha-BHC, alpha-lindane) **
- gamma-HCH (Lindane, gamma-BHC)
- 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
- Methiocarb (Slug-Geta, Grandslam, Mesuroil) * **
- Methomyl (Lanox, Lannate, Acinate) **
- Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
- cis-Permethrin (Ambush, Astro, Pounce) * **
- Phorate (Thimet, Granutox, Geomet, Rampart) * **
- Propoxur (Baygon, Blattanex, Unden, Proprotox) * **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

- Bromodichloromethane (Dichlorobromomethane)
- 2-Butanone (Methyl ethyl ketone (MEK)) *
- Carbon disulfide *
- Chlorobenzene (Monochlorobenzene)
- Chlorodibromomethane (Dibromochloromethane)
- Chloroethane (Ethyl chloride) *
- Chloromethane (Methyl chloride)
- Dichlorodifluoromethane (CFC 12, Freon 12)
- Dichloromethane (Methylene chloride)

- 1,3 & 1,4-Dimethylbenzene (*m*-&*p*-Xylene)
- 1,4-Epoxy butane (Tetrahydrofuran, Diethylene oxide)
- 1-Ethyl-2-methylbenzene (2-Ethyltoluene)
- Hexachlorobutadiene
- Iodomethane (Methyl iodide)
- 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK))
- Methylbenzene (Toluene)
- 2-Propanone (Acetone)
- Tetrachloroethene (Perchloroethene)
- Tetrachloromethane (Carbon tetrachloride)
- 1,2,3,4-Tetramethylbenzene (Prehnitene)
- 1,2,3,5-Tetramethylbenzene (Isodurene)
- Tribromomethane (Bromoform)
- 1,2,3-Trichlorobenzene
- 1,1,1-Trichloroethane (Methylchloroform)
- Trichloromethane (Chloroform)
- 1,2,3-Trimethylbenzene (Hemimellitene)
- 1,2,4-Trimethylbenzene (Pseudocumene)

VOCs not detected

- tert*-Amyl methyl ether (*tert*-amyl methyl ether (TAME))
- Benzene
- Bromobenzene (Phenyl bromide)
- Bromochloromethane (Methylene chlorobromide)
- Bromoethene (Vinyl bromide)
- Bromomethane (Methyl bromide)
- n*-Butylbenzene (1-Phenylbutane)
- sec*-Butylbenzene
- tert*-Butylbenzene
- 3-Chloro-1-propene (3-Chloropropene)
- 1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
- 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
- Chloroethene (Vinyl chloride)
- 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
- 1,2-Dibromoethane (Ethylene dibromide, EDB)
- Dibromomethane (Methylene dibromide)
- trans*-1,4-Dichloro-2-butene ((*Z*)-1,4-Dichloro-2-butene)
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
- 1,3-Dichlorobenzene (*m*-Dichlorobenzene)
- 1,4-Dichlorobenzene (*p*-Dichlorobenzene)
- 1,2-Dichloroethane (Ethylene dichloride)
- 1,1-Dichloroethane (Ethylidene dichloride)
- 1,1-Dichloroethene (Vinylidene chloride)
- trans*-1,2-Dichloroethene ((*E*)-1,2-Dichloroethene)
- cis*-1,2-Dichloroethene ((*Z*)-1,2-Dichloroethene)
- 1,2-Dichloropropane (Propylene dichloride)
- 2,2-Dichloropropane
- 1,3-Dichloropropane (Trimethylene dichloride)
- trans*-1,3-Dichloropropene ((*E*)-1,3-Dichloropropene)
- cis*-1,3-Dichloropropene ((*Z*)-1,3-Dichloropropene)
- 1,1-Dichloropropene
- Diethyl ether (Ethyl ether)
- Diisopropyl ether (Diisopropylether (DIPE))
- 1,2-Dimethylbenzene (*o*-Xylene)
- Ethylbenzene (Styrene)
- Ethyl methacrylate
- Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE))
- Ethylbenzene (Phenylethane)
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK))
- Isopropylbenzene (Cumene)
- p*-Isopropyltoluene (*p*-Cymene)
- Methyl acrylonitrile
- Methyl-2-methacrylate (Methyl methacrylate)
- Methyl-2-propenoate (Methyl acrylate)
- Naphthalene
- 2-Propenenitrile (Acrylonitrile)
- n*-Propylbenzene (Isocumene)
- 1,1,2,2-Tetrachloroethane
- 1,1,1,2-Tetrachloroethane
- 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113)
- 1,2,4-Trichlorobenzene
- 1,1,2-Trichloroethane (Vinyl trichloride)
- Trichloroethene (TCE)
- Trichlorofluoromethane (CFC 11, Freon 11)
- 1,2,3-Trichloropropane (Allyl trichloride)
- 1,3,5-Trimethylbenzene (Mesitylene)

Nutrients in water

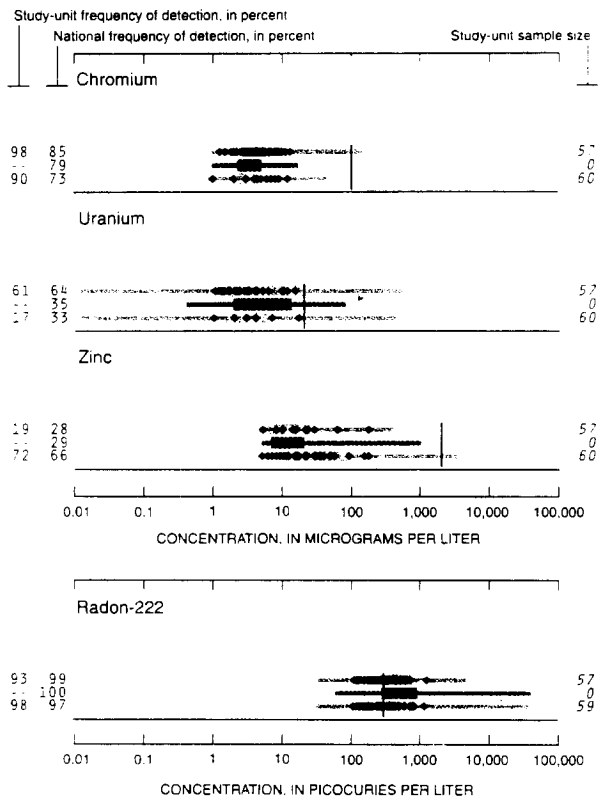

Dissolved solids in water

Trace elements in ground water

Other trace elements detected

Lead
Selenium

Trace elements not detected

Cadmium

Organochlorines in fish tissue (whole body) and bed sediment

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, lower Illinois River Basin, 1995-98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

-- Not measured or sample size less than two

12 Study-unit sample size

National range of concentrations detected, by land use, in 36 NAWQA Study Units, 1991-98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- No benchmark for protection of aquatic life

¹ The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

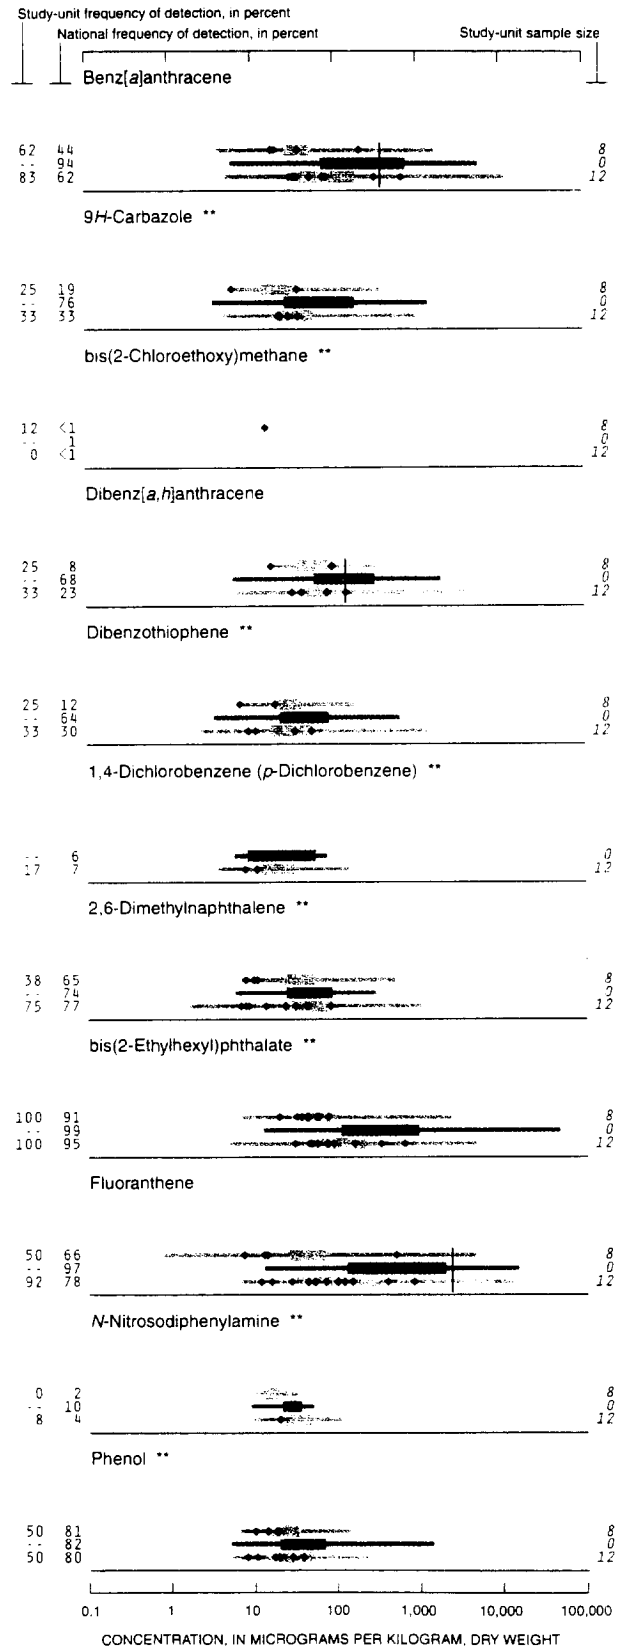

Other organochlorines detected

- DCPA (Dacthal, chlorthal-dimethyl) ***
- Hexachlorobenzene (HCB) **
- Pentachloroanisole (PCA) **

Organochlorines not detected

- Chloroneb (Chloronebe, Demosan) ***
- o,p'*+*p,p'*-DDT (sum of *o,p'*-DDT and *p,p'*-DDT) *
- Endosulfan I (alpha-Endosulfan, Thiodan) ***
- Endrin (Endrine)
- gamma-HCH (Lindane, gamma-BHC, Gammexane) *
- Total-HCH (sum of alpha-HCH, beta-HCH, gamma-HCH, and delta-HCH) **
- Isodrin (Isodrine, Compound 711) ***
- p,p'*-Methoxychlor (Marlate, methoxychlore) **
- o,p'*-Methoxychlor **
- Mirex (Dechlorane) **
- cis*-Permethrin (Ambush, Astro, Pounce) ***
- trans*-Permethrin (Ambush, Astro, Pounce) **
- Toxaphene (Camphechlor, Hercules 3956) ***

Semivolatile organic compounds (SVOCs) in bed sediment

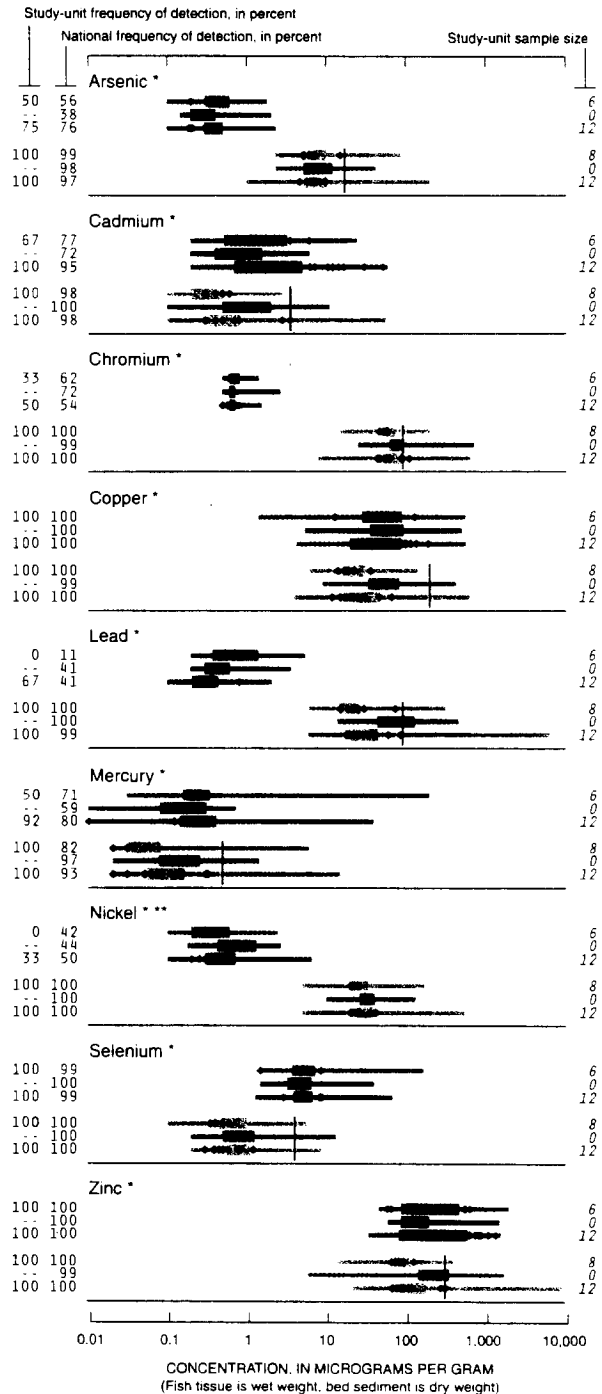

Other SVOCs detected

- Acenaphthene

BIOLOGICAL INDICATORS

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation

APPENDIX—WATER-QUALITY DATA FROM THE EASTERN IOWA BASINS IN A NATIONAL CONTEXT	32

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Eastern Iowa Basins that emerged from an assessment conducted between 1996 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings also are explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

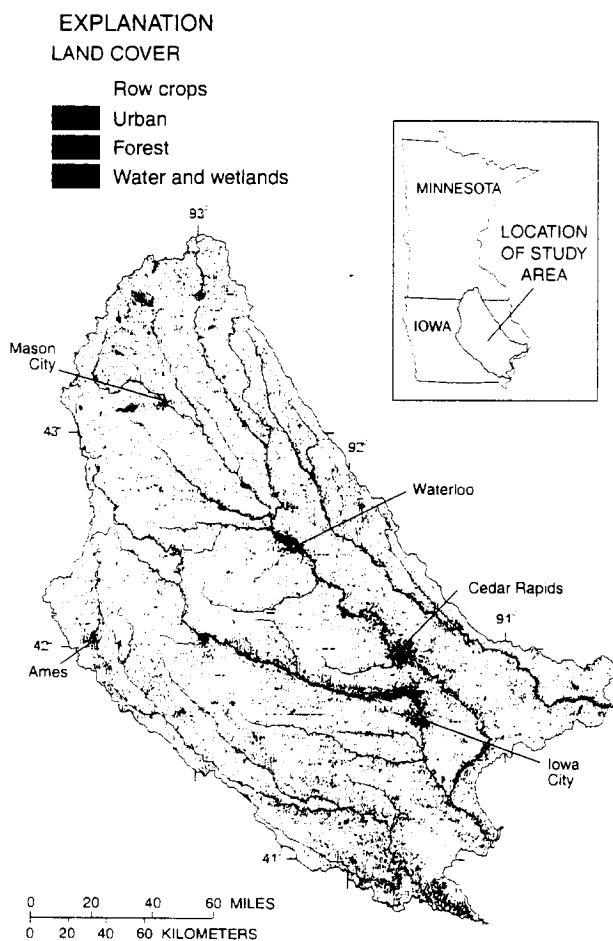

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Eastern Iowa Basins assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Eastern Iowa Basins is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

The Eastern Iowa Basins Study Unit encompasses the Wapsipinicon, the Cedar, the Iowa, and the Skunk River Basins and covers about 19,500 mi² in eastern Iowa and southern Minnesota. In 1990, about 40 percent of the more than 1 million people in the Study Unit were concentrated in cities with populations of greater than 20,000 people. Cedar Rapids is the only city with a population greater than 100,000. Ground water is the major source for municipal, industrial, and domestic supplies. During the study, Iowa City was the largest municipal user of surface water. Over 90 percent of the land in the Study Unit is used for agricultural purposes. Forested areas account for only 4 percent of the land. Data from Eros Data Center, 1994.

Stream And River Highlights

Nitrogen and phosphorus concentrations in streams in the Eastern Iowa Basins Study Unit rank as some of the highest in the Corn Belt (see map, p. 8) as well as the Nation and were higher than the drinking-water standard in many samples. These conditions reflect intensive use of the land for growing crops and dense populations of livestock in some basins.

- Nitrate concentrations in 22 percent of the stream samples exceeded the U.S. Environmental Protection Agency (USEPA) drinking-water standard of 10 mg/L (milligrams per liter). The standard was most frequently exceeded during June, soon after spring fertilizer application. Although many

of the streams sampled are not currently used for drinking-water supplies, the Cedar and Iowa Rivers are the direct or indirect source for Cedar Rapids and Iowa City—two of the largest cities in the study area.

- The highest nitrate concentrations occurred in medium-sized streams draining basins with the most intensive row-crop agriculture and in a stream draining a basin with both intensive row-crop agriculture and dense concentrations of large-scale animal feeding operations. Nitrate concentrations in these streams exceeded 10 mg/L in almost 50 percent of the samples. Conversely, nitrate concentrations were lowest in basins that had greater percentages of pasture, grassland, and forest.
- Total phosphorus concentrations frequently (75 percent of the samples) exceeded the 0.1-mg/L USEPA-recommended goal to minimize algal growth in rivers. Total phosphorus concentrations were greatest in streams and rivers that drain basins with more highly erodible soils and in large river basins that contain the largest cities and towns in the Study Unit.
- The large amounts of nitrogen and phosphorus that are transported to the Mississippi River from the Study Unit represent an economic loss to farmers and a potential environmental threat to downstream waters. The estimated annual loss of 17 to 41 lb/acre (pounds per acre) of nitrogen and 1.2 to 1.5 lb/acre of phosphorus represents a potential loss in crop yield or the cost of additional fertilizer needed to compensate for that flushed from the fields. Nutrients transported to the Mississippi River likely reach the Gulf of Mexico where they contribute to eutrophication and hypoxia.
- Although the use of herbicides and insecticides in the Study Unit is among the most intense nationwide, herbicide concentrations in streams were not among the highest 25 percent nationally, and insecticide concentrations were in the lowest 25 percent nationally. Breakdown compounds (degradates), whose widespread occurrence has only recently been discovered and about which little is known of the human and environmental effects, generally accounted for the majority of the pesticide compounds present in rivers and streams.
- The most commonly used herbicides were the most frequently detected and were generally present in the greatest concentrations. Atrazine and metolachlor were detected in all stream samples. Concentrations generally ranged from 0.1 to 1.0 µg/L (microgram per liter). Atrazine concentrations exceeded the USEPA 3.0-µg/L drinking-water standard in about 10 percent of the samples; exceedances occurred mainly during late-spring runoff.
- Acetochlor, a conditionally registered herbicide that is intended to replace several other commonly used herbicides, was frequently detected, but concentrations were less than 0.1 µg/L in 75 percent of the samples. Mean annual acetochlor concentrations did not exceed the 2.0-µg/L USEPA registration requirement at any site, but concentrations did exceed that level in about 3 percent of the individual samples. The maximum concentration measured during the study (10.6 µg/L) exceeded the level that would require biweekly sampling by water-supply systems.
- Alachlor, metolachlor, and acetochlor degradates are present in relatively high concentrations throughout the year, indicating that they are more persistent than their parent compounds.
- Carbofuran and chlorpyrifos, insecticides that have been identified as posing a high risk to aquatic insects and mussels, were present in as much as 60 percent of the monthly samples during the summer when these insecticides are normally applied.
- Riparian buffer zones influence the quality of water in streams and rivers. Biological communities respond to tree density in riparian buffer zones. Invertebrate taxa indicative of good stream quality increased with increased numbers of trees. In contrast, streams that were not shaded by trees contained large algal growths considered indicative of eutrophication.

Selected Indicators of Stream-Water Quality

	Small Streams		Major Rivers
	Urban	Agricultural	Mixed Land Uses
Pesticides	—		
Pesticide degradates	—		
Nitrate ¹	—		
Total phosphorus ¹	—		
Trace elements ²			
Organo-chlorines ³			
Semivolatile organics ⁵			

- Percentage of samples with concentrations **greater than or equal to** health-related national guidelines for drinking water, protection of aquatic life, or contact recreation
- Percentage of samples with detected concentrations **less than** health-related national guidelines for drinking water, protection of aquatic life, or contact recreation
- Percentage of samples with **no detection**
- Not assessed

Major influences on streams and rivers

- Agricultural storm runoff
- Animal feeding operations
- Tile-line drainage
- Urban areas

Ground-Water Highlights

Compared to surface water, ground water in the Eastern Iowa Basins had substantially lower nutrient concentrations and less frequent detections. Land use, however, had a substantial effect on the quality of water in alluvial aquifers. Pesticide degradates were some of the most commonly detected constituents in these aquifers. Nitrate and methyl *tert*-butyl ether (MTBE) exceeded the USEPA standard or advisory in some of the samples. In contrast, bedrock aquifers, which are generally protected by clay and shale layers, typically had low nitrate concentrations and low frequency of pesticide detections.

- Nitrate concentrations generally decreased with depth in the alluvial aquifers. Biological denitrification may result in decreased nitrate concentration with depth, but it is also possible that the deeper water infiltrated during past years when less fertilizer was used for crops.

- Nutrients move from ground water to streams by natural drainage and tile lines. Nitrate concentrations in 24 of 25 medium-sized streams exceeded 10 mg/L during the sampling period in May 1998 when streamflow originated primarily from ground-water discharge. Nitrate concentrations consistently exceeded 10 mg/L in water from a selected tile line draining to the Iowa River.
- Pesticides were detected in alluvial aquifers underlying both agricultural and urban areas, but shallow ground water in agricultural areas contained greater concentrations than urban areas. A greater variety of pesticide compounds was detected in urban areas than agricultural areas, reflecting a more diverse usage.
- Pesticides most commonly detected in the alluvial aquifers underlying urban areas were atrazine, prometon, and metolachlor. Pesticide concentrations did not exceed established drinking-water standards.
- With the exception of atrazine and metolachlor and prometon in urban areas, pesticides were infrequently detected in alluvial aquifers. Pesticide degradates generally were more commonly detected in the alluvial aquifers than their parent compounds. The greater presence of degradates indicates that many pesticides break down in the soil and that the resulting pesticide degradates are transported to the shallow aquifers.
- MTBE, a common gasoline additive used to increase the octane content or ensure cleaner burning, was detected in 23 percent of samples from alluvial aquifers in urban areas. Concentrations exceeded the USEPA drinking-water advisory in samples from 6 percent of the wells.

Major influences on ground water

- Lawn, garden, and agricultural fertilizers
- Agricultural and urban pesticides
- Leaking underground fuel-storage tanks

INTRODUCTION TO THE EASTERN IOWA BASINS

The Eastern Iowa Basins Study Unit encompasses the Wapsipinicon, the Cedar, the Iowa, and the Skunk River Basins and encompasses about 19,500 mi² (square miles) in eastern Iowa and southern Minnesota (fig. 1). The four major rivers in the Study Unit generally flow in a southeasterly direction and empty into the Mississippi River. The basins of these four major rivers are relatively long and narrow. The Wapsipinicon River originates in southeastern Minnesota and extends about 225 mi (miles) to its confluence with the Mississippi River. The Wapsipinicon River Basin has a drainage area of 2,540 mi². The Cedar River originates in southern Minnesota and joins the Iowa River about 30 mi upstream from the mouth of

the Iowa River. The Iowa River originates in north-central Iowa. The Iowa and the Cedar River Basins cover 12,640 mi², more than 90 percent of which is in Iowa. The Skunk River originates in central Iowa and drains about 4,350 mi².

Geology

Glaciers created a land surface with three distinct regions in the Eastern Iowa Basins Study Unit: the Des Moines Lobe, the Iowan Surface, and the Southern Iowa Drift Plain (fig. 1). The Des Moines Lobe is characterized by low relief with some distinct ridges near the eastern boundary and occasional depressions that form lakes, ponds, and swamps. Glacial till is the dominant surficial mate-

rial, and alluvium is present along the streams. Poorly drained soils have developed on the tills. The Iowan Surface has gently rolling topography with long slopes, low relief, and a mature drainage pattern. The surficial material is primarily glacial drift with thin layers of windblown loess on the ridges and alluvium near the streams. A subregion of the Iowan Surface (Iowan Karst) was defined for this study in an area where bedrock is close to the land surface. In the Southern Iowa Drift Plain, streams have eroded deeply into the glacial drift and loess mantle to produce a steeply rolling terrain with broad, flat drainage divides. Moderately well-drained soils have developed on the loess.

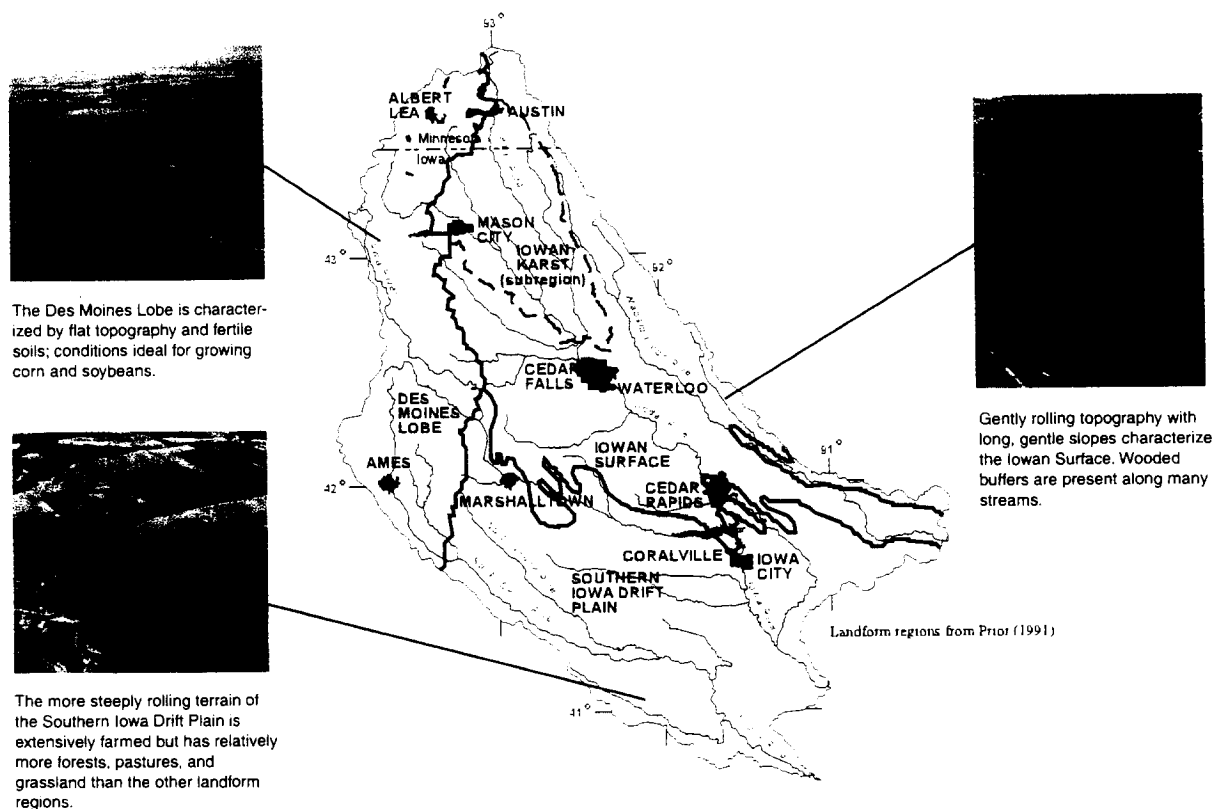

Figure 1. Glacial deposits formed three major landforms with characteristic soils and topography in the Eastern Iowa Basins.

Climate

Water originates as rainfall in late spring through late fall and as snow during winter and early spring. Average annual precipitation in the basins ranges from about 30 inches in the northwestern part of the Study Unit to about 36 inches in the southeast. The greatest rainfall typically occurs during the growing season in spring and summer. The mean April-to-October precipitation is about 25 inches. The most intense 24-hour rainfall (5-year recurrence interval) can be more than 4 inches. Snowfall has been recorded from September to May. The greatest 24-hour snowfall seldom (less than 25 percent of the years) exceeds 10 inches. Yearly rainfall during the study period ranged from below average in 1996 to about average in 1997 and above average in 1998.

Land Use

Because water flows over the land surface or infiltrates the soil,

human activities may have a substantial effect on the quality of ground and surface water. The production of row crops, such as corn, and cover crops, such as alfalfa and small grains, constitutes the major land use in the Study Unit. Land near the streams and rivers has a combination of crops and forests. About 40 percent of the more than 1 million people in the Study Unit are concentrated in cities with populations greater than 20,000.

Water Use

Water used for household, municipal, commercial, industrial, and agriculture purposes originates primarily from ground water. Surface water, although an important supply for several larger cities including Cedar Rapids and Iowa City, is used primarily for cooling water in the generation of electric power.

Water that infiltrates through the soil into underlying sand and gravel deposits and ultimately into

the underlying bedrock formations is used as a water supply for about 94 percent of the population in the Eastern Iowa Basins Study Unit. Rivers and streams are the source of public-water supplies for about 6 percent of the population (fig. 2).

Figure 2. An abundant ground-water resource provides water to municipalities, homes, and industry. Ground water is used by more than 90 percent of the population in the Study Unit.

Figure 3. In the Eastern Iowa Basins, water originating from precipitation flows overland or through loess, till, and alluvial deposits to nearby streams. Areas with high water tables and poor natural drainage have commonly been artificially drained with tile lines. (Graphic created by Suzanne Roberts, U.S. Geological Survey.)

Surface Water

Excess precipitation that does not infiltrate into the soil or evaporate runs off to the streams (fig. 3). Generally, poorly permeable till soils typical of the Des Moines Lobe and steeper slopes typical of the Southern Iowa Drift Plain generate greater overland flow than the moderately well drained loess soils and gentle slopes typical of the Iowa Surface. Overland flow to streams is slowed or reduced by grass, perennials, shrubs, and trees (riparian buffers) where present near streambanks. Runoff to streams averages about 25 percent of the annual precipitation and ranges from less than 7 inches per year in the northern part of the Study Unit to about 9 inches per year in the southeastern part. Overland flow and ground-water discharge are the major sources of streamflow. However, tile lines may be an important source to streams during base flow in areas where they have been installed to

remove standing water from surface depressions and to lower the water table.

Long-term yearly discharge from the Eastern Iowa Basins Study Unit averages about 9.2 million acre-feet. The overall increase in rainfall from 1996 to 1998 was reflected in the substantial increase in yearly stream discharge (fig. 4). Yearly discharge from the Eastern Iowa Basins increased from about 8.6 million acre-feet in 1996 to almost 13.8 million acre-feet in 1998. Yearly discharge was not uniform in the major basins. Discharge from the Wapsipinicon and Iowa River Basins increased in 1997 and 1998, and the discharge from the Skunk River Basin decreased from 1996 to 1998.

Ground Water

Water from rainfall infiltrates through the soil and, depending on whether permeable sand, gravel, and fractured bedrock are present, may continue to move to the deeper aquifers (fig. 3). If low-permeabil-

ity clay or shale lies below the unconsolidated surficial materials, water may move laterally to a nearby stream.

Alluvial material that has been deposited by rivers and streams commonly consists of sand and gravel layers that store and transmit water readily. The alluvial aquifers (fig. 5) are the most frequently used source of ground water in the Eastern Iowa Basins because they are near land surface and can supply large amounts of water. The same properties (shallow depth and permeable material) that make alluvial aquifers excellent sources of water also make the alluvial aquifers susceptible to contamination from surface activities.

Two additional surficial deposits, not assessed during this study, provide water for domestic and municipal supplies. Sand and gravel deposits in low-permeability glacial till generally yield small quantities of water that are used mostly for rural domestic and stock supplies. Also, deep sand and

Figure 4. Stream discharge in the Eastern Iowa Basins ranged from below normal in 1996 to near normal in 1997 and above normal in 1998 (site number in parentheses; see site map in "Study Unit Design" section).

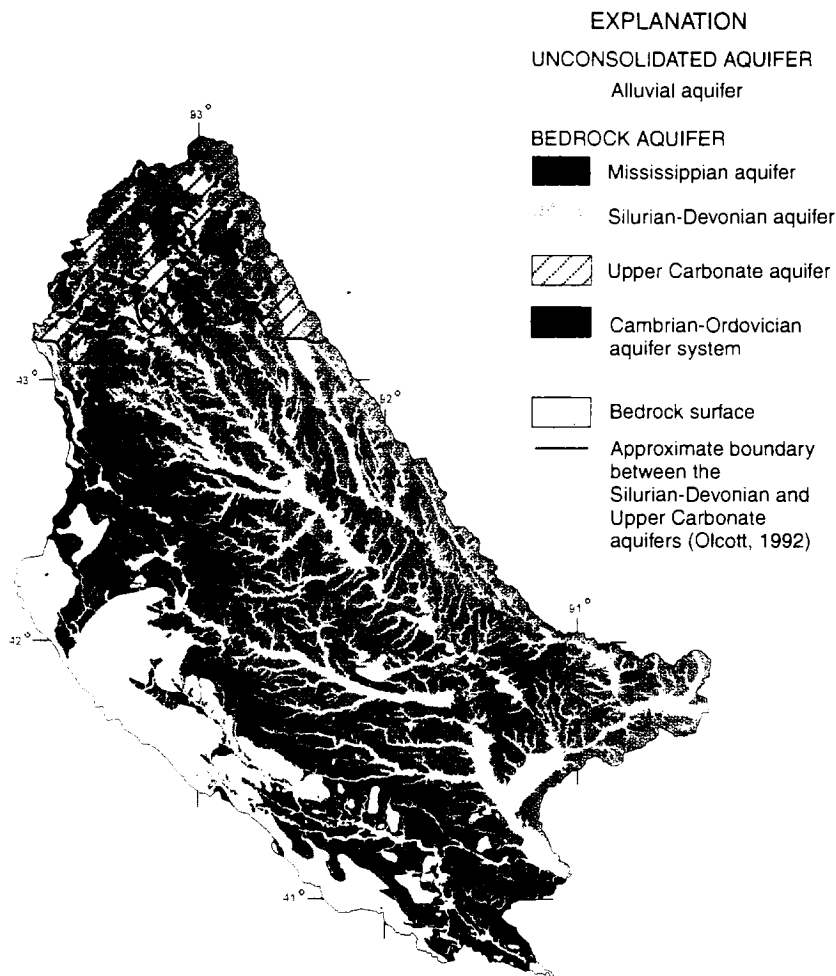

Figure 5. Several major bedrock and unconsolidated aquifers are used as sources of water for domestic, municipal, and industrial supplies. Only the most heavily used aquifers, the Silurian-Devonian and Upper Carbonate aquifers and the alluvial aquifers, were sampled.

gravel deposited in bedrock valleys before the last glacial advance is an important source of water in parts of the Eastern Iowa Basins.

Rock formations (bedrock) generally underlie the clay, silt, sand, and gravel surficial materials and can provide water for use. Bedrock aquifers are generally deep and are protected from surficial contamination. However, in areas such as the

Iowan Karst, bedrock is exposed or is covered by very thin unconsolidated deposits and is susceptible to contamination from urban and agricultural land uses.

The most extensively used bedrock aquifers are the Silurian-Devonian and Upper Carbonate aquifers. The Silurian-Devonian and Upper Carbonate aquifers consist mainly of limestone and

dolomite with locally interbedded shale and evaporite beds. Bedrock aquifers that are used as a source of water in the Study Unit but were not evaluated during this study are the Mississippian aquifer and the Cambrian-Ordovician aquifer system.

MAJOR FINDINGS

Nutrients in Ground Water and Streams

Two naturally occurring nutrients, nitrogen and phosphorus, commonly are applied in the form of fertilizers and manure in agricultural areas to increase the yield of crops and as fertilizer in cities and towns to enhance the appearance of residential lawns, city parks, and golf courses. Nitrogen and phosphorus also are commonly discharged from wastewater-treatment facilities. Nutrients that are not used by plants or attached to soil particles can move to shallow ground water or can be washed into nearby streams during intense rains. Runoff from rainfall and ground-water inflow can transport excess nutrients to streams, causing algal blooms that deplete oxygen for fish and other aquatic organisms. High concentrations of nitrogen in the form of nitrate may make untreated water unsuitable for human consumption. The USEPA has established a Maximum Contaminant Level (MCL) of 10 mg/L (milligrams per liter) for nitrate as nitrogen in drinking water (U.S. Environmental Protection Agency, 1996). High concentrations of nitrogen in the form of ammonia may kill fish and other aquatic organisms. To minimize algal growth in streams and reservoirs, a total phosphorus concentration of 0.10 mg/L or less has been recommended by the USEPA (1986).

Nutrients in Ground Water

Nitrogen and phosphorus are prevalent in ground water. Nitrogen readily moves from the land surface to ground water in the shallow alluvial aquifers but not as readily to most parts of the deeper Silurian-Devonian and Upper Carbonate bedrock aquifers in the

Eastern Iowa Basins. Nitrogen, in the form of nitrate and ammonia, and dissolved phosphorus were detected in more than 65 percent of 124 ground-water samples. Nitrate concentrations were significantly higher in the shallow alluvial aquifers, which have been identified as being susceptible to contamination (Hoyer and Hallberg, 1991), than in the Silurian-Devonian and Upper Carbonate bedrock aquifers (fig. 6). Nitrate concentrations in water samples from monitoring wells screened near the water table in urban areas were higher than concentrations in samples from domestic wells, which generally are screened deeper in the aquifers.

Human and natural factors affect movement of nutrients to ground water. Downward movement of water containing nitrogen and phosphorus is slowed by fine-grained materials overlying the aquifers. The presence of clay in the soil and in the shallow subsurface and low-permeability rocks, such as shale, can slow ground-

water infiltration rates and limit the amount of nutrients at depth. Surficial contamination most affects water near the top of the alluvial aquifers where the clay layer above the water table is thin or nonexistent (see fig. 8, p. 8).

In the Silurian-Devonian and Upper Carbonate aquifers, ground-water ages (determined by analysis of tritium concentrations) were significantly younger and nitrate concentrations were significantly higher in samples from areas where an overlying low-permeability shale layer was absent or where less than 100 feet of unconsolidated deposits overlies the aquifer (Savoca and others, 1999). These two results indicate that longer flow paths (deeper sample depth and thicker clay layer) increase opportunities for sorption, degradation, and dispersion and may contribute to decreases in nutrient concentrations with depth. Alternatively, water deeper in the aquifer may have infiltrated in years when fertilizer use was not as prevalent.

Figure 6. The shallowest ground water is most heavily affected by current land-use practices. Agricultural practices result in higher levels of nitrate in ground water than urban activities.

NUTRIENT CONCENTRATIONS IN STREAMS WERE AMONG THE HIGHEST IN THE NATION

Concentrations of nitrate and total phosphorus in streams in Eastern Iowa Basins rank among the highest in the Nation (fig. 7). The median discharge-weighted nitrate concentrations also were significantly greater in Eastern Iowa Basins streams than in streams sampled elsewhere in the Corn Belt and Northern Great Plains ecoregion (Omernik, 2000)—an area of similar climate, topography, regional geology and soils, and broad land-use patterns. Overall, total nitrogen concentrations were similar to the streams sampled in Illinois and to an agricultural stream sampled in southern Minnesota. Nitrate concentrations were in the upper 25th percentile nationally for 9 of 11 Basic Fixed Sites. The defined reference site (Wapsipinicon River near Tripoli) and the site on the stream draining the Iowan Karst landform (Flood Creek near Powersville) were within the middle 50 percent nationally. Concentrations of total phosphorus ranged from moderate to high in relation to other streams sampled in the United States. Average discharge-weighted total phosphorus concentrations at two sites (Old Mans Creek near Iowa City and Skunk River at Augusta) in the southern part of the Eastern Iowa Basins, where highly erodible loess soils cover most of the basins, were in the upper fifth percentile nationally.

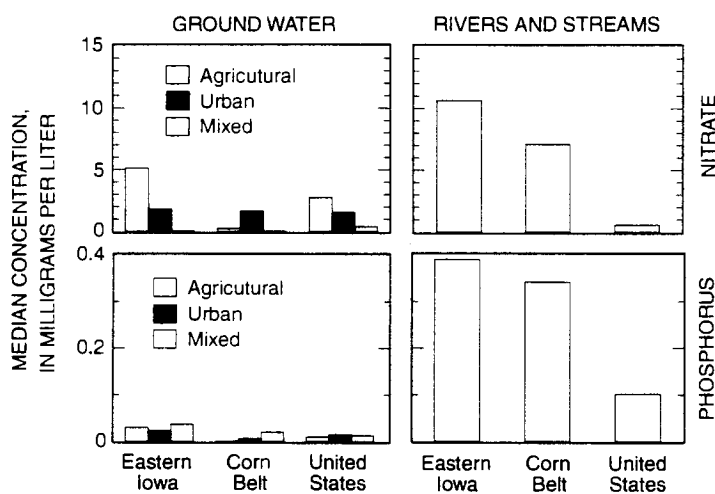

Figure 7. Nitrate and phosphorus concentrations in Eastern Iowa Basins streams and ground water are higher when compared with a wide variety of land uses across the Nation and when compared to similar land use in other parts of the Corn Belt. (Phosphorus in ground water as dissolved orthophosphorus and phosphorus in streams as total phosphorus)

Although substantially lower than in surface water, nitrate concentrations in the alluvial aquifers in agricultural areas in Eastern Iowa Basins are greater than those in ground water sampled elsewhere in the Corn Belt and the Nation. The alluvial aquifer is a relatively susceptible aquifer in contrast to aquifers within glacial till sampled in Illinois; therefore, the ranking of concentrations may not be directly comparable. However, nitrate concentrations in urban areas and in aquifers that serve as a source of water supply for municipal and domestic use in the Eastern Iowa Basins are comparable to those from the rest of the Nation. Dissolved phosphorus concentration in the alluvial aquifers in agricultural areas of Eastern Iowa Basins was greater than in ground water in the rest of the Nation. Increased susceptibility and greater fertilizer use may account for the higher phosphorus concentrations.

Natural processes may remove nitrogen from alluvial aquifers. The relation between nitrogen, dissolved oxygen, and organic carbon concentrations suggests that nitrogen is being biologically trans-

formed and removed from the alluvial aquifers. Nitrate remaining after water moves through or around clay layers may be converted to nitrogen gas in a low-oxygen or oxygen-free environ-

ment in the presence of organic carbon. This process is called denitrification. Nitrate concentrations were significantly higher in alluvial ground water having dissolved oxygen concentrations

Figure 8. Overlying clay and other low-permeability material hinder movement of nitrate to ground water.

greater than 0.5 mg/L and were significantly lower in ground-water samples having increased dissolved organic carbon concentrations (Savoca and others, 2000). Denitrification may be an important natural process that reduces nitrate concentrations before water moves to ground-water supplies or is discharged to streams.

The type of land use affects shallow ground-water quality.

Different uses, whether the land is used for agriculture, homes, business, or industry, are reflected in the nutrient concentrations in the ground water. Animal feeding operations can further affect water quality in areas with intensive row-crop agriculture (fig. 9). Nitrate was detected more frequently (94 percent of samples) and in greater concentrations (median of 5.1 mg/L) in shallow alluvial

aquifers in agricultural areas than in urban areas. Nitrate was detected in 77 percent of samples at a median concentration of 1.8 mg/L from urban areas (fig. 6). Nitrate exceeded the USEPA MCL (10 mg/L as N) in 39 percent of samples from agricultural areas and in none of the samples from urban areas. Dissolved phosphorus concentrations tended to be higher in samples from agricultural areas (median of 0.03 mg/L) than urban areas (median of 0.01 mg/L); however, the difference was not statistically significant. The higher reliance on fertilizers in agricultural areas than in urban areas most likely contributed to the higher nitrate and phosphorus concentrations.

Ammonia is prevalent in shallow urban ground water.

Dissolved ammonia concentrations were significantly higher in samples from urban areas than in samples from agricultural areas (fig. 9). The median dissolved ammonia concentration in samples from shallow urban ground water (0.025 mg/L) was more than twice the median concentration in samples from agricultural areas (0.010 mg/L). Anhydrous ammonia is used frequently as a nitrogen fertilizer for corn, but soil microbes quickly convert ammonia to nitrate.

Conditions in the alluvial aquifers (fig. 9) indicate that ammonia in shallow urban ground water originates, at least partly, from degradation of organic matter most likely derived from human activities. Substantial amounts of organic matter are available in the soil, silt, and clay above the aquifer and dissolved in water within the aquifer. Dissolved oxygen concentrations were significantly lower in urban

areas than in agricultural areas. Microbial degradation of abundant organic matter would result in the decrease in dissolved oxygen concentrations and in the increase of dissolved ammonia concentrations in shallow ground water.

Nutrients move from ground water to streams by natural drainage and tile lines.

At times, ground water contributes a substantial amount of nitrogen to streams in the Eastern Iowa Basins Study Unit. In most parts of the Study

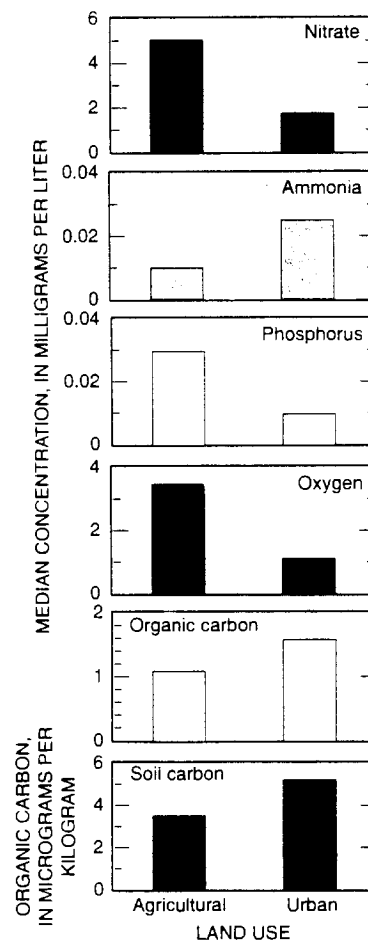

Figure 9. Agricultural and urban land uses contribute nitrogen to shallow alluvial aquifers. Conditions are suitable in urban areas for the formation of ammonia in the organic-enriched aquifers.

Unit, water naturally flows from alluvial aquifers to streams through the streambanks and streambeds. During high base flow in May 1998, nitrate concentrations in samples from 24 of 25 streams in the Eastern Iowa Basins were higher than 10 mg/L. In contrast, nitrate concentrations in these streams ranged from less than 0.05 to 8.3 mg/L during low base flow in August 1997. The high concentrations detected during the spring may be due to the increased ground-water inflow after fertilizer was applied and was readily available for transport.

Shallow tile lines have been installed to remove excess water from the land and to lower the water table in many parts of the Study Unit. These tile lines typically drain water from the upper part of the water table, which generally contains the highest nitrate concentrations to nearby streams. During the summer, the water table may decline below the tile lines due to decreased rainfall and increased evapotranspiration. Tile-line flow and nutrient transport then cease. For example, nitrate concentrations were consistently higher than 10 mg/L in tile-line discharge from April until the end of August when flow in this and other local tile lines ceased (fig. 10). After tile flow ceased, nitrate concentrations in the Iowa River decreased.

When tile flow ceases, streamflow originates from natural ground-water inflow, which traverses deeper and longer flow paths. Water that originates from deep in the alluvial aquifers contains low nitrate concentrations (see previous discussion) due to transformation in the aquifer or

streambed and plant uptake as it passes beneath riparian buffers. These results are similar to those of previous studies (Cambardella and others, 1999; Soenksen, 1996) that documented the importance of tile-line discharge on stream-water quality.

Increased algal growth in late summer and early fall also can contribute to decreased nitrate concentrations in streams (Porter, 2000). Tile-line drainage is an important hydrologic factor that may serve to protect shallow ground water by removing contaminants before they move down into the aquifers; however, tile lines also may enhance the contamination of streams by short circuiting natural processes that remove nitrogen from ground water.

Nutrients in Streams

The concentrations of nutrients in a stream or river are the result of the interaction of human activities and natural factors in the basin. Human activities, agricultural and urban, generally increase the input

of nitrogen and phosphorus into the basin, alter the land surface and drainage patterns (which may affect the amount and timing of rainfall runoff), and alter vegetation on the land and habitat in streams and rivers, resulting in a more rapid flushing of nutrients from the land and downstream in streams and rivers. Natural factors including the amount and timing of rainfall, soil types, and land-surface slope affect the amount of nitrogen and phosphorus washed off fields into nearby streams.

Nitrogen and phosphorus are almost always present in streams and rivers. Nitrate, the most common form of nitrogen in streams and rivers in the Eastern Iowa Basins, was present in more than 98 percent of the samples at concentrations of 0.05 mg/L or greater and was most frequently (80 percent of the samples) present in the range of 1 to 10 mg/L (fig. 11). Nitrate concentrations less than about 0.5 mg/L were generally associated with low streamflow in late summer when nitrogen inputs

Figure 10. Tile lines can contribute substantial amounts of nitrate to streams and rivers. Nitrate concentrations in the Iowa River near Rowan decreased as tile-line discharge ceased.

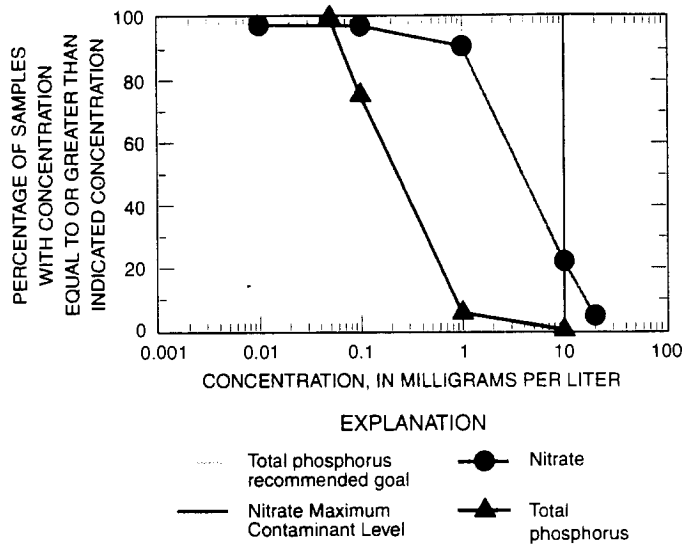

Figure 11. Nitrate concentrations in streams were most often in the range of 1 to 10 mg/L and equaled or exceeded the Maximum Contaminant Level in 22 percent of the samples. In contrast, total phosphorus concentrations equaled or exceeded the 0.1-mg/L goal for minimization of algal growth in 75 percent of the samples.

were low and algal uptake was high. About 22 percent of the samples (fig. 12) contained nitrate concentrations at or above the USEPA's drinking-water standard of 10 mg/L (U.S. Environmental Protection Agency, 1996).

Phosphorus, dissolved in the stream water and attached to sediment particles or organic compounds transported in the stream, was present in all samples. Total phosphorus concentrations exceeded the USEPA goal of 0.1 mg/L (U.S. Environmental Protection Agency, 1986) or less to minimize plant and algal growth about 75 percent of the time. Streams with large total phosphorus concentrations generally contained large suspended-sediment concentrations.

Landform and land use affect nitrogen and phosphorus concentrations. Nitrogen and phosphorus concentrations in streams differed

among landform areas and with land use (fig. 12). Basins of the size where human activities are minimal (background) are not present in eastern Iowa and southern Minnesota. The Wapsipicon River near Tripoli was identified as a reference site, however, because although agricultural land use constitutes more than 90 percent of the basin, substantial areas of riparian forests and wetlands remain. Samples from the reference site generally had the lowest median nutrient concentrations of any stream site studied. Median suspended-sediment concentrations also were the lowest. Biological indicators of water quality at the reference site were better than all other sites in the Study Unit. Extensive floodplain vegetation may decrease direct transport of nutrients from fields to the Wapsipicon River, and extensively wooded banks on

the nonchannelized river may decrease streambank erosion and enhance biological habitat.

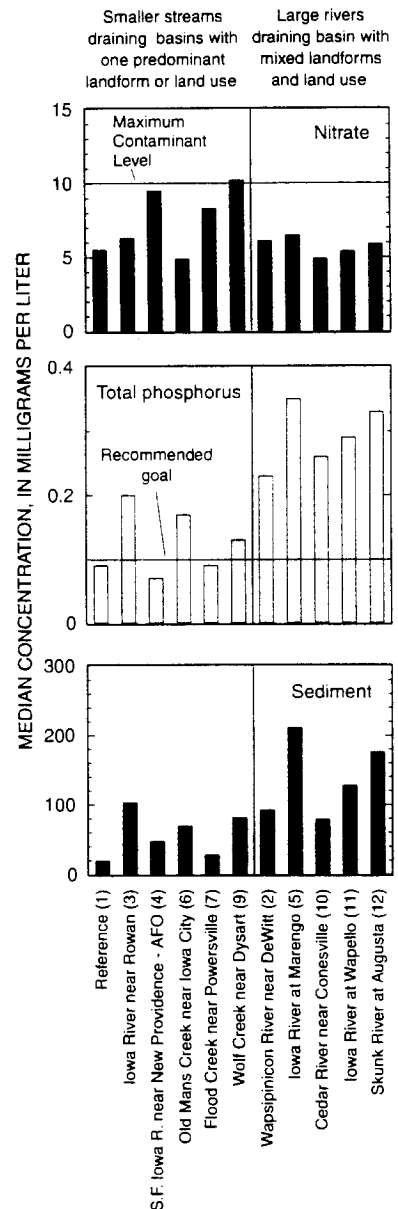

Figure 12. Nitrate concentrations generally were lower in large rivers than in smaller streams. In contrast, total phosphorus concentrations were greater in large rivers than in streams. (Site number in parentheses; see site map in Study Unit Design section. AFO is animal feeding operation.)

Median nitrate concentrations were highest in samples from Wolf Creek, a stream draining an Iowan Surface basin that has more than 80-percent row-crop agriculture, and in samples from the South Fork Iowa River, a stream draining a Des Moines Lobe basin that has concentrated animal-feeding operations (AFO). The median nitrate concentration in samples from Wolf Creek (10.2 mg/L) exceeded the 10-mg/L USEPA MCL. Algal status and biomass in Wolf Creek indicated degraded conditions (from a national perspective), and fish and invertebrate communities were dominated by species tolerant to nutrient and organic enrichment. Wolf Creek flows into the upper end of a reach of the Cedar River that has been listed on the 1998 USEPA Section 303(d) list (Iowa Department of Natural Resources, 2000) as an impaired water body. Wolf Creek may provide substantial amounts of nitrogen that contribute to the degradation of the Cedar River between Waterloo and Cedar Rapids.

Landform features affect phosphorus concentrations. Phosphorus and suspended-sediment concentrations were typically larger in streams that drain the Southern Iowa Drift Plain and the Des Moines Lobe than in other streams. The Southern Iowa Drift Plain typically has steeper slopes than the rest of the Study Unit and contains loess deposits that are easily eroded (Schwarz and Alexander, 1995). Many Des Moines Lobe streams have been extensively channelized; to a great extent, the streambanks and flood plains contain little riparian vegetation, resulting in a greater dominance of phytoplankton than benthic algae and relatively higher rates of stream metabolism that can

influence dissolved-oxygen conditions during base-flow conditions (Porter, 2000).

Intensive row-crop agriculture contributes to greater nitrate concentration. The intensity of row-crop agriculture is partly responsible for the variability of nitrate concentrations in streams. Typically, streams in basins that have a higher percentage of corn and soybeans and less pasture, forest, and CRP (Conservation Reserve Program) acres had higher total nitrogen concentrations (fig. 13). However, large rivers in basins that had a slightly lower percentage of row crops and a slightly larger proportion of urban areas typically had higher total phosphorus concentrations. Large rivers generally contained higher suspended-sediment concentrations than streams, and most large potential point-source phosphorus contributors (large cities) are located on the large rivers.

Increased availability results in greater nutrient concentrations during the spring and early summer. Concentrations of nitrogen and phosphorus varied seasonally in streams in eastern Iowa (fig. 14). Median total dissolved

Figure 13. Streams draining basins that have higher percentages of pasture, grassland, and forests and less land planted in row crops tended to have lower nitrogen concentrations.

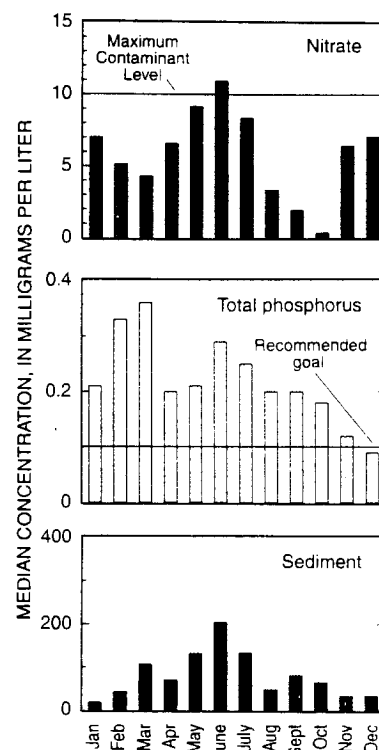

Figure 14. Nitrate concentrations that commonly increase to levels that exceed the Maximum Contaminant Level in June can decrease to levels below detection in October. Total phosphorus concentrations were rarely below the recommended goal for reduction of algal growth.

nitrogen concentrations were highest in June (11.5 mg/L) when nitrogen is transported to streams and rivers by spring and early summer runoff from rainfall. Nitrogen probably originates from that accumulated in the soil following application of chemical fertilizers and manure during the spring and previous fall. Nitrate was the predominant form of nitrogen detected during this period. Total dissolved nitrogen concentrations in streams decreased through the summer as nitrogen was removed from the soil by plant uptake, runoff, and leaching to shallow ground

ANIMAL FEEDING OPERATIONS CONTRIBUTE ADDITIONAL NUTRIENTS TO STREAMS

The median nitrate concentration in samples from the South Fork of the Iowa River (9.5 mg/L) were significantly higher than those in samples from the Iowa River near Rowan (median of 6.3 mg/L), though both streams drain the same landform (Des Moines Lobe) and have similar crop patterns (greater than 80 percent row crops). In addition to row-crop agriculture, the basin of the South Fork Iowa River contains substantially more permitted animal feeding operations (AFO) (29) than the Iowa River Basin upstream from Rowan (8). The density of hogs (fig. 15) in the South Fork basin is more than twice that in the Iowa River Basin (Sorenson and others, 1999). The manure generated from AFOs is commonly applied on fields in substitution for chemical fertilizer. However, in areas where there is dense concentration of AFOs, sufficient land may not always be available to economically dispose of animal wastes, and the potential for overapplication exists. Excess nutrients seep into the ground water and are washed into nearby streams. About 1.8 times more nitrogen and about 2.5 times more phosphorus were transported by the South Fork Iowa River than by the Iowa River (fig. 15). The higher nitrate concentrations and the greater nitrogen and phosphorus yields from the South Fork Iowa River compared to the Iowa River near Rowan may indicate that a reduction in chemical fertilizer application equivalent to the increased manure application has not occurred in the South Fork Basin.

water. Algal and plant growth in the streams during low streamflow in late summer and early fall can result in increased uptake of dissolved nutrients (Porter, 2000). The combination of reduced source loading and instream processing

Figure 15. Large-scale hog production adds to the nitrogen and phosphorus in streams draining basins in the Des Moines Lobe landform. [Hog density data calculated from Iowa Department of Natural Resources (1999) waste-control facility permits.]

results in lowest nitrate concentrations in October. Fall rains, in combination with fertilizer and manure applications, were associated with another rise in nitrogen concentrations beginning in November and peaking in January.

Although nitrate remained the primary form of nitrogen, ammonia and organic nitrogen were more prevalent during the winter.

Runoff from agricultural and urban areas transports substantial amounts of phosphorus to streams, but the timing of peak phosphorus concentrations does not always correspond to peak nitrate concentrations. Phosphorus concentrations peak during periods of high runoff in early spring when substantial amounts of soil are eroded into the streams. The highest median total phosphorus concentrations occurred in February (0.33 mg/L) and March (0.36 mg/L) with a secondary peak in June (0.29 mg/L) (fig. 14). Maximum concentrations corresponded with early seasonal runoff from snowmelt or rainfall. Early summer rains produced runoff that accounted for a secondary peak in total phosphorus concentrations during June.

Transport of nutrients represent an economic loss and a potential environmental threat. The large amounts of nitrogen and phosphorus that are transported from the Study Unit by the Wapsipinicon, Cedar, Iowa, and Skunk Rivers represent an economic loss to farmers and an environmental concern for downstream water.

Nitrogen and phosphorus transported to the Mississippi River increased yearly from 1996 through 1998 (fig. 16). Increased streamflow was a major factor in the increased loads. The estimated mass of nitrogen (load) increased from about 106,000 tons in 1996 to more than 257,000 tons in 1998, and the estimated total phosphorus load increased from 7,500 tons in 1996 to 9,700 tons in 1998.

Figure 16. Increased streamflow from 1996 to 1998 resulted in larger amounts of nitrogen and phosphorus transported from the Study Unit to the Mississippi River.

Transport of nutrients from the Eastern Iowa Basins represents a potential loss in crop yield or the cost of additional fertilizer needed to compensate for that flushed from the fields. Nutrient loads transported from the Eastern Iowa Basins represent an average loss of 17 lb/acre/year of nitrogen and 1.2 lb/acre/year of phosphorus in 1996 and 42 lb/acre/year of nitrogen and 1.6 lb/acre/year of phosphorus in 1998.

Iowa, including the Eastern Iowa Basins, has been identified as a major source of nutrients (Goolsby and others, 1999) that contribute to eutrophication and hypoxia in the Gulf of Mexico (Rabalais, 1996). Alexander and others (2000) estimated that more than 90 percent of the nitrogen reaching the Mississippi River from the Eastern Iowa Basins is transported to the Gulf of Mexico.

Pesticides in Ground Water and Streams

Pesticides (herbicides and insecticides) are used extensively in agricultural and urban settings in the Eastern Iowa Basins to control unwanted vegetation and insects. Triazine (atrazine and cyanazine) and chloroacetanilide (alachlor and metolachlor) herbicides were the most extensively used pesticides during 1996–98. However, in 1994, acetochlor, a herbicide conditionally registered by the USEPA, began to replace alachlor. In 1998, acetochlor use exceeded all other herbicides in Iowa (U.S. Department of Agriculture, 1999). Other classes of low-use herbicides (for example, sulfonylurea and imidazolinone herbicides) also had become more popular. Genetically altered corn and soybeans that are resistant to glyphosate and genetically

altered “Bt corn” that contains the genes allowing corn to produce compounds toxic to damaging insects also were beginning to change pesticide-use patterns. Although urban pesticide-use data were not available, herbicides commonly are used on lawns, golf courses, and road rights-of-way for weed control, and a wide range of insecticides are used for insect control.

Transport of pesticides from the site of application is dependent on the persistence of the compound, its solubility in water, and its tendency to adsorb to soil particles. Pesticide compounds break down at various rates due to biological and chemical processes. Pesticides can be broken down in the soil by bacteria and fungi and nonaffected plants and in streams by microorganisms, algae, and aquatic plants. The older organochlorine pesticides, most of which have been banned (for example, DDT) strongly attach to soil particles and are transported to streams primarily with sediment. In contrast, many herbicides commonly used in the 1990’s (for example, atrazine) are relatively soluble and are transported almost exclusively dissolved in water. Water is the primary mechanism by which most pesticides and their breakdown products (degradates) are leached to ground water. Water transports pesticides and their degradates to streams by overland flow, tile drains, and ground-water inflow.

PESTICIDE CONCENTRATIONS RANK HIGHER IN GROUND WATER THAN IN STREAMS AND RIVERS

Herbicide and insecticide concentrations in streams do not rank among the highest 25th percentile nationally (fig. 17) even though use in the Eastern Iowa Basins is high. Herbicide concentrations rank in the middle 50 percent nationally and in the middle one-third in the Corn Belt. Insecticide concentrations are among the lowest in the Corn Belt and Nation. Reasons for lower pesticide concentrations in the Eastern Iowa Basins compared to other parts of the Nation are not entirely clear but may include these: (1) although pesticide use is high in Eastern Iowa Basins it may be higher in other corn, cotton, and other crop-growing areas of the Nation and (2) soils in Eastern Iowa Basins may be relatively conducive to leaching to ground water or conditions are favorable for breakdown of the pesticides.

In contrast, herbicide and insecticide concentrations in the alluvial aquifers in Eastern Iowa Basins are among the highest 25th percentile in the Corn Belt and Nation (fig. 17). Water in these aquifers has infiltrated within the last 20 years when the use of the analyzed pesticides was the greatest. Because water from the Silurian-Devonian and Upper Carbonate aquifers is generally deeper and has infiltrated before pesticides were commonly used, pesticide concentrations from these aquifers generally were among the lowest in the Nation.

Pesticides in Ground Water

Herbicides are prevalent in the shallow alluvial aquifers. Herbicides are prevalent in the shallow alluvial aquifers but are not common in the deeper Silurian-Devonian and Upper Carbonate bedrock aquifers in the Eastern Iowa Basins. Atrazine and metolachlor were the most frequently detected herbicides in the alluvial aquifers and the Silurian-Devonian and Upper Carbonate aquifers. Atrazine was detected in more than 50 percent of the alluvial aquifer samples

and in 18 percent of the Silurian-Devonian and Upper Carbonate aquifer samples. Metolachlor was detected in 20 percent of the alluvial samples and in 12 percent of the Silurian-Devonian and Upper Carbonate samples. Acetochlor was detected in slightly less than 2 percent of the alluvial aquifer samples but at concentrations less than 0.2 µg/L, which is the concentration of concern for conditional registration. Acetochlor was not detected in samples from the Silurian-Devonian and Upper Carbonate aquifers.

Pesticide degradates commonly constitute the majority of the pesticide mass analyzed. Many of the detected pesticides and pesticide degradates have no established drinking-water standard or aquatic-life criteria, and the potential for these compounds to affect humans or aquatic organisms is unknown. Alachlor ethanesulfonic acid (ESA), atrazine, and metolachlor ESA were detected in more than 30 percent of samples from shallow alluvial (fig. 18) and deep bedrock aquifers.

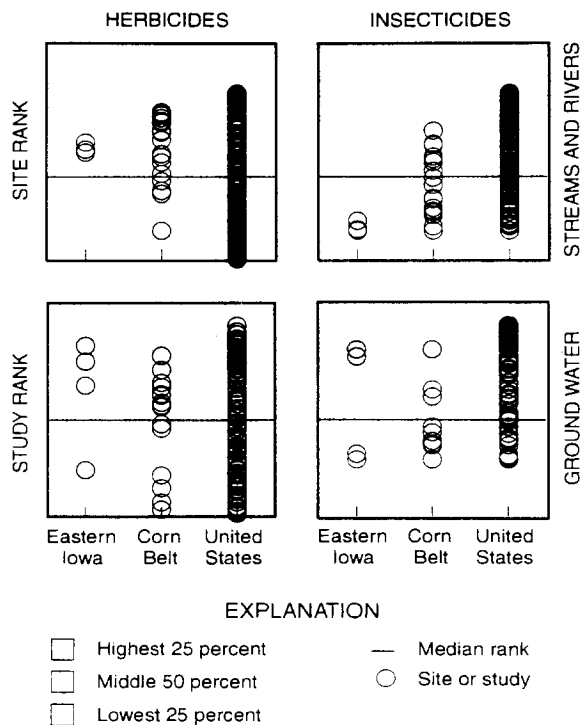

Figure 17. Although pesticides are heavily used, concentrations in the Eastern Iowa Basins streams are not among the highest in the Nation or the Corn Belt. The vulnerability of the alluvial aquifers to contamination is seen in pesticide concentrations in ground-water samples that are among the highest in the Nation.

Figure 18. The pesticide compounds present in streams and rivers and the alluvial aquifers, which are hydraulically connected, were similar but were detected less frequently in ground water. Agricultural herbicides and their degradates were most frequently detected.

Agricultural and urban applications have resulted in sporadic low levels of insecticide contamination in the alluvial aquifers. Chlorpyrifos, an insecticide that was recently reevaluated by the USEPA for safety as part of the Food Quality Protection Act (U.S. Environmental Protection Agency, 2000b), was detected in about 7 percent of the urban land-use samples and about 13 percent of the agricultural land-use samples. The maximum

concentration in urban areas (0.005 $\mu\text{g/L}$) was about four times lower than the maximum concentration in agricultural areas (0.021 $\mu\text{g/L}$). Malathion, an insecticide also currently (2000) under USEPA review, was detected in one sample from an urban land-use well.

Pesticides do not occur everywhere in the Study Unit, and when they do occur, concentrations can be highly variable. This variability in occurrence and concentration of

various pesticide compounds in ground water is probably associated with several factors including the presence of overlying protective layers and land-use practices.

Clay and shale materials hinder movement of pesticides to aquifers. Clay and shale materials hinder movement of pesticides by slowing the movement of water containing pesticides to underlying aquifers. In some instances, water that has infiltrated the ground during the last 40 years when many of the studied compounds were used has not yet reached the deeper parts of the alluvial and bedrock aquifers. The age of the ground water was significantly younger and pesticide concentrations were significantly higher in samples from areas where an overlying bedrock confining unit was absent or where less than 100 feet of unconsolidated deposits overlies the Silurian-Devonian and Upper Carbonate aquifers. Water is most affected by surficial contamination near the top of alluvial aquifers where an overlying clay layer is thin or absent.

Triazine pesticides and degradate concentrations were significantly higher in samples from wells in areas with a thin clay layer above the screened interval than those from wells in areas with thick overlying clay layers. Concentrations decreased with increasing depth in the alluvial aquifers. As with nitrate, these two results indicate that longer and slower flow paths (deeper sample and thicker clay layer) increase opportunities for sorption, degradation, and dispersion of pesticides and may contribute to decreases in pesticide concentrations with depth.

WHAT IS A PESTICIDE DEGRADATE?

Pesticides released into the environment break down into intermediate compounds and, over time, into their constituent molecules (fig. 19). The intermediate compounds are pesticide degradates that may be short-lived or persist for years. The occurrence of atrazine degradates in ground water and surface water is relatively well known, but the occurrence of alachlor, acetochlor, and metolachlor degradates in Iowa have only recently been investigated (Kalkhoff and others, 1998; Kolpin and others, 1997). Little is known about their possible effects on human health and aquatic life (Heydens and others, 2000; Stamper and Tuovinen, 1998). The occurrence and distribution of several common degradates of atrazine, alachlor, acetochlor, cyanazine, and metolachlor were documented in the Eastern Iowa Basins to develop a better understanding of the fate and transport of these compounds and their possible effect on the environment. These compounds generally are the products of the first step in the breakdown of the most commonly used herbicides. Breakdown occurs in the soil but also can take place in plants and in ground water and streams.

Modification of a side carbon chain (atrazine degradation) or the replacement of the halogen (chlorine) with a sulfonic acid or carboxylic acid (acetochlor, alachlor, metolachlor degradation) is commonly the first step in the breakdown of these herbicides. This first step represents a small molecular change that may affect the toxicity, solubility, and persistence of the resulting degradate.

Figure 19. Small molecular changes (shown in red) occur during the initial breakdown of atrazine and metolachlor.

Pesticides are present in alluvial aquifers both in urban and agricultural areas. Pesticides were prevalent in the shallow alluvial aquifers both in agricultural and urban areas (fig. 20). Pesticides were detected in 84 percent of the samples from agricultural areas and in 70 percent of the samples from urban areas. Atrazine and metolachlor were the most frequently detected pesticides in samples from agricultural areas; atrazine and prometon were the most frequently detected pesticides in samples from urban areas. None of the concentrations exceeded USEPA MCLs, but many pesticides do not have MCLs.

Samples from alluvial aquifers in agricultural areas contained an average total pesticide concentration (1.3 µg/L) that was more than seven times the concentration in samples from urban wells (0.17 µg/L). Although total pesticide concentrations were higher in samples from agricultural areas, more compounds were detected in samples from urban areas. Seventeen compounds were detected in samples from urban areas compared to 12 compounds detected in samples from agricultural areas. Herbicide degradates were detected in 94 percent of samples from agricultural areas and 53 percent of the samples from urban areas. Alachlor ESA, metolachlor ESA, and metolachlor oxanilic acid (OA) were the most frequently detected degradates in samples from both agricultural and urban areas; deethylatrazine and deisopropylatrazine were detected frequently in agricultural areas.

Figure 20. Pesticides were frequently detected in the alluvial aquifers in both agricultural and urban areas. Although the total concentrations of pesticides were higher in agricultural areas than in urban areas, more compounds were detected in urban than in agricultural areas.

Pesticides in Streams

The most commonly used herbicides were the most frequently detected. Atrazine and metolachlor, the two most commonly used herbicides in Iowa for row-crop agriculture during 1996–98, were detected in all stream samples (fig. 18). Acetochlor, alachlor, and cyanazine were detected in more than 70 percent of the samples. Most atrazine concentrations (76 percent) exceeded 0.1 µg/L with almost 60 percent of the samples in the 0.1 to 1.0 µg/L range (fig. 21). About 10 percent of the samples exceeded the atrazine MCL level of 3.0 µg/L. Almost half of the samples had metolachlor concentrations in the range from 0.1 to 1.0 µg/L (fig. 21). Other less frequently detected pesticides were carbofuran, 2,4-D, dicamba, EPTC, metribuzin, and trifluralin; these were applied in Iowa at a rate of only 0.6 to 30 percent of the amount applied for atrazine (Sands and Holden, 1996).

Acetochlor, a conditionally registered herbicide that is intended to replace a number of other commonly used herbicides, was frequently detected but most times (75 percent) at concentrations less than 0.1 µg/L. Acetochlor concentrations did not exceed the 2.0-µg/L annual mean concentration registration requirement at any site but did exceed this level in about 3 percent of the individual samples. The maximum concentration (10.6 µg/L) measured during the study exceeded the level that would trigger requirements for biweekly sampling for water-supply systems (U.S. Environmental Protection Agency, 1994).

Few nonagricultural herbicide compounds were detected. Many pesticides are used both in agricultural and urban settings, but only three herbicides used almost exclusively in non-row-crop agriculture and urban settings (prometon, tebuthiuron, and triclopyr) were present in streams in eastern Iowa and southern Minnesota from 1996 through 1998 (fig. 18). Prometon, a

herbicide used for weed control around buildings, fence rows, and under asphalt, was present at very low concentrations (less than 0.1 µg/L) in more than 80 percent of the samples. Prometon is extremely persistent (half-life of hundreds to thousands of days), which may explain the relatively high detection rate relative to its low use. Tebuthiuron, used on road rights-of-way and industrial sites, was detected in 7 percent of the samples. Triclopyr, used on road rights-of-way, industrial sites, and turf grass, was detected in 1 percent of the samples.

Insecticides were detected mainly during the summer. A number of insecticides that have been identified as posing a high risk to aquatic invertebrates were detected in streams from May through September, the months when most application normally occurs (fig. 22). Carbofuran was the most frequently detected insecticide (16 percent of all samples). Although detected in less than 20 percent of all samples, carbofu-

Figure 21. Atrazine and metolachlor were present in more than 50 percent of the samples from rivers and streams at concentrations between 0.1 and 1.0 µg/L. In contrast, acetochlor was present in 76 percent of the samples at concentrations less than 0.1 µg/L.

Figure 22. Insecticides were prevalent in streams only during the late spring and summer. Carbofuran and chlorpyrifos were the most frequently detected insecticides.

ran was detected in 68 percent of the samples collected in June. When present, carbofuran concentrations generally were less than 0.80 µg/L. Chlorpyrifos was detected in about 7 percent of the samples. As with the other insecticides, chlorpyrifos was detected most frequently in June (about 30 percent of the samples). The highest concentration was 0.06 µg/L. Malathion was detected in only three samples in spring and early summer at concentrations that ranged from 0.023 to 0.078 µg/L. Insecticides were detected more frequently in streams than in shallow ground water in the alluvial aquifers. Lower use relative to the herbicides, short half-life, and application during periods of reduced runoff may account for the overall low detection rate and low concentrations of insecticides in rivers and streams.

Pesticide degradates constitute the majority of the pesticide compounds in streams. The pesticide degradate compounds were some of the most frequently detected pesticide compounds in streams (fig. 18) and on average constituted the majority of the pesticide mass in water samples. Acetochlor ESA, alachlor ESA,

metolachlor ESA, and metolachlor OA were detected in more than 75 percent of the samples. The degradates were detected much more frequently than their parent compounds with the exception of atrazine and two of its degradates—deethylatrazine and deisopropylatrazine (fig. 18).

On average, approximately 83 percent of the total pesticide mass (parent compounds and degradates) can be accounted for by 10 common degradates of acetochlor, alachlor, atrazine, cyanazine, and metolachlor. Concentrations of acetochlor ESA, alachlor ESA, and metolachlor ESA commonly were more than 10 times higher than their parent compounds. Although herbicide degradates frequently occur in substantial concentrations in streams, only limited research has been conducted on the acute and chronic human and environmental effects of these compounds (Heydens and others, 2000).

The occurrence of degradates and the ratio of degradate to parent compound were substantially different for the triazine (atrazine and cyanazine) than the chloroacetanilide (acetochlor, alachlor, and metolachlor) compounds. Concentrations of the triazine degradates

tended to follow the pattern of the parent compounds—highest concentrations during the early summer followed by decreasing concentrations during the late summer and fall (fig. 23). However, concentrations of the triazine degradates were lower than their parent compounds except in the fall and winter when they were slightly higher. In contrast, the ESA and OA degradates of alachlor, acetochlor, and metolachlor were present in higher concentrations than their parent compounds throughout the year.

Occurrence of pesticides are related to landform type. The triazine herbicides—atrazine and cyanazine—and their degradates were present in significantly higher concentrations in streams draining soils dominated by windblown

Figure 23. Pesticides and their degradates are readily available for transport to streams and rivers in late spring and early summer after application. A common metolachlor degradate persists at higher concentrations than a common atrazine degradate throughout the year.

Multiple Pesticide Compounds Occur More Frequently in Streams Than in Ground Water

The use of a wide variety of pesticides in the Eastern Iowa Basins is reflected by the presence of multiple compounds in streams and ground water. Two or more compounds were detected in every sample, and five or more compounds were detected in

Figure 24. More than one pesticide compound was always present and more than five compounds were detected in about 80 percent of the stream samples. Multiple degradates were more common than multiple parent compounds in ground water.

more than 80 percent of the stream samples (fig. 24). As many as 16 pesticide compounds were detected in a single stream sample. In contrast, 2 or more compounds were detected in only 17 percent and 5 or more pesticides in less than 2 percent of the ground-water samples.

Multiple degradates were much more frequently detected than multiple parent compounds in ground water. Many pesticide compounds attach to soil particles and are not readily leached to the ground water. However, the pesticide degradates sampled are generally more water soluble and once formed in the soil may move readily to the shallow ground water. Also, several degradates may form from each pesticide, accounting for additional degradate compounds.

The importance of multiple pesticide compounds for human and environmental health is currently unclear. Most toxicity assessments are based on results from a single contaminant.

loess (Southern Iowa Drift Plains) than in streams draining till soils (Des Moines Lobe or the Iowan Surface). Because of differences in soil properties, triazine pesticide-use rates are apparently less in areas dominated by till soils such as the Des Moines Lobe and Iowan Surface landforms (Stoltenberg and Pope, 1990). The high pH of the till soils (increased calcium carbonate content) results in more triazine

herbicides available for plants and greater persistence. Less triazine herbicides have been applied to till soils (particularly in the Des Moines Lobe) because the effects of triazine herbicides can “carry over” to soybeans planted after corn. Results from a regional low-flow synoptic study (Sorenson and others, 1999) indicate that the percentage of blue-green algae in stream periphyton communities

increases with total (parent compounds plus degradates) triazine herbicide concentrations (Porter and others, 2001).

Runoff from rains soon after application washes large quantities of pesticides into streams.

Concentrations of pesticides and their degradates were highest in the late spring and early summer when intense rains occurred soon after application (fig. 23). Pesticides and their degradates are transported from the Eastern Iowa Basins in largest quantities during the late spring and early summer. Pesticide degradates make up the largest part of the pesticide load transported to the Mississippi River. Pesticide data from the Iowa River at Wapello, Iowa, illustrate that the monthly degradate load was higher than the loads of the parent compounds throughout the year (fig. 25) but were particularly dominant during the spring and early summer and late fall and winter periods. Typically, the loads for all compounds were largest during the spring and early summer (March through June) when significant runoff events transported pesticide compounds to streams. In the fall

Figure 25. The most frequently used pesticides begin breaking down before being transported from the Study Unit to the Mississippi River. More than 80 percent of the yearly pesticide load in the Iowa River at Wapello is pesticide degradates. Of the yearly load, about 57 percent was transported from the Study Unit during May, June, and July.

and winter months, however, the pesticide degradates accounted for nearly all of the pesticide loads (fig. 25). Parent compounds accounted for only 3 percent (December) to 27 percent (May) of the total pesticide compounds transported from the Iowa River. Much of the water and dissolved pesticide compounds originated from ground-water inflow during the relatively dry late fall and winter months. The presence of relatively high concentrations of alachlor and metolachlor degradates in the fall and winter, several months after pesticide application when parent compounds have all but disappeared, indicates that these compounds are relatively stable.

Other Organic Compounds

The gasoline additive MTBE was the most commonly detected volatile organic compound in ground water. Shallow alluvial ground water in urban areas is susceptible to contamination from organic compounds resulting from activities such as transportation, manufacturing, and service industries. Volatile organic compounds (VOCs) were detected in 40 percent of alluvial samples from urban areas and 10 percent of the samples from agricultural areas. Methyl *tert*-butyl ether was the most frequently detected VOC and was present in 23 percent of samples from urban areas (fig. 26). Although most detected concentra-

tions were low, MTBE concentrations from two urban monitoring wells were at levels of potential concern for human health (USEPA drinking-water advisory of 20 to 40 µg/L). MTBE was commonly found with other gasoline compounds (benzene, ethylbenzene, toluene, and xylene), indicating that contamination likely originated from leaking fuel storage tanks and possibly from surface spills. MTBE was not detected in agricultural areas. Solvents were detected in less than 15 percent of the samples, and other VOCs were detected in less than 10 percent of the samples.

Water from deeper in the alluvial aquifers and in the deeper Silurian-Devonian and Upper Carbonate

MTBE DETECTION RATES ARE SIMILAR TO THE AVERAGE DETECTION RATE IN THE NATION

Methyl *tert*-butyl ether (MTBE), a compound added to gasoline to enhance the octane content or to ensure cleaner burning with reduced carbon monoxide emissions, was detected in the alluvial aquifers underlying towns and cities in the Eastern Iowa Basins at a rate similar to the average detection rate in the United States (Squillace and others, 1999). However, detection rates (fig. 26) were not as great as in shallow, vulnerable aquifers in Denver, Colorado (Bruce and McMahon, 1996), and other areas where MTBE has been used extensively to reduce carbon monoxide emissions. MTBE also has been detected in areas where MTBE is used only to enhance the octane content (Zorgorski and others, 1997). Although ethanol is commonly added to gasoline in Iowa, MTBE has also been added to increase the octane level. Legislatively mandated sampling of soil and ground water from leaking underground storage tank (LUST) sites in Iowa verified that MTBE is prevalent in gasoline-contaminated areas (Iowa Department of Natural Resources, 2000b). MTBE was present in ground water at about 59 percent of the 523 LUST sites in 248 Iowa towns and cities.

The effects of MTBE on human health are not fully understood, but MTBE has been linked to headaches, nausea, dizziness, and breathing difficulties (Melnick and others, 1997). Experimental studies indicate that MTBE is carcinogenic in rats and mice (Melnick and others, 1997).

Figure 26. The presence of the gasoline additive MTBE in alluvial aquifers in urban areas reflects the common occurrence of MTBE at gasoline-contaminated sites in Iowa.

BIOLOGICAL COMMUNITIES IN STREAMS CONSIST OF ORGANISMS THAT ARE MODERATELY TO HIGHLY TOLERANT OF ENVIRONMENTAL DEGRADATION

Biological communities (algae, fish, and invertebrates) in streams in the Eastern Iowa Basins generally rank in the middle 50th to highest 25th percentile most tolerant of environmental degradation nationally (fig. 27). Commonly, biological communities in streams change in response to environmental changes (degradation). Degradation can result from a variety of factors that modify habitat or other environmental features such as land use, water chemistry, stream-flow, and others. The biological community may change from few individuals of many species to a community of many individuals of a few tolerant species.

Algal status focuses on the changes in the percentage of certain algae in response to increasing siltation and seems to correlate relatively well with higher nutrient concentrations in many regions. Invertebrate status is the average of 11 invertebrate (primarily insects, worms, crayfish, and clams) metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. Fish status is the sum of scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that change (increase) in association with water-quality degradation. For all indicators, higher values indicate a more degraded stream site.

Community differences occur among streams in the Eastern Iowa Basins, but these differences are small in relation to differences across the Nation. From a national perspective, algal status was moderate to high in all Study Unit streams and rivers and corresponds with high concentrations of dissolved and total nutrients. With one exception (Wapsipinicon River near DeWitt), invertebrate status tended to rank in the middle to lowest 25th percentile, indicating a moderate degree of degradation in relation to the rest of the Nation. Because of nutrient enrichment and subsequent abundance of algae and organic material, an abundant food supply is present to support a diverse invertebrate community. From a local and regional perspective, invertebrate status indicated greater degradation in large rivers than small streams. However, lower status in the Skunk River may be associated more with better habitat at that site than any quantitative differences in water chemistry among other large rivers. Fish communities tended to be ranked highest (most degraded) to moderate when compared nationally. Based on the presence of more species sensitive to environmental stress, the fish population at Wapsipinicon River near DeWitt was minimally affected by environmental degradation in relation to other sites nationally.

- Lowest 25 percent nationally

National network represents 140 sites in the NAWQA national basic fixed-site network that have algal, invertebrate (primarily insects, worms, crayfish, clams), and fish data

Figure 27. Status of biological communities—comparison of Eastern Iowa Basins sites to selected national network sites.

bedrock aquifers used for rural domestic supply rarely contained detectable concentrations of VOCs, even though gasoline is commonly stored and solvents are at times used in the vicinity of these wells.

Pesticides banned or restricted in the 1970s and 1980s are still present in fish tissue. Although no longer in use, residue from organochlorine insecticides (chlordane, DDT, dieldrin, and heptachlor epoxide) is still found in fish-tissue samples collected from eastern Iowa streams (Roberts, 1997) but not at levels of concern for human health. Concentrations were relatively higher in agricultural than urban streams, and fish from the Wapsipinicon River Basin contained lower concentrations of contaminants than fish from the Cedar or Iowa River Basins. Although aldrin, an organochlorine pesticide, has been banned since the 1970s, its degradate, dieldrin, was present in five stream samples during or immediately following spring runoff. Dieldrin was present in tissue samples collected from carp at 15 of 16 sites in eastern Iowa, and concentrations in fish seem to be associated with agricultural settings (Roberts, 1997). Concentrations that peaked in sediment deposited in Coralville Reservoir during the 1993 flood indicate that dieldrin is still transported in rivers during high flow (Kalkhoff and Van Metre, 1997). In contrast to the apparent agricultural source of dieldrin, the occurrence and concentration of PCBs (polychlorinated biphenyls) in fish tissue indicate an urban source for this contaminant (Roberts, 1997).

Biological Communities and Stream Habitat

The quality of water entering from runoff and ground water inflow is an important factor that influences the community structure of fish, invertebrates, and algae that live in the rivers and streams of the Eastern Iowa Basins. Stream habitat, the physical conditions in and along streams and rivers, also influences the occurrence and distribution of aquatic organisms. Water-quality degradation and habitat alteration resulting from agricultural and urban activities can adversely affect aquatic communities.

In general, degradation results in the replacement of native species with those that are more tolerant of nutrient and organic enrichment. There also tends to be a reduction in numbers of sensitive species, increases in abundance and dominance of tolerant species, and decreases in the diversity and evenness of biological communities that are typically considered an indicator of environmental stress.

Biological metrics that contain measures of the composition, abundance, function, and tolerance of species to environmental stress are commonly used to evaluate aquatic communities in relation to water quality and habitat conditions.

Fish populations are related to stream size and water-quality conditions. During 1996–98, 67 fish species representing 15 families were collected in six streams and six rivers in the Eastern Iowa Basins (Sullivan, 2000). The species and trophic composition, as well as the abundance and condition of fish communities, varied between the smaller streams and large river sites in the Eastern

Iowa Basins. Measures of fish-community status, tolerance, structure, and index of biotic integrity (IBI) indicated that fish communities also differed among land uses and landforms in the basin (fig. 28). Habitat and water-quality data indicate that differences in species composition between rivers and streams are probably due to more than just stream size. Although differences in stream size and associated habitat differences favor the occurrence of different species, relatively higher concentrations of suspended sediment and phosphorus in large rivers may contribute to habitat degradation and eutrophication that may explain the relatively lower IBI scores at large river sites (Sullivan, 2000).

The two highest IBI-rated river sites were the Wapsipinicon River near DeWitt and the Cedar River at Gilbertville, an integrator site for

Figure 28. Healthy fish populations were present in one of the least affected (reference) and one of the most affected (animal feeding operations) streams in the study area. Factors other than water quality (stream habitat) also have an important effect on fish populations. (Site number in parentheses; see site map in “Study Unit Design” Section.)

the upper Cedar River watershed River sites with the lowest IBI scores include the Skunk River at Augusta and three sites in the Iowa River Basin: Iowa River at Marengo, Old Mans Creek near Iowa City, and the most downstream integrator site (Iowa River at Wapello).

Agriculture and subsequent organic enrichment of the streams have likely reduced habitat, cover, and water-quality requirements for the maintenance of diverse fish populations and communities. However, the small number of fish species in Flood Creek (fig. 27) may be reflective of the karst hydrology in the basin; extended reaches of Flood Creek may be dry during low-flow conditions or periods of drought, limiting fish communities to juvenile fish or those with rapid recolonization rates.

Macroinvertebrate communities in the Eastern Iowa Basins reflect cumulative effects of both land use and downstream succession—the natural sequence of communities from headwater streams to large rivers (Vannote and others, 1980). More than 250 benthic invertebrate taxa were found in collections from submerged woody debris at 12 Basic Fixed Sites (see Glossary). Aquatic insects, including mayflies, net-spinning caddisflies, and midges, accounted for more than one-half of the organisms collected. The abundance of highly tolerant midges (Chironomidae) and worms (Oligochaeta), as well as collector-filterers was

higher in large rivers, whereas the abundance of less-tolerant mayflies, stoneflies, and caddisflies (EPT taxa; see Glossary) was relatively larger in small tributary streams (Brigham and Sadorf, 2001). However, most invertebrate taxa in eastern Iowa streams and rivers are considered to be tolerant of nutrient and organic enrichment (Hilsenhoff, 1987). Stream velocity, rates of stream respiration, minimum dissolved oxygen, wooded-riparian zones, and the composition and abundance of periphyton were the primary factors associated with invertebrate community structure (M.A. Harris, U.S. Geological Survey, written commun., 2000).

In general, invertebrate diversity was lower in unshaded streams with silt, sand, or gravel bottoms (for example, Iowa River near Rowan and Old Mans Creek) than in shaded streams with bedrock or large rocks (for example, Flood Creek and Wapsipinicon River near Tripoli). Despite similarities in agricultural land-use intensity in the Midwestern Corn Belt, invertebrate communities reveal substantial differences in the quality of streams and rivers, corresponding to physical (modifications of stream channels and riparian zones) and hydrologic (rainfall-runoff and ground-water relations) differences among basins (M.A. Harris, U.S. Geological Survey, written commun., 2000).

Algal communities are dominated by nutrient- and sediment-tolerant taxa. More than 330 algal species were found in periphyton

collections from submerged woody debris. Algal communities were dominated by taxa that are tolerant to nutrients and other agricultural contaminants such as herbicides and sediment.

Relative differences are seen in algal status (an indicator of nutrient and sediment enrichment) and biomass among sites from a regional and local perspective. For example, algal biomass (the amount of attached algae) was relatively higher in Old Mans Creek, Flood Creek, and the Cedar River at Gilbertville than other sites. Within the Eastern Iowa Basins, algal status was relatively better in the Wapsipinicon River near Tripoli (the reference site) and in the Cedar River near Gilbertville and Conesville.

During low-flow conditions in August 1997, shaded streams that drain permeable soils (for example, the upper Cedar and Wapsipinicon River Basins) were dominated by periphyton taxa (diatoms, red algae, and green algae) that are a good food source for invertebrates and fish. In contrast, channelized streams and rivers with poor riparian shading, impermeable soils, and slow velocity were dominated by phytoplankton taxa (notably blue-green algae) that are avoided as food sources and contribute to organic enrichment, higher rates of stream respiration, and lower dissolved oxygen concentrations during the night (Sorenson and others, 1999; Porter, 2000).

RIPARIAN BUFFER ZONES INFLUENCE THE QUALITY OF MIDWESTERN STREAMS AND RIVERS

Despite similar land use throughout the Corn Belt region of the Midwest, streams flowing through cropland differ considerably in their ecological characteristics, in part because of differences in riparian buffer zones (see text box). This conclusion is based on an investigation of 70 streams and rivers within three NAWQA Study Units in the upper Midwest during August 1997 (fig. 29; Sorenson and others, 1999; Porter and others, 2001). Specifically, increases in tree cover in buffer zones were associated with aquatic biological communities indicative of good stream quality, reduced nuisance algal growths, and maintenance of sufficient dissolved oxygen concentrations to support diverse communities of aquatic organisms. For example, the number of aquatic insects indicative of good stream quality tended to increase with increases in percentage of tree cover, especially in sites where streamflow and dissolved oxygen conditions were favorable. Fish communities, sampled at 24 sites in the UMIS Study Unit, also indicated better overall conditions in streams with wooded riparian zones than those with more open canopy (Stauffer and others, 2000).

Figure 29. The influence of riparian buffer zones on the quality of 70 Midwest streams and rivers was evaluated in the Upper Mississippi River (UMIS), Eastern Iowa (EIWA), and Lower Illinois River Basins (LIRB).

Streams with less tree cover, and thus less shading, contained relatively large growths of phytoplankton (algae suspended in the water) at levels considered indicative of eutrophication (Porter, 2000). Organic enrichment

resulting from excessive algal production in some Midwestern streams may reduce dissolved oxygen concentrations and be detrimental to other requirements of aquatic organisms.

Shading from tree cover in riparian buffer zones may influence nutrient concentrations indirectly by reducing the growth of phytoplankton. In streams where phytoplankton were abundant (often where buffer zones were thin or lacking), dissolved nitrate concentrations were significantly lower (fig. 30; Porter, 2000). The lower nutrient concentrations may result from uptake by the abundant phytoplankton. Thus, assessments of eutrophication would benefit from consideration of biological communities and the riparian zone, rather than being based solely on nutrient concentrations in the water.

Figure 30. Dissolved nutrient concentrations decreased in eutrophic streams with excessive algal productivity. Rates of nutrient uptake by the algae can exceed rates at which nutrients are transported by streams during low-flow conditions.

Digital images derived from USGS topographic maps were used to estimate the percentage of trees in a riparian buffer zone (a 100-meter width on each side of the stream) for 2- to 3-mile segments upstream from each sampling site, supplemented by vegetation surveys at the sampling site (Sorenson and others, 1999).

Resource agencies, including the U.S. Department of Agriculture, encourage maintenance of strips of trees or grass between cropland and streams as a best management practice. These "riparian buffer zones" are thought to intercept runoff of sediment and chemicals from fields, promote bank stability, and provide shading and habitat for aquatic life (Osborne and Kovacic, 1993). Riparian buffer zones should be considered along with other important factors that affect chemical and biological indicators of stream quality, such as soil drainage properties and stream hydrology (Porter and others, 2001).

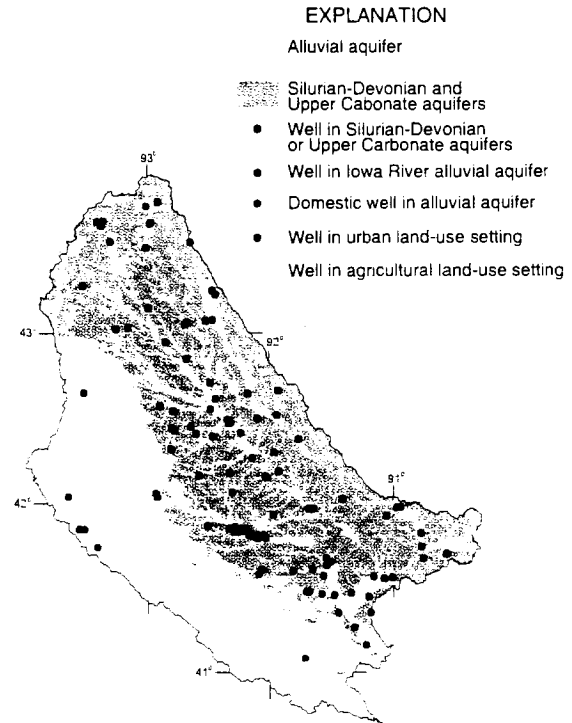

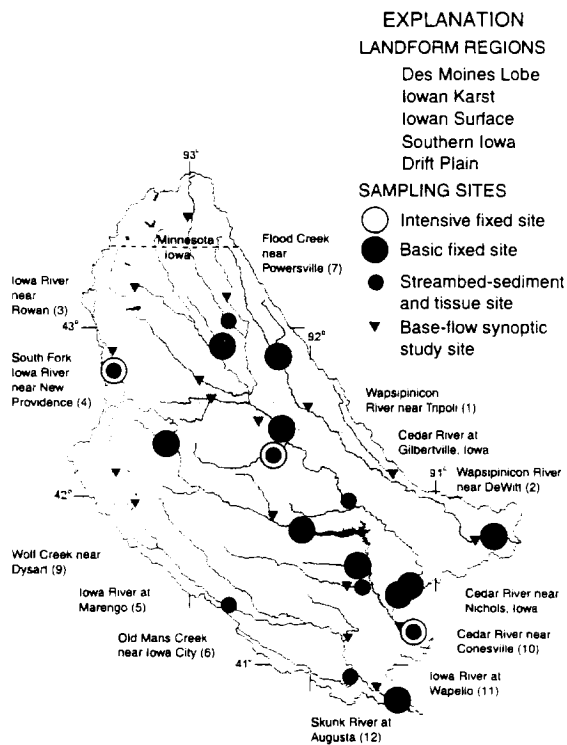

STUDY UNIT DESIGN

The objective of the Eastern Iowa Basins NAWQA study was to assess the water-quality conditions in streams and ground water in the Study Unit. The study design is based on a nationally consistent structure that incorporates an interdisciplinary approach (Gilliom and others, 1995). Stream-water quality was assessed using three interrelated components: stream chemistry, streambed-sediment chemistry, and stream ecology. Ground-water quality of the alluvial aquifers was selected for assessment because these aquifers are the major source of water for municipal and domestic supplies and they provide flow to streams. Water quality in the Silurian-Devonian and Upper Carbonate aquifers also was investigated.

Stream Chemistry

The Basic Fixed Site sampling network was designed to characterize the effects of physiographic differences on water quality in the primarily agricultural Study Unit. Water-chemistry, bed-sediment, and reservoir-core data were collected. Sites were selected on large rivers and smaller streams. Fixed sites on large rivers were located near the mouth of the four major rivers to characterize the integrated effects of differing land use and environmental setting on stream quality. Two additional large river sites were chosen to assess the upper part of the Cedar River and the Iowa River, before it flows into Coralville Reservoir. Fixed sites on streams were selected to characterize each of the physiographic areas. A reference site was selected on a watershed that retains a large amount of bottomland wetlands. Another site was selected to assess the effects of concentrated animal feeding operations on stream quality. A subset of the Basic Fixed Site network was intensively sampled (weekly to

biweekly) through the spring and summer of 1997. Two synoptic studies were conducted during base-flow conditions (high and low base flow) to improve the spatial resolution and to better evaluate the effects of soil type and riparian buffers on stream-water quality and biological communities.

Stream Ecology

Ecological data including fish-tissue chemistry and fish, macroinvertebrate, and algal community structure were collected to provide better understanding of the relations among physical, chemical, and biological characteristics of a stream. Data were collected at the Basic Fixed Site sampling network plus four additional sites to provide better spatial coverage.

Ground-Water Chemistry

The ground-water network was designed to characterize water quality in the most heavily used aquifers in the Study Unit. A Study Unit survey characterized the water quality in the Silurian-Devonian and Upper Carbonate bedrock aquifers, the second greatest source of municipal and domestic supplies in the Study Unit. Another Study Unit survey characterized the water quality of the alluvial aquifers using domestic wells. Land-use studies assessed the occurrence and distribution of water-quality constituents in recently recharged water in the alluvial aquifers. Agricultural and urban land-use effects on quality of shallow ground water was characterized by sampling two networks of monitoring wells constructed at randomly selected sites.

SUMMARY OF DATA COLLECTION IN THE EASTERN IOWA BASINS, 1996-98

Study Component	Constituents were collected and why	Where	When	Frequency
Stream chemistry				
Basic Fixed Sites—large rivers	Major ions, organic carbon, suspended sediment, nutrients, pesticides, and streamflow were determined to describe concentrations and the amount of selected constituents transported from the study area	Streams draining basins from about 2,300 to more than 12,000 square miles that integrate the effects of urban and agricultural land use and physiographic regions	6 in 1996, 5 in 1997-98	Monthly beginning in March 1996 and during selected flood events
Basic Fixed Sites—streams	Major ions, organic carbon, suspended sediment, nutrients, pesticides, and streamflow were determined to evaluate physiographic effects on stream-water quality	Streams draining basins from 120 to 418 square miles of homogeneous land use and physiography	6	Monthly beginning in March 1996 and during selected flood events
Intensive Fixed Sites	Major ions, organic carbon, suspended sediment, nutrients, pesticides, and streamflow were determined to define short-term temporal variability	One large river and two stream Basic Fixed Sites	3	Weekly during 1997 growing season; biweekly for remainder of the year
Base-flow synoptic study	Nutrients, pesticides, organic carbon, and streamflow were determined to refine spatial variability during both low and high base-flow conditions	Streams draining basins ranging from 120 to 530 square miles representing greater than 90 percent agricultural land use	25	August 1997 and May 1998
Bed-sediment chemistry				
Bed sediment and tissue	Trace elements, organochlorine, and semivolatile organic compounds in streambed sediment to determine presence of these potentially toxic, hydrophobic compounds	Ecological sites—Large river and tributary/headwater fixed sites plus four additional sites for better spatial coverage	16	September 1995
Reservoir core study	Trace elements and organochlorine compounds in sediment to determine the historical occurrence (from filling in 1958 to 1993)	Site in a deep depositional zone of the Coralville Reservoir about 1.5 miles upstream from the dam	1	November 1993
Stream ecology				
Bed sediment and tissue	Trace elements and organochlorine compounds in fish tissue to determine occurrence	Ecological sites	16	September 1995
Intensive assessments	Fish, benthic invertebrates, algae, and aquatic and riparian habitat were sampled and described to assess community structure and to document within stream and annual variation	Ecological sites	12	All fixed sites in 1996 and intensive sites in 1997-98
Ecological synoptic survey	Benthic invertebrates, algae, and aquatic and riparian habitat were sampled to assess biological responses in relation to water quality and hydrologic variability	Streams draining basins ranging from 120 to 530 square miles representing greater than 90 percent agricultural land use	25	August 1997
Ground-water chemistry				
Bedrock aquifer survey	Major ions, nutrients, pesticides, pesticide degradates, VOCs, and tritium were determined to assess quality in second most-used aquifer in Study Unit	Existing domestic wells completed in the Silurian-Devonian aquifer (32-700 feet deep)	33	June-July 1996
Alluvial aquifer survey	The same constituents as in bedrock aquifer survey were determined to assess quality in most-used aquifer in the Study Unit	Existing domestic wells completed in unconsolidated alluvial deposits	32	June-July 1998
Land-use effects study—agricultural and urban	The same constituents as in bedrock aquifer survey were determined to assess water-quality differences due to agricultural and urban land use	Newly constructed monitoring wells at sites randomly selected on alluvial deposits and completed at the water table (31 agricultural and 30 urban wells)	61	June-August 1997
Ground-water chemistry special study				
Changing land-use study	The same constituents as in bedrock aquifer survey were determined to assess changes in water-quality due to conversion of row crops to wetlands and prairie	Existing monitoring wells plus three new monitoring wells completed at various depths in the Iowa River alluvial aquifer	28	August 1996 and 1998

GLOSSARY

- Acre-foot**—A volume of water equal to 1 foot in depth and covering 1 acre; equivalent to 43,560 cubic feet or 325,851 gallons.
- Algae**—Chlorophyll-bearing nonvascular, primarily aquatic species that have no true roots, stems, or leaves; most algae are microscopic, but some species can be as large as vascular plants.
- Alluvial aquifer**—A water-bearing deposit of unconsolidated material (sand and gravel) left behind by a river or other flowing water.
- Alluvium**—A general term for clay, silt, sand, and gravel deposited by a river or stream in the bed of the stream or on its flood plain.
- Ammonia**—A compound of nitrogen and hydrogen (NH₃) that is a common by-product of animal waste. Ammonia readily converts to nitrate in soils and streams.
- Aquatic guidelines**—Specific levels of water quality which, if reached, may adversely affect aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.
- Aquifer**—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Base flow**—Sustained, low flow in a stream; groundwater discharge is the source of base flow in most places.
- Basic Fixed Sites**—Sites on streams at which streamflow is measured and samples are collected for temperature, salinity, suspended sediment, major ions, nutrients, and organic carbon to assess the broad-scale spatial and temporal character and transport of inorganic constituents of streamwater in relation to hydrologic conditions and environmental settings.
- Breakdown product**—A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process which may result in a more toxic or a less toxic compound and a more or less persistent compound.
- Concentration**—The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as micrograms per liter (water sample) or micrograms per kilogram (sediment or tissue sample).
- Constituent**—A chemical or biological substance in water, sediment, or biota that can be measured by an analytical method.
- Contamination**—Degradation of water quality compared to original or natural conditions due to human activity.
- Cubic foot per second (ft³/s, or cfs)**—Rate of water discharge representing a volume of 1 cubic foot passing a given point during 1 second, equivalent to approximately 7.48 gallons per second or 448.8 gallons per minute or 0.02832 cubic meter per second.
- Degradate**—See Breakdown product.
- Detection limit**—The minimum concentration of a substance that can be identified, measured, and reported within 99 percent confidence that the analyte concentration is greater than zero; determined from analysis of a sample in a given matrix containing the analyte.
- Discharge**—Rate of fluid flow passing a given point at a given moment in time, expressed as volume per unit of time.
- Drainage basin**—The portion of the surface of the Earth that contributes water to a stream through overland run-off, including tributaries and impoundments.
- Drinking-water standard or guideline**—A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.
- Ecoregion**—An area of similar climate, landform, soil, potential natural vegetation, hydrology, or other ecologically relevant variables.
- EPT richness index**—An index based on the sum of the number of taxa in three insect orders, Ephemeroptera (mayflies), Plecoptera (stoneflies), and Trichoptera (caddisflies), that are composed primarily of species considered to be relatively intolerant to environmental alterations.
- Eutrophication**—The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.
- Ground water**—In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Habitat**—The part of the physical environment where plants and animals live.
- Hypoxia**—Seasonally depleted dissolved oxygen concentrations (less than 2 milligrams per liter) in a water body.
- Index of Biotic Integrity (IBI)**—An aggregated number, or index, based on several attributes or metrics of a fish community that provides an assessment of biological conditions.
- Indicator sites**—Stream sampling sites located at outlets of drainage basins with relatively homogeneous land use and physiographic conditions: most indicator-site basins have drainage areas ranging from 100 to about 400 square miles.

- Integrator or Mixed-use site**—Stream sampling site located at an outlet of a drainage basin that contains multiple environmental settings. Most integrator sites are on major streams with relatively large drainage areas.
- Intolerant organisms**—Organisms that are not adaptable to human alterations to the environment and thus decline in numbers where human alterations occur. See also Tolerant species.
- Karst**—A type of topography that results from dissolution and collapse of carbonate rocks such as limestone and dolomite, and characterized by closed depressions or sinkholes, caves, and underground drainage.
- Leaching**—Refers to movement of pesticides or nutrients from land surface to ground water.
- Load**—General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.
- Loess**—Homogeneous, fine-grained sediment made up primarily of silt and clay, and deposited over a wide area (probably by wind).
- Maximum contaminant level (MCL)**—Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Median**—The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Monitoring well**—A well designed for measuring water levels and testing ground-water quality.
- Mouth**—The place where a stream discharges to a larger stream, a lake, or the sea.
- Nutrient**—Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.
- Overland flow**—The part of surface runoff flowing over land surfaces toward stream channels.
- Periphyton**—Organisms that grow on underwater surfaces; periphyton include algae, bacteria, fungi, protozoa, and other organisms.
- Pesticide**—A chemical applied to crops, rights-of-way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests."
- Physiography**—A description of the surface features of the Earth, with an emphasis on the origin of landforms.
- Plankton**—Floating or weakly swimming organisms at the mercy of the waves and currents. Animals of the group are called zooplankton and the plants are called phytoplankton.
- Radon**—A naturally occurring, colorless, odorless, radioactive gas formed by the disintegration of the element radium; damaging to human lungs when inhaled.
- Recharge**—Water that infiltrates the ground and reaches the saturated zone.
- Reference site**—A NAWQA sampling site selected for its relatively undisturbed conditions.
- Riparian zone**—Pertaining to or located on the bank of a body of water, especially a stream.
- Runoff**—Excess rainwater or snowmelt that is transported to streams by overland flow, tile drains, or ground water.
- Species diversity**—An ecological concept that incorporates both the number of species in a particular sampling area and the evenness with which individuals are distributed among the various species.
- Species (taxa) richness**—The number of species (taxa) present in a defined area or sampling unit.
- Study Unit**—A major hydrologic system of the United States in which NAWQA studies are focused. Study Units are geographically defined by a combination of ground- and surface-water features and generally encompass more than 4,000 square miles of land area.
- Tile drain**—A buried perforated pipe designed to remove excess water from soils.
- Tolerant species**—Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.
- Total concentration**—Refers to the concentration of a constituent regardless of its form (dissolved or bound) in a sample.
- Triazine herbicide**—A class of herbicides containing a symmetrical triazine ring (a nitrogen-heterocyclic ring composed of three nitrogens and three carbons in an alternating sequence). Examples include atrazine, propazine, and simazine.
- Tritium**—A radioactive form of hydrogen with atoms of three times the mass of ordinary hydrogen; can be used to determine the age of water.
- Unconsolidated deposit**—Deposit of loosely bound sediment that typically fills topographically low areas.
- Urban site**—A site that has greater than 50 percent urbanized and less than 25 percent agricultural area.
- Volatile organic compounds (VOCs)**—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

APPENDIX—WATER-QUALITY DATA FROM THE EASTERN IOWA BASINS IN A NATIONAL CONTEXT

For a complete view of Eastern Iowa Basins data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Eastern Iowa Basins. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Eastern Iowa Basins compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, acetochlor concentrations in Eastern Iowa Basins agricultural streams were similar to the national distribution, but the detection frequency was much higher (79 percent compared to 33 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Eastern Iowa Basins, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

-- Not measured or sample size less than two

12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acifluorfen (Blazer, Tackle 2S) **
- Bromacil (Hyvar X, Urox B, Bromax)
- Bromoxynil (Buctril, Brominal) *
- Butylate (Sutan +, Genate Plus, Butilate) **
- DCPA (Dacthal, chlorthal-dimethyl) ***
- Dicamba (Banvel, Dianat, Scotts Proturf)

Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
 2,6-Diethylaniline (Alachlor breakdown product) * **
 Diuron (Crisuron, Karmex, Diurex) **
 EPTC (Eptam, Farmarox, Alirox) * **
 Metribuzin (Lexone, Sencor)
 Molinate (Ordram) * **
 Napropamide (Devrinol) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **
 Picloram (Grazon, Tordon)
 Pronamide (Kerb, Propyzamid) **
 Propachlor (Ramrod, Satecid) **
 Simazine (Princep, Caliber 90)
 Tebuthiuron (Spike, Tebusan)
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **
 Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

Benfluralin (Balan, Benefin, Bonalan) * **
 Chloramben (Amiben, Amilon-WP, Vegiben) **
 Clopyralid (Stinger, Lontrel, Transline) * **
 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
 Dacthal mono-acid (Dacthal breakdown product) * **
 Dinoseb (Dinosebe)
 Ethalfuralin (Sonalan, Curbit) * **
 Fenuron (Fenulon, Fendim) * **
 Fluometuron (Flo-Met, Cotoran) **
 Linuron (Lorox, Linex, Sarclax, Linurex, Afalon) *
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Norflurazon (Evital, Predict, Solicam, Zorial) * **
 Oryzalin (Surflan, Dirimal) * **
 Pebulate (Tillam, PEBC) * **
 Propanil (Stam, Stampede, Wham) * **
 Propham (Tuberite) **
 2,4,5-T **
 2,4,5-TP (Silvex, Fenoprop) **
 Terbacil (Sinbar) **
 Thiobencarb (Bolero, Saturn, Benthicarb) * **
 Triallate (Far-Go, Avadex BW, Tri-allate) *

Pesticides in water—Insecticides

Other insecticides detected

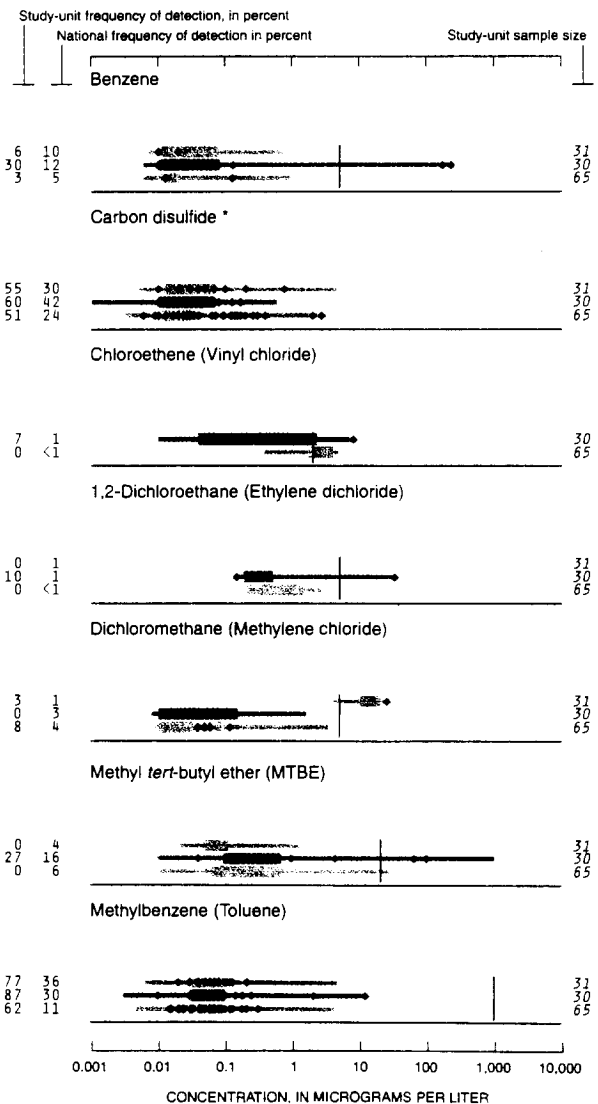

Carbaryl (Carbamine, Denapon, Sevin)
 Carbofuran (Furadan, Curaterr, Yaltox)
 Diazinon (Basudin, Diazatol, Neocidol, Knox Out)
 Dieldrin (Panoram D-31, Octalox, Compound 497)
 Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
 Malathion (Malathion)

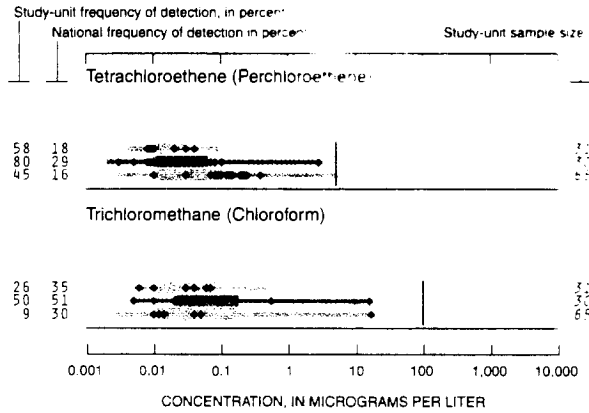

Insecticides not detected

Aldicarb (Temik, Ambush, Pounce)
 Aldicarb sulfone (Standak, aldoxycarb)
 Aldicarb sulfoxide (Aldicarb breakdown product)
 Azinphos-methyl (Guthion, Gusathion M) *
 Disulfoton (Disyston, Di-Syston) **
 Ethoprop (Mocap, Ethoprophos) * **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 Methiocarb (Slug-Geta, Grandslam, Mesurol) * **
 Methomyl (Lanox, Lannate, Acinate) **
 Methyl parathion (Penncap-M, Folidol-M) **
 Oxamyl (Vydate L, Pratt) **
 Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
 cis-Permethrin (Ambush, Astro, Pounce) * **
 Phorate (Thimet, Granutox, Geomet, Rampart) * **
 Propargite (Comite, Omite, Ornamite) * **
 Propoxur (Baygon, Blattatex, Unden, Proprotox) * **
 Terbufos (Contraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

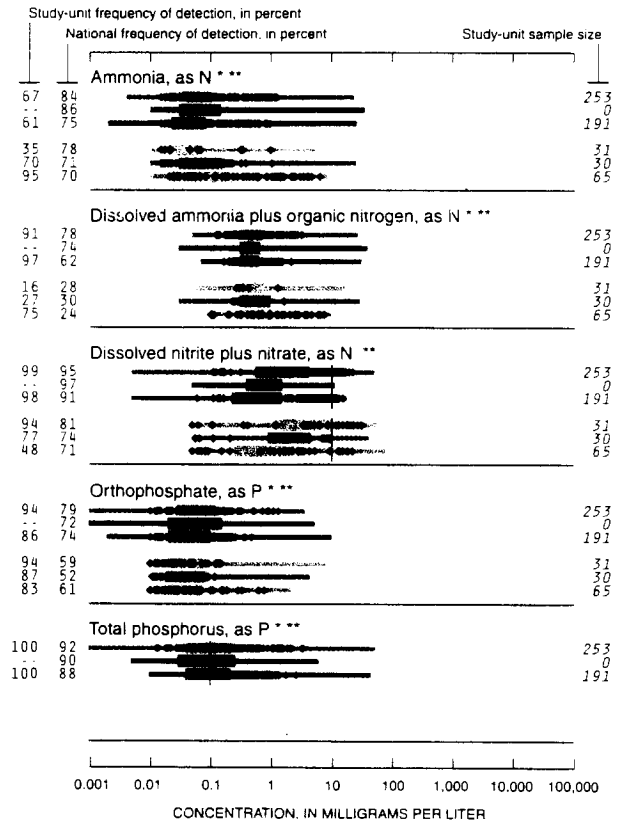

tert-Amylmethylether (*tert*-amyl methyl ether (TAME)) *
Bromodichloromethane (Dibromochloromethane)
Bromomethane (Methyl bromide)
2-Butanone (Methyl ethyl ketone (MEK)) *
n-Butylbenzene (1-Phenylbutane) *
sec-Butylbenzene *
tert-Butylbenzene *
Chlorobenzene (Monochlorobenzene)
Chlorodibromomethane (Dibromochloromethane)
Chloroethane (Ethyl chloride) *
Chloromethane (Methyl chloride)
1,3-Dichlorobenzene (*m*-Dichlorobenzene)
1,4-Dichlorobenzene (*p*-Dichlorobenzene)
Dichlorodifluoromethane (CFC 12, Freon 12)
1,1-Dichloroethane (Ethylidene dichloride) *
1,1-Dichloroethene (Vinylidene chloride)
trans-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
cis-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)
1,2-Dichloropropane (Propylene dichloride)
Diethyl ether (Ethyl ether) *
Diisopropyl ether (Diisopropylether (DIPE)) *
1,2-Dimethylbenzene (*o*-Xylene)
1,3 & 1,4-Dimethylbenzene (*m*-&*p*-Xylene)
1,4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
Ethylbenzene (Phenylethane)
Iodomethane (Methyl iodide) *
Isopropylbenzene (Cumene) *
p-Isopropyltoluene (*p*-Cymene) *
Naphthalene
2-Propanone (Acetone) *
n-Propylbenzene (Isocumene) *
1,2,3,5-Tetramethylbenzene (Isodurene) *
Tribromomethane (Bromoform)
1,2,3-Trichlorobenzene *
1,1,1-Trichloroethane (Methylchloroform)
Trichloroethene (TCE)
1,2,3-Trichloropropane (Allyl trichloride)
1,2,3-Trimethylbenzene (Hemimellitene) *
1,2,4-Trimethylbenzene (Pseudocumene) *
1,3,5-Trimethylbenzene (Mesitylene) *

VOCs not detected

Bromobenzene (Phenyl bromide) *
Bromochloromethane (Methylene chlorobromide)
Bromoethene (Vinyl bromide) *
3-Chloro-1-propene (3-Chloropropene) *
1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
1,2-Dibromoethane (Ethylene dibromide, EDB)
Dibromomethane (Methylene dibromide) *
trans-1,4-Dichloro-2-butene ((Z)-1,4-Dichloro-2-butene) *
1,2-Dichlorobenzene (*o*-Dichlorobenzene)
2,2-Dichloropropane *
1,3-Dichloropropane (Trimethylene dichloride) *
trans-1,3-Dichloropropene ((E)-1,3-Dichloropropene)

cis-1,3-Dichloropropene ((Z)-1,3-Dichloropropene)
1,1-Dichloropropene *
Ethenylbenzene (Styrene)
Ethyl methacrylate *
Hexachlorobutadiene
1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
2-Hexanone (Methyl butyl ketone (MBK)) *
Methyl acrylonitrile *
Methyl-2-methacrylate (Methyl methacrylate) *
4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
Methyl-2-propenoate (Methyl acrylate) *
2-Propenenitrile (Acrylonitrile)
1,1,2-Tetrachloroethane *
1,1,1,2-Tetrachloroethane
Tetrachloromethane (Carbon tetrachloride)
1,2,3,4-Tetramethylbenzene (Prehnitene) *
1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
1,2,4-Trichlorobenzene
1,1,2-Trichloroethane (Vinyl trichloride)
Trichlorofluoromethane (CFC 11, Freon 11)

Nutrients in water

Dissolved solids in water

Trace elements in ground water

Organochlorines in fish tissue (whole body) and bed sediment

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Eastern Iowa Basins, 1996-98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size

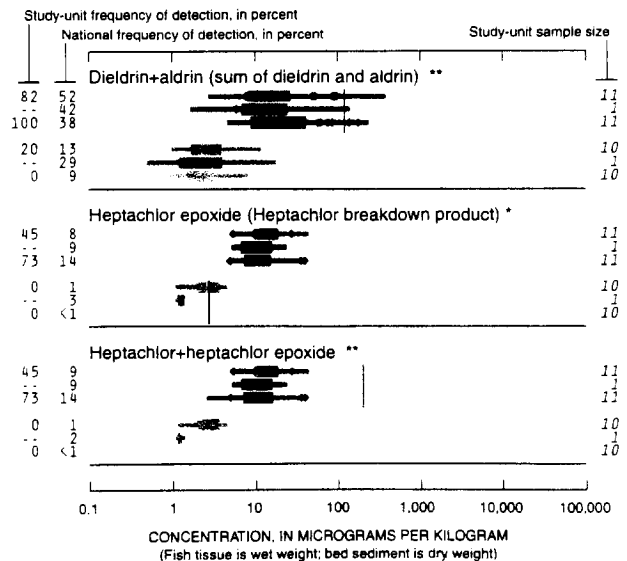

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991-98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- ** No benchmark for protection of aquatic life

¹ The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

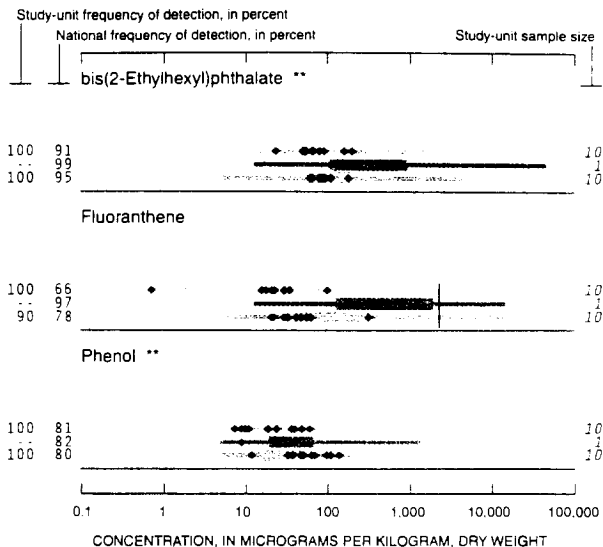

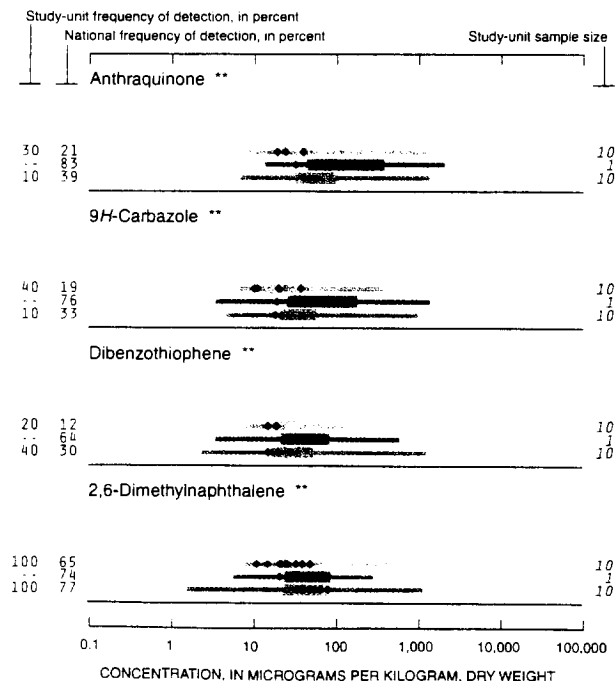

Other organochlorines detected

- DCPA (Dacthal, chlorthal-dimethyl) * **
- Total-HCH (sum of alpha-HCH, beta-HCH, gamma-HCH, and delta-HCH) **
- Mirex (Dechlorane) **
- Pentachloroanisole (PCA) * **

Organochlorines not detected

- Chloroneb (Chloronebe, Demosan) * **
- Endosulfan I (alpha-Endosulfan, Thiodan) * **
- Endrin (Endrine)
- gamma-HCH (Lindane, gamma-BHC, Gammexane) *
- Hexachlorobenzene (HCB) **
- Isodrin (Isodrine, Compound 711) * **
- p,p'-Methoxychlor (Marlate, methoxychlor) * **
- o,p'-Methoxychlor * **
- cis-Permethrin (Ambush, Astro, Pounce) * **
- trans-Permethrin (Ambush, Astro, Pounce) * **
- Toxaphene (Camphechlor, Hercules 3956) * **

Semivolatile organic compounds (SVOCs) in bed sediment

Other SVOCs detected

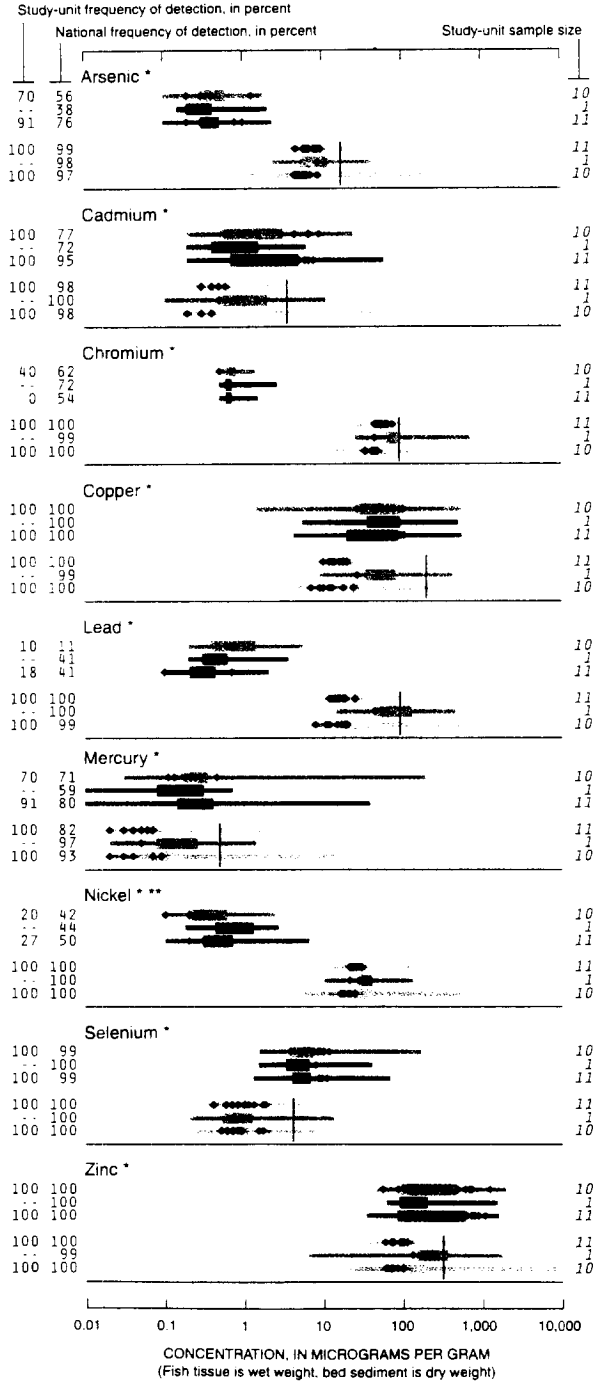

- Acenaphthene
- Acenaphthylene
- Acridine **
- Anthracene

BIOLOGICAL INDICATORS

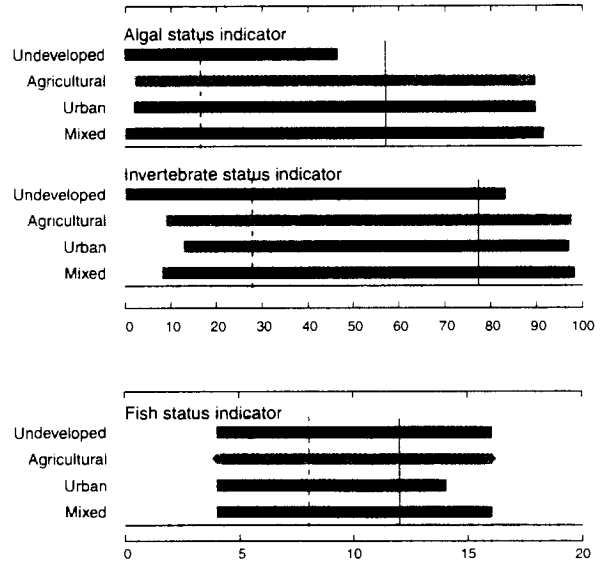

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

A COORDINATED EFFORT

Coordination with agencies and organizations in the Eastern Iowa Basins was integral to the success of this water-quality assessment. We thank personnel from the following agencies and organizations who served as members of our liaison committee and participated in our liaison committee meetings.

U.S. Department of Agriculture Natural Resources Conservation Service Agricultural Research Service	University of Iowa Hygienics Laboratory Limnology Section
U.S. Environmental Protection Agency, Region VII	Environmental Research
U.S. Fish and Wildlife Service	Institute of Hydraulic Research
U.S. Geological Survey Biological Resources Division	Center for Health Effects on the Environment
Iowa Department of Agriculture and Land Stewardship Pesticide Bureau	University of Northern Iowa College of Natural Sciences
Iowa Department of Natural Resources Environmental Protection Division Geological Survey Bureau Fisheries Bureau	Wartburg College Biology Department
Minnesota Department of Natural Resources Minnesota Pollution Control Agency Minnesota Geological Survey	Iowa Farm Bureau Federation Iowa Environmental Council Iowa Ground Water Association
Linn County Iowa REAP	Izaak Walton League
Linn County Iowa Conservation Board	Sierra Club
Johnson County Iowa Board of Supervisors	Dow AgroSciences
Cedar Rapids Water Department	Dupont Agricultural Products
Iowa City Public Works	Novartis Crop Protection
Iowa State University Center for Sustainable Agriculture Department of Botany Extension Service	Monsanto American Cyanamid Company American Corn Growers Association Johnson County Farm Bureau

We thank the following individuals for contributing to this effort.

James Cerveny, Jon Nania, Joel Galloway, Jennifer Tobias, and Matthew Bobier, the primary field personnel, who worked in all conditions to obtain a high-quality data set without which this report would not be possible.

Linda Roberts, the Study Unit biologist, who planned and supervised the collection of algae, macroinvertebrate, and fish samples.

The many U.S. Geological Survey personnel (too many to list) from the Iowa District and surrounding States that assisted in the collection of biological samples and in the construction of equipment shelters.

Scott Yess and Ann Rundstrom of the Fish and Wildlife Service and J. Kent Johnson University of Iowa Hydraulics Institute, who assisted in the collection of fish.

Technicians and chemists at the USGS National Water-Quality Laboratory in Denver, Colorado, who provided analysis of all water samples. Mike Thurman and Elizabeth Scribner and the staff of the U.S. Geological Survey Organic Geochemistry Research laboratory in Lawrence, Kansas, who analyzed all pesticide samples for degradates. Researchers and technicians at the USGS Isotope Tracers Laboratory and the USGS National Research Program Laboratory, who provided tritium and stable isotope analysis.

Tom Wilton of the Iowa Department of Natural Resources who provided a wealth of information, data, and advice that was invaluable in the completion of the water-chemistry and biological parts of the study.

Reviewers—Michael Burkhart, USDA Soil Tilth Laboratory; Susan Heathcote, Iowa Environmental Council; Jim Ellerhoff, Iowa Department of Agriculture and Land Stewardship; Richard Robinson, Iowa Farm Bureau Federation; Bernard Hoyer, Iowa Department of Natural Resources; Geological Survey Bureau. The many colleagues in the U.S. Geological Survey whose technical suggestions substantially improved this report. The editorial reviewers, Lanna Combs and Betty Palcsak.

Editors and publication preparation: Alene Brogan, Mary Kidd, Robert Olmstead, and Ed Swibas.

Look at Surrounding Land, Soil, and Geology for Water Resource Quality

Water resources are affected by land use, soils, and geology in the Upper Mississippi River Basin, according to a recently published report by the U. S. Geological Survey (USGS). Urban, agricultural, and forested land use in combination with geology and soil type result in different degrees of water-resource quality. Surface-water quality was better in forested watersheds than in urban or agricultural watersheds. Ground-water quality was better in aquifers with overlying soils that reduced direct infiltration.

The study of the Upper Mississippi River Basin, conducted from 1995-98, as part of the USGS National Water-Quality Assessment Program, found that streams in forested watersheds like the St. Croix River Basin had less nutrients, sediment, and organic contaminants than streams in agricultural watersheds like the Minnesota River Basin or urban areas like the Twin Cities Metropolitan Area. "Land use a major factor affecting water quality in streams and ground water. However, the type of soils in the watershed or overlying shallow aquifers could have a significant effect", said Jim Stark, the project chief. The findings indicate that agriculture, urbanization, and natural land uses continue to affect water quality.

The quality of urban streams has been affected more than streams in agricultural or forested areas. One component of the study examined biological communities and habitat. Urban streams had reduced fish and invertebrate species richness (numbers of species) and biological diversity compared to agricultural and forested streams. Several factors may be responsible for the comparatively poor condition of aquatic resources in urban streams, including contaminants in the water and sediment, and reduced habitat.

Reduced habitat in urban streams was associated with loss of riparian vegetation, channelization, impoundments, and changes in the pattern of streamflow. The rise and fall of the water in urban streams after rainstorms or snowmelt are much more rapid than streams in other land-use settings. Impervious surfaces such as parking lots, roads, and building roofs do not allow precipitation to soak into the ground; therefore, runoff reaches the streams more quickly and streamflow increases and decreases rapidly. Higher flows scour the stream bottom, reducing habitat.

Agricultural streams in the study were found to receive nonpoint-source inputs of nutrients and sediment. Nitrate concentrations in streams in artificially drained agricultural areas exceeded the U.S. Environmental Protection Agency's (USEPA) drinking water standard of 10 milligrams per liter in about 20 percent of the samples. Stream channels and habitat were also affected by channelization and loss of riparian buffers. The importance of riparian buffers for agricultural streams was shown with a special study. This study found that streams with more trees and shrubs along the banks in riparian buffer zones had more fish and invertebrate species and better ecological integrity than streams without riparian buffer zones.

Streams in forested basins like those in the northern part of the study area were relatively unaffected except by localized activities such as minor wastewater effluent discharges, pesticide applications at tree farms, leaks from septic systems. Nutrients and pesticides did not exceed drinking water standards or criteria to protect aquatic life. Concentrations of nutrients and pesticides were

small compared to urban and agricultural streams.

Ground water supplies about 75 percent of the public and industrial water supply. The major source for this water is the Prairie du Chien-Jordan aquifer. The local quality of the water in the aquifer depends on land use and the type of bedrock or glacial deposits above it. In areas where water can readily seep through the overlying soils to the aquifer, 8 percent of the nitrate samples exceeded the USEPA drinking water standards. In areas where water could not readily reach the aquifer due to low-permeability glacial tills, nitrate standards were not exceeded. Some pesticides were detected in ground water. In areas overlain by till, atrazine (a herbicide used with corn) was detected in 36 percent of the wells, whereas in areas without a low-permeability layer, it was detected in 52 percent of the wells.

The USGS report, "Water Quality in the Upper Mississippi River Basin, Minnesota, Wisconsin, South Dakota, Iowa, and North Dakota, 1995-1998", published as USGS Circular 1211, is available on the World Wide Web as downloadable portable document files (PDF) at <http://water.usgs.gov/nawqa> or in printed form (single copies of the report are at no cost) from Branch of Information Services, P.O. Box 25286, Denver, CO 80225, or by fax request to 303-202-4693. Please specify USGS report C-1211.

The USGS assessment is part of a national program, currently releasing results on surface and ground water in 15 additional major river basins. Check the status and availability of the individual basin reports on the NAWQA website, as well as accessibility to other NAWQA publications and national data sets and maps.

As the nation's largest water, earth and biological science and civilian mapping agency, the USGS works in cooperation with more than 2,000 organizations across the country to provide reliable, impartial, scientific information to resource managers, planners, and other customers. This information is gathered in every state by USGS scientists to minimize the loss of life and property from natural disaster, contribute to the sound conservation, economic and physical development of the nation's natural resources, and enhance the quality of life by monitoring water, biological, energy, and mineral resources.

Selected Findings and Current Perspectives on Urban and Agricultural Water Quality by the National Water-Quality Assessment Program

Studies by the USGS National Water-Quality Assessment (NAWQA) program in the last decade describe water-quality conditions in nearly 120 agricultural and 35 urban watersheds ("urban" primarily refers to residential and commercial development over the last 50 years). The findings show that for both urban and agricultural areas, nonpoint chemical contamination is an issue. Much work still needs to be done in urban areas with point source contamination as well, including infrastructure improvements. Appreciable improvements in overall water quality, however, will depend upon effective management of point and nonpoint sources. The findings also show that water-quality conditions and aquatic health reflect a complex combination of land and chemical use, land-management practices, population density and watershed development, and natural features, such as soils, geology, hydrology, and climate. Contaminant concentrations vary from season to season and from watershed to watershed. Even among seemingly similar land uses and sources of contamination, different areas can have very different degrees of vulnerability and, therefore, have different rates at which improved treatment or management can lead to water-quality improvements.

Water Quality in Agricultural Watersheds

- Nitrogen and phosphorus in surface water commonly exceed levels that contribute to excessive algae. For example, average annual concentrations of phosphorus in nearly 80 percent of streams sampled in agricultural areas were greater than the U. S. Environmental Protection Agency (USEPA) desired goal for preventing nuisance plant growth in streams. Excessive plant growth can lead to low dissolved oxygen, which can be harmful to fish and other aquatic life.
- Nitrate is often elevated above background levels in shallow ground water underlying farmland. Concentrations in about 20 percent of shallow wells sampled in agricultural areas exceeded the USEPA drinking water standard. This result is a concern in rural areas where shallow ground water is used for domestic supply; these domestic wells are not regulated and owners often do not know the quality of their well water or whether their wells are vulnerable to contamination. Nitrate is most often elevated in karst (carbonate) areas or where soils and aquifers consist of sand and gravel. These natural features enable rapid infiltration and downward movement of water and chemicals. Some of the more vulnerable areas are the Central Valley of California, and parts of the Pacific Northwest, the Great Plains, and the Mid-Atlantic region. In contrast, ground-water contaminants underlying farmland in parts of the upper Midwest are barely detectable, despite similar high rates of chemical use. In these areas ground-water contamination may be limited because of relatively impermeable, poorly drained soils and glacial till that cover much of the region, and because tile drains provide quick pathways for runoff to streams.
- Pesticides are widespread. At least one pesticide was detected in more than 95 percent of stream samples. Pesticides were detected in more than 60 percent of shallow wells sampled in agricultural areas.
- Pesticides commonly occur in mixtures. Two-thirds of stream samples collected in agricultural areas contained 5 or more pesticides, and more than one-quarter of the samples contained 10 or more. Ground water contained fewer pesticides; about 30 percent of the wells sampled contained 2 or more.
- Concentrations of pesticides generally are low and below drinking-water standards. However, the risk to humans and the environment from present-day low levels of contaminant exposure remains unclear. For example, current standards and guidelines do not yet account for exposure to mixtures, and many pesticides and their breakdown products do not have standards or guidelines.
- Herbicides—most commonly atrazine and its breakdown product desethylatrazine, and metolachlor, cyanazine, and alachlor—occur more frequently and usually at higher concentrations in agricultural streams and ground water than in urban waters. Their occurrence is linked to their use; they rank in the top five in national herbicide use for agriculture.
- Insecticides that were used in the past still persist in agricultural streams and sediment. DDT was the most commonly detected organochlorine compound, followed by dieldrin and chlordane. Their uses were restricted in the 1970s and 1980s and, yet, more than 20 years later, one or more sediment-quality guidelines were exceeded at more than 20 percent of agricultural sites.

Water Quality in Urban Watersheds

- Concentrations of fecal coliform bacteria commonly exceed recommended standards for water-contact recreation.
- Concentrations of total phosphorus are generally as high in urban streams as in agricultural streams. More than 70 percent of sampled urban streams exceeded the USEPA desired goal for preventing nuisance plant growth.
- Insecticides, such as diazinon, carbaryl, chlorpyrifos, and malathion, occur more frequently, and usually at higher concentrations in urban streams than in agricultural streams. Concentrations are low in urban streams, rarely exceeding USEPA drinking-water standards. However, effects on aquatic life may be more of a concern. Concentrations of insecticides exceeded at least one guideline established to protect aquatic life in every sampled urban stream.
- Herbicides are widespread in surface water (detected in 99 percent of urban stream samples) and ground water (detected in more than 50 percent of sampled wells). Most common are those applied to lawns, golf courses, and road right-of-ways, such as atrazine, simazine, and prometon.
- Similar to agricultural areas, pesticides in urban waters commonly occur in mixtures; nearly 80 percent of stream samples contained 5 or more pesticides. Two of the most commonly detected insecticides in mixtures were diazinon and chlorpyrifos; common herbicides detected were simazine and prometon.
- Sediment in urban streams is associated with higher frequencies of occurrence of DDT, chlordane, and dieldrin and higher concentrations of chlordane and dieldrin than sediment in agricultural streams. Sediment-quality guidelines for organochlorine pesticides were exceeded at 36 percent of sampled urban sites.
- Volatile organic compounds, which are used in plastics, cleaning solvents, gasoline, and industrial operations, occur widely in shallow urban ground water. Some of the most frequently detected of the 60 analyzed compounds were the commercial and industrial solvents trichloroethene (TCE), tetrachloroethene (PCE), and methylene chloride; the gasoline additive methyl tert-butyl ether (MTBE); and the solvent and disinfection by-product of water treatment, trichloromethane (also known as chloroform).
- Concentrations of selected trace elements, such as cadmium, lead, zinc, and mercury, are elevated above background levels in populated urban settings, most likely caused by emissions from industrial and municipal activities and motor vehicles. Sediment cores from streambeds and reservoirs, which can be used to track changes over long time periods, indicate that lead increased from 1940s to the 1970s, and began to decrease after it was removed from gasoline. Concentrations are not yet down to background levels. Decreases also are noted for DDT and chlordane.
- In contrast to lead, DDT, and chlordane, sediment cores indicate that zinc and polycyclic aromatic hydrocarbons (PAHs, which result from fossil fuel combustion) are increasing. These increases most likely relate to increasing motor vehicle traffic in watersheds. Sediment-quality guidelines for PAHs were exceeded at more than 40 percent of urban sites.
- Toxic compounds in streambed sediment in urban areas, such as DDT, chlordane, dieldrin, and PCBs, also were found in fish tissue, often at higher concentrations than in the sediment. One or more organochlorine compounds were detected in 97 percent of whole fish samples collected at urban sites, and PCBs were detected in more than 80 percent of whole fish samples. Concentrations of organochlorine compounds exceeded guidelines to protect wildlife at more than 10 percent of urban sites; wildlife guidelines for PCBs were exceeded at nearly 70 percent of urban sites. These findings have contributed to decisions by some states to issue fish-consumption advisories.
- Deteriorated water quality and sediment, as well as habitat disturbances, contribute to degraded biological communities in urban streams. The greatest effects are seen in areas with the highest human population densities and watershed development. Pollution-tolerant algae and aquatic invertebrates (such as worms and midges), as well as omnivorous fish communities, prevail at the affected sites.

Upper Mississippi River Basin

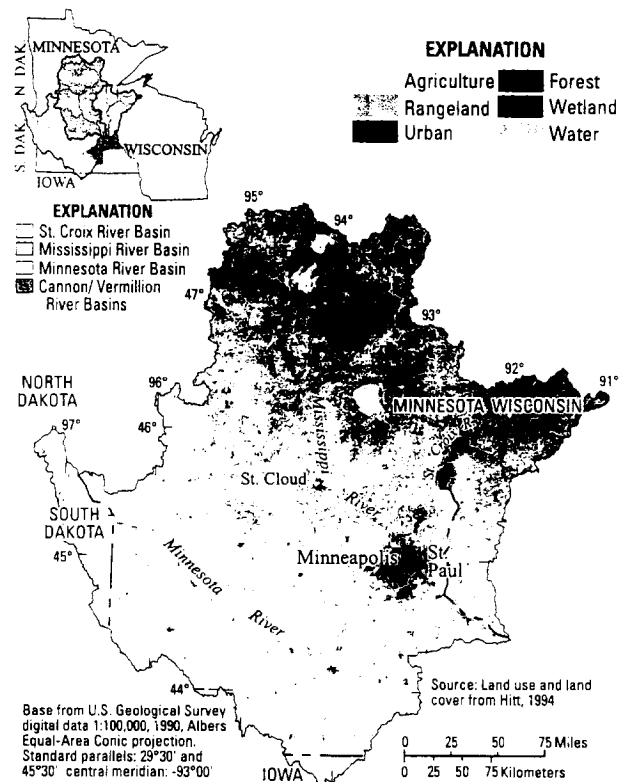

SUMMARY OF MAJOR FINDINGS

The Upper Mississippi River Basin Study Unit encompasses about 47,000 mi² (square miles) in Minnesota, Wisconsin, South Dakota, Iowa, and North Dakota and includes the Twin Cities (Minneapolis and St. Paul) metropolitan area (TCMA). The three major rivers in the Study Unit are the Mississippi, the Minnesota, and the St. Croix. In 1990, about 3.7 million people resided in the Study Unit, mostly in the TCMA. The Mississippi River is the primary source of drinking water for St. Cloud, Minneapolis, and St. Paul in Minnesota. Ground water is the primary source of drinking water in rural and suburban areas.

Highlights of Streams and Aquatic Biology

Elevated concentrations of nutrients (nitrogen and phosphorus) in water are potentially harmful to humans, livestock, and aquatic life. Major sources of nutrients to streams are commercial fertilizers applied to crops, lawns, and gardens; wastewater discharge; leaking septic systems; snowmelt runoff; and animal manure. The total amounts of nitrate and dissolved orthophosphate were greater in streams draining agricultural areas than in streams draining areas with other land uses. Although pesticides (herbicides and insecticides) were commonly detected, most concentrations were less than current drinking-water standards and guidelines and aquatic-life guidelines; however, not all pesticides detected currently have drinking-water standards and guidelines. Samples from most streams in the Study Unit met Federal and State drinking-water standards and guidelines and aquatic-life guidelines. Invertebrate and fish communities were most degraded in urban streams.

- Nitrate concentrations in streams in artificially drained agricultural areas exceeded the U.S. Environmental Protection Agency (USEPA) drinking-water standard of 10 mg/L (milligrams per liter) in about 20 percent of the samples.
- Insecticides and nonagricultural herbicides were detected most frequently in urban areas.
- Agricultural herbicides were detected in streams throughout the Study Unit.
- Urban streams have reduced invertebrate and fish species richness and diversity compared to agricultural streams.
- Algal productivity was greater in agricultural streams than in urban and forest streams, due in part to greater concentrations of nutrients.
- Agricultural streams with wooded riparian cover had greater fish and invertebrate species richness and diversity than agricultural streams lacking wooded riparian cover.

Land use and land cover in the Upper Mississippi River Basin study unit

Trends in Stream-Water Quality and Aquatic Biology

Assessing trends in water quality and aquatic biology is difficult because historical data sets are discontinuous and sampling objectives and analysis methods have varied. Some observable trends are increased nitrate concentrations, based on historical data, and decreased ammonia concentrations in streams in the TCMA during 1984–1993 primarily because of process changes at wastewater treatment facilities. Breakdown products of the pesticide DDT, the use of which was discontinued in the 1970's, are still detectable in fish, streams, and streambed sediment.

Major Influences on Streams and Aquatic Biology

- Application of pesticides and fertilizers in agricultural and urban areas
- Discharges from wastewater treatment facilities
- Runoff from agricultural and urban areas
- Stream modifications and artificial drainage
- Destruction of riparian cover along streambanks
- Contaminants in precipitation and in the atmosphere

Highlights of Conditions in Ground Water

Shallow ground water in the TCMA (less than 50 feet below land surface) commonly contained pesticides, nutrients, and industrial chemicals and detectable concentrations of numerous volatile organic compounds (VOCs). Deeper ground water, typically used for public supply (water supplied for the general public by municipal and private purveyors), contained few pesticides and lower nitrate concentrations. With the exception of naturally occurring radon, deeper ground water met drinking-water standards and guidelines for most chemicals.

- Nitrate concentrations in water from nearly one-half of shallow ground water sampled beneath agricultural areas exceeded the USEPA drinking-water standard (10 mg/L).
- Road salt constituents (sodium and chloride) were detected at greater concentrations in shallow ground water underlying urban areas than other areas.
- Agricultural pesticides were commonly detected in all land-use settings. Concentrations were greatest in agricultural areas.
- Atrazine was the most frequently detected agricultural pesticide. Concentrations were greater in shallow ground water than in deeper ground water.

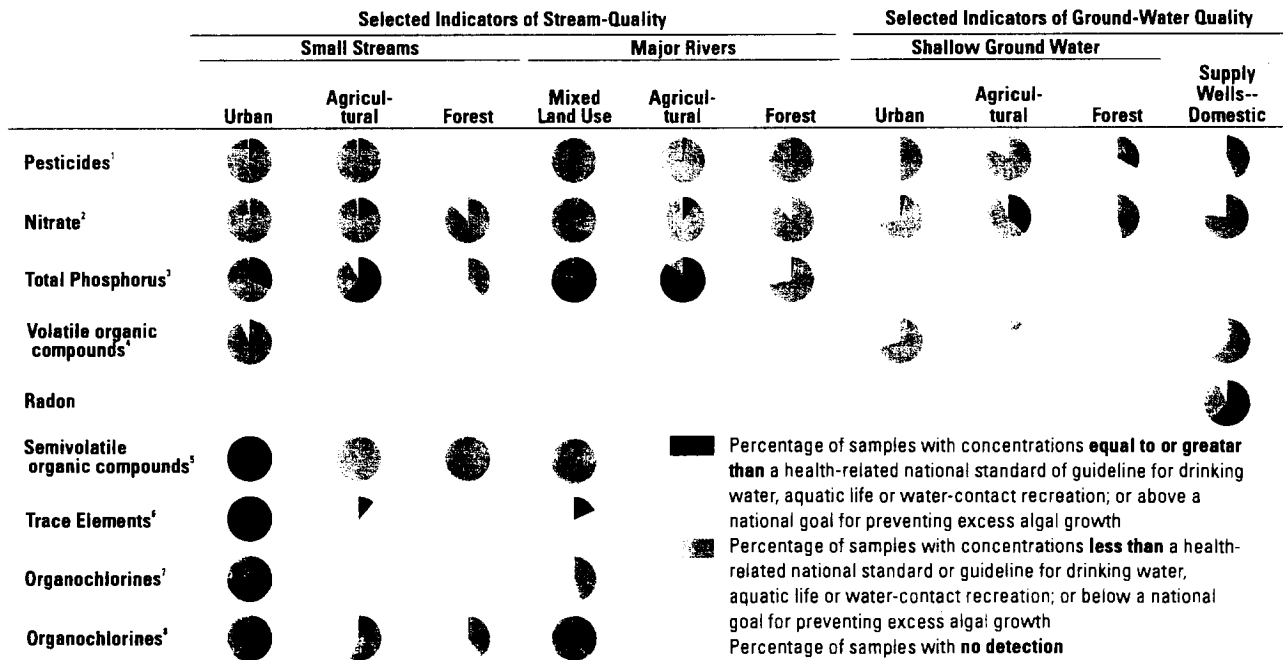

- Prometon was the most frequently detected herbicide in urban areas.
- Ground water in the Prairie du Chien-Jordan aquifer, an important source of drinking water, is protected by overlying confining units in some areas. Concentrations of nitrate, atrazine, and VOCs were lower in these areas than where confining units were absent.
- Radon exceeded the USEPA suspended drinking water standard of 300 pCi/L (picocuries per liter) in more than one-half of the water samples from the Prairie du Chien-Jordan aquifer.

Trends in Ground-Water Quality

Temporal trends in ground-water quality are difficult to define because limited information exists. Spatial trends include greater nitrate and pesticide concentrations in agricultural areas, greater VOC concentrations in urban areas, and few detections of pesticides or VOCs in forested areas.

Major Influences on Ground Water

- Application of pesticides and fertilizers
- Confining units and depth to water
- Urban contaminants (road salts, VOCs)
- Naturally occurring radon gas

¹Insecticides, herbicides, and pesticide metabolites, sampled in water. ²Nitrate (as nitrogen), sampled in water. ³Total phosphorus, sampled in water. ⁴Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water. ⁵Byproducts of fossil-fuel combustion or components of coal and crude oil, sampled in sediment. ⁶Arsenic, mercury, and metals, sampled in sediment. ⁷Organochlorine compounds including DDT and PCBs, sampled in sediment. ⁸Organochlorine compounds including DDT and PCBs, sampled in fish tissue.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in part of the Upper Mississippi River Basin (referred to as the Study Unit in this report) that emerged from an assessment conducted from 1995 to 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions in 36 NAWQA study areas, called study units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality to the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitat as elements of the complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Study Unit assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding encourages effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends, while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the NAWQA Program.

The Upper Mississippi River Basin Study Unit is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

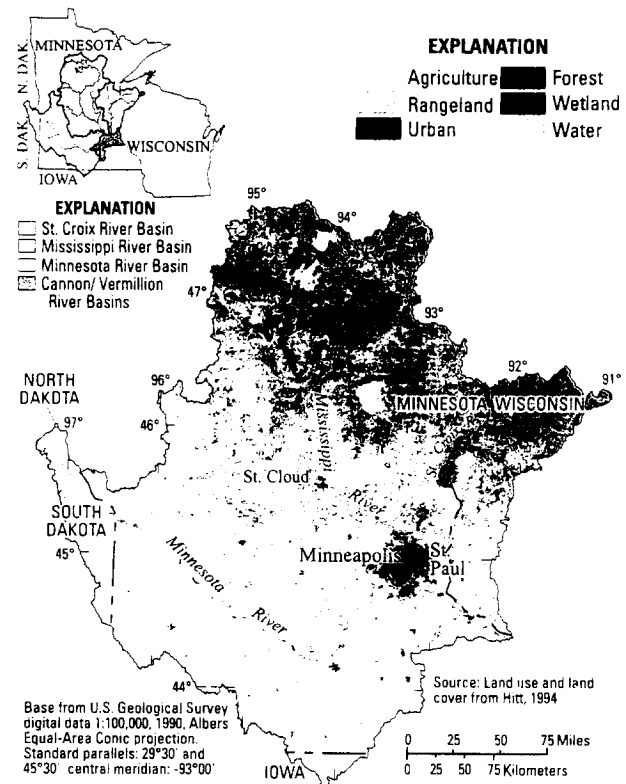

SUMMARY OF MAJOR FINDINGS

The Upper Mississippi River Basin Study Unit encompasses about 47,000 mi² (square miles) in Minnesota, Wisconsin, South Dakota, Iowa, and North Dakota and includes the Twin Cities (Minneapolis and St. Paul) metropolitan area (TCMA). The three major rivers in the Study Unit are the Mississippi, the Minnesota, and the St. Croix. In 1990, about 3.7 million people resided in the Study Unit, mostly in the TCMA. The Mississippi River is the primary source of drinking water for St. Cloud, Minneapolis, and St. Paul in Minnesota. Ground water is the primary source of drinking water in rural and suburban areas.

Highlights of Streams and Aquatic Biology

Elevated concentrations of nutrients (nitrogen and phosphorus) in water are potentially harmful to humans, livestock, and aquatic life. Major sources of nutrients to streams are commercial fertilizers applied to crops, lawns, and gardens; wastewater discharge; leaking septic systems; snowmelt runoff; and animal manure. The total amounts of nitrate and dissolved orthophosphate were greater in streams draining agricultural areas than in streams draining areas with other land uses. Although pesticides (herbicides and insecticides) were commonly detected, most concentrations were less than current drinking-water standards and guidelines and aquatic-life guidelines; however, not all pesticides detected currently have drinking-water standards and guidelines. Samples from most streams in the Study Unit met Federal and State drinking-water standards and guidelines and aquatic-life guidelines. Invertebrate and fish communities were most degraded in urban streams.

- Nitrate concentrations in streams in artificially drained agricultural areas exceeded the U.S. Environmental Protection Agency (USEPA) drinking-water standard of 10 mg/L (milligrams per liter) in about 20 percent of the samples.
- Insecticides and nonagricultural herbicides were detected most frequently in urban areas.
- Agricultural herbicides were detected in streams throughout the Study Unit.
- Urban streams have reduced invertebrate and fish species richness and diversity compared to agricultural streams.
- Algal productivity was greater in agricultural streams than in urban and forest streams, due in part to greater concentrations of nutrients.
- Agricultural streams with wooded riparian cover had greater fish and invertebrate species richness and diversity than agricultural streams lacking wooded riparian cover.

Land use and land cover in the Upper Mississippi River Basin study unit

Trends in Stream-Water Quality and Aquatic Biology

Assessing trends in water quality and aquatic biology is difficult because historical data sets are discontinuous and sampling objectives and analysis methods have varied. Some observable trends are increased nitrate concentrations, based on historical data, and decreased ammonia concentrations in streams in the TCMA during 1984–1993 primarily because of process changes at wastewater treatment facilities. Breakdown products of the pesticide DDT, the use of which was discontinued in the 1970's, are still detectable in fish, streams, and streambed sediment.

Major Influences on Streams and Aquatic Biology

- Application of pesticides and fertilizers in agricultural and urban areas
- Discharges from wastewater treatment facilities
- Runoff from agricultural and urban areas
- Stream modifications and artificial drainage
- Destruction of riparian cover along streambanks
- Contaminants in precipitation and in the atmosphere

Highlights of Conditions in Ground Water

Shallow ground water in the TCMA (less than 50 feet below land surface) commonly contained pesticides, nutrients, and industrial chemicals and detectable concentrations of numerous volatile organic compounds (VOCs). Deeper ground water, typically used for public supply (water supplied for the general public by municipal and private purveyors), contained few pesticides and lower nitrate concentrations. With the exception of naturally occurring radon, deeper ground water met drinking-water standards and guidelines for most chemicals.

- Nitrate concentrations in water from nearly one-half of shallow ground water sampled beneath agricultural areas exceeded the USEPA drinking-water standard (10 mg/L).
- Road salt constituents (sodium and chloride) were detected at greater concentrations in shallow ground water underlying urban areas than other areas.
- Agricultural pesticides were commonly detected in all land-use settings. Concentrations were greatest in agricultural areas.
- Atrazine was the most frequently detected agricultural pesticide. Concentrations were greater in shallow ground water than in deeper ground water.

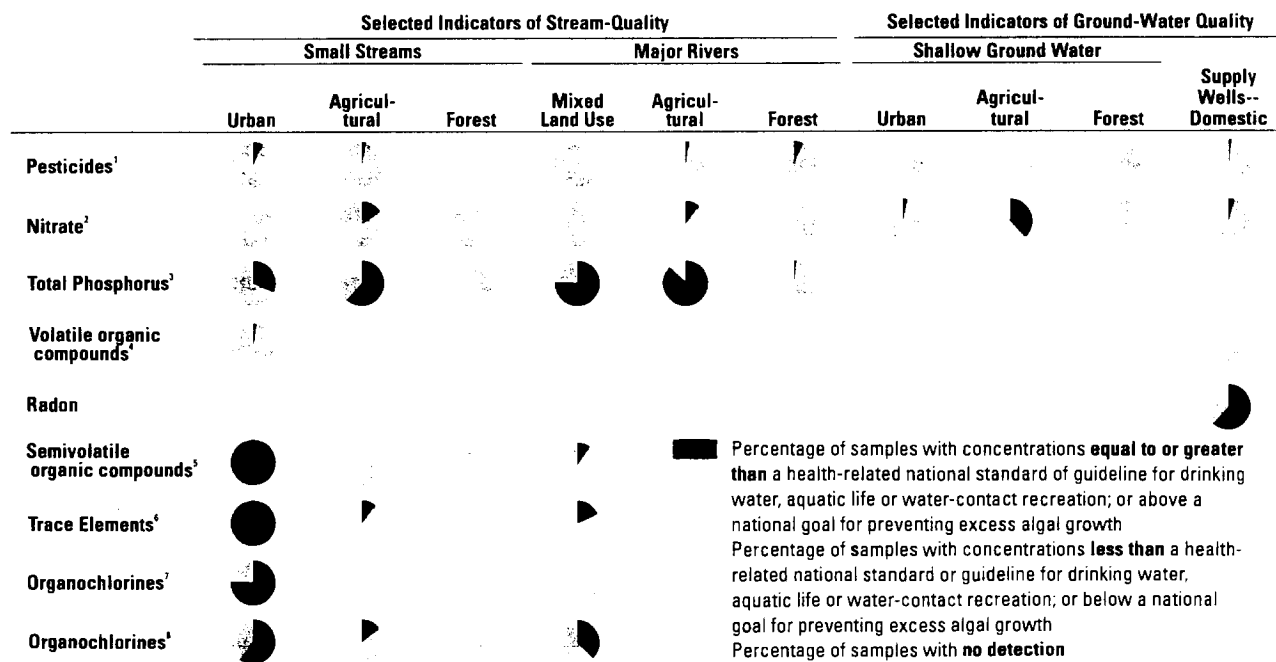

- Prometon was the most frequently detected herbicide in urban areas.
- Ground water in the Prairie du Chien-Jordan aquifer, an important source of drinking water, is protected by overlying confining units in some areas. Concentrations of nitrate, atrazine, and VOCs were lower in these areas than where confining units were absent.
- Radon exceeded the USEPA suspended drinking water standard of 300 pCi/L (picocuries per liter) in more than one-half of the water samples from the Prairie du Chien-Jordan aquifer.

Trends in Ground-Water Quality

Temporal trends in ground-water quality are difficult to define because limited information exists. Spatial trends include greater nitrate and pesticide concentrations in agricultural areas, greater VOC concentrations in urban areas, and few detections of pesticides or VOCs in forested areas.

Major Influences on Ground Water

- Application of pesticides and fertilizers
- Confining units and depth to water
- Urban contaminants (road salts, VOCs)
- Naturally occurring radon gas

¹Insecticides, herbicides, and pesticide metabolites, sampled in water. ²Nitrate (as nitrogen), sampled in water. ³Total phosphorus, sampled in water. ⁴Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water. ⁵Byproducts of fossil-fuel combustion or components of coal and crude oil, sampled in sediment. ⁶Arsenic, mercury, and metals, sampled in sediment. ⁷Organochlorine compounds including DDT and PCBs, sampled in sediment. ⁸Organochlorine compounds including DDT and PCBs, sampled in fish tissue.

INTRODUCTION TO THE UPPER MISSISSIPPI RIVER BASIN

The Upper Mississippi River Basin Study Unit (Study Unit) includes the drainage of the Mississippi River from its source at Lake Itasca, Minnesota, and its major tributaries (the St. Croix and Minnesota Rivers) to the outflow of Lake Pepin, Minnesota (fig. 1). Natural and human factors (climate, hydrology, geology, water use, land use, and land cover) affect surface- and ground-water quality, and aquatic biology in rivers and streams.

Natural Factors Affect Water Quality and Aquatic Biology

Differences in precipitation, evaporation, evapotranspiration, air temperature (fig. 1), and drainage basin characteristics (drainage area, slope, geology, and the capacity of soils to transmit water) affect hydrology and water quality. These differ most from southwest to northeast. Mean annual runoff, which is related to precipitation and evaporation, ranges from less than 2 inches in the headwaters of the Minnesota River to greater than 14 inches in the headwaters of the St. Croix River.

The range from minimum to maximum streamflow is greatest in spring and early summer as a result of rain and melting snow. Streamflow variation is greatest during late summer and fall, when precipitation ranges from drought conditions to locally heavy rains (fig. 2). Streamflow varies least during winter, when ground-water discharge to streams is dominant. During the period of sampling (1996–98), precipitation was greater than the 30-year average, resulting in increased runoff and streamflow. As a result, the amount of sediment, nutrients, pesticides, and other contaminants reaching streams may have been

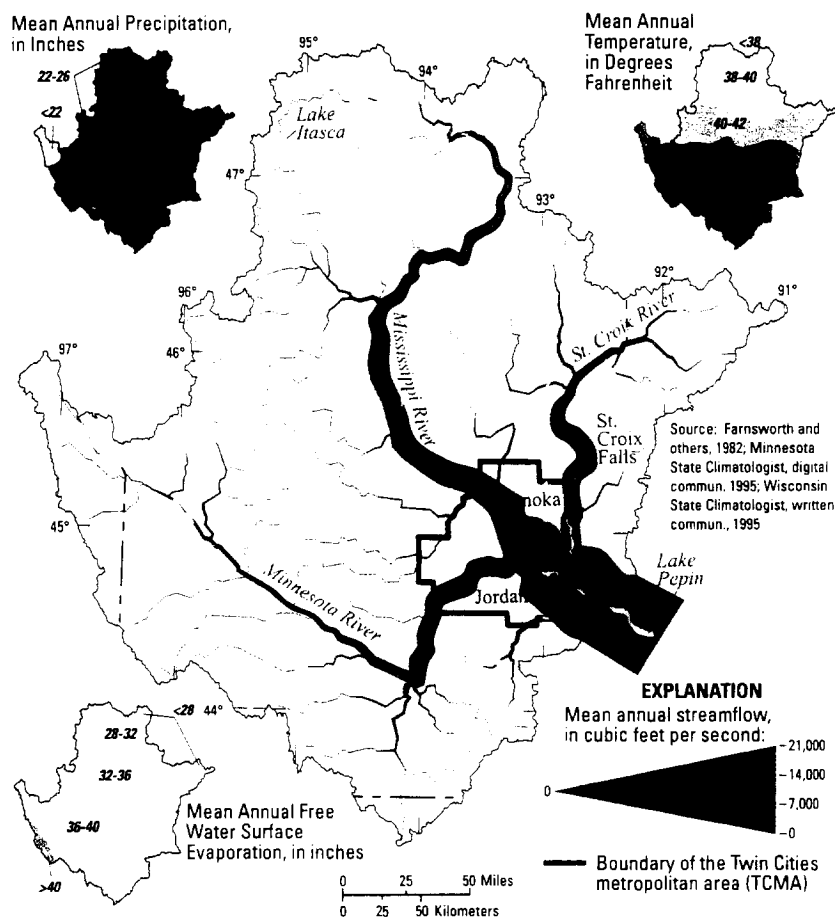

Figure 1. Climatic variables such as precipitation, temperature, and evaporation affected streamflow in the Study Unit, 1961-90.

greater than during periods of normal streamflow.

Water quality is also affected by geologic materials. Most streams in the Study Unit drain the Central

Lowland physiographic province, which is underlain by clay-rich, calcareous (calcium carbonate) glacial deposits (fig. 3). Fewer streams drain the Superior Upland physio-

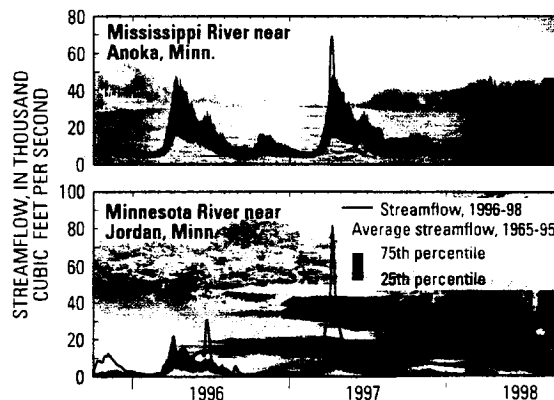

Figure 2. Streamflow during the sampling period (1996-98) in the large rivers in the Study Unit differed from their 30-year average, 1965-95.

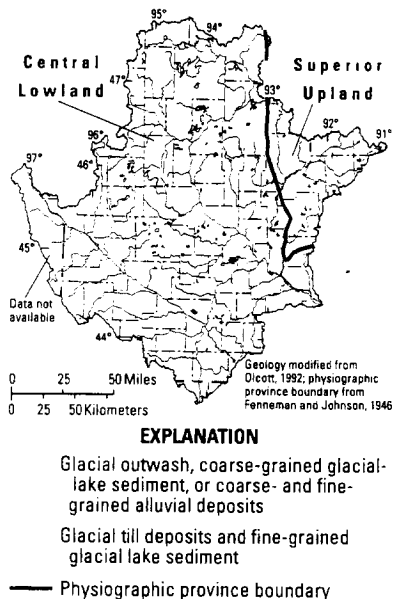

Figure 3. Surficial geology and physiographic provinces can affect water quality in the Study Unit.

graphic province, which is primarily underlain by siliceous (rich in silica), sandy glacial deposits. Water in streams draining the Central Lowland generally has greater alkalinity and greater concentrations of suspended sediment than water in streams draining the Superior Upland.

Human Activities Affect Water Quality and Aquatic Biology

The greatest effects on hydrology, water quality, and aquatic biology occur in areas with the greatest human population densities or where disruption to the natural land cover is substantial. The population of the Study Unit in 1990 was about 3.7 million—16-percent increase from 1970. Seventy-five percent of those people reside in the TCMA.

Land use and land cover in the Study Unit can be categorized into three zones: an agricultural zone across the southwest, a forested

zone across the northeast, and a transitional zone between these areas (fig. 4). About 63 percent of the Study Unit is agricultural (cropland and pasture). The remaining land use and land cover consists of forests (about 22 percent), water and wetlands (about 13 percent), urban (about 2 percent), and other categories (less than 1 percent).

The uses of water and the disposal of wastewater also can affect water quality and streamflow. Based on data from 1990, a daily average of 413 Mgal/d (million gallons of water

per day) was used for public supply (including drinking water) in the Study Unit—59 percent from ground water and 41 percent from surface water (fig. 5). The total of all water used for public supply is equal to about 7 percent of the average streamflow of the Mississippi River upstream from the TCMA, near Anoka, Minn. Wastewater is discharged to streams from about 270 facilities located throughout the Study Unit (Kroening and Andrews, 1997).

Figure 4. Land use and land cover can be categorized into three general zones in the Study Unit.

Figure 5. Ground water supplies the majority of the public drinking water in the Study Unit in 1990. (* Total refers to the combination of surface and ground water in each category.)

MAJOR FINDINGS

This report presents work by the U.S. Geological Survey's National Water-Quality Assessment Program to assess the quality of the Study Unit's water and aquatic resources (fig. 6). The report summarizes historical data and Study Unit data collected during 1995-98.

Land Use Influences Water Quality and Aquatic Biology

Point and nonpoint sources of nutrients, sediments, metals, and organic compounds from industrial, agricultural, and urban land uses are important water-quality issues in the Study Unit. Degradation of streams, including the loss of riparian habitat, reduction in fish populations, loss of habitat for bottom-dwelling organisms, eutrophication, and deterioration of the sanitary quality of streams is also important. Additional issues

include the introduction of toxic substances, such as organic compounds and trace elements that accumulate in sediments and aquatic biota of the rivers. These contaminants can adversely affect the health of aquatic biota and may biomagnify in fish-eating birds and mammals.

Water-quality issues in the TCMA and other urban areas include surface-water contamination from urban runoff and discharge from industrial and wastewater treatment facilities and the introduction of toxic substances to ground water from industrial activities and nonpoint sources. In agricultural areas, including the Minnesota River Basin, water-quality degradation from artificial drainage systems and point and nonpoint sources of sediment, nutrients, and pesticides are of concern. Both urban and agricultural

land uses contribute to the impairment of habitat and eutrophication in the Mississippi River in and downstream from the TCMA. In forested areas, including the St. Croix River Basin and upper reaches of the Mississippi River Basin, water is generally of better quality than elsewhere in the Study Unit. Maintaining the quality of water in the St. Croix River Basin is a priority for the National Park Service and the States of Minnesota and Wisconsin (Minnesota Department of Natural Resources and others, 1995).

Water Quality and Aquatic Biological Conditions Remain Relatively Undisturbed in Forested Areas

White pine forests originally covered much of the upper parts of the St. Croix River Basin and the Mississippi River Basin. These forests were logged during the mid 1800s to early 1900s and are now covered by second-growth forests.

Land-cover disturbances in these forested areas have been minimal, although small farms and towns are common, as is increased development for recreation. Water quality in these forested areas has been affected by minor applications of herbicides at small farms, tree farms, and in lakes (for weed reduction); discharges of wastewater effluent; leaks from septic systems; local stream-channel disturbances from forestry; and localized draining of wetlands. These activities result in small increases in nutrient, pesticide, suspended-sediment, and bacteria concentrations relative to natural conditions. Water-quality and aquatic-biological conditions have probably been affected less by human activities in the forested areas than in other

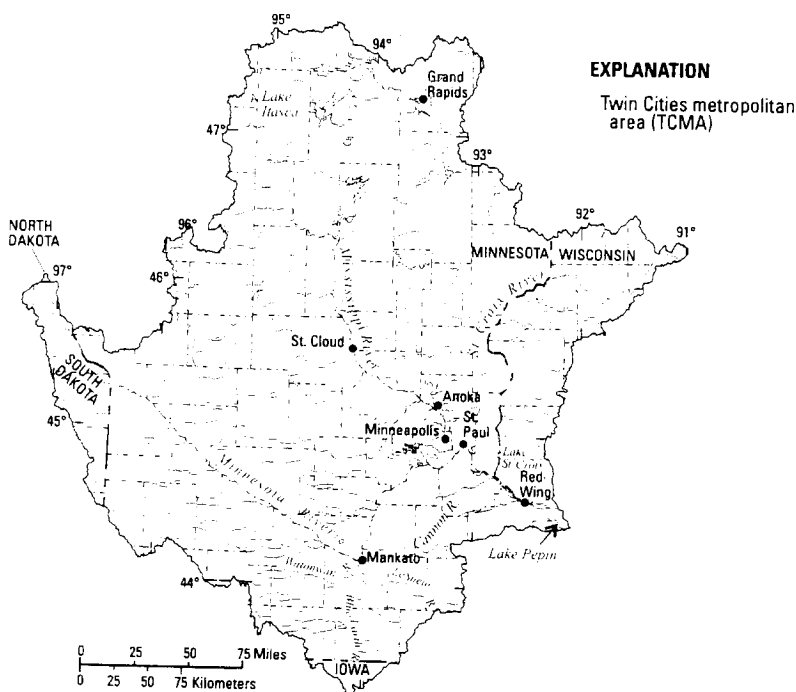

Figure 6. Upper Mississippi River Basin Study Unit, Twin Cities metropolitan area, major rivers and streams, and selected cities.

areas of the Study Unit. Nutrients and pesticides did not exceed drinking-water standards and guidelines for human consumption in streams and in ground water in forested areas. Nitrate and phosphorus yields were low in streams in forested areas (table 1). Suspended-sediment concentrations, which can contribute to degraded water quality and habitat, also were low in streams draining forested areas compared to the rest of the Study Unit.

Table 1. Nitrate and phosphorus yields in pounds per square mile per year in forest streams, 1996-98

STREAM	NITRATE	PHOSPHORUS
Namekagon River	260	— ^a
St. Croix River	160	50

^aYield was not calculated because concentrations were below the analytical reporting limits.

Pesticides were periodically detected in streams and in shallow ground water in forested areas, but concentrations and detection rates were lower than in the rest of the Study Unit (Fallon and others, 1997; Fong, 2000). Trace-element concentrations in streambed sediments corresponded to the composition of the surficial glacial deposits (Kroening and others, 2000). For example, increased concentrations of copper in the forested areas are attributed to naturally occurring sources. Although bacteria concentrations in streams in forested areas were below the USEPA criterion for swimming (Kroening, 1999; U.S. Environmental Protection Agency, 1986), these waters would not be suitable for human consumption without treatment because bacteria counts may occasionally exceed USEPA drinking-water standards.

Physical modifications to streams, such as stream dredging or channelization, have been minimal in forested areas of the Study Unit.

Consequently, aquatic communities are rich and diverse. Streams generally are more shaded than streams in other parts of the Study Unit, resulting in cooler water temperatures. Greater shading, cooler water, and lower concentrations of nutrients may limit algal productivity in these streams draining forested land. Algal communities in forest streams consist of species such as diatoms that are indicative of low nutrient and suspended-sediment concentrations.

Forests dominate the northern portion of the Study Unit. (Photograph courtesy of the National Park Service.)

Increased urbanization and development for recreation contribute to degraded water quality and aquatic life. Management practices that could benefit the quality of streams in these areas include restoration of natural wetlands and riparian vegetation. Eliminating these practices would improve stream habitat and hydraulic conditions and improve the diversity of fish and invertebrate communities.

Many programs and water-quality regulations are in place or are being considered to protect the quality of water in these areas, particularly in the St. Croix River Basin. One example is an effort to restrict increases in phosphorus to the St. Croix River to prevent excessive algal growth in Lake St. Croix (Holmberg and others, 1997).

Agricultural Activities Increase Nutrient and Pesticide Concentrations in Ground Water and Streams and Degrade Aquatic Biological Conditions

Agricultural areas of the Study Unit (fig. 4) include most of the Minnesota River Basin and parts of the Mississippi and St. Croix River Basins. In these areas, much of the land is used for production of row crops, primarily corn and soybeans. Many streams in agricultural areas have been straightened, ditches excavated, and land is commonly cultivated close to the streambanks. Most wetlands in agricultural areas have artificial drainage systems to increase crop production. Agricultural activities disrupt riparian zones in streams, contributing to erosion and runoff of agricultural chemicals and sediment.

Cultivation of land close to streams, artificial drainage, and stream straightening degrade water quality and aquatic habitat. (Photograph by James D. Fallon.)

Nutrient concentrations in surface water and ground water (much of which eventually discharges to streams) were greater in agricultural areas than in other parts of the Study Unit (Payne, 1994; Kroening and Andrews, 1997; Ruhl and others, 2000). Commercial fertilizers and animal manure applied to agricultural

land are sources of nutrients to streams and ground water (Kroening, 1998b; Ruhl and others, 2000). Nutrients that reach streams through artificial drainage or runoff accelerate the growth of algae and aquatic plants, resulting in eutrophication and diminished dissolved oxygen concentrations. In addition to affecting aquatic species, eutrophication also can cause taste and odor problems in water for domestic use.

Nitrate concentrations in streams draining the southern and southeastern parts of the Study Unit,

most notably in the Blue Earth, Le Sueur, and Watonwan Rivers (Payne, 1994), have exceeded the drinking-water standard of 10 mg/L set by the USEPA to prevent methemoglobinemia in infants. Greater than one-half of the samples collected by Payne (1994) exceeded that drinking-water standard. Nitrate yields were greatest in agricultural streams (table 2). Nitrate yields were about 10 times greater in streams draining artificially drained, fine-grained surficial geologic deposits compared to streams draining coarse-grained

deposits (Kroening, 1998a). Nitrate concentrations in shallow ground water are also greatest in the agricultural part of the Study Unit, and generally increased with the intensity of the agricultural activity and decreased with the water-table depth below land surface (Ruhl and others, 2000). (see "Nitrate in a National Context")

Table 2. Nitrate and phosphorus yields in pounds per square mile per year in agricultural streams, 1996-98

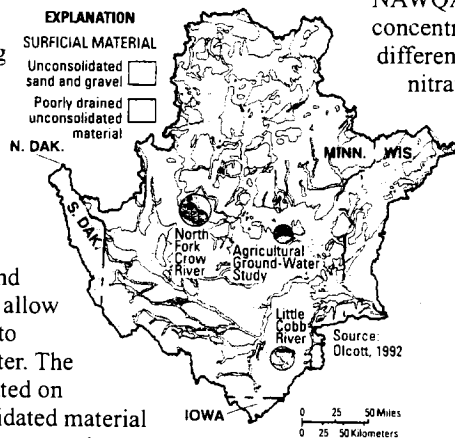

STREAM	NITRATE	PHOSPHORUS
North Fork Crow River	1,400	190
Little Cobb River	15,000	330

NITRATE IN A NATIONAL CONTEXT--CONCENTRATIONS RELATE TO HYDROGEOLOGY AND AGRICULTURAL DRAINAGE IN THE STUDY UNIT

Nitrate concentrations in the Study Unit are related to hydrogeologic setting and agricultural drainage. The application of commercial fertilizers and manure are sources of nitrate in streams and ground water. In general, nitrate concentrations in water are greatest in agricultural areas throughout the Nation (U.S. Geological Survey, 1999) including the Upper Mississippi River Basin. Yet, within agricultural areas within the Study Unit, nitrate concentrations vary due to the hydrogeologic setting.

Two rivers draining agricultural land in the Study Unit were frequently sampled for nitrate (1996-98). The North Fork Crow River is located in an area underlain by unconsolidated, coarse-grained sand and gravel deposits, that allow water and contaminants to infiltrate into ground water. The Little Cobb River is located on poorly drained unconsolidated material that limits the ability of water and contaminants to infiltrate into ground water. Artificial drainage systems (ditches and tiles) have been installed throughout these poorly drained soils to improve agricultural production. These systems also result in more direct transport of contaminants to nearby streams.

Although nitrate application rates from fertilizer and manure were similar in both river basins, nitrate concentrations in the streams were different. The nitrate concentration in the naturally well-drained North Fork Crow River was less than the national average for agricultural streams. In contrast, artificial drainage in the Little Cobb River Basin has contributed to nitrate concentrations in the stream, which rank among the top 2 percent of all streams sampled in the NAWQA Program. Differences between the nitrate concentrations in these two streams (see graph) reflect differences in their hydrogeologic settings. Although nitrate concentrations were low in streams draining surficial sand and gravel deposits, concentrations were greater in ground water--much greater than the national median. (see graph.)

To maintain water quality in streams and ground water, best management practices could include consideration of hydrogeologic setting.

Phosphorus concentrations exceeding the goal of 0.1 mg/L recommended by the USEPA (1986) to prevent eutrophication were measured in agricultural streams (Kroening, 2000). Results from routine sampling showed this concentration was exceeded more frequently (about 75 percent of the samples) in streams fed by artificially drained soils that developed on fine-grained materials than in streams draining coarse-grained materials (about 30 percent of samples). Phosphorus yields were greatest in agricultural streams (table 2). Phosphorus yields were approximately 1.7 times greater in streams draining artificially drained, fine-grained surficial deposits than in streams draining coarse-grained deposits.

Median suspended-sediment concentrations typically ranged from 60 to 120 mg/L in agricultural streams (Kroening, 2000). Suspended-sediment concentrations were greater in streams in artificially drained, fine-grained surficial deposits compared to streams draining coarse-grained deposits. Physical disturbances to stream morphology, hydrology, and instream habitat have been caused by stream straightening, removal of riparian vegetation, drainage of wetlands, and tile drainage systems (see "Riparian Cover and Runoff Potential Affect Aquatic Biology," and "Riparian Buffer Zones Affect the Quality of Midwestern Streams and Rivers," p. 9). These disturbances also contribute to increased concentrations of suspended sediment, relative to streams in other land-use settings.

Pesticides frequently were detected in streams and shallow ground water in agricultural areas

RIPARIAN COVER AND RUNOFF POTENTIAL AFFECT AQUATIC BIOLOGY

An investigation of 24 streams in the Minnesota River Basin during August 1997 determined that there were differences in fish- and invertebrate-community compositions due to both riparian cover and runoff potential (which increases when water infiltration decreases) (Stauffer and others, 2000; ZumBerge, 1999). An Index of Biotic Integrity (IBI--a measure of biological conditions based on several fish-community attributes), an Invertebrate Community Index (ICI--a measure of biological conditions based on several invertebrate community attributes), and species richness were used as measures of resource quality. Streams with wooded riparian cover had better IBI scores, ICI scores, and greater fish and invertebrate species richness than streams with open riparian cover indicating better resource quality. Streams with low runoff potential had better IBI scores, ICI scores, and fish species richness than streams with high runoff potential.

These results suggest that streams with wooded riparian cover had greater resource quality as indicated by fish and invertebrate community measures.

(Fallon and others, 1997; Fallon, 1998; Ruhl and others, 2000). Few concentrations exceeded applicable drinking-water standards and guidelines or aquatic-life guidelines. Herbicides were detected more

frequently than insecticides. Pesticide concentrations in streams typically were greatest from May to July (Fallon and others, 1997). Ground-water samples with detections of one or more pesticides usually coincided with areas of shallow ground water close to the land surface (Hanson, 1998; Ruhl and others, 2000). Organochlorine insecticides were detected in fish tissue but not in streambed sediment (fig. 7, and see "Concentrations of Degradation Products of Agricultural Herbicides were Greater than Their Parent Compounds in Little Cobb River Near Beauford, Minn., 1997," p. 10).

Algal, invertebrate, and fish communities have likely been affected by agriculture. Increased nutrients in agricultural streams have resulted in greater algal abundance and primary production. Algal communities were composed of a large proportion of blue-green algae that are commonly associated with high nutrient concentrations and are not suitable food sources for invertebrates (Kroening, 2000; Lee and ZumBerge, 2000). Contaminants from agricultural practices have likely affected invertebrate communities, which were moderately diverse and composed of mayflies and caddisflies that are relatively sensitive to contaminants. Total fish biomass was high in agricultural streams, probably in response to greater algal abundance and productivity. Although suspended-sediment concentrations were greater in the agricultural streams than in streams in other land-use settings, the presence of fish species such as stonecat and smallmouth bass indicate good water quality in terms of clarity (Goldstein and others, 1999).

RIPARIAN BUFFER ZONES INFLUENCE THE QUALITY OF MIDWESTERN STREAMS AND RIVERS

Despite similar land use throughout the Corn Belt region of the Midwest, streams flowing through cropland differ considerably in their ecological characteristics, in part because of differences in riparian buffer zones (see text boxes). This conclusion is based on an investigation of 70 streams and rivers within three NAWQA Study Units in the upper Midwest during August 1997 (map shown at right; Sorenson and others, 1999; Porter and others, 2001). Specifically, increases in tree cover in buffer zones were associated with aquatic biological communities indicative of good stream quality, reduced nuisance algal growths, and maintenance of sufficient dissolved oxygen concentrations to support diverse communities of aquatic organisms. For example, the number of aquatic insects indicative of good stream quality tended to increase with increases in percentage of tree cover, especially in sites where streamflow and dissolved oxygen conditions were favorable. Fish communities, sampled at 24 sites in the UMIS Study Unit, also indicated better overall conditions in streams with wooded riparian zones than those with more open canopy (Stauffer and others, 2000).

The influence of riparian buffer zones on the quality of 70 midwestern streams and rivers was evaluated in the Upper Mississippi River (UMIS), Eastern Iowa (EIWA), and Lower Illinois River Basins (LIRB).

Streams with less tree cover, and thus less shading, contained relatively large growths of phytoplankton (algae suspended in the water) at levels considered indicative of eutrophication (Porter, 2000). Organic enrichment

resulting from excessive algal production in some midwestern streams may reduce dissolved oxygen concentrations and be detrimental to other requirements of aquatic organisms.

Shading from tree cover in riparian buffer zones may influence nutrient concentrations indirectly by reducing the growth of phytoplankton. In streams where phytoplankton were abundant (often where buffer zones were thin or lacking), dissolved nitrate concentrations were significantly lower (graph shown below; Porter, 2000). The lower nutrient concentrations may result from uptake by the abundant phytoplankton. Thus, assessments of eutrophication would benefit from consideration of biological communities and the riparian zone, rather than being based solely on nutrient concentrations in the water.

Dissolved nutrient concentrations decreased in eutrophic streams with excessive algal productivity. Rates of nutrient uptake by the algae can exceed rates at which nutrients are transported by streams during low-flow conditions.

Digital images derived from USGS topographic maps were used to estimate the percentage of trees in a riparian buffer zone (a 100-meter width on each side of the stream) for 2- to 3-mile segments upstream from each sampling site, supplemented by vegetation surveys at the sampling site (Sorenson and others, 1999).

Resource agencies, including the U.S. Department of Agriculture, encourage maintenance of strips of trees or grass between cropland and streams as a best management practice. These "riparian buffer zones" are thought to intercept runoff of sediment and chemicals from fields, promote bank stability, and provide shading and habitat for aquatic life (Osborne and Kovacic, 1993). Riparian buffer zones should be considered along with other important factors that affect chemical and biological indicators of stream quality, such as soil drainage properties and stream hydrology (Porter and others, 2001).

Figure 7. Atrazine and its degradation product deethylatrazine were the most frequently detected pesticides in streams and shallow ground water in agricultural areas in the Study Unit.

CONCENTRATIONS OF DEGRADATION PRODUCTS OF AGRICULTURAL HERBICIDES WERE GREATER THAN THEIR PARENT COMPOUNDS IN LITTLE COBB RIVER NEAR BEAUFORD, MINNESOTA, 1997

Eight degradation products (metabolites) of four commonly used agricultural herbicides (acetochlor, alachlor, atrazine, and metolachlor) were detected in samples collected from the Little Cobb River, an agricultural stream. Summed metabolite concentrations were always greater than summed parent compound concentrations. Metabolite concentrations were least during the fall and greatest during the summer. Four metabolites were present year round at substantial concentrations (metolachlor-ethane sulfonic acid and metolachlor-, acetochlor-, and alachlor-oxanylic acid). The affects of these metabolites on aquatic and human health are not known, their persistence and relatively high concentrations are a cause for concern.

Water Quality and Aquatic Biological Conditions are Adversely Affected in Urban Areas

The intensity of development in urban areas has adversely affected the quality of streams and ground water. Nonpoint-source contaminants to surface and ground water in urban areas originate from automobiles, road de-icing chemicals, construction, application of pesticides and fertilizers, atmospheric deposition, street debris in urban stream-water runoff, and animal and plant refuse (Hambrook and others, 1997). Major sources of contamination to ground water include spills or improper disposal of industrial or manufacturing chemicals, leachate from solid-waste landfills, and spills and leaks from petroleum storage areas and pipelines (Minnesota Pollution Control Agency, 1986).

Minneapolis, Minn., the largest city in the Study Unit. (Photograph by Scott Murray Photography.)

Several factors can affect the occurrence and distribution of contaminants in surface and ground water in urban areas. Factors affecting urban streams include impervious surfaces, drainage of wetlands, construction of detention ponds, loss of riparian cover, and stream-channel modifications (Riley, 1998). Impervious surfaces cause greater peak streamflow rates of shorter duration from runoff than would occur naturally, and increase transport of contaminants from

streets and parking lots to streams (Riley, 1998). These factors can increase water temperature and degrade habitat and water quality. Average water temperature in TCMA streams increased as the percentage of impervious surface increased (Talmage and others, 1999). Concentrations of nutrients, trace elements, chloride, sodium pesticides, and counts of bacteria were frequently greater in urban streams than those that occur naturally and may inhibit growth, reproduction, and diversity of aquatic biota (Klein, 1979; Pope and Putnam, 1997). Factors affecting shallow ground-water quality

include the composition of surficial material and depth to ground water. Sand and gravel surficial materials increase infiltration and impervious surfaces decrease infiltration to ground water. Shallow ground-water quality generally improves with depth.

Streams and ground water in shallow aquifers in the TCMA contained elevated concentrations of sodium and chloride (Andrews and others, 1998), a result of the application of road de-icers. (see "Chloride in a National Context")

Chloride concentrations in urban streams (Fallon and Chaplin, 2001) frequently exceeded the aquatic-

life criterion of 230 mg/L (U.S. Environmental Protection Agency, 1999). Chloride concentrations were greater in streams with greater percentages of impervious surfaces and may have adversely affected fish diversity. (see "Urbanization Affects Fish Communities and Water Quality in Urban Streams of the Study Unit," p. 12)

All nitrate concentrations in streams were less than the USEPA drinking-water standard of 10 mg/L (Kroening, 1998a, 2000). Less than 10 percent of nitrate concentrations in ground water exceeded the standard (Andrews and others, 1998; Fong and others,

CHLORIDE IN A NATIONAL CONTEXT-- CONCENTRATIONS ARE GREATEST IN NORTHERN URBAN AREAS

Chloride concentrations in urban streams of the Study Unit were substantially greater than in most urban streams sampled throughout the Nation. Median chloride concentrations in ground water overlain by urban areas in the Study Unit were also greater than the national median, although not substantially. Elevated chloride concentrations result from runoff of de-icing chemicals applied to roads and highways during winter storms (Granato, 1996). Because winter conditions are similar across the North-Central and Northeastern United States, the greater median chloride concentrations in other northern study units may also be at least partly the result of de-icing compounds. Sodium chloride (salt) is the primary de-icing compound applied to roads and highways in the Study Unit (Minnesota Department of Transportation, electronic commun., 2000). The environmental setting of the urban portion of the Study Unit, much of it covered with permeable sandy soils, wetlands, and lakes, may allow chloride to be more readily transported to and stored in lakes, wetlands, and shallow ground water (where chloride can persist) as well as being flushed directly to streams. Talmage and others (1999) reported that chloride concentrations were positively correlated with impervious areas (buildings and paved surfaces) in 13 urban streams of the Study Unit. The source of elevated chloride concentrations in urban streams in arid study units are likely from naturally occurring salts concentrated by the evaporation of surface water (Hem, 1992).

Whereas de-icers are applied to roads in other study units throughout the Nation, concentrations in streams and ground water in this Study Unit are likely greater for several reasons. The amount of snowfall and seasonal duration of subfreezing temperatures may be greater in the Study Unit than most other study units. De-icing compounds other than sodium chloride may be used in other study units.

Many samples had chloride concentrations that exceeded the aquatic-life criteria established by the U.S. Environmental Protection Agency (1999). Elevated chloride concentrations in streams may affect biological communities by altering the species composition. Urban streams in the Study Unit were dominated by fish and invertebrate species that are tolerant to degraded physical and chemical conditions, compared to other streams in the Study Unit.

EXPLANATION
Median concentration in urban streams, in milligrams per liter (mg/L)

100.0 - 185.0
40.0 - 99.9
10.0 - 39.9
0.0 - 9.9

URBANIZATION AFFECTS FISH COMMUNITIES AND WATER QUALITY IN URBAN STREAMS OF THE STUDY UNIT

Water quality, instream habitat, and fish-community composition were characterized at urban streams of the Study Unit during low-flow conditions, September 1997. The density of impervious cover (roads, parking lots, and rooftops) generally increases as population density increases and was used as a measure of urbanization. Nutrient and pesticide concentrations were generally low, rarely exceeding concentrations found in agricultural streams. Nutrient concentrations did not change with the percentage of impervious area. In contrast, chloride (fig. a) and sodium (fig. b) (used for road de-icing) concentrations were generally elevated in urban streams and increased as the percentage impervious area increased.

Fish communities within most urban streams were characterized by species that are tolerant to degraded physical and chemical conditions, such as the central mudminnow, fathead minnow, and black bullhead. There were, however, differences in the fish communities among streams. Two measures of community health--the species richness and diversity--decreased as the percentage of impervious area increased (figs. c and d). Factors associated with impervious cover, such as reduced instream habitat, presence of contaminants in water and sediment, alterations to stream channels, and migration barriers, may directly affect fish-community composition.

Concentrations of chloride (a) and sodium (b) in relation to percentage of impervious surface in urban streams of the Study Unit, September 1997

Species richness (c) and diversity (d) in relation to percentage of impervious surface in urban streams of the Study Unit, September 1997

1998). Nitrate and phosphorus yields in urban streams (table 3) were less than in agricultural streams (table 2) and greater than in forest streams (table 1). About 30–37 percent of the total phosphorus concentrations in urban streams exceeded the USEPA's water-quality criterion of 0.1 mg/L (Kroening, 1998a, 2000). The greatest concentrations of nitrate in ground water were from samples of shallow ground water (unconfined surficial sand and gravel aquifers) (Kroening and Andrews, 1997). Areas with the greatest concentrations of nitrate are related to aquifer susceptibility and overlying land use. Nitrate concentrations tend to decrease with increased well depth (Hanson, 1998).

Table 3. Nitrate and phosphorus yields, in pounds per square mile per year in streams in urban areas, 1996-98

Stream	Nitrate (lb/sq mi/yr)	Phosphorus (lb/sq mi/yr)
Shingle Creek	400	130
Nine Mile Creek	510	140

Dissolved-oxygen concentrations in most urban streams usually were greater than the minimum 5 mg/L aquatic-life criterion (U.S. Environmental Protection Agency, 1986) necessary for the protection of aquatic life. Dissolved-oxygen saturation in urban streams during the growing season was generally greater than forest streams and less than agricultural streams.

Pesticides were frequently detected in urban streams and shallow ground water (fig. 8); however, concentrations seldom exceeded

applicable standards or guidelines (Andrews and others, 1998). Concentrations in shallow ground water were generally less than in surface water (Fallon and others, 1997; Andrews and others, 1998). Factors affecting pesticides in surface and ground water include land use, application methods, and atmospheric transport and deposition. In streams and shallow ground water, herbicides commonly used on road rights-of-way were detected (prometon and tebuthiuron), as were agricultural herbicides (atrazine and metolachlor). Insecticides were detected in almost 50 percent of stream water samples (Fallon, 1998) but in less than 5 percent of ground-water samples (fig. 8).

Volatile organic compounds (VOCs) were detected in surface and shallow ground water in the urban part of the Study Unit (fig. 9) (Andrews and others, 1995 and 1998). Some VOCs are suspected carcinogens and may be toxic to humans and wildlife. Although many VOCs were detected in urban streams, concentrations generally were below applicable standards and guidelines. The greatest concentrations occurred in stormwater runoff and winter low flows. The most frequently detected VOCs are components of petroleum products and by-products of petroleum combustion. These VOCs are contributed to streams from engine emissions to the atmosphere and from oil and gasoline leaks from vehicles to parking lots and roadways.

Other contaminants such as polycyclic aromatic hydrocarbons (PAHs), organochlorine compounds (OCs), and trace elements are common in urban streams, frequently at concentrations greater than aquatic-life guidelines (McNellis and others, 2000; Talmage and others, 1999) (see "Organic Contaminants in a National Context"). Urban activities and discharges also contribute to increased concentrations of trace elements (particularly cadmium, copper, lead, and zinc) in some urban streambed sediments. Elevated concentrations of some trace elements can be toxic to humans and aquatic life.

Fecal coliform counts differed widely among urban stream samples collected during September 1997, ranging from about 54 col/100mL (colonies per 100 mL) to more than 11,000 col/100 mL (Talmage and others, 1999). Fecal coliform counts at 8 of 13 sites

Figure 8. Pesticides typically used in agricultural areas were frequently detected in streams and ground water in urban areas in the Study Unit.

Figure 9. More volatile organic compounds (VOCs) were detected in Shingle Creek (an urban stream) than in the shallow ground water in the same land-use setting, indicating that many VOCs break down before infiltrating the shallow ground water.

ORGANIC CONTAMINANTS IN A NATIONAL CONTEXT: CONCENTRATIONS WERE GREATEST IN URBAN STREAMS IN THE STUDY UNIT

Polycyclic aromatic hydrocarbon concentrations in streambed sediment in urban areas are among the greatest in the Nation.

Six polycyclic aromatic hydrocarbon compounds (PAHs) were detected at concentrations above U.S. Environmental Protection Agency (USEPA) aquatic-life criteria. Some are known carcinogens and are toxic to aquatic life. These compounds are generally by-products of combustion of fossil fuels or the burning of wood. Concentrations of PAHs at sites in other land uses were 10 to 100 times less than those in urban areas.

Organochlorine detections are prevalent in urban areas. Some sites had concentrations greater than recommended for the protection of aquatic life or wildlife.

Streambed sediment and fish tissue were analyzed for organochlorine compounds (OCs). Although uses of the insecticide DDT for mosquito control and polychlorinated biphenyls (PCBs) for industrial applications were discontinued in the 1970s, these compounds were still detected in urban streambed sediment in the Study Unit. Twelve of the 13 OCs (insecticides and PCBs) detected in streambed sediment in the Study Unit were found at urban sites. Three OCs including DDT, DDT metabolites (DDE and DDD), and total PCBs were detected in fish tissue at all urban sites in the Study Unit. Total DDT and metabolites in streambed sediment exceeded USEPA water-quality guidelines. PCB concentrations in fish exceeded USEPA standards for wildlife that consume fish.

exceeded the State of Minnesota freshwater standard for recreational use (200 col/100 mL) (Minnesota Pollution Control Agency, 1991). The greater bacteria counts may indicate localized leaking sewer or septic systems or animal waste.

Relatively low nutrient concentrations, stream shading, and contaminants may lead to low algal production in urban streams (Lee and others, 1999). However, nutrient concentrations are a concern because urban streams commonly drain to lakes that are more sensitive to eutrophication. The warmer temperatures and longer residence times of the water in lakes allow greater algal productivity. Invertebrate taxa that indicate good water

quality, such as mayflies and stoneflies, were absent (see "Urban Biological Communities in a National Context"). Fish communities were characterized by a large proportion of species that can tolerate degraded water-quality conditions, such as central mudminnows and fathead minnows (Goldstein and others, 1999; Talmage and others, 1999). Factors that affect biological communities in urban streams include water and sediment chemistry and physical conditions such as hydrology and instream habitat.

Physical alterations, such as channelization and the high percentage of impervious area in urban basins, contribute to greater hydrologic variability (rapid

streamflow increases and decreases during storm events). Waterfalls and dams are common in urban streams in the Study Unit and may be barriers to fish migration (Talmage and others, 1999). Migration barriers can limit the total number of fish species.

Water Quality and Aquatic Biological Conditions have Characteristics Indicative of Dominant Land Uses

Sodium and chloride concentrations were greater in shallow ground water and streams in urban areas than in agricultural or forested areas. Chloride concentrations commonly exceeded the USEPA aquatic-life criteria of 230

URBAN BIOLOGICAL COMMUNITIES IN A NATIONAL CONTEXT- INVERTEBRATE COMMUNITIES REFLECT POOR RESOURCE QUALITY WITHIN URBAN STREAMS IN THE STUDY UNIT

Invertebrate communities indicated that the most degraded conditions occurred in 13 urban streams compared to 26 agricultural streams and 1 forest stream in the Study Unit. Urban streams were also among the most degraded in the Nation. Invertebrate communities in urban streams were composed of pollution tolerant species, such as true flies, with few sensitive species, such as mayflies and stoneflies.

Factors influencing invertebrate communities in urban streams may include elevated concentrations of PCBs, organochlorine pesticides (DDT, DDE and DDD), PAHs, and trace elements in streambed sediments. Concentrations of some of these compounds rank among the greatest in the Nation (McNellis and others, 2001; Kroening and others, 2000). In addition to chemical characteristics, modification to stream hydrology and removal of instream habitat may contribute to degraded conditions for aquatic communities in urban streams in the Study Unit.

Invertebrate Community Status Indicators (ICSI) scores were greatest in urban streams indicating poor aquatic resource (habitat and water) quality. The ICSI is a measure that summarizes species richness, tolerance, dominance, and trophic conditions, and that are associated with water-quality degradation. The indicator values increase with greater resource-quality degradation.

mg/L (Mitton and Payne, 1997; Fong, 2000; Fallon and Chaplin, 2001). Elevated sodium and chloride concentrations are the result of de-icers that are applied more heavily in urban areas.

Concentrations and yields of nutrients and suspended sediment in streams that drain agricultural areas were substantially greater than those that drain urban or forested areas (fig. 10). Increased nutrient concentrations have contributed to accelerated eutrophication and low dissolved-oxygen concentrations (Kroening, 2000), which adversely affect aquatic communities. Eutrophication has been most notable in the Minnesota River Basin. The greatest nitrate concentrations in the Minnesota River Basin were measured during rainfall runoff (Payne, 1994; Kroening and others, 2000). Exceedences of the USEPA drinking-water standard of 10 mg/L for nitrate occurred in less than 4 percent of urban and 38 percent of

agricultural ground-water samples, whereas nitrate was commonly undetected (less than 0.05 mg/L) in forested areas (fig. 11). Nitrate concentrations in shallow ground water increased with agricultural intensity, particularly in unconfined sand and gravel aquifers (Hanson, 1998), suggesting that underlying deeper aquifers, typically used for drinking water, have potential to be contaminated with nitrate (fig. 11) (Fong, 2000).

Figure 10. Nitrate yields were greatest in streams draining agricultural areas in the Study Unit.

Figure 11. Nitrate concentrations were greatest in ground water in agricultural areas of the Study Unit.

The pesticides detected differed by land use. Herbicides were the most frequently detected in surface and ground water. Atrazine and its degradation product, deethylatrazine, were detected in all land-use settings (Fallon and others, 1997; Fong, 2000). Prometon, a herbicide used on road rights-of-way, was the most frequently detected herbicide in ground water in urban settings (Andrews and others, 1998). Organochlorine concentrations in streambed sediment were substantially

greater in urban streams than in agricultural or forest streams (McNellis and others, 2001).

Volatile organic compounds were most commonly detected in urban areas. In ground water, the most frequently detected VOCs (carbon disulfide and chloromethane) were in shallow aquifers in urban areas, but at concentrations generally less than 1 µg/L (fig. 12) (Andrews and others, 1998). VOCs also were detected in ground-water samples from agricultural areas, but at concentrations and detection frequencies less than urban areas (Ruhl and others, 2000). In urban streams, the greatest concentrations of VOCs were detected following storm runoff and during winter low flows.

Figure 12. Total volatile organic compound concentrations were greatest in ground water in urban areas in the Study Unit.

Trace concentrations of PCBs and DDE (a degradation product of DDT) were detected in fish throughout the Study Unit (Biedron and Helwig, 1991). PCB concentrations in common carp fillet tissue have decreased at different rates in each land-use setting since their use was discontinued in the 1970s (Duffee, 1976) (fig. 13). Concentrations of these compounds were greater in fish and sediment from stream reaches near urban areas (Fallon and others, 1997; Lee and Anderson, 1998; McNellis and others, 2001).

Figure 13. Polychlorinated biphenyl concentrations in common carp filets collected from streams in the Study Unit have decreased since 1975.

Streambed-sediment concentrations of lead, zinc (fig. 14), cadmium, and copper were greater in urban areas than other land-use settings (Kroening and others, 2000). In streams draining agricultural and forested areas, trace-element concentrations in streambed sediment probably reflected natural geochemistry. Mercury concentrations in fish livers were greater in streams draining land uses other than urban settings (Kroening and others, 2000). Agricultural and urban activities contribute to elevated suspended-sediment concentrations and bacteria counts in small streams. Suspended-sediment concentrations were greatest in agricultural streams.

Figure 14. Lead and zinc concentrations were greatest in streambed sediments in urban areas in the Study Unit.

Aquatic biological communities are affected by chemical, hydrological, and physical conditions in streams and serve as good indicators of water quality. Community composition indicated more degraded con-

ditions in urban streams than in forest or agricultural streams (Lee and others, 1999; Talmage and others, 1999). Invertebrate communities in urban streams are composed of fewer mayflies, stoneflies, and caddisflies than streams draining agricultural and forested land (fig. 15) (Lee and others, 1999). Fish communities in urban streams were dominated by species tolerant of low dissolved-oxygen concentrations and warm temperatures (Goldstein and others, 1999; Talmage and others, 1999). Fish biomass and phytoplankton biovolume are indicators of stream productivity. The greatest fish biomass (usually in the form of species such as common carp) and phytoplankton biovolumes were measured in agricultural streams (fig. 16).

Figure 15. Total number of mayflies, stoneflies and caddisflies, indicators of good water-quality conditions, was greatest in streams draining forested areas in the Study Unit.

Figure 16. Phytoplankton biovolume and fish biomass were greatest in streams draining agricultural areas in the Study Unit.

Land Use Influences Water-Supply Aquifers

The Prairie du Chien-Jordan aquifer, which occurs in dolomite and sandstone of Cambrian to Ordovician age, is the principal bedrock aquifer throughout much of the Study Unit (fig. 17), supplying approximately 75 percent of the ground water withdrawn in the area for public and industrial supply. In certain areas, termed confined portion, bedrock or glacial deposits having low permeability overlie the aquifer. In other areas, termed unconfined portion, glacial sand and gravel deposits having greater permeability overlie the aquifer. The hydrogeologic characteristics of these overlying units affect the downward movement of water and contaminants from the land surface into the aquifer.

Water in the unconfined portion of the aquifer appears to be affected to a greater degree by human-related activities than water in the confined portion of the aquifer. Nitrate concentrations were greater in the unconfined portion of the aquifer. In the unconfined portion of the aquifer, nitrate in 8 percent of the wells sampled exceeded the USEPA drinking-water standard of 10 mg/L. In the confined portion of the aquifer, no samples exceeded 10 mg/L of nitrate. Phosphorus concentrations generally were about one-tenth of nitrate concentrations. In about 40 percent of water samples from confined and unconfined portions of the aquifer, concentrations of iron and manganese in water samples from confined and unconfined portions of the aquifer exceeded drinking-water guidelines.

Radon concentrations ranged from 100 to 2,700 pCi/L and

exceeded the suspended USEPA drinking-water standard of 300 pCi/L in 68 percent of the water samples from the unconfined portion of the aquifer and 64 percent from the confined portion of the aquifer. Tritium concentrations in ground water indicated that water in the unconfined portion of the aquifer was recharged more recently than water in the confined portion of the aquifer.

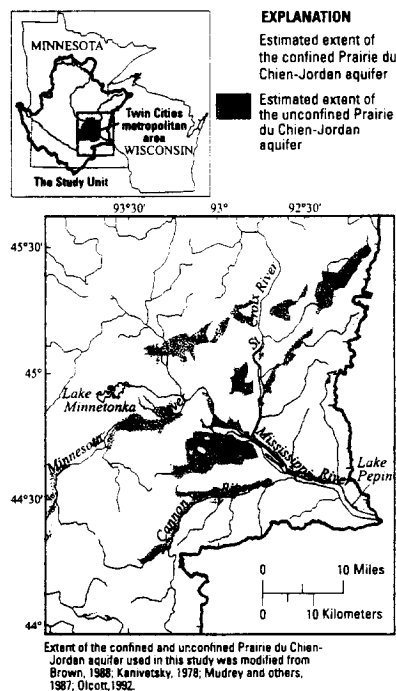

Figure 17. Estimated extent of the Prairie du Chien-Jordan aquifer in part of the Study Unit.

Arsenic concentrations in the confined and unconfined portions of the aquifer ranged from less than the method reporting limit (1 $\mu\text{g/L}$) to 7 $\mu\text{g/L}$. These concentrations do not exceed the current USEPA drinking-water standard of 50 $\mu\text{g/L}$.

Seven different pesticide compounds were detected in water samples. Atrazine and its degradation product, deethylatrazine, were most frequently detected. Atrazine was

detected in water from 36 percent of wells in the confined portion of the aquifer and 52 percent of wells in the unconfined portion of the aquifer. VOCs were detected in 82 percent of the water samples, but none at concentrations exceeding 1 $\mu\text{g/L}$. More VOCs were detected in water samples from the unconfined portion of the aquifer than from the confined portion.

Water Quality and Aquatic Biology of Large Rivers

Water quality and aquatic biology in the large rivers of the Study Unit (the Mississippi, Minnesota, and St. Croix) represent the cumulative quality of their tributaries. The tributaries of the Minnesota River drain primarily agricultural land, the tributaries of the St. Croix River drain primarily forested land, and the tributaries of the Mississippi River drain primarily agricultural and forested land. Because of agricultural activities and natural conditions, water in the Minnesota River contains elevated concentrations and yields of nutrients, suspended sediments, and pesticides (Fallon and others, 1997; Kroening, 2000). The aquatic biological community contains fewer invertebrate and algal taxa, but greater chlorophyll-*a* concentrations associated with greater nutrient concentrations (Kroening, 2000; Lee and ZumBerge, 2000) (fig. 18). In contrast, the St. Croix River and the Mississippi River upstream from the TCMA have low nutrient concentrations, relatively clear water, and low suspended-sediment and pesticide concentrations (Fallon and others, 1997; Fallon, 1998; Kroening, 2000). Downstream from the TCMA, and below the confluence of the Minnesota and St. Croix Rivers, water quality in

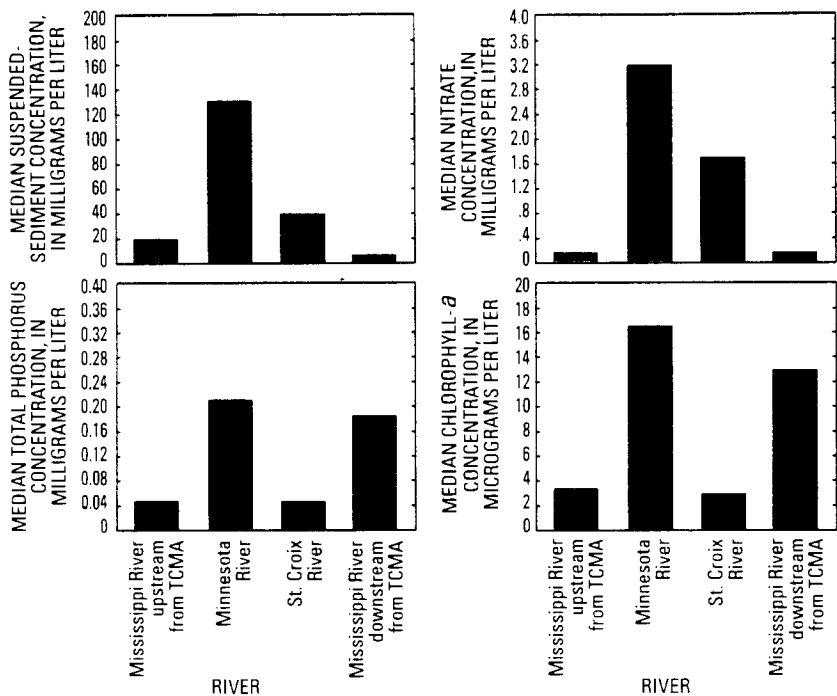

Figure 18. Median concentrations of nitrate, total phosphorus, suspended sediments, and chlorophyll-a were generally lower upstream from the Twin City Metropolitan Area (TCMA) and were greatest in the Minnesota River.

the Mississippi River results from a complex mixture of water and chemical constituents. Concentrations of nutrients, suspended sediments, and pesticides in the Mississippi River increase at the confluence with the Minnesota River and decrease slightly, due to dilution downstream from the confluence with the St. Croix River (fig. 19) (Fallon, 1998; Kroening, 2000).

Aerial view of the confluence of the St. Croix and the Mississippi Rivers. (Photograph by James R. Stark.)

Nitrate concentrations in the Mississippi and St. Croix Rivers did not exceed the USEPA drinking-water standard of 10 mg/L

(Kroening, 1998a, 2000). Eleven percent of the samples from the Minnesota River near Jordan, Minn., exceeded the standard. The most noticeable trends in the Mississippi, Minnesota, and St. Croix Rivers during 1984–93 were an increase in nitrate concentrations and a decrease in total ammonia concentrations in the TCMA (fig. 20) (Kroening and Andrews, 1997). These trends were not observed at other sites. These ammonia reductions are probably the result of nitrification processes used at the three largest wastewater treatment facilities in the TCMA, which convert ammonia-nitrogen to nitrate. This process has resulted in wastewater effluents that are less toxic to fish and other aquatic life. Nitrate concentrations, however, may contribute to eutrophication.

Total phosphorus concentrations in parts of the Minnesota River and in the Mississippi River downstream from the TCMA frequently exceeded the USEPA guideline of 0.1 mg/L to prevent eutrophication

Figure 19. Total nitrogen and phosphorus concentrations in the Mississippi River increase downstream from the confluence of the Minnesota River and decrease downstream from the confluence of the St. Croix River.

Figure 20. Modifications in wastewater-treatment processes have changed measured total nitrate and total ammonia nitrogen concentrations in the Mississippi River at Newport, Minn.

(Kroening, 1998b, 2000). Phosphorus concentrations and loads to the rivers originate from both point and nonpoint sources. The major point sources are wastewater treatment facilities, whereas the major nonpoint sources are from agriculture in the Minnesota River Basin. During low streamflow conditions, more phosphorus comes from wastewater treatment facilities, whereas during high streamflow conditions, nonpoint sources dominate. Dissolved orthophosphate concentrations generally were greatest at sites downstream from wastewater discharges in the TCMA (Kroening, 1998b, 2000). Eutrophication of Lake Pepin has been linked to elevated phosphorus concentrations in the Mississippi River (Minnesota Pollution Control Agency, 1989).

Wastewater treatment facilities introduce contaminants such as nutrients and chloride to streams. (Photograph by Scott Murray Photography.)

Biochemical oxygen demand (BOD) of materials discharged from wastewater treatment facilities

has resulted in dissolved-oxygen concentrations in the Mississippi and Minnesota Rivers (Johnson and Aasen, 1989; Minnesota Pollution Control Agency, 1985) that are sometimes less than the USEPA guideline of 5 mg/L for the protection of aquatic life (U.S. Environmental Protection Agency, 1986).

The runoff of agricultural chemicals and sediment affects water quality in nearby streams and rivers. (Photograph by Scott Murray Photography.)

Suspended sediment adversely affects aquatic life by limiting light and covering habitat. Suspended sediment also transports nutrients, trace elements, and organic compounds attached to particles. The

greatest concentration of suspended sediment in the large rivers was in the Minnesota River (Kroening, 2000). The primary contributors of suspended sediment to the Minnesota River are the tributary watersheds in the central and southeastern parts of the Minnesota River Basin (Payne, 1994). Concentrations were lower in the St. Croix River and in the upper reaches of the Mississippi River.

Pesticides frequently were detected in the large rivers, but no concentrations exceeded applicable drinking-water standards or guidelines (Fallon and others, 1997; Fallon, 1998). Herbicides detected in all large rivers include the row crop herbicides alachlor, atrazine, and its degradation product deethylatrazine, cyanazine, and metolachlor. In and downstream from the TCMA, insecticides were frequently detected in water, and although use was discontinued in the early 1970s, DDT and its degradation products DDE and DDD were frequently detected in fish tissue and bed sediment.

Streambed sediment in the Mississippi River within and downstream from the TCMA contained the greatest number of OCs (Fallon and others, 1997; Fallon, 1998). PCB concentrations in streambed sediments have decreased over time (Anderson and Perry, 1999). Fish tissue concentrations have paralleled this decline (Lee and Anderson, 1998).

Human activities have had a strong influence on the occurrence and distribution of trace elements in large rivers of the Study Unit. The TCMA is the largest source of trace elements to rivers in the Study Unit. Trace-element data collected in the TCMA during 1992 by the Metropolitan Waste Control Com-

Control Commission (1994) indicate that concentrations of most trace elements in the water were less than applicable standards and guidelines, with the periodic exceptions of mercury and copper. Concentrations of cadmium, lead, mercury, and zinc were greatest in streambed-sediment samples within or immediately downstream from the TCMA (Wiener and others, 1984; Kroening and others, 2000). An industrial pretreatment program that began in the early 1980s has reduced the amount of trace elements discharged to the Mississippi River. For example, zinc concentrations have decreased an average of 80 percent (Anderson and Perry, 1999) (fig. 21) since the pretreatment program began.

Treated wastewater and untreated animal waste in the Study Unit also contribute to increased counts of fecal bacteria in the large rivers. Fecal bacteria counts were greatest in the Minnesota River and in the Mississippi River as it flowed through the TCMA. Approximately 40 percent of samples collected in the Minnesota River Basin exceeded the Minnesota and Wisconsin State freshwater standards for recreational use of 200 col/100 mL (Payne, 1994; Wisconsin Department of Natural

Resources, 1997; Minnesota Pollution Control Agency, 1999). Data collected by the Metropolitan Waste Control Commission (1994) indicate that during 1992, 25 percent of the water samples collected in the Mississippi River immediately downstream from the Minnesota River and the Metropolitan Wastewater Treatment Plant outfall exceeded freshwater standards for recreational use regarding bacteria.

Changes in the habitat of the large rivers have been caused by the construction of locks and dams, dredging to maintain navigation channels, modifications to stream morphology, and changes in land use. (see "Riparian Buffer Zones Affect the Quality of Midwestern Streams and Rivers," p. 9). Instream habitat and fish community conditions in the large rivers differ among areas of forest, urban, and agricultural lands. Diverse aquatic biological communities and relatively undisturbed riffle-pool morphology are found in the St. Croix River and the upper reaches of the Mississippi River in forested areas. Drainage of wetlands, loss of riparian vegetation, and channel straightening in the Minnesota River Basin have reduced habitat, modified hydraulic conditions, and changed water quality.

In the Mississippi River, the construction and maintenance of locks and dams have altered physical habitat for fish, invertebrates, and algae by changing streamflow from free-flowing to impounded, and altering the natural hydrology and the physical structure of the channel. As a result, the river has changed from a meandering, flowing system, which periodically overran its banks and flood plain, to a series of impoundments connected by dredged channels where the streamflow and water levels are controlled. The impoundments change the physical structure of the river, the diversity of aquatic habitats, and water quality. Impoundments reduce the velocity and warm the water in the pools. Reduced velocity causes sediment to settle, changing the composition of the substrate on the bottom of impoundments to fine-grained material (sand and silt). Nutrients and contaminants associated with sediment particles are concentrated in the bottom sediments of the pools.

The addition of nutrients from wastewater treatment facilities and from agricultural activities, combined with greater water temperatures and greater light penetration, stimulate algal growth. Concentrations of chlorophyll-*a* and phytoplankton biovolume in the Minnesota River at Jordan, Minn., and in the lower Mississippi River sites at Hastings, Minn., and at Red Wing, Minn., are greater than twice the concentrations measured at the upper Mississippi River site at Royalton, Minn. (Kroening, 2000), indicating greater phytoplankton abundance and primary production (fig. 22). High concentrations of nutrients, coupled with the environmental conditions of sufficient

Figure 21. Annual trace-element load from the Metropolitan Wastewater Treatment Plant by industrial users has decreased since 1981.

light and temperature, can result in eutrophication and subsequent oxygen deficits. Blue-green algal blooms were suspected of causing low dissolved-oxygen concentrations in Lake Pepin during the summer of 1988 (an abnormally dry period) that resulted in fishkills (Minnesota Pollution Control Agency, 1989).

Figure 22. Phytoplankton biovolume was least in the Mississippi River upstream from the Twin Cities Metropolitan Area (TCMA) and was greatest in the Minnesota River.

Invertebrate communities also have been influenced by environmental and morphologic conditions in the large rivers of the Study Unit. Sensitive invertebrate species (mayflies, stoneflies, and caddisflies) were most abundant in the St. Croix River, which drains primarily forested land. These sensitive taxa were least abundant in and downstream from the TCMA (fig. 23), where tolerant taxa such as Diptera (true flies) and Oligochaeta (aquatic worms) composed a large portion of the invertebrate community. Several species of mollusks are no longer present, due to commercial harvesting, loss and modification of habitat, water contamination, deposition of silt, and the introduction of zebra

mussels (Mueller, 1993). Contaminants such as cadmium and mercury in the sediments have accumulated in burrowing mayflies and may present a substantial source of trace element contaminants to fish, particularly in Lake Pepin (Beauvais and others, 1995).

Figure 23. Total number of mayflies, stoneflies, and caddisflies was least downstream from the Twin Cities Metropolitan Area (TCMA) and greatest in the St. Croix River.

Several chemical and physical factors affect the abundance and distribution of fish species. St. Anthony Falls in Minneapolis, Minn., on the Mississippi River, and the dam at St. Croix Falls, Wis., on the St. Croix River, form two major barriers to fish migration. These barriers have resulted in differences in fish species composition (Underhill, 1989). More species occur downstream of the barriers (fig. 24) (Goldstein and others, 1999; Underhill, 1989).

Other differences in the fish community distribution exist among large rivers in the Study Unit. The Mississippi River upstream from the TCMA and the St. Croix River upstream from Taylors Falls have fish species that thrive in cold water. Fish commu-

nities at these river sections are dominated by cool water and riverine species such as redhorse and smallmouth bass. Farther downstream, particularly in the Mississippi River downstream from the TCMA, the fish community consists of catfish, buffalo fish, freshwater drum, carpsuckers, and gizzard shad that tolerate warm water. The pattern of thermal preference is also consistent in the Minnesota and St. Croix Rivers. Lake species that are adapted to still water with high thermal ranges are found in and downstream from the TCMA.

Figure 24. Total number of fish species was greatest in the Lower Mississippi River downstream from the Twin Cities Metropolitan Area (TCMA).

The distribution of fish also differs by trophic status in the large rivers. Upstream from the TCMA, fish (northern hogsucker, golden and shorthead redhorse, hornyhead chub, common shiner, smallmouth bass, and two species of darter) that primarily consume invertebrates species that require a gravel or cobble substrate were abundant compared to downstream from the TCMA where fish (common carp and buffalo fish) that primarily consume detritus were more abundant. Downstream from the TCMA, species that feed on detritus

rely on filter feeding and suctioning of the bottom sediments for fine particulate organic matter.

The reduction in river velocity resulting from hydrologic modifications, such as impoundments, also alters the composition of the fish communities in the rivers. Species downstream from the TCMA tend to be associated with still-water habitats, whereas species upstream from the TCMA are associated more with flowing-water habitat. The abundance of fish (gizzard shad and emerald shiner) that eat plankton in the Mississippi River downstream from the TCMA indicates that a plankton community more common to lakes exists in that part of the river.

Clean drinking water is important to everyone. (Photograph from U.S. Geological Survey files.)

An indicator of the general quality of aquatic resources is the presence of contaminants in fish. Two contaminants, PCBs and DDE (a degradation product of DDT), were the most frequently

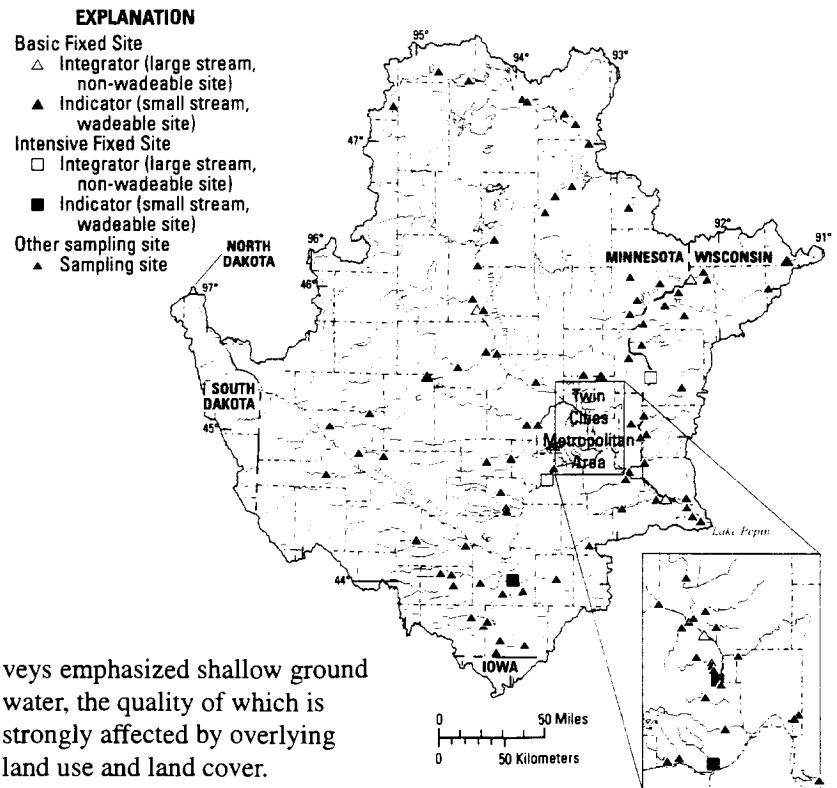

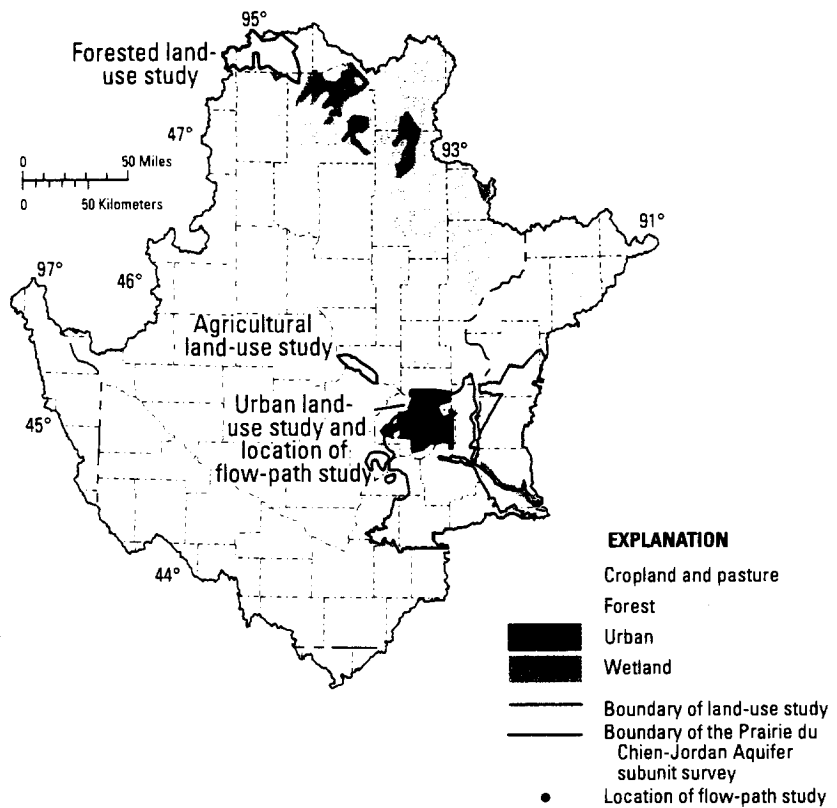

detected OCs in fish in the Study Unit. These contaminants in fish were greatest in the Mississippi River downstream from the TCMA. PCB and DDE concentrations in common carp tissue generally were greater in the Mississippi than in the Minnesota or St. Croix Rivers, and DDE concentrations generally increased in the Mississippi River main stem from Grand Rapids, Minn., downstream to Red Wing, Minn. Although concentrations have decreased over time (Lee and Anderson, 1998), PCBs and DDE continue to be detected in fish tissue, but at relatively low concentrations of less than 1 $\mu\text{g}/\text{kg}$ (micrograms per kilogram).

STUDY UNIT DESIGN

During 1996–98, about 4,200 water-quality aquatic-biological samples from about 240 sites were collected in the Study Unit, processed, and analyzed, using nationally consistent protocols and methods (Gilliom and others, 1995). The NAWQA design included physical, chemical, and aquatic-biological aspects of surface water and ground water for the entire Study Unit. Six sampling components were included in the sampling design. Each component involved measurements of water-quality or aquatic biological characteristics at one or more spatial or temporal scales. Three of the sampling components addressed surface water and aquatic biology, and three addressed ground water. A detailed description of the design and implementation of these water-quality studies is contained in Stark and others (1999).

Water quality in streams was assessed through water-chemistry and aquatic-biological studies. The surface-water and aquatic biology components included (1) stream sites that integrate multiple land uses and encompass large watersheds (integrator site network), (2) stream sites that indicate homogeneous and more specific land uses (indicator site network), and (3) stream sites sampled for special studies (synoptic surveys).

Ground-water quality was assessed for aquifer/land-use combinations using three sampling strategies: (1) a regional study of a selected major aquifer (subunit survey), (2) targeted-area studies in selected land uses (land-use studies), and (3) a localized study of processes occurring along shallow ground-water-flow paths (flow-path study). These studies and sur-

veys emphasized shallow ground water, the quality of which is strongly affected by overlying land use and land cover.

SUMMARY OF DATA COLLECTION IN THE UPPER MISSISSIPPI RIVER BASIN, 1995-98

Study component	Purpose of component and types of data collected	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Basic Fixed Sites— large rivers	Major ions, organic carbon, suspended sediment, nutrients, and streamflow were measured to describe concentrations and amounts of constituents transported in major tributaries in and from the Study Unit.	Sites on the Mississippi, Minnesota, and St. Croix Rivers draining 1,510 to 46,800 mi ² that integrate the effects of agricultural, urban, and forested land use and physiographic regions.	4 in 1996-97; 3 in 1998	Monthly beginning in March 1996 and during selected runoff events
Basic Fixed Sites— indicator tributaries	Major ions, organic carbon, suspended sediment, nutrients, and streamflow were measured to determine the effects of land use (undeveloped, urban, or agricultural) and surficial geology on stream-water quality.	Streams draining 27.3 to 232 mi ² of homogeneous agricultural, urban, or forested areas on unsorted or sorted surficial glacial deposits.	3 in 1996; 2 in 1997-98	Monthly beginning in March 1996 and during selected runoff events
Intensive Fixed Site— large rivers	Major ions, organic carbon, suspended sediment, nutrients, pesticides, and streamflow were determined to define short-term temporal variability.	Sites on the Mississippi, Minnesota, and St. Croix Rivers draining 6,150 to 37,000 mi ² .	3	Monthly beginning in March 1996 and during selected runoff events
Intensive Fixed Site— indicator tributaries	Major ions, organic carbon, suspended sediment, nutrients, pesticides, and streamflow were determined to define short-term temporal variability. Volatile organic compounds were determined at two urban sites.	Streams draining 28.2 to 130 mi ² in homogeneous agricultural and urban areas.	3	Weekly or biweekly during April through August 1997
Snowmelt synoptic survey	Nutrients and suspended sediment were determined using modified NAWQA protocols to characterize instantaneous concentrations and yields during increasing streamflow of snowmelt runoff.	Streams draining 10 to 46,800 mi ² .	41	Once in March or April 1997
Stream Ecology				
Bed sediment and tissue	Trace elements and hydrophobic-organic compounds in fish tissue and streambed sediment to determine occurrence and distribution of these compounds throughout the Study Unit.	Sites with drainage areas from 20 to 47,300 mi ² draining a variety of land use.	Fish sampled at 25 sites, streambed sediment at 27 sites.	1995-96
Basic Fixed Sites— indicator tributaries	Fish, benthic invertebrates, phytoplankton, periphyton, and instream habitat were sampled or characterized to determine the community structure and to evaluate the association between land use and aquatic communities.	Same as for stream chemistry	6 in 1996; 5 in 1997-98	One each fall 1996-98
Basic Fixed Sites— large rivers	Fish, benthic invertebrates, phytoplankton, periphyton, and instream habitat were sampled or characterized to determine the spatial distribution of aquatic communities and to evaluate the association between land use and aquatic communities.	Same as for stream chemistry	7	One each fall 1996-98
Urban synoptic study	Nutrients, suspended sediment, pesticides, organic carbon, phytoplankton, and chlorophyll- <i>a</i> were analyzed. Aquatic community sampling included fish and invertebrate community sampling and instream habitat to determine how water quality and aquatic communities differ in response to changes in population density.	Streams with drainage areas ranging from 9.9 to 152 mi ² draining urban areas in the Twin Cities metropolitan area.	13	September-October 1997
Mid-continent agricultural synoptic study	Nutrients, suspended sediment, pesticides, organic carbon, phytoplankton and chlorophyll- <i>a</i> were analyzed. Aquatic community sampling included fish and invertebrate community sampling and instream habitat characterization to determine how water quality and aquatic communities differ in response to changes in local-scale riparian cover and to basin-scale soils.	Sites with drainage areas from 60 to 317 mi ² draining land that was greater than 87 percent agricultural land use.	24	August 1997
Longitudinal synoptic study	Nutrients, suspended sediment, major ions, pesticides, organic carbon, chlorophyll- <i>a</i> , and organic compounds indicative of wastewater were analyzed. Aquatic community sampling included fish and invertebrates and instream habitat to characterize the water quality and aquatic communities along the Mississippi River.	Sites with drainage areas ranging from 32 to 46,800 mi ² along the Mississippi River main stem from Lake Itasca to Red Wing, Minnesota.	Sampled aquatic communities at 12 sites and water chemistry at 19 sites.	July and August of 1998
Ground-Water Chemistry				
Bedrock aquifer survey	Major ions, nutrients, dissolved organic carbon, trace elements, pesticides, volatile organic compounds, radon, and tritium were analyzed to describe the water quality and natural chemical patterns in unconfined and confined portions of the most frequently used bedrock aquifer in the Study Unit.	Existing domestic wells completed in the Prairie du Chien-Jordan aquifer.	25 wells in the unconfined portion 25 wells in the confined portion	July-September 1996
Land-use effects— surficial aquifer	Major ions, nutrients, dissolved organic carbon, pesticides, volatile organic compounds, and tritium were analyzed to determine the effects of specific land uses (urban, agricultural, and forested) on the quality of shallow ground water.	Monitoring wells completed at the water table in the surficial sand and gravel aquifer.	30 wells in the urban study 29 wells in the agricultural study 15 wells in the forested study	June-July 1996, May-September 1998, June 1998
Variations along flow— surficial aquifer	Major ions, nutrients, dissolved organic carbon, trace elements, pesticides, volatile organic compounds, radon, tritium, dissolved gases, and chlorofluorocarbons were analyzed to describe the effects of urban land use on the quality of shallow ground water along ground-water flow from an area of recharge to an area of discharge to a stream.	Monitoring and multipoint wells (open to the aquifer at different depths) completed in the surficial sand and gravel aquifer.	1 monitoring well and 6 multipoint wells	July 1997, October 1997, August 1998

GLOSSARY

Alkalinity - The alkalinity of a solution is the capacity for solutes it contains to react with and neutralize acid.

Aquatic-life criteria - Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms. See also Water-quality guidelines and Water-quality criteria.

Bioaccumulation - The biological sequestering of a substance at a higher concentration than that at which it occurs in the surrounding environment or medium. Also, the process whereby a substance enters organisms through the gills, epithelial tissues, dietary, or other sources.

Confined aquifer (artesian aquifer) - An aquifer that is completely filled with water under pressure and that is overlain by material that restricts the movement of water.

Degradation products - Compounds resulting from transformation of an organic substance through chemical, photochemical, and/or biochemical reactions.

Drinking-water standard or guideline - A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.

EPT richness index - An index based on the sum of the number of taxa in three insect orders, Ephemeroptera (mayflies), Plecoptera (stoneflies), and Trichoptera (caddisflies), that are composed primarily of species considered to be relatively intolerant to environmental alterations.

Eutrophication - The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.

Human health advisory - Guidance provided by U.S. Environmental Protection Agency, State agencies or scientific organizations, in the absence of regulatory limits, to describe acceptable contaminant levels in drinking water or edible fish.

Index of Biotic Integrity (IBI) - An aggregated number, or index, based on several attributes or metrics of a fish community that provides an assessment of biological conditions.

Load - General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.

Nonpoint source - A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs

from plants and trees are types of nonpoint source pollution.

Organochlorine compound - Synthetic organic compounds containing chlorine. As generally used, term refers to compounds containing mostly or exclusively carbon, hydrogen, and chlorine. Examples include organochlorine insecticides, polychlorinated biphenyls, and some solvents containing chlorine.

Point source - A source at a discrete location such as a discharge pipe, drainage ditch, tunnel, wells, concentrated livestock operation, or floating craft.

Polychlorinated biphenyls (PCBs) - A mixture of chlorinated derivatives of biphenyl, marketed under the trade name Aroclor with a number designating the chlorine content (such as Aroclor 1260). PCBs were used in transformers and capacitors for insulating purposes and in gas pipeline systems as a lubricant. Further sale for new use was banned by law in 1979.

Polycyclic aromatic hydrocarbon (PAH) - A class of organic compounds with a fused-ring aromatic structure. PAHs result from incomplete combustion of organic carbon (including wood), municipal solid waste, and fossil fuels, as well as from natural or anthropogenic introduction of uncombusted coal and oil. PAHs include benzo(a)pyrene, fluoranthene, and pyrene.

Tolerant species - Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.

Unconfined aquifer - An aquifer whose upper surface is a water table; an aquifer containing unconfined ground water.

Water-quality criteria - Specific levels of water quality which, if reached, are expected to render a body of water unsuitable for its designated use. Commonly refers to water-quality criteria established by the U.S. Environmental Protection Agency. Water-quality criteria are based on specific levels of contaminants that would make the water harmful if used for drinking, swimming, farming, fish production, or industrial processes.

Suspended sediment - Particles of rock, sand, soil, and organic detritus carried in suspension in the water column, in contrast to sediment that moves on or near the streambed.

Water-quality guidelines - Specific levels of water quality which, if reached, may adversely affect human health or aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.

Yield - The mass of material or constituent transported by a river in a specified period of time divided by the drainage area of the river basin.

APPENDIX—WATER-QUALITY DATA FROM THE UPPER MISSISSIPPI RIVER BASIN IN A NATIONAL CONTEXT

For a complete view of Upper Mississippi River Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Upper Mississippi River Basin. Selected results for this basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Upper Mississippi River Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, acetochlor concentrations in the Upper Mississippi River Basin agricultural streams were similar to the national distribution, but the detection frequency was much higher (90 percent compared to 33 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Upper Mississippi River Basin, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- ** No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) ***
- Bromacil (Hyvar X, Urox B, Bromax)
- Bromoxynil (Buctril, Brominal) *
- DCPA (Dacthal, chlorthal-dimethyl) ***

R0024571

Dicamba (Banvel, Dianat, Scotts Proturf)
 2,6-Diethylaniline (Alachlor breakdown product) * **
 Dinoseb (Dinosebe)
 Diuron (Crisuron, Karmex, Diurex) **
 EPTC (Eptam, Farmarox, Alirox) * **
 Metribuzin (Lexone, Sencor)
 Napropamide (Devrinol) * **
 Oryzalin (Surflan, Dirimal) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **
 Propachlor (Ramrod, Satecid) **
 Simazine (Princep, Caliber 90)
 Tebuthiuron (Spike, Tebusan)
 Thiobencarb (Bolero, Saturn, Benthicarb) * **
 Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

Butylate (Sutan +, Genate Plus, Butilate) **
 Chloramben (Amiben, Amilon-WP, Vegiben) **
 Clopyralid (Stinger, Lontrel, Transline) * **
 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
 Dacthal mono-acid (Dacthal breakdown product) * **
 Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
 Ethalfuralin (Sonalan, Curbit) * **
 Fenuron (Fenulon, Fenidim) * **
 Fluometuron (Flo-Met, Cotoran) **
 Linuron (Lorox, Linex, Sarclax, Linurex, Afalon) *
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Molinate (Ordram) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Norflurazon (Evtal, Predict, Solicam, Zorial) * **
 Pebulate (Tillam, PEBC) * **
 Picloram (Grazon, Tordon)
 Pronamide (Kerb, Propyzamid) **
 Propanil (Stam, Stampede, Wham) * **
 Propham (Tuberite) **
 2,4,5-T **
 2,4,5-TP (Silvex, Fenoprop) **
 Terbacil (Sinbar) **
 Triallate (Far-Go, Avadex BW, Tri-allate) *
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **

Pesticides in water—Insecticides

Other insecticides detected

Carbaryl (Carbamine, Denapon, Sevin)
 Carbofuran (Furadan, Curaterr, Yaltox)
 Chlorpyrifos (Brodan, Dursban, Lorsban)
 Dieldrin (Panoram D-31, Octalox, Compound 497)

BIOLOGICAL INDICATORS

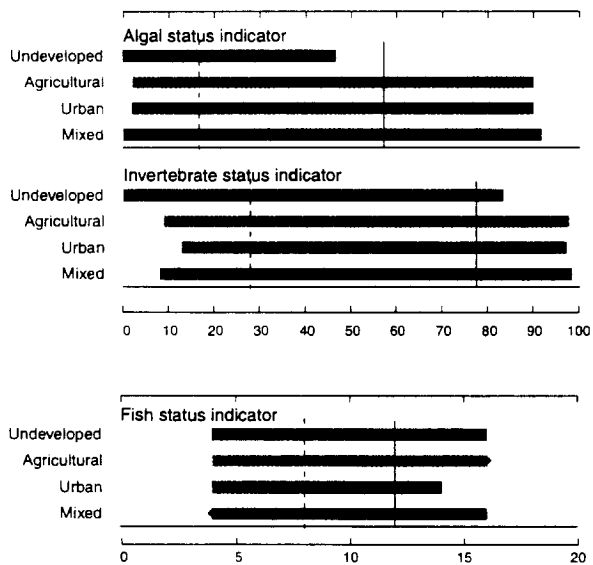

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Central Arizona Basins Study Unit that emerged from an assessment conducted between 1995 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in the 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water-monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Central Arizona Basins assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Central Arizona Basins Study Unit is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

The Central Arizona Basins (CAZB) Study Unit of the National Water-Quality Assessment (NAWQA) Program covers 34,700 square miles in the Central Highlands and Basin and Range Lowlands hydrologic provinces. Phoenix was America's fastest growing city during the 1990s, and a population of about 3.8 million people is concentrated around the cities of Phoenix and Tucson. The climate is arid to semiarid, and dams on major perennial streams in the Central Highlands collect water for use in the Phoenix area. More than 50 percent of the water used in the Study Unit is ground water, which is often the sole source available. More than 70 percent of the water is used for agriculture, which accounts for 5 percent of the land use.

Stream and River Highlights

Most of the perennial streams in the Central Arizona Basins (CAZB) Study Unit drain relatively undeveloped basins in the Central Highlands that are covered by forests and (or) rangeland. The water quality of these forest/rangeland streams is primarily determined by natural factors, such as chemical weathering of rocks and soils. About 24 percent of samples from forest/rangeland streams had concentrations of phosphorus that exceeded the U.S. Environmental Protection Agency's (USEPA) desired goal for prevention of nuisance plant growth (eutrophication), whereas nitrate concentrations were typically less than the background levels for streams nationally. More than 75 percent of samples from the Salt River (above reservoirs) exceeded the USEPA drinking-water guideline for dissolved solids; however, rainfall and snowmelt runoff helped dilute these concentrations in reservoirs and in streamflow leaving the reservoirs.

In the Basin and Range Lowlands, streams typically flow only when it rains (ephemeral streams). Consequently, a small fraction of the nutrients and dissolved solids applied to the land surface by human, animal, and natural sources is transported to streams. The remaining dissolved solids and nutrients are accumulating in basins and can degrade ground-water quality.

Urban streams with perennial flow are sustained by the discharge of treated wastewater (effluent-dependent). Agricultural/urban streams are a combination of wastewater and irrigation return flows. All samples from both the effluent-dependent urban and agricultural/urban streams exceeded the USEPA's desired phosphorus goal for prevention of nuisance plant growth, and dissolved-oxygen concentrations were minimal for fish survival. Organochlorine compounds in streambed sediment and fish tissue from urban and agricultural/urban streams exceeded guidelines for protection of aquatic health and fish-eating wildlife.

- Effluent-dependent urban streams are valuable water resources; however, the water quality is poor.
- Organochlorine insecticides from past agricultural use persist in streams, streambed sediment, and fish tissue and are a concern because they exceed guidelines for protection of aquatic life and fish-eating wildlife.
- Insecticide concentrations in water from streams affected by agricultural and urban land uses were among the highest in the Nation.

Selected Indicators of Stream-Water Quality

	Urban ¹ (effluent-dependent)	Agricultural/ urban ²	Undeveloped ³ (forest/ rangeland)
Pesticides ⁴	—	●	—
Phosphorus ⁵	●	●	●
Nitrate ⁶	●	●	●
Organo-chlorines ⁷	● ⁺	●	—

■ Percentage of samples with concentrations equal to or greater than a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or above a national goal for preventing excess algal growth

▒ Percentage of samples with concentrations less than a health-related national guideline for drinking water, aquatic life, or water-contact recreation; or below a national goal for preventing excess algal growth

○ Percentage of samples with no detection

— Not assessed

¹ 91st Avenue Wastewater Treatment Plant, Santa Cruz River at Cortaro, Santa Cruz River at Tubac, Santa Cruz River near Nogales International Wastewater Treatment Plant (bed sediment only).
² Buckeye Canal near Avondale (surface water only), Hassayampa River near Arlington (surface water only), Buckeye Canal near Hassayampa (bed sediment only).
³ San Pedro River at Charleston, Gila River at Kelvin, Salt River near Roosevelt, Verde River above West Clear Creek, Verde River below Tangle Creek, West Clear Creek.
⁴ Insecticides, herbicides, and pesticide metabolites, sampled in water.
⁵ Total phosphorus, sampled in water.
⁶ Nitrate (as nitrogen), sampled in water.
⁷ Organochlorine compounds including DDT and PCBs, sampled in bed sediment.
⁺ Although the 91st Avenue Wastewater Treatment Plant outfall is classified as urban, past agricultural land use in the area is the source of most organochlorine compounds at this site.

Trends in stream water quality

Water quality of forest/rangeland streams generally is improving over time. From 1950-90, dissolved-solids concentrations decreased in outflow from reservoirs as a result of dilution from increased precipitation and physical and chemical processes in reservoirs. A decrease in nutrient concentrations in forest/rangeland streams in the early 1980s to 1999 could be attributed to decreased contributions from natural sources, better land-use management practices upstream, or increased nitrogen use by aquatic life.

Major Influences on Streams and Rivers

- Natural factors such as chemical weathering of rocks and soil
- Precipitation
- Reservoirs
- Runoff from agricultural and urban lands
- Discharge of treated wastewater to streams

Ground-Water Highlights

Most of the ground water used in the CAZB Study Unit is pumped from basin-fill aquifers in the Basin and Range Lowlands. Water from major aquifers (basinwide) in the West Salt River Valley (WSRV), the Upper Santa Cruz Basin (USCB), and the Sierra Vista subbasin (SVS) generally meets existing USEPA standards and guidelines for drinking water with some exceptions. Nitrate and dissolved-solids concentrations in some samples from the WSRV and USCB exceeded USEPA drinking-water standards and guidelines. Shallow ground water from an agricultural area in the WSRV exceeded drinking-water standards and guidelines for nitrate and dissolved solids in more than 75 percent of samples. More than 90 percent of ground-water samples from the three basins exceeded the USEPA's proposed drinking-water standard for radon. A small percentage of samples exceeded drinking-water standards for arsenic, fluoride, and molybdenum. Samples from urban and agricultural areas contained low concentrations of numerous chemicals (pesticides and volatile organic compounds) that can be linked to household, industrial, and agricultural uses.

- Most of the deep wells yield old ground water that generally has not been affected by land uses in the last 50 years.
- Use of fertilizers and treated wastewater on agricultural and urban lands and the evaporation of irrigation water have resulted in the accumulation of nitrate and dissolved solids in shallow ground water.

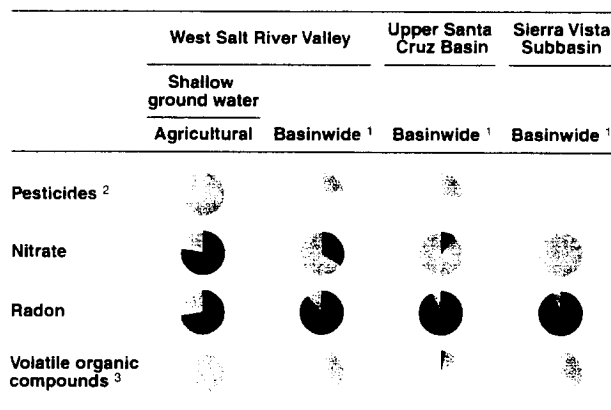

- Adoption of draft or proposed USEPA drinking-water regulations for arsenic, radon, and uranium—constituents that occur naturally in the study area—will require most water suppliers and municipalities to treat their water to remove these constituents or find alternative supplies.
- Pesticides detected in ground-water basins with substantial agricultural and (or) urban development did not exceed USEPA drinking-water standards and guidelines.

Though trends in ground-water quality over time were not determined for the CAZB Study Unit, the data indicate possible future changes. As urban land use spreads with the growing population in the area, ground-water quality is likely to deteriorate, as indicated by detections of pesticides and volatile organic compounds in urban areas. Nitrate and dissolved solids accumulating in shallow ground water in the WSRV have the potential to degrade the quality of deeper drinking-water supplies.

Major Influences on Ground Water

- Geohydrology
- Dissolution of evaporites and other minerals
- Irrigation of agricultural and urban lands
- Agricultural and urban fertilizer and pesticide use

Selected Indicators of Ground-Water Quality

Percentage of samples with concentrations equal to or greater than a health-related national guideline or proposed regulation for drinking water

Percentage of samples with concentrations less than a health-related national guideline or proposed regulation for drinking water

Percentage of samples with no detection

¹ Most wells sampled as part of basinwide surveys were existing domestic (household) wells.

² Insecticides, herbicides, and pesticide metabolites, sampled in water.

³ Solvents, refrigerants, fumigants, and gasoline compounds, sampled in water.

INTRODUCTION TO THE CENTRAL ARIZONA BASINS

The Central Arizona Basins (CAZB) Study Unit encompasses a 34,700-square-mile area in central and southern Arizona and northern Mexico (fig. 1). The Study Unit includes large parts of two hydrologic provinces—the Central Highlands in the north and the Basin and Range Lowlands in the south (U.S. Geological Survey, 1969). Climate, hydrology, geology, land use, and water use are distinctly different in these two provinces.

The Central Highlands (fig. 1) have minimal development and are generally representative of natural conditions. Mountainous terrain with shallow, narrow intermountain basins predominates in

the Central Highlands (Cordy and others, 1998). Forests and rangeland cover most of the province. The largest population is in the town of Prescott—35,785 (Arizona Department of Economic Security, rev. July 7, 2000), and small rural towns dot the region. Agricultural development is minimal except in the northernmost tip of the CAZB.

Most of the perennial streams in the Study Unit are in the Central Highlands (fig. 2). These streams derive their flow from mean annual precipitation of more than 25 inches in the mountains and from rainfall and snowmelt along the Mogollon Rim, which forms the

northeastern border of the CAZB Study Unit.

Major streams having their headwaters in the Central Highlands include the Salt, Verde, and Agua Fria Rivers (fig. 2). These rivers flow year around (perennial) in their upper reaches but are captured for water supply for metropolitan Phoenix, power generation, and flood control before they reach the Basin and Range Lowlands.

Though streams provide most of the water for agricultural use in the Central Highlands, ground water is the main source for municipal and industrial supply (fig. 3). Much of the ground water is pumped from sedimentary deposits of limited

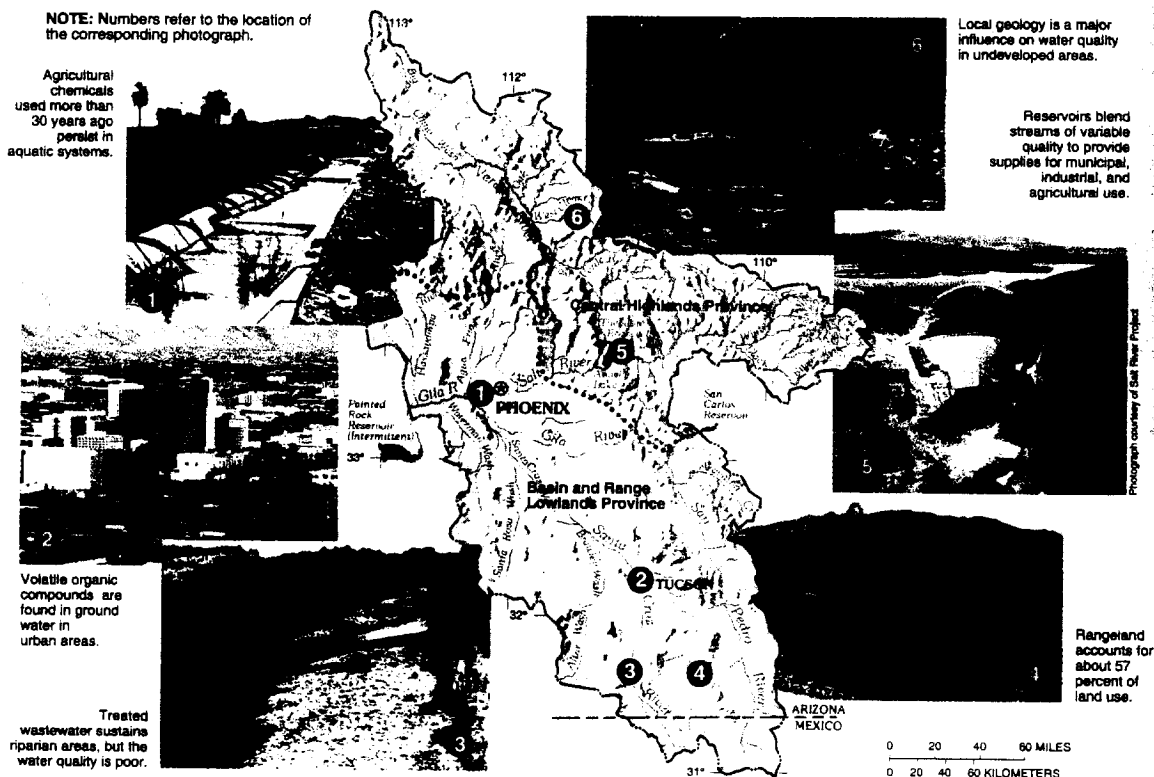

Figure 1. The Central Highlands hydrologic province is mountainous compared to the large, elongate alluvial basins of the Basin and Range Lowlands. Reservoirs capture the perennial streams of the Central Highlands to provide water supplies for the Basin and Range Lowlands.

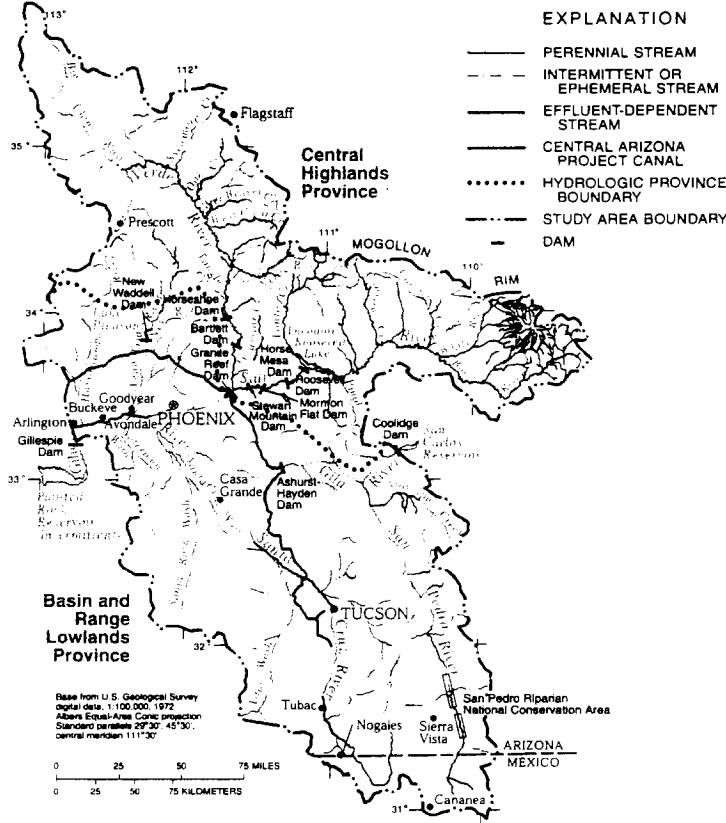

Figure 2. Perennial streams in the Central Highlands, Colorado River water from the Central Arizona Project Canal, ground water, and treated sewage effluent fulfill water demands in the Basin and Range Lowlands.

extent in the valleys. As a result, some of the fastest-growing towns are being forced to seek alternative water supplies (Arizona Department of Water Resources, 1994). Natural factors such as dissolution of minerals in rocks and basin sediments are major influences on ground-water quality in the Central Highlands (Owen-Joyce and Bell, 1983; Marsh, 2000); however, activities such as mining have affected water quality locally (Brown and Favor, 1996).

The Basin and Range Lowlands (fig. 1) are characterized by a lack of perennial streams, the largest water demands, and reli-

ance on ground water. Deep, broad alluvial basins separated by mountain ranges of small areal extent characterize this hydrologic province. The basins are filled with thick deposits of gravel, sand, silt, and clay and include interbedded evaporite deposits and volcanic rocks in places (Anderson and others, 1992). These basin-fill sediments can be 2,000 feet to as much as 12,000 feet thick and constitute the major aquifers that are often referred to as “basin-fill aquifers.” The basin-fill aquifers contain large reserves of ground water that were recharged when Arizona’s climate was much wetter than at

present, possibly thousands of years ago.

Ephemeral streams are characteristic of the Basin and Range Lowlands (fig. 2). Very little natural streamflow is generated because the average annual rainfall is less than 10 to 15 inches except at the highest elevations. With the exception of some small, higher elevation streams and sections of the San Pedro River, most perennial streams in the Basin and Range Lowlands are effluent-dependent; that is, their flow is sustained all year by treated wastewater (fig. 2). Effluent-dependent streams have beneficial uses. They support riparian and aquatic communities where those communities would not otherwise exist. By recharging effluent, cities can accrue “credits” toward pumping of ground water from other locations in a basin (Arizona Department of Water Resources, 1994).

Rangeland is the predominant land use in the Basin and Range Lowlands. The two largest urban areas—Phoenix and Tucson—account for about 5 percent of the land use and include 75 percent of Arizona’s 4.9 million people (Arizona Department of Economic Security, rev. July 7, 2000). Agricultural development, which is mostly west and south of Phoenix, is about 5 percent of the land use (Cordy and others, 1998). Cropland is the primary agricultural land use, and cotton is the main crop.

Water use in the Basin and Range Lowlands represents 96 percent of all water use in the CAZB Study Unit (Cordy and others, 1998). Agriculture is the largest water user (73 percent in 1990; fig. 3). Because of the general lack of surface-water

resources in the Basin and Range Lowlands, ground-water is relied upon heavily to meet agricultural and municipal demands (fig. 3). In areas with substantial agricultural and (or) urban development, ground water has been and continues to be used more quickly than it can be replenished naturally. Ground-water levels have declined several hundred feet in areas with the heaviest pumping, and land subsidence has resulted in a loss in aquifer storage capacity (Arizona Department of Water Resources, 1994). To mitigate some of the

problems caused by overpumping of ground water, Colorado River water is delivered to central Arizona by the Central Arizona Project (CAP) canal (fig. 2). CAP water is used for aquifer recharge and municipal and agricultural purposes.

The study design focused on the effects of land use on water quality. Water, sediment, and biological samples were collected from streams in urban, agricultural, forest, and rangeland areas of the CAZB Study Unit to assess the overall quality of streams as well as the effects of specific land-use practices on stream-water quality (U.S. Geological Survey, 1999). At most sites, water samples were collected monthly from late 1995

through early 1998, and at some stream sites additional samples were collected during storms to assess the effects of stormwater runoff on water quality. Two stream sites were sampled twice monthly for 1 year to determine the occurrence and distribution of pesticides. A single round of sampling for contaminants in streambed sediment and fish tissue was completed in 1995–96 (See “Study Unit Design,” p. 26).

Ground water was sampled from wells in three alluvial basins in the Basin and Range Lowlands—the West Salt River Valley, the Upper Santa Cruz Basin, and the Sierra Vista subbasin. Existing wells were sampled in the three basins to assess overall water quality as well

Figure 3. Water-use data for 1990 show the many sources of water used to meet demands in the CAZB Study Unit.

Figure 4. Streamflow in the Central Highlands increased each year from 1996–98 as indicated by the Verde River below Tangle Creek. In the Basin and Range Lowlands, streamflow is difficult to characterize because it is controlled by dams and (or) wastewater-treatment plants. For the Hassayampa River near Arlington, a Basin and Range Lowlands stream, summer streamflow in 1996 and 1997 was greater than the median historical daily value.

as the effects of human activities on water quality. In the West Salt River Valley, shallow monitoring wells were installed and sampled to determine the effects of irrigated agriculture on shallow groundwater quality. Existing groundwater-quality data were used to assess overall water quality in alluvial basins of the Basin and Range Lowlands that were not sampled.

This report is organized into sections on stream-water quality and ground-water quality. In each section, natural water quality, that is water that has been minimally affected by agricultural or urban development, is discussed followed by a discussion of the effects of human activities on water quality. This organization is designed to assist the reader in understanding the changes in natural water quality that result from human activities.

Understanding climatic and hydrologic conditions during the

sampling period, 1995–98, is useful in interpreting the CAZB study results. The climate of the Study Unit is characterized by variability from place to place and also by large differences in precipitation from one year to the next. Precipitation can be three times greater in wet years than in dry years (Cordy and others, 1998).

In Central Highlands streams, represented by the Verde River below Tangle Creek (fig. 4), daily mean streamflow was successively higher from 1996 through 1998. Streamflow in 1998 generally was greater than the median of historical daily streamflow, and streamflow in 1996 was less than the median of historical daily streamflow (fig. 4).

Streamflow in the Basin and Range Lowlands is difficult to characterize because it is controlled by dams and (or) wastewater-treatment plants. The Hassayampa

River near Arlington is an example of a Basin and Range Lowlands stream that is a combination of effluent and irrigation return flows most of the time, supplemented by flows from storm runoff (fig. 4). Streamflow at the site typically was less than the median historical daily streamflow during 1996 and 1997; however, summer streamflow in those years was greater than the median historical daily streamflow because of increased summer thundershowers. Streamflow during 1998 was about the same as the median of historical daily streamflow.

When streamflow exceeds baseflow as a result of rainfall or snowmelt runoff, dissolved-solids concentrations decrease in streams and reservoirs because of dilution. Nutrient concentrations increase with increased streamflow because precipitation and runoff carry more nutrients to streams.

MAJOR FINDINGS

Natural Stream Water Quality

In the CAZB Study Unit, perennial streams draining areas with little or no agricultural or urban land use represent baseline or “natural” conditions in the basins. These natural streams are referred to as “forest/rangeland streams” in this report because they drain basins that are 93 to 100 percent forest and (or) rangeland. Examples of forest/rangeland streams include the upper Verde, upper Salt, and upper Gila Rivers and West Clear Creek in the Central Highlands province and the upper San Pedro River in the Basin and Range Lowlands province. Because some of the forest/rangeland streams provide drinking water for Phoenix or recharge aquifers used for drinking water, the quality of these streams is compared to drinking-water standards and guidelines as well as to other water-quality criteria.

The water quality of forest/rangeland streams is primarily determined by natural factors. Processes such as chemical weathering of bedrock and soils, biological activity in soils (Likens and others, 1977), ground-

Figure 5. Concentrations of nutrients increase and concentrations of dissolved solids decrease during rainfall or snowmelt runoff.

water discharge to streams, and runoff determine the water quality of these streams. Locally, stream-water quality may be affected by agriculture, mining, or urban land use.

Nutrient and dissolved-solids concentrations fluctuate seasonally in forest/rangeland streams. The patterns of rainfall and snowmelt runoff account for the seasonal fluctuations in concentrations of nutrients (fig. 5). Nutrient concentrations increase in streams during times of rainfall and snowmelt runoff because runoff carries nutrients washed off the land surface to streams, thereby increasing concentrations. Nitrogen in rainfall

and snowmelt also adds to nutrient concentrations in streams. Conversely, during low streamflows, nutrient concentrations are lower because very little runoff reaches streams, and aquatic life in the streams take up the available nutrients.

Seasonal patterns of dissolved-solids concentrations are opposite to those of nutrients. During periods of low flow, the sources of streamflow are springs, which in some areas, such as the upper Salt River Basin, are quite saline (Feth and Hem, 1963). During periods of runoff, flow in streams is diluted, which lowers the dissolved-solids concentrations (fig. 5).

Figure 6. Nitrate concentrations in forest/rangeland streams are significantly lower than the maximum contaminant level of 10 mg/L. Most water samples from the upper Salt River exceeded the secondary maximum contaminant level for dissolved solids (500 mg/L) because saline springs sustain streamflow during periods of low flow.

Nitrate concentrations in forest/rangeland streams were significantly lower than the U.S. Environmental Protection Agency's (USEPA) Maximum Contaminant Level (MCL) of 10 mg/L. Nitrate was detected in 43 percent of the samples from forest/rangeland streams. None of the nitrate concentrations exceeded the MCL, which was established for the protection of human health (fig. 6), and less than 2 percent of the samples had concentrations of nitrate that were greater than the estimated national background concentration in streams of 0.6 mg/L (U.S. Geological Survey, 1999). Concentrations greater than background levels are generally considered to be the result of human activities. Samples that exceeded the background concentration were collected during high flows associated with rainfall or snowmelt runoff.

Twenty-four percent of the samples from forest/rangeland streams exceeded the USEPA desired goal for total phosphorus of 0.1 mg/L for the prevention of nuisance plant growth (fig. 6). The USEPA desired goal of 0.1 mg/L is the same as the estimated national background concentration for phosphorus (U.S. Geological Survey, 1999). Phosphorus enrichment in streams can lead to eutrophication; however, in the forest/rangeland streams, phosphorus concentrations exceeding the USEPA goal are generally limited to periods of rainfall and snowmelt runoff.

Dissolved-solids concentrations exceeded the USEPA Secondary Maximum Contaminant Level (SMCL) in 76 percent of samples from the upper Salt River. None of the samples from the upper San Pedro River or West Clear Creek exceeded the SMCL of 500 mg/L that is based on taste of

drinking water (fig. 6). Samples that exceeded this drinking-water guideline were collected at times when streamflow was sustained by flow from springs. Saline springs drain into the upper Salt River (Feth and Hem, 1963), which accounts for the particularly large number of samples that exceeded the SMCL.

Total DDT concentrations in fish tissue samples from forest/rangeland streams were significantly less than the New York State guideline (Newell and others, 1987) for the protection of fish-eating wildlife. None of the other organochlorine pesticides and PCBs analyzed for were detected in fish tissue from forest/rangeland streams (Gebler, 2000). In addition, organochlorine compounds and PCBs were not detected in streambed sediment from these streams.

Stream water quality generally is improving on the basis of nutrient and dissolved-solids concentrations in forest/rangeland streams. Statistical analysis of nitrogen data for forest/rangeland streams indicates that concentrations have

generally declined since the early 1980s (fig. 7). Phosphorus concentration data showed the same trend as nitrogen. In the upper, undeveloped parts of the Salt and Verde River Basins (upstream from reservoirs) the decrease in nutrients could be from a decrease in contributions from natural sources (see p. 10), a decrease as a result of better land-use management practices upstream, and (or) an increase in nitrogen use by aquatic life.

Dissolved-solids concentrations decreased substantially in outflow from reservoirs on the Verde River from 1950–90 (fig. 7). This downward trend, also seen on the Salt River, probably is caused by both increased rainfall and snowmelt runoff diluting the dissolved-solids concentrations and physical and chemical processes in the reservoirs that remove some dissolved solids from solution.

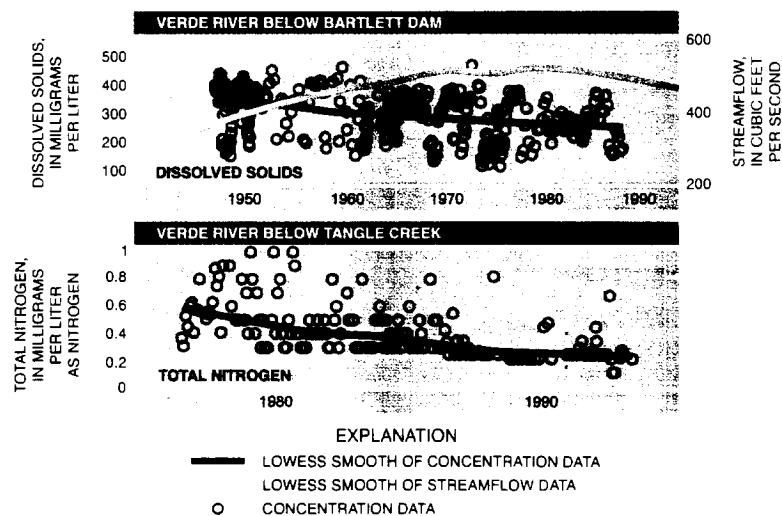

Figure 7. Water quality of forest/rangeland streams has improved, on the basis of decreases in dissolved-solids and nutrient concentrations during the past 30 to 50 years.

Effects of Human Activities on Stream Water Quality

Streams affected by human activities may have elevated concentrations of dissolved solids and nutrients from a variety of activities including urban and agricultural runoff. Manmade compounds such as pesticides and volatile organic compounds (VOCs) in streams are a direct result of human activities. To determine the factors affecting water quality in the CAZB, annual stream loads of dissolved solids (the mass of material transported in the water) entering the basins were compared to annual stream loads leaving the basins (see story at right). In addition, the quantifiable sources of nitrogen and phosphorus (nutrients) coming into major basins and leaving in streamflow were used to identify basins where water quality is affected by human activities (see p. 10). Water-quality characteristics of affected streams are indicative of the local effects of human activities.

Streams sampled in the CAZB that are affected by human activities can be divided into two main categories—**effluent-dependent and agricultural/urban**. Streamflow in effluent-dependent streams is almost entirely treated sewage effluent discharged from wastewater-treatment plants (WWTPs). These streams are referred to in this report as “effluent-dependent” or “effluent-dependent urban” streams (see p. 12) because the effluent reflects urban land uses. Some sampling sites in the CAZB receive irrigation return flows and rainfall runoff from agricultural fields as well as treated effluent, and these streams are referred to as “agricultural/urban” streams.

Dissolved solids are accumulating in basins with agricultural and urban irrigation.

Data collected as part of the CAZB NAWQA study indicate that in 1997, about 1.6 billion kilograms (kg) (1.76 million tons) of dissolved solids were carried into the Basin and Range Lowlands by streams draining the Central Highlands (Verde, Salt, and Gila Rivers) and by the Central Arizona Project (fig. 8). Only 440 million kg (0.48 million tons) were transported out of the study area in streams. The remaining 1.16 billion kg (1.28 million tons) are accumulating in soils, the unsaturated zone, and ground water in irrigated agricultural and urban areas.

Much of the streamflow from the Central Highlands and the Central Arizona Project Canal is used for irrigating agricultural fields and urban landscape. When plants are irrigated in the Basin and Range Lowlands, 50 to 80 percent of the water evaporates or is transpired by plants as pure water. The dissolved solids that were in the evapotranspired water remain in the soil or are concentrated in the water that remains. Over time these salts build up in soils and ground water. To prevent crop damage from salt accumulation, excess irrigation water is commonly applied to leach the salts out of the root zone.

Excess water that percolates below the root zone carries a higher concentration of salts than the original irrigation water (Cordy and Bouwer, 1999). If this deep-percolation water reaches the ground water, the upper part of the aquifer can be contaminated by dissolved solids, nutrients, and pesticide residues. Because deep-percolation water moves slowly through the unsaturated zone and ground water is several hundred feet deep in basins with substantial agricultural and urban development, the effects of the contamination may not be seen in ground water for years or decades after irrigation has declined or ceased.

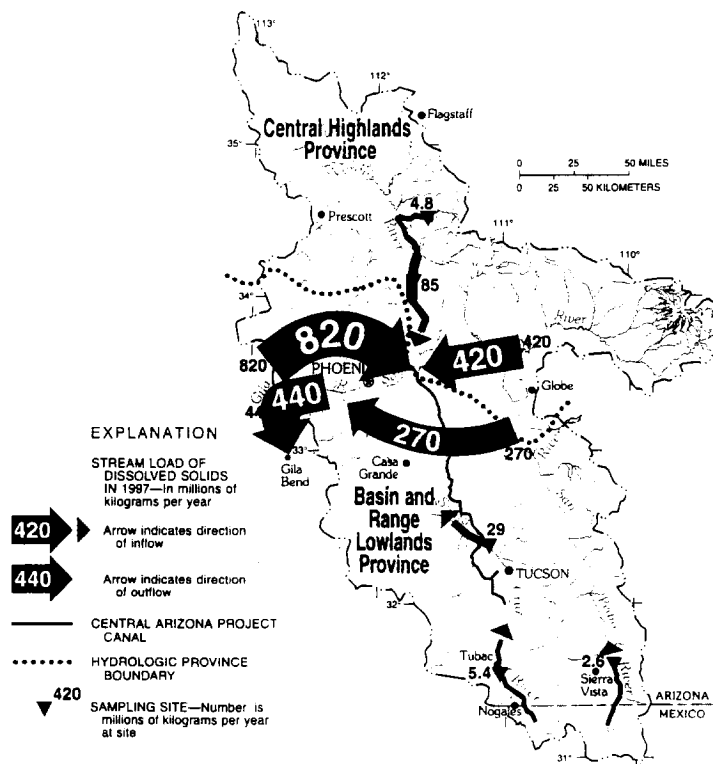

Figure 8. Streams and the CAP canal brought 1.6 billion kilograms of dissolved solids into the Basin and Range Lowlands in 1997, but only 440 million kilograms left the area in streams. The remaining dissolved solids accumulated in soils, the unsaturated zone, and ground water.

What are the sources of nitrogen and phosphorus in basins?

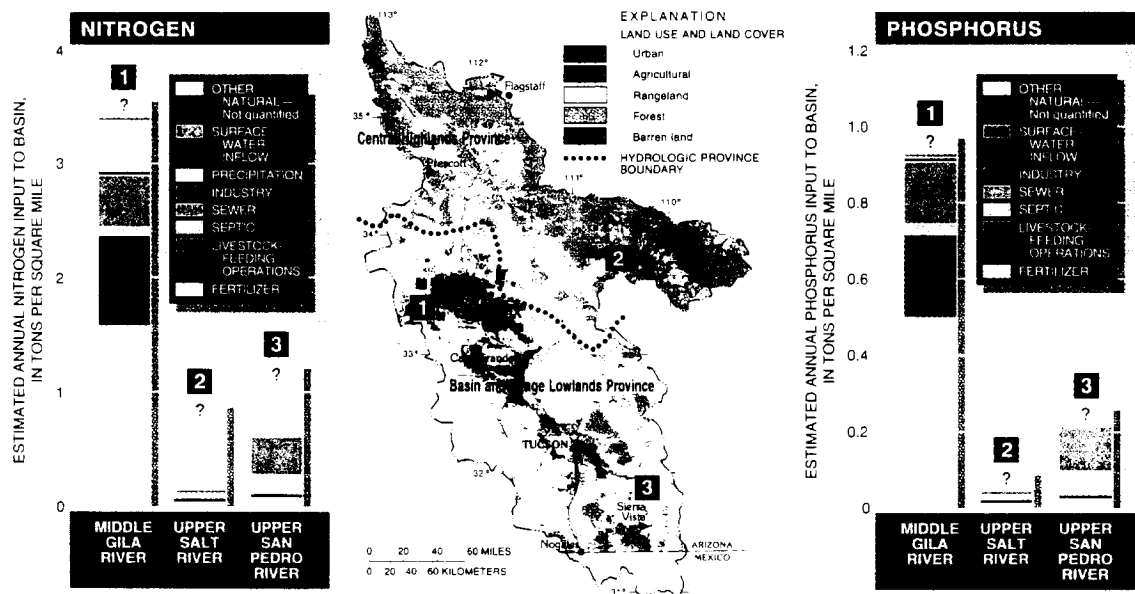

Major sources of nitrogen and phosphorus that can be quantified include fertilizers, livestock-feeding operations (commercial feedlot and dairy operations), inputs to sewer and septic systems, atmospheric deposition, industrial wastes, and streamflow into basins. For the CAZB Study Unit, the quantities of nitrogen and phosphorus contributed by each source annually were determined for selected drainage basins. Sources were quantified using records of fertilizer sales by county, livestock population counts, population and housing census information, National Atmospheric Deposition data for Arizona, USEPA Toxic Release Inventory data, and stream water-quality data collected in the CAZB for the NAWQA Program (Anning, 1998). The quantifiable sources of nitrogen and phosphorus in three basins are shown in figure 9.

Many sources of nitrogen and (or) phosphorus, such as the weathering of geologic formations and soils or the decomposition of vegetation, contribute nutrients to the basins but are difficult, if not impossible, to quantify. As a result, these and other unquantifiable sources of nitrogen and phosphorus are shown in figure 9 with question marks (?) to indicate that the quantities are unknown and may actually exceed the quantifiable sources.

The quantifiable and unquantifiable sources of nitrogen and phosphorus in basins represent potential contributors of nutrients to streams; however, the quantity of nutrients contributed annually from each source does not necessarily reach the streams. Some nutrients may be taken up in terrestrial ecosystems, transported to the ground water, or volatilized to the atmosphere. Conversely, nutrients can enter streams directly when treated sewage effluent from WWTPs is discharged to stream channels or excess irrigation water from agricultural areas discharges to streams. Best management practices and regulation of point-source pollution are methods used to reduce or control the quantity of nutrients entering streams.

In the drainage basins of the upper San Pedro River, upper Salt River, and other perennial streams with minimal agricultural and urban land use, the largest quantifiable source of nitrogen coming into these basins is from precipitation (fig. 9). Sewer and septic systems, livestock-feeding operations, and fertilizers are the largest quantifiable sources of phosphorus in these basins.

In basins with substantial agricultural and (or) urban land use such as the middle Gila River, the quantities of nitrogen and phosphorus from quantifiable sources are much greater per unit area than those for basins with little or no agricultural or urban land use. Additionally, fertilizers, livestock-feeding operations, and sewer (WWTPs) and septic systems account for a larger part of the total nutrients in basins with agricultural and (or) urban land use than in basins without these land uses.

Effluent-dependent streams

Nutrient concentrations in effluent-dependent streams exceeded the background concentrations found in forest/rangeland streams (see fig. 11).

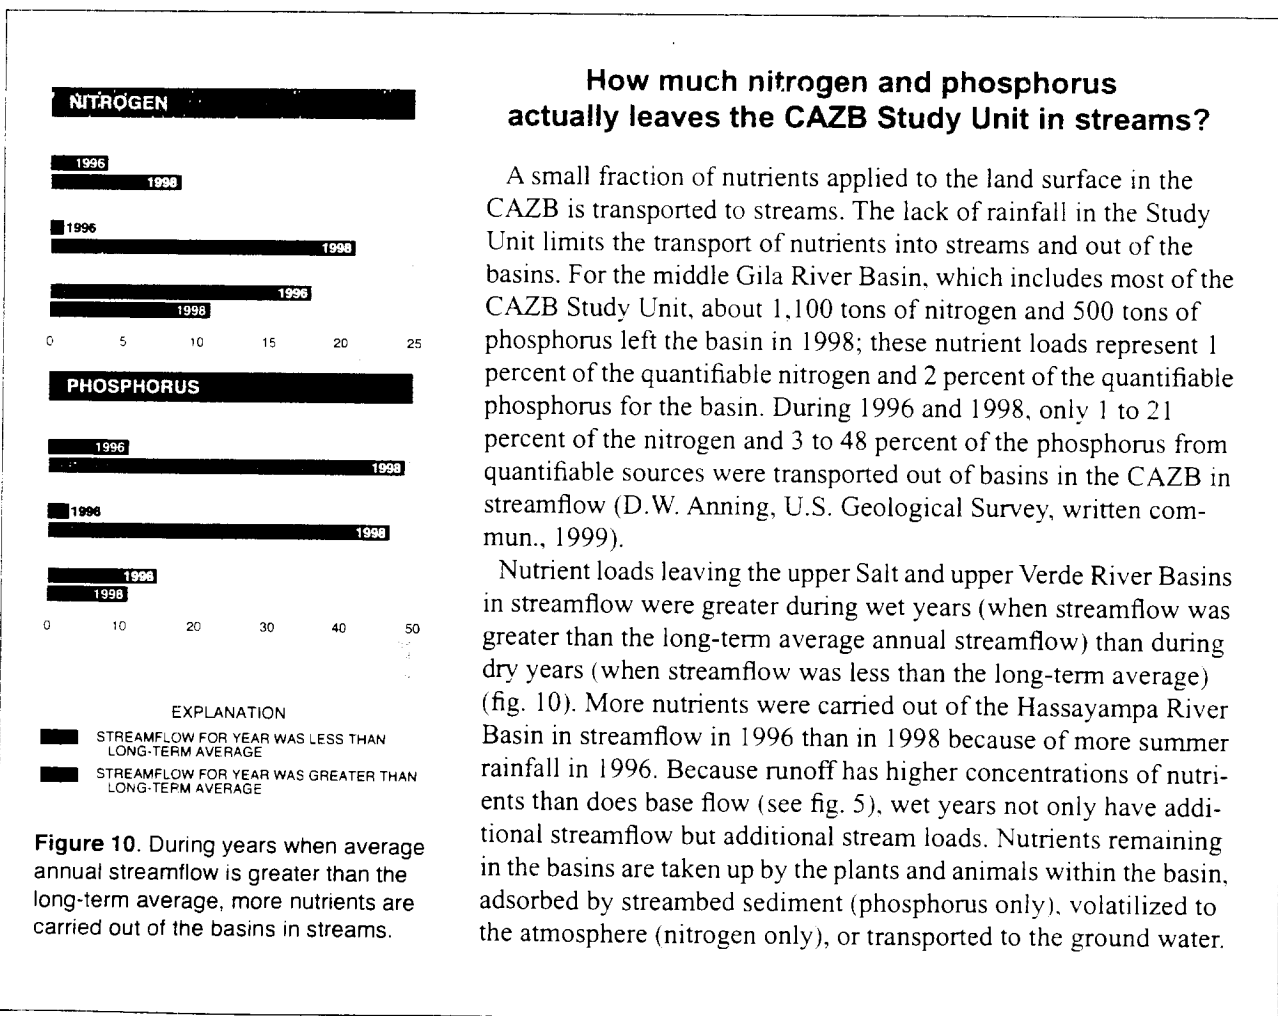

The 91st Avenue WWTP outfall near Phoenix and the Santa Cruz River at Tubac and at Cortaro Road (Tucson; see p. 26 for location of sites) are effluent-dependent streams that were sampled in the CAZB. Data from the San Pedro River at Charleston and the Salt River near Roosevelt represent background values for nutrients in the CAZB because these streams drain areas with relatively little urban or agricultural land use. By

comparison, the nutrient concentrations at the effluent-dependent sites in the CAZB are elevated because the effluent discharged directly into the stream channels is a major source of nitrogen and phosphorus (U.S. Geological Survey, 1999).

Effluent-dependent streams can sustain riparian communities and aquatic life, but the water quality is poor.

Some effluent-dependent streams in the CAZB can support valuable riparian communities with high biodiversity of terrestrial plants and animals; however, dissolved oxygen and phosphorus concentrations in these streams indicate that the water quality is poor. At a minimum, most fish need 3 to 5 mg/L of dis-

solved oxygen (DO) over a long period of time to survive (Swenson and Baldwin, 1965). At the Santa Cruz River at Cortaro, DO concentrations were commonly lower than 3 mg/L (fig. 11), whereas concentrations at the other two effluent-dependent sites were in the minimal range. All the samples from the effluent-dependent streams exceeded the USEPA's desired goal for phosphorus of 0.1 mg/L for prevention of nuisance plant growth (eutrophication) (U.S. Environmental Protection Agency, 1986). Excessive algae and aquatic plant growth can lead to low DO concentrations (U.S. Geological Survey, 1999).

How much nitrogen and phosphorus actually leaves the CAZB Study Unit in streams?

A small fraction of nutrients applied to the land surface in the CAZB is transported to streams. The lack of rainfall in the Study Unit limits the transport of nutrients into streams and out of the basins. For the middle Gila River Basin, which includes most of the CAZB Study Unit, about 1,100 tons of nitrogen and 500 tons of phosphorus left the basin in 1998; these nutrient loads represent 1 percent of the quantifiable nitrogen and 2 percent of the quantifiable phosphorus for the basin. During 1996 and 1998, only 1 to 21 percent of the nitrogen and 3 to 48 percent of the phosphorus from quantifiable sources were transported out of basins in the CAZB in streamflow (D.W. Anning, U.S. Geological Survey, written commun., 1999).

Nutrient loads leaving the upper Salt and upper Verde River Basins in streamflow were greater during wet years (when streamflow was greater than the long-term average annual streamflow) than during dry years (when streamflow was less than the long-term average) (fig. 10). More nutrients were carried out of the Hassayampa River Basin in streamflow in 1996 than in 1998 because of more summer rainfall in 1996. Because runoff has higher concentrations of nutrients than does base flow (see fig. 5), wet years not only have additional streamflow but additional stream loads. Nutrients remaining in the basins are taken up by the plants and animals within the basin, adsorbed by streambed sediment (phosphorus only), volatilized to the atmosphere (nitrogen only), or transported to the ground water.

Effluent-dependent streams are valuable water resources in the CAZB

In many of the urban areas in Arizona, treated sewage effluent from wastewater-treatment plants is discharged into otherwise dry streambeds. Less than a century ago, some of these "effluent-dependent" streams, such as the Santa Cruz River in Tucson (see below) and the Salt River in Phoenix, had natural perennial streamflow, but ground-water pumping, damming of rivers, or other human activities have resulted in a loss of natural streamflow and associated riparian and aquatic communities (Tellman and others, 1997).

In the dry climate of Arizona, effluent-dependent streams provide perennial water resources with a variety of benefits. Effluent-dependent streams can support riparian communities with high biodiversity of terrestrial plants and animals. These streams support limited aquatic invertebrate and fish communities, which are food for organisms higher in the food chain. Riparian plant communities along these streams can help stabilize streambanks, reducing erosion and sedimentation. Trees and bushes provide plant material, creating habitat and food for aquatic organisms and shade that reduces evaporation. Effluent in streams is particularly important to cities and towns in Arizona because it recharges ground water in aquifers and can be used by cities to accrue "recharge credits" that allow for pumping elsewhere in the ground-water basin (Gelt and others, 1999).

Currently (2000), the water quality of effluent-dependent streams limits restoration of instream communities. If the water quality of these streams is improved by upgrading wastewater-treatment methods, it is likely that the streams would be able to support a greater number of aquatic species, and aquatic communities could even begin to resemble those of streams such as the upper San Pedro or upper Salt Rivers.

Newly restored Santa Cruz River near Tubac, Arizona. The Santa Cruz River sustained riparian and aquatic communities in the past (Tellman and others, 1997). Photograph by Walter Hader, Arizona Historical Society, Tucson, 1986.

Santa Cruz River near Tubac, 1997. The effluent-dependent stream at this location is sustained by treated effluent from the local municipal wastewater treatment plant. The thick forest of riparian trees is maintained by perennial streamflow.

Figure 11. Nutrient enrichment in effluent-dependent streams contributes to abundant algal growth, which results in decreased dissolved oxygen and limited aquatic communities.

The level of sewage treatment and the distance effluent travels downstream from the discharge point influence the water quality of effluent-dependent streams.

Ammonia concentrations in effluent at the Santa Cruz River at Cortaro are extremely variable and typically higher than those in the Santa Cruz River at Tubac or the 91st Avenue WWTP (fig. 11). Effluent at the Cortaro site has had secondary treatment, which results in nitrogen remaining in the effluent as ammonia (David Garrett, Pima County Wastewater, oral commun., 2000). In contrast, effluent sampled at the discharge point from the 91st Avenue WWTP has had tertiary treatment in which the ammonia is converted to nitrate. Converting ammonia to nitrate during treatment limits the direct threat of toxicity to fish that ammonia presents, but it does not change the potential for eutrophication of the stream (Mueller and others, 1996).

The lowest nutrient concentrations in effluent-dependent streams were at the Santa Cruz River at Tubac (fig. 11). Effluent in this stream receives secondary treatment and travels about 15 miles downstream to Tubac. As the effluent moves downstream, ammonia is lost to the atmosphere or converted to nitrate,

some nitrate and phosphorus are taken up by plants and aquatic life, and phosphorus may be adsorbed by streambed sediments. Each of these processes reduces concentrations of nitrogen and (or) phosphorus, resulting in lower concentrations with distance downstream from the WWTP.

Abundant algal growth from nutrient enrichment in effluent-dependent streams may adversely affect aquatic organisms. Phosphorus, nitrate, and ammonia in effluent-dependent streams encourage algal growth. Chlorophyll *a* concentrations (fig. 12), which are indicators of the quantity of algae in a stream, were much higher in effluent-dependent streams than in forest/rangeland streams (Gebler, 1998).

Abundant algal growth and the resulting increase in decaying organic material in effluent-dependent streams can cause decreased DO concentrations, particularly at night when plants cease photosynthesis and decrease their oxygen production. The decreased DO can adversely affect aquatic invertebrates and fish.

Figure 12. Nutrients in effluent-dependent streams encourage algal growth, as indicated by chlorophyll *a* concentrations.

Effluent-dependent streams support limited instream communities of aquatic invertebrates. The diversity of pollution-sensitive aquatic invertebrates such as mayflies, stoneflies, and caddisflies in effluent-dependent streams is very low, especially when compared to the high diversity in forest/rangeland streams (fig. 13). Pollution-tolerant species of aquatic worms and midges account for more than 90 percent of the numbers of aquatic invertebrates in effluent-dependent stream reaches sampled in the

Figure 13. Aquatic invertebrate communities in effluent-dependent streams lack diversity.

CAZB (fig. 14). In forest/rangeland streams, mayflies, stoneflies, and caddisflies were the most abundant of all aquatic invertebrate groups, which is consistent with good water quality and instream habitat (Gebler, 1998).

Figure 14. Pollution-tolerant aquatic invertebrates are most abundant in effluent-dependent streams.

Aquatic invertebrates are indica

Aquatic invertebrates are animals such as worms and insects that live in water. Fly fishermen know that game fish such as trout and bass eat insects such as mayflies, stoneflies, and caddisflies. Biologists who study water quality have found that some aquatic invertebrates, such as certain aquatic worms and midges, can tolerate poor water quality. Many types of mayflies, stoneflies, and caddisflies are sensitive to water-quality degradation and are most abundant in streams with good water quality. Biologists can sample for aquatic invertebrates and determine the relative quality of the water by the numbers and types of invertebrates found.

Organochlorine pesticides and PCBs in streambed sediment and fish tissue from effluent-dependent streams exceeded guidelines for protection of aquatic life and fish-eating wildlife. Probable effect levels (PELs) for sediment (Canadian Council of Ministers of the Environment, 1999) were exceeded for DDE and total chlordane in samples from the 91st Avenue WWTP and at a site near the discharge point from the Nogales WWTP into the Santa Cruz River. The PEL is a concentration above which adverse effects to aquatic organisms are predicted to occur frequently. Exceedance of the PEL concentrations indicates that bottom-dwelling aquatic organisms may be adversely affected by toxicity. Total DDT (91st Avenue WWTP) and PCBs (Santa Cruz River at Tubac) in fish-tissue samples exceeded New York State guidelines (Newell and others, 1987) for the protection of fish-eating wildlife. These guidelines are being applied to findings from NAWQA Study Units nationwide. DDT, which breaks down to form DDE and DDD, is associated with past use of DDT in agricultural areas. Use of DDT was discontinued in Arizona in 1969. PCBs were primarily used in industrial and urban settings, but their use was discontinued in 1979. Exceedances of tissue guidelines can result in reduced reproductive ability and other possible adverse effects in wildlife that eat contaminated fish (Faber and Hickey, 1973).

Agricultural/urban streams

As in effluent-dependent streams, nutrient concentrations in agricultural/urban streams were elevated compared with

concentrations in forest/rangeland streams (fig. 11). This is no surprise given that the two agricultural/urban streams—Buckeye Canal near Avondale and Hassayampa River near Arlington—receive effluent from the 91st Avenue WWTP in Phoenix. The effluent is mixed with ground water in Buckeye Canal and used to irrigate cotton and other crops. Downstream, effluent and irrigation return flows in Buckeye Canal are discharged into the Hassayampa River near Arlington. At this point, the water has been used and reused for agricultural irrigation, and nitrate concentrations are typically higher than those in the original effluent (fig. 11) because of the use of fertilizers in the agricultural area near Buckeye.

Herbicides were detected in streams soon after application to agricultural lands, but concentrations did not exceed guidelines for protection of aquatic life. In the West Salt River Valley west of Phoenix, the pre-emergent herbicides dacthal, EPTC, simazine, and trifluralin are applied to tilled fields prior to cotton planting in the early spring to control weeds. They may

be reapplied in the fall to fields where winter crops are grown. These herbicides were detected in surface-water samples from the agricultural/urban streams in the early spring and fall, soon after application. Changes in concentrations of dacthal at the Hassayampa River near Arlington (fig. 15) are representative of the patterns seen for herbicide concentrations at both sites. Agricultural and rainfall runoff carry these pesticides to streams. Because streamflow at these sites is not used for drinking water but does sustain aquatic life, guidelines for the protection of aquatic life were used to evaluate water quality. Aquatic-life guidelines for simazine and trifluralin were not exceeded in any samples from these sites. There are no aquatic-life guidelines for dacthal and EPTC.

Organochlorine pesticides that persist in streambed sediment and in fish tissue from an agricultural/urban stream are a concern for aquatic ecosystem health. PEL concentrations for sediment were exceeded for DDE and DDT at the agricultural/urban stream site on the Buckeye Canal

Figure 15. Herbicides were detected in streams soon after being applied to crops.

near the Hassayampa River (adjacent to the Hassayampa River at Arlington site, see p. 26). Concentrations of DDE in fish-tissue samples from this site exceeded guidelines established by New York State (Newell and others, 1987) for the protection of fish-eating wildlife. Concentrations of toxaphene in two out of three fish-tissue samples from the same site

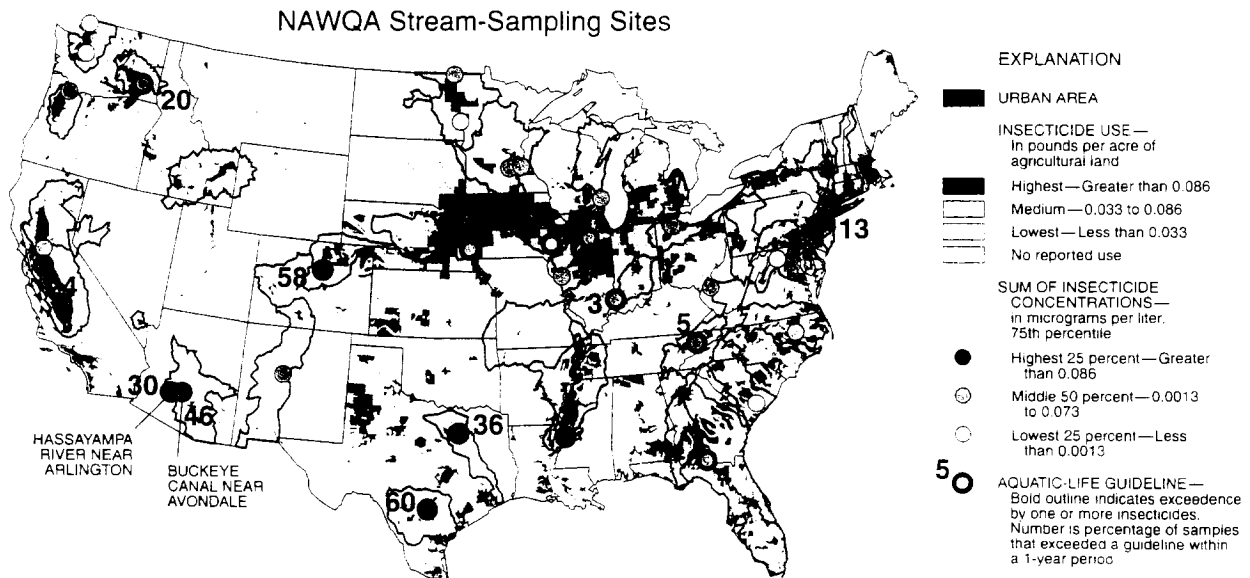

exceeded the National Academy of Science/National Academy of Engineering (1973) guideline for the protection of fish-eating wildlife. Past use of pesticides including DDT, toxaphene, and others on agricultural areas in the West Salt River Valley is the source of these pesticides. Though use of these pesticides was discontinued decades ago, the pesticides persist

over time and their breakdown products continue to enter streams by erosion of contaminated soils, surface-water runoff, and atmospheric deposition. Exceedances of tissue guidelines indicate possible adverse effects, such as reduced reproductive ability and eggshell thinning, to birds and other wildlife that eat contaminated fish (Faber and Hickey, 1973).

In the CAZB Study Unit, insecticide concentrations in agricultural/urban streams are among the highest in the Nation

Pesticides in water were measured at 117 sampling sites on 114 rivers and streams across the United States as part of the NAWQA Program from 1992–1998. At each site, concentrations of all insecticides detected during a 1-year period were summed and categorized as low (lowest 25 percent), middle (middle 50 percent), and high (highest 25 percent) compared to concentrations at all of the sites monitored (see figure below). This information was compared, by county, to insecticide use during the early to mid-1990's on agricultural lands.

In the CAZB Study Unit, insecticide concentrations in streams with mixed agricultural/urban land use were among the highest in the Nation. These sites—the Buckeye Canal near Avondale and the Hassayampa River near Arlington in the West Salt River Valley—are dominated by treated effluent and irrigation return flows that contain insecticides from urban and agricultural land uses. Nearly one-half the samples (46 percent) collected from the Buckeye Canal during 1 year exceeded aquatic-life guidelines for one or more of the following insecticides: diazinon, malathion, lindane, and chlorpyrifos. At the Hassayampa River site, 30 percent of samples collected in a 1-year period exceeded aquatic-life guidelines for one or more of the following pesticides: chlorpyrifos, azinphos-methyl, DDE, dinoseb, malathion, diazinon, and parathion. Although these streams are not used for drinking water, the water quality does present a potential hazard to aquatic life. In addition, little is known about the effects of mixtures of pesticides, even at low concentrations, on aquatic life (Gilliom, 1999).

Insecticide concentrations in streams in the West Salt River Valley near Phoenix are among the highest in the Nation.

Natural Ground-Water Quality

It is important to understand how natural processes affect ground-water quality in order to identify the effects of urban and agricultural development under similar hydrogeologic conditions. In the CAZB, the majority of ground-water basins do not have significant urban or agricultural development. The ground-water quality in these basins is primarily a product of natural processes such as the interaction of ground water with rocks and sediment in the basins (Robertson, 1991).

Natural sources of dissolved-solids and nitrate can control ground-water quality in basins with minimal urban development. Specific-conductance values (an indirect measure of the dissolved-solids concentration) and nitrate concentrations for ground water in basins with minimal urban development increase northward from southeastern Arizona toward the central part of the State (figs. 16 and 17). The increasing specific-conductance values can be attributed to a corresponding increase in evaporite deposits in basin sediments from southeast to northwest (Gellenbeck and Coes, 1999). Evaporite deposits in the basins contain minerals such as halite (salt) and gypsum that can be easily dissolved in ground water. (Robertson, 1991). The increasing nitrate concentrations can be largely attributed to natural sources; however, human activities such as agriculture can be a source in some basins. In some locations in the CAZB, high nitrate concentrations in ground water reported prior to any agricultural or urban development indicate that natural

Figure 16. Nitrate concentrations and specific conductance values in ground water from basins with minimal urban development increase from the southeast to the northwest. (Basins shown below in figure 17.)

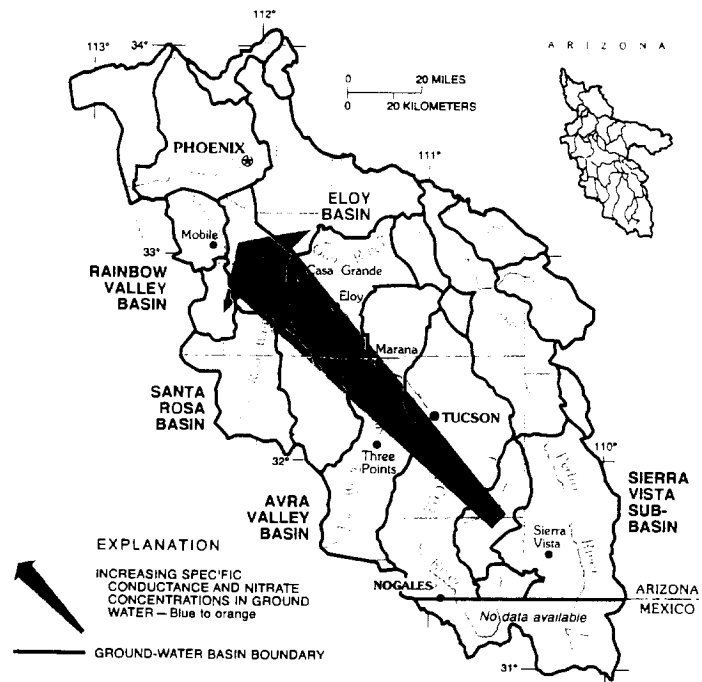

Figure 17. Increasing specific conductance values in ground water from southeast to northwest can be attributed to an increase in soluble evaporite deposits in basin sediments. Increasing nitrate concentrations in the same direction may be the result of naturally occurring nitrate and of human activities that include agriculture.

sources of nitrate are present in some basins (Hem, 1985; Robertson, 1991; Gellenbeck, 1994; Gellenbeck and Coes, 1999). Dissolution of evaporite deposits, decay of buried organic matter, precipitation, weathering of rocks and soils, and fixation by microorganisms are just a few of the possible sources of naturally occurring nitrate in ground water.

Figure 18. Ground water sampled in the CAZB Study Unit generally is from greater depths than ground water sampled in NAWQA Study Units across the Nation.

Quality of deep, older ground water unaffected by human activities

In general, ground water in Arizona is replenished (recharged) at very slow rates because of little precipitation, high evaporation losses, and the long distance water must travel to recharge deep aquifers. In the CAZB, 63 percent of the wells sampled that draw water from aquifers used for drinking water were at least 250 feet deep compared to 26 percent of NAWQA wells sampled nationwide (fig. 18). Recharge takes longer to reach deep aquifers than shallow aquifers; therefore, deep ground water typically was recharged earlier and is older than shallow ground water. Tritium age dating of ground water (see below) confirms that 55 percent of the wells sampled in the CAZB yielded ground water that was recharged prior to 1953 and possibly thousands of years earlier. For example, some ground water in the Upper Santa Cruz Basin was determined to be about 6,500 years old (Kalin, 1994). Across the Nation, only 27 percent of the NAWQA wells sampled for tritium yielded ground water that was recharged prior to 1953.

The age and depth of ground water in the CAZB have important implications for water quality and quantity. Because much of the deep ground water sampled in the CAZB was recharged prior to 1953 and has not mixed with younger recharge, drinking-water quality generally has not been substantially affected by human activities that took place after 1953. The movement of contaminants from the land surface to the deep ground water is hindered by the thickness of basin-fill sediments through which contaminants must travel. Ground-water quantity is affected because ground water pumped from deep aquifers is not being replaced by recharge (see p. 5), resulting in a net decrease in the quantity of ground water available for consumption.

Method for dating ground water

Tritium is a radioactive isotope that can be used to estimate whether ground water has been recharged before or after 1953. Large quantities of tritium were released to the atmosphere during testing of thermonuclear weapons from 1952 until the late 1960s. Atmospheric tritium is incorporated into water molecules in the atmosphere prior to precipitation and recharge to ground water. The concentration of tritium in ground water at a given time is controlled by both the quantity of tritium in the atmosphere when precipitation and recharge occur and the radioactive decay rate of tritium. Ground water that does not contain detectable tritium (less than 2.5 picocuries of tritium per liter) can be assumed to have been recharged prior to 1953, and ground water that does contain detectable tritium (more than 2.5 picocuries of tritium per liter) is assumed to contain some component of ground water that was recharged after 1953.

Tritium concentrations in precipitation are a guide for determining when ground water was recharged.

Concentrations of arsenic, fluoride, and molybdenum exceeded drinking-water standards in samples from major aquifers. The median arsenic concentration in ground water for the three CAZB basins sampled was 4 µg/L. One sample from the Upper Santa Cruz Basin and one sample from the West Salt River Valley exceeded the current MCL for arsenic of 50 µg/L; however, a new, lower standard of 5 µg/L has been proposed by the USEPA because of the cancer risk posed by arsenic in drinking water (U.S. Environmental Protection Agency, rev. August 25, 2000). When arsenic concentrations in ground water sampled in the CAZB are compared to the proposed standard, more than 50 percent of samples from

aquifers in West Salt River Valley that are used for drinking water exceed 5 µg/L. Seventeen percent of samples in the Upper Santa Cruz Basin and 10.5 percent of samples in the Sierra Vista subbasin exceed 5 µg/L. The USEPA may not settle on 5 µg/L, but the new standard is likely to be significantly lower than the current MCL.

The median concentration of fluoride was 0.5 µg/L; about 2 percent of the samples exceeded the current MCL for fluoride of 4 µg/L. The median concentration of molybdenum was 3 µg/L; about 1 percent of the samples exceeded the current lifetime health advisory for molybdenum of 40 µg/L established by the USEPA.

Radon and uranium are detected in most ground-water samples. Radon is a colorless and odorless radioactive gas that is carried in the water pumped from wells (fig. 19) and released to indoor air by activities such as cooking and showering. Breathing radon increases the risk of lung cancer (U.S. Environmental Protection Agency, rev. October 18, 1999). Radon is naturally formed in rocks and soils from the radioactive decay of radium, an intermediate product in the uranium decay process. In the CAZB Study Unit, radon was present in 100 percent of the samples, and uranium was detected in 90 percent of the samples. The median concentrations for radon and uranium were 584 picocuries per liter and 3 micrograms per liter, respectively. Currently (2000), there are no USEPA MCLs for radon and uranium; however, proposed MCLs could result in increased costs for water suppliers to treat drinking water for these constituents or find alternate supplies. Additional costs would probably be passed on to the water user (see information on proposed standards for arsenic, radon, and uranium on p. 20).

Figure 19. Samples are collected at the well head for radon analysis to prevent possible sample contamination from exposure to the atmosphere.

Effects of Human Activities on Ground-Water Quality

The contamination of major aquifers is largely controlled by hydrology and land use (U.S. Geological Survey, 1999). In the CAZB Study Unit, deep ground water that was recharged prior to 1953 typically has not been affected by human activities (see p. 18). In areas with recent recharge (after 1953), ground water is more likely to be contaminated by nutrients and man-made chemicals associated with urban and agricultural land uses.

Ground-water quality deteriorates in irrigated areas. Irrigation water that seeps downward is a principal source of ground-water recharge in irrigated areas of the CAZB. Dissolved-solids concentrations in seepage can be as much as five times those in the original irrigation water (Bouwer, 1990) because of concentration by evaporation and plant use (see p. 9). The greater the dissolved-solids concentration in the applied irrigation water, the greater the concentration in the seepage moving downward to the ground water.

To determine the effects of irrigated agriculture on shallow ground-water quality, nine monitoring wells

were drilled and sampled in the southwestern part of the West Salt River Valley (see "Study Unit Design," p. 26). Because the average depth to ground water in the nine wells is 32 feet (table 1) compared to 230 feet for wells sampled basinwide, irrigation seepage does not have to travel far to reach the shallow ground water in the agricultural area. Sources of irrigation water in this area include treated sewage effluent, water from the Salt River and CAP canal, irrigation return flows, and ground water. Dissolved-solids concentrations of these sources range from about 900 mg/L for treated sewage effluent (Tadayon and others, 1998) to 650 mg/L for CAP water and 470 mg/L for Salt River water (Salt River Project, 1997).

The median dissolved-solids concentration in water from the nine shallow wells exceeded 3,000 mg/L (table 1). In addition, the effects of nitrate from fertilizer applications and reuse of irrigation return flows were evident from the median nitrate concentration that was nearly twice the MCL of 10 mg/L (table 1).

Table 1. Median concentrations of nitrate and dissolved solids were highest in shallow ground water from an agricultural area in the West Salt River Valley

Study area	Median concentration, in milligrams per liter		Average depth to ground water, in feet
	Nitrate	Dissolved solids	
<i>West Salt River Valley</i>			
<i>Agricultural area</i>	19.0	3,050	32
<i>Basinwide</i>	2.7	560	230
<i>Upper Santa Cruz Basin</i>	1.5	305	230
<i>Sierra Vista subbasin</i>	0.78	262	171
<i>U.S. Environmental Protection Agency drinking-water standard</i>	¹ 10	² 500	

¹ Maximum Contaminant Level.

² Secondary Maximum Contaminant Level.

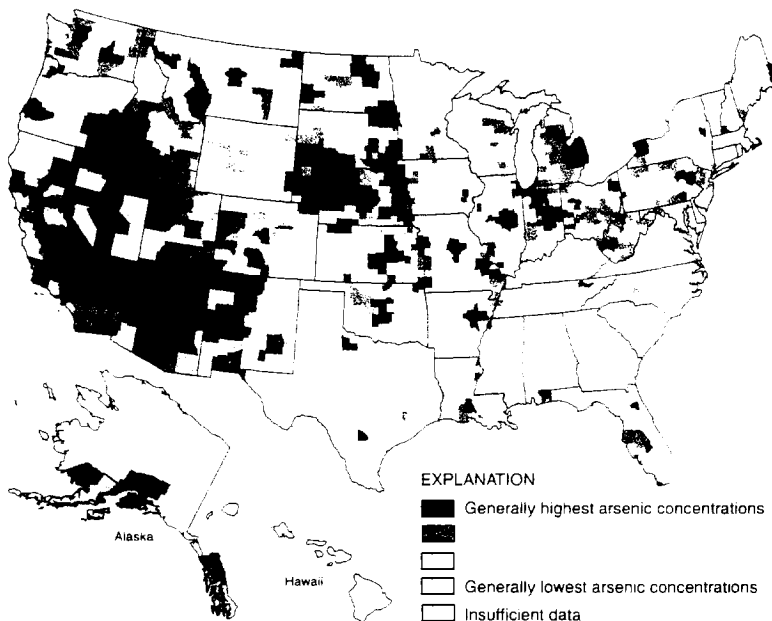

Proposed drinking-water standards for arsenic, radon, and uranium have major implications for ground-water supplies

During 1991–98, arsenic, radon, and uranium were measured in ground-water samples from 36 NAWQA Study Units across the United States. If the ground-water samples from these Study Units are representative of ground water across the Nation, MCLs (see Glossary) proposed by the USEPA for these constituents will affect many water suppliers and municipalities in the United States. Because ground-water supplies in many parts of the Nation will likely exceed the proposed MCLs, public-water systems would be required to either specifically treat their water to decrease concentrations of the constituents or find alternative sources of supply. Costs of these options would probably be passed on to water users.

Arsenic

The current USEPA MCL for arsenic in drinking water, 50 µg/L, is under review after recognition of the risks of developing cancers (National Research Council, 1999). In 2000, the USEPA proposed a new, lower arsenic MCL of 5 µg/L (U.S. Environmental Protection Agency, rev. June 2, 2000). In samples collected in three CAZB basins, only 2 percent exceeded the current USEPA MCL; however, 32 percent exceeded the lower, proposed MCL. In samples collected across the Nation, only 0.6 percent exceeded the current USEPA MCL; however, 14 percent exceeded the lower proposed MCL. Arizona, including the CAZB, is among the areas in the Nation where 10 percent or more of ground-water samples are likely to exceed the lower MCL (figure at right; Welch and others, 2000).

High concentrations of arsenic in ground water are more widespread in the West.

Radon and uranium

Currently, USEPA MCLs for radon and uranium do not exist. Because of public health concerns, including increased risks for developing lung cancer, the USEPA proposed an MCL of 20 µg/L for uranium in 1991. In 1999, the USEPA proposed an MCL of 300 picocuries per liter (pCi/L) for radon; however, if States or water suppliers implement methods to lower radon levels in indoor air, they would only be required to meet an Alternate MCL (AMCL) of 4,000 pCi/L (U.S. Environmental Protection Agency, rev. April 21, 2000; U.S. Environmental Protection Agency, rev. October 18, 1999). Of the ground-water samples collected in the three CAZB basins, 9 percent exceeded the proposed uranium

MCL, 91 percent exceeded the proposed radon MCL, and 1 percent exceeded the proposed radon AMCL. In the NAWQA samples collected nationwide, 4 percent exceeded the proposed uranium MCL, 61 percent exceeded the proposed radon MCL, and 4 percent exceeded the proposed radon AMCL (Dennis Wentz and others, U.S. Geological Survey, written commun., 1999). The Study Units with the highest radon concentrations were in the Colorado Rockies and the Eastern United States. Median concentrations of radon and uranium in the CAZB Study Unit were higher than median concentrations for the United States (figure at right).

Median concentrations of radon and uranium in ground water in the CAZB exceeded those for the Nation.

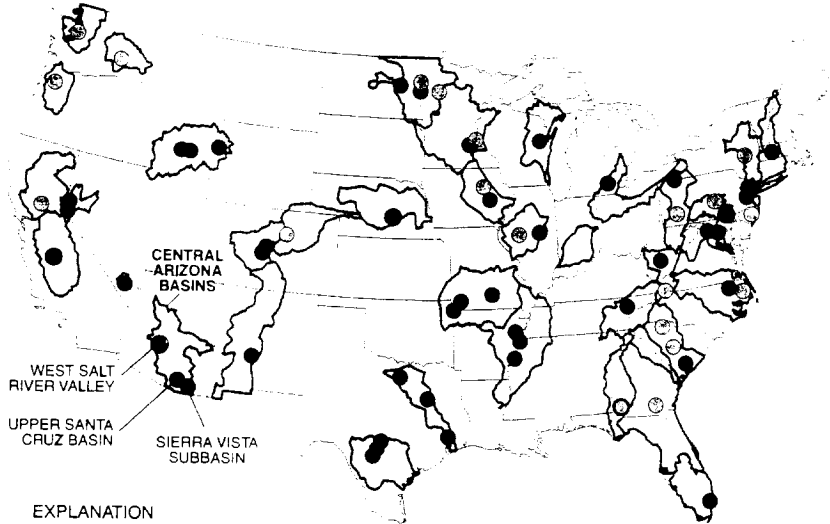

Nitrate concentrations in ground water in the West Salt River Valley are among the highest in the Nation

The study of water quality in deep aquifers that provide drinking water in the West Salt River Valley is one of eight NAWQA ground-water studies nationwide that had more than 10 percent of samples that exceeded the USEPA MCL for nitrate of 10 mg/L (figure at right). Of 35 samples collected basinwide in the West Salt River Valley, 34 percent had concentrations greater than the USEPA MCL. Seventy-eight percent of shallow ground-water samples from the agricultural land-use study in the West Salt River Valley had concentrations greater than the USEPA MCL for nitrate. Only 10 percent of samples from the Upper Santa Cruz Basin and none of the samples from the Sierra Vista subbasin had concentrations that exceeded the USEPA MCL for nitrate.

Excessive nitrate in drinking water is a health concern for children and adults. In children, high nitrate concentrations can result in "blue-baby syndrome," in which oxygen levels in the blood of infants are low, sometimes fatally so (National Governor's Association, 1991).

Birth defects also have been attributed to high nitrate concentrations (National Governor's Association, 1991). In adults, high nitrate concentrations have been associated with cancer (National Academy of Sciences, 1977).

EXPLANATION

PERCENTAGE OF SAMPLES EXCEEDING DRINKING-WATER STANDARD FOR NITRATE OF 10 MILLIGRAMS PER LITER—
Each dot represents a major aquifer

- Greater than 10 percent
- ◐ Less than 10 percent
- Zero samples exceed standard

○ BACKGROUND CONCENTRATION—
Bold outline indicates median values greater than background concentration of 2 milligrams per liter

The CAZB is one of eight Study Units in the Nation with nitrate concentrations in ground water that exceed the drinking-water standard in more than 10 percent of samples.

Sources of nitrate in the Central Arizona Basins Study Unit include evaporite deposits in basin sediments, precipitation, agricultural fertilizers, animal-feeding operations, WWTP outflow, and others

(see p. 10). In areas with agricultural and (or) urban development, sources of nitrate related to human activities are prevalent, whereas precipitation and geologic sources of nitrate predominate in undeveloped areas.

The highest concentrations of nitrate and dissolved solids were in shallow ground water beneath an irrigated agricultural area. Shallow ground water from the agricultural land-use study area in the West Salt River Valley had median concentrations of nitrate (19 mg/L) and dissolved solids (3,050 mg/L) that exceeded the USEPA MCL and SMCL, respectively (table 1). Nitrate and dissolved solids from irrigation and agricultural practices are accumulating in shallow ground water (see p. 9 and 11). The shallow ground water in this area is not used for drinking water, and clay beds reduce the

likelihood of contamination of the aquifers below that are used for drinking water (see p. 22).

Deeper ground water from urban, rangeland, and agricultural areas in other parts of the West Salt River Valley had a median nitrate concentration that was less than the MCL of 10 mg/L; however, the median concentration of dissolved solids exceeded the SMCL of 500 mg/L (table 1). Median concentrations of nitrate from the Upper Santa Cruz Basin and the Sierra Vista subbasin also were less than the MCL, and median concentrations of dissolved solids were less than the SMCL (table 1).

Clay beds that currently protect deep ground water from contamination may not do so in the future.

In the agricultural land-use study area of the West Salt River Valley (fig. 20), the tops of low-permeability clay beds are about 150 to 400 ft below the land surface. These clay beds impede the downward movement of irrigation seepage and reduce the likelihood of contaminants reaching deeper drinking-water supplies. Domestic wells in the area yield water from beneath the protective clay beds. Ground water above the clay beds has higher nitrate and dissolved-solids concentrations than ground water from beneath the clay beds (fig. 21). In this area, ground-water samples from above the clay beds had a median dissolved-solids concentration of 3,050 mg/L and a median nitrate concentration of 19.0 mg/L (table 1). Ground-water samples from below the clay beds had a median dissolved-solids concentration of 702 mg/L and a median nitrate concentration of 1.9 mg/L. Care must be taken in drilling and completing drinking-water wells below the clay beds to ensure that shallow ground water above the clay beds does not contaminate the well and aquifer below.

Figure 20. Low-permeability clay beds in an agricultural area in the West Salt River Valley reduce the likelihood of contamination reaching deeper drinking-water supplies.

Figure 21. Ground water above the clay beds was recharged after 1953 and has been affected by agricultural activities.

Analyses of the tritium from ground water in this area indicated that water above the clay beds generally had been recharged after 1953, and water below the clay beds generally had been recharged before 1953 (see information about age dating ground water on p. 18). Although the clay beds currently reduce the likelihood that irrigation seepage will contaminate the ground water below, future large-scale withdrawals of ground water from below the clay beds could possibly result in the movement of shallow, poor quality water through the clay beds and into the domestic ground-water supply.

Occurrence and distribution of pesticides in ground water in the CAZB reflect both agricultural and urban land uses. Ten pesticides were detected in shallow ground water from the agricultural land-use study area in the West Salt River Valley, west of Phoenix (fig. 22). In other parts of the West Salt River Valley, consisting of agricultural, urban, and rangeland areas, eight pesticides were detected in ground water. Five pesticides were detected in ground water from the Upper Santa Cruz Basin, where there is a mixture of land-use types, but 60 percent of the basin is undeveloped rangeland (Coes and others, 2000). In the Sierra Vista subbasin, where urban and agricultural land uses are minimal (3.3 percent of basin; Coes and others, 1999) and have been minimal in the past, no pesticides were detected in ground-water samples. During 1996–98, the largest quantities of pesticides used among the three basins were for agriculture in the West Salt River Valley (Ken Agnew, University of Arizona, Pesticide Information and Training Office, written commun., 1999).

Figure 22. The largest number of pesticides was detected in an agricultural area in the West Salt River Valley.

Most of the pesticides detected in ground water in the CAZB were herbicides used to control unwanted plants in urban and agricultural areas (fig. 23). Herbicide use in urban areas is indicated by detections of simazine and prometon in the West Salt River Valley and prometon and 2,4-D in the Upper Santa Cruz Basin. These herbicides are used primarily in nonagricultural areas (U.S. Geological Survey, 1999). Detections of atrazine and deethylatrazine (a breakdown product of atrazine) in the West Salt River Valley and the Upper Santa Cruz Basin are an indication that herbicides used in areas of present and historical agriculture are affecting ground-water quality. Atrazine is one of the most heavily used herbicides in agricultural areas in the United States (U.S. Geological Survey, 1999).

Concentrations of pesticides in ground water did not exceed drinking-water standards or guidelines. Although deethylatrazine, simazine, prometon, DDE, atrazine, and diuron were detected in more than 30 percent of the ground-water samples from the agricultural land-use study area of the West Salt River Valley, none of the concentrations exceeded drinking-water standards or guidelines. Similarly, pesticides detected in ground water from the basinwide sampling in the West Salt River Valley during 1996–98 did not exceed drinking-water standards or guidelines.

DDE was detected in 10 (56 percent) of the shallow ground-water samples from the agricultural land-use study area in the West Salt River Valley. Detections of DDE in this area are the result of the persistence of this insecticide breakdown product in the environment and the physical characteristics of the ground-water system in

the area. In particular, the shallow depth to ground water in the agricultural land-use study area means that irrigation seepage and recharge, containing pesticides and their breakdown products, do not have to travel far to contaminate the ground water. Clay layers impede the movement of pesticides into the deeper aquifers in the area. The soils in the agricultural area have been identified as a source of DDE for the ground water (Brown, 1993). The only detection of DDE in the West Salt River Valley outside of the agricultural area was in a sample from the northern part of the Phoenix metropolitan area. DDE was not detected in samples from the Upper Santa Cruz Basin or the Sierra Vista subbasin. The large depths to ground water and small amounts of DDT used in most of the West Salt River Valley, the Upper Santa Cruz Basin, and the Sierra Vista subbasin limit the potential for introduction of DDE to the ground water.

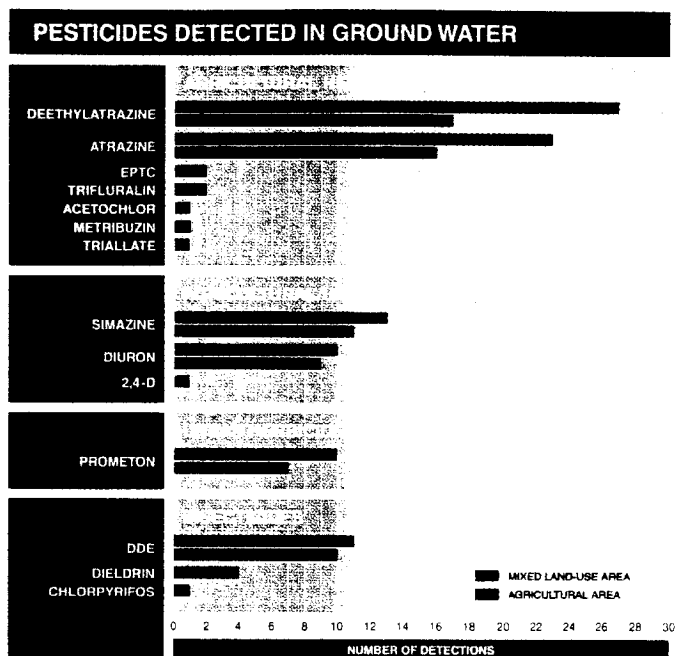

Figure 23. Most of the pesticides detected in ground water in the CAZB were herbicides used in agricultural and urban environments.

Pesticides and Human Health

Laboratory studies, mostly on animals, have shown that pesticides can cause health problems such as birth defects, nerve damage, cancer, and disruption of the endocrine system (USEPA, rev. June 12, 2000). The health effects on humans are not adequately understood, particularly when estimating the risks of exposure to mixtures of pesticides in water (U.S. Geological Survey, 1999). The USEPA determines risk on the basis of toxicity and exposure to a single pesticide (U.S. Environmental Protection Agency, rev. November 17, 1999), whereas NAWQA studies in the CAZB (see p. 24) and nationwide have shown that most contamination in water occurs as pesticide mixtures (U.S. Geological Survey, 1999). The effects of exposure to low concentrations of pesticide mixtures in drinking water is not known and will require further study to determine if standards or guidelines can be developed.

Detections of multiple pesticides indicate the complexity of contamination from land-surface activities. No standards or guidelines currently exist for mixtures of pesticides in drinking water because their effect on human health is not known (U.S. Geological Survey, 1999). All 9 wells in the agricultural land-use study area had 3 or more pesticides detected, whereas only 3 of the 35 wells sampled basinwide in the West Salt River Valley had 3 or more pesticides detected, and none of the wells in the Upper Santa Cruz Basin had 3 or more pesticides detected (fig. 24). No pesticides were detected in the Sierra Vista subbasin.

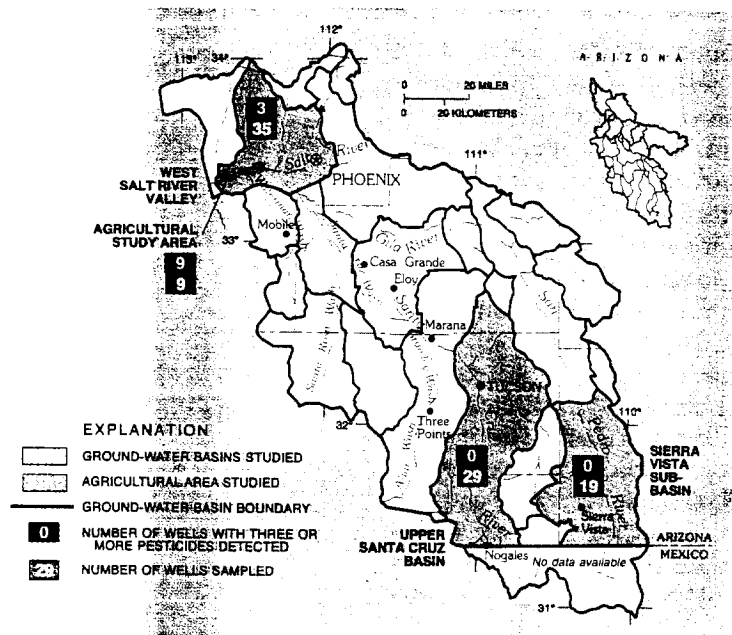

Figure 24. Multiple pesticides were detected in all nine monitoring wells in the agricultural land-use study area of the West Salt River Valley.

Figure 25. The VOCs trichloromethane, 1,2,4-trimethylbenzene, and tetrachloroethene were detected most frequently in ground water.

Volatile organic compounds (VOCs), including gasoline compounds, solvents, and refrigerants, have been identified as a major concern for ground-water contamination in Arizona (Marsh, 1994). Leaking underground storage tanks and disposal of solvents have been linked to most of the documented cases of ground-water contamination by VOCs. Electronic- and aerospace-manufacturing facilities use solvents for degreasing and are known to be sources of some of the largest VOC contamination problems in Arizona. Disposal of solvents from these types of facilities has occurred since the 1950s (Marsh, 1994). Dry-cleaning facilities also have been identified as sources of recent ground-water contamination by VOCs. Some municipal supply wells in the urban areas of Phoenix and Tucson are no longer used because of contamination by VOCs (Marsh, 1994).

VOCs were detected in ground water from all three basins sampled during 1996-98 (fig. 25). Of the 96 samples collected, 33 (34 percent) contained trichloromethane, 24 (24 percent) contained 1,2,4-

trimethylbenzene, and 20 (21 percent) contained tetrachloroethene (otherwise known as perchloroethylene, PCE, a solvent commonly used in dry cleaning). Only two VOC detections exceeded drinking-water regulations—PCE (5.48 µg/L) in the Upper Santa Cruz Basin and 1,2-dibromoethane (0.080 µg/L) in shallow ground water in the agricultural area of the West Salt River Valley.

Shallow ground water from the nine wells in the agricultural land-use study area had the largest number of VOC detections (35). Ground water from the other 35 wells in the West Salt River Valley had 32 detections. The Upper Santa Cruz Basin (18) and the

Sierra Vista subbasin (13) had fewer detections. The larger area of urban land use in the West Salt River Valley appears to be the reason for the greater number of detections there than in the other basins sampled.

Three wells that had five or more VOCs detected in ground water were located in the metropolitan area of Phoenix in the West Salt River Valley. The VOCs detected in these wells were either refrigerants, solvents and chemicals used to make solvents, or gasoline additives. These detections are typical of detections found in small-capacity wells in the metropolitan Phoenix area (Marsh, 1994). Combinations of solvents and gasoline additives are often detected in

ground water because their use is widespread, not necessarily because they are from the same source (Squillace and others, 1999).

Detections of VOCs in ground water in the relatively undeveloped Sierra Vista subbasin indicate that ground water in localized areas of the subbasin may be affected by human activities.

These detections are not widespread; therefore, the effects of human activity on present-day ground-water quality are not considered significant for the entire subbasin. These detections are an “early warning” of what could occur in the future in a basin that is presently considered minimally affected by urban activities.

Trichloromethane was the most commonly detected VOC in the Nation and in the CAZB Study Unit

Trichloromethane (chloroform), tetrachloroethene (PCE), and 1,2,4-trimethylbenzene were three of the five most commonly detected VOCs in the Nation and in the CAZB when concentrations above an assessment level of 0.1 µg/L were considered. The national data collected by the NAWQA Program during 1996–99 represent ambient ground water for all land-use types. Trichloromethane and PCE have been shown to cause cancer in laboratory animals from long-term exposure at concentrations greater than USEPA MCLs.

Trichloromethane is a by-product created during the use of chlorine to disinfect water, a solvent, and a degradation product of carbon tetrachloride. It can enter ground water from lawn irrigation, leaking sewers and water mains, and spills or improper disposal at industrial sites. The use of treated effluent from sewage-treatment plants for irrigation also provides a way for trichloromethane to reach the ground water in the CAZB, specifically in the agricultural land-use study area in the West Salt River Valley.

PCE is a solvent used primarily for degreasing and at dry-cleaning facilities. 1,2,4-trimethylbenzene is used to make trimellitic anhydride, dyes, and pharmaceuticals. Because there are many individual sources of these compounds in urban areas of the CAZB, it is difficult to identify the exact sources of ground-water contamination without site-specific studies, which were beyond the scope of the NAWQA sampling program.

Five most frequently detected volatile organic compounds in the CAZB and the Nation

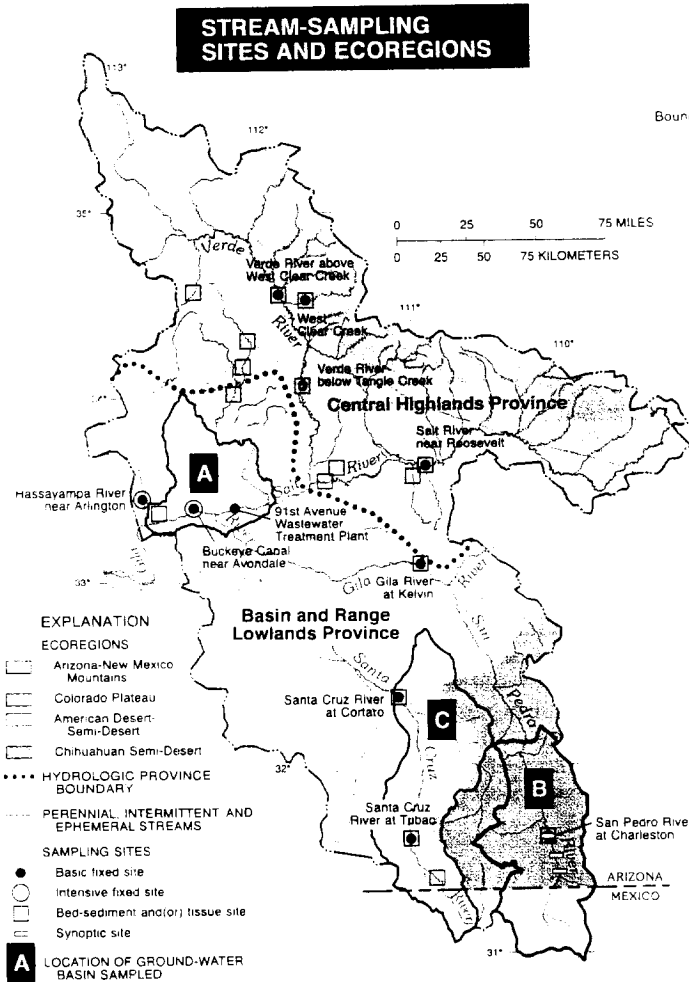

Central Arizona Basins Study Unit		Nation	
Compound name	Frequency of detection, in percent	Compound name	Frequency of detection, in percent
Trichloromethane	16	Trichloromethane	12
PCE	6	Toluene	4
1,2,4-Trimethylbenzene	5	Tetrachloroethene	4
1,2-Dibromoethane	4	Diethylsulfide	4
1,1,1-Trichloroethane	2	1,2,4-Trimethylbenzene	4

(Data include all land-use types; assessment level of 0.1 microgram per liter)

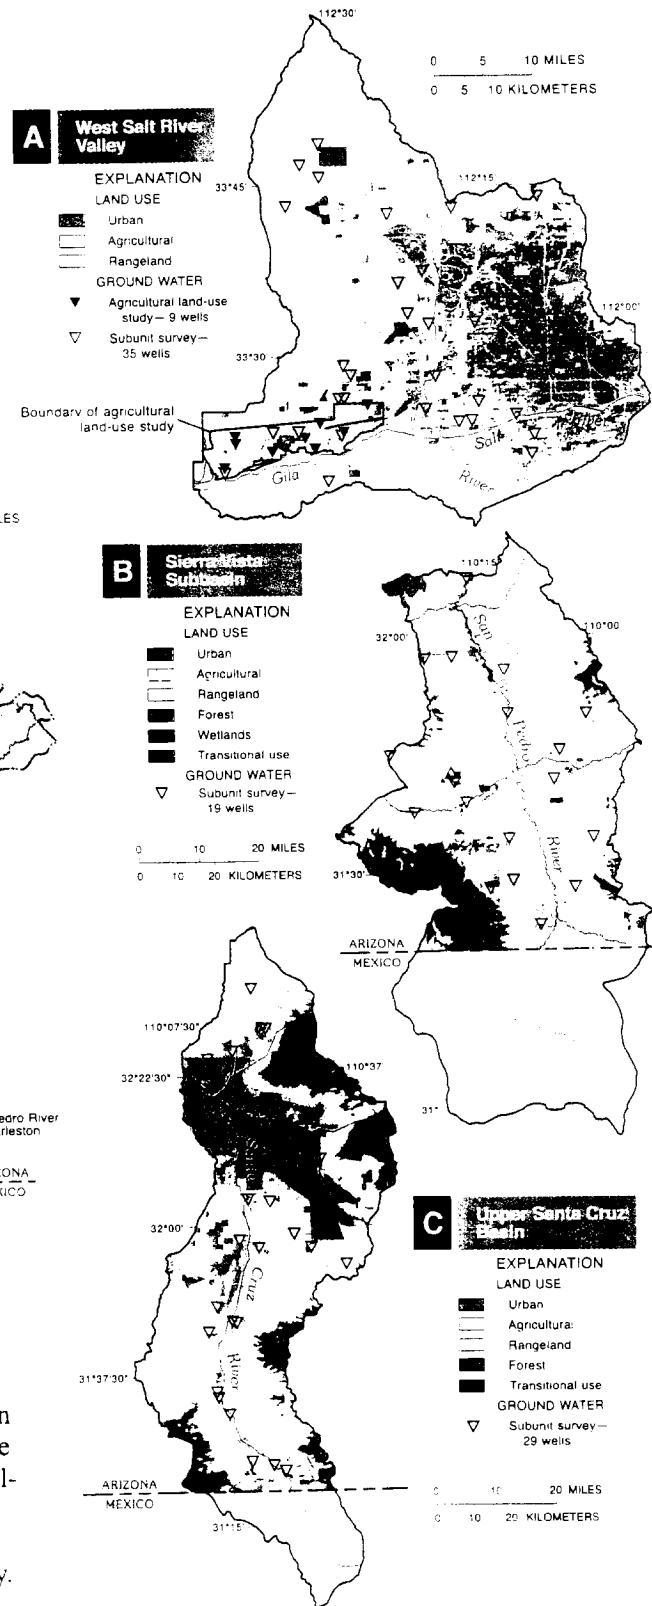

STUDY UNIT DESIGN

The Central Arizona Basins study was designed to provide nationally comparable water-quality data and address local and national questions about water quality. The primary goal of the study was to understand the human and natural factors that affect the chemistry of ground and surface water and communities of aquatic organisms.

Surface-water chemistry and biological-sampling sites were divided between the two main hydrologic

GROUND-WATER-QUALITY-SAMPLING SITES AND LAND USE

provinces in the study area: the Central Highlands and the Basin and Range Lowlands (see above). Ground-water samples were collected in three basins in the Basin and Range Lowlands. Human activities were least in the Sierra Vista subbasin, greatest in the West Salt River Valley, and intermediate in the Upper Santa Cruz Basin. Effects of agricultural activities on ground water were studied in the western part of the West Salt River Valley.

SUMMARY OF DATA COLLECTION IN THE CENTRAL ARIZONA BASINS, 1995-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Basic fixed sites, general water quality	Streamflow, dissolved oxygen, pH, alkalinity, specific conductance, temperature, nutrients, major ions, organic carbon, and suspended sediment were measured to determine occurrence and distribution.	Streams selected to represent urban, mixed agricultural/urban, and forest/rangeland land uses were distributed throughout the study area. Basins ranged from 0 miles (at point sources) to 18,011 square miles.	9	Monthly plus high flows Oct. 1995-Apr. 1998
Intensive fixed sites	Above constituents plus 87 pesticides and 85 volatile organic compounds.	Sites selected closer to urban and (or) agricultural areas so as to be more likely to reflect those land uses.	2	Monthly Jan. 1996-Dec. 1996, increased sampling frequency to approximately twice a month Dec. 1996-Feb. 1998
Fixed sites, dissolved organic carbon	Spectral characteristics of dissolved organic carbon from surface water were measured to determine sources.	Same sites as basic fixed sites and intensive fixed sites.	11	Monthly Jan. 1996-August 1997
Synoptic	Same as basic fixed sites, plus pesticides.	Three locations collocated with key sites for stream ecology synoptic.	3	Quarterly Jan. 97-Oct. 97
Contaminants in bed sediment	Trace elements and (or) organic compounds to determine occurrence and distribution in streambed sediments.	Depositional zones of most basic and intensive stream-chemistry sites plus additional sites.	17	Once May and June 1996
Contaminants in tissues of aquatic biota	Trace elements and (or) organic compounds to determine occurrence and distribution in tissues of fish, clams, and crayfish.	Same sites as sediment samples.	15	Once May and June 1996
Stream Ecology				
Basic sites	Communities of algae, invertebrates, and fish; and instream and riparian habitats surveyed to assess biological conditions of the study area.	Sites collocated with most basic and intensive stream-chemistry sites.	7	Once Oct. 1995-Jan. 1996
			2	Annually 1995-1997
Synoptic	Communities of algae, invertebrates, and fish; and instream and riparian habitats surveyed to evaluate spatial variability.	Nine reaches along one segment of a stream with minimal anthropogenic influences.	9	Once Oct.-Dec. 1996
Ground-Water Chemistry				
Study Unit West Salt River Valley - mixed land use	Nutrients, major ions, trace elements, volatile organic compounds, radon, dissolved organic carbon, and pesticides to assess water quality of the basin's aquifers.	Existing domestic, public-supply, irrigation, livestock, and industrial wells.	35	Once 1996-1997
Study Unit Upper Santa Cruz Basin - mixed land use	Nutrients, major ions, trace elements, volatile organic compounds, radon, dissolved organic carbon, and pesticides to assess water quality of the basin's aquifers.	Existing domestic, public-supply, irrigation, livestock, and industrial wells.	29	Once 1998
Study Unit Sierra Vista subbasin - mixed land use	Nutrients, major ions, trace elements, volatile organic compounds, radon, dissolved organic carbon, and pesticides to assess water quality of the basin's aquifers.	Existing domestic, public-supply, irrigation, and livestock wells.	19	Once 1996
Land use West Salt River Valley - agricultural	Nutrients, major ions, trace elements, volatile organic compounds, radon, dissolved organic carbon, and pesticides to determine effects of agricultural land use on shallow ground-water quality.	Shallow monitoring wells.	9	Twice Aug. 1997 Feb. 1998

GLOSSARY

- Anthropogenic**—A condition or occurrence that is the result of, or is influenced by, human activity.
- Aquatic-life criteria**—Water-quality guidelines for protection of aquatic life. Typically refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms.
- Aquifer**—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Background concentration**—A concentration of a substance in a particular environment that is indicative of minimal influence by human (anthropogenic) sources.
- Base flow**—Sustained, low flow in a stream; ground-water discharge is the source of base flow in most places.
- Basic fixed sites**—Sites on streams at which streamflow is measured and samples are collected for temperature, salinity, suspended sediment, major ions and metals, nutrients, and organic carbon to assess the broad-scale spatial and temporal character and transport of inorganic constituents of streamwater in relation to hydrologic conditions and environmental settings.
- Bed sediment**—The material that temporarily is stationary in the bottom of a stream or other watercourse.
- Bioaccumulation**—The biological sequestering of a substance at a higher concentration than that at which it occurs in the surrounding environment or medium. Also, the process whereby a substance enters organisms through the gills, epithelial tissues, or dietary or other sources.
- Biomass**—The amount of living matter, in the form of organisms, present in a particular habitat, usually expressed as weight per unit area.
- Breakdown product**—A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process that may result in a more toxic or a less toxic compound and a more persistent or less persistent compound.
- Concentration**—The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as milligrams per liter or micrograms per liter (water sample) or micrograms per kilogram (sediment or tissue sample).
- Confining layer**—A layer of sediment or lithologic unit of low permeability that bounds an aquifer.
- Cubic foot per second (ft³/s or cfs)**—Rate of water discharge representing a volume of 1 cubic foot passing a given point during 1 second, equivalent to approximately 7.48 gallons per second or 448.8 gallons per minute or 0.02832 cubic meter per second.
- Dissolved solids**—Amount of minerals, such as salt, that are dissolved in water; amount of dissolved solids is an indicator of salinity or hardness.
- Drainage basin**—The portion of the surface of the Earth that contributes water to a stream through overland runoff, including tributaries and impoundments.
- Drinking-water guideline**—Nonenforceable Federal guideline regarding cosmetic (tooth or skin discoloration) or aesthetic effects (such as taste, color, odor).
- Drinking-water standard**—A threshold concentration in a public drinking-water supply, designed to protect human health or as defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare.
- Ecoregion**—An area of similar climate, landform, soil, potential natural vegetation, hydrology, or other ecologically relevant variables.
- Effluent**—Outflow from a particular source, such as a stream that flows from a lake or liquid waste that flows from a factory or sewage-treatment plant.
- Ephemeral stream**—A stream or part of a stream that flows only in direct response to precipitation or snowmelt. Its channel is above the water table at all times.
- Eutrophication**—The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.
- Evaporite minerals (deposits)**—Minerals or deposits of minerals formed by evaporation of water containing salts. These deposits are common in arid climates.
- Evapotranspiration**—A collective term that includes water lost through evaporation from the soil and surface-water bodies and by plant transpiration.
- Infiltration**—Movement of water, typically downward, into soil or porous rock.
- Intensive fixed sites**—Basic Fixed Sites with increased sampling frequency during selected seasonal periods and analysis of dissolved pesticides for 1 year. Most NAWQA Study Units have one to two integrator Intensive Fixed Sites and one to four indicator Intensive Fixed Sites.
- Intermittent stream**—A stream that flows only when it receives water from rainfall runoff or springs, or from some surface source such as melting snow.
- Invertebrate**—An animal having no backbone or spinal column.
- Irrigation return flow**—The part of irrigation applied to the surface that is not consumed by evapotranspiration or uptake by plants and that migrates to an aquifer or surface-water body.
- Land subsidence**—Compression of soft aquifer materials in a confined aquifer due to pumping of water from the aquifer.
- Leaching**—The removal of materials in solution from soil or rock to ground water; refers to movement of pesticides or nutrients from land surface to ground water.
- Load**—General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.

LOWESS smooth—LOcally WEighted Scatterplot

Smoothing is a statistical method of defining a smooth curve through the middle of a scatterplot to highlight trends or patterns in the data.

Maximum Contaminant Level (MCL)—Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.

Median—The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.

Metabolite—A substance produced in or by biological processes.

Micrograms per liter ($\mu\text{g/L}$)—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most stream water and ground water. One thousand micrograms per liter equals 1 mg/L.

Milligrams per liter (mg/L)—A unit expressing the concentration of chemical constituents in solution as mass (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most stream water and ground water. One thousand micrograms per liter equals 1 mg/L.

Nutrient—Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.

Organochlorine insecticide—A class of organic insecticides containing a high percentage of chlorine. Includes dichlorodiphenylethanes (such as DDT), chlorinated cyclodienes (such as chlordane), and chlorinated benzenes (such as lindane). Most organochlorine insecticides were banned because of their carcinogenicity, tendency to bioaccumulate, and toxicity to wildlife.

Perennial stream—A stream that normally has water in its channel at all times.

Pesticide—A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests."

Picocurie (pCi)—One trillionth (10^{-12}) of the amount of radioactivity represented by a curie (Ci). A curie is the quantity of any radioactive nuclide in which the number of disintegrations is 3.7×10^{10} per second (dps). A picocurie yields 2.22 disintegrations per minute (dpm) or 0.037 dps.

Public-supply withdrawals—Water withdrawn by public and private water suppliers for use within a general community. Water is used for a variety of purposes such as domestic, commercial, industrial, and public water use.

Recharge—Water that infiltrates the ground and reaches the saturated zone.

Riparian—Areas adjacent to rivers and streams with a high density, diversity, and productivity of plant and animal species relative to nearby uplands.

Runoff—Excess rainwater or snowmelt that is transported to streams by overland flow, tile drains, or ground water.

Secondary maximum contaminant level (SMCL)—The maximum contamination level in public water systems that, in the judgment of the U.S. Environmental Protection Agency (USEPA), is acceptable to protect the public welfare. SMCLs are secondary (nonenforceable) drinking water regulations established by the USEPA for contaminants that may adversely affect the odor or appearance of such water.

Specific conductance—A measure of the ability of a liquid to conduct an electrical current.

Tolerant species—Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.

Trace element—An element typically found in only minor amounts (concentrations less than 1.0 milligram per liter) in water; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.

Volatile organic compounds (VOCs)—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

APPENDIX—WATER-QUALITY DATA FROM THE CENTRAL ARIZONA BASINS IN A NATIONAL CONTEXT

For a complete view of Central Arizona Basins data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Central Arizona Basins. Selected results for this Study Unit are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Central Arizona Basins compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, trifluralin concentrations in Central Arizona Basins agricultural streams were similar to the national distribution, but the detection frequency was much higher (76 percent compared to 21 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Central Arizona Basins, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

◆ Detected concentration in Study Unit

66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

--- Not measured or sample size less than two

12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acetochlor (Harness Plus, Surpass) * **
- Benfluralin (Balan, Benefin, Bonalan) * **
- Cyanazine (Bladex, Fortrol)
- Linuron (Lorox, Linex, Sarclex, Linurex, Afalon) *
- Metribuzin (Lexone, Sencor)

Molinate (Ordram) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **
 Prometon (Pramitol, Princep) **
 Pronamide (Kerb, Propyzamid) **
 Propachlor (Ramrod, Satecid) **
 Tebuthiuron (Spike, Tebusan)
 Triallate (Far-Go, Avadex BW, Tri-alleate) *

Herbicides not detected

Acifluorfen (Blazer, Tackle 2S) **
 Alachlor (Lasso, Bronco, Lariat, Bullet) **
 Bentazon (Basagran, Bentazone) **
 Bromacil (Hyvar X, Urox B, Bromax)
 Bromoxynil (Buctril, Brominal) *
 Butylate (Sutan +, Genate Plus, Butilate) **
 Chloramben (Amiben, Amilon-WP, Vegiben) **
 Clopyralid (Stinger, Lontrel, Transline) * **
 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
 Dacthal mono-acid (Dacthal breakdown product) * **
 Dicamba (Banvel, Dianat, Scotts Proturf)
 Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
 2,6-Diethylaniline (Alachlor breakdown product) * **
 Ethalfuralin (Sonalan, Curbit) * **
 Fenuron (Fenulon, Fenidim) * **
 Fluometuron (Flo-Met, Cotoran) **
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistrol) * **
 Metolachlor (Dual, Pennant)
 Napropamide (Devrinol) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Norflurazon (Evital, Predict, Solicam, Zorial) * **
 Oryzalin (Surflan, Dirimal) * **
 Pebulate (Tillam, PEBC) * **
 Picloram (Grazon, Tordon)
 Propanil (Stam, Stampede, Wham) * **
 Propham (Tuberite) **
 2,4,5-T **
 2,4,5-TP (Silvex, Fenoprop) **
 Terbacil (Sinbar) **
 Thiobencarb (Bolero, Saturn, Benthicarb) * **
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **

Pesticides in water—Insecticides

Other insecticides detected

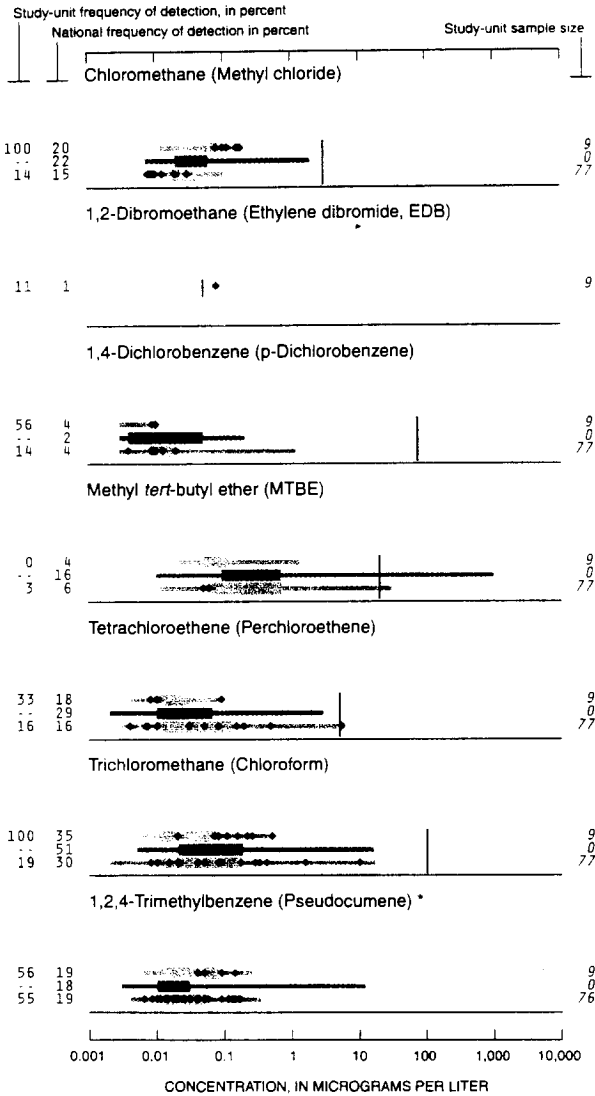

Carbofuran (Furadan, Curaterr, Yaltox)
 Methomyl (Lanox, Lannate, Acinate) **
 Methyl parathion (Penncap-M, Folidol-M) **
 Phorate (Thimet, Granutox, Geomet, Rampart) * **
 Propoxur (Baygon, Blattanex, Uden, Proprotax) * **

Insecticides not detected

Aldicarb (Temik, Ambush, Pounce)
 Aldicarb sulfone (Standak, aldoxycarb)
 Aldicarb sulfoxide (Aldicarb breakdown product)
 Ethoprop (Mocap, Ethoprophos) * **
 Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
 Methiocarb (Slug-Geta, Grandslam, Mesurol) * **
 Oxamyi (Vydate L, Pratt) **
 cis-Permethrin (Ambush, Astro, Pounce) * **
 Propargite (Comite, Ornite, Ornamite) * **
 Terbufos (Conraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

Benzene
 Bromodichloromethane (Dichlorobromomethane)
 Carbon disulfide *
 1-Chloro-2-methylbenzene (o-Chlorotoluene)
 Chlorobenzene (Monochlorobenzene)
 Dichlorodifluoromethane (CFC 12, Freon 12)
 1,1-Dichloroethane (Ethylidene dichloride) *
 1,1-Dichloroethene (Vinylidene chloride)
 Dichloromethane (Methylene chloride)
 1,2-Dimethylbenzene (o-Xylene)
 1,3 & 1,4-Dimethylbenzene (m-&p-Xylene)
 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
 Ethylbenzene (Phenylethane)
 Iodomethane (Methyl iodide) *
 Methylbenzene (Toluene)
 2-Propanone (Acetone) *
 Tribromomethane (Bromoform)
 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
 1,1,1-Trichloroethane (Methylchloroform)
 Trichloroethene (TCE)
 Trichlorofluoromethane (CFC 11, Freon 11)

VOCs not detected

tert-Amylmethylether (tert-amyl methyl ether (TAME)) *
 Bromobenzene (Phenyl bromide) *
 Bromochloromethane (Methylene chlorobromide)
 Bromoethene (Vinyl bromide) *
 Bromomethane (Methyl bromide)
 2-Butanone (Methyl ethyl ketone (MEK)) *
 n-Butylbenzene (1-Phenylbutane) *
 sec-Butylbenzene *
 tert-Butylbenzene *
 3-Chloro-1-propene (3-Chloropropene) *
 1-Chloro-4-methylbenzene (p-Chlorotoluene)
 Chlorodibromomethane (Dibromochloromethane)
 Chloroethane (Ethyl chloride) *
 Chloroethene (Vinyl chloride)
 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
 Dibromomethane (Methylene dibromide) *
 trans-1,4-Dichloro-2-butene ((Z)-1,4-Dichloro-2-butene) *
 1,2-Dichlorobenzene (o-Dichlorobenzene)
 1,3-Dichlorobenzene (m-Dichlorobenzene)
 1,2-Dichloroethane (Ethylene dichloride)
 trans-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
 cis-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)
 1,2-Dichloropropane (Propylene dichloride)
 2,2-Dichloropropane *
 1,3-Dichloropropane (Trimethylene dichloride) *
 trans-1,3-Dichloropropane ((E)-1,3-Dichloropropane)
 cis-1,3-Dichloropropane ((Z)-1,3-Dichloropropane)
 1,1-Dichloropropane *
 Diethyl ether (Ethyl ether) *
 Diisopropyl ether (Diisopropylether (DIPE)) *
 Dimethylbenzenes (Xylenes (total))
 Ethenylbenzene (Styrene)
 Ethyl methacrylate *
 Ethyl tert-butyl ether (Ethyl-t-butyl ether (ETBE)) *
 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
 Hexachlorobutadiene
 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
 2-Hexanone (Methyl butyl ketone (MBK)) *
 Isopropylbenzene (Cumene) *
 p-Isopropyltoluene (p-Cymene) *
 Methyl acrylonitrile *
 Methyl-2-methacrylate (Methyl methacrylate) *
 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
 Methyl-2-propenoate (Methyl acrylate) *
 Naphthalene
 2-Propenenitrile (Acrylonitrile)
 n-Propylbenzene (Isocumene) *
 1,1,1,2-Tetrachloroethane *
 1,1,1,2-Tetrachloroethane
 Tetrachloromethane (Carbon tetrachloride)
 1,2,3,4-Tetramethylbenzene (Prehnitene) *
 1,2,3,5-Tetramethylbenzene (Isodurene) *
 1,2,4-Trichlorobenzene
 1,2,3-Trichlorobenzene *
 1,1,2-Trichloroethane (Vinyl trichloride)
 1,2,3-Trichloropropane (Allyl trichloride)
 1,2,3-Trimethylbenzene (Hemimellitene) *
 1,3,5-Trimethylbenzene (Mesitylene) *

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Central Arizona Basins, 1995–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment¹

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- ** No benchmark for protection of aquatic life

Organochlorines in fish tissue (whole body) and bed sediment

¹ The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

- p,p'*-Methoxychlor (Mariate, methoxychlor) **
- α,p' -Methoxychlor ***
- Mirex (Dechlorane) **

BIOLOGICAL INDICATORS

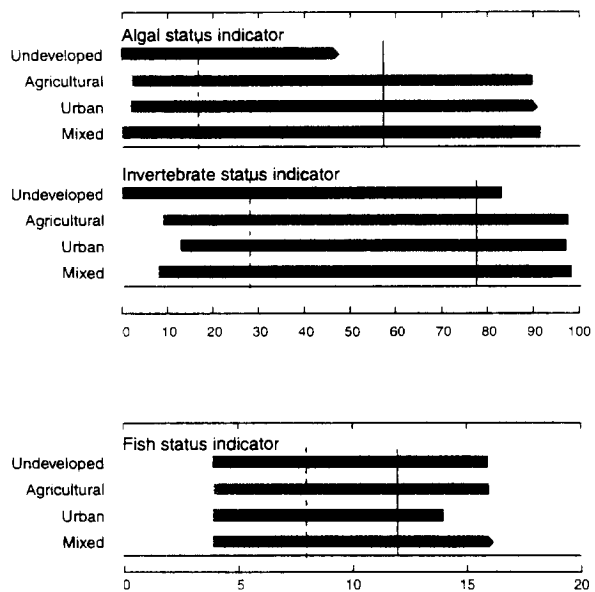

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

We thank the following individuals and organizations for contributing to this effort.

Laurie Wirt (USGS) designed and guided the surface-water-quality sampling program for the CAZB from 1994 to 1996.

Doug Towne and Maureen Freark (ADEQ) coordinated with CAZB to design cooperative ground-water studies in the Upper Santa Cruz Basin and the Sierra Vista subbasin.

Salt River Project, ADEQ, and ADWR provided valuable data for our study.

Buckeye Water Conservation and Drainage District, City of Phoenix, City of Peoria, Town of Buckeye, City of Goodyear, Roosevelt Irrigation District, and numerous individual landowners allowed us access to their wells and data.

Terry Short, Lisa H. Nowell, A.B. Richards, and Steve Goodbred provided invaluable assistance and guidance for the CAZB biological data collection and reports.

Patrice Spindler (ADEQ), Kirke King (USFW), Kirk Young (AzGF), W.L. Minckley, and Paul Marsh (ASU) provided information and expertise for the biological aspects of this project.

Karen Beaulieu, Dave Peyton, Joe Capesius, Christie O'Day, Ann Tillery, Melissa Butler, Todd Ingersol, Ray Davis, David Graham, Ken Galyean, Frank Oliver, Rodrigo Morales, Tasha Lewis, Dawn McDoniel, Herb Pierce, Cory Angeroth (USGS), Tom Rees (volunteer), and Brian Popadac (volunteer) assisted with data collection and compilation.

Sid Alwin, Pat Rigas, Doug Cummings, and John Callahan (USGS) contributed their talents to the preparation of this report.

Norm Spahr and Joe Domagalski (USGS), Marlene Baker (Concerned Citizens About Responsible Environment), Jeanmarie Haney (Tucson Regional Water Council), and many NAWQA Program staff provided valuable reviews of this report.

We extend special thanks and appreciation to our spouses, families, and friends, without whose support we could not have accomplished the work described herein.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Upper Colorado River Basin that emerged from an assessment conducted between 1996 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of instream habitats as elements of a complete water-quality assessment.

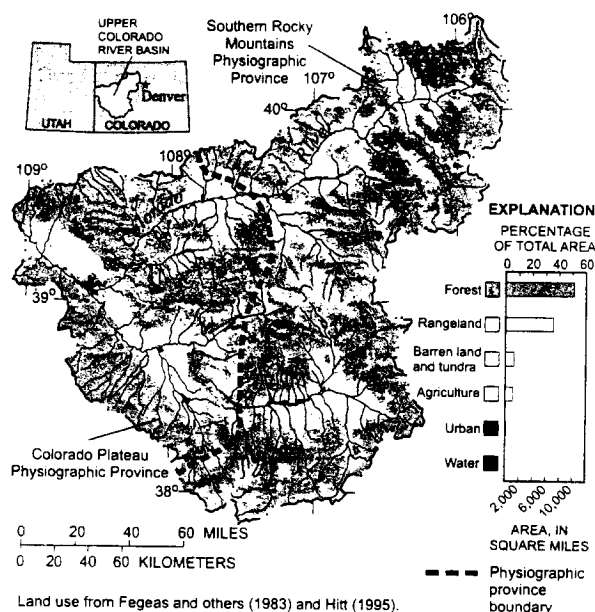

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Upper Colorado River Basin assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Upper Colorado River Basin is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

The Upper Colorado River Basin (UCOL) of the National Water-Quality Assessment (NAWQA) Program includes the 17,800-square-mile drainage basin of the Colorado River upstream from the Colorado-Utah State line. The study area is almost equally divided between the Southern Rocky Mountains and the Colorado Plateau Physiographic Provinces. Population in the basin is approximately 308,000. The major use of water is irrigation, but transmountain diversions provide water to more than 1 million people in the eastern part of Colorado (outside of the study area).

Stream and River Highlights

Streams and rivers in the Upper Colorado River Basin (UCOL) are very different in the two major physiographic provinces. In general, streams within the Southern Rocky Mountains are characterized by lower sediment and dissolved-solids concentrations, cooler temperatures, and somewhat higher gradients than streams in the Colorado Plateau. Sediment, salinity, and nutrient (nitrogen and phosphorus) concentrations increase along the major rivers as the water flows from the upstream areas in the Southern Rocky Mountains down through the Colorado Plateau.

Coupled with the general differences due to physiography and geology are the effects of different land uses. Recreation and urban development are becoming major land-use issues throughout the basin, precious metal mining was historically prevalent in the Southern Rocky Mountains, and intensive agriculture is located in the valleys of the Colorado Plateau.

Most of the streams and rivers sampled within the UCOL met State and Federal water-quality guidelines. Major exceptions to this statement were trace-element concentrations in some streams in the Southern Rocky Mountains and selenium concentrations in some streams in the Colorado Plateau.

- In the Southern Rocky Mountains, concentrations of nutrients (nitrogen and phosphorus) were generally low but were greater in urban streams than in streams in areas with minimal development (p. 6).
- Urban streams in the Southern Rocky Mountains had greater amounts of algae and a change in the invertebrate community from pollution-sensitive insects to pollution-tolerant insects compared to streams in areas with minimal development (p. 6–7). Similarly, in some mining areas of the Southern Rocky Mountains, the invertebrate community was also composed of pollution-tolerant insects, indicating more degraded sites (p. 13).

Selected indicators of Stream-Water Quality

	Southern Rocky Mountains		Colorado Plateau		
	Small Streams	Major Rivers	Small Streams	Major Rivers	Outlet of Study Unit
	Urban	Mining	Agri-culture		
Pesticides ¹	—	—	—	—	—
Nitrate ²	●	●	●	●	●
Total Phosphorus ³	●	●	●	●	●
Trace Elements ⁴	—	●	● ^a	●	●

■ Percentage of samples with concentrations **greater than or equal to** health-related national guidelines for drinking water, protection of aquatic life, or contact recreation

▒ Percentage of samples with concentrations **less than** health-related national guidelines for drinking water, protection of aquatic life, or contact recreation

○ Percentage of samples with **no detection** (^a Percentage is 1 or less and may not be clearly visible)

— Not assessed

¹Insecticides, herbicides, and pesticide metabolites, sampled in water.

²Nitrate (as nitrogen), sampled in water.

³Total phosphorus, sampled in water.

⁴Selenium and metals (such as cadmium, lead, and zinc), sampled in water.

- Concentrations of trace elements, such as cadmium, zinc, copper, and lead, in streambed sediments in many historical mining areas were greater than guidelines for the protection of aquatic life (p. 11–12).
- Pesticides were commonly detected in streams in agricultural areas of the Colorado Plateau during the growing season; however, the concentrations were typically low. Pesticide concentrations that exceeded guidelines for the protection of aquatic life were detected in only 5 of 90 samples (p. 16). Not all detected pesticides have established guidelines.
- The herbicides atrazine and alachlor were detected in more than one-half of the water samples collected in agricultural areas of the Colorado Plateau. These compounds, commonly used for weed control in corn, were also commonly detected in agricultural areas nationwide (p. 17).
- Nutrient and suspended-sediment concentrations in streams in the Colorado Plateau were typically greater than concentrations found in streams in other areas of the UCOL (p. 18–19). These concentrations can generally be associated with a more degraded status of algae, invertebrates, and fish (p. 19).
- Ground water in urban areas recharged in the late 1980s or 1990s tends to have higher concentrations of nitrate than ground water recharged before the 1980s (p. 10).
- Pesticides and volatile organic compounds were detected infrequently and generally at concentrations less than drinking-water standards. In only one sample, dichloromethane and tetrachloroethene, which are solvents, were detected at concentrations greater than their drinking-water standards (p. 10). Low concentrations of methyl *tert*-butyl ether (MTBE), a gasoline additive, were detected in shallow ground water in four of the five urban areas sampled (p. 9).
- Total coliform bacteria were detected in 21 percent of the shallow ground-water samples collected in urban areas in the Southern Rocky Mountains; none of the samples contained the potentially pathogenic *Escherichia coli* (*E. coli*) bacteria (p. 10).
- Radon, a naturally occurring radioactive gas, was detected in all wells sampled in urban areas in the Southern Rocky Mountains. Concentrations were greater than the proposed USEPA drinking-water standard of 300 picocuries per liter. Currently (2000), radon in drinking water is not regulated; however, if a new drinking-water regulation is implemented, treatment of drinking water for radon may be required in the UCOL (p. 9).

Major Influences on Streams and Rivers

- Urban development
- Abandoned/inactive mines
- Agricultural return flows

Ground-Water Highlights

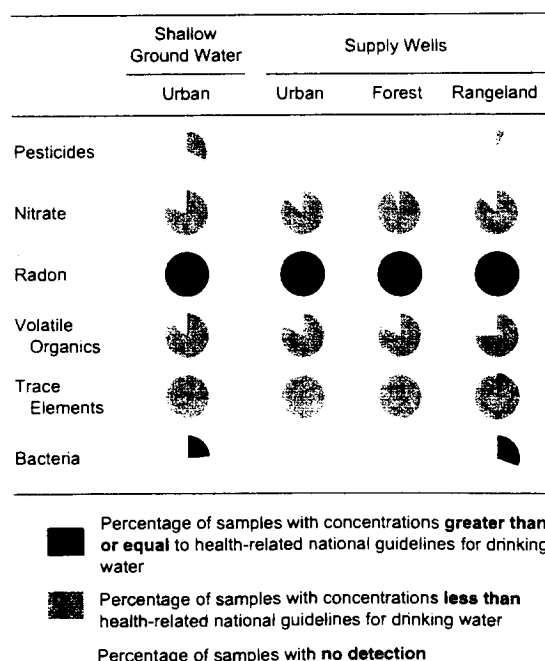

Historical ground-water-quality data for the UCOL are limited. The studies completed in the UCOL by NAWQA provide baseline information that can be used for identifying future water-quality changes. With the exception of radon, ground-water quality in the urban areas of the Southern Rocky Mountains generally met Federal and State standards for drinking water. The presence of a few elevated nitrate concentrations, a few pesticides, and generally low concentrations of volatile organic compounds indicate some influence on the quality of ground water from human activities. Bacteria were detected in ground-water samples and can occur naturally or indicate human influences.

- A concentration of nitrate greater than the U.S. Environmental Protection Agency (USEPA) drinking-water standard was found in 1 of 57 shallow ground-water samples collected in urban land-use settings (p. 8).

Major Influences on Ground Water

- Urban development in the Southern Rocky Mountains
- Natural background conditions

Selected Indicators of Ground-Water Quality

INTRODUCTION TO THE UPPER COLORADO RIVER BASIN

The Upper Colorado River Basin encompasses about 17,800 square miles. The primary river, the Colorado River, originates in the mountains of central Colorado and flows about 230 miles southwest into Utah. The basin is composed of two physiographic provinces: the Southern Rocky Mountains and the Colorado Plateau (fig. 1). The topography varies from rugged mountainous regions in the east to

high plateaus bordered by steep cliffs along valleys in the west. Because of differences in altitude of about 10,000 feet from east to west, the climate ranges from alpine conditions to semiarid/arid conditions. Precipitation ranges from 40 inches or more per year at high elevations in the eastern part of the basin to less than 10 inches per year at low elevations in the western part of the basin (fig. 2).

Snowmelt Runoff Dominates the Streamflow in Many Areas of the UCOL

The amount of water derived from the winter snowpack generally determines the magnitude and quality of streamflow for the UCOL. Streamflows are typically highest in the spring and lowest

The Colorado Plateau contains warm, saline streams that drain sedimentary geologic settings. (Photograph by Jeffrey Deacon, U.S. Geological Survey.)

Urban development is occurring in areas of the Southern Rocky Mountains. (Photograph by Scott Mize, U.S. Geological Survey.)

Cool and clear mountain streams are present in the forested areas of the Southern Rocky Mountains. (Photograph by Scott Mize, U.S. Geological Survey.)

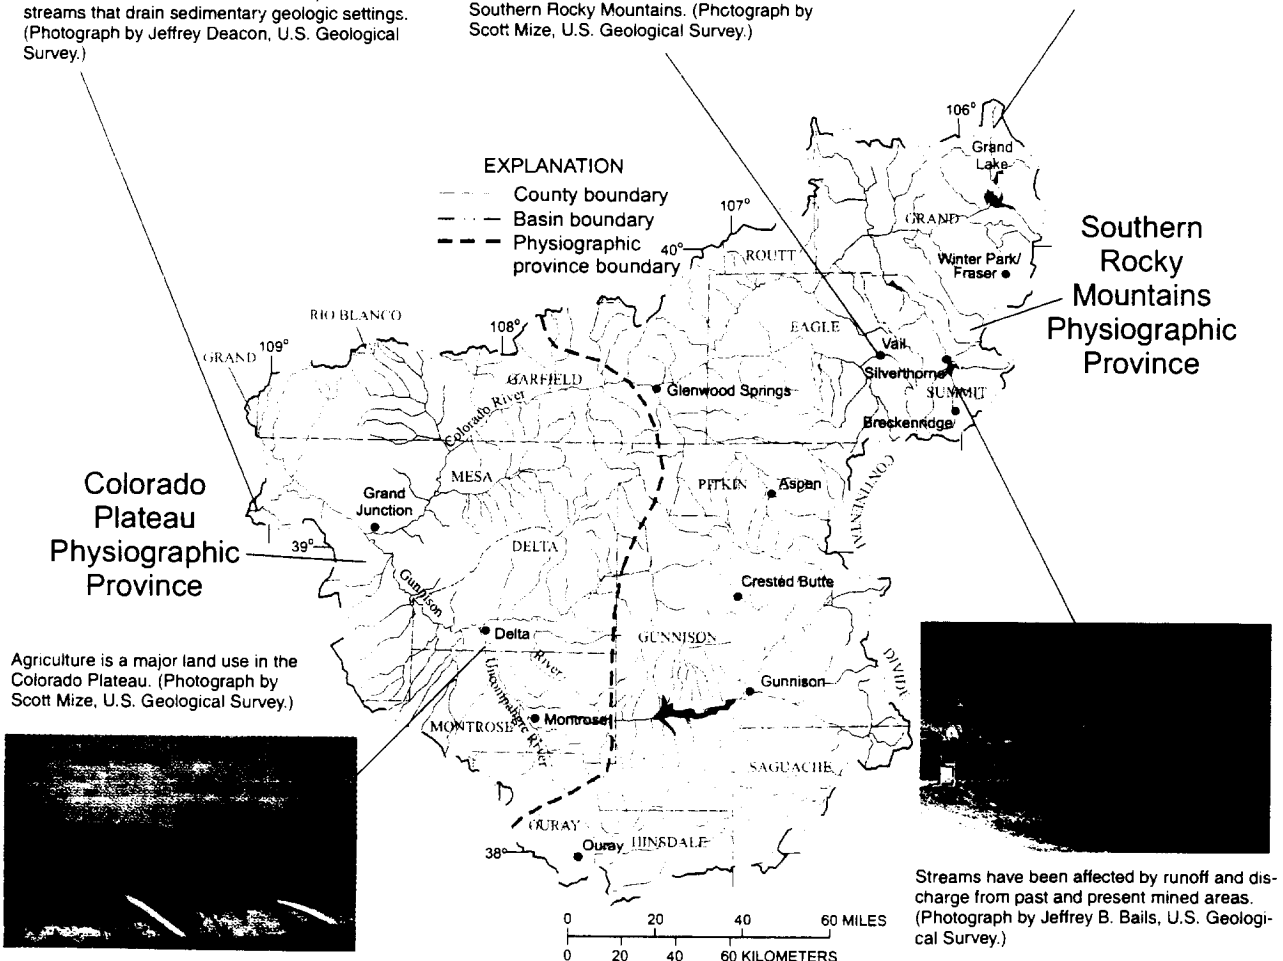

Figure 1. The combinations of physiography and land use produce different environments found in the UCOL. Physiographic provinces from Fenneman, 1946.

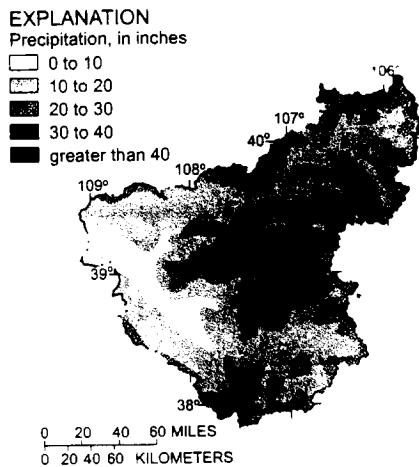

Figure 2. Average annual precipitation (1951–80) in the UCOL (Colorado Climate Center, 1984).

during the winter (fig. 3). The primary data-collection period for the UCOL study was water years 1996–98. Streamflow during water years 1996–97 was above average for most of the basin. Streamflow during water year 1998 was about average. High streamflows will dilute many water-quality constituents, resulting in lower concentrations. Suspended sediment and constituents associated with sediment may have larger concentrations during periods of high flow than during low flow.

Irrigation is the Principal Water Use Within the UCOL

Irrigation accounts for 97 percent of the water use in the UCOL (fig. 4). Ninety-nine percent of the water used in the Study Unit is derived from surface-water sources (U.S. Geological Survey, 1995). Ground water accounts for 1 percent of water use and is an important resource in remote and rural areas where the water is used primarily for domestic purposes.

Water diverted eastward from the UCOL, through transmountain

diversions, is used by many municipalities in the eastern plains of Colorado. This diverted water from the UCOL constitutes about 35 percent of the water supply for the city of Denver (Denver Water Department, 1999) and about 65 percent of the water supply for Colorado Springs (Scott Campbell, Colorado Springs Water Utility, oral commun., 2000). In addition, the Colorado Big Thompson project, using water diverted from the UCOL, provides complete or

partial supply for more than 30 cities and towns in northern Colorado (Northern Colorado Water Conservancy District, 2000). Transmountain diversions can affect the water quality in the basin because the diversions can account for a substantial portion of the local streamflow in upstream areas. In addition, the diverted water commonly has low salinity that is no longer available to dilute more mineralized water in the downstream part of the Study Unit.

Figure 3. Streamflows in the UCOL were above average in water years 1996 and 1997. Water year 1998 streamflow was near average.

Figure 4. Water use in the basin is primarily derived from surface water; however, ground water is used for some domestic and public water supplies. Transmountain diversions to eastern Colorado from the UCOL accounted for about 451 million gallons per day in 1995 (Upper Colorado River Commission, 1999).

Water Quality is Influenced by Geologic Factors

The underlying bedrock in the Study Unit is made up of crystalline and sedimentary rocks (fig. 5). Alluvium consisting of stream, landslide, terrace, and glacial deposits is present in valleys throughout the basin. Weathering of the different geologic units affects water-quality conditions in the basin. The sedimentary, igneous, and metamorphic rocks contribute material such as salts and trace elements to the streams. High concentrations of some materials, particularly salts, are derived from the sedimentary rocks, which are more common in the western part of the basin. Also, highly mineralized areas in the upper basin contribute trace metals to surface and ground water. Selenium occurs naturally in the shale bedrock of the middle and lower reaches of the basin and is present in surface and ground water. In addition, mineral hot springs located primarily in carbonate rock units in the north-

central part of the basin contribute about 13 percent of the total salt load at the outlet of the UCOL (U.S. Department of the Interior, 1995; Butler, 1996).

Water Quality is Influenced by Land Use

The UCOL study was designed to investigate land-use influences on water quality (see "Study Unit Design," page 21, for details). Urban development, mining, and agricultural were the three primary land uses investigated in the UCOL.

Urban development has the potential to affect the quality of surface and ground water by adding nutrients, bacteria, pesticides, hydrocarbons, trace elements, and salts from point and nonpoint sources and by changes to the natural landscape. Urban land use accounts for only 1 percent in the UCOL, which has a population of about 308,000 people (Bureau of the Census, 1999). By the year 2020, the population is projected to increase to more than 500,000

Topography representative of the Southern Rocky Mountains. (Photograph by Jeffrey Deacon, U.S. Geological Survey.)

(Colorado Department of Local Affairs, 2000). Resident population increases do not reflect development and services for vacation properties. There are large seasonal fluctuations in nonresident populations within the basin due to recreational activities. During the 1996–97 ski season, more than 9 million skiers visited ski areas within the UCOL (Colorado Ski Country USA, 2000). Effects on water quality from urban development are evident in some communities in the Southern Rocky Mountains.

Lode and placer mining, a historically significant land use in the UCOL, was common throughout the Southern Rocky Mountains. Streams and ground water have been affected by point-source mine discharge and nonpoint-source runoff from mined areas.

Areas of intensive agriculture are located primarily in the Colorado Plateau. Salinity, sediment, nutrients, pesticides, and selenium and other trace elements are common constituents in agricultural runoff. These constituents can have an adverse effect on the surface water, ground water, and aquatic life.

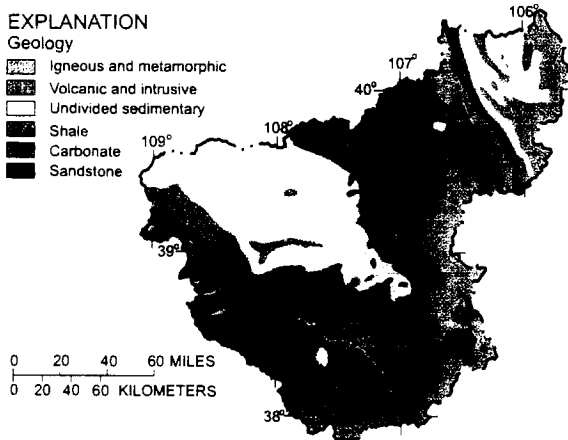

Figure 5. The bedrock geology within the UCOL changes from predominately igneous, metamorphic, and volcanic rock types in the eastern and central areas to predominantly sedimentary rock types in the western areas (Tweto, 1979; Green, 1992).

MAJOR FINDINGS

Urban Development is a Water-Quality Issue Within the Southern Rocky Mountains

Recreation in the mountains of Colorado is becoming a significant land-use activity in many areas. Urban development and the infrastructure to support recreation have increased substantially in the last decade. Between 1990 and 1997, the population increase in Summit and Eagle Counties exceeded 40 percent (<http://www.colorado.edu/libraries/govpubs/colonumb/counties.htm>). In addition to resident population increases, seasonal population fluxes due to recreation are large. These temporary population increases occur in winter during periods of extreme low flow and minimal dilution in rivers and streams.

Although urban development may be only a small percentage of total watershed area, development and transportation systems tend to be adjacent to riparian areas in mountainous terrain (fig. 6). This land-use pattern has placed human populations in locations that have the greatest effects on the quality of the water resources. Surface- and ground-water studies were implemented to investigate the water-quality issues in urban areas of the Southern Rocky Mountains.

Surface-water studies investigated the effects of urban land use. Two stream-monitoring sites were located in areas of urban development (fig. 6). The Gore Creek site is downstream from Vail, and the East River site is downstream from Crested Butte. Development in Vail is approaching build-out, whereas there is potential for large increases of development in the Crested Butte area. The Colorado River below

Baker Gulch, a reference site with little urban development in the Southern Rocky Mountains, was also sampled monthly to provide a comparison with other sites.

Nutrient concentrations at sites in areas of urban development were greater than concentrations at the reference site. Concentrations of nitrite plus nitrate and total phosphorus were slightly elevated at Gore Creek and East River compared to reference concentrations (fig. 7). Concentrations for nitrate were below the 10-mg/L Colorado instream standard at all three sites. Un-ionized ammonia concentrations, computed from dissolved ammonia, pH, and temperature, did not exceed State instream standards. Dissolved and orthophosphate

phosphorus concentrations were greater at Gore Creek than the other sites. Gore Creek and East River are not wastewater-effluent-dominated streams such as might be found in large metropolitan areas; however, small amounts of nitrogen and phosphorus can increase algal growth and eutrophication processes.

The amount of algae and the types of aquatic invertebrates (insects) are influenced by nutrient enrichment from urban sources. The amount of algae (algal biovolume) determined from algae samples collected in 1996 and 1997 was largest in Gore Creek (fig. 8), where nutrient levels were higher. The percentage of the invertebrate community represented by pollution sensitive insects

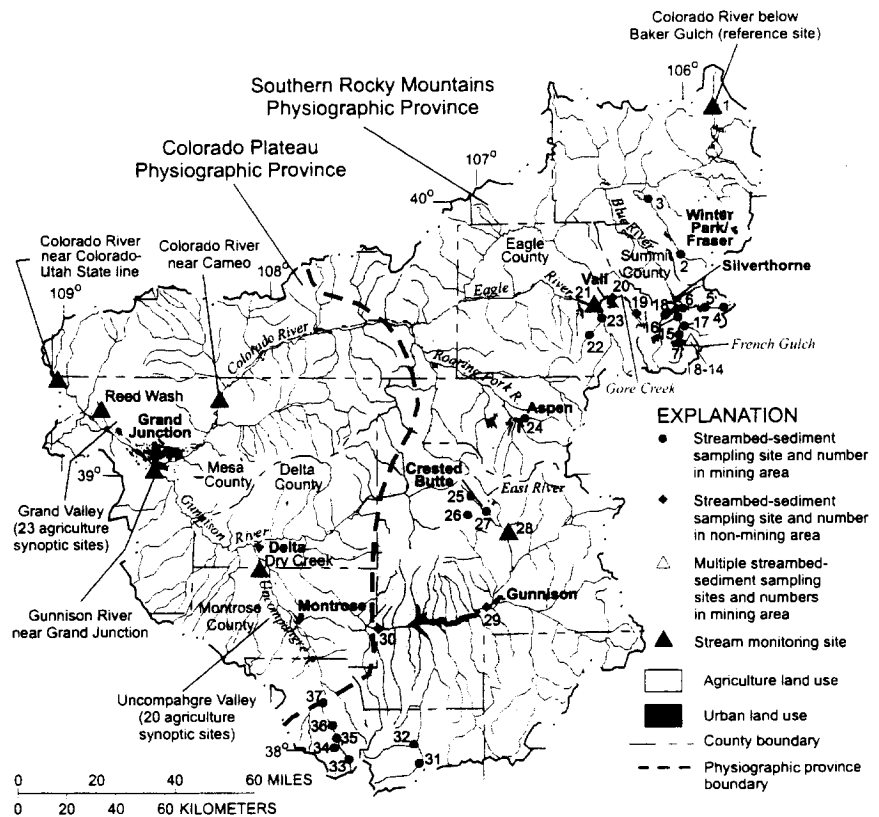

Figure 6. Sampling sites and study areas were selected to assess effects of urban, mining, and agricultural land uses on water quality.

Figure 7. Concentrations of nitrite plus nitrate and total phosphorus were greater at sites with urban development (Gore Creek and East River) than at the reference site (Colorado River below Baker Gulch). Sites shown in order of increasing urban development. A log scale is used due to the large range of concentrations.

Figure 8. Algal biovolume (the amount of algae) was greater at Gore Creek, which also has greater urban development. The percentage of mayflies, stoneflies, and caddisflies decreased, and the percentage of midges (indicative of more degraded water quality) increased with urban development. Sites shown in order of increasing urban development.

Figure 9. Nutrient concentrations were greatest during the late winter low-flow period prior to peak snowmelt runoff. This pattern was similar for total phosphorus at East River and for nitrite plus nitrate and total phosphorus at Gore Creek.

(mayflies, stoneflies, and caddisflies) was greater at sites with less urban influence (Colorado River below Baker Gulch, fig. 8). The percentage of midges (insects generally tolerant of pollution) increased with increasing urban influence (East River and Gore Creek sites, fig. 8). Even though the percentage of midges was greater at Gore Creek, the invertebrate status of Gore Creek was less degraded than other urban sites in the NAWQA Program (p. 8).

Nutrient concentrations were generally largest during winter.

Concentrations of nitrite plus nitrate and dissolved and total phosphorus were greatest during the late winter low-flow period prior to snowmelt runoff (fig. 9). With the onset of snowmelt runoff, nutrient concentrations were diluted. Algal uptake of nutrients during warm weather (July-October) probably lower concentrations during the summer. With reduced dilution and diminished algal uptake, nutrient concentrations increase again during the winter low-flow period.

Ground-water studies investigated the effects of urban land use on water in selected alluvial aquifers.

Although many communities in the UCOL rely on surface water as their primary source of drinking water, a few mountain towns and many thousands of individual homes in the Southern Rocky Mountains use ground water as their primary water source. Effects of urban land use can be indicated by elevated concentrations of nitrate, detections of synthetic organic compounds (pesticides and VOCs), and bacteria.

BIOLOGICAL MEASURES INDICATE THAT URBAN SITES IN THE UCOL ARE LESS DEGRADED WHEN COMPARED TO OTHER URBAN SITES NATIONALLY

Within the UCOL, there are changes in the algal and invertebrate communities in areas of urban development. Algal biovolume (amount of algae) and midges (insects considered more tolerant of degraded conditions) were greater at sites with urban development than sites with little urban development. However, with the exception of algal status at the Gore Creek site, biological indices for UCOL urban sites are in the lowest 25 percent of urban sites from other NAWQA Study Units. The Gore Creek watershed is more urbanized than the East River watershed, and the changes in the algal community reflect increased nutrient concentrations at this site, making it more typical of other urban sites nationally. The invertebrate and fish communities are ranked among the least degraded nationally at both UCOL urban sites.

Site name	Biological indicators		
	Algal status	Invertebrate status	Fish status
Colorado River below Baker Gulch (reference site)	■	■	■
East River (area of urban development)	■	■	■
Gore Creek (area of urban development)	□	■	■

EXPLANATION

■ Lowest 25 percent nationally, least degraded sites

□ Middle 50 percent nationally

Explanation of Biological Rankings

The three selected biological indicators respond to changes in stream degradation. Degradation can result from a variety of factors that modify habitat or other environmental features such as land use, water chemistry, and flow. Algal status focuses on the changes in the percentage of certain algae in response to increasing siltation and often is positively correlated with higher nutrient concentrations in many regions of the Nation. Invertebrate status is the average of 11 invertebrate metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. Fish status focuses on changes in the percentage of tolerant fish species that make up the total number of fish. "Tolerant" fish are reported to thrive in degraded water quality. For all indicators, higher values indicate degraded water quality.

Ground water was sampled from shallow monitoring wells in the Crested Butte, Gunnison, Silverthorne, Vail, and Winter Park/Fraser areas (fig. 6). Domestic (household and private) and public supply drinking-water wells of various depths were also sampled in urban areas throughout the Southern Rocky Mountains.

Some ground-water samples collected in urban areas contained elevated levels of nitrate. Nutrients in ground water can originate from various natural sources (such as atmospheric deposition or

dissolution of geologic materials); however, elevated concentrations in ground water are often related to human activities, such as effluent from septic systems or the application of fertilizers. Nitrate concentrations greater than the USEPA Maximum Contaminant Level (MCL) drinking-water standard of 10 mg/L (U.S. Environmental Protection Agency, 1996) were detected in one sample collected from a shallow monitoring well in an urban area but in none of the drinking-water wells. Nutrient concentrations in undeveloped areas

(determined from data from the 20 NAWQA Study Units that began in 1991) indicate a national background concentration for nitrate of 2.0 mg/L (U.S. Geological Survey, 1999). The undeveloped areas are considered to be minimally affected by agriculture, urban development, or associated land uses. Twenty percent of the samples collected from monitoring wells (and none of the samples collected from drinking-water wells) contained nitrate concentrations greater than 2.0 mg/L. These findings indicate that portions of the

shallow ground-water system have been affected by urban land use, but these effects were not found in the deeper ground water used for drinking water.

Generally, low levels of pesticides and volatile organic compounds were detected in ground water from shallow alluvial aquifers in urban areas. Most agriculture (and pesticide use) in the basin occurs in the Colorado Plateau where ground-water studies were not conducted. The pesticides that

were detected in the ground water sampled in the Southern Rocky Mountains were primarily herbicides used for controlling grasses and weeds in nonagricultural areas. Concentrations were very low (less than 0.1 µg/L) for most of the pesticides detected. Two herbicides, bromacil and prometon, were detected in urban areas at concentrations less than the USEPA drinking-water guidelines (U.S. Environmental Protection Agency, 1996).

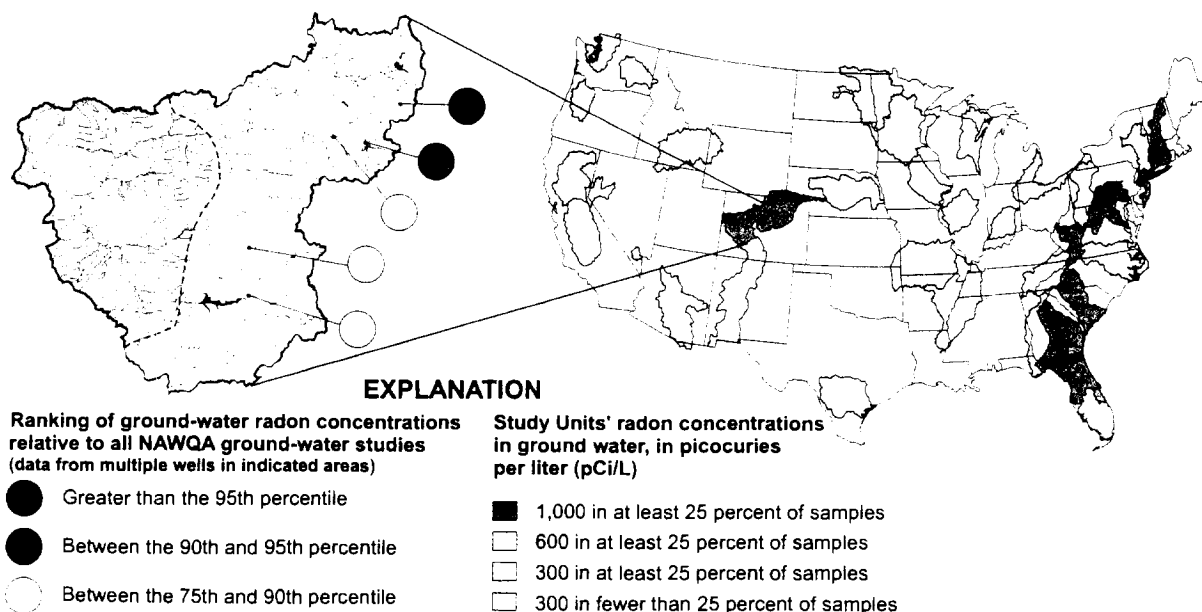

Volatile organic compounds (VOCs) were detected in ground-water samples at generally low concentrations. The six most frequently detected VOCs were methyl *tert*-butyl ether (MTBE), tetrachloroethene, chloroform, 1,1,1-trichloroethane, 1,2,4-trimethylbenzene, and dichloromethane (fig. 10). MTBE, a gasoline additive, was detected in at least one well in four of the five urban areas where shallow ground water was sampled. In addition,

RADON CONCENTRATIONS IN UCOL GROUND WATER WERE GENERALLY HIGHER THAN OTHER AREAS OF THE NATION

Radon concentrations in alluvial aquifers of the UCOL are among the highest of all NAWQA ground-water samples nationwide (S.J. Ryker, USGS, written commun., 1999). Radon is a naturally occurring, colorless, odorless, radioactive gas derived from the decay of uranium. Radon has been identified as a human carcinogen and can enter a building from seepage of air through dirt floors, cracks in concrete floors or walls, floor drains, or through the use of water supplied from wells. A greater risk of exposure to radon exists in urban areas due to the prevalence of enclosed structures, such as basements, which can trap radon gas.

Though the USEPA does not currently (2000) regulate radon in drinking water, there is a proposed maximum contaminant level (MCL) of 300 picocuries per liter (pCi/L) for radon in drinking water (U.S. Environmental Protection Agency, 1999). Radon concentrations were greater than the proposed MCL for all wells sampled in the Southern Rocky Mountains. Higher radon concentrations were measured in the Winter Park/Fraser and Silverthorne areas. Igneous and metamorphic rocks, which can contain uranium-bearing minerals, are common rock types in these areas.

Figure 10. Volatile organic compounds were detected at low frequencies in monitoring and drinking-water wells sampled in the Southern Rocky Mountains. With a few exceptions (2 samples), concentrations of VOCs were substantially less than water-quality standards. All concentrations shown are greater than 0 µg/L. (MCL, maximum contaminant level; HA, health advisory.)

MTBE was detected in water from one municipal well. MTBE concentrations greater than the drinking-water lifetime health advisory of 20–40 µg/L (U.S. Environmental Protection Agency, 1997) were not detected. However, once MTBE enters the ground water, it is less vulnerable to decomposition and travels farther than other

gasoline compounds (Squillace and others, 1996).

Tetrachloroethene is present in solvents for adhesives and is also a by-product of dry cleaning. Chloroform can occur naturally or result from the chlorination of drinking water. 1,1,1-Trichloroethane is present in solvents and cleaning agents. 1,2,4-Trimethylbenzene is present in petroleum by-products.

Dichloromethane is predominantly used as a solvent in paint strippers and removers. Concentrations of dichloromethane and tetrachloroethene were greater than the USEPA drinking-water standard of 5 µg/L at one site in Silverthorne.

Total coliform bacteria were detected in 21 percent of the ground-water samples collected in urban areas. Total coliform bacteria were detected only in samples collected from the shallow monitoring wells and in none of the water samples from drinking-water wells. Bacteria in ground water may occur naturally in soils or may be related to human or animal waste and, therefore, may be an indication of the sanitary quality of the water (Myers and Sylvester, 1997). However, the presence of total coliform bacteria does not necessarily indicate the presence of potentially pathogenic bacteria such as *Escherichia coli* (*E. coli*), which was not detected in any of the samples.

Urban land use in the Southern Rocky Mountains, near Fraser, Colorado. (Photograph by Jeffrey B. Bails, U.S. Geological Survey.)

Chlorofluorocarbons (CFCs) were used to determine the age of ground water

Shallow ground water, which is used for drinking water in part of the Southern Rocky Mountains, is generally young (less than 10 years old) and is more susceptible to contamination as a result of land-use practices. The age of the ground water refers to the time from when the water recharged, or entered, the aquifer to the time it was withdrawn from the aquifer. The presence of contaminants, if any, in ground water can reflect land-use conditions at the time of recharge. The age of the ground water was determined in five urban areas where water-quality samples were collected from shallow alluvial aquifers. The age of ground water at most of the sites sampled ranged from 0 to 10 years old. Ground-water ages of greater than 10 years were found in 7 of 25 wells.

In the samples where CFC dates were obtained, four of the five nitrate concentrations greater than 2.0 mg/L were from recently recharged ground water (10 years or younger). This is an indication that current land use may be affecting water quality. Increasing urban development may add nitrate to the ground water from different sources, such as septic systems, application of fertilizers, and domestic animal wastes. Effects of increased urban development on ground-water resources are not extensive in the study area at present.

The Quality of Streams and Rivers is Affected by Historical Mining Activities

Streams affected by mine drainage, from abandoned/inactive mines, are present throughout much of the Rocky Mountains of Colorado. Metal mining in the UCOL has been an important part of the economy of Colorado since the late 1800s. As a result, many streams in the upper part of the basin contain heavy metals and other toxic elements that affect stream-water quality. Knowledge of mine-drainage effects on a body of water is essential for assessing water quality with regard to human consumption, recreation, and aquatic life.

Because of the potential exposure of aquatic organisms to trace elements in streambed sediment, trace-element concentrations in streambed sediment serve as an indicator of potential toxicity to aquatic life. Sampling trace ele-

ments in streambed sediment can be used to identify stream reaches affected by mining and can be used to determine sources of trace elements. The occurrence and distribution of trace elements were characterized by collecting streambed-sediment samples at 29 sites in mining districts (fig. 6 and table 1) and at 8 background (non-mining) sites in the Southern Rocky Mountains.

Concentrations of cadmium, copper, lead, and zinc in streambed sediment were high at some sites downstream from mining areas (Deacon and Driver, 1999). Median concentrations of cadmium (Cd) and zinc (Zn) in samples from most mining districts exceeded the Canadian Sediment Quality Guidelines Probable Effect Level (PEL), which is a sediment guideline (fig. 11). The PEL defines the concentration level above which adverse effects to aquatic biota are predicted to occur

Mining land use in the Southern Rocky Mountains. (Photograph by Jeffrey Deacon, U.S. Geological Survey.)

frequently (Canadian Council of Ministers of the Environment, 1999). National sediment concentration guidelines have not been established for the United States. Concentrations of copper and lead were also elevated and exceeded the PEL in several mining districts. The mining and mineralized areas of the UCOL generally result in higher trace-element concentrations in streambed sediment than are detected in other areas studied within the NAWQA Program (p. 12).

Collecting samples from several types of media provides a better understanding of trace elements in the environment. In addition to streambed sediment, which can store trace elements, the overlying stream water can also be a source of trace-element exposure to aquatic organisms. Because invertebrates are continuously exposed to water-quality conditions, these organisms integrate effects of contaminants over time and provide a measurement of water quality. Invertebrate indicators of streams contaminated by trace elements include reduced abundance and a shift in commu-

Table 1. Mining districts and sampling sites in the Southern Rocky Mountains

Mining district ¹	River/Stream [site number(s) in figure 6] ²
Aspen	Hunter Creek (24)

Figure 11. Median concentrations of cadmium and zinc in streambed sediments were greater than the Canadian Probable Effect Level in most mining districts of the UCOL.

nity composition from sensitive insects, such as mayflies, to more tolerant insects, such as midges. Lower mayfly abundance can be related to increased trace-element concentrations (Clements and Kiffney, 1995; Clements, 1994;

Kiffney and Clements, 1994). Concentrations of trace elements in transplanted aquatic moss also provide information about the occurrence and bioavailability of trace elements (Carter and Porter, 1997). In order to assess the source(s) and environmental effects of trace

elements, a more detailed study was conducted in the Blue River Basin; this study included the collection of water, streambed sediments, reservoir sediments, and aquatic moss samples and an assessment of the habitat and invertebrate communities.

TRACE ELEMENTS IN STREAMBED SEDIMENTS OF THE UCOL WERE OFTEN GREATER THAN CONCENTRATIONS DETECTED AT OTHER SITES NATIONALLY

The median concentrations for cadmium, copper, lead, and zinc in streambed sediment from sites in the UCOL were higher than the median concentrations of the same trace elements sampled in other Study Units of the national NAWQA Program. The data available on trace elements include 541 samples from the NAWQA Study Units (Rice, 1999) and 37 samples from the UCOL. Mineralized areas and historical mining activities in the UCOL have resulted in higher concentrations of some trace elements in streams than those concentrations that typically are found in other parts of the United States.

Collecting sediment core samples on Dillon Reservoir. (Photograph by Norman Spahr, U.S. Geological Survey.)

Mining activities have affected trace-element concentrations and aquatic invertebrates in French Gulch and the Blue River. Samples from different media were used to investigate the effects of mining activities on the water quality and associated biota at 10 sites along the Blue River and French Gulch, a tributary of the Blue River (fig. 12). Sites 2 and 3 (fig. 12) are background sites on French Gulch and are minimally affected by mining activities. Zinc concentrations in water and streambed sediment and zinc accumulated by aquatic moss at these background sites were lower than those from sites downstream from the mined areas. The invertebrate community structure (as indicated by mayfly abundance and percent midges) was minimally affected at the background sites.

Although habitat conditions at site 4 were degraded and zinc concentrations were greater than those upstream, the invertebrate community was not found to be signifi-

cantly degraded. Farther downstream, where underground mine seepage contributes to surface runoff (site 6), zinc concentrations in the water, streambed sediment, and aquatic moss were high and the invertebrate communities were degraded. The most affected site along French Gulch was site 7, located near the confluence with the Blue River.

Site 1, upstream from French Gulch on the Blue River, was characterized by lower zinc concentrations in water, moss, and sediment than downstream sites, indicating that the French Gulch basin is contributing zinc to the Blue River. Downstream from the confluence of French Gulch with the Blue River (site 8), concentrations of zinc in water, moss, and streambed sediment were higher than background levels but slightly lower than in French Gulch. Also at site 8, brown trout livers had the highest concentrations of zinc of any sites sampled in the Southern Rocky Mountains (Deacon and Stephens, 1998). The invertebrate community in the Blue River downstream from French Gulch was degraded (site 8). The site conditions remain moderately affected downstream to Dillon Reservoir (site 10).

Mining activities have affected trace-element concentrations in the bottom sediment of Dillon Reservoir. Dillon Reservoir was constructed in 1963 in an area with a long history of mining activity. Sources of trace elements in Dillon Reservoir, a drinking-water supply for the city of Denver, are located in the Blue River, Snake River, and Tenmile Creek Basins. The reservoir is accumulating some trace elements. For example, loads calculated using streamflow and

water concentration indicate that only 37 percent of the zinc that enters Dillon Reservoir leaves the reservoir (fig. 12, top left graph).

Sediment cores were collected at several locations in Dillon Reservoir. Concentrations of lead and zinc throughout the core collected near the dam exceeded the PEL. Cadmium, lead, and zinc concentrations in sediment cores from the Blue River, Snake River, and Tenmile Creek arms of the reservoir also were above the PEL (values for zinc are shown in the top of fig. 12).

Although bottom sediment concentrations of some trace elements exceeded the PEL, concentrations in the water column were not high. The concentrations of trace elements in the reservoir water column did not exceed the Colorado surface-water-quality standards.

Sediment core from Dillon Reservoir. (Photograph by Norman Spahr, U.S. Geological Survey.)

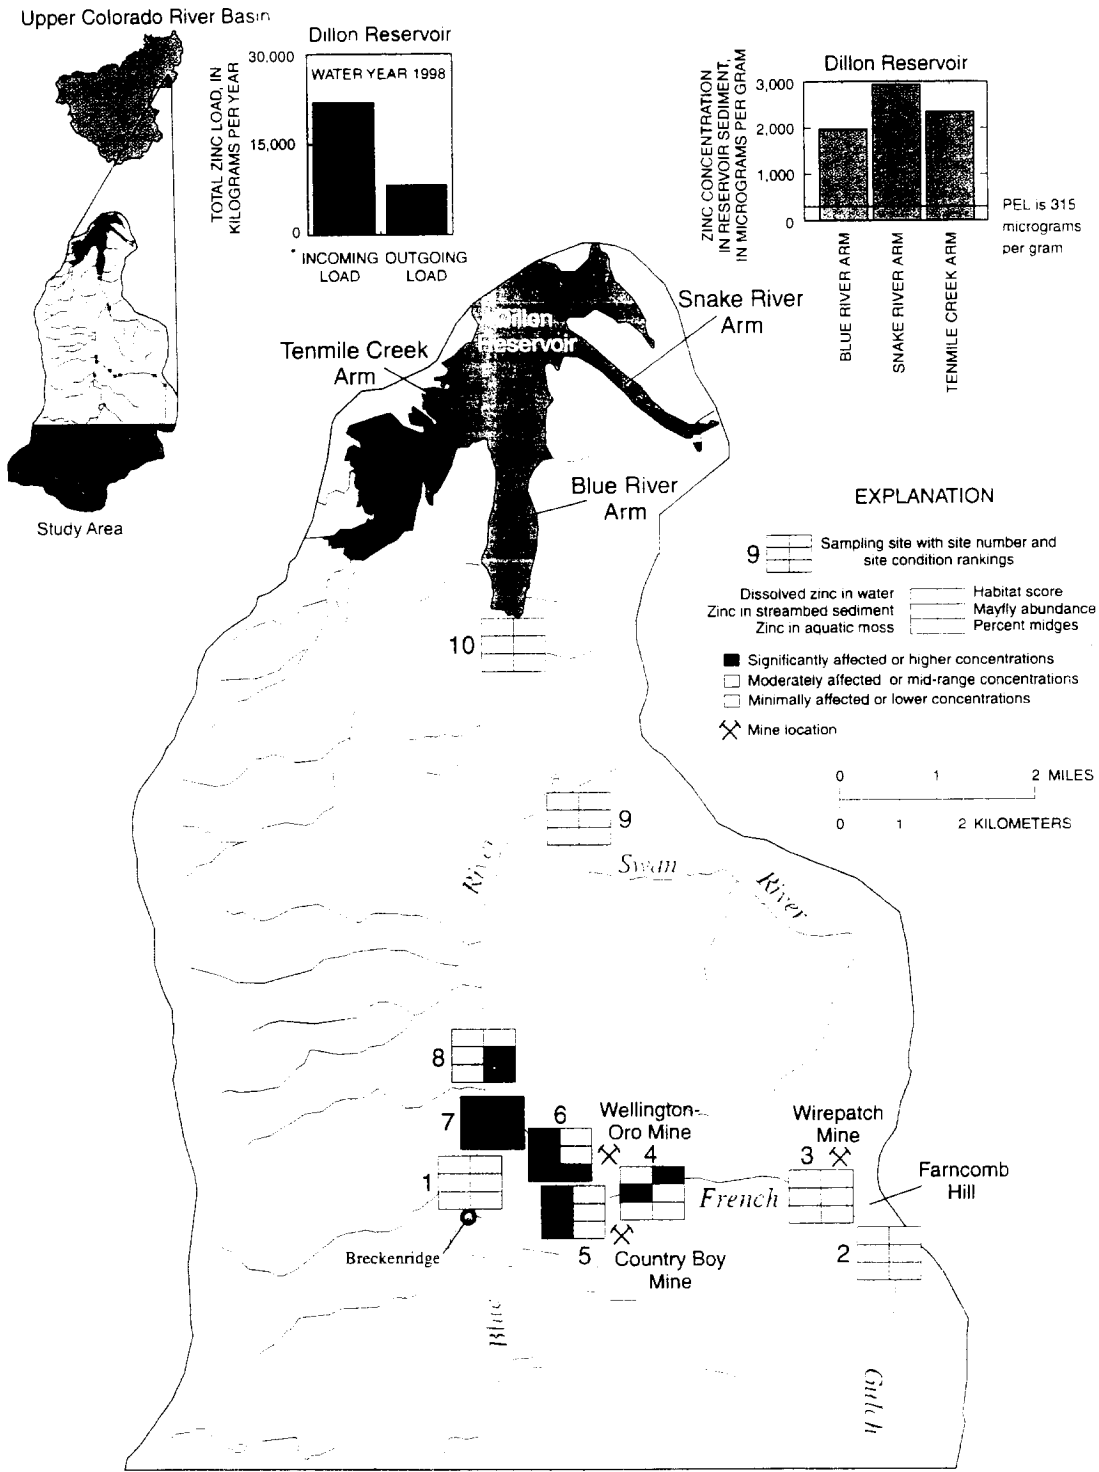

Figure 12. Different types of sampling media provide a better understanding of conditions at sites sampled in the Blue River Basin. Dillon Reservoir sediments are accumulating some trace elements originating from mining areas.

Selenium in Western Colorado

Selenium, a naturally occurring trace element, is common throughout the Western United States in marine sedimentary rocks. It is an essential micronutrient for birds, fish, and animals (Mayland, 1994) but at high concentrations can be highly toxic to fish and wildlife. Selenium can be very mobile in the environment and the mobility can be accelerated by irrigation. As irrigation water is applied to soils containing selenium, the selenium is leached out of the soils and into surface and ground water. Selenium in wetlands, ponds, and lakes is incorporated into bed sediment and can be bioaccumulated by wildlife, including fish and birds (Ohlendorf and others, 1986). Areas of the Western United States susceptible to selenium contamination from irrigation, which include

the Grand and Uncompahgre Valleys in western Colorado, have been identified by Seiler and others (1999). Extensive irrigated agriculture is present in the Grand and Uncompahgre Valleys of the Colorado Plateau in western Colorado (fig. 6). Irrigation drainage from these areas may account for as much as 75 percent of the selenium load in the Colorado River near the Colorado-Utah State line (Butler and others, 1996). It is estimated that 61 percent of the selenium load to Lake Powell in Utah originates from these agricultural areas in the UCOL (Engberg, 1999). Primary source areas of selenium in western Colorado are the western one-half of the Grand Valley and the eastern side of the Uncompahgre River Valley where the residual soils and alluvium are derived primarily from the Mancos Shale, a marine shale containing selenium.

A study in 1991–93 of irrigation drainage in the Grand and Uncompahgre River Valleys detected relatively high concentrations of selenium in many surface-water and streambed-sediment samples (Butler and others, 1996). Concentrations of selenium greater than the aquatic-life guidelines were also detected in the UCOL surface-water sampling in agricultural areas during 1995–98 and at one streambed-sediment sampling site in 1995. Investigations of selenium in western Colorado for remediation planning are continuing through the U.S. Department of the Interior National Irrigation Water Quality Program and the Gunnison Basin Selenium Task Force.

Water-Quality Characteristics of Agricultural Areas

Agricultural land use constitutes about 5 percent of the Study Unit area (fig. 6). Within the Southern Rocky Mountains, agricultural land is almost exclusively hay meadows. The agricultural areas of the Colorado Plateau (principally the Grand Valley near Grand Junction in Mesa County and the Uncompahgre Valley near Delta and Montrose in Delta and Montrose Counties, fig. 6) produce hay, corn, small grains, dry beans, onions, melons, fruit, and grapes. The Grand Valley has about 70,000 acres of irrigated land, and the Uncompahgre Valley contains about 86,000 irrigated acres (Butler and others, 1996). The market value of agricultural products produced in Delta, Mesa, and Montrose Counties was about 145 million dollars in 1992 (Bureau of the Census, 1994). Pesticides, nutrients, and sediment are water-quality issues commonly associated with agricultural land use.

Pesticides were sampled in different media. Pesticides were investigated in surface water by periodic monitoring at 2 agricultural sites and a one-time synoptic sampling at 43 agricultural sites. Fish were collected once at three agricultural sites and the tissues analyzed for organochlorine pesticides. Organochlorine pesticides in streambed sediments were sampled once at six agricultural sites. Ground-water samples were not collected in the agricultural areas of the UCOL because ground water is generally not used for public water supply in these areas.

Collecting water samples at an agricultural drain in the Grand Valley. (Photograph by Norman Spahr, U.S. Geological Survey.)

Pesticides were commonly detected in agricultural areas of the UCOL, but concentrations were generally low. Most pesticide detections in surface water were not at concentrations of concern. Freshwater aquatic-life guidelines were exceeded occasionally; however, guidelines have not been established for all compounds. Only 5 of the 90 samples collected in the agricultural areas contained pesticides that exceeded established guidelines. The pesticides that exceeded guidelines for protection of freshwater aquatic life are azinphos-methyl, 1 of 24 samples at Reed Wash; carbaryl, 2 synoptic sites, Indian Wash and Orchard Mesa Drain in the Grand Valley; diazinon, 1 synoptic site, Indian Wash; diuron, 1 synoptic site, Indian Wash; and *gamma*-HCH, 1 synoptic site, the drain at Blossom Road in the Uncompahgre Valley.

Pesticide detections and concentrations showed seasonal patterns. Periodic sampling at two

agricultural streams showed that the total number of pesticides detected was greatest during April through August (Bauch and Spahr, 2000). Pesticide detections per month for Dry Creek are shown in figure 13. Concentrations of atrazine were found to be greater from May through August than during other periods of the year (fig. 13). The seasonal pattern of concentrations was similar for other pesticides and reflects the growing season for the Grand and Uncompahgre Valleys.

Pesticides were detected in 40 of 43 agricultural streams.

Thirty-one pesticides (21 herbicides and 10 insecticides) were detected at least once during a May 1998 agricultural stream synoptic study in the Grand Valley and Uncompahgre Valley areas. Atrazine and alachlor were detected in more than 50 percent of the samples. Concentrations of atrazine did not exceed aquatic-life guidelines. Guidelines are not available for alachlor.

Some insecticides have persisted in streambed sediment and fish tissue, although their use has been banned or restricted. DDT was banned in 1972, but DDT or its

Agriculture and the San Juan Mountains near Montrose. (Photograph by Norman Spahr, U.S. Geological Survey.)

breakdown products, DDE and DDD, were detected in streambed sediments at five of the six agricultural sites sampled and in fish tissue at all three of the agricultural sites where fish tissue samples were collected (Stephens and Deacon, 1998). Concentrations of DDT and DDE in streambed sediment at two sites exceeded the Canadian Sediment Quality Guidelines PEL (Canadian Council of Ministers of the Environment, 1999). The DDD concentration at one site exceeded the PEL. Dieldrin (a restricted use insecticide since 1974) was detected in streambed sediments at two of the six sites and in fish tissue at all three sites. Insecticides detected in fish tissue and streambed sediments were generally not detected in

Figure 13. The number of pesticide detections and median atrazine concentrations in surface water are greater during the spring and summer months. Atrazine is commonly used for season-long weed control in corn.

HERBICIDES COMMONLY DETECTED IN THE UCOL WERE ALSO COMMONLY DETECTED IN OTHER AGRICULTURAL AREAS NATIONALLY

The three most commonly detected herbicides at the two agricultural monitoring sites in the UCOL (one site each in the Grand and Uncompahgre Valleys) also were among the top 10 herbicides detected in surface-water samples at 62 agricultural sites in 35 nationally distributed NAWQA Study Units. The percentages of samples with detections for atrazine, alachlor, and metolachlor are shown below and are based on more than 1,550 samples for the national sites and 39 samples at the UCOL sites. Atrazine, alachlor, and metolachlor are commonly used for weed control in corn. Alachlor and metolachlor are also used for weed control in dry beans. Other herbi-

cides that were frequently detected (present in over one-third of the samples) in the UCOL but not shown in the graph include trifluralin, DCPA, 2,4-D, cyanazine, and deethylatrazine (a breakdown product of atrazine).

These herbicides also were commonly detected at other agricultural sites across the Nation. Median concentrations of the commonly detected herbicides in the UCOL were less than or similar to the median concentrations for the national sites. Concentrations of atrazine and metolachlor were less than the Canadian guidelines for the protection of aquatic life [1.8 µg/L for atrazine and 7.8 µg/L for metolachlor (Environment Canada, 1999)]. Guidelines have not been established for alachlor.

water samples from the same site, probably because these compounds are relatively insoluble in water. Occurrence of organochlorine pesticides, even at low concentrations, is becoming increasingly relevant because of recent evidence linking these compounds to endocrine disruption (Goodbred and others, 1997).

Nutrient concentrations in streams and rivers reflect point and nonpoint sources. National background concentrations have been determined for some forms of nutrients: total nitrogen in streams (1.0 mg/L), nitrate in streams (0.6 mg/L), and total phosphorus in

streams (0.1 mg/L) (U.S. Geological Survey, 1999). Relative concentrations of nutrients in surface water are linked to the amounts and types of substances used and discharged in different land-use settings. These substances can then reach the stream through point sources (such as wastewater discharge) or nonpoint sources (such as precipitation or runoff from agricultural areas). Estimated amounts of fertilizer applied during 1997 in Delta, Mesa, and Montrose Counties were about 14,100,000 pounds of nitrogen and 1,800,000 pounds of phosphorus (Jeffrey Stoner, U.S. Geological Survey, written

commun., 2000). Fertilizer use in these counties accounted for about 77 percent of the total estimated fertilizer usage for the UCOL.

Nutrient concentrations in areas of agricultural land use were generally greater than in areas of other land uses. Median concentrations of ammonia, nitrite plus nitrate, total phosphorus, dissolved phosphorus, and orthophosphate were greater at agriculture sites than at the Colorado Plateau reference and mixed land-use sites (fig. 14). The Colorado Plateau reference site has some limited agriculture upstream (livestock/hay meadows), so is not representa-

Figure 14. Concentrations of nutrients in agricultural areas of the UCOL were greater than concentrations in other land-use settings. A log scale is used due to the large range of concentrations.

tive of natural conditions but is probably representative of small streams in the Colorado Plateau. Median concentrations of nutrients at agricultural sites also were

greater than median concentrations at mixed land-use and urban sites within the Southern Rocky Mountains. The urban areas shown in the bar chart are downstream from Vail

and Crested Butte, Colorado (fig. 6), and are streams that are not dominated by wastewater effluent such as might be found in large metropolitan areas. Concentrations of nitrite and nitrate were within State standards for agricultural water use. Water from the agricultural streams is not commonly used for domestic supply.

Geology and agriculture contribute to elevated suspended-sediment concentrations in the Colorado Plateau. Suspended-sediment concentrations in the streams and rivers of the Colorado Plateau were much greater than concentrations in the Southern Rocky Mountains (fig. 15), due in large part to differences between the sedimentary geology of the

NITROGEN CONCENTRATIONS AT THE UCOL AGRICULTURAL SITES WERE GREATER THAN CONCENTRATIONS FOR MANY AGRICULTURAL SITES NATIONWIDE

Total nitrogen (the sum of nitrite, nitrate, ammonia, and organic nitrogen) concentrations at the UCOL agricultural monitoring sites (Reed Wash and Dry Creek) were ranked in the group of national agricultural sites with the highest concentrations. The map below shows a comparison of average annual total nitrogen concentrations at the two UCOL agricultural sites with agricultural sites in other NAWQA Study Units. The average concentrations for the UCOL sites were 3.8 milligrams per liter for Reed Wash and 3.2 milligrams per liter for Dry Creek and are less than State instream standards. Average annual total phosphorus concentrations at the two agricultural sites in the UCOL also ranked among the group of national agricultural sites with the highest total phosphorus concentrations.

TOTAL NITROGEN IN STREAMS—AGRICULTURAL AREAS

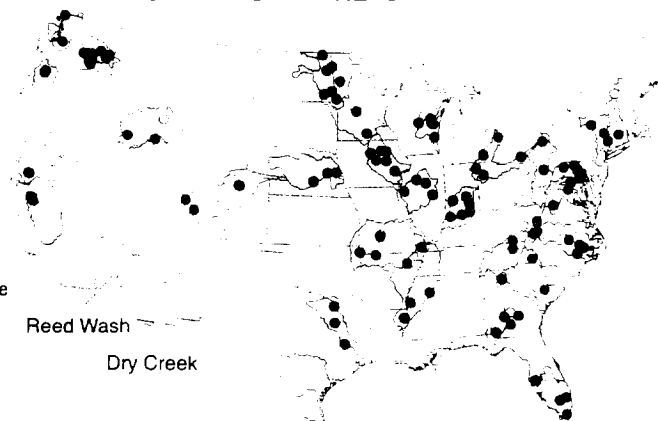

EXPLANATION

Average annual concentration of total nitrogen, in milligrams per liter

- Highest (greater than 2.9)
- Medium (0.64 to 2.9)
- Lowest (less than 0.64)

Average annual total nitrogen input, in pounds per acre, by county, for 1995–98. Inputs are from fertilizer, manure, and the atmosphere

- Greater than 25 pounds per acre
- 6 to 25 pounds per acre
- Less than 6 pounds per acre

Colorado Plateau and the igneous-metamorphic geology of the Southern Rocky Mountains. Agricultural return flows also contribute to the greater sediment concentrations measured at the agricultural sites.

The reference site in the Colorado Plateau also had elevated sediment concentrations. Any rain or snowmelt event in these areas tends to substantially increase the sediment concentrations of streams and rivers because of the high erodibility of the soils.

Figure 15. Suspended-sediment concentrations were greatest in the agricultural areas of the Colorado Plateau.

Sediment and water-quality sampling at Reed Wash. (Photograph by Norman Spahr, U.S. Geological Survey.)

BIOLOGICAL MEASURES INDICATE THAT UCOL AGRICULTURAL AND COLORADO PLATEAU MIXED LAND-USE SITES RANK AMONG THE MORE DEGRADED SITES NATIONALLY

The elevated nutrient and sediment concentrations found in the agricultural and surrounding areas of the Colorado Plateau help to explain the prevalence of more tolerant biological species. Algal, invertebrate, and fish communities in the Colorado Plateau generally consist of species more tolerant to nutrients and sediments. These result in higher degradation rankings for all three biological measures. The biological measures in the Colorado Plateau indicate that agricultural and mixed land-use sites in the UCOL are above the national average in terms of degradation. These rankings compare UCOL agricultural sites to other NAWQA agricultural sites and UCOL mixed land-use sites to other NAWQA mixed land-use sites nationally.

Site name	Biological indicator		
	Algal status	Invertebrate status	Fish status
Dry Creek (agricultural site)	□	■	■
Reed Wash (agricultural site)	■	■	■
Colorado River near Cameo (Colorado Plateau mixed land use)	■	□	□
Gunnison River near Grand Junction (Colorado Plateau mixed land use)	■	■	■
Colorado River at State line (Colorado Plateau mixed land use)	■	■	□

EXPLANATION
 □ Middle 50 percent nationally
 ■ Highest 25 percent nationally, most degraded sites

Explanation of Biological Rankings

The three selected biological indicators respond to changes in stream degradation. Degradation can result from a variety of factors that modify habitat or other environmental features such as land use, water chemistry, and flow. Algal status focuses on the changes in the percentage of certain algae in response to increasing siltation and often is positively correlated with higher nutrient concentrations in many regions of the Nation. Invertebrate status is the average of 11 invertebrate metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. Fish status focuses on changes in the percentage of tolerant fish species that make up the total number of fish. "Tolerant" fish are reported to thrive in degraded water quality. For all indicators, higher values indicate degraded water quality.

Salinity in the Colorado River Basin

A serious water-quality issue in the Colorado River Basin is salinity defined as the concentration of dissolved mineral salts or total dissolved solids in water. Salinity increases in the Colorado River in a downstream direction; the dissolved-solids concentration is about 50 mg/L in the upstream mountain areas and averages about 850 mg/L at Imperial Dam, Arizona (Kircher, 1984). In the UCOL, annual dissolved-solids loads in the Colorado River ranged from about 17,700 tons at Hot Sulphur Springs in the Southern Rocky Mountains to more than 3,300,000 tons near the Colorado-Utah State line.

Major sources of salinity in the Colorado River Basin are mineral springs and nonpoint-source runoff. The major human influence is irrigated agriculture. About 11 percent of the salt load in the Colorado River near the U.S.–Mexico border is contributed from the Grand Valley and Uncompahgre Valley (lower Gunnison River Basin) agricultural areas (U.S. Department of the Interior, 1999). Much of the soil in these areas is derived from and overlies the Mancos Shale, a saline marine deposit. Deep percolation of irrigation water and seepage losses from irrigation systems leach salt from the soil and shale, increasing the salinity of return flows. Salinity-control projects have been constructed throughout the Colorado River Basin, including two projects in the UCOL—the Grand Valley Unit and the Lower Gunnison Basin Unit.

As part of the study of salinity in the Colorado River Basin, trends in dissolved-solids concentrations in the basin have been investigated in numerous studies (Vaill and Butler, 1999; Bauch and Spahr, 1998; Butler, 1996; Liebermann and others, 1989; Kircher, 1984). The most recent study (Vaill and

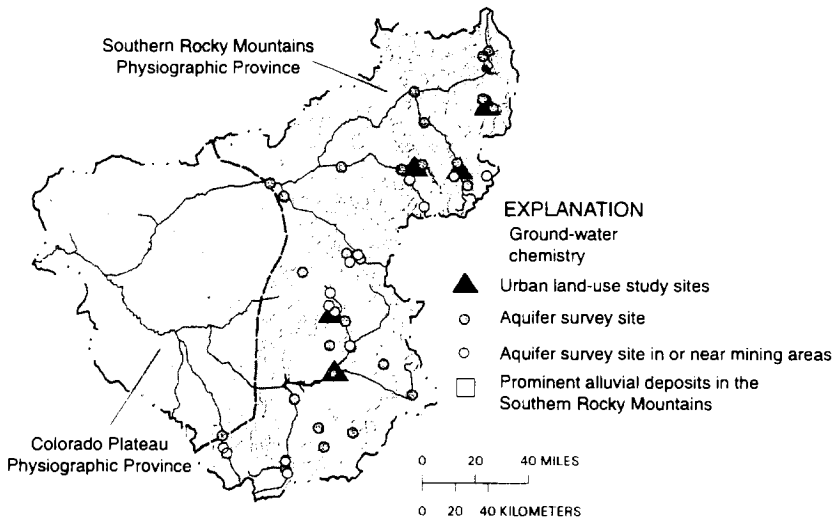

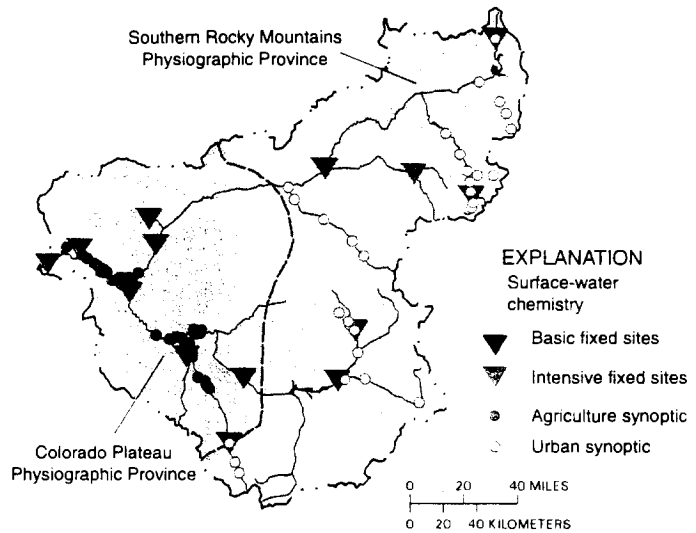

Mean annual dissolved-solids loads increase greatly between sites in the Southern Rocky Mountains and sites in the Colorado Plateau. Data based on water years 1970 to 1993. (Butler, 1996; Bauch and Spahr, 1998)

Butler, 1999) determined that since the 1960s there have been, in general, downward trends in flow-adjusted annual and monthly dissolved-solids concentrations and loads in the Colorado River Basin upstream from Lake Powell in Utah, except in the Yampa River Basin. In the UCOL, there were downward trends both upstream and downstream from the salinity-control projects in the Grand Valley and the lower Gunnison River Basin. With the downward trends as evidence, it appears that both natural processes and human efforts such as salinity-control projects may be decreasing salinity loading in the Colorado River Basin.

STUDY UNIT DESIGN

SURFACE-WATER CHEMISTRY

The basic fixed site network was established to investigate the differences in stream-water quality associated with land use and environmental settings within the UCOL. Basic fixed sites were sampled monthly to determine temporal variability of water-quality constituents. The three intensive fixed sites (a subset of the basic fixed site network) were sampled weekly to monthly to further define temporal variability. Synoptic studies were designed to investigate agriculture and urban development effects on water quality. Synoptic sites were sampled one or two times to determine spatial influences of land use on water chemistry.

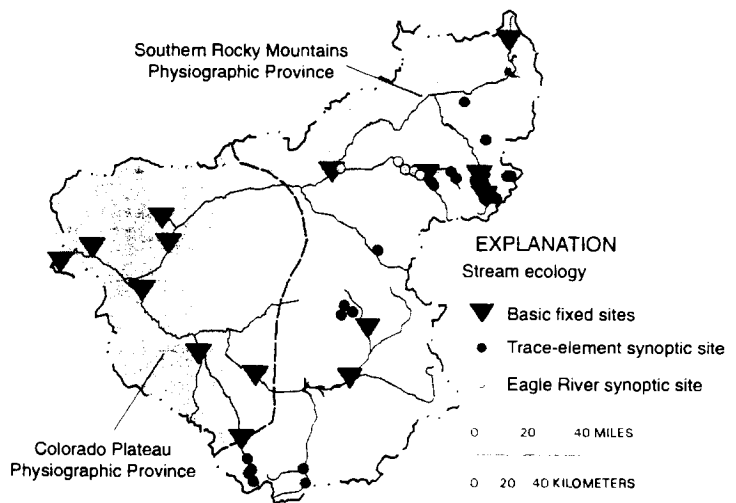

GROUND-WATER CHEMISTRY

To evaluate the effects of urban land use on shallow ground-water quality, five areas within the Southern Rocky Mountains that are undergoing urban development and use ground water as a primary drinking-water source, were studied. An overall assessment of water quality in predominantly alluvial aquifers of the Southern Rocky Mountains was also completed. In addition to the overall assessment, wells were selected in or near mining areas. Alluvial aquifers were selected for these studies because they are generally productive and can be susceptible to land-use practices.

STREAM ECOLOGY

Ecological assessments were done at all basic fixed sites plus one additional site on the Blue River. A synoptic study in mining areas of the Southern Rocky Mountains investigated trace elements in streambed sediment, aquatic moss, and surface water. A characterization of the algal and invertebrate communities and nutrient concentrations in surface water was completed at five sites on the Eagle River.

SUMMARY OF DATA COLLECTION IN THE UPPER COLORADO RIVER BASIN, 1996-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Surface-Water Chemistry				
Basic fixed sites—general water chemistry	Monthly samples collected for major ions, nutrients, organic carbon, and suspended sediment to describe concentration variability and loads. Daily streamflow also collected or computed.	Streams and rivers representing urban development, mining, agricultural, and mixed land use.	14	Monthly plus additional high- or low-flow samples for water years 1996-98
Intensive fixed sites	All constituents collected for the fixed sites. Weekly to monthly samples collected to describe temporal variability in pesticide and volatile organic compounds concentrations.	A subset of the fixed site network. One site representing urban development, one site representing agricultural land use, and the outlet of the Study Unit.	3	Weekly to monthly plus additional high- or low-flow samples for water year 1997
Synoptic sites—agriculture	One time sample to describe the spatial variability of pesticides and nutrients in agricultural areas.	Agricultural drains, streams and rivers in the Grand and Uncompahgre Valleys. Outlet of the Study Unit.	43	May 1998
Synoptic sites—urban development	Nutrient and algae samples along an upstream to downstream profile in areas of urban development to investigate influences of urban development.	Upstream to downstream sites along seven tributary rivers.	30	March and September 1998
Ground-Water Chemistry				
Land-use effects—Urban	Samples collected for major ions, nutrients, 18 trace elements, radon, dissolved organic carbon, 87 pesticides, 86 volatile organic compounds, bacteria (total coliform and <i>E. coli</i>), and chlorofluorocarbons to describe the effects of urban development on the shallow ground water in five urban areas of the Southern Rocky Mountains.	Shallow monitoring wells	25	Spring and Fall 1997
Aquifer survey—Southern Rocky Mountains	Samples collected for major ions, nutrients, 18 trace elements, radon, dissolved organic carbon, 47 pesticides, 86 volatile organic compounds, and bacteria (total coliform and <i>E. coli</i>) to describe the water-quality conditions in selected alluvial aquifers throughout the Southern Rocky Mountains Physiographic Province.	Private and municipal drinking-water wells Monitoring well Spring	28 1 1	Once in 1997
Aquifer survey—Southern Rocky Mountains in or near mining areas	Samples collected for same as above (except that 13 of these sites were not sampled for pesticides or volatile organic compounds) to describe the water-quality conditions in selected alluvial aquifers throughout the Southern Rocky Mountains Physiographic Province for wells located in or near mining areas.	Private and municipal drinking-water wells Spring	14 1	Once in 1997
Stream Ecology				
Basic fixed sites	Fish, invertebrate, and algae communities, trace elements, and organics in streambed sediment and fish tissue, and habitat data were collected to assess the occurrence and distribution within the UCOL.	Streams and rivers representing urban development, mining, agricultural, and mixed land use.	15	Fish community, invertebrate community, and algae August, 1996-98; Habitat August 1996; Streambed sediment and fish tissue August-October 1995
Synoptic sites—trace elements	Trace-element concentrations in streambed sediment, aquatic moss, and water; and invertebrate community structure to assess the spatial extent and magnitude of trace-element contamination from mining areas.	Areas of mining land use and background sites in areas of no mining.	32	August 1998
Synoptic sites—Eagle River	Invertebrates, algae, and nutrients in water to characterize current conditions in an area of extensive urban development.	Sites within and downstream from developed areas. Additional sites in areas that may be developed in the future.	5	February and September 1997

GLOSSARY

- Algae**—Chlorophyll-bearing, nonvascular, primarily aquatic species that have no true roots, stems, or leaves; most algae are microscopic, but some species can be as large as vascular plants.
- Alluvium**—Deposits of clay, silt, sand, gravel or other particulate rock material left by a river in a streambed, on a flood plain, delta, or at the base of a mountain.
- Alluvial aquifer**—A water-bearing deposit of unconsolidated material (sand and gravel) left behind by a river or other flowing water.
- Ammonia**—A compound of nitrogen and hydrogen (NH₃) that is a common by-product of animal waste. Ammonia readily converts to nitrate in soils and streams.
- Aquatic-life guideline**—Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms. See also Water-quality guidelines.
- Basin**—See Drainage basin.
- Benthic invertebrates**—Insects, mollusks, crustaceans, worms, and other organisms without a backbone that live in, on, or near the bottom of lakes, streams, or oceans.
- Bioaccumulation**—The biological sequestering of a substance at a higher concentration than that at which it occurs in the surrounding environment or medium. Also, the process whereby a substance enters organisms through the gills, epithelial tissues, dietary, or other sources.
- Breakdown product**—A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process which may result in a more toxic or a less toxic compound and a more persistent or less persistent compound.
- Chlorofluorocarbons**—A class of volatile compounds consisting of carbon, chlorine, and fluorine. Commonly called freons, which have been used in refrigeration mechanisms, as blowing agents in the fabrication of flexible and rigid foams, and, until several years ago, as propellants in spray cans.
- Community**—In ecology, the species that interact in a common area.
- Concentration**—The amount or mass of a substance present in a given volume or mass of sample. Usually expressed as microgram per liter (water sample) or micrograms per kilogram (sediment or tissue sample).
- Confluence**—The flowing together of two or more streams; the place where a tributary joins the main stream.
- Constituent**—A chemical or biological substance in water, sediment, or biota that can be measured by an analytical method.
- Cubic foot per second (ft³/s, or cfs)**—Rate of water discharge representing a volume of 1 cubic foot passing a given point during 1 second, equivalent to approximately 7.48 gallons per second or 448.8 gallons per minute or 0.02832 cubic meter per second.
- Detect**—To determine the presence of a compound.
- DDT**—Dichloro-diphenyl-trichloroethane. An organochlorine insecticide no longer registered for use in the United States.
- Discharge**—Rate of fluid flow passing a given point at a given moment in time, expressed as volume per unit of time.
- Dissolved constituent**—Operationally defined as a constituent that passes through a 0.45-micrometer filter.
- Drainage basin**—The portion of the surface of the Earth that contributes water to a stream through overland runoff, including tributaries and impoundments.
- Eutrophication**—The process by which water becomes enriched with plant nutrients, most commonly phosphorus and nitrogen.
- Health advisory**—Nonregulatory levels of contaminants in drinking water that may be used as guidance in the absence of regulatory limits. Advisories consist of estimates of concentrations that would result in no known or anticipated health effects (for carcinogens, a specified cancer risk) determined for a child or for an adult for various exposure periods.
- Instream standards**—See Water-quality standards.
- Invertebrate**—An animal having no backbone or spinal column. See also Benthic invertebrates.
- Load**—General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.
- Maximum contaminant level (MCL)**—Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Median**—The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Micrograms per liter (µg/L)**—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most streamwater and ground water. One thousand micrograms per liter equals 1 mg/L.
- Midge**—A small fly in the family Chironomidae. The larval (juvenile) life stages are aquatic.

Milligrams per liter (mg/L)— A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most stream-water and ground water. One thousand micrograms per liter equals 1 mg/L.

Monitoring well— A well designed for measuring water levels and testing ground-water quality.

Mouth— The place where a stream discharges to a larger stream, a lake, or the sea.

Nitrate— An ion consisting of nitrogen and oxygen (NO_3^-). Nitrate is a plant nutrient and is very mobile in soils.

Nonpoint source— A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs from plants and trees are types of nonpoint source pollution.

Nutrient— Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.

Organochlorine pesticide— A class of organic insecticides containing a high percentage of chlorine. Includes dichlorodiphenylethanes (such as DDT), chlorinated cyclodienes (such as chlordane), and chlorinated benzenes (such as lindane). Most organochlorine insecticides were banned because of their carcinogenicity, tendency to bioaccumulate, and toxicity to wildlife.

Pesticide— A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents or other "pests".

Phosphorus— A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.

Picocurie (pCi)— One trillionth (10^{-12}) of the amount of radioactivity represented by a curie (Ci). A curie is the amount of radioactivity that yields 3.7×10^{10} radioactive disintegrations per second (dps). A picocurie yields 2.22 disintegrations per minute (dpm) or 0.037 dps.

Radon— A naturally occurring, colorless, odorless, radioactive gas formed by the disintegration of the element radium; damaging to human lungs when inhaled.

Reference site— A NAWQA sampling site selected for its relatively undisturbed conditions.

Sediment— Particles, derived from rocks or biological materials, that have been transported by a fluid or other natural process, suspended or settled in water.

Species— Populations of organisms that may interbreed and produce fertile offspring having similar structure, habits, and functions.

Streambed sediment— The material that temporarily is stationary in the bottom of a stream or other watercourse.

Study Unit— A major hydrologic system of the United States in which NAWQA studies are focused. Study Units are geographically defined by a combination of ground- and surface-water features and generally encompass more than 4,000 square miles of land area.

Surface water— An open body of water, such as a lake, river, or stream.

Suspended sediment— Particles of rock, sand, soil, and organic detritus carried in suspension in the water column, in contrast to sediment that moves on or near the streambed.

Synoptic sites— Sites sampled during a short-term investigation of specific water-quality conditions during selected seasonal or hydrologic conditions to provide improved spatial resolution for critical water-quality conditions.

Trace element— An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, zinc and selenium.

Un-ionized ammonia— The neutral form of ammonia-nitrogen in water, usually occurring as NH_4OH . Un-ionized ammonia is the principal form of ammonia that is toxic to aquatic life. The relative proportion of un-ionized to ionized ammonia (NH_4^+) is controlled by water temperature and pH. At temperatures and pH values typical of most natural waters, the ionized form is dominant.

Volatile organic compounds (VOCs)— Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

Water-quality guidelines— Specific levels of water quality which, if reached, may adversely affect human health or aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.

Water-quality standards— State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.

Water year— The continuous 12-month period, October 1 through September 30, in U.S. Geological Survey reports dealing with the surface-water supply. The water year is designated by the calendar year in which it ends and which includes 9 of the 12 months. Thus, the year ending September 30, 1980, is referred to as water year 1980.

- Spahr, N.E., and Wynn, K.H., 1997, Nitrogen and phosphorus in surface waters of the Upper Colorado River Basin: *Journal of the American Water Resources Association*, v. 33, no. 3, p. 547-560.

APPENDIX—WATER-QUALITY DATA FROM THE UPPER COLORADO RIVER BASIN IN A NATIONAL CONTEXT

For a complete view of Upper Colorado River Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Upper Colorado River Basin. Selected results for this Basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Upper Colorado River Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, simazine concentrations in Upper Colorado River Basin agricultural streams were similar to the national distribution, but the detection frequency was much higher (72 percent compared to 18 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Upper Colorado River Basin, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- .. Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- .. No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acetochlor (Harness Plus, Surpass) * **
- Benfluralin (Balan, Benefin, Bonalan) * **
- Bentazon (Basagran, Bentazone) **
- Bromacil (Hyvar X, Urox B, Bromax)
- Cyanazine (Bladex, Fortrol)
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
- Dicamba (Banvel, Dianat, Scotts Proturf)
- EPTC (Eptam, Farmarox, Allrox) * **
- Ethalfuralin (Sonalan, Curbit) * **
- Oryzalin (Surlan, Dirimal) * **
- Prometon (Pramitol, Princep) **
- Simazine (Princep, Caliber 90)
- Tebuthiuron (Spike, Tebusan)
- Trifluralin (Treflan, Gowan, Tri-4, Trific)

Herbicides not detected

- Acifluorfen (Blazer, Tackle 2S) **
- Bromoxynil (Buctril, Brominal) *
- Butylate (Sutan +, Genate Plus, Butilate) **
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) * **
- Dacthal mono-acid (Dacthal breakdown product) * **
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) * **
- 2,6-Diethylaniiline (Alachlor breakdown product) * **
- Dinoseb (Dinoseb)
- Diuron (Crisuron, Karmex, Diurex) **

Fenuron (Fenulon, Fenidim) * **
 Fluometuron (Flo-Met, Cotoran) **
 Linuron (Lorox, Linex, Sarclex, Linurex, Afaion) *
 MCPA (Rhomene, Rhonox, Chiptox)
 MCPB (Thistro) * **
 Metribuzin (Lexone, Sencor)
 Molinate (Ordram) * **
 Napropamide (Devrinol) * **
 Neburon (Neburea, Neburyl, Noruben) * **
 Norflurazon (E vital, Predict, Solicam, Zorial) * **
 Pebulate (Tillam, PEBC) * **
 Pendimethalin (Pre-M, Prowl, Stomp) * **
 Picloram (Grazon, Tordon)
 Pronamide (Kerb, Propyzamid) **
 Propachlor (Flamrod, Satecid) **
 Propanil (Stam, Stampede, Wham) * **
 Propham (Tuberite) **
 2,4,5-T **
 2,4,5-TP (Silvex, Fenoprop) **
 Terbacil (Sinbar) **
 Thiobencarb (Bolero, Saturn, Benthicarb) * **
 Triallate (Far-Go, Avadex BW, Tri-allate) *
 Triclopyr (Garlon, Grandstand, Redeem, Remedy) * **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Pesticides in water—Insecticides

Other insecticides detected

Carbaryl (Carbamine, Denapon, Sevin)
 Carbofuran (Furadan, Curaterr, Yaltox)
 Chlorpyrifos (Brodan, Dursban, Lorsban)
 Diazinon (Basudin, Diazatol, Neocidol, Knox Out)
 gamma-HCH (Lindane, gamma-BHC)
 Malathion (Malathion)
cis-Permethrin (Ambush, Astro, Pounce) * **
 Phorate (Thimet, Granutox, Geomet, Rampart) * **
 Propargite (Comite, Omite, Ornamate) * **
 Terbufos (Contraven, Counter, Pilarfox) **

Insecticides not detected

Aldicarb (Temik, Ambush, Pounce)
 Aldicarb sulfone (Standak, aldoxycarb)
 Aldicarb sulfoxide (Aldicarb breakdown product)
 Dieldrin (Panoram D-31, Octalox, Compound 497)
 Disulfoton (Disyston, Di-Syston) **
 Ethoprop (Mocap, Ethoprophos) * **
 Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
 alpha-HCH (alpha-BHC, alpha-lindane) **
 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
 Methiocarb (Slug-Geta, Grandslam, Mesuro) * **
 Methomyl (Lanox, Lannate, Acinate) **
 Methyl parathion (Pennacap-M, Folidol-M) **
 Oxamyl (Vydate L, Pratt) **
 Parathion (Roethyl-P, Alkron, Panthion, Phoskii) *
 Propoxur (Baygon, Blattanex, Unden, Proprotol) * **

Other VOCs detected

Benzene
 Bromodichloromethane (Dichlorobromomethane)
 2-Butanone (Methyl ethyl ketone (MEK)) *
n-Butylbenzene (1-Phenylbutane) *
sec-Butylbenzene *
 Carbon disulfide *
 Chloroethane (Ethyl chloride) *
 Chloromethane (Methyl chloride)
 1,3-Dichlorobenzene (*m*-Dichlorobenzene)
 Dichlorodifluoromethane (CFC 12, Freon 12)
 Dichloromethane (Methylene chloride)
 Diethyl ether (Ethyl ether) *
 1,2-Dimethylbenzene (*o*-Xylene)
 1,3 & 1,4-Dimethylbenzene (*m*-&*p*-Xylene)
 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
 Ethenylbenzene (Styrene)
 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
 Ethylbenzene (Phenylethane)
 Iodomethane (Methyl iodide) *
 Isopropylbenzene (Cumene) *
p-Isopropyltoluene (*p*-Cymene) *
 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
 Methylbenzene (Toluene)
 Naphthalene
 2-Propanone (Acetone) *
n-Propylbenzene (Isocumene) *
 Tetrachloroethene (Perchloroethene)
 Tetrachloromethane (Carbon tetrachloride)
 1,2,3,5-Tetramethylbenzene (Isodurene) *
 1,1,1-Trichloroethane (Methylchloroform)
 Trichloroethene (TCE)
 Trichloromethane (Chloroform)
 1,2,3-Trimethylbenzene (Hemimellitene) *
 1,3,5-Trimethylbenzene (Mesitylene) *

VOCs not detected

tert-Amyl methyl ether (*tert*-amyl methyl ether (TAME)) *
 Bromobenzene (Phenyl bromide) *
 Bromochloromethane (Methylene chlorobromide)
 Bromoethene (Vinyl bromide) *
 Bromomethane (Methyl bromide)
tert-Butylbenzene *
 3-Chloro-1-propene (3-Chloropropene) *
 1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
 Chlorobenzene (Monochlorobenzene)
 Chlorodibromomethane (Dibromochloromethane)
 Chloroethene (Vinyl chloride)
 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
 1,2-Dibromoethane (Ethylene dibromide, EDB)
 Dibromomethane (Methylene dibromide) *
trans-1,4-Dichloro-2-butene ((*Z*)-1,4-Dichloro-2-butene) *
 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
 1,4-Dichlorobenzene (*p*-Dichlorobenzene)

- 1,2-Dichloroethane (Ethylene dichloride)
- 1,1-Dichloroethane (Ethylidene dichloride) *
- 1,1-Dichloroethene (Vinylidene chloride)
- trans*-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
- cis*-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)

BIOLOGICAL INDICATORS

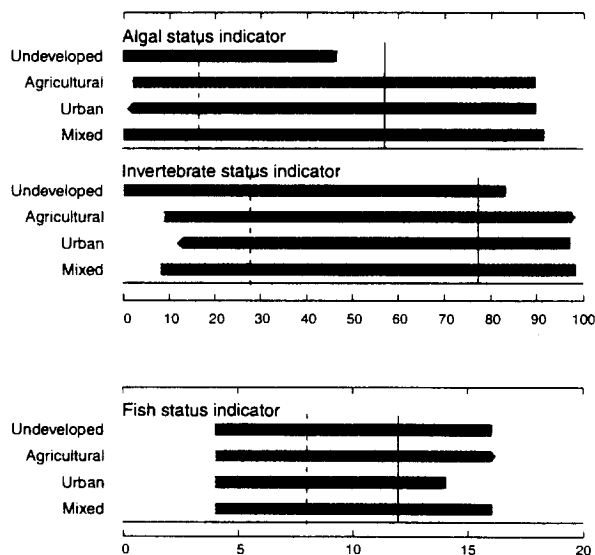

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation

Biological indicator value, Upper Colorado River Basin, by land use, 1996-98

- ◆ Biological status assessed at a site

National ranges of biological indicators, in 16 NAWQA Study Units, 1994-98

- Streams in undeveloped areas

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Sacramento River Basin that emerged from an assessment conducted between 1994 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials of State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Sacramento River Basin assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Sacramento River Basin is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

New reports on water quality

USGS recently released reports on water quality in 16 major river basins and aquifers across the Nation. The assessments indicate that the Nation's waters are generally suitable for irrigation, drinking water supply, and other home and recreational use. Major challenges remain, however, in protecting aquatic resources from nonpoint sources of pesticides, nutrients, metals, petroleum-based compounds, naturally occurring pollutants and other contaminants that continue to enter waterways in every basin.

Because each of the assessments adheres to a nationally consistent design and sampling methods, managers and planners in a specific locality or watershed can compare their water-quality conditions to those in other geographic regions. Collectively the assessments advance an understanding of the status of our Nation's waters and whether it is getting better or worse over time.

Pollution levels vary from season to season and among watersheds because of differences in land and chemical use, land-management practices, degree of watershed development, and natural features, such as soils, geology, hydrology, and climate. Understanding these variations and their causes helps in the implementation of effective management for water-quality improvement in specific geographic areas.

If you are interested in receiving additional information or would like to discuss water-resource topics of interest to you, please contact the NAWQA Program at (703) 648-5716 or through email at nawqa_info@usgs.gov. A map of the NAWQA assessments and additional ordering information, including USGS Circular report numbers, are provided in the enclosed brochure.

Information supports water-resource decisions by communities and states

A sampling of the types of information contained in the newly released assessments is provided, as well as examples of how this information is used to support science-based decisions at all levels for resource management and the protection of drinking water and aquatic ecosystems. For more details, go to the USGS website: <http://water.usgs.gov/nawqa>.

- Increased nutrients from the St. Croix River tributaries are increasing the rate of eutrophication in Lake St. Croix, **Minnesota**. In response to these findings, a multi-agency, cooperative agreement was signed to implement a protection strategy for the St. Croix River.
- **Mississippi Embayment** ground water is good for drinking-water supply; however, concentrations of DDT in streams and rivers are often higher than national norms. These results have contributed to decisions by the State of Mississippi to establish fish-consumption advisories for selected organochlorine compounds and other contaminants.
- Findings in 14 major urban centers across the Nation, including **San Antonio and Dallas, Texas** show that lead, PCBs, and DDT are decreasing since restrictions on their use in the 1970s. In contrast, the studies show that polycyclic aromatic hydrocarbons (PAHs) and zinc are increasing in watersheds experiencing urban growth and increased motor vehicle traffic.
- Fish and aquatic invertebrate communities are commonly impaired in the urbanized parts of **New Jersey**. The findings suggest that the amount of impervious road area and density of development affect the amount of runoff in a watershed and are important considerations in maintaining stream quality. These findings are used by the State of New Jersey in its development of realistic stream management and restoration goals for urbanized streams, to be adopted in the State's Watershed Management Plans.

---SEE BACK FOR MORE---

- Conservation tillage practices by farmers have resulted in reduced sediment erosion to streams in **northwestern Ohio** and **northeastern Indiana**.
- Diazinon, used by homeowners on lawns and gardens, was frequently detected in urban streams in the **Puget Sound** and **Sacramento River Basins**, often exceeding guidelines for protecting aquatic life.
- Nutrients are elevated and have resulted in increased algal growth in areas of urban development in the Southern Rocky Mountains. These findings were used by officials in **Grand County, Colorado** to help support legislation requiring improved septic systems and annual septic system monitoring in an effort to prevent further water-quality degradation.
- Concentrations of two pesticides—alachlor and cyanazine—have decreased in the **Illinois River** since 1991 because of decreased use of these pesticides by farmers. Relations between chemicals used in agricultural and urban settings, and the types and concentrations of contaminants in streams and ground water, are seen in every basin.
- Herbicide degradation products, which are mostly non-regulated, are commonly 10 times the concentration of parent compounds in the Iowa River, Iowa. On the basis of these findings, local officials in the city of **Cedar Rapids, Iowa** require monitoring and analysis of herbicide degradation products in the city water supplies.
- Since the Surface Mining Control and Reclamation Act of 1977, stream quality in the coal regions of the **Allegheny and Monongahela River Basins in Pennsylvania** and **West Virginia** and the **Kanawha River Basin in West Virginia** and **Virginia** has improved because of decreased acidity, but the diversity and abundance of aquatic organisms are reduced compared to unmined areas.
- Findings for Shingle Creek and 13 other major streams in the **Minneapolis metropolitan area** indicate clear relations between chloride concentrations and impervious surfaces and snowmelt. The information, placed in the context of other sampled urban watersheds throughout the Nation, helped to demonstrate to the Shingle Creek Watershed Management Commission that elevated chloride in Shingle Creek was not a local stockpile issue. The Commission has since recommended a metropolitan approach to assess current practices of road salt use, which is leading to improved strategies needed to meet **Minnesota** standards.

“The NAWQA Program is essential to understanding the impact of land-use changes on the quality of water flowing to the Great Lakes...Findings are directly applicable to resource managers and planners and transferable throughout the Great Lakes Basin” (Great Lakes Commission, composed of 8 states).

“The Florida Everglades has the misfortune to exhibit some of the highest concentrations of mercury in its fish and wildlife. The USGS has brought together scientists of many disciplines and enabled the South Florida Mercury Science Program to develop a deeper understanding of the scope, scale, status, and trends of mercury problems in Florida. This has thereby greatly enhanced our ability to model and manage the factors that contribute to this problem” (Dr. Thomas Atkeson, Florida Department of Environmental Protection).

“The NAWQA Program [provides data to] the U.S. Environmental Protection Agency (USEPA) [to help in their] implementation of the new pesticide law...Food Quality Protection Act (FQPA), passed in August 1996. USEPA has been required to factor potential exposures to pesticides through drinking water into already complex procedures used to set pesticide “tolerance levels” in foods...We do not have all the answers yet by any means, but we in USEPA who are charged with implementing this part of the new FQPA are greatly impressed with the knowledge and expertise contributed by NAWQA Program scientists and managers to assist USEPA in addressing the questions” (Joseph Merenda, Office of Pesticide Programs, USEPA).

SUMMARY OF MAJOR FINDINGS

Stream and River Highlights

The water quality of the Sacramento River and its major tributaries supports most beneficial uses most of the time, including drinking and irrigation water, recreation, and protection of fish and other aquatic life. Most of the water in the Sacramento River and its major tributaries, such as the Feather and American rivers, is derived from melting snow that enters the rivers by managed discharges of water from reservoirs. Because the snow is pure, much of the Sacramento River and its large tributaries have low concentrations of dissolved minerals. Although water quality of the Sacramento River is good most of the year, seasonal events, such as agricultural runoff or runoff from historical mining operations, may affect this quality. Variable climatic conditions and variation in amounts of rainfall, coupled with competing demands for water uses, affect the aquatic ecology of this basin. Management of the major rivers for the migration and reproduction of chinook salmon and other salmonid fish is a major concern in the Sacramento River Basin.

- Pesticides can affect the suitability of water for drinking and can also be toxic to aquatic organisms. In previous years, the concentrations of pesticides used on rice were sufficiently high to affect the health of aquatic life in streams draining the rice growing areas and to contribute to taste and odor problems for treated drinking water withdrawn from the lower Sacramento River. The concentrations of rice pesticides in agricultural streams and major rivers are now at acceptable levels.
- Organophosphate insecticides, a group of pesticides used in agricultural and urban areas, enter the Sacramento River from multiple sources at concentrations that exceed recommended criteria for protection of aquatic life. Although the concentrations in agricultural and urban streams sometimes exceed amounts that are toxic to zooplankton in laboratory tests, the toxicity is greatly reduced or eliminated when concentrations of these pesticides are diluted by the Sacramento River.

- Phosphorus, a plant nutrient related to algal growth, was elevated in most samples collected in agricultural and urban streams.
- Mercury from historical mining activities has been a pervasive and prevalent problem of the Sacramento River Basin and downstream locations. Mercury concentrations in water exceeded recommended guidelines for the protection of aquatic life during this study.
- Salmonid fish reproduce in mountain streams, with subsequent migration to marine waters and final migration back to the mountain streams for reproduction. Water management projects (reservoirs and dams) have blocked the normal migration routes, forcing fish to move to less desirable habitats, thus affecting their reproduction.

The Sacramento River Basin Study Unit has a wide range of land uses that encompass about 70,000 square kilometers in California. The large cropland and pasture area is known as the Sacramento Valley. The Sacramento River is the largest river in California and supplies drinking and irrigation water to communities and farms in both northern and southern California. In 1995, over 2.2 million people lived within the Study Unit boundary, with more than 1 million in the Sacramento metropolitan area.

- Optimal temperature of rivers for fish migration is maintained most of the time, but temperature management can be difficult during a drought.
- Reservoirs have affected habitats of bottom-dwelling aquatic insect populations downstream from the dams. This may affect the food supply for critical life stages of fish.
- Nonnative fish and other nonnative aquatic species have affected streams in the Sacramento Valley. Nonnative species may outcompete native species, resulting in new aquatic community assemblages, thus creating an imbalance in formerly stable ecosystems.

Major Influences on Streams and Rivers

- Year-to-year variation in precipitation amounts
- Runoff from agricultural, urban, and mining areas
- Existence and maintenance of water-supply and flood-control projects

Selected Indicators of Stream-Water Quality

	Small Streams			Major Rivers
	Urban	Agricultural	Mining	Mixed Land Uses
Pesticides ¹			—

⁶ Organochlorine compounds including DDT and PCBs, sampled in fish tissue.

⁷ Miscellaneous industrial chemicals and combustion by-products, sampled in sediment.

Ground-Water Highlights

Ground water of the Sacramento Valley accumulated in aquifers from precipitation in low hills surrounding

the valley and from infiltration of rain, rivers, and irrigation on the valley floor. Ground water is affected by agricultural and urban land uses.

- Bentazon, a herbicide applied to rice fields, was detected in 71 percent of shallow wells sampled in the rice-growing area, despite having been suspended from use since 1989. Bentazon concentrations measured in this study did not exceed any existing drinking-water standard. To protect rivers from pesticide contamination, the rice-field water is required, by means of mechanical controls, to remain on the fields for about 1 month. During that time, pesticide levels decrease by various processes, but evaporation of the water may increase the salinity of the shallow ground water by leaving salts behind.
- Urban growth of the Sacramento metropolitan area has affected ground-water quality. Nitrate concentrations are elevated but are below drinking-water standards in most wells.
- Some of the most heavily used portion of the southeastern Sacramento Valley aquifer was shown to generally have good water quality suitable for drinking and other uses. Only about 3 percent of the ground-water samples collected had nitrate or trichloroethene concentrations that exceeded a drinking-water standard. Radon concentrations exceeded guidelines in most of the domestic wells sampled.

Major Influences on Ground Water

- Agricultural and urban land-use practices
- Soil and aquifer properties

INTRODUCTION TO THE SACRAMENTO RIVER BASIN

The Sacramento River Basin occupies nearly 70,000 square kilometers (km²) in the north central part of California (fig. 1). The Sacramento River is the largest river in California, with an average annual runoff of 27 billion cubic

meters (m³) (Domagalski and Brown, 1998). The basin includes all or parts of six landforms or physiographic provinces—the Great Basin, the Middle Cascade Mountains, the Sierra Nevada, the Klamath Mountains, the Coast

Ranges, and the Sacramento Valley (fig. 1). The Sacramento Valley is the low-lying province of the basin; the other provinces are mountainous. Land use in the mountainous regions of the basin is principally forest, although forest

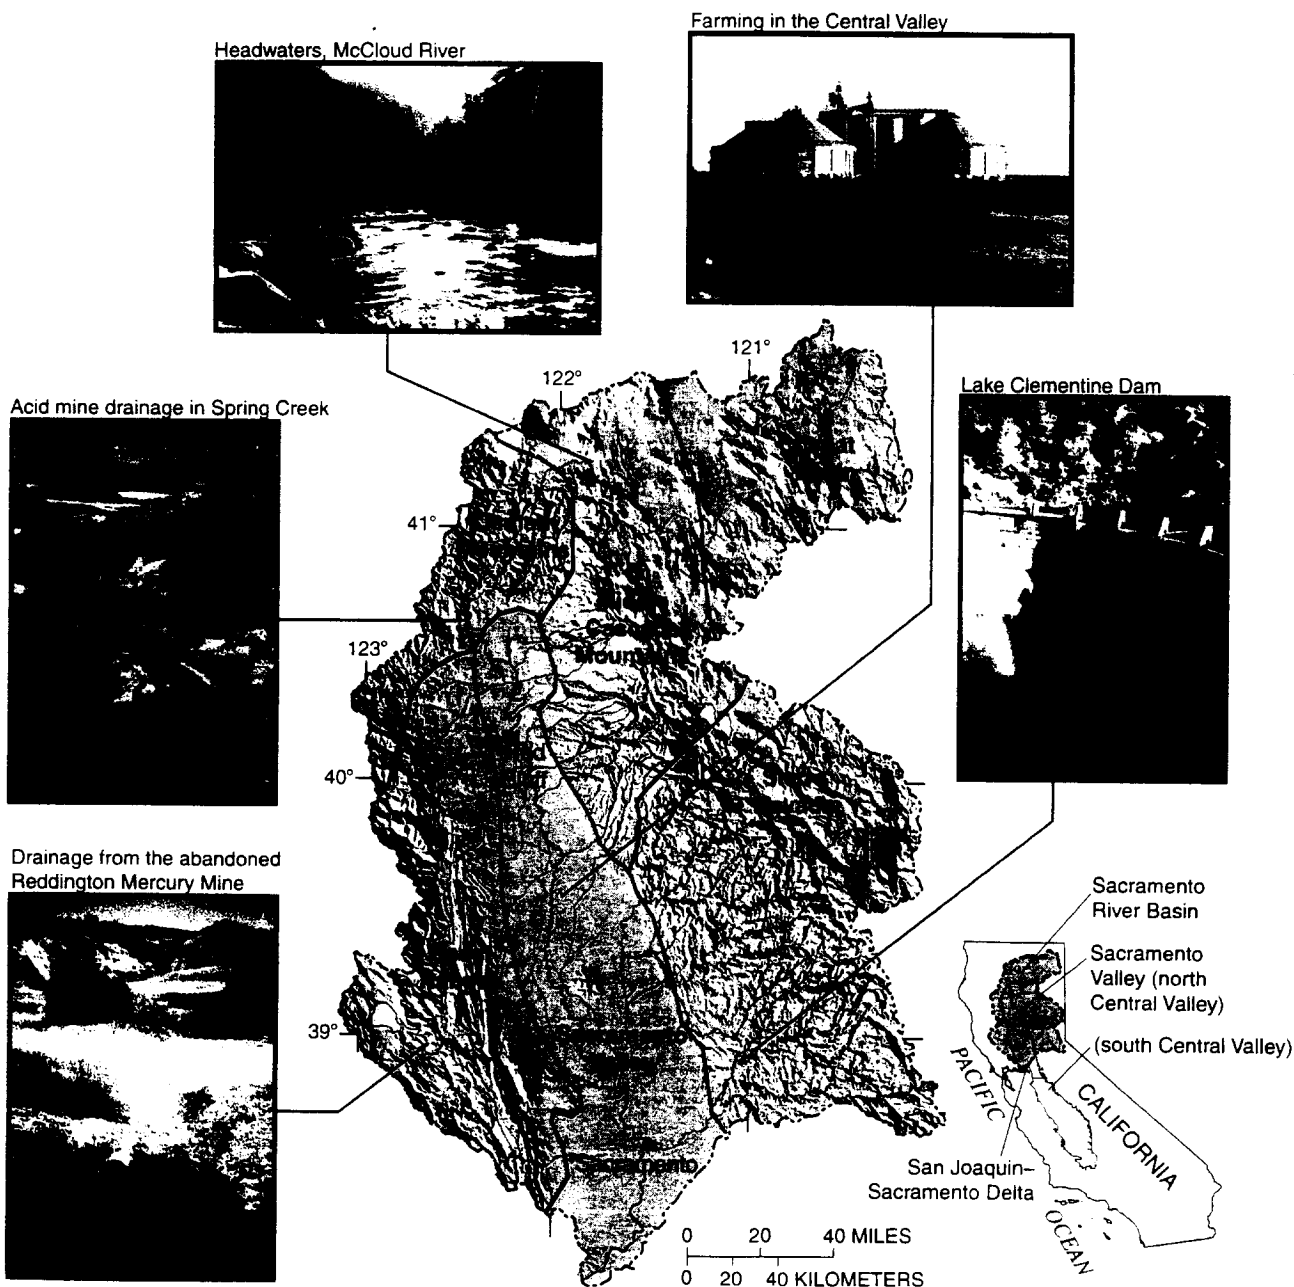

Figure 1. Physiographic provinces in the Sacramento River Basin. Physiographic provinces are regions defined principally by geologic and topographic features.

and rangeland are mixed in regions of the Coast Ranges and the Great Basin. Domagalski and others (1998) have provided more information on the physiographic provinces of the Sacramento River Basin.

The Sacramento Valley is the northern portion of the Central Valley of California and is fully contained in the Study Unit. The Sacramento Valley has the greatest population of any part of the basin, and it is there that the greatest effects or potential effects on surface and ground water are likely to occur from land-use activities. The Sacramento Valley is also the area of greatest water use in the basin.

Land-Use Effects on Water Quality and Stream Habitat

The Sacramento Valley supports a diverse agricultural economy, much of which depends on the availability of irrigation water. Water is collected in reservoirs at several locations within the mountains surrounding the Sacramento Valley and is released according to allocations for agricultural, urban, and environmental needs. The reservoirs also are managed for flood control. The reservoirs provide flood protection and allow the storage of water during dry years, but the placement of dams at the reservoirs has blocked migration routes for salmonid fish.

More than 8,000 km² of the Sacramento Valley are irrigated. The major crops are rice, fruits, nuts, tomatoes, sugar beets, corn, alfalfa, and wheat. Dairy products also are an important agricultural commodity. The land areas adjacent to the Sacramento Valley are mostly forested (fig. 1).

The largest cities of the basin are in the Sacramento Valley and include Chico, Red Bluff, Redding, and Sacramento. The Sacramento metropolitan area is home to more than 1 million people, which is nearly half of the total population (U.S. Department of Commerce, 1992) in the basin.

Previous mining for copper, lead, and zinc (fig. 2) in the Klamath Mountains has resulted in acid mine drainage (drainage of acidic waters from mines) into part of Keswick Reservoir, which is

located immediately downstream from Shasta Lake. The drainage includes both mined metals and nonmined metals such as cadmium. Mercury that was used in previous mining within the Coast Ranges (fig. 3) enters the Sacramento Valley through Cache and Putah creeks. Although neither creek flows directly into the Sacramento River during low-flow conditions, the load of mercury can be transported to downstream receiving waters, including the San Francisco Bay, during stormwater runoff

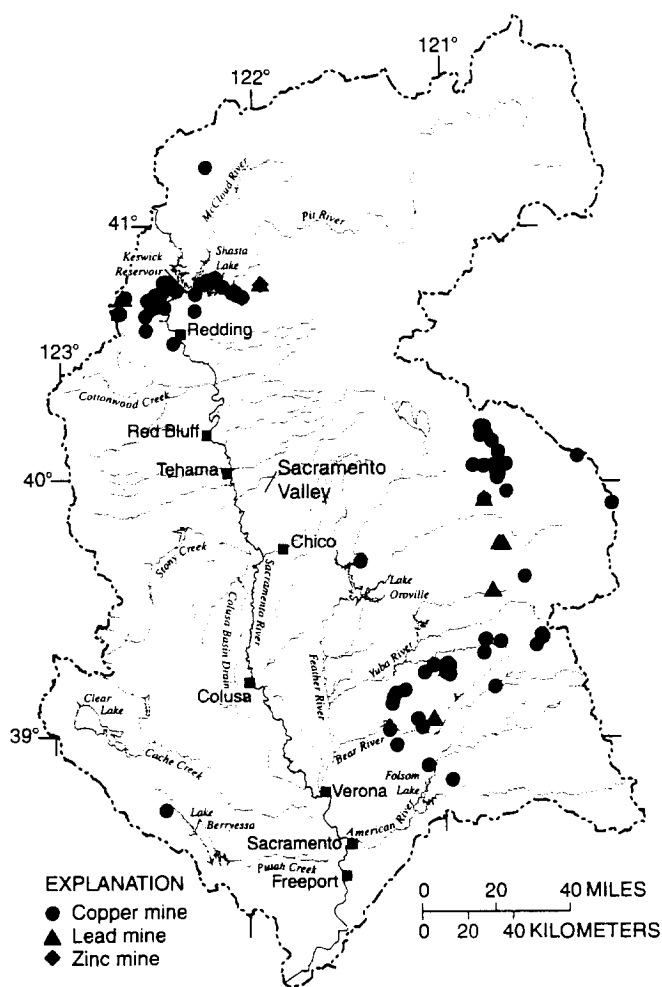

Figure 2. Locations of copper, lead, and zinc mines. The most severe case of drainage of acidic waters from mines has been in the region near Shasta Lake.

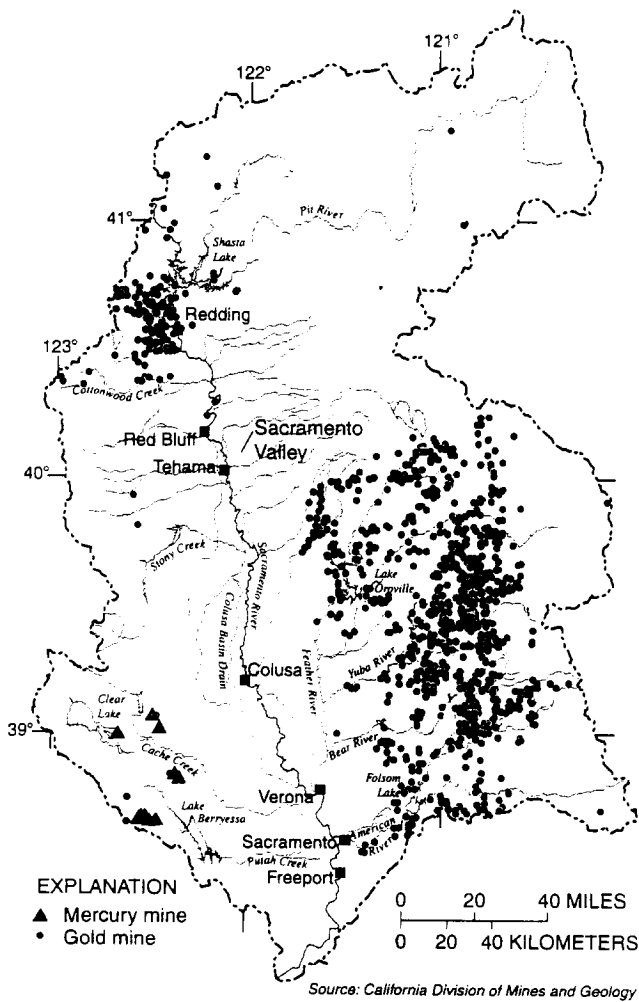

Figure 3. Locations of gold and mercury mines. The era of gold mining began in 1849 after the discovery of placer deposits in the American River.

conditions. Mercury also can enter the Sacramento River from the Sierra Nevada, where it was used in historical gold mining (fig. 3).

Water Use in California

Water storage, transportation, and allocation in California are strategically managed to take into account the wide diversity of the State's geography and physiography. Water is stored in nonpopulated areas of California and then transferred by natural stream channels or man-made canals to areas of demand. Reservoirs within the Sacramento River Basin have been constructed in the mountainous areas just adjacent to the valley. All major rivers of the Sacramento River Basin have one or more reservoirs, which were

constructed during the late 1940s to late 1960s mainly for flood control. Storage capacity of the reservoirs is managed to capture runoff from winter storms. However, stored water is not used solely in the Sacramento River Basin; it is transported to other locations in California and is a major source of supply for Los Angeles and other southern California communities.

Total water use in the Sacramento River Basin is about 18 billion cubic meters per year (m^3/yr). Allocations of water for agricultural, urban, and environmental uses are made according to the California water plan (California Department of Water Resources, 1998) but are modified on the basis of the yearly conditions of reservoir storage. For example, during drought years, total allocations are decreased. Pie charts in figure 4 show the percentage of allocations during average years of rainfall for 1995 and projected for 2020. Of those allocations, surface water provides 82 percent and ground water 18 percent of the total demand. During drought years, surface water drops to about 75 percent and ground water rises to about 25 percent of total demand.

Figure 4. Water allocations for average rainfall years for 1995 and projected for 2020.

Effects of Hydrologic Conditions on Study Results

The average annual precipitation for the entire Sacramento River Basin is 914 millimeters (mm), most of which falls as rain or snow during November through March. Because little or no rain falls during the summer growing season, irrigation is required for successful agriculture. Most of the water-quality samples for the Sacramento River Basin study were collected between the fall of 1995 and the spring of

1998, which covered a series of wet winters. Precipitation amounts in northern California are variable and dependent on the location of the Pacific jet stream. The average annual rainfall at the city of Sacramento is about 460 mm. Since the 1940s, however, as little as 140 mm and as much as 915-mm have been recorded in a year.

Two major hydrological events occurred during the period of this study. The first, a major flood, occurred during the winter of 1996–97. Flooding began on January 1, 1997, and affected a major part of the Sacramento River downstream from Shasta Lake as well as tributaries to the Sacramento River, especially the Feather and Yuba rivers. Some streams, such as the Yuba River, had the highest recorded stream-flow following the rainfall associated with the flood of January 1, 1997 (fig. 5). The

second major hydrological event was the El Niño episode of 1997–98. The term “El Niño” refers to an “ocean–atmosphere phenomenon” during which wind and ocean current in the equatorial Pacific result in warmer-than-normal water along the North and South American Pacific coasts. El Niño winters frequently bring higher-than-normal precipitation in northern California because of a southward shift of the storm tracks and jet stream over North America.

Study Design Focuses on Land Use

Chemical and biological samples were collected from rivers and streams within, or downstream from, forested, urban, agricultural, and mining areas to assess overall quality and effects of specific land-use practices. In most cases, river or stream sampling sites were located in the Sacramento

Valley—the region of both the highest water use and where many potential effects on water quality had occurred and are likely to occur. At some sites, water samples were collected monthly and during storms to assess the effects of storm runoff on contaminant transport. Other sites were sampled only monthly, usually during normal flows. Shallow ground water was sampled from three areas—the highly used part of the southeastern Sacramento Valley aquifer, downstream from rice fields, and downstream from the recently urbanized area of metropolitan Sacramento. Domestic wells (existing wells) were sampled for the southeastern Sacramento Valley aquifer study area, whereas monitoring wells (drilled for this study) were sampled for the rice and urban land-use study areas.

Figure 5. Yuba River hydrograph. The highest recorded discharge for the lower Yuba River occurred shortly after a large rainfall on January 1, 1997.

MAJOR FINDINGS

Surface Water

Water of the Sacramento River and its major tributaries is generally of good quality; the source is snow that melts and collects in upstream reservoirs and is released in response to water needs or flood control. The amount of dissolved solids in the Sacramento River and its major tributaries (Yuba, Feather, and American rivers) was low at all of the sampled locations (fig. 6). Higher median concentrations of dissolved solids occurred at agricultural sites such as the Sacramento Slough and Colusa Basin Drain, but those are diluted upon mixing with Sacramento River water (Domagalski and Dileanis, 2000). Nutrient concentrations such as nitrate also were low throughout the Sacramento River Basin (Domagalski and Dileanis, 2000) (fig. 7), and drinking-water standards for nitrate were not exceeded during the course of this study. At some locations, algae attached to streambed material was abundant, indicating that further investigation of nutrient dynamics and their consequences to the streams of

Figure 6. Concentrations of dissolved solids at the fixed sites. The highest concentrations were measured at the agricultural, mining, and urban sites. (EPA, Environmental Protection Agency)

Figure 7. Concentrations of nitrite plus nitrate at the fixed sites. The highest concentrations were measured at the mining and urban sites.

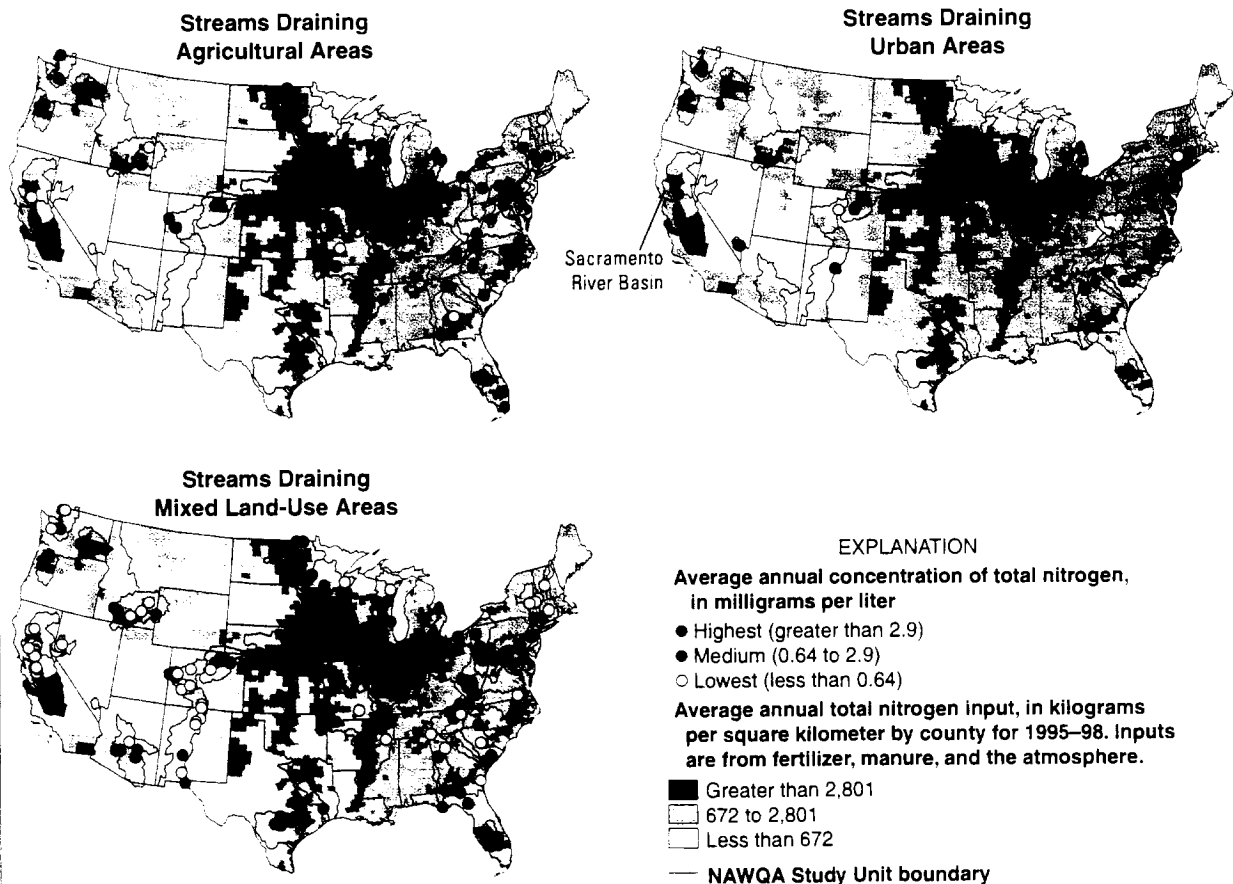

this watershed is warranted. Excess algal growth, which is usually related to higher-than-normal nutrient inputs to streams, is a water-quality concern when the algae affect the aquatic community (because of dissolved oxygen depletion). No such effects were observed in the Sacramento River or its major tributaries. Excess algae also can contribute to taste and odor problems in drinking water.

Some stream segments are listed as “impaired” by various contaminants (U.S. Environmental Protection Agency, accessed January 2, 2000). An impairment means that a standard of water quality for beneficial uses (for example, as a source of drinking water or for recreation or industrial use) is not being met. The impaired water bodies shown in figure 8 are mainly affected by nonpoint sources of contaminants from agriculture or from a combination of point and nonpoint sources from abandoned mines. Water-quality objectives are usually not met only during conditions of stormwater-driven runoff. The Clean Water Act requires States to maintain a listing of

NUTRIENTS IN A NATIONAL CONTEXT

Nutrient concentrations in the streams of mixed land-use and agricultural regions of the Sacramento River Basin tend to be lower relative to those measured in other areas of the United States with similar fertilizer applications within their watersheds. The maps show nitrogen; phosphorus concentrations have a very similar pattern. Elevated concentrations of nitrogen or phosphorus can stimulate nuisance growth of algae. The nutrient concentrations tend to be less than those of adjacent areas in California, agricultural areas of the Pacific Northwest, and large areas of the midcontinent region. In contrast to mixed land-use streams, nutrient concentrations of the urban stream are among the highest of similar urban streams throughout the United States. The lower concentrations in streams of mixed land-use probably can be attributed to dilution by streamflow. The Sacramento River and its major tributaries are derived from melting snow, which has low nutrient concentrations. These rivers tend to dilute the agricultural drainage, and therefore nutrient concentrations remain low in the major rivers. In addition, some instream processes remove nutrients, such as algal growth that incorporates nutrients in algae biomass. The urban stream, Arcade Creek, is entirely within an urbanized area, and all runoff to the stream is affected by that urban land use. The only inputs of water to Arcade Creek are from impacted land. The range in nutrient concentrations for all NAWQA Study Units is shown in the Appendix.

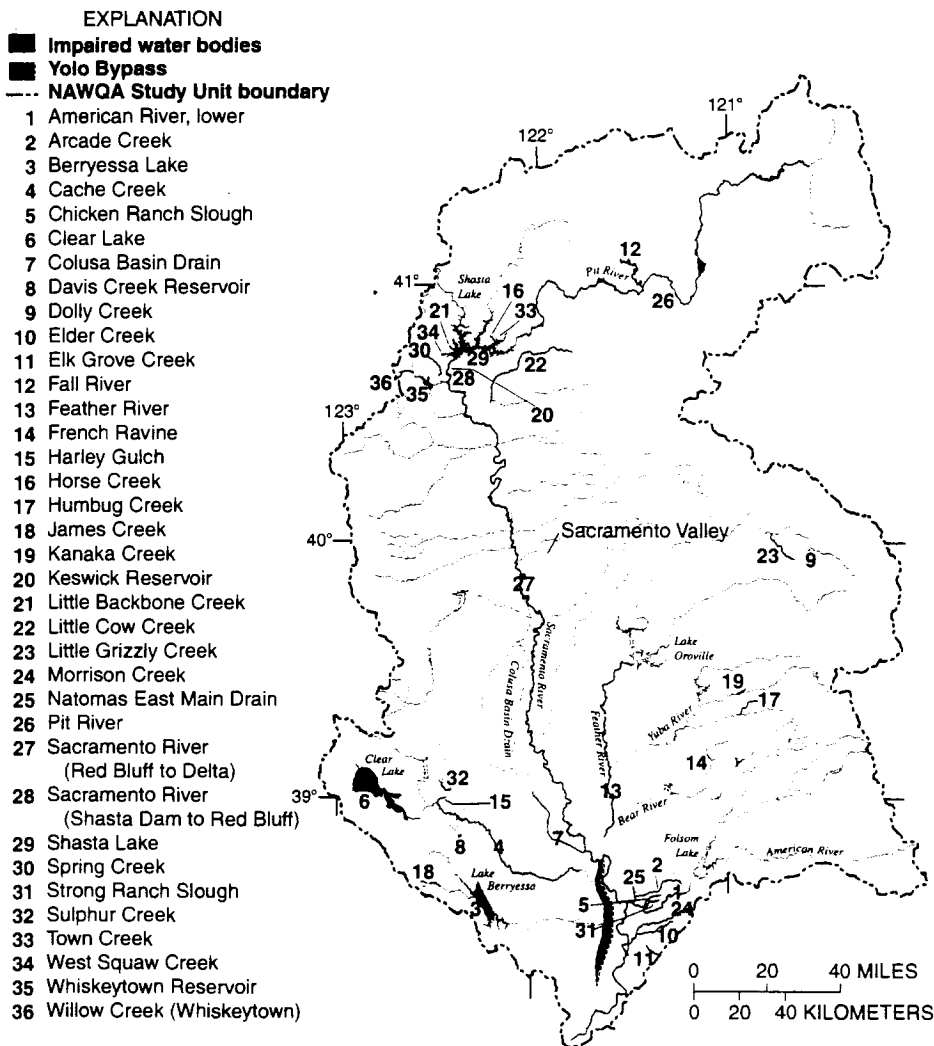

Figure 8. Impaired water bodies of the Sacramento River Basin according to the California 303(d) list (U.S. Environmental Protection Agency, accessed January 2, 2000). Impaired water bodies require the implementation of a management plan called a Total Maximum Daily Load (TMDL) to bring the water body into compliance with existing standards. Most of the impairments are the result of pesticides from agricultural or urban use, or from metals derived from historical mining operations.

impaired water bodies for the purpose of establishing a Total Maximum Daily Load (TMDL). A TMDL is a plan to restore the beneficial uses of the stream or to otherwise correct the impairment. The most prevalent listings in the Sacramento River Basin are for organophosphate pesticides and

mercury, for which TMDLs currently are being considered.

Pesticides in Surface Water

The concentrations of molinate and other pesticides (used in rice farming) measured during this study in the Colusa Basin Drain or in the

Sacramento River, represent a significant improvement over concentrations measured in previous years (Domagalski, 2000). The major pesticides that have been used on rice are molinate, thiobencarb, and carbofuran. Rice farming requires that fields be flooded with water throughout the growing season. Molinate and thiobencarb are applied to control aquatic grasses and weeds, whereas carbofuran is applied to control insects. During the late 1970s, the levels of rice pesticides in the Colusa Basin Drain were sometimes acutely toxic to fish such as carp (*Cyprinus carpio*) (Bennett and others, 1998). The toxicity was attributed to molinate.

In the early 1980s, consumers of drinking water in the city of Sacramento reported an objectionable taste, which was attributed to thiobencarb. A management program was enacted to reduce the levels of these pesticides in streams. The plan requires that rice-field water be retained on fields for 1 month following pesticide application to allow concentrations in water to be reduced through mechanisms such as volatilization, biological processes, or sunlight-induced degradation. Sampling of rice pesticides during this study showed that concentrations occasionally were in excess of management objectives in agricultural streams but always were very low in the Sacramento River (fig. 9). A target concentration

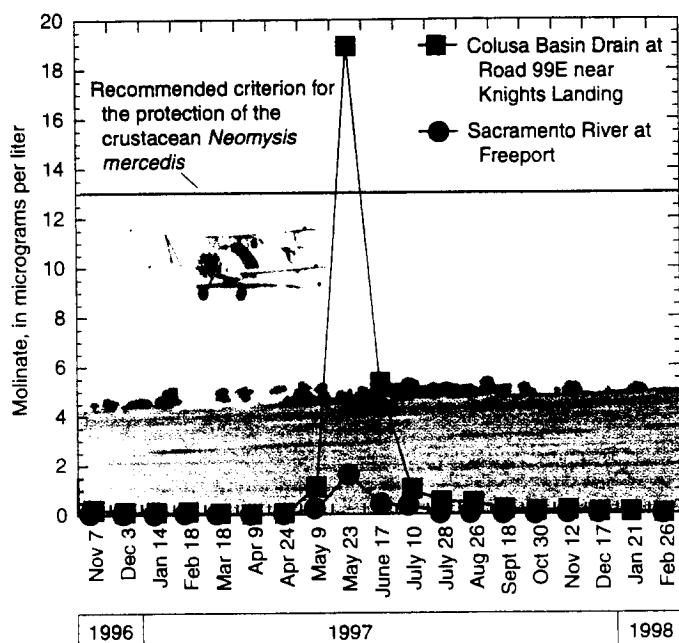

Figure 9. Concentrations of molinate at the Colusa Basin Drain at Road 99E near Knights Landing and Sacramento River at Freeport sites. The water in the Colusa Basin Drain is primarily agricultural drainage.

of 13 micrograms per liter ($\mu\text{g/L}$) of molinate in water was chosen for management of this herbicide. That level was chosen to protect the crustacean *Neomysis mercedis*, an important part of the food chain for young fish (Harrington, 1990). Concentrations in agricultural streams exceeded the target at least during 1 month of the year. Concentrations in the Sacramento River were always below those reported to be harmful to *N. mercedis* (Domagalski, 2000).

Pesticides also are transported to the Sacramento River, its tributaries, and agricultural drainage canals during winter storms (Kuivila and Foe, 1995; MacCoy and others, 1995; Domagalski, 1996). The pesticide that is considered a major problem for stormwater-driven transport is diazinon because of its toxicity to

aquatic organisms and its high detection frequency. Diazinon is toxic to some species of zooplankton, such as *Ceriodaphnia dubia*, at low concentrations ($0.35 \mu\text{g/L}$) (Amato and others, 1992). The zooplankton species *C. dubia*, is used in laboratory assays to test water for toxicity (U.S. Environmental Protection Agency, 1991a,b). Diazinon is applied to orchard crops, especially almonds, prunes, and stone fruits, during December and January to protect trees from insects that lay eggs in the trees during the winter and hatch the following spring. Toxic concentrations in tributaries to the Sacramento River can occur when agricultural areas contribute storm runoff; toxic concentrations rarely occur in the Sacramento River itself (MacCoy and others, 1995). Diazinon was present in

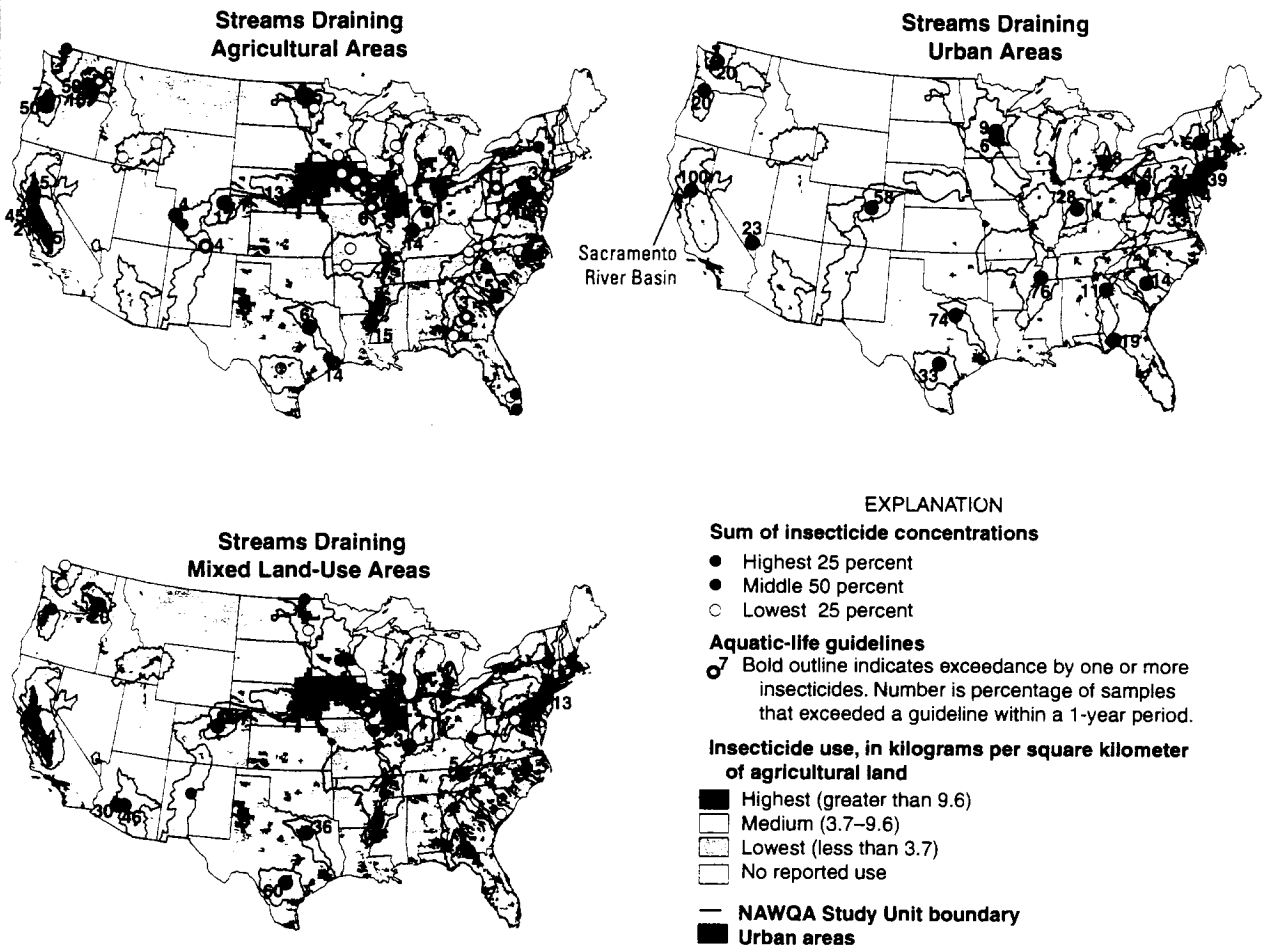

stormwater runoff at a number of sites in 1994 (Domagalski, 1996), and in nonstorm flows during 1996 through 1998. In the 1994 study, the Feather River was shown to be the greatest source of diazinon to the Sacramento River during a single storm, but other streams probably contributed to the diazinon load in the Sacramento River as well. This depended in part on the timing of diazinon applications and the location of greatest rainfall. The results of the routine samplings for diazinon during stable flow conditions at Arcade Creek near Del Paso Heights, Colusa Basin Drain at Road 99E near Knights Landing, and Sacramento River at Freeport are shown in figure 10. No stormwater runoff samples were collected. The highest concentrations during this NAWQA study occurred at Arcade Creek near Del Paso Heights, an urban site. Concentrations of diazinon in Arcade Creek that are toxic to *C. dubia* can occur in any season and result from household pesticide use and urban runoff. A standard for diazinon of $0.08 \mu\text{g/L}$ was proposed by the International Commission for the Great Lakes. As figure 10 shows, that standard was frequently exceeded at the Arcade Creek near Del Paso Heights site.

Pesticides of Historical Use

Pesticides that are no longer used, such as DDT, can still be detected in streambed sediments and the tissues of aquatic organisms because of their persistent chemical characteristics. Concentrations of pesticides such as DDT and its breakdown products tended to be low to nondetectable in the

ORGANOPHOSPHATE INSECTICIDES IN AGRICULTURAL AND URBAN STREAMS IN A NATIONAL CONTEXT

Organophosphate insecticides such as diazinon, chlorpyrifos, and malathion are toxic at low concentrations to some aquatic organisms. Some species of zooplankton are affected by diazinon concentrations as low as 0.35 µg/L. Diazinon levels at the urban stream, Arcade Creek, were elevated at various times of the year and exceeded recommended criteria for the protection of aquatic life for every measurement taken. Those levels were among the highest in the Nation. Most of the diazinon measured at the Arcade Creek site probably originated from household use throughout the watershed. Runoff from yards from either rainwater or irrigation water contributes to the loading of diazinon to stormwater drains that ultimately discharge into the creek. Diazinon enters agricultural drainage mainly in stormwater runoff because it is sprayed on orchards during the rainy winter season. Previous studies have shown that concentrations of diazinon in agricultural streams can be elevated less than a day after rainfall. Although diazinon concentrations of agricultural streams also were among the highest in the Nation, only one sample from those streams taken in this study exceeded recommended criteria. The range in diazinon concentrations for all NAWQA Study Units is shown in the Appendix.

Figure 10. Concentrations of diazinon at the Colusa Basin Drain at Road 99E near Knights Landing, Arcade Creek near Del Paso Heights, and Sacramento River at Freeport sites. The highest concentrations were in the urban stream, Arcade Creek.

streambed sediments of the Sacramento River (MacCoy and Domagalski, 1999). Concentrations were higher in the streambed sediment of agricultural and urban streams. At some agricultural sites, and the urban site on Arcade Creek, the concentrations of DDT or its breakdown products in streambed sediment exceeded the Canadian sediment quality guidelines. The Canadian guidelines are designed to limit the accumulation of specific contaminants in organisms to levels below those that may adversely affect aquatic life (Canadian Council of Ministers of the Environment, 1995).

Concentrations of DDT or its breakdown products such as *p,p'*-DDE, or other organochlorine

insecticide residues, were very low in the tissues of aquatic organisms collected in the Sacramento River and its large tributaries (fig. 11). Concentrations of *p,p'*-DDE in the tissues of aquatic organisms collected from agricultural drainage sites were higher (fig. 11). The levels found in tissues of aquatic organisms from the agricultural drainage sites probably do not pose a health risk for humans but are above criteria developed by the New York State Department of Environmental Conservation (Newell and others, 1987) for protection of fish-eating wildlife such as birds. No national criteria exist to protect fish-eating wildlife from organochlorine compounds

such as DDT or its breakdown products; New York's are the only criteria available for comparison. The levels of *p,p'*-DDE found in the tissue of aquatic organisms tended to be relatively high when compared with other NAWQA Study Units. The range in concentrations for DDT and its breakdown products for all NAWQA Study Units is shown in the Appendix.

Metals in Water and Streambed Sediment

Acid mine drainage has been a serious environmental problem in the northern portion of the Sacramento River Basin (Alpers and others, 2000a,b). Several streams are listed as impaired (fig. 8) because of high concentrations of metals such as cadmium, copper, lead, and zinc. Metals concentrations in previous years have been toxic to fish in the upper Sacramento River near and downstream from Redding (Alpers and others, 2000a,b). Recent mitigation efforts at one of the more contaminated sites in the Spring Creek drainage near Shasta Lake have significantly lowered concentrations of metals in the Sacramento River, and no toxic effects to fish were observed during the course of this investigation (Alpers and others, 2000a,b). However, elevated levels of metals such as copper in streambed sediment can still be measured in the upper Sacramento River Basin downstream from Redding (MacCoy and Domagalski, 1999). Copper and other metals may still affect aquatic organisms.

Figure 11. Concentrations of *p,p'*-DDE (a DDT breakdown product) in biota from the Sacramento River Basin. The use of DDT in the United States was terminated in 1972.

Trace Metals in Aquatic Organisms

For the NAWQA Program, looking for trace metals includes sampling streambed sediment and tissues of aquatic organisms. In theory, the transfer of metals from the streambed sediment into aquatic organisms can be understood by knowing the concentrations and geochemical forms of the trace metals in both the sediment and biota, as long as the feeding behaviors of the organisms are also understood. A predictive model of metals in tissue that is based on the amounts in streambed sediment could be developed from these studies. In practice, this becomes difficult because the actual bioavailability of metals in sediment can vary from site to site. For

example, the concentrations measured in aquatic organisms may not be fully assimilated into the cellular material of the organism but rather may be present as undigested material or even attached to external body parts. Because metals contamination from acid mine drainage is an important water-quality issue for the upper Sacramento River Basin, and knowledge of the actual bioavailability of metals in the mine drainage is essential for current and future management of the mine waste, a collaborative study was completed by the Sacramento River Basin NAWQA Program and the National Research Program of the USGS (Cain and others, 2000). In that study, biologists examined streambed sediment and the cytosol from the caddisfly, an aquatic insect widely distributed

in the upper Sacramento River and part of the food chain for a variety of fishes, including salmonid species. Cytosol is cellular material that can be isolated from aquatic insects. Biologists analyzed both whole body samples and cytosol samples for metals. Metal concentrations in cytosol provide a good indication of the potential effects on aquatic organisms from acid mine drainage. Aquatic insects also were sampled in a nearby reference stream that was unaffected by acid mine drainage. Elevated levels of cadmium, copper, lead, and zinc, derived from acid mine drainage, could clearly be distinguished in the cytosol samples, and it was shown that metals from the acid mine drainage were transported at least 120 kilometers downstream from the mine sources.

Figure 12. Mercury pathways in aquatic systems.

Mercury in Water and Streambed Sediment

Mercury is currently considered the most serious water-quality problem in the Sacramento River, some tributaries of the Sacramento River, and downstream locations including the San Francisco Bay (Domagalski, 1998). Mercury can enter streams or aquatic systems through either atmospheric deposition or transport from geological or man-made sources (fig. 12). Several processes contribute to the subsequent bioaccumulation of mercury in fish tissue. Because of the presence of mercury in the tissue of certain fish species, advisories have been posted for several

water bodies, and more advisories are planned, both within the Sacramento River Basin and in the San Francisco Bay. Specific advisories for fish species and locations are listed on the California Office of Environmental Health Hazards Assessment Web site at <http://www.oehha.org/fish.html>. A recent study (Davis and others, 2000) documented mercury levels of concern to human health in sport fish collected in the lower Sacramento and Feather rivers.

Although atmospheric mercury is the principal cause of mercury contamination of water bodies in other parts of the United States, especially the midwestern and eastern United States, the cause is

different in California. Geologic and anthropogenic sources, especially from historical mining for both mercury and gold, are the main reasons for mercury problems in the Sacramento River Basin (Domagalski, 1998). Mercury was mined in the Coast Ranges near Clear Lake and at locations east and south of Clear Lake (fig. 3), and it was used in the recovery of gold from ore and stream deposits during the late 19th century (fig. 3).

Decades of gold mining in the Sierra Nevada have resulted in the deposition of mercury in the streambed sediments of the gold mining region. The release of mercury from ore to streambed sediments in the mercury mining regions of the Coast Ranges also

Figure 13. Concentrations of mercury in streambed sediment at select locations of the Sacramento River Basin.

has occurred (Hunerlach and others, 1999). The construction of reservoirs in the lower Sierra Nevada between 1948 and 1968 has had the positive effect of reducing the amount of mercury transported downstream (Slotton and others, 1997). Reservoirs trap mercury because suspended sediment, the principal means by which it is transported, tends to settle to the bottom. This trapping of mercury will have future implications on the management of these reservoirs, including potential dam removal. Some dams are being considered for removal in order to restore habitat for fish. Residual mercury from mining operations is present in the streambed sediments

downstream from the Sierra Nevada reservoirs, as indicated by the NAWQA Program for the Sacramento River Basin. Concentrations of mercury in the streambed sediments of 24 sites sampled during the NAWQA Program are shown in figure 13. The highest concentrations of mercury in streambed sediment were measured in samples collected from sites downstream from the Sierra Nevada and the Coast Ranges. Sites on the Sacramento River downstream from the Feather River tended to have higher mercury concentrations relative to sites sampled upstream from the confluence of these two rivers because of historical gold mining.

The U.S. Environmental Protection Agency (EPA) has recommended water-quality criteria for mercury to protect aquatic life and human health. A recommended criterion of 12 nanograms per liter (ng/L) of total mercury in water was proposed by the EPA in 1985 (Marshack, 1995). That criterion is supposed to limit the amount of mercury accumulation in fish tissue and thereby protect human health. The 12-ng/L criterion was exceeded mainly during runoff conditions at all fixed sites during the timeframe of this investigation. In 1999, the recommended level was revised to 50 ng/L (U.S. Environmental Protection Agency,

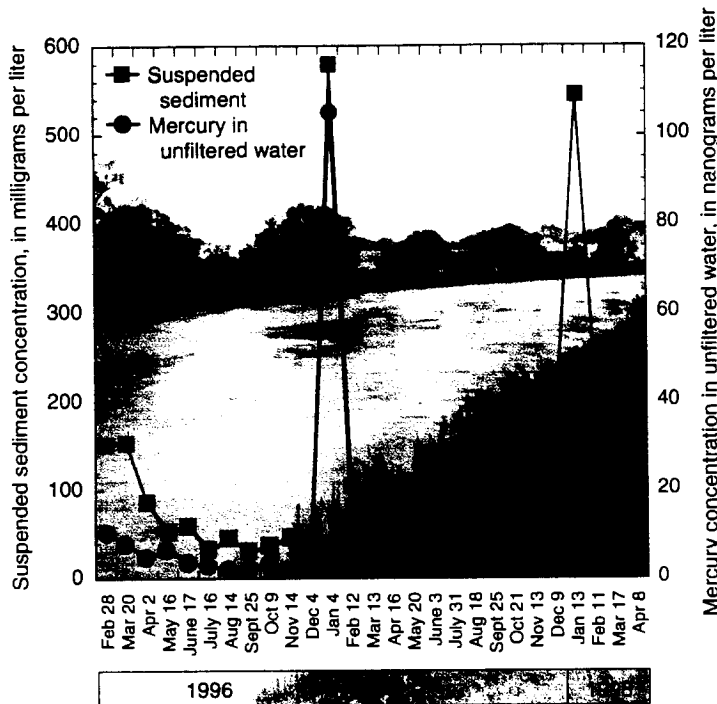

Figure 14. Mercury and suspended sediment concentrations for the Sacramento River at Colusa site. Mercury concentrations increase with sediment concentrations because mercury is attached to sediment particles.

1999). The 50-ng/L level was exceeded only at Cache Creek at Rumsey, Sacramento River at Colusa, and the Yolo Bypass at Interstate 80. Continued monitoring of mercury levels in fish tissue will be required to determine if the 50-ng/L criteria is effective. Time series plots of mercury and suspended sediment for the Sacramento River at Colusa are shown in figure 14. The higher concentrations of mercury correlate well with suspended sediment because much of the load of total mercury is transported with the suspended material (Alpers and others, 2000b).

Methylmercury is the most bioaccumulative form of mercury in the environment because it builds up in organisms more readily than other forms of mercury. It is a toxic form of mercury that can bioaccumulate in

the tissues of aquatic organisms and cause human health problems if fish with high levels are consumed. Methylmercury usually is formed by bacterially mediated reactions in sediments. Concentrations in water were measured at selected sites on the Sacramento River and at sites receiving agricultural drainage to assess the effects of agricultural activities on the production or the levels of methylmercury.

Concentrations of methylmercury in unfiltered water are shown in figure 15. The highest median concentration was 0.19 ng/L, which represents the samples collected at the Colusa Basin Drain at Road 99E near Knights Landing site. There is no water-quality standard in California or in any other State that is based on methylmercury concentrations in water. However,

a concentration at or below 0.1 ng/L of methylmercury has been suggested as being representative of pristine water (Rudd, 1995). That concentration is typical of rivers upstream from wetland environments and away from mercury sources (Rudd, 1995). The median methylmercury concentrations for the Sacramento River sites were slightly above 0.1 ng/L and maximum concentrations approach 2 ng/L. It is not known how or if those levels of methylmercury in water contribute to elevated levels of mercury in fish tissue.

There was a seasonal component to methylmercury concentrations for the sites at which they were measured for this study. The lowest concentrations were measured during middle to late summer (fig. 16). Higher concentrations tended to be measured during the autumn to winter months. The magnitude of the concentrations may also have been related to precipitation and runoff conditions. The highest concentrations for the period of this study were measured during January and February of 1997 and were attributed to the January 1997 flood. During the subsequent El Niño winter of 1997–98, higher-than-normal amounts of rain were recorded for much of the Sacramento River Basin, although there was no single storm of the magnitude of the January 1997 flood. Methylmercury concentrations increased during the El Niño winter, but not to the extent of the flood of the previous year. The effect of these methylmercury concentrations on downstream water bodies, such as the San Francisco Bay, has not been determined.

Figure 15. Concentrations of methylmercury at select locations in the Sacramento River Basin. Methylmercury is the form of mercury most likely to accumulate in aquatic species such as fish.

Ambient Toxicity Monitoring by California State Agencies

Ambient toxicity testing uses laboratory bioassays to assess the effect of contaminants on aquatic life. Essentially, the tests answer the question: Can specific types of fish, invertebrates, and algae species continue to live, grow, and reproduce in water samples collected from water bodies? The EPA protocols (U.S. Environmental Protection Agency, 1991a,b) for conducting chronic toxicity tests on freshwater species include representatives from three phyla and trophic levels. The three species are the fathead minnow, a small planktonic crustacean (*C. dubia*), and a planktonic green alga (*Selenastrum capricornutum*). These three species have been used to evaluate ambient water quality in the Sacramento River Basin since

1986. California regulatory agencies rely on the tests for evaluating compliance with narrative toxicity objectives, which state that “all waters shall be maintained free of toxic substances in concentrations that produce detrimental physiological responses in aquatic life” (Marshack, 1995). Testing has changed from conducting broad watershed surveys that determine the spatial and temporal distribution of toxicity to conducting detailed follow-up studies that couple toxicity testing with a Toxicity Identification Evaluation (TIE) to identify specific chemicals and land uses responsible for toxicity. Water-quality data from the NAWQA Program are useful in determining the exposure of aquatic organisms to specific groups of contaminants such as organophosphate pesticides. Results from 13 years of monitoring suggest that the EPA toxicity tests are powerful tools for assessing water quality.

The toxicity testing program in the Sacramento River watershed was the first indicator of the potential water-quality problems currently associated with pesticide runoff from urban areas and orchards. Using *C. dubia* tests, pulses of toxicity have been detected over a 10-year period throughout the Sacramento Valley in waters that receive drainage from orchards (de Vlaming and others, 2000). The toxicity has been linked to diazinon applied to dormant orchards and chlorpyrifos applied to nondormant orchards. *C. dubia* also was effective in identifying toxicity attributed to drainage from rice fields. Rice-field drainage also was toxic to two important local species, larval striped bass and an invertebrate, *N. mercedis*. The invertebrate toxicity was caused by methyl parathion and carbofuran. As mentioned previously, a rice management program has eliminated the toxicity to all three species. *C. dubia* toxicity is detected throughout the year in waters that receive drainage from urban areas (fig. 10). This toxicity is attributed to diazinon and chlorpyrifos. Although most toxicity has been detected with *C. dubia* and linked to insecticides, other examples of ambient water toxicity have been identified. In areas of the Sacramento Valley that receive acid mine drainage, toxicity to *S. capricornutum* and *C. dubia* has been linked to copper and zinc. Mine remediation projects have reduced both metal concentrations and toxicity. Concentrations of copper and zinc measured in this NAWQA Program confirm that metal concentrations are below toxic levels (Alpers and others, 2000b). *S. capricornutum* toxicity has been documented in

Figure 16. Seasonal changes of methylmercury concentrations. The highest concentrations were measured during high streamflow and following rainfall.

waters that receive agricultural or urban runoff. Some of the toxicity can be attributed to the herbicide diuron, also detected in samples collected by the NAWQA Program; however, additional unidentified toxicants are present. Fathead minnow toxicity has been traced to ammonia originating from dairies and wastewater treatment plants. Taken together, the results of the last decade reveal that all three testing procedures, in association with TIEs and chemical analyses, have been effective for the identification of an array of toxicants originating from various sources. In several cases, alternative land-use practices or management strategies have improved water quality, as demonstrated by toxicity test monitoring. Because resources are not available for monitoring the complete array of potential contaminants, toxicity testing is a useful tool for focusing on chemicals present in a water body at toxic levels.

NAWQA Participation with Local Water-Quality Programs

All NAWQA Study Units maintain communication and program coordination with a liaison committee of outside parties interested in water quality within the respective basins. During the early part of this NAWQA study, two significant programs were taking shape that involved new approaches to understanding and promoting the better management of water quality in the Sacramento River Basin.

In 1994, Congress recognized the need to develop a coordinated, technically sound, adequately funded program that would focus on establishing toxic pollutant standards for the Sacramento River Basin. Congress then appropriated funds for the Sacramento River Toxic Pollutant Control Program (SRTPCP) and has continued to support the program.

The long-term objective of the SRTPCP is to develop and

implement a program that will bring the Sacramento River and its tributaries into compliance with water-quality standards for toxic pollutants and thereby protect beneficial uses. A second objective of the SRTPCP is to help form a viable organization of watershed stakeholders. The stakeholder organization is intended to address not only the related toxic-pollutant issues of the watershed, but also the broader water-quality and watershed issues that must be resolved to protect and enhance surface and ground water throughout the basin.

The broader program to be conducted by this stakeholder organization has been named the Sacramento River Watershed Program (SRWP). The SRWP, although initiated with funding provided under the SRTPCP, is much broader in scope than the SRTPCP. The SRWP is intended to provide a forum to address a broad array of water-quality-related issues within the watershed, not just issues on toxic pollutants. Other issues that may be addressed under the broader watershed program include, but are not limited to, conventional water quality (including sediment, temperature, and dissolved solids), habitat, endangered species, streamflow, and ground-water issues.

The NAWQA Program participates in various committees of the SRWP, including the monitoring committee, to share data. Data from the NAWQA Program are shared with the SRWP and are used to help interpret the current water-quality conditions and to help guide the continued management of the water resources of the Sacramento River Basin.

Aquatic Biology

Changes in land use in the Sacramento River Basin have had major effects on the streams in the basin and on the aquatic communities dependent on them. Riparian forests and wetlands have been removed or degraded. Water development activities, particularly construction of dams and reservoirs, have altered natural flow and water temperature. The seasonal nature of higher temperatures along a stretch of the Sacramento River downstream from Shasta Lake is shown in figure 17. Water diversions for irrigation result in less water in the Sacramento River and rapidly increasing temperatures that are potentially harmful to certain fish in the spring and summer, especially downstream from the site on the Sacramento River above Bend Bridge near Red Bluff.

Collectively, these changes in streams have resulted in corresponding changes in native ecological communities, including species extirpation and population declines in remaining native species (Moyle and Nichols, 1974; Brown and Moyle, 1993; Brown, 2000). These declines have resulted in the listing of a number of animal and plant species as threatened or endangered under State or Federal law.

Native fish species are still common in Sacramento River Basin streams

Thirty-five species of fish were collected, including 12 species native to California. Statistical techniques were used to categorize sites on the basis of similar fish groupings. Four species of fish were collected at mountain

streams—rainbow trout, brown trout, riffle sculpin, and chinook salmon. These species are generally associated with cold, clear water and are considered intolerant of other environmental conditions such as warm water. Only brown trout is an introduced species. Rainbow trout were collected at all sites and were the most abundant species, representing 74 percent of the fish collected.

Fish were also sampled at sites below the mountains but above the valley floor. Those sites are referred to as the foothill sites. Twenty-one species of fish, including 13 native species, were collected at the nine sites in the foothill group. None of the introduced species was abundant, and no introduced species represented more than 3 percent of the fish collected. Native minnows, hardhead, Sacramento pikeminnow, speckled dace, California roach, and Sacramento sucker dominated sites in this group.

Twenty-four species of fish, including nine native species, were collected at the three large river sites, which are located at low elevations on the larger rivers. Native species tended to be more abundant. The most abundant native species were Sacramento pikeminnow, Sacramento sucker, tule perch, and prickly sculpin. No introduced species exceeded 7 percent of the catch.

Agricultural land sites within the Sacramento Valley were dominated by introduced species and included sites on natural and artificial waterways that were heavily influenced by agricultural land uses or water management activities. Twenty species were collected at these sites, including only three native species.

Figure 17. Temperature of the Sacramento River at select locations. Seasonal increases are caused by diversion of river water for irrigation.

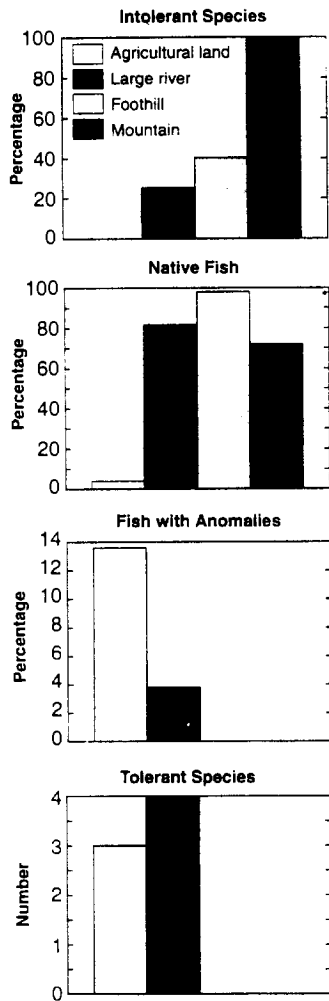

Figure 18. Characteristics of fish from ecological studies.

The group of fish at the agricultural land sites had the lowest percentage of native fish, the lowest percentage of intolerant fish, and the highest percentage of fish with external anomalies (fig. 18), indicating degraded environmental conditions. Intolerant fish are defined as those that are not adaptable to human alterations to the environment and thus decline in numbers when these alterations occur. The agricultural land site group also had a low number of native species

compared with the large river and foothill site groups. In summary, the fish site data indicate that the agricultural land site group had the most degraded environmental conditions, the foothill and mountain site groups had the best conditions, and the large river site group had somewhat intermediate conditions.

Previous studies of fish community structure in California have established correlations between the increasing numbers of introduced fish species in Central Valley streams and the disturbances caused by human activities (Moyle and Nichols, 1974; Brown and Moyle, 1993; Brown, 2000). Environmental disturbances associated with human activities include changes in water quality, streamflow, and habitat. Changes in streamflow, in particular changes in quantity and timing, have been identified as very important determinants of the structure of California fish communities (Baltz and Moyle, 1993; Moyle and Light, 1996a,b; Brown, 2000).

Differences in water quantity and water management have subsequent effects on water quality and habitat. Although these observations do not provide definitive support for the primary importance of streamflow in maintaining populations of native fish species, such relations and their effects on native fishes warrant consideration whenever changes in water management are being considered. Assessments of resident fish communities may be useful in determining the effectiveness of such changes in restoring natural ecological functions.

Streams without large reservoirs supported higher abundance of aquatic insects than streams with large reservoirs

Aquatic insect communities were compared at 23 locations including sites on two streams, Big Chico and Deer creeks, which have no major dams. Most streams sampled as part of this NAWQA Program have at least one major water project that affects a portion of the natural channels. Big Chico and Deer creeks are, therefore, unique in this study in that their flows are largely unregulated. Statistical analyses of the aquatic insect communities show that some sites on Deer and Big Chico creeks have more species and greater abundances of benthic macroinvertebrates compared with sites downstream from dams on the other streams sampled. Further research is needed to verify and evaluate these relations.

Populations of anadromous salmonids, including steelhead, rainbow trout, and chinook salmon, have declined throughout the Central Valley, resulting in protection of the remaining populations under Federal and State endangered species legislation (Yoshiyama and others, 1998). The reasons for the declines are complex and interactive; however, the construction of dams and reservoirs on California streams and rivers is widely recognized as one of the important factors (Yoshiyama and others, 1998). Dams and reservoirs block established migration routes, causing fish to reproduce in less desirable habitats. Another ecological effect from dams and reservoirs can be

AQUATIC BIOLOGY IN A NATIONAL CONTEXT

Biological indicators of water and habitat quality for 6 sites in the Sacramento River Basin were compared with similar data from 140 sites from NAWQA Study Units throughout the Nation. Because the rankings have not been calibrated for Sacramento River Basin streams, they should not be interpreted as designating “good” and “bad” water quality in streams. The sites simply score higher or lower in relation to other NAWQA sites, which represent a wide range of environmental settings.

The Yuba River site ranked among the least degraded sites nationally for all three indicators. The consistently low scores for this site can be attributed to abundant native fishes and the presence of healthy invertebrate and algal communities associated with cool water and abundant riffle habitats. The Arcade Creek and Colusa Basin Drain sites ranked among the most degraded sites nationally for all three indicators. This score may have to do more with the harsh nature of the physical environment than with water quality. Flow at these sites fluctuates widely because of storm runoff and variation in urban runoff. Biological communities in such streams tend to have few species, resulting in low indicator scores. Local determination of habitat and water quality is better accomplished using locally derived data, as has been demonstrated for Central Valley fish (Brown, 2000; May and Brown, 2000) and invertebrate communities (Brown and May, 2000a,b).

Comparisons of biological indicators of water quality from Sacramento River Basin sites with other sites with biological data from the NAWQA Program¹

Site Name	National Land Use Category ¹	Fish Status	Invertebrate Status	Algal Status
Colusa Basin Drain at Road 99E near Knights Landing	Agriculture	■	■	■
Sacramento River at Colusa	Mixed	■	■	■
Yuba River near Marysville	Mixed	■	■	■
Feather River near Nicolaus	Mixed	■	■	■
American River at Sacramento	Mixed	■	■	■
Arcade Creek near Del Paso Heights	Urban	■	■	■

¹Represents 140 sites from NAWQA Study Units throughout the United States with algal, invertebrate (primarily insects, worms, crayfish, clams), and fish data. “Mixed” indicates a combination of agricultural, urban, and other use.

- Highest 25 percent nationally (comparatively more degraded)
- Middle 50 percent nationally
- Lowest 25 percent nationally (comparatively less degraded)

changes in downstream populations of aquatic insects. This is potentially important to anadromous and resident fish populations because aquatic insects are a critical food source for nearly all species of fish at some life stage.

The implication of this study is that construction of dams and reservoirs in the foothills has either submerged the productive habitat in Central Valley streams or altered them indirectly through downstream effects on ecological conditions. The importance of other downstream effects, such as disruption of sediment transport, has been recognized for anadromous salmonids. As a result of this recognition, a variety of projects are underway or are being proposed to improve conditions for anadromous fishes and to restore ecological processes in general.

Ground Water

Ground-water quality was investigated in the portion of the aquifer of the southeastern Sacramento Valley used for domestic purposes or irrigation and in the shallow portion of the aquifer below the valley's two major land uses—rice cultivation and land that had been urbanized from 5 to 25 years ago. The southeastern Sacramento Valley was chosen for investigation because it is in that region that domestic and irrigation usage of ground water is highest. Although ground water is used in other parts of the valley, its usage is not as great as in the southeastern Sacramento Valley.

The ground-water quality of some areas of the Sacramento Valley, such as the southwestern portion, is not entirely suitable for human or agricultural use because of the presence of elevated

concentrations of boron, fluoride, chloride, nitrate, and sulfate (Hull, 1984; Davisson and Criss, 1993). The study conducted in the southeastern Sacramento Valley aquifer was designed to address the suitability of a portion of the aquifer. Specifically, only existing domestic wells were sampled.

Out of 31 wells sampled, only one sample exceeded the drinking water standard for nitrate. The median concentration of nitrate was 1.3 mg/L. Previous NAWQA investigations have found a median nitrate concentration of 0.48 mg/L in major aquifers throughout the United States (Nolan and Stoner, 2000). Therefore, the wells sampled in this study have nitrate values above the national median.

One or more pesticides were detected in 9 of 31, or 29 percent, of the wells of the southeastern Sacramento Valley (fig. 19). Simazine was detected in three wells, but the concentrations were very low and were not close to any drinking-water standard. Bentazon was one of the more frequently detected pesticides. Bentazon is a

herbicide that was used on rice, but its use was suspended in 1989 pending a review; then, in 1992, it was formally banned by the California Department of Pesticide Regulation (Miller-Maes and others, 1993). All bentazon concentrations were below drinking-water standards.

Volatile organic chemicals (VOCs) are not causing any apparent water-quality problems in the shallow aquifer of the southeastern Sacramento Valley. In one of the wells sampled, which is down-gradient from a known point source, eight different VOCs were detected. One of those VOCs (trichloroethene, measured at 5.5 µg/L) exceeded current drinking-water standards (primary MCL is 5 µg/L).

The effects of rice cultivation—one of the most prevalent agricultural practices in the Sacramento Valley—on ground water were examined by drilling and sampling 28 new wells (fig. 20). The wells were drilled to completion near the water table so that the agricultural effects on the most

Figure 19. Percentage of wells having one or more detected pesticides for the three ground-water studies.

recent water that entered the ground could be assessed. Rice cultivation requires that fields be flooded for the duration of the growing season, which lasts from May through September.

Pesticides were more frequently detected in the wells of the rice land-use study area compared with other regions outside the rice study area. One or more pesticides were detected in 25 of 28 (89 percent) of the wells sampled (fig. 19). The most frequently detected pesticide of the rice study was bentazon, a herbicide used in rice fields until suspension in 1989 and a formal ban in 1992. Although no observed concentrations exceeded drinking-water standards, the high detection frequency, almost 10 years since the last known use, suggests that bentazon is easily transported to ground water and does not readily degrade in ground water. Molinate,

another herbicide used on rice, was detected in 7 out of 28 wells. Thiobencarb, also a herbicide, was found in three wells; carbofuran, an insecticide used on rice, was detected in four. Herbicides and insecticides are applied to rice at the same time, shortly after planting in May. The most heavily used pesticides on rice are molinate, thiobencarb, and carbofuran. Therefore, it is not surprising to see these compounds in the ground water under the rice land-use region. None of the pesticide concentrations that were measured exceeded any known water-quality standard.

Nutrient concentrations tended to be low in the ground water under the rice fields. The median nitrate concentration was 2 mg/L, and no concentrations exceeded a drinking-water standard. The median nitrate concentration

measured in previous NAWQA investigations in agricultural land use settings was 3.4 mg/L (Nolan and Stoner, 2000).

Dissolved solids were elevated in rice fields relative to the other ground water sampled in this study. The elevated concentrations are most likely related to evaporation of irrigation water, which leaves behind salt. The effects of these increases in dissolved solids on deeper portions of the aquifer are unknown.

The effects of recent urbanization on the quality of shallow ground water were investigated as part of this NAWQA study (fig. 21). The chosen metropolitan area was that of the city and surrounding counties of Sacramento. The part of the metropolitan area developed between 5 and 25 years ago was chosen for the investigation because it was assumed that the water quality of older urban land might have degraded water quality because it was developed prior to the passage of the Clean Water Act and the period of more recent environmental awareness.

Trichloromethane was the most frequently detected volatile organic chemical (16 of 19 wells). The concentrations were always very low and did not exceed any drinking-water standards. The presence of trichloromethane can be attributed to lawn irrigation using water treated by chlorination. One or more pesticides were detected in 6 of 19 (32 percent) of the wells sampled in the urban land-use study (fig. 19). Atrazine, or its degradation product, was the most frequently detected pesticide in the shallow ground water under the recently urbanized area. The

Figure 20. Drilling and installing a new monitoring well in the rice-growing region of the Sacramento Valley.

Figure 21. Drilling and installation of a new monitoring well in the Sacramento metropolitan area. This study of shallow ground water was the first of its kind within the Sacramento metropolitan area.

occurrence of atrazine in ground water could not be attributed to either current urban land use or past agricultural production. All atrazine concentrations were below drinking-water standards.

An examination of the nitrate data revealed the highest potential contamination of ground water from recent urban development. Although no wells had concentrations of nitrate above the drinking-water standard, one well had a concentration of 8 mg/L, and 5 of the 19 (26 percent) of the sampled wells had concentrations that exceeded 5 mg/L. The median concentration of nitrate was 2.4 mg/L. The median concentration of nitrate in ground water under urban areas measured in previous NAWQA investigations was 1.6 mg/L (Nolan and Stoner, 2000).

With the exception of arsenic, trace elements generally were not found to be a problem from the

perspective of human toxicity. Some wells did have high concentrations of iron and manganese. The primary drinking-water standard for cadmium (5 $\mu\text{g/L}$) was exceeded in three wells of the rice land-use study. The source of that cadmium is unknown. Arsenic exceeded the current drinking-water standard of 50 $\mu\text{g/L}$ in one urban well and approached the drinking-water standard in three other wells. Arsenic would be more problematic if the drinking-water standard were lowered to 5 $\mu\text{g/L}$, as proposed by the EPA (U.S. Environmental Protection Agency, 2000). At that level, the standard would be exceeded in 53 percent of the urban wells, 39 percent of the rice land-use wells, and 48 percent of the domestic wells sampled in the southeastern Sacramento Valley. Iron and manganese dissolve when oxygen is absent in the ground water. Although generally nontoxic, these two metals can

limit the beneficial uses of the ground water because they may precipitate when the ground water is exposed to air. The precipitation can be severe enough to adversely affect household uses of water as well as plumbing.

Radon concentrations exceeded the EPA proposed drinking-water standard of 300 picocuries per liter in 90 percent of the domestic wells sampled. The median concentration from wells sampled in the southeastern Sacramento Valley was 495 picocuries per liter. Radon is a colorless gas formed from the radioactive decay of radium. Radium is produced by the radioactive decay of uranium, which has a half-life of 4.4 billion years, whereas the half-life of solid radium is 1,620 years. Radon, on the other hand, has a half-life of only 3.8 days. Because radon is a gas, it moves easily in underground geologic environments and readily enters ground water. Regions of the country with geologic formations containing granite, volcanic rocks, certain types of shale known as dark shale, and some sedimentary and metamorphic rocks are more likely to have soil or ground water enriched in radon. Those conditions exist in the Sacramento River Basin. The health effects of consuming water containing radon at levels determined in this study have not been identified.

STUDY UNIT DESIGN

Stream Chemistry

Basic and Intensive Fixed Sites (see Glossary) were selected to assess the occurrence of dissolved compounds and select compounds associated with solid materials in stream water or streambed sediment. Basic Fixed Sites were sampled less frequently and for fewer compounds than Intensive Fixed Sites.

Basic and Intensive Fixed Sites

1. Sacramento River above Bend Bridge near Red Bluff
2. Sacramento River at Colusa
3. Yuba River at Marysville
4. Feather River near Nicolaus
5. Cache Creek at Rumsey
6. Colusa Basin Drain at Road 99E near Knights Landing
7. Sacramento Slough near Knights Landing
8. Sacramento River at Verona
9. Arcade Creek near Del Paso Heights
10. American River at Sacramento
11. Sacramento River at Freeport
12. Yolo Bypass at Interstate 80 near West Sacramento

Special Studies

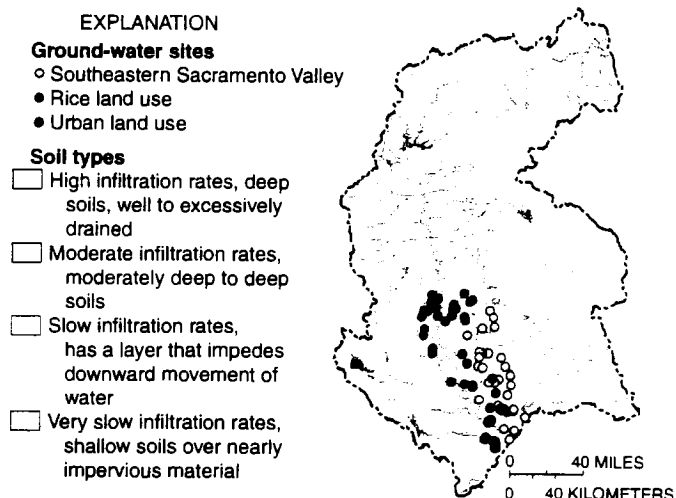

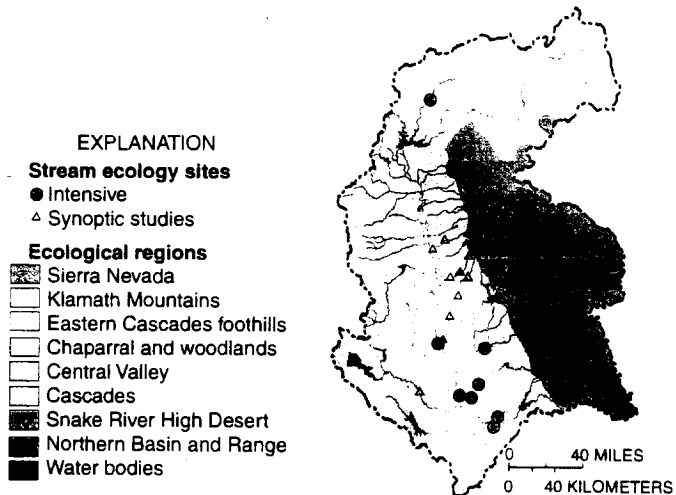

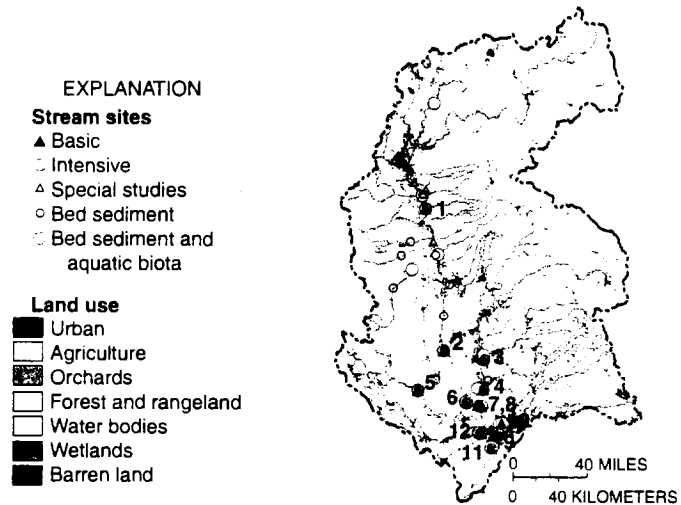

A study of metals transport from an acid mine drainage site and a generalized study of mercury transport along a reach of the Sacramento River downstream from Shasta Lake were completed.

Stream Ecology

Ecological assessments were completed along mountain to valley reaches (synoptic studies) of 3 streams, at 7 of the 12 Basic Fixed Sites, and at 1 reference site to determine variations in the community structure of aquatic biota.

Ground-Water Chemistry

Surveys of water quality in a used portion of the Sacramento Valley aquifer and the effects of agricultural and urban land uses on water quality were completed.

SUMMARY OF DATA COLLECTION IN THE SACRAMENTO RIVER BASIN, 1994-98

Study component	What data were collected and why	Types of sites sampled	Number of sites	Sampling frequency and period
Stream Chemistry				
Basic Fixed Sites— General water chemistry	Streamflow, nutrients, major ions, suspended sediment, water temperature, specific conductance, organic carbon, trace metals, mercury, dissolved oxygen, alkalinity and pH; to describe concentrations, loads, and seasonal variations.	Large rivers, most with continuous streamflow measurements available; streams with continuous streamflow measurements that drain forested, agricultural, and mining areas.	8	Monthly, 02/97-04/98
Intensive Fixed Sites— Agricultural and large river	In addition to the above constituents, 84 pesticides; to describe concentrations and seasonal variations.	One agricultural stream that drains primarily agricultural areas; one large river site near the mouth of the basin.	3	Monthly, 02/96-04/98; Monthly for pesticides, 11/96-03/97 and 08/97-04/98; twice per month for pesticides 04/97-07/97
Intensive Fixed Sites—Urban	The same constituents as Basic Fixed Sites and Intensive Fixed Sites and, in addition, 85 volatile organic compounds; to describe concentrations and seasonal variations.	One stream that drains a primarily urbanized area.	1	Monthly for pesticides and volatile organic chemicals, 11/96-12/96 and 01/98-04/98; twice monthly for pesticides, 01/97-11/97. Storm sampling for volatile organic chemicals, 04/96 and 10/96
Contaminants in streambed sediments	Trace elements and organic compounds; to determine presence of potentially toxic compounds attached to streambed sediments.	Depositional zones of large rivers and select tributaries, including fixed sites.	17 in 1996; 19 in 1997	One sampling for trace elements and organic compounds in 1995; one sampling for trace elements in 1997
Contaminants in tissues of aquatic organisms	Asiatic clams and bottom-feeding fish were collected to determine the presence of contaminants that can accumulate in tissues of aquatic organisms. The tissue samples were analyzed for trace elements and organic compounds.	Fixed sites and other select sites of large rivers and select tributaries.	17	One sampling in 1997
Stream Ecology				
Intensive Assessments	Fish, macroinvertebrates, and algae; to assess biological communities and habitat in streams representing primary ecological regions.	Sites at or near a fixed site or at a pristine or reference location.	9	Three samplings, 1996-98
Synoptic Studies	Fish, macroinvertebrates, and algae; to determine spatial distribution and community structure of aquatic species and habitat.	Sites along an elevation gradient from the Sierra Nevada to the Sacramento Valley.	14	Two samplings, 1997-98
Ground-Water Chemistry				
Aquifer Survey	Major ions, nutrients, pesticides, trace elements, volatile organic compounds, and radon; to describe the overall water quality and natural chemistry in a surficial aquifer.	Domestic wells in the southeastern Sacramento Valley.	31 wells	Once in 1996
Land-Use Effects— Agriculture (rice)	Major ions, nutrients, trace elements, and pesticides; to describe the water quality and natural chemistry in a surficial aquifer in an agricultural setting.	Newly drilled monitoring wells completed near the water table in a surficial aquifer beneath or near rice fields.	28 wells	Once in 1997
Land-Use Effects— Urban	Major ions, nutrients, pesticides, trace elements, volatile organic compounds, and radon; to describe the overall water quality and natural chemistry in a surficial aquifer.	Newly drilled monitoring wells completed near the water table in a surficial aquifer beneath a recently urbanized area.	19 wells	Once in 1998
Special Studies				
Sacramento River Trace Metals Study	Trace elements measured in whole water, filtered water, ultrafiltered water, and on colloids.	Sacramento River and select tributaries including an acid mine drainage site.	19	During selected high flow and low-flow stream conditions, 07/96-06/97

GLOSSARY

- Amalgamation**—The dissolving or blending of a metal (commonly gold and silver) in mercury to separate it from its parent material.
- Aquatic guidelines**—Specific levels of water quality which, if reached, may adversely affect aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.
- Aquatic-life criteria**—Water-quality guidelines for protection of aquatic life. Often refers to U.S. Environmental Protection Agency water-quality criteria for protection of aquatic organisms. See also Water-quality guidelines and Water-quality standards.
- Aquifer**—A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.
- Basic Fixed Sites**—Sites on streams at which streamflow is measured and samples are collected for temperature, salinity, suspended sediment, major ions and metals, nutrients, and organic carbon to assess the broad-scale spatial and temporal character and transport of inorganic constituents of stream water in relation to hydrologic conditions and environmental settings.
- Bed sediment**—The material at the bottom of a stream or other watercourse.
- Benthic invertebrates**—Insects, mollusks, crustaceans, worms, and other organisms without a backbone that live in, on, or near the bottom of lakes, streams, or oceans.
- Bioaccumulation**—The biological sequestering of a substance at a higher concentration than that at which it occurs in the surrounding environment or medium. Also, the process whereby a substance enters organisms through the gills, epithelial tissues, dietary, or other sources.
- Bioavailability**—The capacity of a chemical constituent to be taken up by living organisms either through physical contact or by ingestion.
- Criterion**—A standard rule or test on which a judgment or decision can be based.
- Dissolved solids**—Amount of minerals, such as salt, that are dissolved in water; amount of dissolved solids is an indicator of salinity or hardness.
- Drainage basin**—The portion of the surface of the earth that contributes water to a stream through overland runoff, including tributaries and impoundments.
- Drinking-water standard or guideline**—A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.
- Ecological studies**—Studies of biological communities and habitat characteristics to evaluate the effects of physical and chemical characteristics of water and hydrologic conditions on aquatic biota and to determine how biological and habitat characteristics differ among environmental settings in NAWQA Study Units.
- Ecoregion**—An area of similar climate, landform, soil, potential natural vegetation, hydrology, or other ecologically relevant variables.
- Ecosystem**—The interacting populations of plants, animals, and microorganisms occupying an area, plus their physical environment.
- Ground water**—In general, any water that exists beneath the land surface, but more commonly applied to water in fully saturated soils and geologic formations.
- Habitat**—The part of the physical environment where plants and animals live.
- Hydrograph**—Graph showing variation of water elevation, velocity, streamflow, or other property of water with respect to time.
- Intensive Fixed Sites**—Basic Fixed Sites with increased sampling frequency during selected seasonal periods and analysis of dissolved pesticides for 1 year.
- Maximum contaminant level (MCL)**—Maximum permissible level of a contaminant in water that is delivered to any user of a public water system. MCLs are enforceable standards established by the U.S. Environmental Protection Agency.
- Median**—The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.
- Micrograms per liter ($\mu\text{g/L}$)**—A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most stream water and ground water. One thousand micrograms per liter equals 1 milligram per liter (mg/L).
- Nitrate**—An ion consisting of nitrogen and oxygen (NO_3^-). Nitrate is a plant nutrient and is very mobile in soils.
- Nonpoint source**—A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs from plants and trees are types of nonpoint source pollution.
- Nutrient**—An element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.

- Organochlorine compound**—Synthetic organic compounds containing chlorine. As generally used, the term refers to compounds containing mostly or exclusively carbon, hydrogen, and chlorine. Examples include organochlorine insecticides, polychlorinated biphenyls, and some solvents containing chlorine.
- Organophosphate insecticides**—A class of insecticides derived from phosphoric acid. They tend to have high acute toxicity to vertebrates. Although readily metabolized by vertebrates, some metabolic products are more toxic than the parent compound.
- Phosphorus**—A nutrient essential for growth that can play a key role in stimulating aquatic growth in lakes and streams.
- Plankton**—Floating or weakly swimming organisms whose migration is controlled by waves and currents. Animals of the group are called zooplankton and the plants are called phytoplankton.
- Point source**—A source at a discrete location such as a discharge pipe, drainage ditch, tunnel, well, concentrated livestock operation, or floating craft.
- Polychlorinated biphenyls (PCBs)**—A mixture of chlorinated derivatives of biphenyl, marketed under the trade name Aroclor with a number designating the chlorine content (such as Aroclor 1260). PCBs were used in transformers and capacitors for insulating purposes and in gas pipeline systems as a lubricant. Further sale for new use was banned by law in 1979.
- Radon**—A naturally occurring, colorless, odorless, radioactive gas formed by the disintegration of the element radium; damaging to human lungs when inhaled.
- Recharge**—Water that infiltrates the ground and reaches the saturated zone.
- Runoff**—Excess rainwater or snowmelt that is transported to streams by overland flow, tile drains, or ground water.
- Semivolatile organic compound (SVOC)**—Operationally defined as a group of synthetic organic compounds that are solvent-extractable and that can be determined by gas chromatography/mass spectrometry. SVOCs include phenols, phthalates, and polycyclic aromatic hydrocarbons (PAHs).
- Suspended sediment**—Particles of rock, sand, soil, and organic detritus carried in suspension in the water column, in contrast to sediment that moves on or near the streambed.
- Tolerant species**—Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.
- Trace element**—An element found in only minor amounts (concentrations less than 1.0 milligram per liter) in water or sediment; includes arsenic, cadmium, chromium, copper, lead, mercury, nickel, and zinc.
- Volatile organic compounds (VOCs)**—Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.
- Water-quality guidelines**—Specific levels of water quality which, if reached, may adversely affect human health or aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.
- Water-quality standards**—State-adopted and U.S. Environmental Protection Agency-approved ambient standards for water bodies. Standards include the use of the water body and the water-quality criteria that must be met to protect the designated use or uses.
- Watershed**—See Drainage basin.
- Water table**—The point below the land surface where ground water is first encountered and below which the earth is saturated. Depth to the water table varies widely across the country.
- Wetlands**—Ecosystems whose soil is saturated for long periods seasonally or continuously, including marshes, swamps, and ephemeral ponds.

APPENDIX—WATER-QUALITY DATA FROM THE SACRAMENTO RIVER BASIN IN A NATIONAL CONTEXT

For a complete view of Sacramento River Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctc/nawqa/home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Sacramento River Basin. Selected results for this basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Sacramento River Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, molinate concentrations in Sacramento River Basin agricultural streams were similar to the national distribution, but the detection frequency was much higher (100 percent compared to 7 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Sacramento River Basin, 1994–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments

- No benchmark for drinking-water quality
- ** No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Alachlor (Lasso, Bronco, Lariat, Bullet) **
- Atrazine (AAtrex, Atrex, Atred, Gesaprim)
- Benfluralin (Balan, Benefin, Bonalan) ***
- Bromacil (Hyvar X, Urox B, Bromax)
- Bromoxynil (Buctril, Brominal) *
- Cyanazine (Bladex, Fortrol)
- Deethylatrazine (Atrazine breakdown product) ***
- Dichlorprop (2,4-DP, Seritox 50, Lentemul) ***
- 2,6-Diethylaniline (Alachlor breakdown product) ***
- MCPA (Rhomene, Rhonox, Chiptox)
- Metribuzin (Lexone, Sencor)
- Napropamide (Devrinol) ***
- Norflurazon (Evital, Predict, Solicam, Zorial) ***
- Oryzalin (Surflan, Dirimal) ***
- Pebulate (Tillam, PEBC) ***
- Pendimethalin (Pre-M, Prowl, Stomp) **
- Pronamide (Kerb, Propyzamid) **
- Propanil (Stam, Stampede, Wham) **
- Tebuthiuron (Spike, Tebusan)
- Triclopyr (Garlon, Grandstand, Redeem, Remedy) ***

Herbicides not detected

- Acetochlor (Harness Plus, Surpass) ***
- Acifluorfen (Blazer, Tackle 2S) **
- Butylate (Sutan +, Genate Plus, Butilate) **
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) ***
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) ***
- Dacthal mono-acid (Dacthal breakdown product) ***
- Dicamba (Banvel, Dianat, Scotts Proturf)
- Dinoseb (Dinosebe)
- Ethalfuralin (Sonaian, Curbit) ***
- Fenuron (Fenuon, Fenidim) ***
- Fluometuron (Flo-Met, Cotoran) **
- Linuron (Lorox, Linex, Sarclax, Linurex, Afalon) *
- MCPB (Thistrol) ***
- Neburon (Neburea, Neburyl, Noruben) ***
- Picloram (Grazone, Tordon)
- Propachlor (Ramrod, Satecid) **
- Propham (Tuberite) **
- 2,4,5-T **
- 2,4,5-TP (Silvex, Fenoprop) **
- Terbacil (Sinbar) **
- Triallate (Far-Go, Avadex BW, Tri-allate) *

Pesticides in water—Insecticides

Other insecticides detected

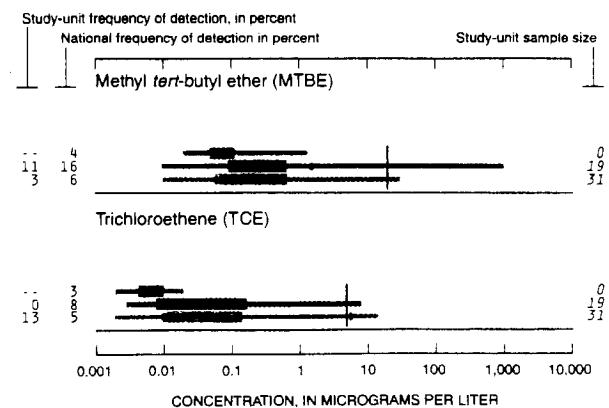

- Azinphos-methyl (Guthion, Gusathion M) *
- p,p'-DDE
- Propargite (Comite, Omite, Ornamate) **

Insecticides not detected

- Aldicarb (Temik, Ambush, Pounce)
- Aldicarb sulfone (Standak, aldoxycarb)
- Aldicarb sulfoxide (Aldicarb breakdown product)
- Dieldrin (Panoram D-31, Octalox, Compound 497)
- Disulfoton (Disyston, Di-Syston) **
- Ethoprop (Mocap, Ethoprophos) ***
- Fonofos (Dyfonate, Capfos, Cudgei, Tycap) **
- alpha-HCH (alpha-BHC, alpha-lindane) **
- gamma-HCH (Lindane, gamma-BHC)
- 3-Hydroxycarbofuran (Carbofuran breakdown product) ***
- Methiocarb (Slug-Geta, Grandslam, Mesurol) ***
- Methomyl (Lanox, Lannate, Acinate) **
- Methyl parathion (Pennacap-M, Folidol-M) **
- Oxamyl (Vydate L, Pratt) **
- Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
- cis-Permethrin (Ambush, Astro, Pounce) ***
- Phorate (Thimet, Granutox, Geomet, Rampart) ***
- Propoxur (Baygon, Blattanex, Unden, Proprotox) ***
- Terbufos (Conraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Other VOCs detected

- Bromodichloromethane (Dichlorobromomethane)
- Carbon disulfide *
- Chloromethane (Methyl chloride)
- Dichlorodifluoromethane (CFC 12, Freon 12)
- 1,2-Dichloroethane (Ethylene dichloride)
- 1,1-Dichloroethane (Ethylidene dichloride) *
- cis*-1,2-Dichloroethene ((Z)-1,2-Dichloroethene)
- Ethenylbenzene (Styrene)
- Iodomethane (Methyl iodide) *
- Tetrachloroethene (Perchloroethene)
- Tetrachloromethane (Carbon tetrachloride)
- 1,1,1-Trichloroethane (Methylchloroform)
- Trichlorofluoromethane (CFC 11, Freon 11)
- 1,2,4-Trimethylbenzene (Pseudocumene) *

VOCs not detected

- tert*-Amyl methyl ether (*tert*-amyl methyl ether (TAME)) *
- Benzene
- Bromobenzene (Phenyl bromide) *
- Bromochloromethane (Methylene chlorobromide)
- Bromoethene (Vinyl bromide) *
- Bromomethane (Methyl bromide)
- 2-Butanone (Methyl ethyl ketone (MEK)) *
- n*-Butylbenzene (1-Phenylbutane) *
- sec*-Butylbenzene *
- tert*-Butylbenzene *
- 3-Chloro-1-propene (3-Chloropropene) *
- 1-Chloro-2-methylbenzene (*o*-Chlorotoluene)
- 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
- Chlorobenzene (Monochlorobenzene)
- Chlorodibromomethane (Dibromochloromethane)
- Chloroethane (Ethyl chloride) *
- Chloroethene (Vinyl chloride)
- 1,2-Dibromo-3-chloropropane (DBCP, Nemagon)
- 1,2-Dibromoethane (Ethylene dibromide, EDB)
- Dibromomethane (Methylene dibromide) *
- trans*-1,4-Dichloro-2-butene ((Z)-1,4-Dichloro-2-butene) *
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
- 1,3-Dichlorobenzene (*m*-Dichlorobenzene)
- 1,4-Dichlorobenzene (*p*-Dichlorobenzene)
- 1,1-Dichloroethene (Vinylidene chloride)
- trans*-1,2-Dichloroethene ((E)-1,2-Dichloroethene)
- Dichloromethane (Methylene chloride)
- 1,2-Dichloropropane (Propylene dichloride)
- 2,2-Dichloropropane *
- 1,3-Dichloropropane (Trimethylene dichloride) *
- trans*-1,3-Dichloropropene ((E)-1,3-Dichloropropene)
- cis*-1,3-Dichloropropene ((Z)-1,3-Dichloropropene)
- 1,1-Dichloropropene *
- Diethyl ether (Ethyl ether) *
- Diisopropyl ether (Diisopropylether (DIPE)) *
- 1,2-Dimethylbenzene (*o*-Xylene)
- 1,3 & 1,4-Dimethylbenzene (*m*-&*p*-Xylene)
- 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
- Ethyl methacrylate *
- Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
- 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
- Ethylbenzene (Phenylethane)
- Hexachlorobutadiene
- 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
- 2-Hexanone (Methyl butyl ketone (MBK)) *
- Isopropylbenzene (Cumene) *
- p*-Isopropyltoluene (*p*-Cymene) *
- Methyl acrylonitrile *

- Methyl-2-methacrylate (Methyl methacrylate) *
- 4-Methyl-2-pentanone (Methyl isobutyl ketone (MIBK)) *
- Methyl-2-propenoate (Methyl acrylate) *
- Methylbenzene (Toluene)
- Naphthalene
- 2-Propanone (Acetone) *
- 2-Propenenitrile (Acrylonitrile)
- n*-Propylbenzene (Isocumene) *
- 1,1,2,2-Tetrachloroethane *
- 1,1,1,2-Tetrachloroethane
- 1,2,3,4-Tetramethylbenzene (Prehnitene) *
- 1,2,3,5-Tetramethylbenzene (Isodurene) *
- Tribromomethane (Bromoform)
- 1,1,2-Trichloro-1,2,2-trifluoroethane (Freon 113) *
- 1,2,4-Trichlorobenzene
- 1,2,3-Trichlorobenzene *
- 1,1,2-Trichloroethane (Vinyl trichloride)
- 1,2,3-Trichloropropane (Allyl trichloride)
- 1,2,3-Trimethylbenzene (Hemimellitene) *

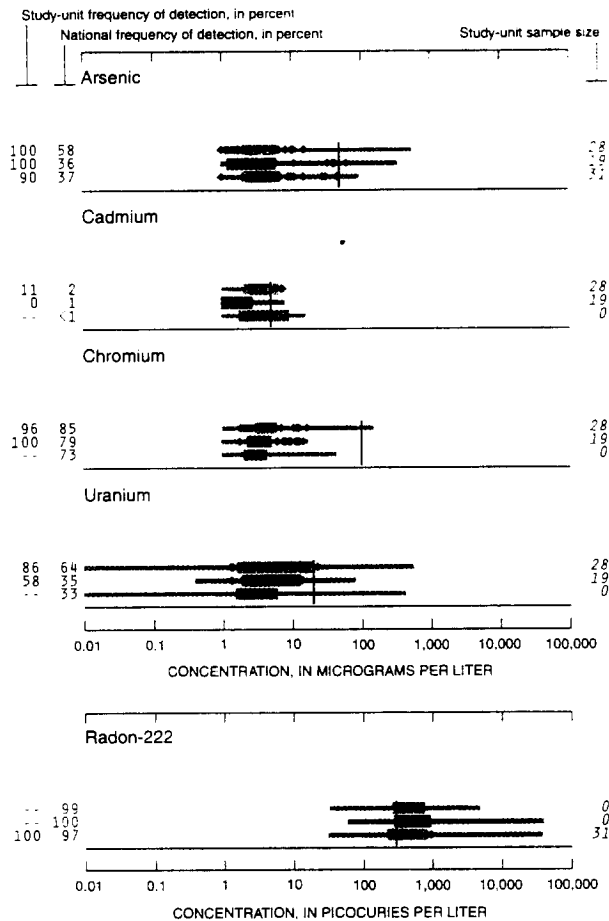

Nutrients in water

Dissolved solids in water

Trace elements in ground water

Other trace elements detected

Selenium
Zinc

Trace elements not detected

Lead

Organochlorines in fish tissue (whole body) and bed sediment

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Sacramento River Basin, 1994-98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

◆ Detected concentration in Study Unit

56 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency

--- Not measured or sample size less than two

12 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991-98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife

BIOLOGICAL INDICATORS

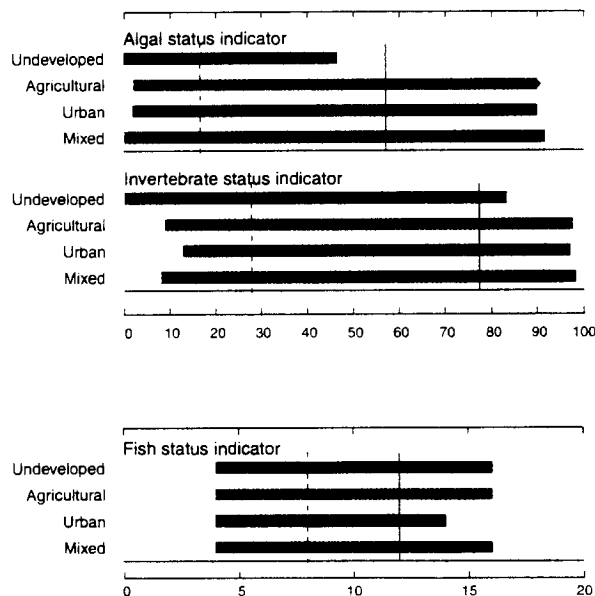

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

A COORDINATED EFFORT

Coordination with agencies and organizations in the Sacramento River Basin was integral to the success of this water-quality assessment. We thank those who served as members of our liaison committee.

Federal Agencies

U.S. Environmental Protection Agency
U.S. Fish and Wildlife Service
Bureau of Reclamation
National Marine Fisheries Service

State Agencies

California Regional Water Quality Control Board
California Department of Water Resources
California Department of Fish and Game
California Division of Mines and Geology
California State Water Resources Control Board

Other

University of California, Davis

We also thank the following organizations for contributing to this effort.

We are grateful to the Sacramento River Watershed Program (SRWP) and the Sacramento Regional County Sanitation District (SRCSD). The SRWP was initiated in 1995, just as the NAWQA Program initiated most of the water-quality sample collection activities in the basin. The SRWP has the following mission statement: "To ensure that current and potential uses of the watershed's resources are sustained, restored, and where possible, enhanced, while promoting the long-term social and economic vitality of the region." The current SRWP membership includes a diverse group of stakeholders interested in water quality of the Sacramento River Basin. The infrastructure of the SRWP provides a unique means of achieving the NAWQA goals of coordination. The SRCSD anticipated the need for a more comprehensive approach to water-quality management of the Sacramento River Basin. As a result, the SRCSD was instrumental in developing the Sacramento River Toxic Pollutant Control Program and was a partner with the Sacramento River Basin NAWQA Program in a detailed study of trace metals in the Sacramento River system. Other agencies contributing to or helping to facilitate funding for that study include the California State Water Resources Control Board, the U.S. Environmental Protection Agency, and the National Marine Fisheries Service.

NATIONAL WATER-QUALITY ASSESSMENT PROGRAM

THIS REPORT summarizes major findings about water quality in the Puget Sound Basin that emerged from an assessment conducted between 1996 and 1998 by the U.S. Geological Survey (USGS) National Water-Quality Assessment (NAWQA) Program. Water quality is discussed in terms of local and regional issues and compared to conditions found in all 36 NAWQA study areas, called Study Units, assessed to date. Findings are also explained in the context of selected national benchmarks, such as those for drinking-water quality and the protection of aquatic organisms. The NAWQA Program was not intended to assess the quality of the Nation's drinking water, such as by monitoring water from household taps. Rather, the assessments focus on the quality of the resource itself, thereby complementing many ongoing Federal, State, and local drinking-water monitoring programs. The comparisons made in this report to drinking-water standards and guidelines are only in the context of the available untreated resource. Finally, this report includes information about the status of aquatic communities and the condition of in-stream habitats as elements of a complete water-quality assessment.

Many topics covered in this report reflect the concerns of officials in State and Federal agencies, water-resource managers, and members of stakeholder groups who provided advice and input during the Puget Sound River Basin assessment. Basin residents who wish to know more about water quality in the areas where they live will find this report informative as well.

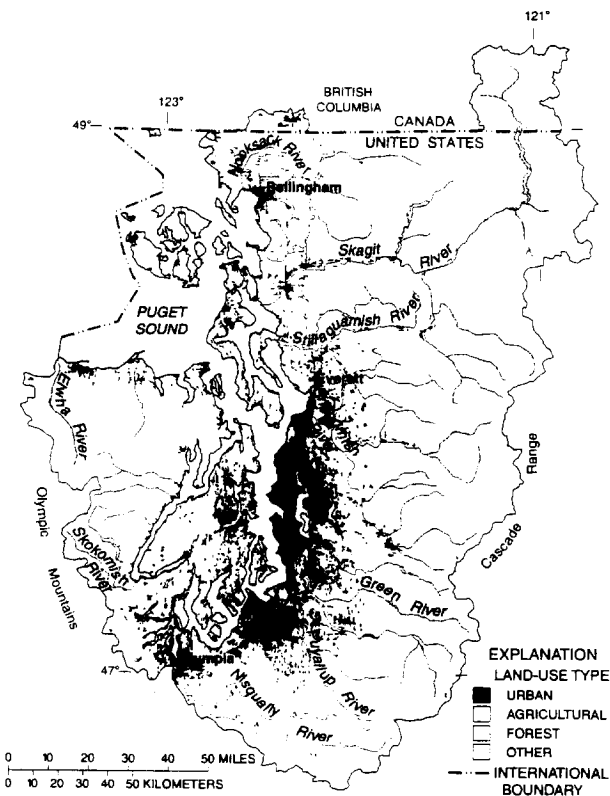

THE NAWQA PROGRAM seeks to improve scientific and public understanding of water quality in the Nation's major river basins and ground-water systems. Better understanding facilitates effective resource management, accurate identification of water-quality priorities, and successful development of strategies that protect and restore water quality. Guided by a nationally consistent study design and shaped by ongoing communication with local, State, and Federal agencies, NAWQA assessments support the investigation of local issues and trends while providing a firm foundation for understanding water quality at regional and national scales. The ability to integrate local and national scales of data collection and analysis is a unique feature of the USGS NAWQA Program.

The Puget Sound Basin is one of 51 water-quality assessments initiated since 1991, when the U.S. Congress appropriated funds for the USGS to begin the NAWQA Program. As indicated on the map, 36 assessments have been completed, and 15 more assessments will conclude in 2001. Collectively, these assessments cover about one-half of the land area of the United States and include water resources that are available to more than 60 percent of the U.S. population.

SUMMARY OF MAJOR FINDINGS

Stream and River Highlights

Streams and rivers in the Puget Sound Basin met most Federal and State water-quality guidelines. In general, large rivers were more likely to meet guidelines than were small streams. Concentrations of fecal bacteria frequently exceeded U.S. Environmental Protection Agency (USEPA) recreational criteria and State standards protecting beneficial uses of surface water, and insecticide concentrations were occasionally higher than guidelines recommended to protect aquatic life. A total of 74 man-made organic chemicals were detected in streams and rivers, with different mixtures of chemicals linked to agricultural and urban settings. Though most chemical concentrations appeared to be low, guidelines for drinking water and aquatic life that

The Puget Sound Basin is a 13,700-square-mile area of mountains and coastal lowlands in western Washington State and portions of British Columbia. About 4 million people live in the basin, mainly in metropolitan areas of Seattle, Tacoma, Everett, Bellingham, and Olympia. Headwaters of major rivers provide much of the drinking water for these metropolitan areas. Ground water is the primary source of drinking water in rural areas and, increasingly, for new suburbs.

	Selected Indicators of Stream-Water Quality			
	Small Streams			Major Rivers
	Urban	Agricultural	Undeveloped and Forest	Mixed Land Uses

Semivolatile organics ⁴	●	●	◐	◐

Percentage of samples with concentrations equal to or greater than a health-related national guideline for drinking water or aquatic life; or above a national goal for preventing excess algal growth
 Percentage of samples with concentrations less than a health-related national guideline for drinking water or aquatic life; or below a national goal for preventing excess algal growth
 — Percentage of samples with no detection
 — Not assessed

are needed to make a full assessment do not exist for more than half the compounds detected.

- The insecticide diazinon, commonly used by homeowners on lawns and gardens, was frequently detected in urban streams at concentrations that exceeded guidelines for protecting aquatic life (p. 6).
- The average concentration of total nitrogen in small streams draining agricultural lands was twice the concentration in streams draining urban areas and over 40 times the concentration in streams draining undeveloped areas. Concentrations of total phosphorus were less dependent on land use, and concentrations above the USEPA desired goal of 0.1 mg/L to prevent excessive plant growth were detected in rivers and streams in all but undeveloped areas (p. 11).
- Concentrations of *E. coli* bacteria exceeded USEPA criteria for moderate water-contact recreation, including swimming, in 15 of 31 small streams. Livestock, pet, and wildlife wastes, and to some extent human sewage, are likely sources of these bacteria (p. 13).

¹ Insecticides, herbicides, and pesticide metabolites, sampled in water.
² Total phosphorus and nitrate (as nitrogen), sampled in water.
³ Organochlorine compounds including DDT and PCBs, sampled in fish tissue.
⁴ Miscellaneous industrial chemicals and combustion by-products, sampled in sediment.

- Urban expansion into forested areas is changing stream habitats, in part because of changes in water quality. Streams in urban and agricultural areas are warmer and support less diverse populations of insects than those in forested areas (p. 14).

Trends in Surface-Water Quality

Concentrations of nitrate and phosphorus in the Nooksack and Green Rivers did not change between 1980 and 1997. During the same period, concentrations of nitrate in the Skokomish River and in Big Soos and Newaukum Creeks increased slightly (p. 12).

Major Influences on Streams and Rivers

- Contaminants in runoff from urban and agricultural land surfaces
- Degraded stream habitat in urban and agricultural areas

Ground-Water Highlights

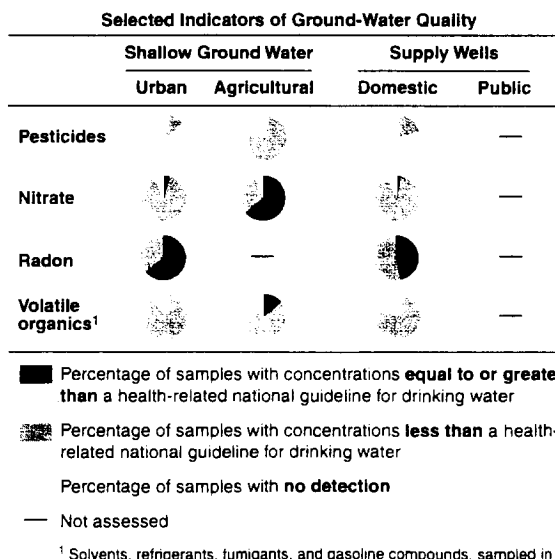

Reliance on ground water as a source of drinking water is increasing with urban and suburban development. With some exceptions, ground water is of high quality. However, as indicated by elevated concentrations of nitrate and the presence of pesticides and other organic compounds, shallow ground water in both urban and agricultural settings is vulnerable to contamination. Monitoring wells in urban residential areas generally contained low-concentration mixtures of chemicals associated with transportation and household activities. Shallow ground water, at depths tapped for domestic supply in agricultural areas, contained fertilizer residues (nitrate) at concentrations that commonly exceeded the drinking-water standard. Other agricultural chemicals were also frequently detected, though mostly at concentrations below current Federal and State drinking-water guidelines.

- Use of fertilizers on urban lawns and gardens and drainage from septic systems have elevated nitrate concentrations in shallow ground water beneath urban residential areas. In most samples, these concentrations were substantially less than the drinking-water standard (p. 17).

- Pesticides were not detected in wells that are more than 120 feet deep, the depth below which most large public-supply wells withdraw water. Pesticides were detected in wells that are less than 100 feet deep, the range of many rural and suburban domestic wells, but concentrations met drinking-water guidelines. Only about half of the detected pesticides have guidelines, and no benchmarks are available to assess the significance of low-concentration mixtures of pesticides (p. 16).
- Applications of fertilizers and dairy and poultry manure to cropland in agricultural areas of the Nooksack River Basin have increased nitrate concentrations above the USEPA drinking-water standard in about 60 percent of the shallow ground water sampled (p. 18).
- Prior to 1977, 1,2-dichloropropane was one of the ingredients in fumigants used on potatoes and berries in the Nooksack River Basin. Currently used fumigants contain only trace amounts of this compound, and their application is not likely contaminating ground water to concentrations exceeding drinking-water standards (p. 19).

Major Influences on Ground Water

- Poultry and dairy waste
- Lawn and garden fertilizers
- Septic systems
- Fumigants no longer in use

INTRODUCTION TO THE PUGET SOUND BASIN

The Puget Sound Basin encompasses the 13,700-square-mile area that drains to Puget Sound and adjacent marine waters. Included are all or part of 13 counties in western Washington, as well as the headwaters of the Skagit River and part of the Nooksack River in British Columbia, Canada. Streams and rivers drain three physiographic provinces—the Olympic Mountains in the west, the Cascade Range in the east, and the Puget Lowlands in the center of the basin (fig. 1).

Land Use Affects Water Quality and Stream Habitat

Nearly 4 million people, or about 70 percent of Washington State's population, live in the Puget Sound Basin. Urban growth is rapid; by 2020, the population is

expected to increase by 1.1 million people, with most growth in urban and suburban areas. Urban and agricultural land uses, which cover about 9 and 6 percent of the basin, respectively (fig. 2), are concentrated in the lowlands. Forest dominates land use and cover in the basin and is concentrated in the foothills and mountains (see map, p. 1).

The quality of water and aquatic biota has been affected by a range of forestry, agricultural, and urban development practices. The chemical quality of surface water in the foothills and mountains is

Figure 2. Land use and cover in the basin is predominantly forest.

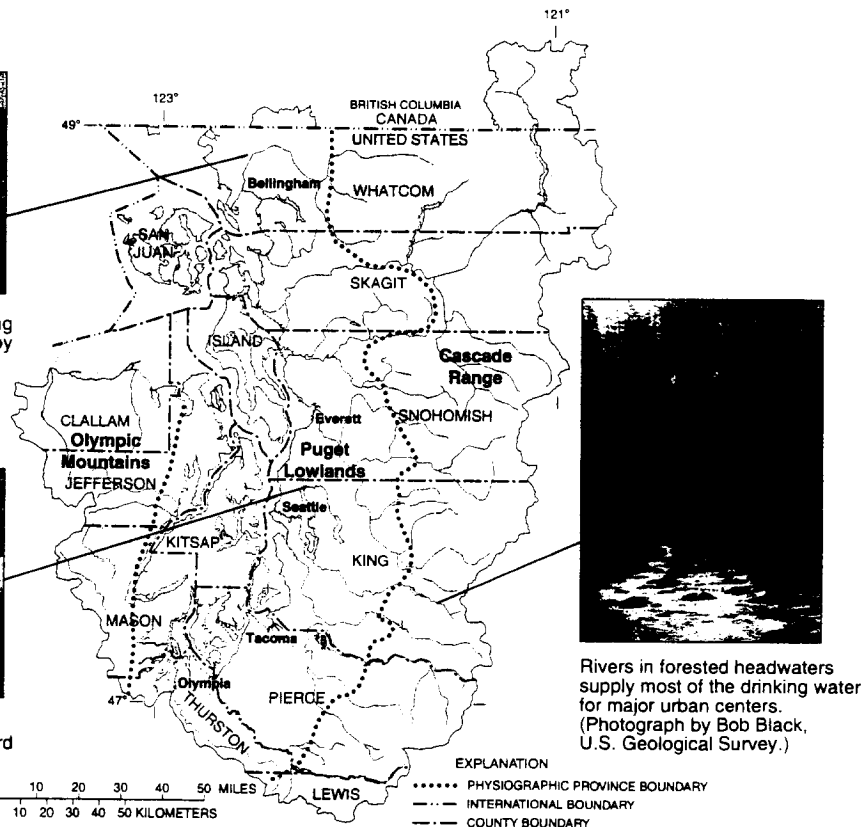

generally suitable for most uses. However, the physical hydrology, water temperature, and biologic integrity of streams have been influenced to varying degrees by logging (Black and Silkey, 1998).

Streambank vegetation is sparse along an agricultural stream. (Photograph by Bob Black, U.S. Geological Survey.)

Urban land use is concentrated in the Puget Lowlands. (Photograph by Ward Staubitz, U.S. Geological Survey.)

Rivers in forested headwaters supply most of the drinking water for major urban centers. (Photograph by Bob Black, U.S. Geological Survey.)

Figure 1. Streams and rivers drain three physiographic provinces in the Puget Sound Basin (Black and Silkey, 1998).

The quality of ground water in the upper watersheds probably differs little from natural conditions.

Because of development, many streams in the Puget Lowlands have undergone changes in structure and function with a trend toward simplification of stream channels and loss of habitat (Black and Silkey, 1998). Sources of contaminants to lowland streams and lower reaches of large rivers are largely nonpoint because most major point sources discharge directly to Puget Sound. Compared with that in small streams in the Puget Lowlands, the quality of water in the lower reaches of large rivers is better because much of the flow is derived from the forested headwaters.

More than half of the agricultural acreage in the basin is located in Whatcom, Skagit, and Snohomish Counties. Agricultural land use consists of about 60 percent cropland and 40 percent pasture. Livestock produce a large amount of manure that is applied as fertilizer to cropland, sometimes in excess amounts, resulting in runoff of nitrogen and phosphorus to surface water and leaching of nitrate to ground water. Runoff from agricultural areas also carries sediment, pesticides, and bacteria to streams (Staubitz and others, 1997). Pesticides and fumigant-related compounds are present, usually at low concentrations, in shallow ground water in agricultural areas.

Heavy industry is generally located on the shores of the urban bays and along the lower reaches of their influent tributaries, such as Commencement Bay and the Puyallup River in Tacoma and

Elliott Bay and the Duwamish Waterway in Seattle. High-density commercial and residential development occurs primarily within and adjacent to the major cities. Development in recent years has continued around the periphery of these urban areas but has trended toward lower density. This trend has resulted in increasing urban sprawl in the central Puget Sound Basin (fig. 3).

Urban land-use activities have had a significant impact on the quality of streams in the Puget Sound Basin (Staubitz and others, 1997). Water-quality concerns related to urban development include providing

adequate sewage treatment and disposal; transport of contaminants to streams by storm runoff, and preservation of stream corridors.

Water Availability Is a Major Issue

Although surface water provides most of the drinking water for the major urban centers (fig. 4), ground water is used in rural areas, and reliance on ground water as a source of drinking water is increasing with urban and suburban development (Staubitz and others, 1997).

Water availability has been and will continue to be a major, long-term issue in the Puget Sound Basin. It is now widely recognized that ground-water withdrawals can

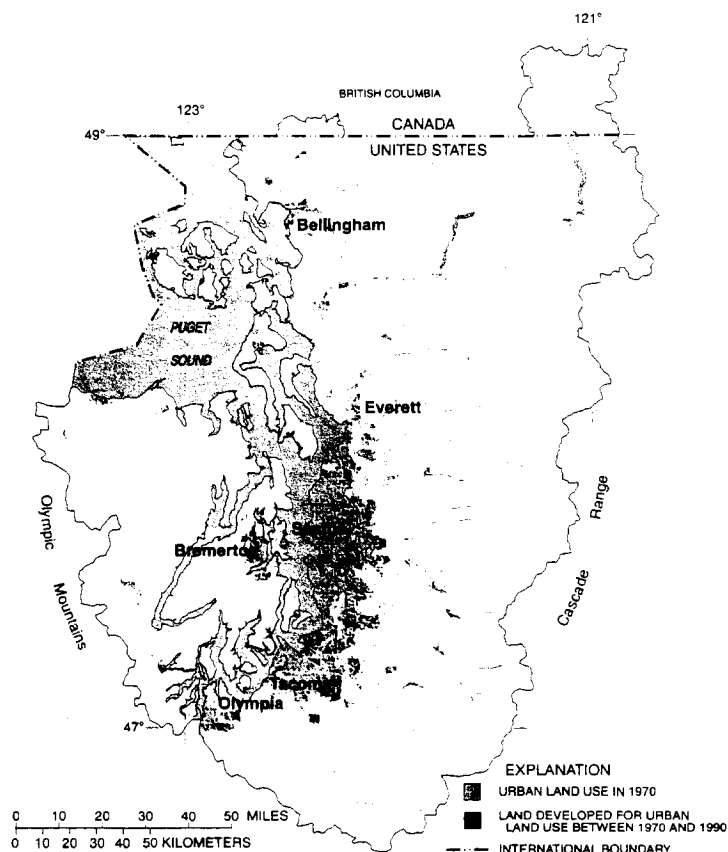

Figure 3. Recent urban development in the Puget Sound Basin has been around the periphery of established urban areas.

Figure 4. Excluding water used for hydroelectric power, 41 percent of water was used for domestic supply in 1995. Ground water accounted for 47 percent of all withdrawals.

deplete streamflows (Morgan and Jones, 1999), and one of the increasing demands for surface water is the need to maintain instream flows for fish and other aquatic biota.

Hydrologic Conditions Probably Affected Study Results

Surface water was sampled during 1996 and 1997 when rainfall and streamflows generally

were above the 30-year average (fig. 5). Because of increased runoff during periods of rainfall, larger amounts of sediment, nutrients, pesticides, bacteria, and other contaminants may have been transported from the land surface into streams and rivers than during drier years. High flows due to runoff from paved surfaces can also alter stream habitat.

Figure 5. Streams and rivers were sampled during 1996 and 1997 when streamflows generally were above the 30-year average.

Some Ground Water Is Susceptible to Contamination

Shallow ground water (less than 100 feet deep) in the Puget Lowlands is more susceptible to contamination in areas where the overlying sediments are coarse grained than where they are fine grained (see p. 16 and map, p. 20). This is because rainfall, or applied irrigation water, seep relatively easily through coarse-grained sediments and can transport contaminants to ground water.

Study Design Focuses on Land Use

Chemical and biological samples were collected from a mix of rivers and streams in forested, urban, and agricultural areas to assess overall quality as well as the effects of specific land-use practices. At some sites, water samples were collected monthly and during storms to assess the effects of storm runoff on contaminant washoff. Other sites were sampled only once, usually during normal flows.

Shallow ground water was sampled from aquifers in coarse-grained glacial deposits considered to be the most at risk to contamination. Water from these aquifers was sampled to assess general water quality and specifically to assess the quality of water in agricultural and residential areas. Monitoring wells and domestic wells were sampled. Data from a previous sampling of public-supply wells (Ryker and Williamson, 1996) are used to help evaluate the quality of drinking water and the quality of deep ground water. (See table 3, page 21 for details on study design.)

MAJOR FINDINGS

Pesticides in Surface Water Were Indicative of Upstream Land Uses, and More Pesticides Were Detected in Streams Than in Rivers

Twenty-nine pesticides were detected in Fishtrap Creek, which drains an agricultural area in the Nooksack River Basin (see map; p. 20), compared with 21 in Thornton Creek, an urban stream. In Fishtrap Creek, the more frequent detections of the herbicides atrazine and metolachlor, used more in agricultural areas, and less frequent detections of the herbicides dichlobenil and prometon (fig. 6), used more in urban areas, are consistent with the predominant land use in the

drainage basin. Urban-use pesticides in Fishtrap Creek are probably transported from urban areas in the upper and lower parts of the basin.

The two large rivers sampled for pesticides, the Nooksack and Duwamish (see map; p. 20), integrate land-use effects. The herbicides prometon, simazine, and tebutiuron, which are used in urban settings, were detected frequently in the Duwamish River (fig. 6). This is indicative of the urban land use surrounding and

Table 1. Concentrations of three insecticides were sometimes above chronic guidelines for the protection of aquatic life

Insecticide	Aquatic life guideline (micrograms per liter) ¹	Percentage of all samples exceeding guideline	Site in exceedance and (percentage of samples)	Range of concentrations detected at the site (micrograms per liter)
Chlorpyrifos	0.041	1	Thornton (2)	0.006–0.074
Diazinon	0.08	9	Thornton (20) Fishtrap (3) Duwamish (4)	0.003–0.501 0.004–0.113 0.004–0.083
Lindane	0.01	1	Thornton (2)	0.02

¹ U.S. Geological Survey, 1999a.

immediately upstream from the sampling site. Metolachlor, an agricultural herbicide, was detected more often in the Duwamish River than in the Nooksack River, which was sampled in an agricultural setting. Metolachlor in the Duwamish River was likely transported from agricultural areas upstream from the mostly urbanized lower part of the basin, where samples were collected.

Pesticides transported to the Nooksack and Duwamish Rivers are diluted by the volume of high-quality water from forested headwaters, resulting in lower detection frequencies compared with Fishtrap and Thornton Creeks (fig. 6). In addition to lower detection frequencies, fewer pesticides were detected in the large rivers.

Diazinon was the most frequently detected insecticide in both small streams and large rivers (fig. 6). It is used heavily in urban areas of the Puget Sound Basin, and its frequent detection, sometimes at concentrations exceeding the chronic guideline for the protection of aquatic life (table 1), prompted a more focused study of pesticides in urban streams in Seattle and surrounding King County (see page 7).

Figure 6. Pesticides detected in small streams (A) and large rivers (B) were indicative of land use, but detection frequencies in large rivers were lower because of dilution by flows from forested headwaters.

Concentrations of Pesticides in Surface Water Draining Urban and Agricultural Areas Sometimes Exceeded Guidelines for the Protection of Aquatic Life

The insecticides chlorpyrifos, diazinon, and lindane were sometimes detected at concentrations above chronic guidelines for the protection of aquatic life (table 1). Concentrations of diazinon exceeded its guide-

line in 9 percent of all samples, and in Thornton Creek, concentrations exceeded the guideline in 20 percent of samples. It is estimated that about half the 83,000 pounds of diazinon applied annually in the Puget Sound Basin are applied in King County (Tetra Tech Incorporated, 1988). Diazinon is the insecticide purchased most frequently by King County residents (fig. 7).

Pesticides Applied to Lawns and Gardens, As Well As Those Applied in Nonresidential Areas, Are Sources of Pesticides in Urban Streams

Because of the prevalence of diazinon and other pesticides in Thornton Creek, the USGS collaborated with the Washington State Department of Ecology and the King County Hazardous Waste Management Program to study pesticides in streams in 10 urban and suburban watersheds in King County (see map, p. 20). Samples were collected during April and May 1998 when retail sales of pesticides are highest (Voss and others, 1999), and they were collected during storms when runoff can transport pesticides to streams.

Because USGS and Washington State Department of Ecology laboratories both participated in the study, additional pesticides not included in the NAWQA study were analyzed. To help determine sources of pesticides detected, King County provided sales data for pesticides sold in 10 large home and garden stores during 1997.

Twenty-three of 98 pesticides analyzed for were detected in the urban streams. Homeowner use as a source of pesticides in streams is indicated for compounds like the herbicide 2,4-D and the insecticide diazinon, which were detected in all streams and were sold frequently in the home and garden stores (fig. 7). Some pesticides sold in stores were not detected in streams, indicating that other factors, like the rate at which a compound breaks down, affect the relation between usage and detection.

Almost half of the pesticides detected in the streams had no retail sales, indicating that they are usually not applied by homeowners. In urban areas, pesticides are also applied in commercial areas, along road rights-of-way, and in parks and recreational areas.

¹ Unit retail sales for these herbicides total to 140,000 units.

² Unit retail sales for these insecticides total to 66,000 units.

³ Unit retail sales for these fungicides total to 1,700 units.

Figure 7. A comparison of pesticides detected in urban streams with retail sales data suggests that homeowner and nonresidential applications both are sources of pesticides in streams. Sales were reported in units, which represent a bag, bottle, or other package containing the pesticide.

Insecticides in Thornton Creek Were Also Detected in Urban Streams Throughout the Nation

Throughout the Nation, the insecticides diazinon, carbaryl, chlorpyrifos, and malathion were detected much more frequently in streams draining urban basins than in streams draining agricultural basins (U.S. Geological Survey, 1999b). Except for carbaryl, these pesticides also were detected more frequently in Thornton Creek, an urban stream, than in Fishtrap Creek, an agricultural stream (fig. 6).

Detection of these pesticides is related to usage. For example, diazinon and chlorpyrifos, which nationally rank 1 and 4 among insecticides used for homes and gardens, rank 1 and 2 in unit sales of insecticides sold by home improvement stores in urban and suburban areas of King County (fig. 7).

Insecticides in streams are a concern because even at relatively low concentrations they can exceed guidelines for the protection of aquatic life (table 1).

Areas where pesticides are applied in urban settings are often in close proximity to streams. (Photograph by Sandra Embrey, U.S. Geological Survey.)

Although detection frequencies vary, insecticides in Thornton Creek were typical of those detected in urban streams in other Study Units throughout the Nation.

Historically Used Pesticides and PCBs Are Still Detected in Streambed Sediments and Fish Tissue

Streambed sediment and whole fish (sculpin, a bottom fish) tissue were analyzed at sites throughout the basin (see map, p. 20) in 1995 for organochlorine pesticides and PCBs. These compounds have been shown to have negative impacts on the health of aquatic organisms as well as the organisms that consume them. More organochlorine compounds were detected in both streambed sediments and fish tissue at sites surrounded by agricultural and urban land uses than at sites in undeveloped, forest, or mixed-land-use areas (fig. 8).

Figure 8. Organochlorine compounds, including the insecticide DDT and PCBs, in streambed sediments and fish tissue were primarily detected in urban and agricultural streams.

Fish Tissue Contamination is Related to Urban and Agricultural Land Uses

The relation between land use and the probability of detecting organochlorine compounds in fish (sculpin) tissue were statistically significant. This relation suggests that urban and agricultural land uses both contribute to the probability that a fish is contaminated with organochlorine pesticides. The probability of detecting total PCBs in fish was significantly related to urban land use only (Black and others, 2000). These relations also suggest that there is a land-use threshold below which the probability of finding organochlorine compounds in fish tissue is unlikely (fig. 9).

Organochlorine Compounds in Streambed Sediment and Fish May Be a Concern for Aquatic Ecosystems

Organochlorine pesticides were detected in streambed sediment at 3 of 19 sites (fig. 10). At Thornton Creek, an urban stream, levels of DDE (a breakdown product of DDT) and DDT exceeded the Canadian Council of Ministers of the Environment's (Canadian Council of Ministers of the Environment, 1995) probable effects level (PEL). Compounds exceeding the PEL are likely to result in adverse effects on aquatic organisms. It is important to note that levels of DDT in Thornton Creek sediment were higher than either one of its breakdown products, DDD and DDE. This may indicate that land disturbances in the basin have reintroduced buried soils contaminated with DDT.

Organochlorine compounds were also detected in the tissue of whole bottom fish (sculpin) collected at 8 of 18 study sites (fig. 11).

Figure 9. The probability of detecting specific organochlorine compounds in one or more fish (sculpin) at a site increased with the percentage of urban and agricultural land in the drainage basin. Dieldrin, *cis*-Chlordane, and *p,p'*-DDT relations are based on the percentage of agriculture plus urban land upstream from the sampling site. The total PCBs relation is based on the percent of urban land upstream from the sampling site.

Figure 10. Concentrations of organochlorine compounds in streambed sediment in the Puget Sound Basin sometimes exceeded Canadian probable effects levels (PELs). Compounds above the PELs may have negative impacts on aquatic organisms.

The largest number and highest concentrations of these compounds were in the fish collected from urban sites. At some sites, total PCBs and DDT concentrations were equal to or above the New York State Department of Environmental Conservation (NYSDEC) criteria for the protection of fish-eating wildlife (Newell and others, 1987).

Generally, the concentrations of organochlorine compounds in sediment and fish tissue were in the middle 50 percent nationally (see Appendix). Occasionally, concentrations of DDE, total chlordane, and total DDT were in the upper 25 percent of those reported nationally.

Whole sculpin (*Cottus*) were analyzed for

organochlorine compounds. (Photograph by Ward W. Staubitz, U.S. Geological Survey.)

Figure 11. Concentrations of organochlorine compounds in fish (sculpin) tissue from streams in the Puget Sound Basin sometimes exceeded New York State Department of Environmental Conservation (NYSDEC) criteria. Concentrations above criteria may have a detrimental effect on fish-eating organisms.

Characteristics and historical uses of organochlorine compounds detected in Puget Sound Basin fish tissue and streambed sediment

Organochlorine compounds are synthetic organic compounds containing chlorine. As generally used, the term refers to compounds containing mostly or exclusively carbon, hydrogen, and chlorine. Examples include organochlorine insecticides, polychlorinated biphenyls, and some solvents containing chlorine.

Chlordane (Octachloro-4,7-methanotetrahydroindane) is an organochlorine insecticide no longer registered for use in the United States. Technical chlordane is a mixture in which the primary components are

cis- and *trans*-chlordane, *cis*- and *trans*-nonachlor, and heptachlor.

DDT (Dichloro-diphenyl-trichloroethane) is an organochlorine insecticide no longer registered for use in the United States.

Dieldrin is an organochlorine insecticide no longer registered for use in the United States. It is also a breakdown product of the insecticide aldrin.

Heptachlor epoxide is a breakdown product of the organochlorine insecticide heptachlor. It was used in the United States until the 1970s.

Hexachlorobenzene (HCB) is a fungicide used as a seed and soil treatment. It was discontinued from use in the United States in the 1980s.

Polychlorinated biphenyls (PCBs) are a mixture of chlorinated derivatives of biphenyl, marketed under the trade name Aroclor with a number designating the chlorine content (such as Aroclor 1260). PCBs were used in transformers and capacitors for insulating purposes and in gas pipeline systems as a lubricant. Further sale for new use was banned by law in 1979.

Streams and Rivers in Developed Areas Were Enriched with Nutrients Relative to Those in Undeveloped Areas

The highest average concentrations of total nitrogen were in small streams draining agricultural areas. The concentrations were nearly twice those in streams draining urban areas and over 40 times the average concentrations in streams draining undeveloped land (table 2). Drainage basins in agricultural areas also yielded the most nitrogen per square mile (fig. 12). Concentrations and yields of total nitrogen in Puget Sound Basin streams and rivers correlate with usage and atmospheric deposition of nitrogen in drainage basins (Inkpen and Embrey, 1998). Fertilizers used in both agricultural and urban areas, manure associated with dairy farms, and atmospheric deposition are sources of nitrogen in Puget Sound Basin rivers (Embrey and Inkpen, 1998).

Concentrations of Phosphorus in Some Streams and Rivers May Promote Excessive Plant Growth

Average concentrations of total phosphorus exceeding the USEPA desired goal of 0.1 mg/L to prevent excessive plant growth were detected in streams and rivers in all land-use areas except undeveloped land

Table 2. Highest average concentrations of total nitrogen were in streams draining agricultural areas. Average concentrations of total phosphorus exceeding the USEPA desired goal of 0.1 mg/L to prevent excessive plant growth (shown in bold) were present in streams in urban, agricultural, and forested basins

River or stream	Average total nitrogen concentration (milligrams per liter)	Average total phosphorus concentration (milligrams per liter)	Basin area size	Land use/land cover (dominant land use in mixed) ¹
Fishtrap	3.54	0.086	small	agricultural
Newaukum	2.82	0.210	small	agricultural
Thornton	1.73	0.131	small	urban
Big Soos	1.20	0.054	small	urban
Springbrook	1.10	0.165	small	urban
Nooksack, Brennan	0.66	0.301	large	mixed (agricultural)
Duwamish	0.65	0.089	large	mixed (urban)
Nooksack, North Cedarville	0.39	0.152	large	mixed (forest)
Skokomish	0.13	0.078	large	mixed (forest)
North Fork Skokomish	0.07	0.012	small	undeveloped
Green	0.07	0.012	small	forest

¹Forest land that is not logged is designated undeveloped. In basins with mixed land use, the land use in the part of the basin where samples were collected is usually considered the dominant land use.

Figure 12. Basins in agricultural areas yielded the most nitrogen per square mile. The forested area upstream from the Nooksack River at North Cedarville yielded the most phosphorus. In basins with mixed land use, the dominant land use is indicated. The Green River above Twin Camp Creek and North Fork Skokomish River fall into the stream category because their drainage basins are relatively small.

(table 2). Unlike total nitrogen, concentrations of total phosphorus in streams and rivers in the Puget Sound Basin do not correlate with usage and atmospheric deposition of phosphorus in drainage basins (Inkpen and Embrey, 1998). This is because phosphorus attaches to soil particles and usually remains close to application areas unless it is transported to rivers by soil erosion.

Because of the importance of erosion in transporting phosphorus to streams, yields of total phosphorus correlate with yields of suspended sediment. The highest yields of both suspended sediment and total phosphorus were in the Nooksack River at North Cedarville, which drains a forested area.

Erosion of unstable streambanks and landslides transport sediment and phosphorus to headwater streams in the Nooksack River Basin. Most of the unstable streambanks are associated with road construction and logging (U.S. Forest Service, 1995).

Concentrations of Nitrate and Phosphorus in Streams and Rivers Have Not Changed or Have Only Slightly Increased with Time

Concentrations of nitrate, one of the major forms of nitrogen in water, and of total phosphorus have not changed much over the period 1980 to 1997 in several Puget Sound Basin rivers and streams (fig. 13). In three streams, nitrate concentrations have increased by a small amount, 0.014 mg/L per year or less. Only in

Site name (land use and cover, dominant in mixed)	Nitrate, as N		Total phosphorus	
	Trend	Rate of change, in mg/L per year	Trend	Rate of change, in mg/L per year

Nooksack River at Brennan (mixed, agricultural)	—	—	—	—
Nooksack River at N. Cedarville (mixed, forest)	—	—	—	—
Green River at Renton Junction (mixed, urban)	—	—	—	—
Big Soos Creek (urban)	↑	0.010	—	—
Newaukum Creek (agricultural)	↑	0.014	↑	0.002

— No trend or no value ↑ Significant upward trend mg/L=milligrams per liter

Figure 13. In three of six rivers and streams monitored by the Washington State Department of Ecology and King County, nutrient concentrations have remained stable from 1980 to 1997. In three others, concentrations of nitrate have gradually increased with time.

Newaukum Creek did concentrations of both nitrogen and phosphorus increase over time. Although data were not collected to determine the cause, trends often reflect land-use changes. For example, urban development might be a factor related to increasing nitrate concentrations in Big Soos Creek and in Newaukum Creek, which drains an agricultural basin with hobby farms and residential development.

Runoff During Rainstorms Contributes Contaminants to Streams, Indicating Nonpoint Sources

Washoff of nutrients and pesticides during storms causes both seasonal and short-term temporal variations in concentrations. A typical seasonal pattern for Puget Sound Basin streams and rivers is illustrated by lower concentrations of nitrogen and phosphorus in Newaukum Creek from July

through October when rainfall amounts are lowest (fig. 14).

Commonly used pesticides, such as diazinon, often had higher concentrations during rainstorms when they were washed off from areas of application (fig. 15). Even when daily rainfall amounts were small, less than 0.05 inch, diazinon concentrations increased in Thornton Creek.

Figure 14. Nutrient concentrations in Newaukum Creek were highest during the rainy winter and spring periods. Concentrations were lowest during late summer-early fall when rainfall amounts are lowest.

Figure 15. Peak concentrations of diazinon in Thornton Creek often occurred during spring rainstorms, which can produce an inch or more of rain in a day.

Bacteria Indicate the Presence of Fecal Contamination in Many Puget Lowland Streams

A study of 31 small lowland streams showed fecal coliform, *E. coli*, and enterococci bacteria to be present in every stream sampled during base flow. The presence of *E. coli* and enterococci bacteria is evidence that fecal contamination has occurred. During base flow, fecal contamination in urban streams could result from leaky sewer systems, failing septic

systems, and direct fecal inputs from pets and wildlife, including waterfowl. In agricultural and rural streams, fecal contamination is likely to be mostly from animals, including farm animals (dairy and beef cattle, and horses). Other sources could be wildlife, with perhaps some input from onsite septic systems.

Concentrations of all three fecal-indicator bacteria frequently exceeded standards and criteria (fig. 16); 81 percent of all sites had concentrations of fecal coliforms

Concentrations of bacteria in urban streams, which are attractive recreation areas, often exceed recommended concentrations for moderate water-contact recreation. (Photograph by Ward W. Staubitz, U.S. Geological Survey.)

Figure 16. Concentrations of *E. coli* and enterococci bacteria exceeded U.S. Environmental Protection Agency recreational criteria, and fecal coliform bacteria exceeded Washington State standards in many lowland streams. Concentrations of bacteria in single samples were compared with criteria and standards. USEPA criteria for moderate full-body contact recreation apply to a single sample (U.S. Environmental Protection Agency, 1986). Washington State standards for fecal coliform bacteria apply to the geometric mean of concentrations in samples collected during a period of no more than 30 days (State of Washington, 1992). Because no minimum number of samples is specified, the standard is routinely applied to concentrations in single samples (Hallock and others, 1996).

exceeding Washington State standards, and 48 percent of all sites had levels of *E. coli* exceeding USEPA's recommended concentration for moderate water-contact recreation. Because concentrations of *E. coli* and enterococci are related to cases of gastrointestinal illness in swimmers (U.S. Environmental Protection Agency, 1986), there could be some risk of illness to children and adults playing and swimming in these accessible streams.

The types of fecal bacteria and their concentrations in streams were similar among urban, agricultural, and rural areas (fig. 16). However, concentrations of *E. coli* in the urban and agricultural streams were all well above those in the upper Green River in the forested headwaters of the basin.

Stream Habitat and Health Are Degraded in Agricultural and Urban Streams

During the late summer and early fall, between 1995 and 1998, the USGS and the Washington State Department of Ecology evaluated instream and riparian (streamside) habitat conditions at 45 sites. These evaluations indicated that habitat conditions at streams draining urban

Figure 17. Values of selected habitat variables indicate that habitat conditions are degraded in agricultural and urban streams compared with streams in forest and undeveloped land. For each habitat variable, except temperature, multiple measurements were taken within a 330- to 660-foot-long stream reach at each study site.

and agricultural basins were significantly different from those at streams draining basins with forest and undeveloped land (fig. 17). Compared with either urban or agricultural sites, forest and undeveloped stream sites had a much higher percentage of cobble substrate, ideal for a diverse population of aquatic organisms, and a lower percentage of sand, detrimental to salmon spawning. In addition, forest and undeveloped sites had a much higher variability in water flow velocities than either urban or agricultural sites. More variability in flow velocities increases habitat diversity and wildlife diversity. Midday water temperatures were also much lower in the forested streams. The higher temperatures observed in the agricultural and urban streams are not ideal for native salmon and other aquatic organisms.

Human Activities Have Altered Aquatic Invertebrate Communities

As part of the USGS and Washington State Department of Ecology habitat data collection, aquatic invertebrates (insects and worms) were also collected from multiple riffle habitats at all 45 sites. A number of invertebrate community measures were examined to evaluate the status and quality of the aquatic invertebrate community. For each invertebrate community measure, values were lower, significantly so in some cases, at the urban and agricultural sites (fig. 18).

Urban development and agriculture can reduce habitat quality, alter typical stream flows, and increase chemical contaminants and temperatures, all of which are reflected in invertebrate community measures. A reduction in the total number of different invertebrates, stoneflies, mayflies, intolerant invertebrates, and percentage of predatory invertebrates indicates stream ecosystem degradation. For example, the total number of different invertebrates was much higher at the forest and undeveloped sites. A greater number of different invertebrates indicates a less degraded stream system capable of supporting more numerous desirable species such as salmon.

A summation of many invertebrate community measures is also shown in figure 18. This measure is known as a Benthic Index of Biological Integrity (BIBI) and is an overall indication of the biological integrity or health of a particular stream site (Black and MacCoy, 2000). As seen in figure 18, urban and agricultural systems have lower biological integrity scores than the forest and undeveloped sites.

Figure 18. As indicated by the average values of six different invertebrate community indicators of stream ecosystem conditions, conditions were better at sites in forest and undeveloped land than at sites in urban and agricultural areas. Lower values suggest a more degraded stream site. Taxa are different types of invertebrates.

Streams in Urban and Agricultural Areas Have Less Than Optimal Amounts of Forest and Undeveloped Land to Support Healthy Aquatic Invertebrate Communities

A total of 46 different aquatic invertebrate taxa were identified at 45 sites throughout the Puget Sound Basin. Of the 46, only 4 taxa prefer watersheds with low forest/undeveloped land cover, whereas 19 taxa prefer watersheds with high forest/undeveloped land cover (fig. 19). These results indicate that streams in watersheds dominated by urban and agricultural land are optimally suited for only a few of the different taxa and many of these taxa are indicators of degraded stream ecosystems. Watersheds dominated by forest and undeveloped land are preferred by a much larger number of different invertebrate taxa, many of which are indicators of healthy stream systems.

Figure 19. More different aquatic invertebrate types (taxa) prefer streams that have watersheds with greater than 75 percent forest/undeveloped land cover. Each bar represents the preferred range of forest/undeveloped land cover

for the specified number of invertebrate taxa out of the 46 taxa identified in the Puget Sound Basin. An animal is healthiest when it is in its preferred range. This figure indicates that more different invertebrate taxa prefer sites in forested/undeveloped watersheds, but not that more invertebrate taxa or total numbers of invertebrates were found at these sites. The method used to determine preferred land-cover percentages was based on the work of Line and others (1994).

Puget Sound Stream Invertebrate Status Ranged from High to Low When Compared with National Levels

In the Puget Sound Basin, aquatic invertebrates collected at the 11 fixed monitoring sites were compared with those collected at 140 NAWQA sites nationwide. An **Invertebrate status index** (Tom Cuffney, U.S. Geological Survey, written commun., 2000) was developed by averaging 11 invertebrate metrics that summarized changes in richness, tolerance, food preference, and dominance associated with water-quality degradation. Invertebrate status scores in the basin ranged from low (less degraded) for streams in forest and undeveloped areas to high (more degraded) for other streams. As indicated by the invertebrate status scores, some Puget Sound Basin streams are highly degraded. This is the result

of poor habitat conditions and possibly water chemistry. As shown in figure 17, high midday water temperatures and percent sand were observed in urban and agricultural streams, both of which have

negative effects on aquatic organisms. In addition, numerous pesticides, some at concentrations above guidelines set to protect aquatic life, were detected at these sites (see Appendix).

Invertebrate status index by land use and cover for Puget Sound Basin sites in relation to national conditions. A low invertebrate status index score represents a less degraded stream site. *Mixed land uses can have an agricultural, urban, or forestry influence (table 2).

Ground-Water Quality is Generally Good

Prior to conducting field studies, an analysis of existing data was conducted to determine which Puget Sound Basin aquifers are most at risk to contamination. Unconfined aquifers that are overlain by coarse-grained glacial deposits (see map, p. 20) were found to be the most susceptible to contamination (see sidebar). Aquifers in coarse-grained glacial deposits in the Puget Sound Basin are collectively referred to as the Fraser aquifer. Three studies were conducted in the unconfined part of the Fraser aquifer (Inkpen and others, 2000). A study-unit survey was conducted by randomly selecting 30 domestic wells without regard to land use to evaluate the overall quality of shallow ground water. Ground-water-quality studies were also conducted in residential areas in Pierce and Thurston Counties

Figure 20. Median nitrate concentrations in shallow ground water sampled for the study-unit survey (varied land use) were low. Higher nitrate concentrations were more common in both the residential land-use and agricultural land-use studies.

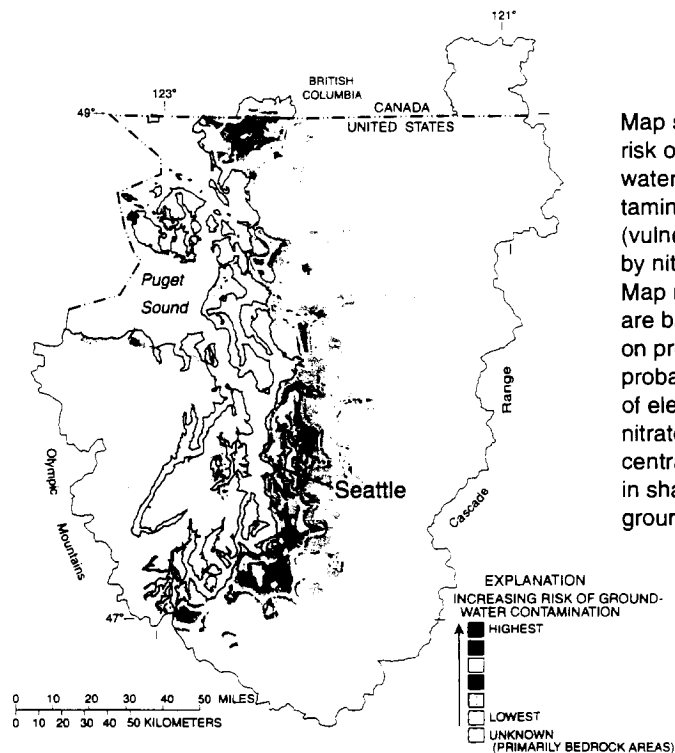

and in an agricultural area in Whatcom County (see map, p. 20) to examine the influence of these important land-use categories on shallow ground water. Shallow ground water in all parts of the Fraser aquifer sampled is used for domestic supplies.

The study-unit survey results indicate that ground water is of generally good quality, as only one well did not meet a drinking-water standard (for nitrate). Nitrate was detected in

most wells, but the concentrations were low, having a median concentration of 1.0 mg/L (fig. 20). Pesticides were detected in 20 percent of study-unit survey wells (fig. 21) but were present at low concentrations (less than 0.2 µg/L) (micrograms per liter) and were well below drinking-water standards or guidelines. Based on data from a previous study (Ryker and Williamson, 1996), pesticides were not detected in wells more than

Predicting Ground-Water Susceptibility and Vulnerability

A statistical model (Tesoriero and Voss, 1997; Erwin and Tesoriero, 1997) was created to predict which areas are (1) most likely to become contaminated if sources of contaminants are present (susceptibility) and (2) at the greatest risk of contamination, based on current land-use practices (vulnerability). Well depth, surficial geology, and land use were the factors that significantly correlated with elevated nitrate concentrations and were used in the models. Shallow ground water in areas with coarse-grained glacial deposits at the surface were the most susceptible to contamination. These areas become increasingly vulnerable to nitrate contamination as the amount of agricultural and urban land use increases. Vulnerable areas include the intensive agricultural areas in the northern part of the Study Unit as well as urban areas extending north and south of Seattle.

Map shows risk of ground-water contamination (vulnerability) by nitrate. Map results are based on predicted probabilities of elevated nitrate concentrations in shallow ground water.

120 feet deep (Bortleson and Ebbert, 2000). Volatile organic compounds were detected frequently (80 percent of wells sampled) but were present at low concentrations (less than 1 µg/L).

Radon concentrations exceeded the proposed drinking-water standard of 300 picocuries per liter (U.S. Environmental Protection Agency, 1999a) in about 50 percent of the domestic and monitoring wells sampled for radon (table 3, p. 21). Radon is a naturally occurring product from the decay of uranium. The median concentration of radon in ground water in the Puget Sound Basin was 320 picocuries per liter. Elevated radon concentrations are by no means unique to the Puget Sound Basin. In fact, radon concentrations in ground water collected for NAWQA studies throughout the Nation exceeded the proposed standard more often and had a higher median value (420 picocuries per liter) than in the Puget Sound Basin (Wentz and others, 1999).

Nitrate Concentrations in Shallow Ground Water Beneath Residential Areas Were Elevated, but Concentrations of Other Compounds Were Low

Although nitrate concentrations in shallow ground water beneath the residential areas in Pierce and Thurston Counties were elevated compared with those in ground water sampled by the study-unit survey (fig. 20), only one sample exceeded the drinking-water standard. Stable isotope measurements of nitrogen in nitrate suggest that septic-system effluent is a significant source of nitrate in unsewered areas. Additional nitrate sources are indicated by the similar concentrations of nitrate in sewerred and unsewered areas (Inkpen and others, 2000). Some nitrate in ground water in unsewered areas and most nitrate in sewerred areas is likely from the application of fertilizers to lawns and gardens.

Pesticides Were Rarely Detected in Ground Water Beneath Residential Areas

In spite of the vulnerability of the unconfined Fraser aquifer, only a few pesticides were detected (fig. 21) and these were at low concentrations (less than 0.2 microgram per liter) beneath residential areas developed since 1970. These results suggest that pesticides currently used in residential areas may pose little risk to ground water. However, it should be noted that several commonly used pesticides (glyphosate, for example) were not analyzed.

Volatile Organic Compounds Were Detected Frequently at Low Concentrations in Ground Water Beneath Residential Areas

Although volatile organic compounds (VOCs) were detected in over 90 percent of shallow ground-water samples in residential areas, concentrations were low (fig. 22). Most detections were less than 0.05 µg/L,

Figure 21. A pesticide was detected in less than 15 percent of shallow ground-water samples beneath residential areas, and the most frequently detected compounds were each detected in less than 10 percent of these samples.

Figure 22. Volatile organic compounds were frequently detected at low concentrations in shallow ground water beneath residential areas.

and none was above drinking-water standards or guidelines. Solvents, chlorinated by-products, and fuel-related compounds were the most commonly detected VOCs.

High Nitrate Concentrations and Fumigant-Related Compounds Were Detected in Shallow Ground Water Beneath an Agricultural Area

Nitrate concentrations in more than half of the shallow ground water sampled for the agricultural land-use study exceeded the drinking-water standard. Major sources of nitrate are animal manure from poultry and dairy operations and fertilizers applied to crops. High concentrations of nitrate have persisted for many years in wells sampled in this aquifer (Hii and others, 1999), suggesting that land applications of manure and inorganic fertilizers are contributing nitrate to this aquifer at a sufficient rate to sustain these levels (fig. 23).

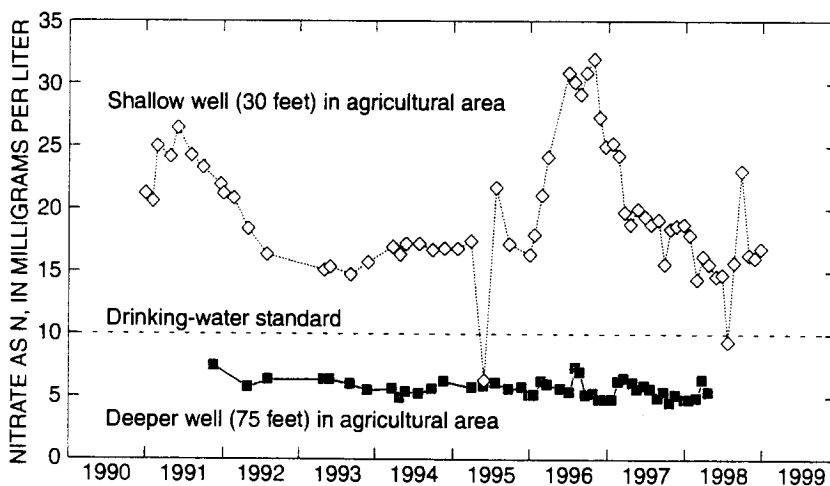

Figure 23. Nitrate concentrations in shallow ground water often exceeded the drinking-water standard (10 milligrams per liter), with high concentrations persisting for many years. Nitrate concentrations in deeper ground water, while elevated, generally met the drinking-water standard. Both the shallow and deeper ground water are used for domestic supplies.

Reactions in the Riparian Zone Remove Nitrate from Ground Water

Nitrate concentrations in ground water in the agricultural land-use study area commonly exceeded 10 mg/L, a concentration that can promote excessive plant growth in streams where this ground water discharges. A detailed analysis of water-quality changes along ground-water flow paths was conducted in this area (flow-path study area, p. 20). High nitrate concentrations persisted throughout much of the shallow aquifer. It was not until ground water reached the riparian zone of Fishtrap Creek that nitrate concentrations decreased to low levels (fig. 24). A decrease in nitrate concentrations in ground water concurrent with an increase in nitrogen gas (N_2) concentrations in this zone is evidence that nitrate is

Figure 24. Nitrate concentrations in ground water remain high until water seeps through stream sediments that favor microbial denitrification. This process can effectively transform nitrate to nitrogen gas before the water discharges to the stream.

being converted to N_2 by denitrification (Tesoriero and others, 2000).

High Concentrations of 1,2-Dichloropropane Were Probably Caused by Applications of Older Fumigant Formulations

The most commonly detected volatile organic compounds in the agricultural land-use study area were associated with the application of fumigants to soils prior to planting. One or more fumigant-related compounds (1,2-dichloropropane, 1,2,2-trichloropropane, and 1,2,3-trichloropropane) were detected in over half of the samples. Each of these compounds is present in varying amounts in historically and/or presently used fumigants. Concentrations of 1,2-dichloropropane in water from two wells were above the drinking-water standard for this compound (fig. 25).

The amount of 1,2-dichloropropane and 1,2,3-trichloropropane in fumigant formulations has dropped substantially over the past few decades (Zearth and others, 1998), while the amount of 1,2,2-trichloropropane has decreased only slightly.

The relative amounts of these chloropropanes in ground water were compared with those present in

fumigant formulations to determine the origin of these compounds in ground water (Tesoriero and others,

in press). Results indicate that high concentrations of 1,2-dichloropropane in ground water are largely due to older formulations (fig. 26).

Figure 25. Fumigant-related compounds were detected frequently in shallow ground water in the agricultural land-use study area. Concentrations of 1,2-dichloropropane exceeded the drinking-water standard in two samples.

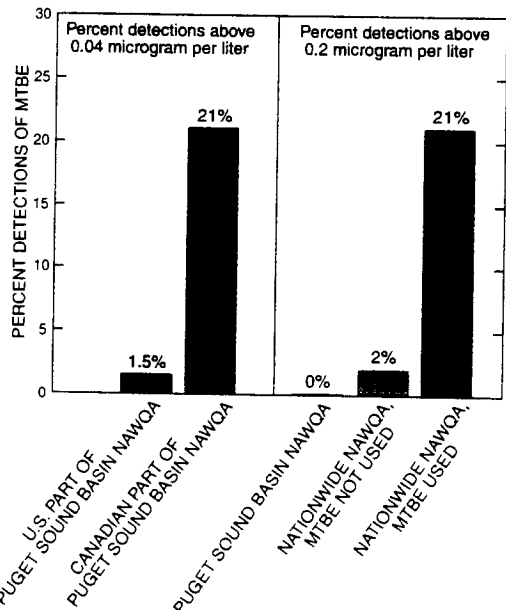

Figure 26. Based on the relative amounts of chloropropanes in samples, higher concentrations of 1,2-dichloropropane are likely derived from older fumigant formulations.

MTBE Was Rarely Detected in Ground Water in the Puget Sound Basin

Areas that exceed air-quality standards for carbon monoxide are required to use a fuel oxygenate to comply with the Clean Air Act of 1990. Methyl *tert*-butyl ether (MTBE) is the most widely used oxygenate in the United States. However, frequent detections of MTBE, sometimes high concentrations, in ground water in areas where this compound is used has caused the USEPA to recommend that it be discontinued or reduced (U.S. Environmental Protection Agency, 1999b). MTBE is used in the Canadian part of the Puget Sound Basin but not in the U.S. part. Not surprisingly, detections of this compound were more frequent in the Canadian part of the Study Unit. When detected, MTBE concentrations were low (less than

Region	Percent detections above 0.04 µg/L	Percent detections above 0.2 µg/L
U.S. PART OF PUGET SOUND BASIN	1.5%	0%
CANADIAN PART OF PUGET SOUND BASIN	21%	21%
NATIONWIDE (MTBE NOT USED)	0%	2%
NATIONWIDE (MTBE USED)	1.5%	21%

The detection frequency of MTBE in shallow ground water in the Puget Sound Basin was less than detection frequencies in other parts of the Nation (Squillace, 1999). Ethanol, not MTBE, is used as a fuel oxygenate in the U.S. part of the Puget Sound Basin.

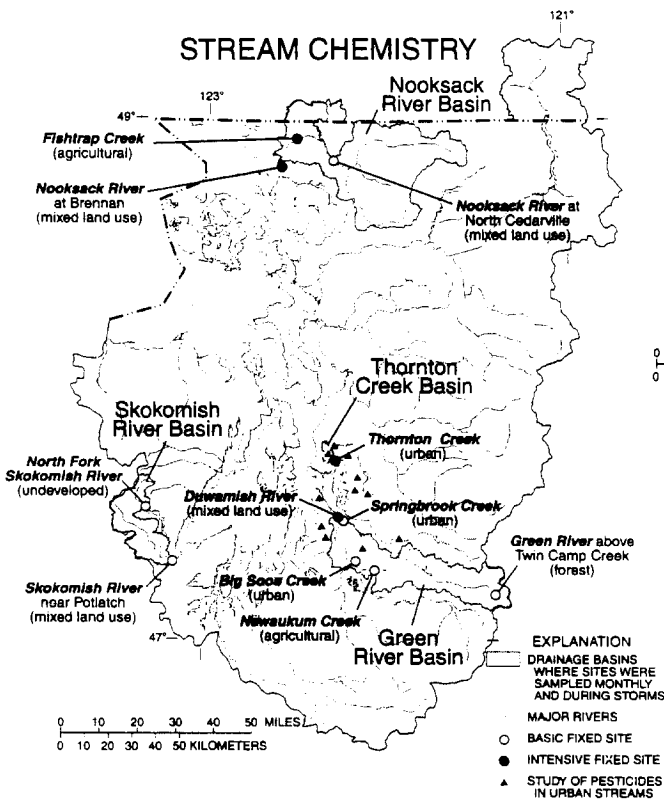

0.2 microgram per liter). Low concentrations of MTBE are likely derived from nonpoint sources, such

as stormwater runoff or atmospheric deposition, or from diluted point sources (Squillace and others, 1996).

STUDY UNIT DESIGN

The Puget Sound Basin study was designed to address local and national goals of providing widely comparable water-quality data focused on stream chemistry, stream ecology, and ground-water chemistry.

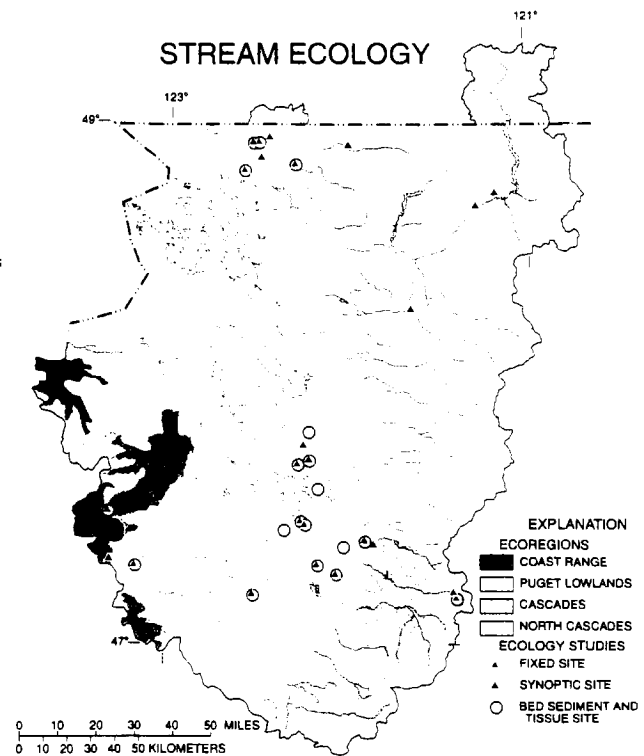

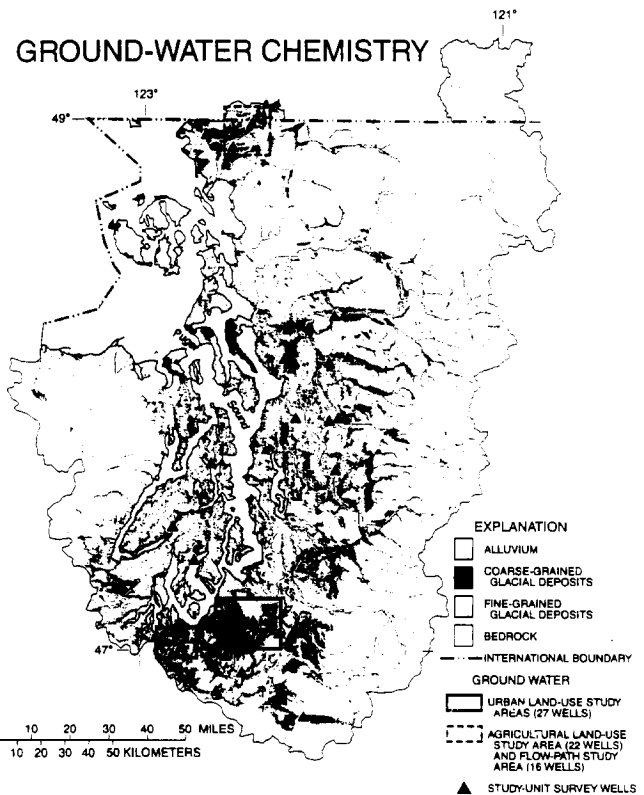

Of the 12 major and numerous minor tributaries to the Puget Sound, sampling was concentrated in four representative drainage basins: the Nooksack and Green River Basins with varied land uses, the Thornton Creek Basin in a totally urban environment, and the Skokomish River Basin, which is mostly forested.

Some sampling was done outside these areas for special studies, such as the study of pesticides in urban streams.

Wells sampled for the survey of ground-water quality in the Study Unit were distributed throughout the Puget Lowlands. Agricultural effects on ground-water quality and changes in quality along flow paths were evaluated using wells located in the lower Nooksack River Basin. Wells sampled in residential areas surrounding Olympia and Tacoma were used for determining urban land-use effects on shallow ground-water quality.

Stream ecology, bed sediment, and aquatic biota sampling was done at all the fixed stream-chemistry sites, and one or more of these types of samples were

collected at 14 other sites. Two-thirds of the sites were within the Puget Lowlands, while the remainder were in other ecoregions (Black and Silkey, 1998).

Table 3. Summary of data collection in the Puget Sound Basin, 1994–98¹

Stream Chemistry				
Basic fixed sites—general water quality	Streamflow, dissolved oxygen, pH, alkalinity, specific conductance, temperature, nutrients, major ions, trace elements, organic carbon, and suspended sediment were measured to determine occurrence and concentration.	Streams draining basins ranging in size from 12 to 790 square miles, reflecting forest and mixed land use, and widely distributed geographically within the Study Unit.	7	Monthly plus storms Mar. 1996–Apr. 1998
Intensive fixed-sites—pesticides and VOCs	Above constituents plus 87 pesticides and 85 volatile organic compounds.	Sites selected for closer proximity to and more direct influence from agricultural and urban land uses plus integration of mixed-use larger basins.	3 1	Weekly to monthly Mar. 1996–May 1997 Weekly to monthly Mar. 1996–May 1998
Synoptic sites—pesticides	Streamflow, pH, specific conductance, temperature plus pesticides during varying flow conditions to relate occurrences and concentrations to retail sales of pesticides.	Sites predominantly influenced by urban residential land use plus 1 reference site.	13	2 to 4 samples over storm hydrograph Apr.–May 1998
Contaminants in bed sediment	Trace elements and organic compounds to determine occurrence and distribution in streambed sediment.	Depositional zones of all basic and intensive stream-chemistry sites plus additional sites.	19	Once Sept. 1995
Contaminants in fish tissue	Trace elements and organic compounds in the tissue of whole fish.	Same sites from which bed sediment samples were collected.	18	Once Sept. 1995
Stream Ecology				
Fixed sites	Invertebrate, algae, and fish communities, streamflow, basic water chemistry, and riparian habitat conditions surveyed to assess biological communities in the basin.	Sites collected with basic and intensive stream-chemistry sites and having contributing drainage areas from 12 to 790 square miles.	11	Annually 1995–97
Synoptic	Invertebrate, algae, and fish communities, streamflow, nutrients, and habitat conditions surveyed to determine land-use effects on biological communities.	4 bed sediment and tissue sites and 10 other sites influenced by various land uses, with contributing drainage areas ranging from 3 to 48 square miles.	14	Once Sept.–Oct. 1996
Ground-Water Chemistry				
Study Unit—varied land use	Nutrients, major ions, pesticides, volatile organic compounds, and radon in shallow, unconfined glacial outwash aquifer to assess the drinking-water quality of domestic wells in the Fraser aquifer.	Existing domestic supply wells widely distributed through the Puget Lowlands.	30	Once 1996
Land use—residential	Above compounds to determine effects of urban land use on ground-water quality in the Fraser aquifer. One-half of the wells were sampled for radon.	Monitoring wells in urban residential areas with both sewer and private septic systems.	27	Once 1996–97
Land use—agricultural	Above compounds, except radon, to determine effects of agricultural land use on ground-water quality in the Fraser aquifer.	Monitoring wells (18) and existing domestic supply wells (4) in an area of intensive row crops (raspberries, for example).	22	Once 1997–98
Flow path—agricultural	Above compounds, except radon, to determine changes in water quality occurring as water moves from recharge to discharge areas.	Shallow and deep monitoring wells along flow paths in an agricultural watershed.	16	Varied 1997–98
Special Studies				
Synoptic study—microbiology and wastewater chemicals	Turbidity, pH, specific conductance, temperature, wastewater chemicals, fecal-indicator bacteria, coliphage, and coliphage serotypes to determine occurrence and distribution in the Puget Lowlands and infer sources of fecal contamination.	Sites predominantly influenced by urban and agricultural land use.	31	Once Aug. 1998
Land use and scale	Invertebrates, instream habitat, and riparian condition data from USGS and Washington State Department of Ecology sites (common protocol) were combined to evaluate land-use impacts at different spatial scales.	Indicator sites with smaller drainage basins and mixed land uses.	20 USGS 25 WDOE	Annually Aug.–Sept. 1995–97
Drinking-water assessment—pesticides	Pesticides collected in previous study used to estimate detection probability.	Public-supply wells throughout the Study Unit.	78	Once 1994

¹Most data were collected 1996–98.

GLOSSARY

Aquatic guidelines - Specific levels of water quality which, if reached, may adversely affect aquatic life. These are nonenforceable guidelines issued by a governmental agency or other institution.

Aquifer - A water-bearing layer of soil, sand, gravel, or rock that will yield usable quantities of water to a well.

Atmospheric deposition - The transfer of substances from the air to the surface of the Earth, either in wet form (rain, fog, snow, dew, frost, hail) or in dry form (gases, aerosols, particles).

Base flow - Sustained, low flow in a stream; ground-water discharge is the source of base flow in most places.

Basic fixed sites - Sites on streams at which streamflow is measured and samples are collected for temperature, salinity, suspended sediment, major ions and metals, nutrients, and organic carbon to assess the broad-scale spatial and temporal character and transport of inorganic constituents of streamwater in relation to hydrologic conditions and environmental settings.

Benthic invertebrates - Insects, mollusks, crustaceans, worms, and other organisms without a backbone that live in, on, or near the bottom of lakes, streams, or oceans.

Breakdown product - A compound derived by chemical, biological, or physical action upon a pesticide. The breakdown is a natural process that may result in a more toxic or a less toxic compound and a more persistent or less persistent compound.

Chlorinated solvent - A volatile organic compound containing chlorine. Some common solvents are trichloroethylene, tetrachloroethylene, and carbon tetrachloride.

Coliphages - Bacteriophages, a type of virus, that infect and replicate in coliform bacteria and appear to be present wherever total and fecal coliforms are found.

Coliphage serotypes - Groups of coliphages that can be identified and used to infer sources of coliform bacteria.

Community - In ecology, the species that interact in a common area.

Denitrification - A process by which oxidized forms of nitrogen such as nitrate (NO_3^-) are reduced to form nitrites, nitrogen oxides, ammonia, or free nitrogen: commonly brought about by the action of denitrifying bacteria and usually resulting in the release of nitrogen to the air.

Detection limit - The minimum concentration of a substance that can be identified, measured, and reported within 99 percent confidence that the analyte concentration is greater than zero; determined from analysis of a sample in a given matrix containing the analyte.

Drainage basin - The portion of the surface of the Earth that contributes water to a stream through overland runoff, including tributaries and impoundments.

Drinking-water standard or guideline - A threshold concentration in a public drinking-water supply, designed to protect human health. As defined here, standards are U.S. Environmental Protection Agency regulations that specify the maximum contamination levels for public water systems required to protect the public welfare; guidelines have no regulatory status and are issued in an advisory capacity.

Ecoregion - An area of similar climate, landform, soil, potential natural vegetation, hydrology, or other ecologically relevant variables.

Fecal bacteria - Microscopic single-celled organisms (primarily fecal coliforms and fecal streptococci) found in the wastes of warm-blooded animals. Their presence in water is used to assess the sanitary quality of water for body-contact recreation or for consumption. Their presence indicates contamination by the wastes of warm-blooded animals and the possible presence of pathogenic (disease producing) organisms.

Flow-path study - A study to examine the relations of land-use practices, ground-water flow, and contaminant occurrence and transport. A flow-path study is conducted within a land-use study.

Freshwater chronic criteria - The highest concentration of a contaminant that freshwater aquatic organisms can be exposed to for an extended period of time (4 days) without adverse effects. See also Water-quality criteria.

Fumigant - A substance or mixture of substances that produces gas, vapor, fume, or smoke intended to destroy insects, bacteria, or rodents.

Habitat - The part of the physical environment where plants and animals live.

Headwaters - The source and upper part of a stream.

Intensive fixed sites - Basic fixed sites with increased sampling frequency during selected seasonal periods and analysis of dissolved pesticides and volatile organic compounds for 1 year. Most NAWQA Study Units have one to two integrator intensive fixed sites and one to four indicator intensive fixed sites.

Intolerant organisms - Organisms that are not adaptable to human alterations to the environment and thus decline in numbers where human alterations occur. See also Tolerant species.

Land-use study - A study that is a subset of the study-unit survey and has the goal of relating the quality of shallow ground water to land use. See also Study-unit survey.

Load - General term that refers to a material or constituent in solution, in suspension, or in transport; usually expressed in terms of mass or volume.

Median - The middle or central value in a distribution of data ranked in order of magnitude. The median is also known as the 50th percentile.

Metabolite - A substance produced in or by biological processes.

Micrograms per liter ($\mu\text{g/L}$) - A unit expressing the concentration of constituents in solution as weight (micrograms) of solute per unit volume (liter) of water; equivalent to one part per billion in most streamwater and ground water. One thousand micrograms per liter equals 1 mg/L .

Milligrams per liter (mg/L) - A unit expressing the concentration of chemical constituents in solution as weight (milligrams) of solute per unit volume (liter) of water; equivalent to one part per million in most streamwater and ground water. One thousand micrograms per liter equals 1 mg/L .

Nonpoint source - A pollution source that cannot be defined as originating from discrete points such as pipe discharge. Areas of fertilizer and pesticide applications, atmospheric deposition, manure, and natural inputs from plants and trees are types of nonpoint source pollution.

Nutrient - Element or compound essential for animal and plant growth. Common nutrients in fertilizer include nitrogen, phosphorus, and potassium.

Pesticide - A chemical applied to crops, rights of way, lawns, or residences to control weeds, insects, fungi, nematodes, rodents, or other "pests."

Picocurie (pCi) - One trillionth (10^{-12}) of the amount of radioactivity represented by a curie (Ci). A curie is the amount of radioactivity that yields 3.7×10^{10} radioactive disintegrations per second (dps). A picocurie yields 2.22 disintegrations per minute (dpm) or 0.037 dps.

Radon - A naturally occurring, colorless, odorless, radioactive gas formed by the disintegration of the element radium; damaging to human lungs when inhaled.

Riparian - Areas adjacent to rivers and streams with a high density, diversity, and productivity of plant and animal species relative to nearby uplands.

Study Unit - A major hydrologic system of the United States in which NAWQA studies are focused. Study Units are geographically defined by a combination of ground- and surface-water features and generally encompass more than 4,000 square miles of land area.

Study-unit survey - Broad assessment of the water-quality conditions of the major aquifer systems of each Study Unit. The study-unit survey relies primarily on sampling existing wells and, wherever possible, on existing data collected by other agencies and programs. Typically, 20 to 30 wells are sampled in each of three to five aquifer subunits.

Synoptic sites - Sites sampled during a short-term investigation of specific water-quality conditions during selected seasonal or hydrologic conditions to provide improved spatial resolution for critical water-quality conditions.

Taxon (plural taxa) - Any identifiable group of taxonomically related organisms.

Tolerant species - Those species that are adaptable to (tolerant of) human alterations to the environment and often increase in number when human alterations occur.

Unconsolidated deposit - Deposit of loosely bound sediment that typically fills topographically low areas.

Volatile organic compounds (VOCs) - Organic chemicals that have a high vapor pressure relative to their water solubility. VOCs include components of gasoline, fuel oils, and lubricants, as well as organic solvents, fumigants, some inert ingredients in pesticides, and some by-products of chlorine disinfection.

Water-quality criteria - Specific levels of water quality which, if reached, are expected to render a body of water unsuitable for its designated use. Commonly refers to water-quality criteria established by the U.S. Environmental Protection Agency. Water-quality criteria are based on specific levels of pollutants that would make the water harmful if used for drinking, swimming, farming, fish production, or industrial processes.

Yield - The mass of material or constituent transported by a river in a specified period of time divided by the drainage area of the river basin.

APPENDIX—WATER-QUALITY DATA FROM THE PUGET SOUND BASIN IN A NATIONAL CONTEXT

For a complete view of Puget Sound Basin data and for additional information about specific benchmarks used, visit our Web site at <http://water.usgs.gov/nawqa/>. Also visit the NAWQA Data Warehouse for access to NAWQA data sets at <http://infotrek.er.usgs.gov/wdbctx/nawqa/nawqa.home>.

This appendix is a summary of chemical concentrations and biological indicators assessed in the Puget Sound Basin. Selected results for this basin are graphically compared to results from as many as 36 NAWQA Study Units investigated from 1991 to 1998 and to national water-quality benchmarks for human health, aquatic life, or fish-eating wildlife. The chemical and biological indicators shown were selected on the basis of frequent detection, detection at concentrations above a national benchmark, or regulatory or scientific importance. The graphs illustrate how conditions associated with each land use sampled in the Puget Sound Basin compare to results from across the Nation, and how conditions compare among the several land uses. Graphs for chemicals show only detected concentrations and, thus, care must be taken to evaluate detection frequencies in addition to concentrations when comparing study-unit and national results. For example, simazine concentrations in Puget Sound Basin agricultural streams were similar to the national distribution, but the detection frequency was much higher (97 percent compared to 61 percent).

CHEMICALS IN WATER

Concentrations and detection frequencies, Puget Sound Basin, 1996–98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size. For ground water, the number of samples is equal to the number of wells sampled

National ranges of detected concentrations, by land use, in 36 NAWQA Study Units, 1991–98—Ranges include only samples in which a chemical was detected

National water-quality benchmarks

National benchmarks include standards and guidelines related to drinking-water quality, criteria for protecting the health of aquatic life, and a goal for preventing stream eutrophication due to phosphorus. Sources include the U.S. Environmental Protection Agency and the Canadian Council of Ministers of the Environment

- | Drinking-water quality (applies to ground water and surface water)
- | Protection of aquatic life (applies to surface water only)
- | Prevention of eutrophication in streams not flowing directly into lakes or impoundments
- No benchmark for drinking-water quality
- ** No benchmark for protection of aquatic life

Pesticides in water—Herbicides

Other herbicides detected

- Acetochlor (Harness Plus, Surpass) **
- Alachlor (Lasso, Bronco, Lariat, Bullet) **
- Bromacil (Hyvar X, Urox B, Bromax)
- DCPA (Dacthal, chlorthal-dimethyl) **
- Dicamba (Banvel, Dianat, Scotts Proturf)
- Dinoseb (Dinoseb)
- Diuron (Crisuron, Karmex, Diurex) **
- EPTC (Eptam, Farmarox, Alirox) **
- Fluometuron (Flo-Met, Cotoran) **
- Linuron (Lorox, Linex, Sarclax, Linurex, Afalon) *
- MCPA (Rhomene, Rhonox, Chiptox)
- Metolachlor (Dual, Pennant)
- Metribuzin (Lexone, Sencor)
- Molinate (Ordran) **
- Napropamide (Devrinol) **
- Norflurazon (Evtal, Predict, Solicam, Zorial) **
- Oryzalin (Surflan, Dirimal) **
- Pebulate (Tillam, PEBC) **
- Pronamide (Kerb, Propyzamid) **
- Terbacil (Sinbar) **
- Triclopyr (Garlon, Grandstand, Redeem, Remedy) **
- Trifluralin (Treflan, Gowan, Tri-4, Trific)

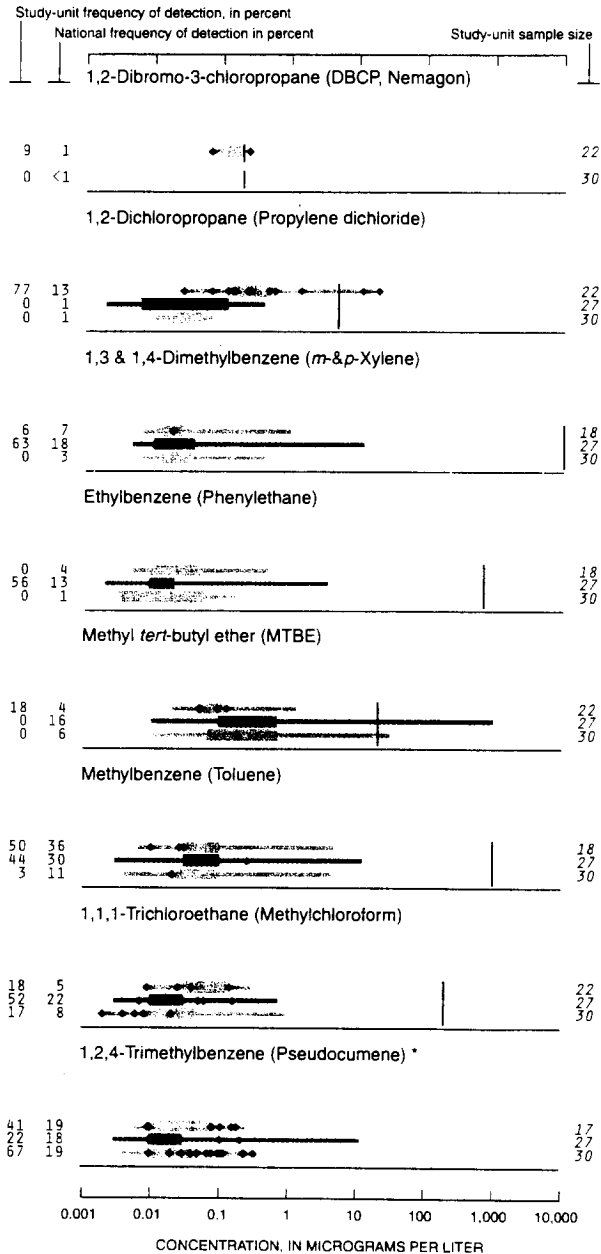

Herbicides not detected

- Acifluorfen (Blazer, Tackle 2S) **
- Benfluralin (Balan, Benefin, Bonalan) * **
- Bentazon (Basagran, Bentazone) **
- Bromoxynil (Buctril, Brominal) *
- Butylate (Sutan +, Genate Plus, Butilate) **
- Chloramben (Amiben, Amilon-WP, Vegiben) **
- Clopyralid (Stinger, Lontrel, Transline) * **
- Cyanazine (Bladex, Fortrol)
- 2,4-DB (Butyrac, Butoxone, Embutox Plus, Embutone) * **
- Dacthal mono-acid (Dacthal breakdown product) * **
- Dichloroprop (2,4-DP, Seritox 50, Lentemul) * **
- 2,6-Diethylaniline (Alachlor breakdown product) * **
- Ethalfuralin (Sonalan, Curbit) * **
- Fenuron (Fenulon, Fenidim) * **
- MCPB (Thistrol) * **
- Neburon (Neburea, Neburyl, Noruben) * **
- Pendimethalin (Pre-M, Prowl, Stomp) * **
- Picloram (Grazon, Tordon)
- Propachlor (Ramrod, Satecid) **
- Propanil (Stam, Stampede, Wham) * **
- Propham (Tuberite) **
- 2,4,5-T **
- 2,4,5-TP (Silvex, Fenoprop) **
- Thiobencarb (Bolero, Saturn, Benthicarb) * **
- Triallate (Far-Go, Avadex BW, Tri-allate) *

- Methomyl (Lanox, Lannate, Acinate) **
- Methyl parathion (Penncap-M, Folidol-M) **
- Parathion (Roethyl-P, Alkron, Panthion, Phoskil) *
- cis-Permethrin (Ambush, Astro, Pounce) * **
- Phorate (Thimet, Granutox, Geomet, Rampart) * **
- Propoxur (Baygon, Blattanex, Uden, Proprotox) * **
- Terbufos (Contraven, Counter, Pilarfox) **

Volatile organic compounds (VOCs) in ground water

These graphs represent data from 16 Study Units, sampled from 1996 to 1998

Pesticides in water—Insecticides

Other insecticides detected

- Carbaryl (Carbamine, Denapon, Sevin)
- Carbofuran (Furadan, Curaterr, Yaltox)
- Ethoprop (Mocap, Ethoprophos) * **
- Malathion (Malathion)
- Oxamyl (Vydate L, Pratt) **
- Propargite (Comite, Omite, Ornamate) * **

Insecticides not detected

- Aldicarb (Temik, Ambush, Pounce)
- Aldicarb sulfone (Standak, aldoxycarb)
- Aldicarb sulfoxide (Aldicarb breakdown product)
- Azinphos-methyl (Guthion, Gusathion M) *
- p,p'-DDE
- Dieldrin (Panoram D-31, Octalox, Compound 497)
- Disulfoton (Disyston, Di-Syston) **
- Fonofos (Dyfonate, Capfos, Cudgel, Tycap) **
- alpha-HCH (alpha-BHC, alpha-lindane) **
- 3-Hydroxycarbofuran (Carbofuran breakdown product) * **
- Methiocarb (Slug-Geta, Grandslam, Mesuro) * **

Other VOCs detected

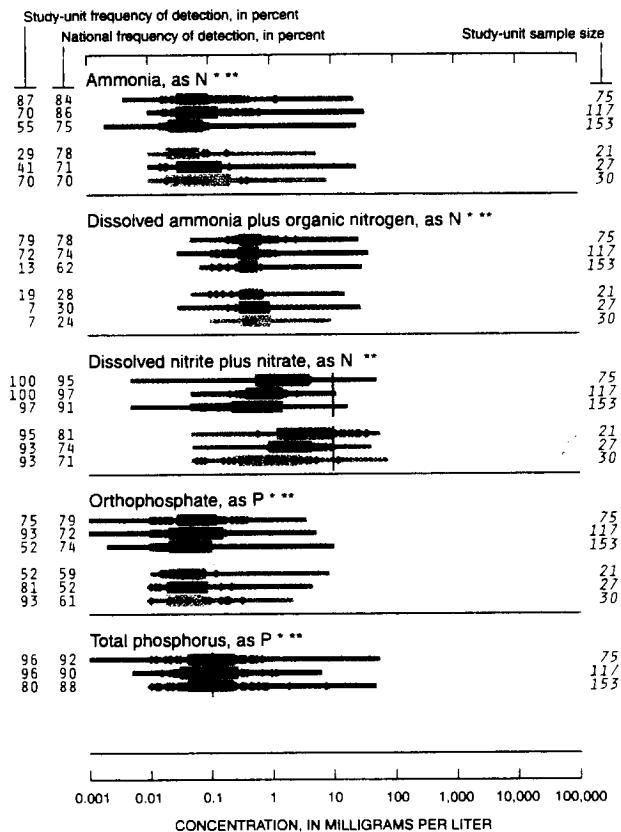

- Benzene
- Bromodichloromethane (Dichlorobromomethane)
- Carbon disulfide *
- 1-Chloro-2-methylbenzene (o-Chlorotoluene)
- Chlorobenzene (Monochlorobenzene)
- Chlorodibromomethane (Dibromochloromethane)
- Chloromethane (Methyl chloride)

R0024745

Dichlorodifluoromethane (CFC 12, Freon 12)
 1,2-Dichloroethane (Ethylene dichloride)
 Dichloromethane (Methylene chloride)
 1,3-Dichloropropane (Trimethylene dichloride) *
 1,2-Dimethylbenzene (*o*-Xylene)
 1-4-Epoxy butane (Tetrahydrofuran, Diethylene oxide) *
 1-Ethyl-2-methylbenzene (2-Ethyltoluene) *
 Iodomethane (Methyl iodide) *
 Isopropylbenzene (Cumene) *
 2-Propanone (Acetone) *
 n-Propylbenzene (Isocumene) *
 Tetrachloroethene (Perchloroethene)
 Trichloroethene (TCE) *
 Trichlorofluoromethane (CFC 11, Freon 11)
 Trichloromethane (Chloroform)
 1,2,3-Trichloropropane (Allyl trichloride)
 1,2,3-Trimethylbenzene (Hemimellitene) *
 1,3,5-Trimethylbenzene (Mesitylene) *

VOCs not detected
tert-Amyl methyl ether (*tert*-amyl methyl ether (TAME)) *
 Bromobenzene (Phenyl bromide) *
 Bromochloromethane (Methylene chlorobromide)
 Bromoethene (Vinyl bromide) *
 Bromomethane (Methyl bromide)
 2-Butanone (Methyl ethyl ketone (MEK)) *
n-Butylbenzene (1-Phenylbutane) *
sec-Butylbenzene *
tert-Butylbenzene *
 3-Chloro-1-propene (3-Chloropropene) *
 1-Chloro-4-methylbenzene (*p*-Chlorotoluene)
 Chloroethane (Ethyl chloride) *
 Chloroethene (Vinyl chloride)
 1,2-Dibromoethane (Ethylene dibromide, EDB)
 Dibromomethane (Methylene dibromide) *
trans-1,4-Dichloro-2-butene ((*Z*)-1,4-Dichloro-2-butene) *
 1,2-Dichlorobenzene (*o*-Dichlorobenzene)
 1,3-Dichlorobenzene (*m*-Dichlorobenzene)
 1,4-Dichlorobenzene (*p*-Dichlorobenzene)
 1,1-Dichloroethane (Ethylidene dichloride) *
 1,1-Dichloroethene (Vinylidene chloride)
trans-1,2-Dichloroethene ((*E*)-1,2-Dichloroethene)
cis-1,2-Dichloroethene ((*Z*)-1,2-Dichloroethene)
 2,2-Dichloropropane *
trans-1,3-Dichloropropene ((*E*)-1,3-Dichloropropene)
cis-1,3-Dichloropropene ((*Z*)-1,3-Dichloropropene)
 1,1-Dichloropropene *
 Diethyl ether (Ethyl ether) *
 Diisopropyl ether (Diisopropylether (DIPE)) *
 Ethenylbenzene (Styrene)
 Ethyl methacrylate *
 Ethyl *tert*-butyl ether (Ethyl-*t*-butyl ether (ETBE)) *
 Hexachlorobutadiene
 1,1,1,2,2,2-Hexachloroethane (Hexachloroethane)
 2-Hexanone (Methyl butyl ketone (MBK)) *
p-Isopropyltoluene (*p*-Cymene) *

CHEMICALS IN FISH TISSUE AND BED SEDIMENT

Concentrations and detection frequencies, Puget Sound Basin, 1996-98—Detection sensitivity varies among chemicals and, thus, frequencies are not directly comparable among chemicals. Study-unit frequencies of detection are based on small sample sizes; the applicable sample size is specified in each graph

- ◆ Detected concentration in Study Unit
- 66 38 Frequencies of detection, in percent. Detection frequencies were not censored at any common reporting limit. The left-hand column is the study-unit frequency and the right-hand column is the national frequency
- Not measured or sample size less than two
- 12 Study-unit sample size

National ranges of concentrations detected, by land use, in 36 NAWQA Study Units, 1991-98—Ranges include only samples in which a chemical was detected

National benchmarks for fish tissue and bed sediment

National benchmarks include standards and guidelines related to criteria for protection of the health of fish-eating wildlife and aquatic organisms. Sources include the U.S. Environmental Protection Agency, other Federal and State agencies, and the Canadian Council of Ministers of the Environment

- | Protection of fish-eating wildlife (applies to fish tissue)
- | Protection of aquatic life (applies to bed sediment)
- No benchmark for protection of fish-eating wildlife
- No benchmark for protection of aquatic life

Organochlorines in fish tissue (whole body) and bed sediment

¹ The national detection frequencies for total PCB in sediment are biased low because about 30 percent of samples nationally had elevated detection levels compared to this Study Unit. See <http://water.usgs.gov/nawqa/> for additional information.

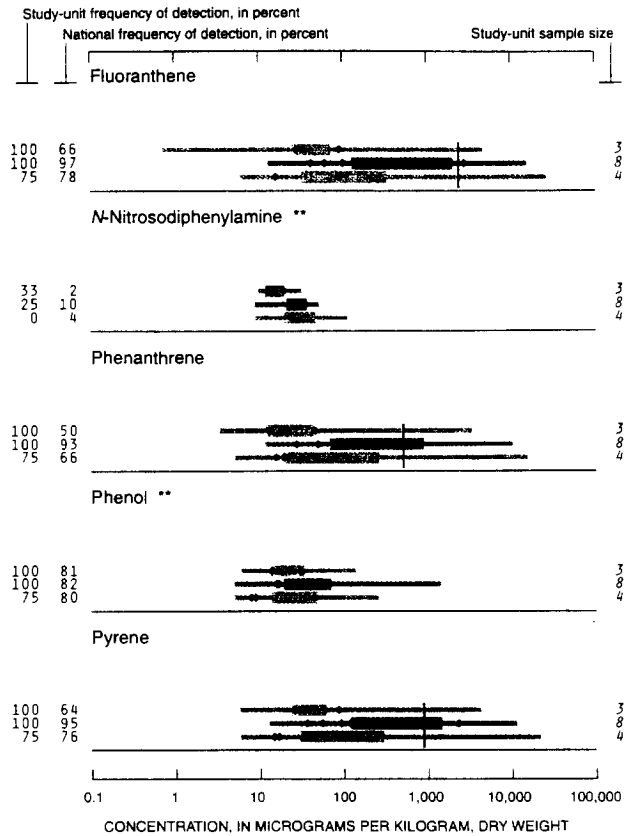

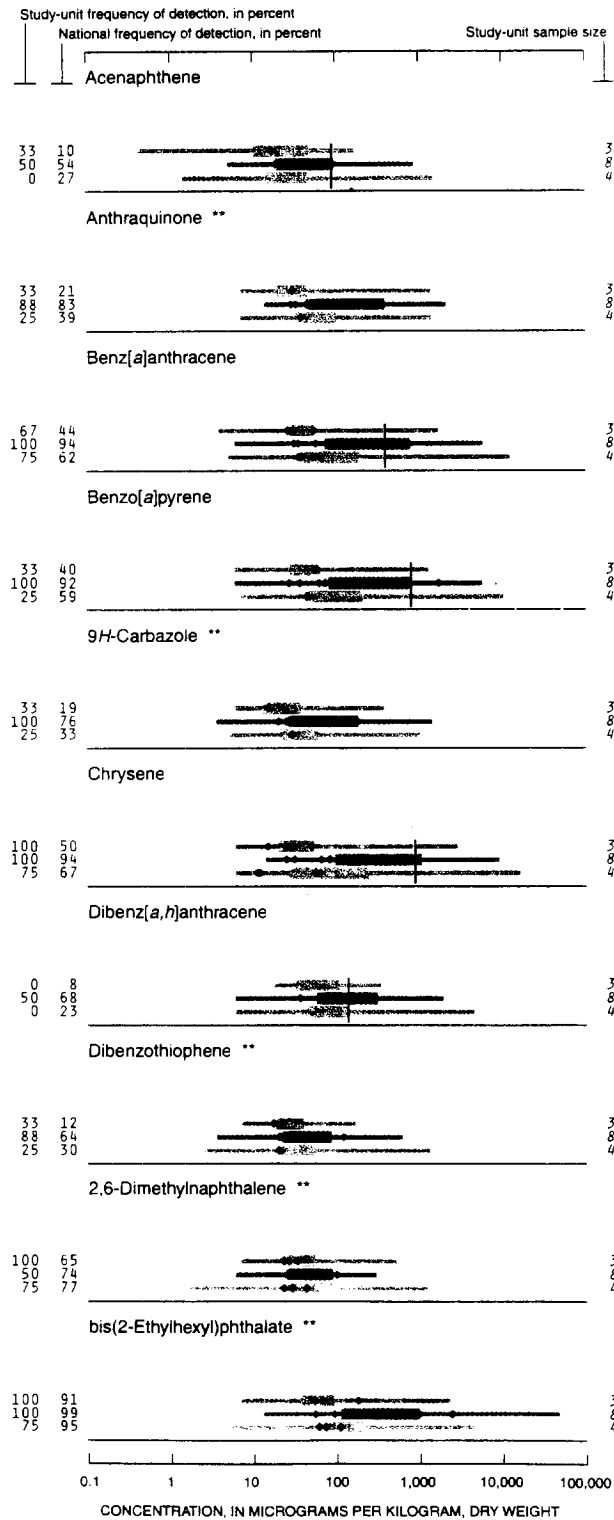

Other organochlorines detected

- o,p'+p,p'-DDD (sum of o,p'-DDD and p,p'-DDD) *
- Heptachlor epoxide (Heptachlor breakdown product) *
- Heptachlor+heptachlor epoxide (sum of heptachlor and heptachlor epoxide) **
- Hexachlorobenzene (HCB) **
- Pentachloroanisole (PCA) ***

Organochlorines not detected

- Chloroneb (Chloronebe, Demosan) ***
- DCPA (Daclhal, chlorthal-dimethyl) ***
- Endosulfan I (alpha-Endosulfan, Thiodan) ***
- Endrin (Endrine)
- gamma-HCH (Lindane, gamma-BHC, Gammexane) *
- Total-HCH (sum of alpha-HCH, beta-HCH, gamma-HCH, and delta-HCH) **
- Isodrin (Isodrine, Compound 711) ***
- p,p'-Methoxychlor (Marlate, methoxychlore) **
- o,p'-Methoxychlor ***
- Mirex (Dechlorane) **
- cis-Permethrin (Ambush, Astro, Pounce) **
- trans-Permethrin (Ambush, Astro, Pounce) **
- Toxaphene (Camphechlor, Hercules 3956) **

Semivolatile organic compounds (SVOCs) in bed sediment

Dimethylphthalate **
9H-Fluorene (Fluorene)
Indeno[1,2,3-*cd*]pyrene **
Isoquinoline **
1-Methyl-9H-fluorene **
2-Methylantracene **
4,5-Methylenephenanthrene **
1-Methylphenanthrene **
1-Methylpyrene **
Naphthalene
Phenanthridine **
2,3,6-Trimethylnaphthalene **

SVOCs not detected

C8-Alkylphenol **
Benzo[c]cinnoline **
4-Bromophenyl-phenylether **
4-Chloro-3-methylphenol **
bis(2-Chloroethoxy)methane **

- 2-Chloronaphthalene **
- 2-Chlorophenol **
- 4-Chlorophenyl-phenylether **
- 1,2-Dichlorobenzene (*o*-Dichlorobenzene) **
- 1,3-Dichlorobenzene (*m*-Dichlorobenzene) **
- 1,4-Dichlorobenzene (*p*-Dichlorobenzene) **
- 2,4-Dinitrotoluene **
- Isophorone **
- Nitrobenzene **
- N*-Nitrosodi-*n*-propylamine **
- Pentachloronitrobenzene **
- Quinoline **
- 1,2,4-Trichlorobenzene **

Trace elements in fish tissue (livers) and bed sediment

BIOLOGICAL INDICATORS

Higher national scores suggest habitat disturbance, water-quality degradation, or naturally harsh conditions. The status of algae, invertebrates (insects, worms, and clams), and fish provide a record of water-quality and stream conditions that water-chemistry indicators may not reveal. **Algal status** focuses on the changes in the percentage of certain algae in response to increasing siltation, and it often correlates with higher nutrient concentrations in some regions. **Invertebrate status** averages 11 metrics that summarize changes in richness, tolerance, trophic conditions, and dominance associated with water-quality degradation. **Fish status** sums the scores of four fish metrics (percent tolerant, omnivorous, non-native individuals, and percent individuals with external anomalies) that increase in association with water-quality degradation.

Biological indicator value, Puget Sound Basin, by land use, 1996-98

- ◆ Biological status assessed at a site

National ranges of biological indicators, in 16 NAWQA Study Units, 1994-98

- Streams in undeveloped areas
- Streams in agricultural areas
- Streams in urban areas
- Streams in mixed-land-use areas
- 75th percentile
- - - 25th percentile

Dear Colleague:

Enclosed is a new report from the U.S. Geological Survey Puget Sound Basin Study Unit of the National Water Quality Assessment (NAWQA) Program.

USGS Circular 1216, "Water Quality in the Puget Sound Basin, Washington and British Columbia, 1996-98," summarizes surface-water quality, ground-water quality, biology, and ecological conditions from data collected during three years of intensive study on selected streams and ground water in the Puget Sound Basin. The report also compares water-quality conditions and biological characteristics observed in Puget Sound Basin streams and ground water with conditions observed in other NAWQA study units across the Nation.

The Puget Sound Basin NAWQA reports are available online, or can be ordered, at:
<http://wa.water.usgs.gov/ps.nawqa.html>

Thank you for your interest,

Sandra S. Embrey
Chief Puget Sound Basin NAWQA

R0024750

Coordination with agencies and organizations in the Puget Sound Basin was integral to the success of this water-quality assessment. We thank those who served as members of our liaison committee.

Federal Agencies

Washington Environmental Council
Washington Toxics Coalition

We thank the following individuals for contributing to this effort.

- Gil Bortleson (USGS, Washington District) participated in the design of the study and authored several reports.
- Dale Davis (Washington State Department of Ecology) was a partner and coauthor in the study of pesticides in streams.
- Sue Davis (Thurston County), Mindy Fohn (City of Bremerton), Keith Grellner (Kitsap County), Ray Hanowell (Pierce County), Joe Joy (Washington State Department of Ecology), and Ginny Stern (Washington State Department of Health) helped in the design of the microbiological studies.
- Annette Frahm and George Perry (King County) provided sales data for pesticides, conducted toxicity tests, and coauthored a fact sheet about pesticides in urban streams.
- Kathleen Greene, Joseph Gilbert, Gary Holloway, Brett Smith, and Greg Justin (USGS, Washington District) played a major role in the collection and compilation of water-quality and streamflow data.
- Emily Inkpen (USGS, Washington District) collected and compiled water-quality data and authored a number of reports.
- Dr. James Karr (University of Washington) provided advice on the analysis of macroinvertebrate data.
- Moon Kim, Raegan Huffman, Stephanie Leisle, Mark Munn, Steve Sumioka, and Ann Vanderpool (USGS, Washington District); Steve Goodbred and Terry Short (USGS, Western Region); Mariabeth Silkey and Michael Hummling (University of Washington); and Dave Serdar and Art Johnson (Washington State Department of Ecology) provided field support and assisted in data collection.
- Hugh Liebscher and Basil Hii (Environment Canada) provided water level and chemistry data for wells in Canada.
- Dorene MacCoy (USGS, Idaho District) helped collect and interpret biological data and helped produce a number of reports.
- Rob Plotnikoff (Washington State Department of Ecology) provided macroinvertebrate and habitat data.
- Dr. Mark Sobsey, Fu-Chih Hsu, and Douglas Wait (University of North Carolina, Chapel Hill) provided technical assistance and laboratory analyses for the microbiological study.
- Ward Staubitz (USGS, Virginia District), project chief until April 1997, played a major role in the design of the study.
- Ian Waite and Dennis Wentz (USGS, Oregon District) provided fish tissue data from the Willamette Basin, Oregon.
- Frank Voss (USGS, Washington District) managed the project data base and produced a number of reports.

Appreciation is extended to those individuals who reviewed this report or helped prepare it.
